Abstract

Since its inception in the 1970s, email has emerged as an irreplaceable medium for global communication. Despite its ubiquity, the system is plagued by security vulnerabilities, such as email spoofing. Among the various countermeasures, the Sender Policy Framework (SPF) remains a seminal and commonly deployed solution, working by specifying a list of authorized IP addresses for sending email.

While SPF might seem simple on the surface, the practical management of its records proves to be challenging; for example, although syntactical errors are uncommon (0.4%), evaluation-phase challenges are prevalent (7.7%), leading to potential disruptions in email delivery.

In our paper, we conduct a comprehensive study on the SPF extension, drawing from 17 months of weekly data snapshots that span 176 million domains across four top-level domains; we delve into the reasons behind such prevalent evaluation errors. Simultaneously, we undertake an ethical methodology to explore how SMTP servers *validate* SPF records and evaluate the effectiveness of widely-used software implementations. Our study unveils potential attack vectors that could be exploited for DNS amplification attacks or disrupt mail distribution; for instance, we demonstrate how an attacker could temporarily impede email reception by exploiting flaws in SPF validation mechanisms. We also conduct a qualitative study among email administrators to gain insights into the practical implementation and usage of SPF and SPF validators. Based on our findings, we provide recommendations designed to reconcile these discrepancies and bolster the SPF ecosystem's overall security.

1 Introduction

Email, often referred to as electronic correspondence, has been a dominant mode of global communication since its advent in the 1970s. Although there are now numerous other ways to communicate, the ubiquity of email continues to expand, offering cross-platform versatility.

However, despite its widespread use, email remains susceptible to security shortcomings. This is largely because its foundational protocol, the Simple Mail Transfer Protocol (SMTP), was designed in an era with different security norms [39] and thus lacks inherent features for verifying sender authenticity, making them vulnerable to a variety of security risks, such as email spoofing attacks [12, 14, 18].

To mitigate these threats, there have been a number of different email security protocols and extensions such as SPF [23], DKIM [10], DMARC [21], BIMI [9], etc. SPF, or Sender Policy Framework, is among the earliest solutions aimed at preventing email sender spoofing and was proposed in 2003, and first documented in 2006 [41]. Its operation is straightforward: the domain owner specifies a list of authorized IP addresses via DNS `TXT` records[1] so that a receiving mail server can verify if the source IP address of an incoming email is on that authorized list.

However, the apparent simplicity is misleading; managing `SPF` records can be intricate and misconfigured `SPF` records are quite common, exposing domains to phishing and spoofing, or limiting deliverability. An additional layer of complexity is added if `SPF` records depend on other `SPF` records not under the control of the domain owner, e.g., those belonging to hosting providers, as a domain owner must then also monitor those third-party records for changes.

Furthermore, over time, operational practice diverged from the original guidelines in RFC4408 [41] and the later updates in RFC7208 [23], increasing the potential for misconfigurations and vulnerabilities. For example, the `SPF` records of email hosting providers may point to multiple other `SPF` records to utilize their infrastructure, requiring the receiver to make more than 10 DNS queries, a practice that is actually prohibited by the RFC7208 [23]. Consequently, we observe a variety of implementation quirks in the wild. For example, our analysis reveals that certain email software comes configured with lenient DNS query limits by default, while some of their earlier versions lack query limitations

[1] For conciseness, we refer to these as `SPF` records in this paper.

altogether. Our experiment indicates that these outdated and vulnerable software might still be in existence and can be used as reflectors to launch stealthy DoS attacks.

In this paper, we present a comprehensive study of the SPF ecosystem to bridge the gap between operational practice and challenges in real-word SPF deployment. To examine the sender-side (i.e., the domain name owners), we employ 17 months of daily SPF record snapshots covering *all* second-level domains across the .com, .org, .net, and .se top-level domains. For assessing the receiver-side, we reduce the ethical impact associated with sending unsolicited emails by leveraging ambiguities in the RFC regarding *when* to initiate SPF record checks.

Our investigative approach is multi-faceted, aiming to unearth not just common misconfigurations but also to delve into the *why* behind them; this is achieved through a blend of quantitative analysis, based on our comprehensive scans, and qualitative insights, gathered through surveys of network operators. Our contributions are as follows:

- We conduct a large-scale longitudinal analysis of the SPF ecosystem both from sender side and recipient side. We find that the vast majority of SPF records are *syntactically* correct, with fewer than 0.4% errors. However, issues arise during the evaluation phase, where many records (6.5%) incur excessive DNS lookups, exceeding the RFC-defined limit of 10.
- We identify two primary sources of such misconfigurations: first, two popular hosting providers that incorporate too many domains in their SPF records, and second, oversights by SMTP administrators who neglect to remove obsolete SPF records after service migration.
- We outline an attack scenario that can temporarily prevent victims from receiving emails by causing their SPF validators to experience extended DNS resolution delays, all while the victims remain unaware due to the absence of emails in their inbox.
- We conduct a survey among mail operators to understand the SPF landscape in practice. Our survey reveals that even large email providers managing over 1,000 accounts often deviate from required limits in RFCs [23], highlighting a disconnect between outdated standards and current operational needs.
- Finally, we offer a set of community-focused recommendations aimed at mitigating potential abuse and bridging the gap between nearly two-decade-old standards and contemporary SPF usage.

On a constructive note, our study uncovers straightforward avenues for improving SPF validation to achieve its intended security goals. In the interest of collaborative research and actionable insights, we make our entire analysis code and dataset publicly available at

https://spf-measurement.github.io

2 Background

2.1 Simple Mail Transfer Protocol (SMTP)

Simple Mail Transfer Protocol (SMTP) is the protocol employed for email exchange over the Internet. The email process commences with the user composing an email in their Mail User Agent (MUA). This email is then transmitted to the sender's Mail Transfer Agent (MTA), either via SMTP or HTTP. The sending MTA subsequently identifies the recipient MTA's address through the Domain Name System (DNS), establishes a Transmission Control Protocol (TCP) session with the target host, and transfers the email using SMTP. The process involves the execution of several SMTP commands, including:

- HELO/EHLO commences communication with the server. They serve as greeting messages, wherein the sending server usually declares its name. The EHLO command is an extended version, prompting servers to notify the client about the extended features they support.
- MAIL FROM specifies the sender's email address, thereby informing the server about the origin of the email. It also sets the return path for delivery status notifications.
- RCPT TO indicates the recipient's email address. The server acknowledges each valid recipient with a positive response.
- DATA describes the actual email content. This command is followed by the email message, including headers and body. In the email message header, the sender can also specify one or more *From* address(es), which is generally shown as the from address in the display of the recipient's MUA [32]. For readability, we refer to this *From*–commonly know as the RFC5322.From–as Header From.

Subsequently, the Mail Delivery Agent (MDA) delivers the email to the recipient using HTTP, IMAP, or POP3 protocols [22].

2.2 Sender Authentication

SMTP has no built-in security mechanisms; theoretically, an attacker can manipulate the address in the MAIL command and in the Header From field to spoof the sender domain [21, 37]. To mitigate these attacks, various security extensions have been proposed.

2.2.1 Sender Policy Framework (SPF)

With SPF, domain owners can publish a policy with which a receiving mail server can assess whether a sending IPv4 or

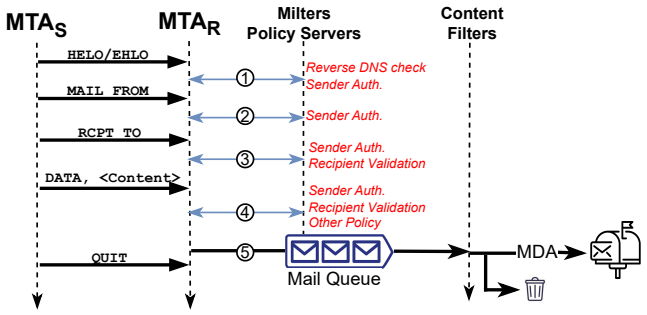

Figure 1: An overview of SPF validation flow at various stages of the SMTP transaction. Upon receipt of the `HELO/EHLO` command, either the MTA natively or through milters can initiate a reverse DNS lookup for the incoming IP address. The standard [23] requires that SPF validation must be performed on the `MAIL FROM` identity, but also suggests doing it on the `HELO/EHLO` as well. So, after the `MAIL` command, sender authentication can be executed at any point during the SMTP connection by milters or policy servers. Notably, SPF validation can even occur post-queue in the content filter stage (e.g., SpamAssassin [6]).

IPv6 address may deliver a message for a specific domain. This is done via a DNS `TXT` record at the sending domain. Policies are described in a `TXT` record (the previously used SPF DNS resource record (RR) has been discontinued [23]) using `mechanisms` with `qualifiers` and `modifiers` and SPF verifiers check policy of `HELO` identity (recommended) and `MAIL FROM` identity (must) against the connecting IP address. Furthermore, SPF supports the use of `macros` expanded based on characteristics of the message.

Mechanisms Mechanisms serve as the main method of defining policy; In total, eight mechanisms are defined: `A`, `ip4`, `ip6`, `mx`, `ptr` (discouraged as per RFC [23]), `exists`, `include`, and `all`. `ip4` and `ip6` allow specifying permitted sender addresses or networks for a domain. For example, the following configuration authorizes emails only from the IP address 10.0.0.1, while rejecting all others.

```
example.com   TXT   "v=spf1 ip4:10.0.0.1 -all"
```

In addition, `mx` allows the IP addresses of a domains' `MX` records, `ptr` allows all clients whose reverse DNS name is in the domain (easily forged and therefore discouraged), `a` if a given FQDN resolves to a connecting IP and `exists` if a given domain exists, which is mostly useful with `macros`. Finally, the `all` record sets a default policy for all addresses not matched by earlier mechanisms.

In this paper, we primarily focus on the `include` mechanism. This mechanism allows referring to `SPF` records of another FQDN. This is especially useful when domain name owners outsource their email service to a third-party provider, e.g., Google. A domain owner can then simply include `_spf.google.com` managed by Google to ensure `SPF` is appropriately configured.

```
example.com   TXT   "v=spf1 include:_spf.google.com -all"
```

This mechanism is also useful if domain owners require other third-party services for specialized tasks; for instance, a domain owner using QQ.com for email hosting may also wish to utilize a bulk email service like Mailchimp or SendGrid. Hence, email hosting providers like Google Workspace [5] or QQ.com [19] publish their SPF records to be included by domain owners through the `include` mechanism, and often explicitly document that users should do this.

Qualifiers Qualifiers specify the disposition if a mechanism matches. Absence of a qualifier defaults to `+ (pass)`.

- `+ (pass)`: Positive disposition.
- `- (fail)`: Negative disposition. Commonly used with the `all` mechanism to reject all senders not explicitly listed.
- `? (neutral)`: No disposition.
- `~(softfail)`: a negative disposition but not a strong one (i.e., hinting that sender is probably not authorized).

Modifiers Currently, the `exp=` and the `redirect=` modifier are specified in RFC4408 [41]. `exp=` should point to an FQDN whose TXT record explains the reason for a negative disposition. `redirect=` works similar to `include`, even though subtly different. As `redirect=` is rarely used in practice (apart from `gmail.com`), we focus in `include` in this work.

SPF Errors and Security Considerations SPF relies on DNS records for its operation. Evaluation can fail if the `SPF` records are inaccessible or malformed. Generally, two types of errors can arise during the evaluation of an `SPF` record, often resulting in email rejection:

- `temperrors` occur when the SPF validator encounters a transient issue, such as a DNS timeout. The validator may retry the operation later.
- `permerrors` occur when the SPF validator successfully retrieves a DNS record but fails to interpret it correctly.

A classic example that triggers a *permerror* is when the number of required DNS queries to evaluate an SPF record exceeds the standard limit of 10. This usually happens when multiple mechanisms refer to other DNS records, such as through `include` mechanisms. The standard imposes this limit to alleviate undue stress on DNS infrastructure.[2] In situations where the referenced SPF record does not resolve due to an empty DNS response or errors such as `NXDOMAIN`, this condition is termed a *void lookup*. The RFC states that the number of void lookups `should` be limited to two.

[2] It is worth highlighting that this is distinct from `CNAME` records, which map one domain name to another in DNS. `CNAME` expansion is usually the responsibility of DNS resolvers, while `include` mechanisms in SPF are expanded by the SPF validator.

TLD	Domains w/ MX	Domains with MX records		
		SPF	SPF include	SPF include with Ext.
.com	75.8 M	48 M (63.2%)	28.9 M (60.3%)	28.8 M (99.6%)
.net	6.5 M	3.5 M (53.8%)	2 M (57.1%)	1.98 M (99.6%)
.org	5.8 M	3.2 M (55.2%)	1.9 M (59.3%)	1.9 M (99.7%)
.se	845 K	439 K (52%)	365 K (83.1%)	365 K (99.7%)

Table 1: Overview of the datasets. The number and percentage of the domains that have SPF records are as-of March 27, 2023.

SPF Validator Ecosystem SPF validation occurs either natively within the recipient MTA using SPF libraries (e.g., libspf2 [45]) or via external extensions, which can fall into three categories based on the timing of the SPF check.

- Before Queue Milter (e.g., milter-greylist [46]) or Milter, in short, is a flexible framework for pre-queue email filtering and modification. Milters can reject emails *during the SMTP transaction*.
- Policy Server (e.g., iRedAPD [44]) makes routing decisions based on predefined policies, such as rejecting an email if SPF fails.
- Post-Queue Content Filter (e.g., SpamAssassin [6]) operates after the MTA queues the mail, focusing on content-based attributes like message body and attachments.

We explain how these extensions can make SPF queries in Figure 1.

2.2.2 Other Extensions for Sender Authentication

Although not the primary focus of this paper, there are additional security extensions designed to support sender authentication. Two notable examples are briefly explained below:

- `DomainKeys Identified Mail (DKIM)` enables an email receiver to confirm the integrity of a received message by embedding a digital signature within the email header. The receiver can then fetch the corresponding public key from the DNS to verify this signature.
- `Domain-based Message Authentication Reporting and Conformance (DMARC)` allows domain owners to publish a policy within the DNS that dictates certain actions for email receivers to follow when SPF and DKIM validation fails.

In summary, DKIM serves to provide both the integrity of the message and its authenticity, while DMARC furnishes a policy framework for email receivers to act upon in cases where SPF and DKIM validation fails.

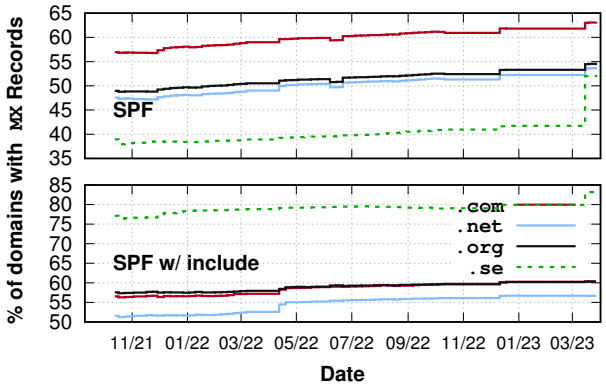

Figure 2: The percentage of domains with `SPF` records is increasing; the spike on March 15, 2023 for `.se` domains is because around 100K domains using loopia.se as their email hosting provider added an `SPF` record to their domain.

3 SPF for Outbound Emails

We first focus on domain name owners who *publish* `SPF` records and how they are deployed and managed.

3.1 Datasets

To scan a vast number of registered domains, we conduct DNS scans across four top-level domains (TLDs): the most widely used three generic TLDs (gTLDs) `.com`, `.org`, and `.net` gTLDs and a country-code TLD (ccTLD), `.se`, recognized for its aggressive deployment for email security protocols such as DANE [24] or DMARC [4]. Initially, we gather daily zone files from the respective registries for each of the four TLDs, namely Verisign for `.com` and `.net`, Public Internet Registry for `.org`, and Internetstiftelsen for `.se`. This allows us to acquire the Name Server (`NS`) information for *all second-level domains* (SLDs). For each of SLDs, we fetch `SPF` records for each domain. In total, our snapshots span 17 months of 176 M domains from October 13th, 2021 to March 27th, 2023, which is summarized in Table 1.

3.2 SPF Record Prevalence

We now first examine how `SPF` records are deployed by domain name owners. Figure 2 shows the percentage of domains that have `SPF` records during our measurement period. First of all, we see a stable increasing trend across all four TLDs; for example, the deployment rate in `.com` domains increased from 56.9% to 63.2% during our measurement period. Similarly, we also observe that a prevalent usage of `include`, which indicates that the domain name owners import other SPF policy for their domains; for example, in the case of `.se`, we find that 83% of domains with `MX` records use external SPF policies. We now examine whether the policy is from other parties; since it is not straightforward

TLD	Percentage Changes of Mechanism (Δ)							
	a	mx	include	ip4	ip6	ptr	exists	all
.com	-3.4	-3.8	+3.9	-2.0	-0.3	-0.8	-0.0	+0.2
.net	-2.9	-3.1	+5.1	-3.1	+0.0	-0.7	-0.0	+0.5
.org	-3.4	-3.9	+2.7	-1.8	-0.3	-1.1	-0.0	+0.3
.se	-9.1	-9.1	+6.2	-7.3	-0.9	-0.2	-0.0	+0.3

Table 2: Percentage change (%) in the usage of each mechanism between our initial snapshot on October 13, 2021, and our final snapshot on March 27, 2023; only `include` and `all` mechanisms have increased across the TLDs, as indicated by a green background.

to compare whether two domains (base domain and the domain in `include`) are managed by the same entity[3], thus we compare whether the domains share same organizational domain [21] or not.

Remarkably, across all TLDs, we find that 99.8% utilize included `SPF` records where at least one of the included domains has a different organizational domain than the base domain. This strongly suggests that the majority are employing the `include` mechanism to import SPF policies from external sources; Such a trend is further substantiated when examining the changes in mechanism usage over our measurement period; Table 2 reveals the evolution in the percentage distribution of each mechanism within SPF records. Notably, we observe that only the `include` and `all` mechanisms have seen an increase in usage across the TLDs, further emphasizing the dependence on external policies and the general move towards stricter email authentication. This phenomenon can be attributed to the prevalent use of third-party mail hosting providers. These providers frequently recommend that their clients employ the `include` mechanism to reference their `SPF` records, which may encompass a broad array of authorized IP addresses.

3.3 SPF Records Management

The management of `SPF` records is crucial due to their role in authorizing the SMTP server of the sender domain. When checking the incoming IP address against SPF records, receiving SMTP servers can encounter a variety of errors, which largely fall into two categories: syntax and evaluation errors.

Syntax Error: `SPF` records that do not follow the syntax of the standard [23] can be instantly detected during the parsing process. The syntax of the record is validated first before the evaluation, thus if there are any syntax errors anywhere in the record, it is determined as `permerror`, terminating the SPF evaluation process immediately without further evaluation.

[3]One possible approach is to leverage WHOIS record, but the infrastructure is heavily rate-limited and notoriously inconsistent [25] and many domains are registered through privacy-preserving services, making it challenging to identify the actual owner [11].

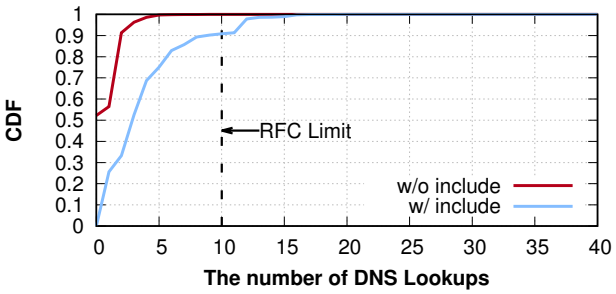

Figure 3: More than 9.2% of SPF records with `include` requires more than 10 DNS look ups. Note that the *x* axis extends to 175!

Evaluation Error: `SPF` records have the ability to reference other DNS records, such as `A` records, through mechanisms. This means that even if an `SPF` record appears valid, it can be deemed invalid during the evaluation process if, for instance, the domain name in the `include` or `a` does not exist. Furthermore, even if all mechanisms within an `SPF` record are successfully evaluated, the validation can still fail if it requires a large number of DNS lookups during the evaluation process since it can impose a significant performance overhead on the receiving server. To address this, the standard [23] mandates issuing a `permerror` when the total number of DNS lookups exceeds 10. One challenge is that domain owners may not promptly detect these errors, especially *when the `SPF` records referenced by mechanisms (e.g., `include`) are managed by other domains*; for example, if `SPF` records included from other domains cause extra look ups, the total number of DNS lookups may exceed 10, resulting in a `Permerror`.

3.3.1 Results

We use our latest scan and focus on 55 M domains that have `SPF` records to assess the accuracy of these `SPF` records by fully resolving all mechanisms contained within them. Table 3 shows the results. First of all, upon examining the syntax of `SPF` records, we find that they *look* well-managed; for example, only 0.003% of SPF records do miss some values for specific `a` or `mx` mechanisms.

However, when focusing on evaluation errors, more prevalent issues emerge. For instance, we find 690,554 domains (1.2%) with incorrectly configured mechanisms that are unresolvable. Even more concerning is the issue of excessive DNS lookups during SPF evaluation; specifically, 3,584,014 (6.5%) domains require more than 10 DNS lookups for evaluation. This is particularly significant because RFC7208 [23] mandates generating a `permerror` outcome in such cases, potentially disrupting email delivery.

Given that most domains in the `include` mechanisms originate from sources external to the base domain (Table 1), mainly due to hosting providers, this widespread occurrence is expected; for example, `SPF` records using `include` mechanisms require a considerably higher number of DNS

Type	Reasons	# of domains	Example
Syntax	Missing Values: ip4 and ip6	7,827 (0.01%)	"v=spf1 ip4: -all"
	Missing Values: a and mx	2,127 (0.003%)	"v=spf1 a: -all"
	Invalid Value	23,147 (0.04%)	"v=spf1 ip4:1.2.3 -all"
	Unknown Mechanism	53,466 (0.1%)	"v=spf1 mx -al"
	Recursive Value	55,907 (0.1%)	a.com TXT "v=spf1 include:a.com -all"
	Multiple SPF records	82,606 (0.15%)	a.com TXT "v=spf1 a -all" a.com TXT "v=spf1 mx -all"
Evaluation	Missing Records: TXT record	85,140 (0.16%)	a.com TXT "v=spf1 include:b.com -all" % *b.com does not exist.*
	Missing Records: MX record	324,524 (0.6%)	a.com TXT "v=spf1 mx:b.com -all" % *MX record of b.com does not exist.*
	Missing Records: A record	280,890 (0.5%)	a.com TXT "v=spf1 a -all" % *A record does not exist.*
	Too many DNS lookups	3,548,014 (6.5%)	a.com TXT "v=spf include:a1.com -all" % *a1.com includes a2.com, etc.*

Table 3: The most popular reasons and their examples of SPF record errors are shown.

lookups compared to those without such mechanisms. As depicted in Figure 3, 3,564,056 (9.2%) of these SPF records, with at least one include, require over 10 lookups.

To investigate if this is a result of popular hosting providers' misconfigurations, we evaluate each domain listed in a include mechanisms. We count their occurrences in SPF records; Figure 4 depicts that 50% of SPF records reference six other SPF records from well-known hosting providers[4]. Next, we also do so, but focusing on those that require more than 10 DNS lookups; interestingly, 2,983,114 (83.7%) of them reference just two SPF records[5]. These are associated with Hostgator and Bluehost, each of their customers requiring 10 and 13 lookups, respectively. Still, 616,581 (17.3%) of the domains that demand more than 10 lookups do not reference these two major hosting providers. We delve into this subset of domains in the following section.

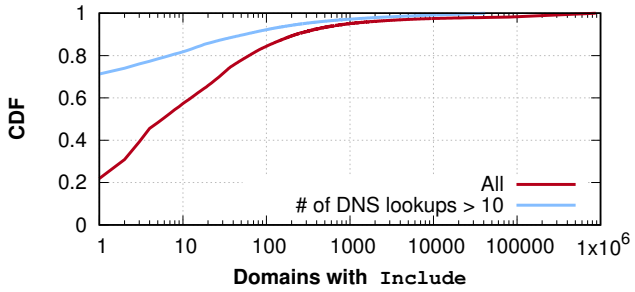

Figure 4: As of March 27th, 2023, only six SPF records appear in the include mechanisms for 50% of all SPF records. Remarkably, just two SPF records—managed by two specific hosting providers—account for 83.7% of the SPF records that require more than 10 DNS lookups for evaluation.

4 Superfluous SPF records

We have discovered that around 616K domains require more than 10 DNS lookups but they do not include either Hostgator or Bluehost. This raises an immediate question: why do these domains require many lookups? In this section, our goal is to determine the essentiality of all the IP addresses or prefixes specified as approved senders in their SPF records, and whether any redundant mechanisms are in place. For instance, if an email server transitions to a different host or opts for an alternative hosting provider, the administrator must update their DNS entries accordingly; for example, in 2023, Microsoft hotmail accounts encountered email outages due to their SPF records not being updated despite changes in their actual email server IP addresses [1]. Therefore, the prudent approach would involve retaining their historical include mechanism (i.e., those that might be considered superfluous) while simultaneously introducing new SPF records to ensure proper functionality.

[4] outlook.com (11.6%), google.com (10.3%), secureserver.net (9.0%), registrar-servers.com (8.4%), websitewelcome.com (6.3%), mailchannels.net (2.7%)

[5] websitewelcome.com and bluehost.com

The domains with superfluous SPF records does not seem to cause any operational problems; however, it may amplify the required DNS lookups causing delivery issue. In this section, we aim to find the domains having superfluous SPF records that persist despite alterations to the sending MTAs.

4.1 Methodology

To assess whether an SPF record contains superfluous entries, we first need to infer the ideal minimally covering SPF record for a domain. While, for a small set of major mail providers, these are published on their websites and can be assumed to be up-to-date, this is not the case for the average domain. Hence, while we can–and do–collect the documentation pages of large email providers to get ground-truth on their ideal SPF policy, we face a gap when it comes to smaller setups.

To bridge this gap, we work on the receiving mail servers communicated via MX records that are also responsible for sending emails for a domain. Even though this assumption is especially not true for large providers, we found it to be a common case also, e.g., signified by 350K domains in March 27, 2023 having mx as the only mechanism in their SPF policy. Nevertheless, such domains may also leverage external senders *in addition* to in-house sending, e.g., for newsletters.

Rank	MX Records	Inferred SPF Records	# of Domains	Prob.	SPF Updated	# of Flatten Domains	# of Domains w/ Stale SPF
1	*.google.com	_spf.google.com	4,357,014	95.9%	✗	2,836	–
2	*.outlook.com	spf.protection.outlook.com	3,974,407	93.4%	✓	1,324	182 (13.7%)
3	*.registrar-servers.com	spf.efwd.registrar-servers.com	3,782,396	98.4%	✗	201	–
4	*.googlemail.com	_spf.google.com	1,226,471	99.0%	✗	2,836	–
5	*.ovh.com	mx.ovh.com	571,484	95.2%	✓	48	10 (20.8%)
6	*.jellyfish.systems	spf.web-hosting.com	509,629	97.7%	✓	86	51 (59.3%)
7	*.hostinger.com	_spf.mail.hostinger.com	467,240	93.9%	✓	167	43 (26.3%)
8	*.qq.com	spf.mail.qq.com	465,717	97.9%	✓	151	44 (29.1%)
9	*.titan.email	spf.titan.email	427,060	99.2%	✓	38	9 (23.6%)
10	*.gandi.net	_mailcust.gandi.net	389,624	97.0%	✗	22	–

Table 4: The table lists the top 10 popular MX records, inferred SPF records, and their occurrence probabilities. Additionally, it indicates (1) if the IP addresses in the SPF records have been updated, (2) the number of domains that have flattened their SPF records, and (3) the domains with stale SPF records despite updates from their hosting provider.

4.1.1 Inferring SPF Records from MX Records

To infer the minimal SPF record of a domain, we first assume that domains utilizing third-party hosting services should have at least one include mechanism. Now, we compute the *likelihood* that a domain with a specific MX record, mx_x also includes an SPF record, spf_y in their include mechanism. To be precise, we follow these steps:

1. For a given domain name, we generate a list of tuples that consist of all possible combinations of its MX records and the domains in their include mechanisms; for example, if a domain name has a two MX records and three include mechanisms, we generate a total of 6 tuples.
2. We repeat this process for all domains and count the occurrence of domains for each tuple (mx_m, spf_n), which we define as $d(mx_m, spf_n)$.
3. For each tuple, we calculate a conditional probability, $P(spf_k|mx_m) = \frac{d(mx_m,spf_k)}{\sum_{i=1}^{n} d(mx_m,spf_i)}$ where $1 \leq k \leq n$ and n is the number of observed SPF records with mx_m.

Using this approach on our latest snapshot, we obtain 31,876,212 tuples along with their conditional probability. To evaluate our metric, we manually survey the top 10 email hosting providers to obtain the mapping of their MX records and SPF records for their customers.

As shown in Table 4, we find that all of their probabilities are above 93%, each of which aligns with our manual survey. It is worth noting that attaining an absolute 100% probability is practically unfeasible; even in the case of a domain featuring a highly prevalent MX record (e.g., smtp.google.com), the inclusion of superfluous SPF records can diminish the likelihood of achieving a perfect match with _spf.google.com to a value lower than 100%.

Since our objective is to establish a mapping of MX records to their corresponding SPF records for popular hosting providers, we consider only those cases where the probability of SPF record given MX record, $P(spf_k|mx_m)$ is above 90%, and the number of domains associated with such records is more than 100, which leaves us 3,141 tuples of MX records and their corresponding SPF records; clearly, this threshold introduces a trade-off between the size of the tuple list and accuracy. We delve into this topic in more detail in 8.2.

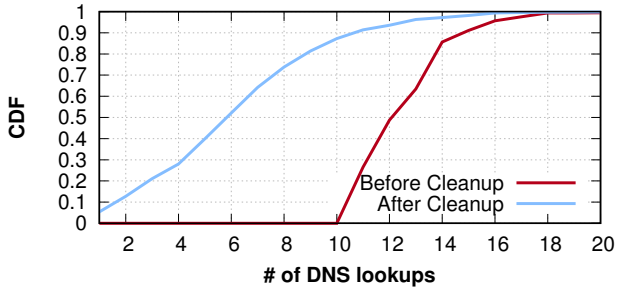

Figure 5: Removing superfluous SPF records can effectively reduce the number of required DNS lookups.

4.2 Domains with Superfluous SPF Records

Next, we identify the domains that have superfluous SPF records. To accurately pinpoint these redundant SPF records, we first only consider the domains for which we know all of the associated MX records for the SPF records in their include mechanisms using our compiled datasets, which leaves us with a total of 24,832 domains. Next, we delve into quantifying the number of domains that possess *superfluous* SPF records, ones that are not tied to any MX records; to be precise, we label an SPF record as superfluous if its corresponding MX records are not present in our dataset.

Remarkably, our analysis reveals that 20,124 (81.0%) of these domains are burdened with superfluous SPF records. Such redundant records could be problematic, raising the likelihood of mail delivery complications due to these extraneous SPF entries. The resolution of this concern lies in the removal of these superfluous SPF records; as shown in Figure 5, we can observe that 17,554 (87.2%) of these domains can effectively streamline their lookup within 10,

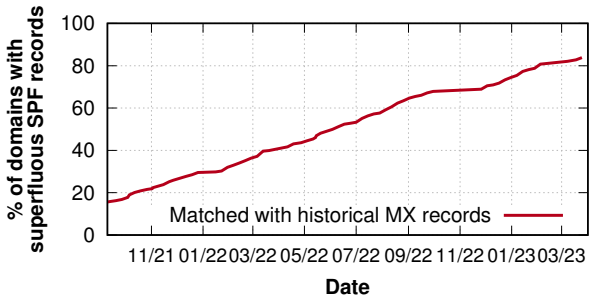

Figure 6: The percentage of domains with superfluous SPF records from our latest snapshot that match with historical MX records.

thereby alleviating the potential mail delivery problem.

4.3 Why Superfluous Records Exist

As elaborated in §4.1, a potential drawback of our methodology arises when sending MTAs are not represented in the MX records, leading to false-positives in our identification of superfluous SPF records.

We now investigate if these superfluous SPF records have any correlation with historical or outdated MX records that a domain might have previously used; if such a connection exists, it could strongly suggest that the presence of these superfluous records may be due to domain owners neglecting to update their SPF configurations in a timely manner. This scenario could arise when domains transition their email services from one hosting provider to another, inadvertently overlooking the removal of the former SPF records.

We examine if the MX records linked to these superfluous SPF records can be traced among the entire history of MX records used by the domain; in essence, we ascertain whether these superfluous SPF records can indeed be aligned with any of the domain's previous (and now outdated) MX records.

For the 20,124 domains that have superfluous SPF records in our latest snapshot, we found that 18,936 (94.1%) domains *have changed their MX records during our measurement period.* Now, for each historical snapshot, we examine if we can find any MX records that correspond to the superfluous SPF records, which is shown in Figure 6; we find that a substantial majority of these superfluous SPF records 16,884 (83.9%) stem from obsolete SPF entries that have not been removed following the migration of mail servers. Interestingly, for 15.3% of these superfluous SPF records, we can find their corresponding MX records in our initial snapshot, suggesting these redundant entries have persisted for at least 15 months.

4.4 Case study: SPF Flattening

To mitigate the recursive nature of SPF records, the concept of *SPF flattening* has been proposed [42]. This technique involves fully evaluating the SPF records and explicitly listing all the assessed IP addresses or prefixes, thereby eliminating the need for include mechanisms. While SPF flattening is effective in reducing the recursion introduced by include mechanisms, it comes with its own set of challenges. Specifically, this approach becomes less reliable when IP addresses within the nested SPF records undergo changes. If these flattened addresses are not updated in a timely manner to reflect such modifications, email delivery may face disruptions.

To evaluate this possible issue, we employ a two-step approach: first, for each domain, we examine if the set of allowed IP addresses can fully cover all the permitted IP addresses specified in the SPF record tied to its MX record. This is done by comparing with our pre-established groundtruth dataset. Next, we monitor for any changes in IP addresses within the SPF records of providers throughout our measurement period.

From the steps, we observe that six providers that have implemented such updates, which suggest that the domains using these hosting providers and relying on flattened SPF records could potentially face complications in email delivery; the results are presented in Table 4.

Interestingly, we discover that numerous domains which have transitioned to flattened domain structures have not yet updated their SPF records, rendering them stale; for instance, among the domains using JellyFish and adopted flattened SPF records, 59.3% of them have neglected to revise their SPF records, despite the fact that the SPF records of the hosting provider itself have been updated. This discrepancy could potentially lead to email rejections due to SPF validation failures.

5 SPF for Inbound Emails

In the previous section, we have found that 6.5% of domains serve SPF records that require more than 10 DNS lookups, which may cause the email receivers to reject incoming emails from the domains since it raises permerror; however, such a high percentage might indicate that *some receiving MTAs may allow more than that.*

Now, we shift our focus to the SMTP servers that check SPF records for incoming emails. In this section, we primarily focus on the DNS lookup limit specified in the standard for: (1) total DNS lookup and (2) void lookup.

5.1 Methodology

At first glance, it might seem straightforward to measure how MTAs impose limits on DNS lookups of SPF records; we could set up our own MTAs and serve an SPF record that incurs many DNS lookups by utilizing nested include mechanisms. Subsequently, we could send emails to selected MTAs and tally the number of incoming DNS queries; this measurement methodology has been employed in prior

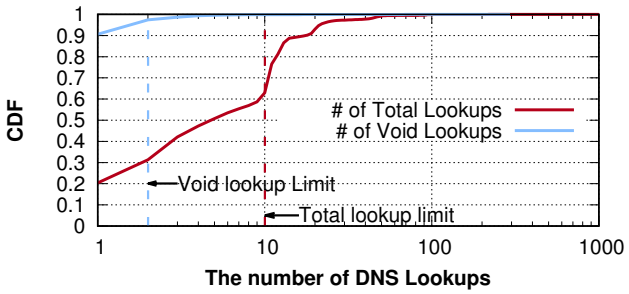

Figure 7: CDF of the number of DNS requests that our DNS authoritative server receives; 40% servers violate the total lookup limit recommendation in practice. Note that x axis extends to 25,117![6]

studies to gauge the deployment of SPF checks for incoming emails [14, 36]. However, we argue that this approach could elicit ethical dilemmas especially when the objective is to measure many MTAs; taking explicit permission from many recipients is practically not feasible, which may classify our action as unsolicited sending, thereby potentially causing inconvenience or even harm. Instead, we leverage an RFC ambiguity to trigger DNS queries from MTAs.

Alternative Approach: We note that RFC7208 [23] does not specify the SMTP command that should trigger the receiving MTAs to perform the resolution of the `SPF` record; given that the SPF check is performed on the domain name in the `MAIL FROM` header, we may expect that some SMTP servers may send DNS queries for `SPF` records once it receives the `MAIL FROM` command from the sender; for example, we find that MTA software such as `postfix` with the `iRedAPD` extension sends DNS queries for the `SPF` record after `RCPT TO` command. This implies that it may be possible to trigger DNS queries for SPF records *without sending emails* to the recipient's inbox if it looks up `SPF` records as soon as it receives the domain name; theoretically, as the `MAIL FROM` header contains the sender's domain name, it may be enough for them to lookup `SPF` records; thus we only send the `HELO`, `MAIL FROM`, and `RCPT TO` commands to determine if it triggers DNS queries, and then terminate our SMTP connection *without* executing the `DATA` command to avoid transferring email data.

However, we acknowledge that our methodology could potentially identify fewer vulnerable receiving MTAs because most email spam filters or SPF milters perform an `SPF` record check once the mail data is transferred. Nevertheless, we believe that this approach is appropriate for understanding the vulnerability empirically without adversely affecting the MTAs in the wild. Furthermore, we obtain a set of unique `MX` records by scanning zone files, and then resolve their IP addresses while removing those that share the same IP addresses to limit the number of MX servers.

Name	Type	Ver.	DNS # of Lookups N_{lim}	DNS # of Lookups V_{lim}	DNS Timeout (s) t_{lim}	DNS Timeout (s) T_{lim}
libspf2 [45]	Lib	latest	10	1	5	∞
Mail::SPF::Query [27]	Lib	< 1.8	∞	1	15	∞
Mail::SPF::Query [27]	Lib	> 1.8	10	1	15	∞
pyspf [49]	Lib	latest	10	2	2	20
milter-greylist [46]	M	latest	10	10	5	∞
spfmilter [50]	M	latest	10	2	5	20
mtpolicyd [47]	PS	latest	10	2	30	∞
policyd-spf [48]	PS	latest	20	1	5	20
iRedAPD [44]	PS	< 5.1	∞	∞	3	∞
iRedAPD [44]	PS	≥ 5.1	20	20	3	∞
SpamAssassin [6]	CF	latest	20	1	3	5
RSpamD [3]	CF	latest	30	30	1	∞

Table 5: The lists 10 popular SPF libraries (`Lib`), milters (`M`), policy servers (`PS`), and content filters (`CF`). Here, N_{lim} and V_{lim} represent the limits on DNS and void lookups, respectively; for example, Mail::SPF::Query and iRedAPD have no N_{lim}, resulting in endless DNS requests (highlighted in red). t_{lim} and T_{lim} indicate DNS timeout values for individual and total SPF evaluations, respectively. When parallel SPF validation is not supported, the SMTP server is vulnerable to DoS attack for inbound emails (highlighted in yellow).

Experiment Process:

We purchase a domain name, `a.com`, and configure our customized DNS authoritative server and SMTP server using Postfix [30]. From the latest snapshot of four zone files, we examine the `MX` records and their corresponding IP addresses to create a unique set of MTAs, yielding 1,886,825 `MX` records in total and then proceed as follows:

1. For each `MX` record, mx_a, we generate two unique subdomains: $mx_a.t.a.com$ and $mx_a.v.a.com$ to serve two types of `SPF` records to evaluate their DNS lookup and void lookup limits. To assess the DNS lookup limit, we serve `SPF` records featuring 50 `include` mechanisms, which incurs 51 DNS lookups. For the void lookup limit, the `SPF` record includes 50 `include` mechanisms, 36 of which lead to void lookups; we provide an explanation of the choice of parameters in §8.2.
2. We establish two SMTP connections to the target MX server: one for gauging the total lookup limit (Exp. #1) and another for probing the void lookup limit (Exp. #2). In each connection, we issue a `HELO` command featuring the unique subdomain.

[6] Along with this SMTP server, we found that two additional SMTP servers sent duplicate queries over 1,000 times; we attempted to contact them using common administrator email addresses (e.g., `postmaster@`) and the admin name in the `rname` field of the `SOA` record, but we were unable to reach them. This could be due to SPF validators that store `SPF` records in their database and periodically update the `SPF` records for security purposes (e.g., iRedAPD converts SPF records of specified domains to IP addresses on an hourly basis).

3. Subsequently, we transmit our `MAIL FROM` address with `noreply` as the username.
4. Next, we send a `RCPT TO` command with `postmaster` as the username.
5. We pause for 3 seconds to allow sufficient time for the `SPF` queries to reach our DNS authoritative servers, after which we terminate the SMTP connection.
6. All incoming DNS queries are logged for analysis.

We conducted these experiments from Feburary 28, 2024 to March 16, 2024. Along with this, we investigate 10 popular SPF libraries, milters, policy servers, and content filters, as detailed in Table 5, through source code analysis and testing.

5.1.1 Ethical Considerations

Our approach does not involve sending unsolicited emails; however, we intend to discuss the potential implications for email service providers explicitly before sharing our findings. Firstly, we correctly set up reverse DNS record and remove duplicates from the `MX` records and their resolved IP addresses to ensure that we communicate with no more than one server.

We also took extra care to ensure our SMTP scanner is fully compliant with the RFCs; for instance, we have programmed our scanner to disconnect following the `QUIT` command, mirroring the behavior of a well-behaved SMTP client. This attention to detail is crucial; failing to comply with this standard, such as by disconnecting without the proper command, could unnecessarily alert system administrators. It is worth noting that throughout our scanning period, we did not receive any automated abuse reports or personalized feedback from operators.

We acknowledge that we have not asked for any explicit consent to connect to the IP addresses mapped to `MX` records, which may violate one of the four principles of the Menlo Report [15], "Respect for Persons"; unfortunately, it is practically impossible for us to obtain an informed consent from all email operators and also, emailing them to ask for approval will be considered as unsolicited email. Thus, we decided not to ask for consent. However, it is important to note that the inability to obtain informed consent does not imply a disregard for respect towards individuals [35]. To ensure we follow the guidelines by the Menlo report [15], we did not send any emails and tried our best not to contact multiple email operators by deduplicating the adddresses. We believe in the value of publishing our findings, considering the potential benefits and the preventative aspect of our research in mitigating future harm by informing the community, thereby justifying our approach amidst ethical concerns.

5.2 Results

With our methodology, we successfully connect to 1.2M (64%) SMTP servers out of 1.89M ones in total and find that 81,843 (6.8% of 1.2M) initiate `SPF` queries prior to issuing the `DATA` command; this suggests that most SMTP servers opt for SPF validation after the `DATA` command, likely to exploit the policy flexibility available at this stage.

Now, we focus on the number of DNS queries we receive. Figure 7 shows the results. First, we find that 903 servers (1.1%) send more than 51 queries, but they do so by *issuing duplicated `SPF` queries*. This could be due to either (1) SPF validation taking place from multiple extensions, (2) the involvement of multiple DNS resolvers executing identical queries, or (3) the use of SPF validators that lack DNS lookup limits as elaborated in §2. We will further explore this in §6. Among them, we find that 195 SMTP servers queried for all 50 `include` in our `SPF` record; this strongly suggests that some SMTP servers use `SPF` validators that *do not have any total lookup limit*. Out of these 195 servers, 165 of them maintain a void lookup limit as they aborted `SPF` resolution right after querying the set number of domains that incur `NXDOMAIN` responses in Exp. #2; the rest (30) requested all 36 domains that result in void lookups, which indicates that these servers could potentially serve as reflectors for launching DNS queries against a targeted victim's authoritative server. Interestingly, even for those who made < 51 queries in Exp. # 1, we find that 39 SMTP servers made all 36 void lookups, which indicates that they do not have a void lookup limit even though they have a total lookup limit.

These findings corroborate the hypothesis that a substantial number of SMTP servers operate with lax or even unlimited lookup limits. As validated in Table 5, both `Mail::SPF::Query` and `iRedAPD` lack a DNS lookup cap. Given that the iRedAPD's patch was in August 2022, this signals potential vulnerabilities in numerous mail servers.

5.3 Threat Model

Each MTA establishes its own timeout limits for SPF validation. If the corresponding SPF validator does not support parallel processing of incoming SMTP connections, attackers can exploit this timeout leading to interruptions in processing valid incoming emails for a victim recipient MTA.

Preliminaries: To execute this attack, attackers should have (1) a domain name (2) a custom authoritative server for the domain to serve DNS records and manipulate DNS response time. More details on the execution is introduced in §5.4.

1. **DoS attack:** the attackers can disrupt the processing of benign incoming emails by deliberately slowing down DNS responses during SPF validation, causing timeouts and thus either delaying or outright denying email processing.
2. **Low economic barrier:** the attacker may (1) register a domain name using the TLDs that offer domain names at no cost (e.g., .ml [33]) (2) utilize a free-tier hosting service

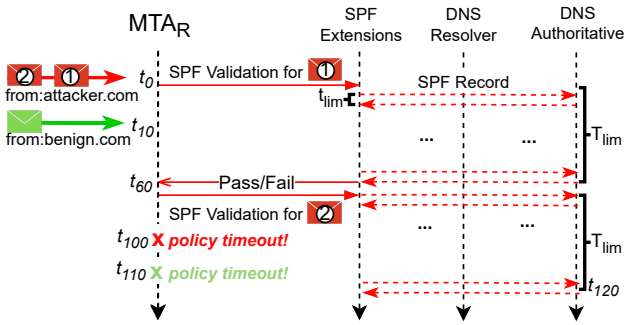

Figure 8: Certain SPF validators (e.g., iRedAPD or libspf2), do not support parallel SPF validation. In such cases, attackers can introduce delays up to either T_{lim} or $t_{\text{lim}} \times N_{\text{lim}}$ seconds; Each MTA has its own timeout limit for SPF validation, denoted as M_{lim}. Should the delay exceed this threshold, subsequent incoming emails may be rejected.

(e.g., AWS micro instance) to operate a customized DNS server designed to return DNS responses with extra delays.

5.4 DoS Attack for Inbound Emails

Each MTA sets individual timeout limits for SPF validation, leading to variations in the waiting time for process completion. For example, when a Policy Server is responsible for validation, the MTA may wait until a *policy service timeout* is triggered. Likewise, a *Milter command timeout* comes into play when Milter handles the validation. In the case of Postfix, the default settings specify a 100-second limit for policy service timeout and a 30-second limit for Milter timeout during SPF validation for incoming emails [31]. Should SPF validation exceed these predefined timeframes, the SMTP connection handling the email will be terminated.

This feature becomes a vulnerability when the SPF validators in use *do not support parallel SPF validation and dns lookups continue even after MTA aborts the connection*; as a result, if the validation process exceeds the *policy service timeout*, it can cause a cascade of timeouts, leading to the rejection of multiple incoming emails. This makes the emails undeliverable to the recipient MTA, effectively serving as a Denial-of-Service (DoS) attack vector.

For example, iRedAPD imposes a limit of 3 seconds (t_{lim}) for each DNS query and a maximum of 20 DNS lookups (N_{lim}); an attacker can exploit these constraints to induce delays. Specifically, by carefully crafting DNS responses that take exactly 3 seconds to resolve, the attacker can cause the SPF validation process to last for up to 60 seconds (3 seconds $\times$ 20). This can lead to a SPF validation exceeding the system's configured timeouts, effectively becoming a bottleneck and causing incoming emails to be rejected.

However, in practice, t_{lim} is also influenced by the DNS resolver's own timeout settings. Should the DNS resolver that the SPF validator employs have a shorter timeout value, the resolver could trigger its own timeout, potentially reducing the window for attack but also complicating the validation process. In such a scenario, attackers can take advantage of the fact that *CNAME record expansion is managed by the DNS resolvers, thus not contributing to* N_{lim}; this allows the attacker to induce the resolver into initiating a fresh DNS request, effectively resetting the resolver's timeout. For example, consider the attacker sets up the following SPF and DNS records:

```
a.com      TXT    "v=spf1 include:r1.a.com"
r1.a.com   CNAME  r2.a.com
r2.a.com   TXT    "v=spf1 include:r3.a.com"
r3.a.com   CNAME  r4.a.com
```

In this example, the attacker has purposely created a chain of `CNAME` records to prolong the DNS lookup process; when the DNS resolver reaches the `CNAME` record at `r1.a.com`, it is compelled to initiate a new DNS request for `r2.a.com`. Subsequently, the request for `r2.a.com` leads to another `CNAME` record (`r3.a.com`), triggering yet another DNS request and resetting the timeout. This can be extended further, thereby increasing the time needed for SPF validation but decreasing the chance to trigger t_{lim}.

By sending two emails simultaneously, the attacker can cause a cumulative delay of 120 seconds; given that Postfix's default policy service timeout is 100 seconds [31], all incoming emails in the 20-second window following the initial delay—from t_0 to t_{20}—would be rejected. This situation is illustrated in Figure 8. Specifically, the second email initiates its SPF validation at t_{60} and will hit the policy timeout, leading to termination of the SMTP connection at t_{100}, but blocking further SPF validation until t_{120}.

It is worth noting that SPF validation often occurs after the `RCPT TO` command; this allows attackers to potentially initiate a DoS attack without actually dispatching emails, making detection and mitigation more challenging.

5.4.1 Responsible Disclosure

We have reported a vulnerability concerning our proposed attack to the corresponding GitHub repository's issue tracker.[7] The previously identified issue with Mail::SPF::Query versions that were susceptible has been resolved. Furthermore, to assist users in assessing the security of their domains, we have incorporated a search feature on our website to let them inspect the status of their SMTP servers. Importantly, this feature is designed to prevent the scraping of entire lists.

6 SPF Validation in Practice

In this section, we augment our empirical data with a survey conducted in late 2022 to gain a more comprehensive view

[7] `https://github.com/iredmail/iRedAPD/issues/19`

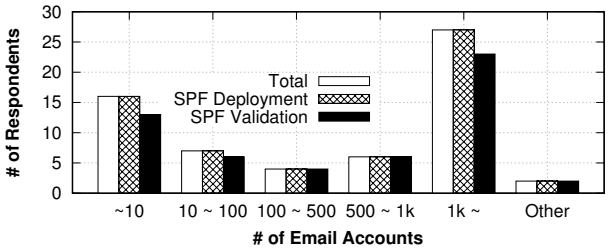

Figure 9: The figure shows the distribution of the number of email accounts managed by each of the 62 respondents who answered both questions regarding SPF deployment and SPF validation support; note that all respondents serving as SMTP administrators confirmed the deployment of `SPF` records.

of SPF validation in the email ecosystem. While our passive measurements and in-lab tests provide valuable quantitative insights, they are based on publicly accessible information and open-source software. The survey fills the knowledge gap, offering a qualitative look at operational practices and challenges in real-world SPF deployments.

6.1 Survey Methodology

We sourced participants for our survey from specialized mailing lists, including the Mail Operators' List (MailOP) [2], the North American Network Operators' Group (NANOG) [29], and Email Security Standards in the European Union (MESSEU) [28]. Of the initial 95 respondents, 74 engaged with at least one survey question; The participant demographics, summarized in Figure 9, reveal a wide range of mail-setup sizes: from 16 operators overseeing fewer than 10 accounts, to 25 operators responsible for more than 1,000 accounts. This variety suggests that our survey offers a broad view of the mail operator landscape. In summary, our diverse participant sample enhances our understanding of email infrastructure; also, the input from mail operators is particularly valuable as it plays a critical role in the standardization of protocols within the email ecosystem.

However, we also note that our survey has limitations worth noting for proper interpretation of the results. The small sample size offers a qualitative view rather than a basis for broader generalization. While we targeted knowledgeable operators, we did not verify their responses, which may introduce self-reporting and social desirability biases. Participation was voluntary, potentially leading to self-selection bias. Despite these limitations, our survey provides valuable qualitative insights into email operations, complementing our technical findings.

Ethical Considerations: Our survey focuses on organizations rather than individuals and collects factual data on system deployments. Our Institutional Review Board (IRB) confirmed that this does not qualify as human subject research, eliminating the need for studying protocol evaluations. Nonetheless, we adhered to best practices similar to those for human subject research, informing participants of their data access rights and the ability to withdraw at any time.

6.2 Operational Practice for SPF Validation

SPF Deployment and Validation: We first understand how they *deploy* email security protocols by publishing `SPF` records; interestingly, we observe that all of the participants (74) answered that they publish SPF for source validation; among them, 45 (60.8%) and 39 (52.7%) deployed DKIM and DMARC for the same purpose as well. In contrast, the adoption rates for other protocols aimed at encryption and receiver validation are somewhat lower; for example, MTA-STS is used by 13 participants (17.6%) and DANE by 19 (25.7%).

Regarding SPF validation, 62 participants responded to whether their SMTP server validates sender's SPF record or not and 54 participants (87.1%) answered yes, while only 8 explicitly indicated they do not.[8]; these findings underscore the critical importance of SPF in the realm of sender authentication. Firstly, among the 32 participants aware of when SPF validation occurs, we observe a multi-stage process: 3 perform validation after the `HELO/EHLO` command, 7 after the `MAIL FROM` command, 10 after the `RCPT TO` command, and 12 (37.5%) proceed after the `DATA` command. This variability underscores the feasibility of the attack vectors we propose, making it challenging for receivers to detect their unwitting role as reflectors when they check before the `DATA` command. Secondly, 14 participants (26%) report utilizing *multiple* extensions for SPF validation, potentially increasing the volume of DNS requests for each validation process. This aligns with our experiments, showing that 1.1% of SMTP servers issue more than 51 queries during SPF validation.

RFC Recommendation vs. Practice: Among the 14 participants who were aware of their SPF lookup limits, three have opted to increase these limits, and one has additionally raised the void lookup limit, suggesting that the current RFC guidelines may not align with practical operational needs; interestingly, *all four operators serve customer bases exceeding 1,000 accounts*, suggesting that the existing limits in RFC7208 for lookup limits may not adequately serve large-scale email operators. We also note that four of these participants have extended their total SPF resolution timeout.

Software Update and Others: Of the 61 participants who responded to questions about software update frequency, 13

[8] The remaining 12 respondents did not answer the question.

disclose that they *do not* update their SPF validation software periodically, with one explicitly stating they never do so. This raises concerns about the potential vulnerabilities in their SPF validation process.

SPF Validator Usage: Out of 54 participants who responded to questions about which SPF validator they use, 19 (35%) reported to use SpamAssassin [6], 14 (26%) use policyd-spf [48], 6 (11%) use libspf2 [45], 14 (26%) use Rspamd [3]. 14 (26%) participants use MTAs that natively support SPF validation while 4 (7.4%) of them did not know which validator they used. Out of the remaining 4 participants, one reported to use mtpolicyd [47], one iRedAPD [44], one amavisd-new [43], and one participant use Google's in-house solution. Note that 18 (33%) participants reported to have multiple SPF validators.

In summary, our survey reveals diverse practices in SPF validation among operators, suggesting both potential vulnerabilities and adaptability, with notable deviations from RFC7208 and varying degrees of operational vigilance.

7 Related Work

SPF Deployment for Outbound Emails: There have been a few studies that have focused on the deployment of `SPF` *records*; for example, Mori et al. [26] investigated the top 500 Alexa domains in 2011, finding that half had deployed `SPF` records but also noting common syntactic errors in their SPF policies. Foster et al. [17] extended this work by examining the Alexa 1M domains in 2015, revealing that 40% of these domains had valid `SPF` records. Hu et al. [18] and Wang et al. [40] continued this trend by showing increasing deployment rates, 44.9% and 54.1% respectively, in subsequent years. Recently, in 2023, Czybik et al. [13] conducted a scan of 12 million domains, revealing that 56.5% have implemented `SPF` records and Blechschmidt et al. [7] reported a 41% `SPF` deployment ratio among the DomCop Top 10M domains.

SPF Validation for Inbound Emails: The evaluation of SPF validation policies for inbound emails presents unique challenges. Earlier studies have primarily resorted to one of three methods: (1) analyzing popular email server logs, such as Gmail, (2) registering with popular email service providers and testing their services, or (3) sending emails to assess validation protocols. For example, Durumeric et al. [16] examined SMTP handshake logs for emails sent to and from Gmail between 2014 and 2015; their results showed that Gmail successfully validated 92% of incoming emails using SPF. Similarly, Foster et al. [17] evaluated popular email providers and found that 15 out of 22 had `SPF` records for outgoing emails. Moreover, 20 out of these 22 providers performed SPF validation for incoming emails, although only 10 actively enforced the SPF results.

More recent research by Hu et al. [18] revealed that 31 out of 35 top email providers validated `SPF` records for inbound messages while Blechschmidt et al. [7] revealed 46 of 47 providers did so. This underscores the widespread adoption of SPF validation in the wild.

In 2021, Casey et al. [14] *sent* 26K *legitimate* emails to measure SPF, DKIM, and DMARC validation rates, discovering that up to 85% of domains performed SPF validation for incoming emails. For a separate set of domains, they also measured SPF behavior by making an SMTP connection and then aborting the connection right *after* sending the `DATA` command but before sending any email content, which allowed them to measure SPF validation behavior of 1,574 MTAs. For our study, we intentionally disconnect *before* the `DATA` command since this command is intended for sending emails and might potentially activate spam extensions, leading to unnecessary computational resource consumption.

SPF Misconfiguration: Misconfiguration of SPF policies is a significant concern, as highlighted by numerous studies; for example, Durumeric et al. [16] reported that 29% of mail servers had overly permissive SPF policies that included more than 10,000 addresses. Hu et al. [18] indicated that 0.1% of domains in the Alexa 1M dataset had an `SPF` record that allowed all IP addresses to pass.

Tatang et al. [38] performed a graph-based analysis on the Alexa 1M dataset and observed that many domains included overly broad SPF policies from large providers like Amazon or SendGrid, making them vulnerable to spoofing attacks. Moreover, they found domains that permitted IP addresses from as many as 9,000 different ASes, marking them as potential targets for attackers. Scheffler et al. [36] discovered that several email servers did not adhere to RFC limits on the number of SPF referrals by connecting to *the entire IPv4 address space and sending emails using popular usernames*, thereby exposing a gap in compliance with standards.

Recent studies have even also pointed to potential security vulnerabilities in SPF implementations; Jeitner et al. [20] discovered possible injection and buffer overflow vulnerabilities in two popular SPF implementations, namely `policyd-spf` and `libspf2`.

While these previous works offer valuable insights into SPF misconfigurations, our study distinguishes itself by aiming for a comprehensive evaluation of the current SPF landscape. Our study extends these prior works in two ways. First, we undertake what is, to our knowledge, the most comprehensive assessment of SPF deployment, covering 176 million domains and their respective misconfigurations across a 15-month period. Second, our investigation is not solely confined to descriptive statistics; we also delve into the root causes

of prevalent misconfigurations. We employ a mixture of quantitative measurement data and qualitative analysis to explore the underlying mechanisms contributing to these issues. Specifically, we examine the security implications of exceeding RFC-recommended DNS lookup limits and investigate the rationale behind why email operators may choose to deviate from these guidelines.

8 Concluding Discussion

We presented a multi-faceted, deep-dive investigation into SPF records and their management, encompassing both a quantitative analysis based on comprehensive scans and qualitative insights obtained through operator surveys. We found that a significant majority (60.2%) of SPF records use the include mechanisms, largely depending on external domains. Most SPF records are syntactically correct, however, they falter in the evaluation phase—primarily due to excessive DNS lookups that surpass RFC-imposed limits; our study points to two major culprits behind these misconfigurations: popular hosting providers with large number of include in their SPF records and SMTP administrators failing to update obsolete records post-migration. We demonstrate a novel attack vector causing disruptions in email receipt without alerting the victim. Our operator surveys reveal that many large-scale email providers deviate from RFC best practices, underscoring a significant gap between existing standards and current operational requirements.

In summary, our work serves as a comprehensive resource for understanding the state of SPF management, its security implications, and avenues for improvement. It is our hope that this paper will act as a catalyst for more secure and effective email systems moving forward.

8.1 Recommendations

Altogether, our findings illuminate the present landscape of SPF deployment and management. We offer insights on revisions needed for existing recommendations and RFCs.

- Given the increase in (nested) SPF policies over time, we suggest increasing the current lookup limit of 10 to, e.g., 20 as it is already handled in several implementations.
- Domain owners and email operators should make use of subdomains for (e.g., newsletter) sending or other tasks delegated to an external email service provider to avoid the 'too many lookups' issue. These subdomains can then have a smaller SPF policy, only including, e.g., the service used for newsletters (news.example.com) or the CRM software (support.example.com).
- Email service providers on-boarding a new client should not only validate that client's SPF policy for the correct inclusion of *the provider's records*, but should also check whether their customers have superfluous records.
- Non-parallel email receipt/milter execution should be avoided, and milter operators should more clearly document it if their implementation or certain configurations for their software leads to non-parallel email receipt.
- Depending on the preferences of an email operator, they might choose to perform SPF queries after the remote server indicates the end-of-data ('.\n\n'), but before accepting a message; this approach can be advantageous for protecting against the attack we proposed. However, this strategy might result in missing the opportunity to reject connections from unauthorized sources early, leading to memory consumption (to load the message in the DATA command). Therefore, email operators must carefully configure their systems according to their needs.

Furthermore, we have to acknowledge that especially milter libraries for established protocols like SPF are a part of the often forgotten and regularly maintained by but a few essential building blocks of modern technology such as NTP [34]. They hardly change, thus often hardly require maintenance–unless vulnerabilities occur [8]–and hence it becomes easy for such milter projects to slide into obscurity and abandonment.

Finally, the common truth of operating digital infrastructure also remains true; operators should regularly check for updates to components of their setups.

8.2 Limitations

Our study has several limitations. First, our analysis of superfluous SPF records based on MX records is susceptible to false positives. This inaccuracy can be attributed to two factors: (1) Domains not listed in MX records might still be legitimate email senders, such as newsletter services. (2) Our 90% threshold heuristic may not universally hold true. To overcome these limitations, we confined our analysis to domains with more than 100 associated senders and corroborated our results with ground-truth data from the top 10 email providers.

Second, in §5, we have classified SMTP servers that perform more than 50 record lookups as vulnerable, which may introduce false positives. However, as elaborated in Table 5, our analysis indicates the maximum lookup limit identified across all evaluated software is 30, suggesting a lower likelihood of false positives.

Third, SPF queries were received from 81,843 (6.8%) recipient MTAs we successfully connected to. Despite appearing modest, we believe that this number represents a well-balanced trade-off compared to the numbers obtained by sending emails (e.g. 26K SPF validating MTAs in [14]). Furthermore, we evaluated 10 popular open-source SPF validators; although there is a chance that some less widely used software may have been missed, we have still covered validators of 49 (91%) administrators who participated in our survey.

Fourth, we used `postmaster` as the recipient username. Out of 1.2M servers we were able to successfully connect to, we got a `negative` response to the `RCPT TO` command for (679K) 56% of them, which indicates the absence of this user; MTAs are also often set up to whitelist `postmaster` address. Thus, even if `RCPT TO` command succeeds, sender validation might not take place.

Fifth, it is important to note that our study intentionally excludes the consideration of additional lookup limits resulting from `MX` or `PTR` records within an `SPF` record. This decision was made to avoid the ethical implications associated with initiating four connections to the same SMTP server.

Sixth, when identifying superfluous `SPF` records, we seek out the `SPF` records and their corresponding `MX` records to create a *pseudo-ground truth dataset* by focusing on the popular `SPF` records associated with more than 100 domains. Aiming for a high level of confidence in mapping to pinpoint superfluous records, we adopt a conservative threshold of 100 domains; for example, reducing this threshold to 20 domains notably expands the coverage, from 20,124 to 39,632 domains with superfluous records. However, we believe this adjustment leads to a high number of false positives.

Lastly, our analysis covers all second-level domains within four TLDs, thus not accounting for other domains that operate under subdomains.

Acknowledgments

We thank anonymous reviewers and our shepherd for their helpful comments. We are also thankful to Laura Atkins and Grant Taylor for giving valuable feedback on our work and Marteen Aertsen for his assistance with the survey to MEESEU, as well as to the email operators in the MailOP, NANOG, and MEESEU mailing lists who took part in our survey. This research was supported in part by NSF grant CNS-2323137, CNS-2247306, and the Institute of Information & communications Technology Planning & Evaluation (IITP) grant funded by the Korea government (MSIT) [RS-2023-00215700, Trustworthy Metaverse: blockchain-enabled convergence research].

9 Appendix

9.1 Survey Questionnaire

All the questions except in §9.1.1 were optional. In questions where we had `Other (please specify)` as the last option, a textbox was there for the participants to specify their answer. SCQ denotes single choice question, MCQ denotes multiple choice question, and YN denotes yes no question.

9.1.1 Page 1: Consent Form

Participants were presented with the following two mandatory consent questions:

- I consent voluntarily to be a participant in this study and understand that I can refuse to answer questions and I can withdraw from the study at any time, without having to give a reason.
- I understand that information I provide will be used for scientific reports and publications.

If the participant answered `No` to any of the above questions, the survey would end with no further input.

9.1.2 Page 2: Email Service

Both the questions came with a textbox.

- Would you be willing to provide the name of the organization whose e-mail service you manage? (If you don't want to, please enter `No`.)
- Would you mind sharing the name of the domain whose e-mail service you manage? We'd like the main domain name, not the domain name of your mail server. For example, example.com, not mx.example.com. (If you don't want to give the name, please enter `No`.)

9.1.3 Page 3: SMTP Service

SCQ What is the name of your email server software? Or, what is the name of your MTA? Options were `Postfix`, `Exim`, `Sendmail`, `Qmail`, `Exchange`, `Haraka`, `MDaemon`, `hMailServer`, and `Other (please specify)`.

SCQ Are you using any framework, setup tool, or how to for your mail server? Options were `iRedMail`, `Mailcow`, `OpenExchange`, `Plesk`, `Webmin`, `Mail-in-a-box`, `(ISP) Mail Server Howto`, and `Other (please specify)`.

SCQ How many email accounts exist under your operated infrastructure? Options were `< 10`, `10 - 50`, `50 100`, `100 500`, `> 500`, and `Other (please specify)`. This was a single choice question.

SCQ How many emails does your system receive on average per day? Options were `< 10`, `10 - 100`, `101 - 1000`, `> 1000`, and `Other (please specify)`.

SCQ How many concurrent connections can your mail server/ MTA handle on average? Options were `< 10`, `10 - 100`, `101 - 1000`, `> 1000`, and `Other (please specify)`.

SCQ Do you frequently update your MTA or associated plugins and mail filters? By update, we mean following the releases for the associated software and installing them regularly. Options were `Always`, `Often Sometimes`, `Rarely`, and `Never`.

Date If yes, approximately when did you last update your MTA or any of the plugins and mail filters? This had a datepicker.

MCQ What security email protocols do you use? Options were `SPF`, `Often DKIM`, `DMARC`, `BIMI`, `MTA-STS`, `DANE`, `STARTTLS`, `ARC`, and `Other (please specify)`.

9.1.4 Page 4: SPF Validation

YN Does your email server validate the sender's SPF record when it receives an email? Options were `Yes` and `No`. If the answer to this question is `No`, survey ends with no further input.

9.1.5 Page 5: SPF Validator

MCQ What is the name of your SPF validator? In other words, which plugin (i.e. milter, policy server, content filter) is doing the SPF validation when an email comes to your server? If your MTA natively supports SPF validation, please mark "MTA Native". Options were `SpamAssassin`, `policyd-spf`, `iRedAPD`, `libspf/libspf2`, `RSpamd`, `MTA Native`, `Don't Know`, and `Other (please specify)`.

YN Did you set up the SPF validator yourself? If the answer to this question is `No`, survey ends with no further input.

9.1.6 Page 6: Self-managed SPF Validator

MCQ When does your SPF validator perform the SPF check of the sender domain? Options were `After the HELO/EHLO command`, `After the MAIL command`, `After the RCPT command`, `After the DATA command`, and `After the email is received`.

YN Did you change any of the default values in your SPF validator? (Like changing the default DNS timeout of SPF validation). If the answer to this question is `No`, survey ends with no further input.

9.1.7 Page 7: SPF Validator Default Value Change

- Did you change any of the following default values in your SPF validator? If yes, please indicate how did you change them. Otherwise, please select the "leave as-is" option. FYI, the RFC recommendation for total DNS lookup and void lookup limits is 10, and 2 respectively. This question had three options: `Number of permitted DNS lookups per SPF check before an SPF permanent error is raised`, `Number of void DNS lookups per SPF check before an SPF permanent error is raised`, and `DNS timeout per SPF check before an SPF permanent error is raised`. Each option had three single choice radio buttons: `Increase`, `Leave as-is`, and `Decrease`.
- Please provide any rationales behind such updates (if you did so). This question had a textbox.

A Formal Analysis of SCTP: Attack Synthesis and Patch Verification

Abstract

SCTP is a transport protocol offering features such as multi-homing, multi-streaming, and message-oriented delivery. Its two main implementations were subjected to conformance tests using the PACKETDRILL tool. Conformance testing is not exhaustive and a recent vulnerability (CVE-2021-3772) showed SCTP is not immune to attacks. Changes addressing the vulnerability were implemented, but the question remains whether other flaws might persist in the protocol design.

We study the security of the SCTP design, taking a rigorous approach rooted in formal methods. We create a formal PROMELA model of SCTP, and define 10 properties capturing the essential protocol functionality based on its RFC specification and consultation with the lead RFC author. Then we show using the SPIN model checker that our model satisfies these properties. We next define 4 representative attacker models – Off-Path, where the attacker is an outsider that can spoof the port and IP of a peer; Evil-Server, where the attacker is a malicious peer; Replay, where an attacker can capture and replay, but not modify, packets; and On-Path, where the attacker controls the channel between peers. SCTP was designed to be secure against Off-Path attackers, and we study the additional models in order to understand how its security degrades for successively more powerful attacker types. We modify an attack synthesis tool designed for transport protocols, KORG, to support our SCTP model and 4 attacker models.

We synthesize the vulnerability reported in CVE-2021-3772 in the Off-Path attacker model, when the patch is disabled, and we show that when enabled, the patch eliminates the vulnerability. We also manually identify two ambiguities in the RFC, and using KORG, we show that each, if misinterpreted, opens the protocol to a new Off-Path attack. We show that SCTP is vulnerable to a variety of attacks when it is misused in the Evil-Server, Replay, or On-Path attacker models (for which it was not designed). We discuss these and, when possible, mitigations thereof. Finally, we propose two RFC errata – one to eliminate each ambiguity – of which so far, the SCTP RFC committee has accepted one.

*Contributed equally.
†Listed alphabetically.

1 Introduction

Transport protocols play a crucial role in transmitting data across the Internet either directly – as in UDP [3] and DCCP [22], which provide unreliable communication, and TCP [20] and SCTP [58], which provide reliable communication – or by supporting secure protocols – e.g., UDP supports DTLS [51] and QUIC [31], while TCP supports TLS [50]. Thus, it is critical that transport protocols are designed and implemented to be bug-free and secure.

SCTP is a transport layer protocol proposed as an alternative to TCP, offering new features, such as multi-homing, multi-streaming, and message-oriented delivery. Among other use-cases, it is the data channel for WebRTC [5], which is used by such applications as Facebook Messenger [35], Microsoft Teams [37], and Discord [65]. The design of SCTP is described in RFC documents, the most recent one being RFC 9260 [58], and implemented in Linux [2] and FreeBSD [4]. These implementations were tested using PACKETDRILL [1, 14] and analyzed with WIRESHARK [52]. Some limited efforts also analyzed the SCTP design using formal methods. The works in [62, 63] focused only on bugs and did not consider attacks, while the work in [53] focused on attacks, but modeled only limited aspects of connection establishment to compare the resilience of SCTP and TCP to SYN-FLOOD attacks. A recent vulnerability – CVE-2021-3772 [49] – shows the importance of conducting a much more comprehensive formal analysis. Although a patch was proposed in RFC 9260 [58], and adapted by FreeBSD, the question remains whether other flaws might persist in the protocol design and whether the patch might have introduced additional vulnerabilities. To the best of our knowledge, no prior works formally analyzed the entire SCTP connection establishment and teardown routines in a security context.

In this work, we take an approach rooted in formal methods to study the security of SCTP. Our approach is based on *attack*

synthesis, where the goal is, given a program that behaves correctly, and an attacker model, to find an attack that can lead the program to behave incorrectly.[1] Specifically, we use an attack synthesis tool called KORG [67] which can find attacks where an attacker manipulates two protocol peers in order to induce a denial of service (DoS). Combined with other formal methods, such as model checking, this approach allows us to precisely study the behaviors of SCTP under different DoS attacker models.

Model Design and Verification. We start by creating finite state machine (FSM) models for the consecutive SCTP designs specified in RFCs 4960 [55] and 9260 [58], and writing ten properties the models should satisfy based on a close reading of the RFC documents and discussions with the lead SCTP author [2]. Our properties are defined in Linear Temporal Logic (LTL) and characterize the standard establishment and teardown routines, the proper functioning of the cookie timer, and the fact that SCTP does not support half-open connections. Using the SPIN model checker, we automatically verify that our SCTP model meets these properties (behaves correctly) when not under attack.

Attack Synthesis. We use an attack synthesis tool for transport protocols called KORG, based on LTL model-checking [67]. KORG automatically finds DoS attacks against the protocol's handshake (establishment and teardown) in which an attacker, constrained to scenarios with two peers, sends and receives messages in order to guide the peers into a deleterious state or loop. Note that KORG does not find other types of attacks, such as statistical attacks against pseudo-random values used in the protocol or side-channel attacks against protocol implementations, and is limited to aspects of the protocol (such as its handshake) which are inherently finite-state. Consequently, KORG cannot be used to study the commonly used Dolev-Yao attacker model [19], in which the attacker is allowed to launch an unbounded number of simultaneous connections, making it the wrong choice to study cryptographic protocols such as TLS. This limitation is acceptable because the Dolev-Yao attacker model is inappropriate for studying DoS attacks against transport protocol handshakes, as we do in this paper.[3] KORG is based on LTL model-checking, thus it suffers from state-space explosion and so does not scale to systems with large state-spaces. However, the handshake mechanisms of transport protocols such as TCP, DCCP, and SCTP are small, and their correctness criteria can be written in LTL, so KORG is an appropriate choice for this context.

We define four attacker models (Off-Path, Evil-Server, Replay, and On-Path), which are representative for transport protocols and provide a wide range of attacker capabilities allowing us to understand the behavior of SCTP when under DoS attack by an attacker who cannot open additional connections parallel to the one under attack. The Off-Path attacker model describes an attacker who may or may not know the IP address or port of either peer, but cannot read the messages in-transit, and does not know the authentication secrets (which in SCTP are called the "vtags") of the association. Thus, its injected messages should theoretically be ignored. In the Evil-Server attacker model, one peer in an association is malicious, and aims to guide the other peer into some vulnerable state. The Replay attacker model describes an attacker capable of capturing messages from the communication channel and replaying them without modification. In the On-Path attacker model, the attacker controls the channel connecting the peers, and can intercept, drop, and inject authenticated messages at-will. Note that SCTP was designed to withstand Off-Path attackers but was not designed to be fully robust against the other three attacker models. Thus, we study the Evil-Server, Replay, and On-Path attacker models only to understand what could happen in a "worst case scenario".

Using KORG, we automatically synthesize DoS attacks against our SCTP model, for each LTL property and attacker model. In the Off-Path case, we automatically find the attack from CVE-2021-3772. We find numerous DoS attacks in the Evil-Server and On-Path attacker models, e.g., an Evil-Server attack that establishes a connection with the victim peer and then leaves it stranded, and an On-Path attack that injects messages guiding both peers into Shutdown_Received (an illegal passive/passive teardown). These results highlight the importance of implementation level defenses against an Evil-Server, and an end-to-end security model to prevent On-Path attacks. We also find one Replay attack, highlighting the criticality of the transmission sequence number (TSN).

Patch Verification. We next configure the model to include the patch introduced in RFC 9260 [58] and show that the patch fixes the problem, i.e., the LTL property that was violated by the attack is now met under the attacker model where that attack was discovered. We further show that of the ten LTL properties we use to specify the correctness of SCTP, none which were satisfied before the patch are violated after it is introduced, in any of the four attacker models we study. KORG is sound and complete, meaning, (1) if it finds an attack then the attack is real (against the model), and (2) if any attacks against the model and property exist, of the type KORG looks for, then given sufficient time and memory, KORG will find one [67]. If KORG runs out of time or memory without finding an attack, it will report "Search not completed". While this might happen for larger state machines, it did not happen for the SCTP model and any of the properties or attacker models we studied in this paper. Thus, our analysis suffices to show

[1] This is totally different from program synthesis, where the problem is, given some property, to conjure a program that satisfies it.

[2] We do not seek to construct a complete set of properties, as we're interested in studying the security-relevant behaviors of SCTP rather than creating an all-encompassing specification. Also, defining a complete specification in LTL is impractical, as LTL is optimized for efficient model checking.

[3] The Dolev-Yao attacker, by definition, controls the communication channels and therefore can pull off a DoS trivially. Therefore, any DoS attack discovered using Dolev-Yao must be manually analyzed to confirm that it is non-trivial.

that the patch does not enable any vulnerability against any property which was previously upheld, from the list of ten properties we specify, in any of the four attacker models we study. However, it does not carry any implications for other kinds of attacks, such as statistical attacks against the itag/vtag scheme or side-channel attacks against implementations; nor does it imply anything about properties or attacker models other than the ones we studied. It is therefore possible that the patch could introduce an attack outside the scope of what we analyzed using KORG.

RFC Disambiguation. Motivated by the fact that CVE-2021-3772 was caused by a lack of clarity in RFC 4960, we carefully manually analyze its replacement, RFC 9260, for ambiguities. We identify two portions of RFC 9260 that seem ambiguous, and show that each can be interpreted in two ways. We confirm the correct interpretation for each by consulting with the lead SCTP RFC author; then model the incorrect interpretation and synthesize attacks against it. We propose RFC errata to clarify the correct interpretation of each. Finally, we use PACKETDRILL [14] to confirm that the Linux and FreeBSD implementations interpret the ambiguous portions correctly. Note, the FreeBSD implementation was co-authored by the lead SCTP RFC author, so naturally it interprets the RFC correctly.

Contributions. We summarize our contributions:

- *Model:* We model the original SCTP RFC [55] using PROMELA. Our model can be configured with or without the CVE patch from RFC 9260 [58]. It is endorsed by the lead SCTP RFC author and faithfully captures the SCTP connection and teardown routines, including the exchange of messages, the user-on-the-loop and its commands, and the handling out-of-the-blue packets.
- *Verification:* We formalize ten novel correctness properties for SCTP in LTL based on a close reading of the RFCs and use SPIN to prove that our model satisfies all ten when no attacker is present.
- *Attack Synthesis:* We introduce four attacker models for SCTP. Then we modify KORG to support *packets* and *replay attacks*, and use it to synthesize DoS attacks in the context of each. For Off-Path, we rediscover the CVE before the patch was applied, but not after. For Evil-Server, we find four attacks that, depending on implementation details, could leave a victim peer deadlocked or stranded in some liveness cycle, unable to automatically de-associate. For Replay, we find one attack that, depending on the security of the TSN, could prevent two peers from establishing a connection. We find six similar On-Path attacks where the attacker leads the peers into some illegal state or cycle, violating a property.
- *Patch Verification:* We show that the patch fixes the problem, i.e. the property that was violated by the attack is now met under the attacker model wherein the CVE attack was discovered. Moreover, we show that in each attacker model, the patch does not open the protocol to any vulnerabilities of the kind KORG looks for against properties which were not previously vulnerable to attack.
- *RFC Disambiguation:* We identify two ambiguities in RFC 9260, each of which, we show, could be reasonably misinterpreted in a way that opens the protocol to a new vulnerability. We confirm that neither implementation makes either mistake, and to avoid mistakes in future implementations, we suggest two RFC errata clarifying the ambiguities. So far, one was accepted by the SCTP RFC committee.

Note that our model only captures two agents. Thus, it cannot be used to study DoS scenarios where a party might start an unbounded number of parallel SCTP connections. Our approach does not scale for such unbounded scenarios and a different approach would be needed. We discuss such approaches and how they compare to ours in Section 4.1.

Ethics. We disclosed all of our results to the chair of the SCTP RFC committee, resulting in an RFC erratum.

Code. All of our results are reproducible with our open source code, available at https://github.com/sctpfm.

2 SCTP

In this section we overview SCTP and previous efforts to validate it, as well as our approach to analyzing its security.

2.1 Overview

SCTP is a transport protocol proposed as an alternative to TCP, offering enhanced performance, security features, and greater flexibility. It is specified in several RFCs, each introducing significant modifications. RFC 9260 [58], which obsolesced RFC 4960 [55], made numerous small clarifications and improvements, including a critical patch for CVE-2021-3772. On the other hand, RFC 4960, which obsolesced the original specification in RFC 2960 [59], introduced major structural changes to the protocol as described in the errata RFC 4460 [15]. SCTP is implemented in Linux [2] and FreeBSD [4].

SCTP is a two peer protocol where each peer runs the same state machine. However, during connection establishment, the two peers play different roles – while one peer progresses through the *active* routine in the state machine, the other peer must take a corresponding sequence of *passive* transitions.[4] For teardown there are two options: graceful or graceless. During graceful tear-down, one peer can act actively and the other passively, or they can both take an active role. Graceless teardown happens in a single step.

Peer States. An SCTP peer is identified by a set of IP addresses and a port number. At any given time, each peer exists in one of finitely many states: Closed, in which no association exists; Cookie_Wait and Cookie_Echoed, used during active establishment; Established, in which an association exists and data can be transferred; Shutdown_Received and

[4] SCTP also supports an initialization routine where both peers are active, called "initialization collision". However, this routine is described in the RFC as an edge-case, rather than an intended use-case.

Shutdown_Ack_Sent, used by the passive peer during teardown; and Shutdown_Pending and Shutdown_Sent, used by the active peer during teardown. In active/active teardown, both peers use Shutdown_Ack_Sent.

Packets. An SCTP packet consists of a common header and a number of chunks. An essential component of the connection establishment design is authentication of packets between the peers using a random integer called the *verification tag*, or vtag, which is initialized using an *initiate tag*, or itag, during establishment. The packet header contains the source and destination port number, vtag, and a checksum. The chunk types are `INIT`, `INIT_ACK`, `COOKIE_ECHO`, and `COOKIE_ACK`, used during establishment; `DATA` and `DATA_ACK`, used for data transmission once an association has been established; `ERROR`, used to communicate when an error has occurred; `SHUTDOWN`, `SHUTDOWN_ACK`, and `SHUTDOWN_COMPLETE`, used during graceful teardown; `ABORT`, used during graceless teardown; and `HEARTBEAT` and `HEARTBEAT_ACK`, used for crash detection. Chunks contain parameters, e.g., `INIT` and `INIT_ACK` chunks (but no others) contain an itag, and (only) `INIT_ACK` chunks contain a *state cookie*, which includes a message authentication code, a timestamp indicating when the cookie was created, and a cookie lifespan. There are various kinds of `ERROR` chunks, each indicating a different error condition, e.g., `COOKIE_ERROR` which indicates receipt of a valid but expired state cookie. Much like TCP, SCTP uses sequence numbers, called Transmission Sequence Numbers (TSNs). The initial TSN in an association is proposed by an active participant in the connection establishment routine, and is incremented with each data transmission thereafter.

Connection Establishment. In active/passive establishment (Figure 1), the active peer sends a packet with an `INIT` chunk, containing a nonzero random itag. For the remainder of the association, this (active) peer will only accept packets from the passive peer that contain a vtag equal to the itag in the `INIT` it sent. The passive peer replies with a packet containing an `INIT_ACK` chunk, which also contains a nonzero random itag. For the remainder of the association, the passive peer will only accept packets which contain this itag value as the vtag in the common header. By checking the vtag, each peer protects itself from processing packets sent by an attacker not knowing the recipient's vtag.

Connection Teardown. Teardown can occur gracefully, via the active/passive or active/active routines, or gracelessly, with an `ABORT`. During active/passive teardown (Figure 2), the active peer sends a `SHUTDOWN` chunk, to which the passive peer responds with `SHUTDOWN_ACK`. The active peer then sends `SHUTDOWN_COMPLETE` and both transition to Closed. Active/active teardown is also possible, in which the peers exchange, in the following order: `SHUTDOWN`, `SHUTDOWN_ACK`, and `SHUTDOWN_COMPLETE` messages. The third option is that a peer can gracelessly abort a connection by sending an `ABORT` chunk. In this case, both peers immediately transition to Closed. Once the association is closed, the vtags are forgotten, and when either peer enters a new association, it will randomly choose a new itag (to become its vtag).

Timers. The SCTP connection routines use three timers: Init, Cookie, and Shutdown. The goal of the Init Timer is to stop the active peer in an establishment routine from getting stuck waiting forever for the passive peer to respond to its `INIT` with an `INIT_ACK`. The goal of the Cookie Timer is similar: it stops that same active peer from getting stuck waiting forever for the passive peer to respond to its `COOKIE_ECHO`. The Shutdown Timer plays a similar role but in the teardown routine, stopping the active peer in teardown from getting stuck waiting for a `SHUTDOWN_ACK`.

Out-of-the-Blue Packet Handling. In SCTP a message is considered *out-of-the-blue* (OOTB) if the recipient cannot determine to which association the message belongs, i.e., if it has an incorrect vtag, or is an `INIT` with a zero-valued itag. Specifically, an OOTB message will be discarded if: 1) it was not sent from a unicast IP, 2) it is an `ABORT` with an incorrect vtag, 3) it is an `INIT` with a zero itag or incorrect vtag[5], 4) it is a `COOKIE_ECHO`, `SHUTDOWN_COMPLETE`, or `COOKIE_ERROR`, and is either unexpected in the current state or has an incorrect vtag, or 5) it has a zero itag or incorrect vtag.

Unexpected Packet Handling. A message is *unexpected* if it is not OOTB, but nevertheless, the recipient does not expect it. SCTP handles unexpected packets as described in Algr. 1.

Algorithm 1 Unexpected Packet Handling

```
Require: Unexpected msg
  if msg.chunk = INIT then
    if state = Cookie_Wait or msg does not indicate new
    addresses added then
      Send INIT_ACK with vtag = msg.itag
    else
      Discard msg and send ABORT with vtag = msg.itag
    end if
  else if msg.chunk = COOKIE_ECHO then
    if msg.timestamp is expired then
      Send COOKIE_ERROR
    else if msg has fresh parameters then
      Form a new association
    else
      Set vtag = msg.vtag /* init collision */
      goto Established
    end if
  else if msg.chunk = SHUTDOWN_ACK then
    Send SHUTDOWN_COMPLETE with vtag = msg.vtag
  else
    Discard msg
  end if
```

Other Functionality. Other functionalities of SCTP include a "tie-tag" nonce mechanism used to authenticate a

[5] Per RFC 4960, respond with an `ABORT` having the vtag of the current association. But per RFC 9260, discard it.

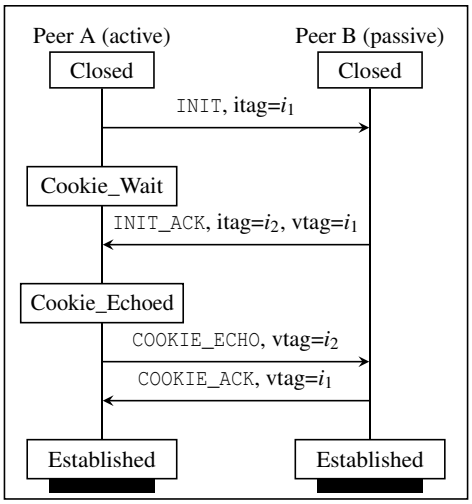

Figure 1: Message sequence chart illustrating SCTP active/-passive establishment routine. Time flows from the top down.

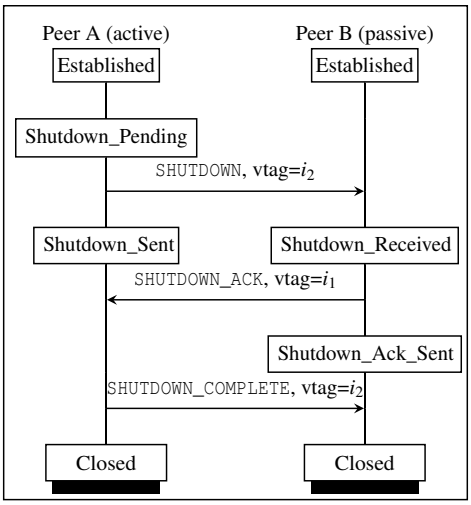

Figure 2: SCTP active/passive teardown.

reconnecting peer after a restart; congestion control[6]; fragmentation and reassembly of DATA chunks; chunk bundling; support for the Internet Control Message Protocol (ICMP); and multihoming. We do not consider this functionality in our analysis, and we refer the reader to [58] for more details.

2.2 Prior Validation

Conformance testing. The Linux and FreeBSD implementations were tested with PACKETDRILL [1] and fuzz-tests, suggesting they are crash-free and follow the RFCs. But this does not necessarily imply the *design* in the RFCs behaves correctly in the (a) absence or (b) presence of an attacker.

Formal analysis. For (a), some prior works formally analyzed SCTP using Colored Petri Net models [40, 62, 63, 68] in CPNTOOLS. This software can check for livelocks (i.e. liveness violations) and deadlocks (stuck states), but it cannot model-check arbitrary logical properties, which seriously limits the use-cases for such models. One prior work studied (b), modeling the four-way handshake used by SCTP and comparing it to the three-way handshake used by TCP in the presence of an attacker, with the Uppaal model-checker [53]. However, the model is closed-source and does not include the teardown routine. It is unclear whether the model includes OOTB or unexpected packet handling. We summarize the differences between these prior models and our own in Table 1. Finally, the IETF published a security memo for SCTP, but it is not a comprehensive analysis, rather, it simply summarizes prior conversations about security from the SCTP user-group [56].

CVE-2021-3772 attack and patch. As reported in CVE-2021-3772 [49], the prior version of SCTP specified in RFCs 2960 [59] and 4960 [55] is vulnerable to a denial-of-service attack. The reported vulnerability worked as follows. Suppose SCTP peers A and B have established a connection and an off-channel attacker knows the IP addresses and ports of the two peers, but not the vtags of their existing connection. The attacker spoofs B and sends a packet containing an INIT to A. The attacker uses a zero vtag as required for packets containing an INIT. The attacker must use an illegal parameter in the INIT, e.g., a zero itag.

Peer A, having already established a connection, treats the packet as out-of-the-blue, per RFC 2960 §8.4 and 5.1, which specify that as an association was established, A should respond to the INIT containing illegal parameters with an ABORT and go to Closed. But in RFCs 2960 and 4960, it is unspecified which vtag should be used in the ABORT. Some implementations used the expected vtag, which is where a vulnerability arises. Since the attacker spoofed the IP and port of Peer B, Peer A sends the ABORT to Peer B, not the attacker. When Peer B receives the ABORT, it sees the correct vtag, and tears down the connection. Thus, by injecting a single packet with zero-valued tags, the attacker tears down the connection, pulling off a DoS. The attack is illustrated in Figure 3.

RFC 9260 patches CVE-2021-3772 using a strict defensive measure, wherein OOTB INIT packets with empty or zero itags are discarded, without response. FreeBSD [4] uses this patch. Linux, on the other hand, adopts a different patch [39], wherein the peer receiving the ABORT with the zero vtag simply ignores it (rather than close the connection).

3 Our SCTP Model

In this section, we describe our SCTP PROMELA model and properties that guide our analysis.

[6](based on TCP congestion control)

Vanit-Anunchai [63]	4960	N	Y	Y	Y	Y	Y	Y	N
Saini and Fehnker [53]	4960	N	Y	N	N	N	Y	Y	Y
Ours	4960 & 9260	Y	Y	Y	Y	Y	Y	Y	Y

Table 1: Prior formal SCTP analyses versus ours. RFC column reports modeled version, and open-source column reports whether the model is open-source. The remaining columns report whether the model includes the establish and teardown routines, OOTB logic, or unexpected packet handling; and if it can be used to check for livelocks or deadlocks, or to verify arbitrary properties.

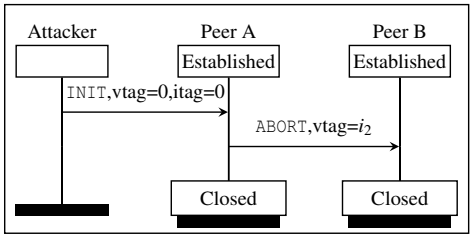

Figure 3: CVE-2021-3772 Attack. Peers A and B begin having established an association with vtags i_1, i_2 (resp.). The Attacker transmits an invalid `INIT` chunk to A, spoofing the port and IP of B. Peer A responds by sending a valid `ABORT` to B, which closes the association. By sending a single invalid `INIT` the Attacker performs a DoS.

3.1 Overview

As we are primarily interested in denial-of-service attacks, and in order to avoid state-space explosion, we selectively model the SCTP connection establishment and teardown routines. This allows us to automatically and exhaustively explore, simulate, and verify the critical, security-relevant aspects of SCTP. Our model captures the following aspects of SCTP per RFC 9260 [58]: internal peer states, packet verification using the itag and vtag, timers, TSNs, and handling for invalid, unexpected, and OOTB packets. We made only the abstractions listed in Section 3.4.

Although our model is fully faithful to the SCTP RFC [58], and is an executable program, it is not a network library and cannot be used in place of the existing Linux or FreeBSD implementations. This is because of the abstractions and simplifications mentioned above, and also because it does not implement API hooks for higher-level applications, nor syscalls to transmit over the Internet. It is simply a model of SCTP with which we can formally verify correctness properties.

3.2 Model Details

We describe our SCTP model in PROMELA, focusing on internal peer states, packet verification, invalid packet defense mechanisms, timeouts, and OOTB packet handling.

Mathematical Preliminaries. Linear Temporal Logic is a modal logic for reasoning about program executions. In LTL, we say a program P *models* a property ϕ, written $P \models \phi$, if ϕ holds over every execution of P. If ϕ holds over some but not all executions of P, then we write $P \not\models \phi$.

The LTL language is given by predicates (e.g., "Peer A is in Established" or "Peer B's cookie timer is inactive"); the temporal operators "next", "always", "eventually", and "until"; and the logical operators of negation, conjunction, and disjunction. An LTL model-checker is a tool that, given P and ϕ, can automatically check whether or not $P \models \phi$ [7]. We use the model-checker SPIN[8], whose language is PROMELA.

We use $\|$ to denote rendezvous composition, so, $S = P \| Q$ denotes that the program S equals the composition of P with Q. Specifically, matching *send* transitions of P and *receive* transitions of Q occur in lockstep, and vice versa. Note, in our model, we actually build a process called a "channel" to capture network delay, and we rendezvous-compose the channel with the two peers to build asynchronous communication (which is more realistic). The $\|$ operator is commutative and associative. For more details, refer to §2 of [67].

Internal Peer States. Our model consists of two peers (A and B) and a channel connecting them. That is, we study the system $S = \text{PEERA} \| \text{CHANNEL} \| \text{PEERB}$. Each peer is represented by an identical FSM, illustrated in Figure 5. Transitions between states occur based on the receipt of user commands, or communication and message processing.

The channel connecting the two peers contains an internal single-message buffer in each direction (meaning it can hold two messages at once, one traveling from left to right and the other from right to left). It does not drop, corrupt, nor create messages, and cannot accept a new message in a given direction until the old one was delivered. In other words, it is lossless and FIFO, in that it guarantees every delivered message was sent and messages are delivered in order. The entire setup is illustrated in Figure 4.

Packet Verification and Invalid Packet Defenses. We model each SCTP message as consisting of a message chunk, a vtag, and an itag. Each of these components are modeled using enums, which in PROMELA are called `mtypes`. The message

[7] LTL model-checking is decidable, and reduces to checking Büchi Automata intersection emptiness, which is PSPACE-complete.

[8] version 6.5.2

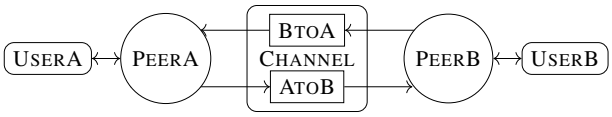

Figure 4: The system UserA || PeerA || Channel || PeerB || UserB. Channel contains a size-1 FIFO buffer in each direction (AtoB and BtoA, respectively). Arrows indicate communication direction. Composition between Channel and peers is rendezvous (the buffers are inside Channel).

chunk denotes the meaning of the message, e.g., a message with an `INIT` chunk is called an *initiate message* and is used to initiate a connection establishment routine. The itag and vtag are used to verify the authenticity of the sender of the message, as described in Section 2.2. In our model there are three kinds of tags: expected (`E`), unexpected (`U`), or none (`N`). A tag is expected if (1) it is a non-zero itag on an `INIT` or `INIT_ACK` chunk, or (2) it is the other peer's vtag in the existing association. Otherwise, it is unexpected. The none type is reserved for packets that do not carry the given tag type – e.g., only `INIT` and `INIT_ACK` chunks carry an itag, so in the other types of messages, the itag is `N`. The BNF grammar for messages in our model is given in Figure 6. We also support an option where the *msg* can be extended with a TSN.

Upon receiving a message, our model checks that the tags are set as expected, depending on the message and state. If a message has an unexpected tag then the model employs the defenses specified in the RFC, e.g., silently discarding the message or responding with an `ABORT`. These defenses can be configured with or without the CVE patch from RFC 9260.

Active and Passive Connection Routines. Our SCTP model implements active/passive establishment and teardown, as well as active/active teardown, but not active/active establishment (a.k.a. "`INIT` collision"), precisely as described in Section 2 and illustrated in Figures 1 and 2, with the caveat that the itag and vtag are abstracted (as described above). We also capture the TSN proposal and use throughout an association, although this feature can be turned off in our model to reduce the state-space for more efficient verification.

Out-of-the-Blue and Unexpected Packets. Our model faithfully captures OOTB logic described in §8.4 of RFCs 4960 and 9260, with only the exceptions given in Section 3.4.

3.3 Ambiguities in the RFC

While reading 9260 [58] in order to build our model, we found two ambiguities. In each case, we reported the ambiguity to the lead SCTP RFC author, confirmed the correct interpretation of the ambiguous text with them, and suggested a clarifying erratum.

The first ambiguity is in §5.2.1, during the description of how a peer should react upon receiving an unexpected `INIT`:

> *Upon receipt of an `INIT` chunk in the Cookie_Echoed state, an endpoint MUST respond with an `INIT_ACK` chunk using the same parameters it sent in its original `INIT` chunk (including its Initiate Tag, unchanged), provided that no new address has been added to the forming association.*

Consider two peers - A and B - initially both in Closed, in addition to some attacker who can spoof the port and IP of B. Suppose these machines engage in the sequence of events illustrated in Figure 7. At the end of the sequence, what value should the vtag V take?

A problem arises if a reader interprets "the same parameters" to include the vtag, implying that the vtag of the `INIT_ACK` should come from the `INIT` that the responding endpoint sent. Then V should take the itag of the message, i.e. $V = i_1$. The fact that this is wrong (and the correct assignment is $V = i_2$) only becomes clear if you fully understand how itags and vtags are used in both directions. To make the text unambiguous, we suggest the following erratum:

> The verification tag used in the packet containing the `INIT_ACK` chunk MUST be the initiate tag of the newly received `INIT` chunk.

The second ambiguity we identify is in §8.5, which says:

> *When receiving an SCTP packet, the endpoint MUST ensure that the value in the Verification Tag field of the received SCTP packet matches its own tag.*

The problem is that §8.5 does not say *when* the vtag check should happen with respect to other checks. In particular, §3.3.3 says that an endpoint in Cookie_Wait who receives an `INIT_ACK` with an invalid itag should respond with an `ABORT`– but it is unclear whether this still applies before or after the vtag check in §8.5. Under the former interpretation, an endpoint in Cookie_Wait who receives an `INIT_ACK` with both an invalid itag and an invalid vtag would respond with an `ABORT`, whereas under the latter interpretation, the endpoint would silently discard the packet. To clarify the ambiguity, we proposed the following erratum, which the SCTP RFC committee accepted [61]:

> When receiving an SCTP packet, the endpoint MUST first ensure that the value in the Verification Tag field of the received SCTP packet matches its own tag before processing any chunks or changing its state.

3.4 Abstractions and Limitations

Our model is fully faithful to the SCTP RFC, modulo the following abstractions and limitations.

- **Unicast peers.** In the RFC, OOTB messages from non-unicast peers are discarded; we model all peers as unicast.
- **No crashes or restarts.** In our model, peers never crash or restart. Thus we also omit crash detection (including `HEARTBEAT` and `HEARTBEAT_ACK` chunks).
- **Tags are abstracted.** We do not model tie-tags, which are used when reconnecting a peer to an existing association after a restart. In the RFC, itags and vtags are integer-valued and chosen randomly. But we model tags as the "expected" value,

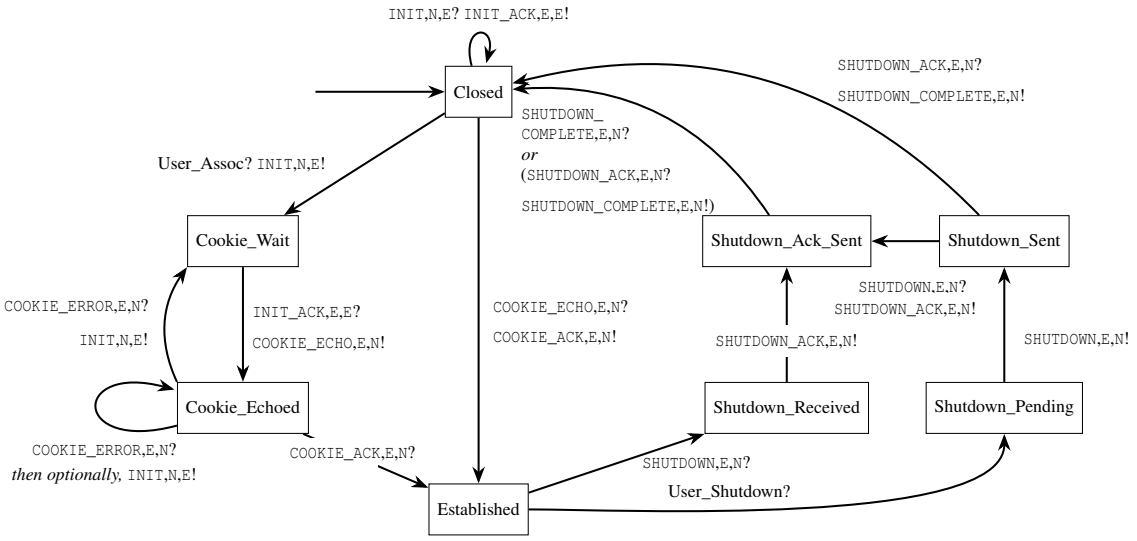

Figure 5: SCTP Finite State Machine. $x,v,i?$ (or $x,v,i!$) denotes receive (or send) chunk x with vtag v and itag i. Events in multi-event transitions occur in the order they are listed. Logic for OOTB packets, ABORT messages or User_Abort commands, unexpected user commands, and data exchange are ommitted but faithfully implemented in the model and described in this paper.

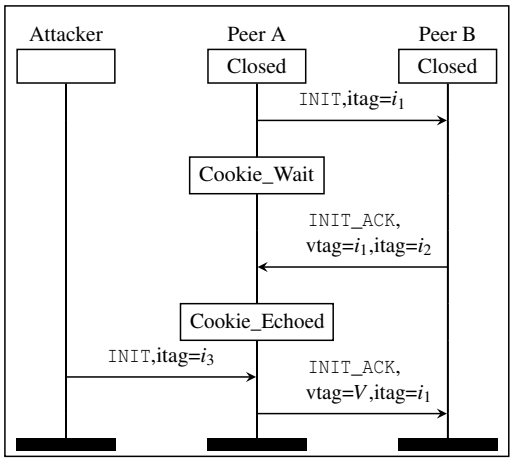

Figure 7: First ambiguity. What value should V take? See Section 3.3.

an "unexpected" value, or "none", since this level of detail is all that matters for our properties. A side-effect is that we cannot study INIT collision. INIT collision is not included in the State Association Diagram in RFC 9260 §4, nor in the various association flows throughout the RFC document, leading us to believe it is not a protocol feature but rather an edge-case the protocol is designed to withstand.

• **Perfect channel.** We do not model packet loss, reordering, nor corruption, nor how SCTP deals with these scenarios.

• **Peers do not exchange data while in Established.** Because we focus on denial-of-service attacks, modeling data exchange while in Established is unnecessary; rather, we focused on the connection and disconnection of peers. We did model data transmission outside of Established, in case it caused edge-case behaviors during teardown.

• **Packets only ever contain one chunk.** Since we also do not model (or write properties about) fragmentation, bundling, or reassembly, we can simulate multi-chunk transmissions by sending consecutive single-chunk messages.

• **Simplified packet structure.** We choose not to model packet structure details relevant to only DATA packets, e.g.: stream sequence number, payload protocol identifier, and variable length. We also do not model ICMP messages.

3.5 Correctness Properties

Next we transcribe ten logical properties we believe SCTP should satisfy. Note, we do not intend to create a *complete* set of properties that captures all behaviors of SCTP. Rather, we design our properties to capture the security-relevant behavior of SCTP. Each property is implemented in PROMELA using

LTL. We justify each using the RFCs [55,58] and our intuition about the security SCTP should provide.

ϕ_1: A peer in Closed either stays still or transitions to Established or Cookie_Wait. This is based on the routine described in §5.1, as well as the Association State Diagram in §4. If a closed peer could transition to any state other than Established or Cookie_Wait, it could de-synchronize with the other peer, breaking the four-way handshake and potentially leading to a deadlock, livelock, or other problem.

ϕ_2: One of the following always eventually happens: the peers are both in Closed, the peers are both in Established, or one of the peers changes state. The property we want to capture here, "no half-open connections", is stated in §1.5.1, was verified in the related work by Saini and Fehnker [53], and was studied for TCP in two prior works [47, 67]. But we have to formalize it subtly, because in the case of an in-transit `ABORT`, it is possible for one peer to temporarily be in Established while the other is in Closed; so we write it as a liveness property, saying half-open states eventually end.

ϕ_3: If a peer transitions out of Shutdown_Ack_Sent then it must transition into Closed. We derived this from the Association State Diagram in §4. Every transition out of Shutdown_Ack_Sent described in the RFC ends up in either Closed or Shutdown_Ack_Sent. If this property fails, it would imply a flaw in the graceful teardown routine, and could cause a deadlock, livelock, or other problem.

ϕ_4: If a peer is in Cookie_Echoed then its cookie timer is actively ticking. Per §5.1 C), the peer starts the cookie timer upon entering Cookie_Echoed. Per §4 step 3), when the timer expires it is reset, up to a fixed number of times, at which point the peer returns to Closed. If the property fails, then the active peer in an establishment could get stuck in Cookie_Echoed forever, opening a new opportunity for DoS.

ϕ_5: The peers are never both in Shutdown_Received. This property follows from inspection of the Association State Diagram in §4. From a security perspective, if both peers were in Shutdown_Received, this would indicate that neither initiated the shutdown (yet both are shutting down); the only logical explanation for which is some kind of DoS.

ϕ_6: If a peer transitions out of Shutdown_Received then it must transition into either Shutdown_Ack_Sent or Closed. The transition to Shutdown_Ack_Sent is shown in the Association State Diagram in §4. The transition to Closed can occur upon receiving either a User_Abort from the user or an `ABORT` from the other peer. No other transitions out of Shutdown_Received are given in the RFC. If this property fails, it could de-synchronize the teardown handshake, potentially leading to an unsafe behavior. For example, if a peer transitioned from Shutdown_Received to Established, it would end up in a half-open connection.

ϕ_7: If Peer A is in Cookie_Echoed then B must not be in Shutdown_Received. We derived this from the Association Diagram in §4, which shows A must receive an `INIT_ACK` while in the Cookie_Wait and then send a `COOKIE_ECHO` in order to transition into Cookie_Echoed. B must have been in Closed to send an `INIT_ACK` in the first place, hence B cannot be in Shutdown_Received. This property relates to the synchronization between the peers: if one is establishing a connection while the other is tearing down, then they are de-synchronized, and the protocol has failed.

ϕ_8: Suppose that in the last time-step, Peer A was in Closed and Peer B was in Established. Suppose neither user issued a User_Abort, and neither peer had a timer time out. Then if Peer A changed state, it must have changed to either Established, or the implicit, intermediary state in Cookie_Wait in which it received `INIT_ACK` but did not yet transmit `COOKIE_ECHO`. The transitions from Closed to Established and the described intermediary state are implicit in the Association State Diagram in §4. The timer caveat is described in §4 step 2, and the aborting caveat is in §9.1. If the property fails, the four-way handshake ended, yet was not completed successfully, did not time out, and was not aborted, so somehow, the protocol failed.

ϕ_9: The same as ϕ_8 but the roles are reversed. The property is: *Suppose that in the last time-step, Peer B was in Closed and Peer A was in Established...*

ϕ_{10}: Once connection termination initiates, both peers eventually reach Closed. This follows from the description of connection termination in §9. Once connection termination is initiated, there is no way to recover the association.

For the On-Path attacker model, ϕ_8 and ϕ_9 are symmetric. For the other attacker models, the properties are distinct, because the attacker model's network topology is asymmetric.

3.6 Validating Our Model

Our model allows us to execute and reason about any component of the peer logic in isolation, or two interacting peers. To verify our model, we extracted the properties listed above from the SCTP RFCs, and then used the model-checker to prove that our model satisfies all of the properties. We interactively guided SPIN to drive the model through various connection flows (which we compared to the RFC text), and we manually compared our logic for handling OOTB packets to the corresponding C code in Linux and FreeBSD. Finally, we used SPIN to prove there were no deadlocks or livelocks (liveness cycles) and all the peer states are reachable.

4 SCTP Attack Synthesis

In this section we provide details on attack synthesis and KORG, the tool we used. Next, we describe four attacker models we defined and used for our analysis. Finally, we present the changes we had to make to KORG to handle our SCTP model, and the four attacker models we considered.

4.1 Attack Synthesis

LTL program synthesis is the problem of, given an LTL specification ϕ, automatically deriving a compliant program P (for which $P \models \phi$). *LTL attack synthesis* is fundamentally different (logically dual), and cannot be solved using program synthesis alone. In attack synthesis, the problem is flipped: given a program S and property ϕ, where S is already compliant ($S \models \phi$), if $S = P \parallel Q$ consists of an *invariant component* P (that the attacker cannot change) and a *variant component* Q (that the attacker can change), we ask whether there exists some modification A such that, if we replace Q with A, the new system $S' = P \parallel A$ is non-compliant ($S' \not\models \phi$). In other words, we study a system that behaves correctly, and ask if we can change some constrained aspect so that it behaves incorrectly. If so, we call this modification A an "attack".

There are multiple kinds of attacks one might try to synthesize, depending on the nature of the protocol and the attacker goal. We use use KORG [67], which leverages SPIN [28] to synthesize attacks against arbitrary LTL properties of transport protocols. LTL includes safety properties – which say that something bad never happens (e.g., ϕ_4) – and liveness properties – which say that something good eventually happens (e.g., ϕ_{10}). The main difference between SPIN and verifiers such as PROVERIF [13] and TAMARIN [44] is that SPIN only supports finite-state models and LTL, whereas PROVERIF and TAMARIN support infinite-state models, and other kinds of properties such as forward secrecy and trace equivalence. However, this expressiveness comes at a cost, which is that the unbounded verification of liveness properties in the cryptographic verification setting is undecidable [7].[9] Cryptographic verifiers can verify liveness properties in a bounded fashion, i.e., by confirming that something good happens within a bounded number of steps (TAMARIN does this [8]); or in an unbounded fashion, by relying on human input in the form of proof hints (see e.g., [60, 70]).

In contrast, an LTL model checker such as SPIN can only reason about finite state-spaces, but, can automatically verify both safety and liveness properties of finite systems (such as the SCTP handshake) in an unbounded fashion, by exploiting the omega-regularity of LTL over finite Kripke structures [28]. KORG is proven to be sound (it has no false-positives) and complete (if attacks of the kind KORG looks for exist, given enough resources, KORG will find one) [67]; with the caveat that it is restricted to small, finite-state systems with LTL specifications. Since the SCTP handshake does not use any cryptographic primitives other than the cookie, and can be described using a small, finite-state model, and since we want to determine whether any attacks whatsoever exist against certain properties (and not just attacks of a certain size), we choose KORG for our analysis; but if we aimed to study a cryptographic or infinite-state protocol such as TLS or Signal (see: [17, 36], resp.), we would need a verifier such as PROVERIF or TAMARIN, or a hybrid approach combining multiple tools, as in [18]. Note, KORG was previously successfully applied to TCP and DCCP [47, 67], and adds the attack synthesis functionality to SPIN, which itself has existed for 35 years; has been applied to dozens of real systems including the Mars rover [29], PathStar access server [30], and ISO/IEEE P11073-20601 medical communication protocol [24]; spawned a dedicated formal methods conference, currently in its 30th year[10]; and earned the 2002 ACM Software System Award.

KORG requires four inputs: an invariant component P (e.g., the SCTP model) and variant component Q (which in our case is part of the attacker model), both in PROMELA; an LTL correctness property ϕ, such that the composite system consisting of both P and Q satisfies ϕ ($P \parallel Q \models \phi$); and a YAML file encoding the grammar (I/O) of Q (which become the I/O of the attacker). KORG generates an model with these inputs in which Q is replaced with a process called a *daisy*, that can nondeterministically send or receive messages specified in the grammar. Next, it modifies ϕ to have a precondition saying the daisy terminates, and then asks SPIN to verify or disprove the modified property for the modified model. Either KORG reports no attacks exist, or SPIN outputs a counterexample execution, which KORG parses into an attack A. For more refer to [67]. The inputs to KORG needed to reproduce each of our experiments are documented in the paper artifacts.

KORG is limited by the level of detail in the model, the definition of "attack" used by KORG [67], and the attacker models and properties considered. Thus there could exist other attacks beyond those KORG synthesizes, which violate other properties or work in other attacker models; or attacks other than the type that KORG can find (e.g., statistical ones); or attacks that cannot be found without a more detailed model. These limitations are inherent to all attack synthesis techniques.

4.2 Attacker Models

We define an *attacker model* to be a formal description of the placement and capabilities of the attacker and protocol peer(s) on the network. We create four attacker models: Off-Path, Evil-Server, Replay, and On-Path. They are general-purpose and applicable to any transport protocol, and we contribute them to KORG. Of these, SCTP was only designed to be fully robust against an Off-Path attacker; we study the others to understand what could happen in a "worst-case" scenario. Note, we model only DoS attacks with two agents. Our approach does not scale for scenarios with unbounded parallel sessions, such as Dolev-Yao.

Off-Path. This is the primary attacker model discussed in the IETF SCTP security memo [56] and is what SCTP was designed to be fully secure against. In this model, an attacker

[9] Indeed, even simple reachability problems such as secrecy are not in general decidable for finite, straight-line, role descriptions in PROVERIF or TAMARIN, and so often the human using the tool must supply proof hints.

[10] https://spin-web.github.io/SPIN2023/

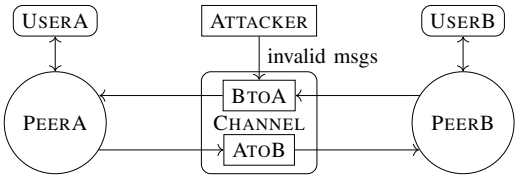

Figure 8: Off-Path Attacker Model: S = ATTACKER ‖ USERA ‖ PEERA ‖ CHANNEL ‖ PEERB ‖ USERB. The attacker can transmit messages into the BtoA buffer, but cannot receive messages, nor block messages in-transit. The attacker can send only chunks having an invalid itag and vtag (as it is not privy to the association).

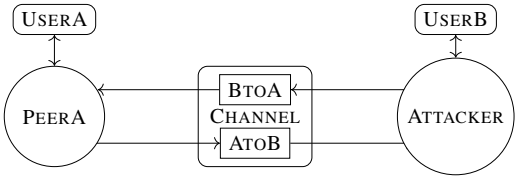

Figure 9: Evil-Server Attacker Model: S = USERA ‖ PEERA ‖ CHANNEL ‖ ATTACKER ‖ USERB. Peer B is prefixed with an attacker, whose code consists of a finite, terminating sequence of communication operations.

who does not know either vtag communicates with one peer in order to disrupt a connection between the two peers. The vtag mechanism in SCTP was designed to defend against such an attacker. See Figure 8.

Evil-Server. In this model, one of the peers behaves maliciously. The attacker takes the form of a finite sequence of malicious instructions inserted before the code of Peer B, after which B behaves like normal. The purpose of this attacker model is to study the degree to which an adversary capable of temporarily controlling one peer in a connection can negatively impact the other. For example, could it cause the second peer to deadlock? See Figure 9.

Replay. In this model (Figure 10), the attacker can replay captured packets without modification. SCTP was designed to withstand most replay attacks using its TSN mechanism, as discussed in IETF TSVWG 115 [42].

On-Path. In this attacker model, the attacker controls the

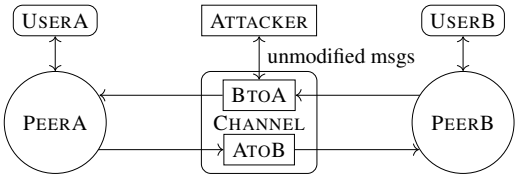

Figure 10: Replay Attacker Model: S = ATTACKER ‖ USERA ‖ PEERA ‖ CHANNEL ‖ PEERB ‖ USERB. The attacker can capture and re-transmit messages in BtoA, but cannot edit captured messages, nor block those in transit.

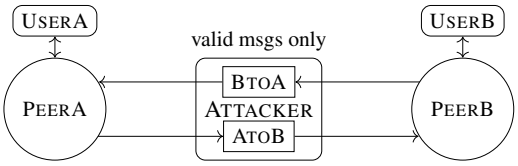

Figure 11: On-Path Attacker Model: S = USERA ‖ PEERA ‖ ATTACKER ‖ PEERB ‖ USERB. The attacker is allowed to perform a finite sequence of send/receive actions, in which it only sends valid messages (but can receive anything). Once this sequence terminates, it behaves like an honest channel.

channel connecting the two peers, and can drop or insert valid messages at-will. SCTP was not designed to provide security against such an attacker and we study this attacker model only to understand what the "worst case scenario" for SCTP looks like (e.g., as studied in [34]). See Figure 11.

4.3 Changes to KORG

We improved KORG to support our SCTP analysis in four ways. (1) Since KORG was originally hard-coded for enum-style packets, we extended KORG to support arbitrary finite packet types. This was needed to support our SCTP model (Figure 6). (2) We modified KORG to report any attacks it finds even if it fails to exhaust the search-space. Previously, it would report an error and discard any results if the space was not exhausted. (3) To save time, we disabled the preliminary step where KORG verifies that the property holds in the absence of an attacker, instead manually performing this step in SPIN. (4) We extended KORG to support replay attackers.

A replay attacker is one capable of capturing and replaying messages. Although the replay attacker model reasons about packets received, the attacks this model produces form a subset of those produced by the *On-Path* attacker; thus, soundness and completeness follow from the proofs in the KORG paper. Our replay attacker synthesis implementation supports packet capture and replay over the same or different channels. In the latter case, the attacker can capture a message from one channel and replay it into another. It also supports packet storage in a memory buffer with configurable size, though, the verification complexity increases exponentially with the memory bound. Finally, to support the state change that happens when a new vtag is chosen, we added a feature where a special message can be configured to flush the storage.

We also contribute our SCTP model and four attacker models in a format amenable to KORG. We document the attacker models in Section 4.2. Excluding the models, our modifications required changing 80 lines of preexisting code and adding 213 lines of new functionality in KORG, in addition to 102 lines of shell-script to automate our experiments. All modifications are available with the paper artifacts.

5 Experimental Results

We next present our experimental results. Our SCTP model satisfies all ten properties in the absence of an attacker. To examine whether these properties still hold when an attacker is present, we synthesize attacks using the four attacker models. Then, we enable the CVE patch described in RFC 9260 and repeat our analysis, in order to check whether the patch resolves the vulnerability, and/or introduces any new attack vectors. Finally, we show how new attacks are enabled if either ambiguity in Section 3.3 is misinterpreted. Analysis runtimes are related in the appendix.

5.1 Experimental Methodology

Each time we run KORG, we ask it to synthesize ≤ 10 attacks. In our experience, after the first ten, subsequent attacks tend to be repetitive, differing only by actions that do not impact the attack outcome. We configure KORG with a default search depth of 600,000, and a maximum depth of 2,400,000. In our experience, these parameters balance fast-performance on smaller properties with the ability to also attack more complex ones, without needing to run on a cluster. While KORG may run out of time or memory without finding an attack for larger finite state machines, in the experiments presented in this section, KORG never runs out of memory. It either finds at least one attack or fully exhausts the search-space before hitting the configured maximum search depth. Recall, however, that we only study attacker models involving two agents (i.e., one association). KORG does not scale to larger attacker models such as Dolev-Yao, which might involve an unbounded number of agents. We make certain assumptions or optimizations in the different attacker models.

• *Off-Path:* We assume the Off-Path attacker knows the port and IP of a peer, since otherwise, all its (spoofed) messages will be immediately discarded.[11] To reduce the search-space, we assume the attacker does not send `DATA` or `COOKIE_ERROR` chunks, which cannot change the receiving peer's state. We further reduce the space by first synthesizing attacks against the establishment routine, where the attacker could only send messages that are used during establishment; and then doing the same for teardown. Our search is complete despite this split because the FSM is inherently Markovian and our properties do not look back more than one state in the past. In our open-source artifacts, we provide code illustrating how this optimization can be repeated for any transport protocol.

• *Evil-Server:* We assume the Evil-Server attacker only sends valid messages, since it knows the current vtags. To reduce the search-space, we assume it does not send `DATA`.

• *Replay:* We configure the replay attacker to have a memory size of two — we find that more memory causes state-space explosion making exhaustive verification infeasible. We also configure it to discard all messages in memory upon receiving an `INIT`, allowing us to correctly model the vtag change between multiple connection and teardown cycles.

• *On-Path:* We perform the same optimizations as in the Off-Path attacker model. And like in the Evil-Server attacker model, we assume the attacker only sends valid messages.

[11] The ports and IP of a peer might not change between associations [57].

```
BTOA ! COOKIE_ACK, U, N;        (repeat twice more)
BTOA ! COOKIE_ECHO, U, N;
BTOA ! COOKIE_ACK, U, N;        (repeat 6 more times)
BTOA ! COOKIE_ECHO, U, N;
BTOA ! INIT, N, U;                    /* attack */
```

Figure 12: Automatically synthesized CVE attack in the Off-Path attacker model. BTOA is the channel from the attacker to the peer being attacked. Only the final line matters.

5.2 Attacks

We generate at least one attack in each attacker model, all of which we summarize in Table 2. However, recall that SCTP was only designed to withstand Off-Path attacks, so, results in the other attacker models do not negatively impact our perspective on the security of SCTP. And in the Off-Path model, we find only the CVE attack with the patch is disabled, and no attacks when the patch is enabled. Therefore, our results can be seen as affirming the security of SCTP. We discuss results for each attacker model in detail below.

Off-Path. KORG found a variant of the attack reported in CVE-2021-3772, given in Figure 12. The variant differs only from the CVE in that it begins by transmitting some OOTB messages that are discarded and have no impact on the outcome. It ends with the transmission of an `INIT` with an unexpected (zero) itag, which is the CVE attack.

Evil-Server. KORG synthesizes four attacks. The first attack models a scenario in which the Shutdown Timer is configured to a very large value, and thus the attacker can cause a peer in active teardown to (essentially) deadlock by never responding to its `SHUTDOWN` message. In the second attack, the attacker exploits the unexpected packet logic in §5.2.4 to guide a peer out of passive teardown and back into Established. The third and fourth attacks are similar and involve guiding one peer through establishment to de-synchronize it with the other, leading to a half-open connection. Although SCTP was not designed to withstand an Evil-Server, it can nevertheless be configured to defend against attacks like those we found through the appropriate configuration of timers.

Replay. KORG synthesizes one attack where the attacker captures and replays an `ABORT` message sent by a peer before both peers establish a new TSN. The attacker can keep replaying the `ABORT` message indefinitely, preventing the peers

Model	Prop.	Synthesized Attacks	Category
Off-Path	ϕ_9	1 variant of the CVE attack.	Attack
	ϕ_8	1 opportunistic `INIT` attack (Fig. 14).	Misinterpretation
	ϕ_4	1 opportunistic `INIT_ACK` attack (Fig 15).	Misinterpretation
Evil-Server	ϕ_1	1 where the attacker guides A through passive establishment. Then when A attempts active teardown, if its Shutdown Timer never fires, it deadlocks.	Misuse
	ϕ_6	1 where the attacker guides A to Shutdown_Received, then sends it an unexpected `COOKIE_ECHO`, causing it to go back to Established.	Misuse
	ϕ_8	1 where the attacker guides A through most of active establishment before aborting the connection. When the attack terminates, B receives the en-route `COOKIE_ECHO` and completes passive establishment, creating a half-open connection.	Misuse
	ϕ_9	1 where the attacker guides A through passive establishment then terminates. If B then attempts active establishment, the property fails, since the peers are de-synchronized.	Misuse
Replay	ϕ_2	1 where the attacker sends an `ABORT` before the peers establish a TSN for the association.	Misuse
On-Path	ϕ_5	4 attacks where the attacker manipulates both peers into Shutdown_Received.	Misuse
	ϕ_8	2 where the attacker spoofs A to guide B through passive establishment.	Misuse
	ϕ_9	2 where the attacker spoofs B to guide A through passive establishment.	Misuse

Table 2: Attacks found without the patch.

from establishing a connection. This attack is hard to pull off because it requires one of the peers to first `ABORT` and then attempt to re-establish a connection. No other attacks were found. This is expected, as the OOTB logic and TSNs should prevent a replay attacker from injecting old packets.

On-Path. KORG synthesizes four similar attacks where the attacker guides both peers into an association, and then spoofs each peer, sending a `SHUTDOWN` to the other. In general, an On-Path attacker is so powerful that we expect it can manipulate either peer into any state it pleases, as it totally controls the network, so this is unsurprising. KORG synthesizes two more attacks, one for each of the half-open properties, both similar to the last attack reported with the Evil-Server attacker model. These results reinforce the IETF SCTP security memo's statement that "only a strong end-to-end security model can prevent" On-Path attacks.

Note, the reason we do not rediscover the CVE attack in the Evil-Server or On-Path attacker model is that we restrict the attacker in both to only send valid messages, whereas the CVE attack requires an invalid `INIT`. We put this restriction in place in our model to avoid state-space explosion. In general, every attack that is possible in the Off-Path attacker model is also possible in the Evil-Server and On-Path ones.[12]

5.3 Patch Verification

Next, we re-run our analysis with the CVE patch enabled. In the Off-Path attacker model, KORG terminates without finding any attacks. Since KORG found the vulnerability in the Off-Path attacker model when the patch was disabled, and reports no attacks in that same attacker model when the patch is enabled, and as KORG is complete, this suffices to prove that the patch resolves the vulnerability. In the other attacker models, we find the exact same attacks as those reported in Table 2, and nothing more. This proves the patch does not decrease the security of the protocol as it pertains to attacks in any of the four attacker models we study and against the ten LTL properties we specify. However, it does not mean that no new attacks are introduced outside the scope of our analysis, such as, statistical or side-channel attacks or attacks against other properties or in other attacker models besides those listed. Also, our analysis is inherently limited to the attacker models we study, in which the attacker can only perform DoS attacks against a single association involving two agents.

[12] (up to isomorphism)

5.4 Ambiguity Analysis

Next, for each of the two ambiguities, we configure our model with the incorrect interpretation thereof and synthesize attacks against it. We find that the incorrect interpretation of either ambiguous portion could enable a DoS attack, which we illustrate in Figure 14 and Figure 15, respectively, in the Appendix. We consulted with the lead SCTP RFC author who confirmed that the ambiguities we highlighted, if misinterpreted, could open the protocol to attacks such as those we found – and that these attacks will not work if the ambiguous sections are interpreted correctly. Out of concern that a real implementation might have misinterpreted the RFC, we manually analyzed the source for both the Linux and FreeBSD implementations, and tested both implementations with PACKETDRILL, finding that neither made either mistake.

6 Related Work

There are many automated attack discovery tools, each crafted to a particular variety of bug or mechanism of attack, e.g., SNAKE [33] (which fuzzes network protocols), TCPWN [32]

(which finds throughput attacks against TCP congestion control implementations), TAMARIN [44] and PROVERIF [13] (which find attacks against secrecy in cryptographic protocols), KORG [67] (which finds communication attacks against network protocols), and so on. Some of these tools (e.g., KORG) are general purpose, designed to attack any correctness property within a generic specification language, while others (e.g., TAMARIN or PROVERIF) are more specialized, designed to target specific types of properties such as secrecy and trace-equivalence. One work, which studied TCP and ABP, suggested reactive controller synthesis (RCS) as an alternative to KORG's approach [41]. KORG generates attacks that sometimes succeed, depending on choices made by the peers, whereas the RCS method only outputs attacks that always succeed; but such attacks do not always exist. Another approach, which Fiterau-Brostean et. al. [21] successfully applied to various SSH [71] and DTLS [51] implementations, describes incorrect behaviors using automata (rather than properties). This specification style makes sense when generic bug patterns are known ahead of time.

Formal methods such as theorem proving, model checking, property-based testing, and attack synthesis for protocols have been applied to TLS [17] and accountable proxying over it [12], QUIC [43], Bluetooth [69], 5G [9] and its key-establishment stack [45], TCP congestion control [6] and the combination of Karn's Algorithm and the RTO computation upon which it relies [66], the TCP establishment routine [46, 47, 67], and contactless EMV payments [10, 48], to name a few. Compared to many of these systems, such as TCP which has been studied for over 30 years [11, 25, 27, 32, 33, 47, 54, 67], much less is known about the security of SCTP, particularly from an FM perspective.

Of the prior works that applied formal methods to the security of SCTP, only the Uppaal analysis by Saini and Fehnker [53] used a technology (model-checking) that can verify arbitrary properties. They reported two properties in their paper; the first is similar to our ϕ_2. The second says an adversary only capable of sending `INIT` packets cannot cause a victim peer to change state. This property is trivial for us because we use an FSM model where the peer states are precisely the model states. And in our model, the only transition out of Closed that happens upon receiving an `INIT` is a self-loop that sends an `INIT_ACK` and returns to Closed. In contrast, in Saini and Fehnker's model the peer state is a variable in memory, while the model states are totally different (e.g., LC1, LC2). Thus, the property merits verification in their model but not ours. Saini and Fehnker's work is the only one we are aware of that studied SCTP in the context of an attacker using formal methods. But their attacker was only capable of sending `INIT` messages, in contrast to our attacker models which are much more sophisticated, and their attacker could not spoof the port and IP of a peer. Hence, they could not model (and so did not find) the CVE attack.

Another line of inquiry aims to model the performance of SCTP, e.g., using numerical analyses and simulations [16]. For example, Fu and Atiquzzaman built an analytical model of SCTP congestion control, including *multihoming*, an SCTP feature not available in TCP. They compared their model to simulations and found it to be accurate in estimating steady-state throughput of multihomed paths [23]. Such models are also used to evaluate new features, e.g., as in [72].

7 Conclusion

In this work we formally modeled SCTP and specified ten novel LTL correctness properties based on a close reading of the RFCs. We proved that in the absence of an attacker, the protocol satisfies all ten properties. We used KORG to synthesize attacks against our model for four novel attacker models, Off-Path, Evil-Server, Replay, and On-Path, and for two configurations of the SCTP model – one without the RFC 9260 patch and another with it. This required improvements to KORG, which we open-sourced with the paper artifacts. Without the patch, we found the CVE-2021-3772 attack in the Off-Path attacker model; a variety of Evil-Server and On-Path attacks; and one Replay attack. Then we repeated our analysis with the patch, and found that it eliminated the CVE vulnerability. We found that the patch did not impact the security of the protocol with respect to properties other than the one violated by the CVE attack in the Off-Path attacker model, nor did it change any of the results in the other (less realistic) attacker models. Recall, however, that our analysis is limited to DoS attacks involving just two agents in an association, because KORG does not scale to attacker models with very large (let alone unbounded) state-spaces.

We also explored extending KORG to not just discover vulnerabilities, but synthesize patches too. We found the task infeasible as the search space for edits is enormous, and each edit requires re-verifying. And since PROMELA does composition over FIFO channels, reasoning about the composite Kripke Structure and tying it back to the PROMELA encoding proved very challenging. Though we failed to synthesize patches in this work, we believe patch synthesis may be plausible in a more automata-theoretic context.

Our attacks highlight the need to explicitly handle unexpected but valid packets and set reasonable timer values. We reported two ambiguities in RFC 9260, each of which could be misinterpreted in a way that could lead to a vulnerability. We analyzed the Linux and FreeBSD SCTP implementations using PACKETDRILL and found both correctly interpreted the ambiguous portions of text. We concluded with recommendations for how the portions could be made unambiguous in errata. So far, our second recommendation for an erratum was accepted by the SCTP RFC committee.

8 Appendix

History of CVE-2021-3772. The vuln. reported in CVE-2021-3772 arose from the following text in RFC 4960 [55]: "If the value of the Initiate Tag in a received `INIT` chunk is found to be 0, the receiver MUST treat it as an error and close the association by transmitting an `ABORT`." As shown in Fig. 3, if an implementation did not check the validity of the `INIT` before transmitting an `ABORT`, then the RFC allowed for a DoS where the attacker would transmit an invalid `INIT` and trigger the victim to close an otherwise valid association. This vuln. was first reported in the SCTP mailing list [26] and then in CVE-2021-3772 [49]. The vuln. was subsequently patched in Linux by swapping the order of operations, to ensure the vtag is always checked before the itag [38]. The RFC was updated in 9260 [58] to say: "If the value of the Initiate Tag in a received `INIT` chunk is found to be 0, the receiver MUST silently discard the packet." ... and FreeBSD [4] implemented this patch when it was updated to reflect the new RFC.

User Model. The user nondeterministically sends User_Assoc, User_Abort, and User_Shutdown.

Additional Errata. We suggest incorporating the self-loop at Closed that occurs upon receiving a `SHUTDOWN_COMPLETE`, into the State Association Diagram in Section 4. We suggest incorporating "`INIT` collision" into that same diagramWe suggest expanding 5.2 to explain how to handle other unexpected chunks, e.g., `COOKIE_ERROR`, `SHUTDOWN_COMPLETE`, etc.

Performance We time our experiments and patch verification tasks, and almost always, KORG terminates in seconds

```
/* P1 */ G((st[0] == Closed) -> (X(F(st[0] == Closed
|| st[0] == Established || st[0] == CookieWait))))
/* P2 */ G(F(st[0] != ost[0] || st[1] != ost[1] ||
(st[0] == Closed && st[1] == Closed) ||
(st[0] == Established && st[1] == Established)))
/* P3 */ G((st[0] != ost[0] && ost[0] ==
ShutdownAckSent) -> (st[0] == Closed))
/* P4 */ G(F(st[0] != CookieEchoed ||
timers[0] == T1_COOKIE))
/* P5 */ G(st[0] != ShutdownReceived ||
st[1] != ShutdownReceived)
/* P6 */ G((st[0] != ost[0] && ost[0] ==
ShutdownReceived) -> (st[0] == ShutdownAckSent ||
st[0] == Closed))
/* P7 */ G(st[0] != CookieEchoed || st[1] !=
ShutdownReceived)
/* P8 */ G((ost[1] == Established && ost[0] ==
Closed && everAborted == false && everTimedOut ==
false && ost[0] != st[0]) -> (st[0] == Established
|| st[0] == IntermediaryCookieWait))
/* P9 */ G((ost[0] == Established && ost[1] ==
Closed && everAborted == false && everTimedOut ==
false && ost[1] != st[1]) -> (st[1] == Established
|| st[1] == IntermediaryCookieWait))
/* P10 */ G((ost[0] == Established && (st[0] ==
ShutdownSent || st[0] == ShutdownReceived))
-> F(st[0] == Closed))
```

Figure 13: Our 10 LTL properties are formulated in PROMELA. We define our atomic propositions as follows in PROMELA, where `st` holds the state of each peer, `ost` holds the prior one, and `timers` holds the peers' timers.

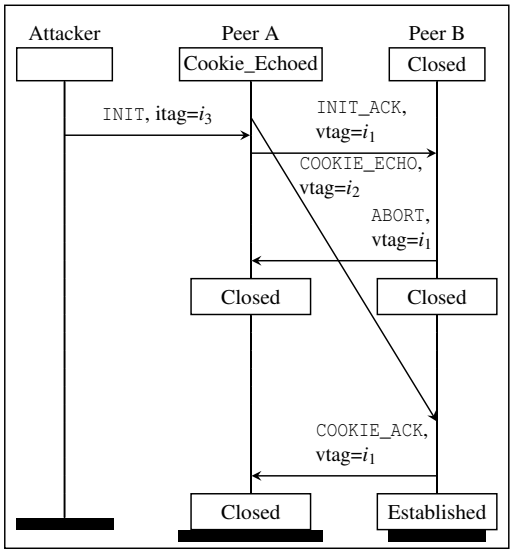

Figure 14: First ambiguity attack.

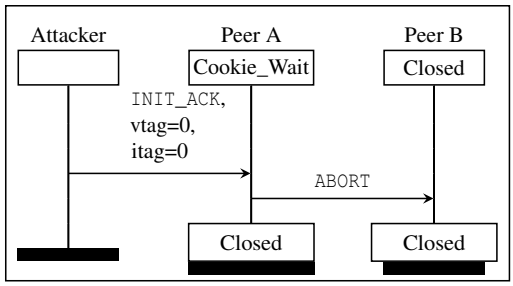

Figure 15: Second ambiguity attack.

```
chan attacker_mem = [2] of {
    mtype:msgs,mtype:tag,mtype:tag,byte };
active proctype attacker_replay() {
  mtype:msgs b_0; mtype:tag b_1, b_2; byte b_3;
  do :: atomic { AtoB ?? <b_0, b_1, b_2, b_3>
    -> attacker_mem ! b_0, b_1, b_2, b_3; }
  :: atomic { attacker_mem ?? b_0, b_1, b_2, b_3
    -> AtoB ! b_0, b_1, b_2, b_3; }
  :: atomic { attacker_mem ?? b_0, b_1, b_2, b_3; }
  :: break; od }
```

Figure 16: The replay attacker gadget.

or minutes, with one interesting exception. In the Off-Path experiments, KORG takes about two hours to confirm that no attacks exist against ϕ_8, and about 1.5hrs to find the CVE attack against ϕ_9. Recall that ϕ_8 and ϕ_9 are identical, except that the peer roles are reversed. Further inspection reveals these two properties are the largest in our property set, and the Off-Path attacker model is the largest attacker model. The reason these two analyses take longer follows, as KORG reduces to LTL model-checking, the runtime of which is polynomial in the size of the model and $O(\log^2|\phi|)$ in the size of ϕ [64].

	Off-Path		Evil-Server		Replay		On-Path

Abstract

Recent research has shown a growing number of side-channel vulnerabilities in transport layer protocols, such as TCP and UDP. Those side channels can be exploited by adversaries to launch nefarious attacks. In this paper, we present Athena, an automated tool for detecting, quantifying and explaining side-channel vulnerabilities in vanilla implementations of transport layer protocols. Unlike prior tools, Athena adopts a novel graph-based analysis, making it scalable enough to be the first side-channel analysis tool that can comprehensively analyze the TCP and UDP implementations in several operating systems with significantly higher coverage than the state-of-the-art. Moreover, Athena uses an entropy-based algorithm to identify the most important vulnerabilities. Evaluation on several benchmarks including Linux, FreeBSD, OpenBSD and two open-source IPv4 implementations suggests that Athena can narrow down critical side channels to a single digit (among over 1000 candidates) with a low false positive rate. Besides covering known side channels, Athena also discovers 30 new potential attack surfaces.

1 Introduction

Transmission Control Protocol (TCP) and User Datagram Protocol (UDP) are the two most widely used transport layer protocols for reliable and low-latency data transmission between network hosts. However, recent research has shown growing concerns about the susceptibility of side-channel vulnerabilities in these protocols, which can be exploited by adversaries to launch nefarious attacks. Some typical forms of these attacks can expose sensitive information, such as port numbers [2, 10, 22, 23], the existence of an active client in the Internet, and even hijack connections between a server and a targeted client [17]. These side channels primarily lurk in the shared resources that are created and managed by the server's operating systems; the resources are shared across multiple connections established with different clients [6, 7, 10, 11, 13, 16, 19, 22, 23, 25].

Despite an increasing number of identified side channels in transport layer protocols, the majority of those side channels are manually identified, which require extensive domain knowledge and manual effort. Moreover, the manual analysis cannot guarantee full code coverage as there might still be unknown side channels lurking in TCP and UDP protocols, and a new kernel update might introduce new side channels. Recent work [7, 12] follows a more promising approach. They develop a concrete/abstract model of the stand-alone version of a TCP implementation and use a static model checking technique to *automatically* identify side channels in those models. For example, Cao et al. [7] were able to detect 10 side channels in their analysis. However, due to the limited scalability of model checking technique, they were unable to analyze the entire TCP implementation, and bounded model checking cannot guarantee full code coverage either. This resulted in an inadequate analysis of complex protocol behavior and interactions with other components/layers, rendering poor coverage and an imprecise model of the analyzed TCP implementation. Finally, existing approaches require further manual effort to diagnose the root cause of side channels, such as why the side channels exist, when they can be triggered and how they can be observed by an attacker. *This paper, therefore, aims to fill this gap by developing an automated approach for developers to systematically identify side-channel vulnerabilities in TCP and UDP implementations, as well as an automated diagnostic mechanism to locate their root causes.*

Prior work [7, 12] identifies side channels in transport protocols as a violation of a non-interference property: given two instances of the same server state where only security sensitive properties are different, whether sending a set of packets (inputs) to the two servers will result in different responses. However, identifying such non-interference violations directly via model checking is costly. For instance, SCENT [7] reports an exponentially growing running time with regard to the number of packets and its execution time reaches over 10,000 seconds with 4 incoming packets. Ensafi et al. [12] report extreme running time (over 3 days) and memory usage (>16GB) on an abstract model of implementation code. In contrast, our

observation is that one can detect the same violations with a much lower cost and scalable manner in two stages: (1) identify all *tainted* branches whose outcomes are affected by sensitive properties, and (2) identify the sensitive branches that influence different responses, i.e., sinks (e.g., the existence or absence of protocol actions such as sending out a network packet). Hence, one can detect side channels by asking the following question: *is there any tainted branch (with respect to the sensitive properties) that leads to different sinks in a control flow graph (CFG)?* Nonetheless, reporting all tainted branches that might reach a sink is inadequate for at least two reasons. First, even with a precise static taint analysis, such branches are enormous in the entire implementation of transport layer protocols (empirically, we found between 572 to 1651 tainted branches in Linux UDP and TCP implementations). So a manual inspection of all tainted branches is infeasible. Second, tainted branches do not shed too much light on *why* there is a side channel and *how* to fix it.

Based on the above observations, we design and implement a static analysis-based systematic side-channel analysis tool called Athena. Athena first models side channels in the transport protocols as a *graph search* problem based on the abstraction of tainted control flow graph (τCFG). To tackle the challenges of reporting and diagnosing all tainted/sensitive branches, Athena introduces an entropy-based approach motivated by *entropy* in information theory [28] to localize the *most important* side channels, and also develop a set of rules to automatically *explain* why the side channels exist (e.g., by observing whether an ACK message is sent or not in Established state, an attacker can reveal the secret values used by TCP) and how the side channels can be observed by an attacker. Finally, to comprehensively identify side channels under our threat model in protocol implementations, Athena adopts an *iterative* "rank-and-replace" approach that mimics how side channels are mitigated in transport layer protocols and then identifies the remaining ones. Our approach greatly improves scalability and usability of prior protocol side-channel analyses [7, 12] as both static taint analysis and CFG construction can be directly applied to protocol implementations without modifying or abstracting the source code, and they both scale to a large code base. Moreover, entropy-based graph-search algorithm also enjoys a complexity that is linear to graph size. Hence, Athena is able to analyze *entire implementations* of transport protocols, while prior work only analyzes their abstract models or partial code due to scalability limit.

We implement Athena and evaluate it on several benchmarks of TCP and UDP implementations, including Linux 3.19, Linux 4.8, FreeBSD 13.2 and OpenBSD 7.4 IPv4 kernel code, as well as two open-source IPv4 implementations on GitHub [24, 31][1]. Athena reports 34 side channels in the TCP model and 8 side channels in the UDP model in total. Athena further extracts information from these flows and provides diagnostic information such as the most critical branches and states needed to trigger the side channel.

Contributions. In this paper, we make the following contributions.

- We model the detection of side-channel vulnerabilities of transport layer protocols as a graph-search problem. Based on the graph, we develop an entropy-based approach to rank side channels according to their importance. Moreover, we develop an iterative rank-and-replace loop to identify a comprehensive list of side channels, i.e., no more side channels exist after the reported ones are fixed;
- We design and implement Athena, an automated tool that detects, quantifies and explains side-channel vulnerabilities thoroughly in the entire implementations of transport layer protocols. Athena is open-sourced at https://github.com/athena-paper/athena;
- We evaluate Athena with the TCP and UDP implementations of Linux 3.19, Linux 4.8, FreeBSD 13.2, OpenBSD 7.4 and two open-source programs (microps [24], picotcp [31]). Athena reports 42 side-channel vulnerabilities, including 30 new side channels, 7 known ones and only 5 false positives.

2 Transport Layer Protocols

Transport layer protocols operate at the transport layer of the TCP/IP Internet protocol stack. They are responsible for establishing communication between applications running on different hosts. The two most commonly used protocols are TCP and UDP.

TCP. TCP (Transmission Control Protocol) is a connection-oriented protocol that requires a logical connection to be established between the two hosts through a three-way handshake before data is exchanged. It ensures reliable and ordered delivery of data packets between applications (e.g., SSH and FTP) on different hosts through various mechanisms, such as flow control, congestion control, and error recovery. TCP is, however, vulnerable to a variety of attacks since security was not the primary concern in the TCP design. Some typical attacks include SYN flooding attacks [21], TCP session hijacking attacks [17], and blind RST attacks [27]. Many such attacks involve guessing certain connection secrets, namely sequence (SEQ) numbers and acknowledge (ACK) numbers. Therefore, the inference of these numbers has become a vital part of TCP attacks [1, 6, 11, 12, 25].

UDP. Unlike TCP, UDP (User Datagram Protocol) is a connection-less protocol that does not require any handshake or logical connection between hosts. As such, it does not provide any guarantees for reliable delivery of packets or ordered delivery of data. This feature makes UDP faster and more efficient than TCP. Hence, it is commonly used in applications

[1] The most starred TCP implementations written in C on Github.

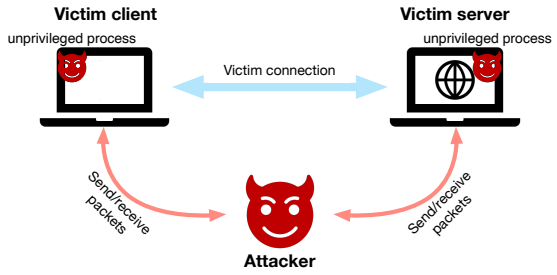

Figure 1: Threat model. An aided off-path attack also utilizes an unprivileged processes residing in the victim machines.

where real-time communication and low latency are critical. One of the most common applications that extensively use UDP is DNS (Domain Name System). DNS queries and responses are sent in UDP packets between clients and servers.

An important type of attack in systems using UDP protocols is the UDP port inference attack [22], as applications relying on UDP usually hide the client port to provide some level of integrity. Attackers use UDP port inference as a stepping stone to performing DNS cache poisoning attacks [22, 23, 29].

3 Overview

3.1 Threat Model

In line with prior work [15], we consider both a client and a server can be the victims of side-channel attacks. In this setting, we assume that the victim client and the victim server have already established TCP/UDP communication, and there is an off-path attacker (as shown in Figure 1). We also consider two different capabilities for such attackers: (a) *Unaided off-path attacker (*Adv_u*)*, and (b) *Aided off-path attacker (*Adv_a*)*. In our analysis, we distinguish the two types of threat models by different sets of sinks observable to an attacker.

Unaided off-path attacker (Adv_u). In this threat model, we assume an off-path attacker who can send TCP/UDP messages (either with their own IP address or spoofed ones with the target client's or server's IP address) to the victim client/server. However, being off-path, the attacker does not have the capability to eavesdrop on the active connection or inject/modify the packet transmitting between the client and the server (shown in Figure 1). Furthermore, the threat model assumes that attackers do not have any control over or aid from any unprivileged/privileged processes running on the victim client/server. Instead, attackers attempt to infer the system connection states only through the side channels discovered in protocol implementations directly or indirectly, such as global counters [6], IPID hash collisions [13] and SYN-backlogs [7]. To reflect this threat model in our analysis, we mark packet transmission functions as sinks, as only transmitted packets are observable by unaided off-path attackers.

Aided off-path attacker (Adv_a). In this threat model, we assume that Adv_a possesses the same capabilities as Adv_u and has additional control over or assistance from an unprivileged process running on the victim client/server. This attack model is consistent with the ones in prior work [2, 25, 26], wherein the unprivileged process is a sandboxed malicious script on the victim's machine injected by the attacker. Running on the application layer, the script cannot directly tamper with the data sent to/received from another host but can observe various networking parameters and statistics, or interact with the network stack on its behalf [2] and stealthily notify the Adv_u to help Adv_u launch attacks. For example, we assume an unprivileged process in one of the victim's machines can read `netstat` files (located in `/proc/net` which only requires normal access privilege) and stealthily report any change to Adv_a [2, 26]. To reflect this threat model in our analysis, we mark functions that modify local counters as sinks.

Attacker's goals. Attackers attempt to exploit side-channel vulnerabilities to infer the state of the victim's connection. Specifically, they would like to infer (a) the port number of the client victim used for the connection (for TCP and UDP), (b) the sequence (SEQ) number from the client (for TCP only), and/or (c) the acknowledge (ACK) number expected by the server (for TCP only). Such information is security sensitive for the following reasons. If an attacker successfully learns the port number, she can determine whether there exists an active connection between the client and server. If SEQ number is further inferred, she can trick the victims into prematurely closing the TCP connection by crafting an RST fragment (e.g., TCP Reset Attack [27]). If all three numbers are inferred, the attacker can arbitrarily inject their own data into the connection, and essentially hijack the connection (e.g., TCP Session Hijacking Attack [17]).

3.2 Illustrative Example

Figure 2 shows simplified code snippets in the Linux implementation of TCP; we use it to demonstrate a known side channel in the Linux implementation of TCP [26].

The first code snippet (from `tcp_rcv_established`) handles incoming packets when the socket is in the ESTABLISHED state. Here, the system first validates the incoming packet's SEQ and ACK number by matching them against the expected numbers (lines 2-5). If the header length is too short (line 6), the packet is discarded. Otherwise, it further validates the incoming packet in function `tcp_validate_incoming` (the second code snippet). Only when the sequence number is legit and RST, SYN flags satisfy required states (line 14-17), sink function `tcp_send_dupack` is being called; otherwise, the packet is discarded or the system calls a sink function `tcp_send_challenge_ack` to send out a SYN challenge. Similarly, the decision of sending out a SYN challenge or discard the packet between lines 24 and 29 also depends on the sequence number and the RST flag.

In this example, the sequence number of the host (i.e., the value of `tp->rcv_nxt`) is security sensitive. The sensitive

```
1  // In tcp_rcv_established(), tcp_input.c:
2  if ((tcp_flag_word(th) & TCP_HP_BITS) ==
3      tp->pred_flags &&
4      TCP_SKB_CB(skb)->seq == tp->rcv_nxt &&
5      !after(TCP_SKB_CB(skb)->ack_seq, tp->
           snd_nxt))
6    if (len <= tcp_header_len) {
7      goto discard;
8    }
9  ...
10 if (!tcp_validate_incoming(sk, skb, th, 1))
11   return;
12
13 // In tcp_validate_incoming(), tcp_input.c:
14 if (!tcp_sequence(tp, TCP_SKB_CB(skb)->seq,
15     TCP_SKB_CB(skb)->end_seq)) {
16   if (!th->rst) {
17     if (th->syn)
18       goto syn_challenge;
19     tcp_send_dupack(sk, skb);
20   }
21   goto discard;
22 }
23 ...
24 if (th->rst) {
25   if (TCP_SKB_CB(skb)->seq != tp->rcv_nxt) {
26     tcp_send_challenge_ack(sk);
27   }
28   goto discard;
29 }
```

Figure 2: A simplified code snippet of a side channel in TCP

data affects the outcomes of multiple branches in the code, including the ones at lines 4, 14 and 25. Hence, an attacker is able to reveal the sequence number of the host by observing which sink function is executed, or neither of them are called. For example, prior work [26] demonstrates how to reveal the sequence number via a side channel attack as illustrated in Figure 3. While an off-path attacker is unable to observe the existence/absence of a DUP ACK packet between client and server directly, an unprivileged process on the victim server can monitor `netstat` counters (located in `/proc/net/`). Depending on if the counter is incremented or not, the attacker can reveal if the sequence number of an incoming packet (crafted by the attacker) is smaller or greater than the sequence number of the host. In the source code, this vulnerability is reflected by the branch at lines 14-15, where sink function `tcp_send_dupack` is called only when the incoming sequence number is within a specific window.

Prior research [7, 12] recognizes side channels in transport layer protocols as a breach of the non-interference principle: when two hosts (e.g., the servers on the left and right respectively in Figure 3) possess identical states, except for sensitive security attributes, transmitting a particular set of packets to both hosts should not produce dissimilar responses. Moreover, they either use bounded model checking [7] on partial code or model checking on abstract model of implementation [11] to detect violations of the non-interference principle. While existing tools were able to unveil side channels in transport layer protocols, using model checking methods is both expensive

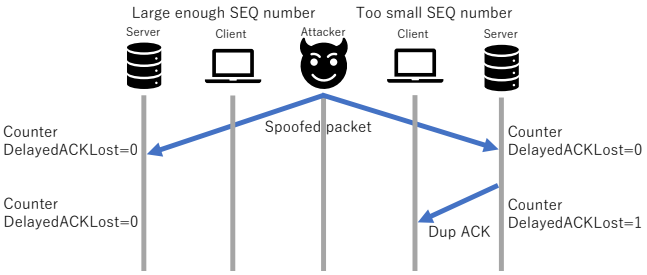

Figure 3: An illustration of the DUP ACK side-channel attack

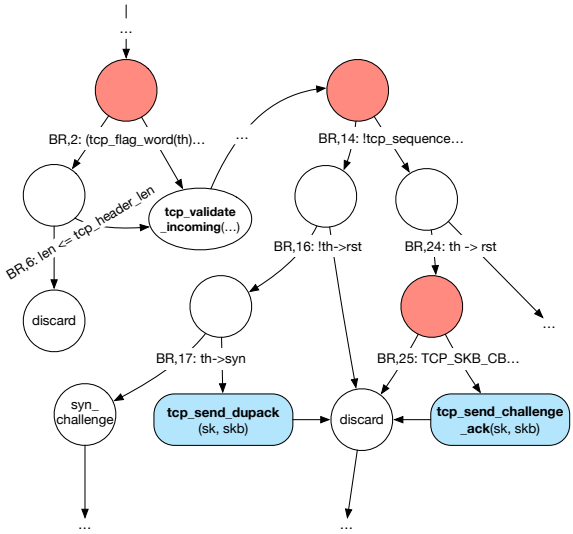

Figure 4: A simplified tainted CFG of the TCP code snippets

and incomplete in terms of code coverage.

3.3 Why is Detecting Protocol Side Channels a Graph Search Problem?

In this paper, we recognize side channels in transport layer protocols (e.g., TCP and UDP) as a graph search problem. As shown in Section 3.2, different values of the host's sequence number `tp->rcv_nxt` lead the protocol executions to take different control flow paths. Since each distinct control flow path may eventually refer to disparate behavior of the system observable from the outside of that system (e.g., sending an DUP ACK packet, or sending a Challenge ACK packet, or discard the incoming packet), an off-path attacker can infer the sensitive status of the socket, thus leading to side-channel information leakage. In other words, when secret information, i.e., *sources* (e.g., `tp->rcv_nxt`), has any influence on the existence or absence of protocol actions such as sending out or dropping off a message, i.e., invocation of *sinks*, it signifies the existence of side channels in the transport protocols.

We leverage this intuition and develop a new graph-based approach that detects and ranks potential side channels in implementations of transport layer protocols. We call con-

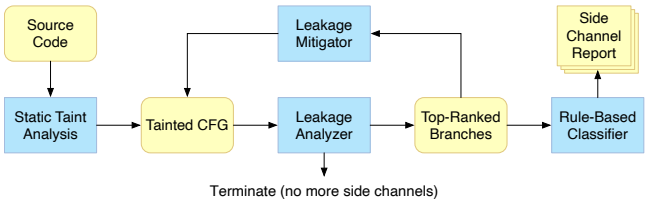

Figure 5: System overview

trol flow graph (CFG) with tainted branches and distinct sink nodes a *tainted CFG*. In essence, we aim to detect side channels by identifying tainted branches (with respect to the sensitive sources) that lead to *multiple* sinks (i.e., packet exchanges between the target system and the outside world) in the corresponding tainted CFG of the transport layer protocol implementation. For example, Figure 4 represents a simplified tainted CFG of the example code in Figure 2. In this graph, red nodes denote tainted branches (whose execution is dependent on the secret sources), and the sink functions are marked in blue. Note that the red node with label (`BR,14:!tcp_sequence...`) is the root cause of the side channel attack in Figure 3; depending on its outcome, the host can either reach sink function `tcp_send_dupack` or simply discard the packet (i.e., going through no sink function).

Why control-flows? Arguably, data-flow leakage where sources are directly leaked to sinks (e.g., directly sending out the sequence number to an off-path attacker) reveals more information than control-flow leakage. However, TCP and UDP implementations are unlikely to have any data-flow leakage due to their designs. We also confirmed this intuition via a static taint analysis, which detects no explicit data-flow leakage in Linux and FreeBSD implementations.

3.4 Workflow of Athena

In our approach, Athena takes tainted CFG (e.g., the one in Figure 4) as an input and reports a list of potential side channels that are both important and complete (i.e., if the reported ones are fixed, there are no remaining side channels). While the approach sounds intuitive, the main technical challenges are two-fold: (1) how to measure the importance of side channels, and (2) how to identify a *small* set of important sensitive branches that are also complete. For example, even in the simplified CFG in Figure 4, there are 3 distinct sensitive branches where each might cause a side channel. For the complete TCP implementation in Linux 3.19 IPv4 kernel, there are 1651 candidates of potential side channels!

To tackle the challenges, Athena follows a novel *rank-and-replace* loop to iteratively identify the most important side channels in each iteration, and then pursue the analysis as if they had been "replaced" with side-channel-free counterparts, until no more side channels are detected. Figure 5 shows an overview of Athena with three major components:

- **Leakage analyzer** (Section 4.3.1): we introduce an entropy-based metric to measure the importance of sensitive branches in a tainted CFG. For example, the red node with label (`BR,14:!tcp_sequence...`) has the highest importance as intuitively, it has direct impact on all possible outcomes: call `tcp_send_dupack`, call `tcp_send_challenge_ack`, or call no sink at all;

- **Leakage mitigator** (Section 4.3.2): inspired by how side channels in transport layer protocol implementations are mitigated in practice, we introduce a special node called *wildcard node* to mimic the effect of fixing a side channel by injecting noise. The revised taint CFG where all top-ranked branches are replaced by wildcard node is being analyzed in the next iteration;

- **Rule-based classifier** (Section 4.4): for each reported top-ranked branch in each iteration, Athena also utilizes the tainted CFG to automatically distill useful information such as the protocol states (e.g., ESTABLISHED) needed to trigger the side channel and the distinct outputs that an attacker can observe to reveal sensitive data. For the node with label (`BR,14:!tcp_sequence...`) in Figure 4, Athena reports that it can be triggered in ESTABLISHED state, and an attacker can observe whether a local counter is updated or not to reveal sensitive data.

With the innovations above, Athena reports 11 side channels for the full version of the tainted CFG of the TCP implementation in Linux 3.19, out of 1651 sensitive branches in the original tainted CFG. Moreover, the reported 11 side channels cover all previously reported ones that exist in the Linux code that we have analyzed. Among the 11 reports, 8 are new, only 1 is false positive, and 2 are previously reported (including the one with label (`BR,14:!tcp_sequence...`).

4 Design Details

4.1 Sources and Sink Functions

To analyze side channels in TCP and UDP, we first need to specify the following items for each protocol:

- Sources: secret data that a side channel might reveal,
- Sink functions: a set of functions of TCP and UDP implementations that an attacker might observe directly or indirectly if a function is called or not,
- Entry point: the starting point of execution. This is typically the function that receives network packages.

In this section, we use Linux implementation as an example to illustrate our design. Our design, however, is generic and can be applied to other operating systems with minimal extra effort to choose source/sink functions of similar functionality.

4.1.1 TCP

As discussed in Section 3.1, we consider the port number, SEQ number and ACK number to be the secret sources in a TCP implementation (called **3-tuple**). For example, Linux implementation stores the sources in the `tcp_sock` data structure, and therefore we mark the structure as the source.

A typical transport layer protocol implementation may have multiple entry points. For instance, the Linux TCP implementation has two different entry points for handling incoming packets in different states: (1) `tcp_rcv_state_process()` function, which handles all TCP states except *ESTABLISHED* and *TIME-WAIT* states, and (2) `tcp_rcv_established()` function, which handles packets in the *ESTABLISHED* state.

In the unaided threat model, an attacker may observe outgoing packets (sent by function `tcp_send_ack()` from the host). We mark a series of functions calling the send function as sinks. In the aided threat model, the execution of macro `NET_INC_STATS` (which increments a counter under `/proc/net` by 1) can be detected locally. Hence, the macro is also marked as a sink with the aided threat model.

4.1.2 UDP

The UDP protocol is more straightforward compared to TCP. There are two handlers in the Linux UDP implementation: (i) the `udp_rcv()` function for handling incoming UDP packets, and (ii) `udp_err()` for handling incoming error messages with embedded UDP packets. They are registered as the two entry points for UDP analysis. In both routines, the system checks the sensitive port number to find the existence of UDP connections (i.e., if there has been communication between the hosts) by looking up in a structure `udp_table`. Therefore, we label `udp_table` as the source in UDP protocol.

In the unaided threat model, an attacker may observe the invocation of `icmp_send()` and `update_or_create_fnhe()`. Hence, they are marked as sinks of UDP. In the aided threat model, the execution of macro `UDP_INC_STATS_BH` is marked as another sink, similarly as in TCP.

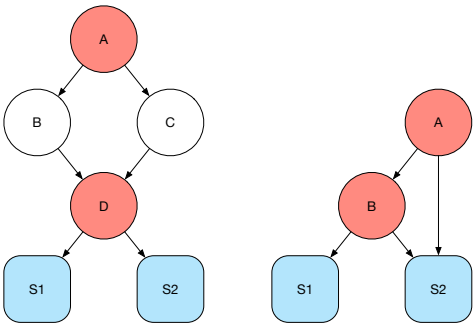
4.2 Tainted CFG

In this work, we use a *tainted* control flow graph, or simply τCFG, as the basis of side channel analysis. We first introduce τCFG and highlight why it is useful for identifying side channels in Transport Layer Protocol implementations.

A tainted control flow graph $\tau\text{CFG} = \langle V, E, T, S \rangle$ consists of a CFG $\langle V, E \rangle$, a set of tainted branching nodes T and a set of sink nodes S. As standard, a CFG $\langle V, E \rangle$ is a graphic representation of the control flow of a program. It is a directed graph where the nodes represent basic blocks of code and the edges represent the flow of control between the blocks. Each basic block represents a sequence of instructions that are executed without any jumps or branches, while the edges connect the basic blocks to show the flow of control between them. Conditional statements and loops are represented as nodes with multiple outgoing edges, each corresponding to a possible branch or jump target in the program.

Given a set of sources, say H, of a transport layer protocol implementation, a branching node is *tainted* if there are two initial host states m_1 and m_2 that only differ on the value of sources H (i.e., for any public variable $x \notin H$, we have $m_1(x) = m_2(x)$) such that control flows right after that branch are different when the protocol implementation is executed under m_1 and m_2, respectively. Note that with any sound static taint analysis, which identifies a set of variables whose value explicitly or implicitly depends on H, computing a set of tainted branching nodes T is straightforward: we collect the set of branching nodes whose branching condition uses at least one tainted variable.

Finally, S is a set of sink nodes where each node represents a call to a sink function (Section 4.1). For technical connivance, we assume that the sink nodes set also contains a special node $\emptyset$ which represents the absence of any sink function (i.e., $\emptyset \in S$). Moreover, each node in CFG without an outgoing edge must be a sink node, including the absence node $\emptyset$. Note that there might be multiple incoming edges to sink nodes (including the absence node) in τCFG by definition.



With τCFG, we define a *critical branch* as follows:

Definition 1 (Critical Branch)**.** *Given a tainted CFG $\langle V, E, T, S \rangle$, a branching node $v \in V$ is* critical *if it is both tainted (i.e., $v \in T$) and it can reach at least two distinct sink nodes in the corresponding CFG $\langle V, E \rangle$.*

We note that the critical branch serves as a proper graphic abstraction for analyzing side channels in implementations of Transport Layer Protocols since by definition, the absence of a critical branch in τCFG implies the absence of side channels. The reason is that if there is no critical branch, then for any two instances of the same host state where only security-sensitive properties are different, sending a set of packets (inputs) to the two hosts will always result in the same responses (i.e., sink function calls). Compared to directly analyzing if a transport layer protocol implementation can produce different responses when its host source values change [7, 12], constructing τCFG and computing critical branches in a τCFG is more scalable. τCFG further enables quantification and mitigation of side channels as we will elaborate in Section 4.3. One potential limitation of analyzing τCFG, however, is that a critical branch does not necessarily always cause a side channel. For example, a control-flow path in CFG might be infeasible in program execution (e.g., due to unreachable code). However, as we show in the evaluation (Section 6), our analysis built on τCFG is precise enough in practice.

4.3 Identifying Side Channels

Based on τCFG, one naive approach is to report all critical branches identified in a τCFG. However, the naive approach is

(a) (b)

Figure 6: Example τCFGs

problematic for a couple of reasons. First, a critical branch is not necessarily the *root cause* of a side channel. For example, consider the τCFG in Figure 6a where the tainted branches are in red and the sink nodes are marked as blue squares. Although the top node A is a critical node as it can reach both sinks S1 and S2, it makes no *impact* on which sink is reached. Intuitively, node D constitutes a side channel as depending on its branch outcome, either node S1 or S2 is reached (i.e., its branch outcome controls which sink node is reached).

Second, not all critical branches are equally important since they leak different amount of information, and moreover, they might be dependent on each other. For example, consider the τCFG in Figure 6b where the tainted branches are in red and the sink nodes are marked as blue squares. Intuitively, the red node B leaks more information than node A since by observing if S1 or S2 is reached, we can derive which branch is taken at node B. However, we can only do so for node A when S1 is reached. Moreover, if node B is replaced by always producing S2, then node A becomes non-critical since it can only reach sink S2 after the replacement. In other words, node A depends on node B in terms of criticalness.

Third, even with a precise static taint analysis, critical branches are enormous in the full implementation of transport protocols; for example, our analysis finds 185 critical branches in total in the TCP implementation of Linux 3.19.

4.3.1 Quantifying Critical Branches

To tackle the challenge of simply reporting all critical branches, we develop a novel quantification algorithm based on the concept of *entropy*, which is commonly used in information theory [28, 30]. Intuitively, for each node in τCFG, its entropy quantifies the *uncertainty* of reaching sink functions from that node. Moreover, the *change* of entropy before and after executing a branch (i.e., a branching node) measures the knowledge being learnt (by the attacker) via revealing the branch outcome.

In general, τCFG is not acyclic due to loops. However, to make entropy computation simple and efficient, we assume that τCFG is modified to be acyclic by removing backward edges (i.e., edges from the loop body to the loop condition) before further analysis. Removing the backward edges needs extra caution as it might remove a path from a tainted branch in the loop to an earlier call to a sink in the same loop. Athena avoids the issue by tainting the top node (loop head) whenever there is a tainted branch in the loop on backward edge removal. Hence, the tainted loop head will now reach all sinks in the loop and consequently detect potential side channels in a conservative way. Our evaluation results also suggest that the analysis on acyclic τCFG has high accuracy, as the top results match previously reported side channels [7] (Section 6.3).

Next, we provide a more formal and precise definition of node entropy in an acyclic tainted CFG, τCFG. For a node v in τCFG with sink nodes S, the entropy of v measures the uncertainty of which sink that v will eventually reach.

Definition 2 (Entropy of node)**.** *Let $\tau CFG = (V, E, T, S)$ be an acyclic tainted CFG. For a node $v \in V$, let $\mathcal{H}_S(v)$ be the entropy of reaching the sink set S from v, defined as:*

$$\mathcal{H}_S(v) = \begin{cases} 0, & v \in S \\ -\sum_{s \in S} P(v,s) \log_2 P(v,s) & v \notin S \end{cases}$$

where $P(v,s)$ is the probability that node v reaches node s.

Note that the entropy of any sink node is 0, since it 100% reaches itself but nothing else. For any other node, $\mathcal{H}_S$ is defined as the Shannon entropy [28, 30] on the probability that node v reaches some sink node. For example, consider the τCFG in Figure 6b and assume that each outgoing edge has a 50% chance. Then, we have $\mathcal{H}_{\{S_1,S_2\}}(A) = -0.25\log_2(0.25) - 0.75\log_2(0.75) = 0.81$ and $\mathcal{H}_{\{S_1,S_2\}}(B) = -0.5\log_2(0.5) - 0.5\log_2(0.5) = 1$.

While entropy measures the absolute value of uncertainty, the *difference* of a node and its successor measures how much knowledge is learned by the fact that control flow transfers to the successor. Since a node might have multiple successors, we define the *leakage* of a node as the maximum entropy differences between itself and among its all successors.

Definition 3 (Leakage of node)**.** *Let $\tau CFG = \langle V, E, T, S \rangle$ be an acyclic tainted CFG. For a node $v \in V$, let $succ(v)$ denote the set of the successors of v in τCFG. Let $\mathcal{L}(v)$ be the leakage of v defined as: $\mathcal{L}(v) = \max_{i \in succ(v)} \mathcal{H}_S(v) - \mathcal{H}_S(i)$.*

Returning to the τCFG in Figure 6b, given the assumption that each outgoing edge has a 50% chance, we have $\mathcal{L}(A) = 0.81 - 0 = 0.81$ and $\mathcal{L}(B) = 1 - 0 = 1$. Hence, node A is less critical than node B, which is consistent with our intuition since by observing if S1 or S2 is reached, we can derive which branch of B is taken. However, we can only do so for node A when S1 is reached.

Moreover, we note that the leakage definition also solves the challenge illustrated in Figure 6a. Assume that each outgoing edge has a 50% chance. It is easy to compute that the entropy of all nodes, i.e., A, B, C, and D is 1. Hence, the leakage of node A is 0, which correctly indicates that the node itself does not introduce any side channels.

Finally, we fill in an important missing piece in Definition 2, i.e., $P(v,s)$— the probability that node v reaches a sink node s. One subtlety is that for each branching node, we need to know the probability that it reaches each of its successors. For a tainted branch, we use a simplification assumption that each outgoing edge of the same node has the same probability[2]. For a public branch, we assume the worst-case scenario that an attacker can craft public inputs to direct to the more beneficial successor (i.e., the one with a larger entropy, as taking the branch might see a bigger leakage down the road). Hence, a public branch inherits the probability from the successor with maximum entropy.

Definition 4 (Probability of reaching a node)**.** *Let $\tau CFG = \langle V,E,T,S\rangle$ be an acyclic tainted CFG. For a node $v \in V$, let*

- *$succ(v)$ denote the set of the immediate successors of v in G*
- *m_v be the one with maximum entropy among $succ(v)$*

For two nodes u and v, let $P(u,v)$ be the probability that u reaches v, which is defined as:

$$P(u,v) = \begin{cases} 1, & u = v \\ 1/|succ(u)|, & v \in succ(u) \wedge u \in T \\ 0, & v \in succ(u) \neq m_v \wedge u \notin T \\ 1, & v \in succ(u) = m_v \wedge u \notin T \\ \sum_{i \in succ(u)} P(u,i)P(i,v), & v \notin succ(u) \end{cases}$$

Note that when $v \notin succ(u)$, u might still reach v indirectly. Hence, the last case inductively computes indirect reachability. Moreover, since the graph is acyclic, $P(u,v)$ for any two reachable nodes u,v, and further, the entropy of each node, can be computed efficiently by a topological sort and calculate the probability of reaching and entropy from the deepest nodes iteratively with dynamic programming. The computation complexity is just $O(|V|)$.

4.3.2 Ranking and Replacing Critical Branches

The previous approach only finds the most important critical branches. But fixing only the top-ranked critical branches is insufficient, as there might be other (less important) critical branches that are vulnerable to side channel attacks.

To identify all side channels with the given set of sources and sinks in a tainted CFG, Athena takes an iterative approach that mimics how side channels are mitigated in real implementations: Athena first reports all top-ranked critical branches in iteration 1, say A_1. Then, it marks those branches as "replaced" (by side-channel-free code)[3] and reruns the quantification algorithm on the τCFG with replaced nodes and reports all top-ranked critical branches in iteration 2, say A_2. Athena continues until all critical branches have zero leakage. So in the end, when Athena terminates after N iterations, all reported side channels are $A_1 \cup A_2 \cup \cdots \cup A_N$.

```
1  // vulnerable code in Linux 3.19
2  static unsigned int challenge_count;
3
4  ... reset challenge_count to 0 at fixed
       interval ..
5  if (++challenge_count <=
       sysctl_tcp_challenge_ack_limit) {
6    NET_INC_STATS_BH(sock_net(sk),
         LINUX_MIB_TCPCHALLENGEACK);
7    tcp_send_ack(sk);
8  }
```

```
1  // mitgated code in Linux 4.8
2  static unsigned int challenge_count;
3  struct tcp_sock *tp = tcp_sk(sk);
4  u32 count, now;
5
6  ..reset challenge_count to a random number at
       fixed interval..
7  count = READ_ONCE(challenge_count);
8  if (count > 0) {
9    WRITE_ONCE(challenge_count, count - 1);
10   NET_INC_STATS(sock_net(sk),
         LINUX_MIB_TCPCHALLENGEACK);
11   tcp_send_ack(sk);
12 }
```

Figure 7: Code snippet from `tcp_send_challenge_ack` function before and after a side channel is mitigated.

One challenge of the iterative approach is to model "replaced" nodes and incorporate them into the quantification algorithm (Section 4.3.1). To do so, we first observe that side channels of Transport Layer Protocols are typically mitigated by adding noise [6]. Compared to completely removing a side channel by unifying outcomes of a sensitive branch (e.g., ensuring that a packet is always sent whichever branch is taken), injecting noise is more suitable (though less secure) since implementations of Transport Layer Protocols must obey their protocol specifications (e.g., RFC 793).

For example, consider the code snippets in Figure 7 where the code on the top (from Linux 3.19) has a side channel at line 5. The reason is that variable `challenge_count` is tainted by sensitive information: the number of times that `++challenge_count` is executed reveals a sensitive host state (expected sequence number). Hence, by observing the absence of an acknowledgement packet when `challenge_count` reaches the limit, an attacker reveals sensitive host state. The code at bottom (from Linux 4.8) mitigates the side channel by resetting `challenge_count` to a random number instead of 0 at line 6 (we omit the details on the specific random number for simplicity). Therefore, observing the absence of an acknowledgement packet only reveals the fact that the random counter reaches 0 after it is decreased by

[2]We assume the uniform distribution for its simplicity and adequacy in practice (note that only the relative ranking, rather than the probabilities, matters in our context). While it is possible to use techniques like profiling to define a more precise model, we also note the concern that an adversary may draft inputs so that the system deviates from how it "usually" works - and thus invalidating the profiling data.

[3]Note that code replacement does not truly happen during our analysis, that is just an analysis construct.

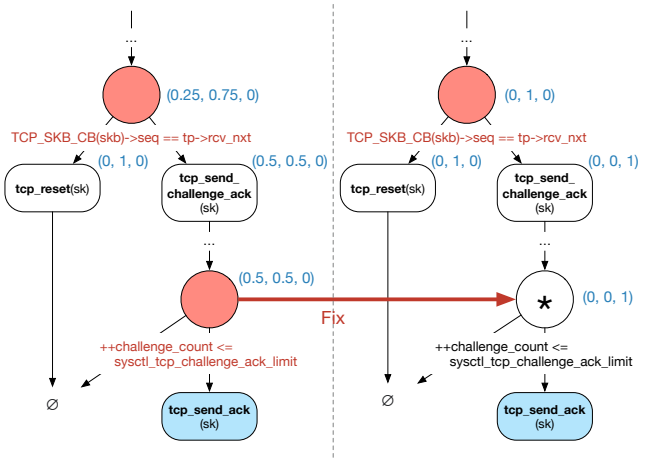


Figure 8: Simplified τCFG before and after the top-ranked critical branch is replaced by wildcard node. The blue triple represents the probability of reaching sink node `tcp_send_ack`, absence node $\emptyset$, and wildcard node * respectively.

one in each execution of `tcp_send_challenge_ack`. Hence, it no longer reveals the sensitive host state. It is worth mentioning that such randomization-based mitigation are very common, and there has been similar mitigation in FreeBSD.

To model such replaced/fixed branches, we note that the replaced code neither calls sink function `tcp_send_ack(sk)` 100% of the time nor skips the call (i.e., reach absence node $\emptyset$) 100% of the time. Although there is uncertainty on which sink will be reached, the uncertainty is due to *randomness* rather than public or secret inputs. To reflect this observation, we introduce a special sink node called *wildcard node*, denoted by $*$ and replace each replaced node with a wildcard node. Most rules of Definition 4 remain the same with a wildcard node. The only change is that we redefine successors of a node to *exclude* nodes that surely reach wildcard node, i.e., $succ^*(v) = \{i \mid i \in succ(v) \wedge P(i,*) \neq 1\}$ and use $succ^*(v)$ instead of $succ(v)$ in Definition 4, as well as include an additional rule in case all successors are * nodes.

$$P(u,*) = 1 \text{ if } succ^*(u) \text{ is empty}$$
$$P(u,v) = 0 \text{ if } succ^*(u) \text{ is empty} \wedge v \neq *$$

The special rules of handling wildcard nodes are motivated by the randomness introduced to each replaced node, e.g., a uniform distribution on reaching all normal sink nodes by the injected noise. Therefore, its distribution does not contribute to its parent unless all of its siblings are also wildcard nodes.

Example. Consider a simplified τCFG of the vulnerable code in Linux 3.19 shown on the left of Figure 8. Based on the revised algorithm above that handles wildcard node, we can compute the probability of reaching each sink as the blue triple attached to each node. Since there is no wildcard node, the distributions are identical to the ones according to Definition 4. Since the lower red node has the maximum leakage of 1, Athena reports it and replaces it with a wildcard node as shown on the right of Figure 8.

In the revised graph, the wildcard node, say node A, has $P(A,*) = 1$ as it is a wildcard node (case 1 of Definition 4). Hence, the leakage of the wildcard node is 0 according to Definition 2. The interesting case is the leakage of the nodes above it. The parent of node A, say node B, has no successors according to the revised successor definition $succ^*$. Hence, $P(B,*) = 1$ and $P(B,v) = 0$ for other nodes. For the top red node, say node C, $succ^*(C)$ only contains its left child. Hence, by Definition 2 with $succ^*$ instead of $succ$, node C inherits the distribution from its left child, as shown in the figure, resulting in a leakage of 0. Therefore, there is no more side channels in the replaced τCFG on the right. The intuition behind why nodes that 100% reach wildcard node are excluded in the computation is that such nodes can *cast* to any distribution, such as the triple (0,1,0) on the left child of node C, meaning that the probability that reaching sink node `tcp_send_ack`, absence node $\emptyset$, and wildcard node * are 0%, 100% and 0% respectively. Hence, the combined distribution is the same as simply excluding the casted distributions.

4.4 Categorizing Side Channels

Next, we categorize the detected side channels based on (1) the packet handler function being called, and (2) the distinct reachable sink nodes, to gain a better understanding of the detected side channels. In particular, the TCP receive routine invokes one of the several packet handler functions w.r.t. the state of the current connection. For example, `tcp_rcv_established()` handles incoming packets when the connection is in the ESTABLISHED state. By tracking which function is called along the control-flow path, Athena outputs the TCP state required for triggering the side channel. For UDP, the results are categorized based on the initial packet handler function called (`udp_rcv()` or `udp_err()`).

To compute the distinct reachable sink nodes, recall that in the process of entropy calculation, we also keep track of the probability that a critical branch reaches one of the sinks (or does not reach the sinks at all). For example, if a branching block has 0.5 probability to reach `tcp_send_ack()`, and another 0.5 probability of reaching the absence sink, then an attacker learn sensitive data by observing two different outputs: Immediate ACK vs NULL.

5 Implementation

In this section, we briefly discuss the implementation details of the main components of Athena.

Static taint analysis. We implemented the static taint analysis toolchain in C++ within the LLVM framework. The toolchain

is inherited from PIDGIN [18], which is built on top of a summary-based points-to analysis, DSA [20]. Our extension to the original implementation consists of ∼3K LOC. With context-sensitivity, we perform inter-procedural information flow analysis to find out the branches tainted by the sensitive sources. For soundness, both explicit and implicit flows are analyzed. The branches help us annotate the program's CFG, producing the τCFG discussed in Section 4.2. We also add an edge from each non-sink node without any outgoing edge to a special absence node $\emptyset$.

Leakage analyzer and leakage mitigator. The leakage analyzer and the leakage mitigator are written in Python together as a combined component. In a nutshell, this component reads the original τCFG or τCFG from the previous iteration and performs ranking and replacement according to the methods in Section 4.3.1 and Section 4.3.2. The leakage analyzer calculates each node's entropy and leakage in a bottom-up fashion through graph search. Once each node's entropy is computed, it reports the top-ranked branches with the highest leakage. These identified branches are then processed with the leakage mitigator to generate the τCFG with wildcard nodes. Athena iterates over these steps until there are no more side channels.

Rule-based classifier. After retrieving the finalized list of top-ranked branches from the previous steps, we use a rule-based classifier written in Python to categorize the nature of the side channels. The algorithm extracts control-flow paths from τCFG and examines their target source code, to check 1) which sinks will the critical branches lead to, and 2) what system state would be needed to trigger the critical branches.

6 Evaluation

We evaluate Athena with several implementations of TCP/UDP IPv4, including Linux 3.19 and 4.8[4], FreeBSD 13.2, OpenBSD 7.4[5], as well as two open-source implementations named microps [24] and picotcp [31].

- **Reduction**: Can entropy-based rank-and-replace approach significantly reduce the number of reported side channels?
- **Efficacy**: Can Athena detect all known side channels and uncover new side channels in the TCP and UDP implementations being analyzed?
- **Precision**: How many of side channels reported by Athena are false positives?
- **Performance**: Does Athena scale to the full implementations of TCP and UDP?

[4]Due to the limitation of the points-to analysis DSA used by PIDGIN, the latest Linux version we can analyze by a compatible LLVM is 4.8. We present the results of 3.19 and 4.8 in this section and discuss the number of vulnerabilities remaining in the latest Linux kernel in Section 6.6.

[5]The latest product release.

	# tainted branches	# critical branches	# reported branches
Linux/TCP (Adv_u)	1651	185	6
Linux/TCP (Adv_a)	1651	528	5
Linux/UDP (Adv_u)	572	59	3
Linux/UDP (Adv_a)	572	354	3
FreeBSD/TCP (Adv_u)	843	199	10
FreeBSD/UDP (Adv_u)	310	28	1
OpenBSD/TCP (Adv_u)	751	173	10
OpenBSD/UDP (Adv_u)	302	27	1
microps	204	35	2
picotcp	505	75	1

Table 1: Reported branches by various strategies.

- **Exploitablity**: For the detected side channels, how feasible is it to exploit them to launch real-world attacks?

6.1 Evaluation Setup

Sources and sinks of interest. As discussed in Section 4.1, we marked several sources and sinks in our analysis. In Linux, we mark the struct sock variable sk (*tcp_input.c: L1593*) as the source in the TCP protocol, tcp_send_ack() and tcp_send_delayed_ack() as sinks (for unaided attacker model Adv_u), tcp_send_challenge_ack() and tcp_send_dupack() as sinks (for aided attacker model Adv_a). For UDP, we mark the `struct udp_table` variable `udp_table` (*udp.c: L117*) as the source, `icmp_send()`, `ipv4_sk_update_pmtu()`, `ipv4_sk_redirect()`, `UDP_STATS_INC_BH` as sinks.

Sources and sinks in FreeBSD and OpenBSD are similar to those in Linux. We mark the struct tcpcb variable `tp` (*tcp_input.c: L611*) as the source, `tcp_output()` and `tcp_response()` as the sink. For UDP, we mark the struct inpcbinfo variable `pcbinfo` as a sink, and `icmp_error()` as a sink function. In BSD systems, the local counters are not exposed to unprivileged processes, and therefore the aided threat model Adv_a is not applicable for FreeBSD and OpenBSD.

In the open source implementations, we mark the equivalent structures `tcp_pcb pcb` (microps) and `pico_tcp_hdr hdr` (picotcp) as sources, and the function `tcp_send()` as the sink.

6.2 Reduction

To evaluate the effectiveness of the iterative rank-and-replace approach of Athena, we compare it with two plausible solutions that report (1) all tainted branches, and (2) all critical branches (see Definition 1) to further demonstrate how much reduction (in terms of # reported sensitive branches) does Athena achieve. The result is summarized in Table 1.

In the Linux TCP module, there are 1651 tainted branches in both threat models. The total tainted branches are the same as the two settings only differ in their sink functions. By counting only the critical branches (i.e., the ones that at least reach two distinct sinks, including the absence sink), the number

of suspicious branches drops to 185 (88.7% drop) and 528 (68.0% drop) in the Adv_u and Adv_a settings, respectively. Finally, Athena only reports 6 (99.6% drop) and 5 (99.7% drop) most important branches responsible for all side channels in the analyzed code. In the Linux UDP module, the reduction rate is also significant. We see reduction rates of 88.8% (under Adv_u setting) and 32.7% (Adv_a) when using critical branches, and reduction rates of 99.3% (Adv_u) and 99.4% (Adv_a) by counting only the most critical ones.

In the FreeBSD modules, Athena shows a similar reduction rate (recall that only the unaided threat model is applicable for FreeBSD). There are 843 tainted branches in TCP, which are reduced to 199 (76.3% drop) and finally, 10 are reported (98.8% drop). In UDP, 310 tainted branches are reduced to 28 (91.0% drop) and finally only 1 is reported (99.7% drop).

Similarly, 751 (resp. 302) tainted branches are reduced to 173 (resp. 27) in OpenBSD TCP (resp. OpenBSD UDP) – for a 77.0% drop (resp. 91.1% drop). On the open source implementations, Athena has reduction rates of 82.8% (204 to 35, microps) and 85.1% (505 to 75, picotcp) in terms of critical branches. By counting only the most critical ones, the reduction rates are 99.0% (204 to 2, microps) and 99.8% (505 to 1, picotcp).

It is worth noting that the non-reported critical branches are either removed while replacing the reported ones, or reported and replaced in later iterations. Since our algorithm only terminates when there are no more reported critical branches left, it soundly detects all side channels per our threat model. We further discuss the precision of Athena in Section 6.4.

6.3 Efficacy

Next, we evaluate Athena's efficacy of identifying side channels by answering whether Athena can (1) detect existing side channels (under the same threat model as ours) that were *manually identified* by prior work [6, 22, 23, 26]; and (2) uncover new ones. Table 2 and 3 show the side channels in all benchmarks, reported by prior work under the same threat models (as described in Section 3.1, marked in yellow). Athena successfully reported all side channels in those works. We note that [7] reports 6 more side channels (entries 6-C, 7-C, 8-C and 9-B, 10-B, 11-B in the Table 3 of [7]), which were not identified by Athena. We manually verified that these reported branches do not exist in the Linux kernel code base that we have analyzed. We also searched for them in the GitHub repository associated with the paper[6], but we still did not find those branches or similar branches in the repository.

Other than those 6 entries that we confirmed to be absent in the Linux code base, Athena fully covers all other previously reported side channels [6, 7, 22, 23, 25, 26] in Linux and FreeBSD; it also uncovers new side channels because of more complete source code coverage. We further analyze those new side channels in Section 6.6.

[6] https://github.com/seclab-ucr/SCENT.

6.4 Precision

Next, we evaluate the precision of Athena's reported side channels. For this, we count the number of branches which are true positives (i.e., their branch outcomes depend on the sources) among the reported most critical sensitive branches.

As shown in Table 2 and Table 3, Athena reports 42 side channels in 5 transport layer protocol implementations. After manual investigation, we found that 5 out of the 42 side channels are false positives (the red entries in both tables) due to the imprecision of our static taint analysis. The root cause of the false positives is originated from the underlying points-to analysis used by Athena. In some cases, the points-to analysis falsely links data structures of inconsistent types to the same alias, resulting in a *field-insensitive* taint of certain objects. For example, entry 2 in Table 2 reports a branch `if (th->ack)`, which checks the `ack` flag of an incoming packet's header. Although the structure `th` is derived from a non-sensitive field in a `sock` structure, it is tainted as the points-to analysis is unable to differentiate sensitive fields from non-sensitive fields in the `sock` structure. We manually confirmed that all 5 false positives have the same root cause in the points-to analysis.

The remaining side channels are all true positives, which include 7 that were reported in prior works, and 30 remaining ones newly identified by Athena.

6.5 Performance

Running time.. On a commodity desktop computer with a 3.8GHz 8-core CPU and 32GB of RAM, Athena takes 12 minutes (7 minutes on static taint analysis and 5 minutes on graph search) and 5 minutes (2 minutes on static taint analysis and 3 minutes on graph search) for the Linux TCP and UDP modules. For the FreeBSD's and OpenBSD's TCP and UDP modules, it takes 9 minutes (6 minutes on static taint analysis and 3 minutes on graph searching) and 3 minutes (2 minutes on static taint analysis and 1 minute on graph searching) respectively. The analysis takes less than 1 minute on the open-source implementations microps [24] and picotcp [31].

Code coverage.. Athena covers 15,020 and 7,436 LoC of Linux v3.19 TCP/UDP implementations, 11,507 and 4,120 LoC of FreeBSD 13.2 TCP/UDP implementations, 10,068 and 2,503 Loc of OpenBSD 7.4 TCP/UDP implementations, 3,498 LoC of microps and 5,678 LoC of picotcp, respectively. We did not analyze the whole TCP module of Linux and BSDs since the rest of the code is unreachable from the input/receive functions, the entry functions of our analysis.

6.6 Exploitability of Reported Side Channels

Tables 2 and 3 show the violations that Athena found in the TCP and UDP implementations. Athena discovered 37 true positives in total. Based on the criteria we described in

Index	System	Critical branch	Iteration	Triggering state	Different outputs
1	Linux (Adv_u)	`if (((tp->rcv_nxt - tp->rcv_wup) > inet_csk(sk)->icsk_ack.rcv_mss && __tcp_select_window(sk) >= tp->rcv_wnd) || tcp_in_quickack_mode(sk) || (ofo_possible && skb_peek(&tp->out_of_order_queue)))`	1	Any non-closing	Immediate ACK vs Delayed ACK
2		`if (th->ack)`	2	SYN-SENT	ACK pkt vs NULL
3		`if (TCP_SKB_CB(skb)->end_seq != TCP_SKB_CB(skb)->seq && before(TCP_SKB_CB(skb)->seq, tp->rcv_nxt))`	2	ESTABLISHED	ACK pkt vs NULL
4		`if (++challenge_count <= sysctl_tcp_challenge_ack_limit)`	3	Any non-closing	ACK pkt vs NULL
5		`case TCP_FIN_WAIT1`	3	ESTABLISHED	ACK pkt vs NULL
6		`case TCP_FIN_WAIT2`	3	ESTABLISHED	ACK pkt vs NULL
7	Linux (Adv_a)	`if (!tcp_sequence(tp, TCP_SKB_CB(skb)->seq, TCP_SKB_CB(skb)->end_seq))`	1	ESTABLISHED	Local counter update vs NULL
8		`if (TCP_SKB_CB(skb)-end_seq != TCP_SKB_CB(skb)->seq before(TCP_SKB_CB(skb)->seq, tp-rcv_nxt))`	1	ESTABLISHED	Local counter update vs NULL
9		`if (++challenge_count <= sysctl_tcp_challenge_ack_limit)`	1	ESTABLISHED	Local counter update vs NULL
10		`if (before(ack, prior_snd_una - tp->max_window))`	1	ESTABLISHED	Local counter update vs NULL
11		`if (!tcp_validate_incoming(sk, skb, th, 1))`	1	ESTABLISHED	Local counter update vs NULL
12	FreeBSD (Adv_u)	`if (needoutput || (tp->t_flags & TF_ACKNOW))`	1	Any non-closing	TCP pkt vs NULL
13		`if (th->th_ack != tp->snd_una)`	1	LAST-ACK	TCP pkt vs NULL
14		`if (DELAY_ACK(tp, tlen))`	1	Any non-closing	TCP pkt vs NULL
15		`if (tp->snd_una == tp->snd_max)`	1	Any non-closing	TCP pkt vs NULL
16		`if (avail > 0 || tp->t_flags & TF_ACKNOW)`	1	LAST-ACK	TCP pkt vs NULL
17		`if (SEQ_GT(onxt, tp->snd_nxt))`	1	LAST-ACK	TCP pkt vs NULL
18		`if (tp->t_state == TCPS_SYN_RECEIVED && (thflags & TH_ACK) && (SEQ_GT(tp->snd_una, th->th_ack) || SEQ_GT(th->th_ack, tp->snd_max)) )`	1	SYN-RCVD	ACK pkt vs NULL
19		`if (SEQ_LT(th->th_ack, tp->snd_recover))`	2	Any non-closing	TCP pkt vs NULL
20		`if (pps > 0)`	1	SYN-RCVD	TCP pkt vs NULL
21		`if (V_tcp_insecure_rst || tp->last_ack_sent == th->th_seq)`	1	Except LISTEN/ SYS-SENT	ACK pkt vs NULL
22	OpenBSD (Adv_u)	`if (so->so_snd.sb_cc || tp->t_flags & TF_NEEDOUTPUT)`	1	Any non-closing	TCP pkt vs NULL
23		`if (tp->t_flags (TF_ACKNOW|TF_NEEDOUTPUT))`	1	Any non-closing	TCP pkt vs NULL
24		`if (SEQ_LT(th->th_ack, tp->snd_last))`	1	Any non-closing	TCP pkt vs NULL
25		`if (tp->t_flags (TF_ACKNOW|TF_NEEDOUTPUT))`	1	FIN	TCP pkt vs NULL
26		`if (SEQ_LT(th->th_ack, tp->snd_last))`	1	LAST-ACK	TCP pkt vs NULL
27		`case TCPS_TIME_WAIT`	2	TIME-WAIT	TCP pkt vs NULL
28		`case TCPS_LAST_ACK`	2	LAST-ACK	TCP pkt vs NULL
29		`if (tp->t_flags & TF_ACKNOW)`	3	SYN-RCVD	TCP pkt vs NULL
30		`if (tp->rcv_wnd == 0 && th->th_seq == tp->rcv_nxt)`	1	ESTABLISHED	TCP pkt vs NULL
31		`if (opti.ts_present && (tiflags & TH_RST) == 0 && tp->ts_recent && TSTMP_LT(opti.ts_val, tp->ts_recent))`	1	Except LISTEN/ SYN-SENT	TCP pkt vs NULL
32	microps	`if (seg->ack <= pcb->iss || seg->ack > pcb->snd.nxt)`	1	SYN-SENT	RST pkt vs NULL
33		`if (!acceptable)`	1	TIME-WAIT	ACK pkt vs NULL
34	picotcp	`if ((t->cwnd >= t->in_flight) && (t->snd_nxt > t->snd_last_out))`	1	Any non-closing	RST pkt vs NULL

Table 2: Reported Branches on TCP. **No color**: new positives, **Yellow**: previously reported positives, **Red**: False positives

Index	System	Critical branch	Iteration	Different outputs
1	Linux (Adv_u)	`if (fib_lookup(dev_net(dst->dev), fl4, res) == 0)`	1	PMTU update vs NULL
2		`if (fib_lookup(net, fl4, res) == 0)`	2	Gateway update vs NULL
3		`if (sk != NULL)`	3	ICMP pkt vs NULL
4	Linux (Adv_a)	`if (count)`	4	Local counter update vs NULL
5		`if (count)`	5	Local counter update vs NULL
6		`if (sk != NULL)`	6	Local counter update vs NULL
7	FreeBSD (Adv_u)	`if (rc == -ENOMEM)`	7	ICMP pkt vs NULL
8	OpenBSD (Adv_u)	`if (inp == NULL)`	8	ICMP pkt vs NULL

Table 3: Reported Branches on UDP. **No color**: new positives, **Yellow**: previously reported positives, **Red**: False positives

Section 4.4, the reported positives can be categorized into 3 classes, which shed light on their exploitability.

Exploitable under unaided off-path attacker model.: Side channels 4, 20 in Table 2 and side channels 3, 7, 8 in Table 3 are caused by certain global rate limits on outgoing packets. In Linux, there are two frequently used global rate limits: `sysctl_tcp_challenge_ack_limit` and `sysctl_icmp_msgs_burst` (`V_icmp_rates` is the equivalent in BSD systems). Prior work has exploited these limits for remote attackers to infer whether a port is in use [22], or whether a guessed ACK number is correct [6] by sending spoofed packets and observe the response from the victim system. Side channel 8 in Table 3 is newly discovered by Athena. It is very similar to the reported ones in Linux (side channel 3) and FreeBSD (side channel 7), and it can be exploited using a similar attack. For the previously reported TCP side channels in Linux and FreeBSD (side channels 4 and 20 respectively in Table 2), no equivalent side channel exists in OpenBSD.

Side channels 1 and 2 in Table 3 involve changes in the routing table, specifically the Path MTU and gateway address for certain hosts. Both the global rate limits aforementioned and the routing table affect whether an outgoing packet (TCP or ICMP) would be sent. Prior work has shown a remote two-stage attack that infers UDP port number without observing the direct responses from the victim system [23]. No equivalent side channels are found in FreeBSD and OpenBSD.

Exploitable under aided off-path attacker model.: Side channels 7-11 in Table 2 and 5 in Table 3 are induced by the sink `netstat` counter that Linux maintains for diagnostic and statistical propose. When a certain operation is executed, the system increments one of these non-decreasing counters, and moreover, the value of the counter is shared globally across all users and processes on the host machine. Furthermore, the file that contains the `netstat` counters (under `/proc/net`) is set to be readable by all users (i.e., has the `-r--r--r--` permission on Linux). This allows even an unprivileged malicious process (similar to the one in the aided off-path attacker model Adv_a described in Section 3.1) to be able to observe if such an operation is performed. All the side channels in this category can be exploited by constantly checking the corresponding local counter. A proof-of-concept attack covering all such side-channels is described in Section 6.7. Since BSD systems do not maintain a publicly visible set of statistical counters, the equivalent side channels are not found.

Uncertain exploitability.: It is uncertain whether the remaining side channels can lead to exploitable in practice, but most of them do exhibit possible vulnerabilities. Side channels 1, 14, 23, 25, and 29 in Table 2 are associated with a TCP socket-specific option *quick_ack*, which controls whether to send a response ACK packet immediately. If an adversary is able to measure the response time of certain crafted packets and filter out network noise, they may reveal SEQ numbers.

Side channels 5, 6, 13, 16, 17, 27, 28 and 33 in Table 2 involve branches that trigger a system state transition into a closing state. Since the transition from an active state into a closing state in TCP is one-way, an attacker cannot learn information about the active connections. However, if the attacker can also control system-level processes that can prevent the connection from actually closing (i.e., staying in the state for a long time), they may exploit these branches. We leave a more thorough study of these side channels as future work.

Results on different Linux versions.: Athena analyzed both Linux 3.19 and 4.8, and the results of the latter are mostly the same as 3.19, except for a minor branch condition change and randomness-based mitigation for side channel 4 in Table 2.

In addition, we manually checked the source code of the most recent Linux kernel (v6.4.0, as of July 2023) to verify the number of the vulnerabilities reported by Athena are still present in the latest version of the Linux kernel. We found that 12 out of 14 vulnerabilities reported by Athena are still present in the latest version. The exceptions are side channels 1 and 3 in Table 3. The reason is that the code in the latest version has been rewritten and the problematic branches are removed. It is also worth mentioning that the critical branch of side channel 2 in Table 3 has slightly different conditions in the latest version. However, the side channel still persists.

6.7 A Sample Proof-of-Concept Attack

In this section, we show a Proof-of-Concept (PoC) attack based on side channel 9 in Table 2. The attack flow is shown in Figure 9 where we have a victim server S, a victim client

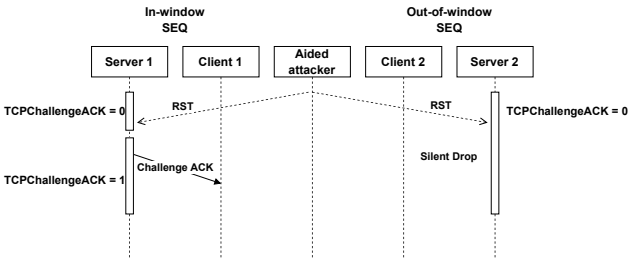

Figure 9: The flow of the PoC attack

C, and an attacker A. In line with previous work [26], we assume that the victim server and victim client have an active TCP connection (in ESTABLISHED state) and Attacker A controls an unprivileged process on S.

Attack Steps.: (1) The attacker A reads the file `/net/proc/netstat` (readable to all processes) on S through the controlled process. The attacker thus monitors the value of the field TCPChallengeACK. (2) The attacker then sends a spoofed RST packet to the server S, with client C's IP address, correct port numbers (the port used for the connection), and a guessed sequence number. (3) The attacker checks whether the monitored value of TCPChallengeACK has increased. If so, she can infer that the previously guessed number is in-window. Otherwise, the guessed number is far from the true sequence number. (4) If the guessed number is not in-window, the attacker repeats step 2.

Experimental results.: We have implemented and tested this PoC attack on a Debian 10-based machine with 100 attempts. In each attempt, the attacker starts with a random guess and then adjusts the guess depending on the outcome of each step. The PoC attack succeeds 69 out of 100 attempts where the failures are due to time-outs when the guessed sequence numbers are all far from the true sequence number. It takes an average of 4.2 seconds when the attack succeeds.

7 Related Work

Side-channel detection.. The most related works are SCENT [7] and the work by Ensafi et al. [12] as they also target side channels in transport layer protocols. They are both built on model checking, a form of static analysis that is likely to be more precise than static taint analysis and CFG-based analysis. For instance, model checking is immune to unreachable code and infeasible execution paths in CFG. However, the very precision also comes with a cost as they are unable to analyze the full vanilla implementations of TCP and UDP and suffer from long running time due to scalability limitation of model checking and inherent coverage limitation of bounded model checking. Moreover, they are unable to diagnose the root cause of the side channels, such as why the side channels exist, when they can be triggered, and how they can be observed by an attacker. In contrast, Athena trades precision for efficiency and full code coverage. Moreover, it automatically ranks side channels according to their importance and provides an informative report on each detected side channel.

Detecting secret-dependent branches is a common practice in identifying *timing* side channels in programs. For example, cryptographic libraries follow *constant-time programming paradigm* [3] to rule out timing side channels. Essentially, the constant-time programming paradigm prohibits both control-flow paths and memory-access patterns from depending on program secrets. Hence, information flow analysis can be used to detect both branch conditions (the same as tainted branches in this paper) and memory access addresses that are tainted by secrets [5, 32, 34]. However, as shown in Table 1, simply reporting tainted branches is infeasible for detecting side channels of transport layer protocols; Athena successfully reduces the reported tainted branches from thousands to a single digit number.

TCP side-channel attacks.. TCP side channels have been widely studied in the literature. Researchers have shown that various globally shared resources could be exploited as side channels to reveal secrets in TCP connections, such as IPID [13, 14], challenge ACK limit [6, 7], SYN-backlog [7] and local netstat counters [26]. The leakage of such connection secrets may grant attackers the capability to learn information about, or even manipulate, the victim's connection. Prior work has also shown that an attacker may utilize these side channels to scan idle ports [12], infer the existence of connection [6], count packets in transmission [19], measure round-trip-time [1, 33], detect intentional packet drop [11], and even hijack the connection [6, 9, 16, 25].

UDP side-channel attacks.. UDP side-channel attacks mainly target application-layer programs, particularly the Domain Name System (DNS). Several studies have exposed various vulnerabilities due to side channels in UDP, such as the works by Man et al. [22, 23]. SADDNS [22] discovered that the global ICMP rate limit, which was implemented to minimize bandwidth usage, forwarding costs, and mitigate the possibility of ICMP flooding attacks [4, 8], may be exploited by malicious attackers to infer the port numbers utilized by UDP-based services. With the revealed port number, an attacker could launch more powerful attacks, such as a DNS cache poisoning attack. In addition, another study by Man et al. [23] demonstrated yet another ICMP-based side channel that permits attackers to infer the UDP port number by forging ICMP error messages with an embedded UDP header, which enables the attacker to alter the host's routing table.

8 Discussion and Future Work

Limitations of the static analysis. There are several approximations in the static analysis of our approach. We discuss the impact of each next.

- Field-sensitivity issues in the current version of the points-to analysis have negative impacts on precision

(exemplified in Section 6.4). While the empirical study shows that the resulting implementation produces a low false-positive rate for TCP/UDP code we have analyzed, this might not be the case for other implementations. For example, the use of complex data structures and union types usually downgrade analysis precision as they are challenging for sound points-to analyses. So Athena might have more false positives when the program has frequent use of those features.

- For the soundness of our analysis, Athena taints the loop head whenever there is a tainted branch in the loop on backward edge removal (Section 4.3.1). However, doing so may over-taint call paths, which leads to an over-approximation of critical branches and hence, imprecise branch possibilities/entropy computation. Athena's approach of removing backward edges does not result in any false negatives in the TCP/UDP implementations being analyzed, but it remains an open question of how to remove backward edges in a both sound and precise manner beyond those implementations.

- The uniform distribution assumption on branch outcomes might deviate from the ground-truth distribution of branch outcomes. Take an example of a branch leading to both a sink node and an absence node. If there is practically 75% chance of reaching the sink, then the branch has 0.811 entropy. Meanwhile, the uniform assumption would approximate the branch to have 1 entropy, thus resulting in different entropy values of the branch. But we note that the change in entropy values may or may not change the overall ranking of critical branches. Moreover, a change in the ranking only affects the *quality* of reports (i.e., the number of top-ranked positives in each iteration and how many iterations Athena takes until termination). The uniform distribution assumption will not lead to false negatives.

Generalizability of Athena. While we present the instantiations of Athena exclusively in TCP/UDP implementations, our insight and algorithm are general and they can be applied to other network protocols, and even other scenarios with some extra effort. We believe that the workflow of the analysis would remain the same for other scenarios, though extra domain knowledge is needed. One example is manual specification of sources and sinks. For TCP/UDP implementations, such manual efforts are relatively low since the sources are usually specified in TCP/UDP standards (e.g., RFCs) and attack papers, and the sinks are specified by the threat model. However, the task of identifying sources and sinks may not be as easy for other scenarios as it may require domain expertises. In addition, one also needs domain knowledge to understand the severity and the exploitability (e.g., what could be the potentially different outputs) of reported side channels. Moreover, as discussed earlier, several approximations in the static analysis of our approach might turn out to be problematic for other scenarios. For example, some coding styles with intensive use of pointer arithmetic, design of complex data structures, and different memory allocation strategies might have negative impacts on analysis precision. In such cases, fine-turning the static analysis used by Athena is required to achieve a low false-positive rate.

Responsible disclosure.. We have reported our findings to the Linux, FreeBSD, and OpenBSD community.

9 Conclusion

This paper presents Athena, an automated tool for developers to detect side-channel vulnerabilities in vanilla implementations of TCP and UDP. Additionally, an automated diagnostic mechanism is developed to rank these vulnerabilities according to their importance, and further, pinpoint their origins. We evaluate Athena on several TCP and UDP implementations including Linux, FreeBSD and OpenBSD kernels; Athena successfully detects both previously reported side-channel vulnerabilities and new vulnerabilities within our threat model, with a low false positive rate. In the future, we plan to address the limitations of our static analysis, extend our approach to other protocols, such as QUIC, as well as more general scenarios, such as network traffic analysis.

Abstract

Mix-Nets are used to provide anonymity by passing a list of inputs through a collection of mix servers. Each server mixes the entries to create a new anonymized list, so that the correspondence between the output and the input is hidden. These Mix-Nets are used in numerous protocols in which the anonymity of participants is required, for example voting or electronic exam protocols. Some of these protocols have been proven secure using automated tools such as the cryptographic protocol verifier ProVerif, although they use the Mix-Net incorrectly. We propose a more detailed formal model of exponentiation and re-encryption Mix-Nets in the applied Π-Calculus, the language used by ProVerif, and show that using this model we can automatically discover attacks based on the incorrect use of the Mix-Net. In particular, we (re-)discover attacks on four cryptographic protocols using ProVerif: we show that an electronic exam protocol, two electronic voting protocols, and the "Crypto Santa" protocol do not satisfy the desired privacy properties. We then fix the vulnerable protocols by adding missing zero-knowledge proofs and analyze the resulting protocols using ProVerif. Again, in addition to the common abstract modeling of Zero Knowledge Proofs (ZKP), we also use a special model corresponding to weak (malleable) ZKPs. We show that in this case all attacks persist, and that we (re)discover these attacks automatically.

1 Introduction

The concept of Mix-Networks was introduced by David Chaum in 1981 [10] as a tool for achieving anonymity. The purpose of a Mix Network is to hide the correspondence between its input and output vectors. On a high level, a Mix-Net is run by a set of senders and a collection of mix servers, and works as follows. Each sender delivers its input to the first mix server. Each mix server privately shuffles its inputs list, and forwards the shuffled list to the next server. Unless all mix servers are corrupted, a Mix-Net should guarantee that the link between the senders and their associated messages in the output list remains secret to a third party.

Due to their importance in providing anonymity to the communicating parties, Mix-Nets play a significant role in building systems where privacy is a key security requirement, such as e-voting systems [14, 29] or e-exams [27]. In the context of voting, they are used to hide the link between voters and their votes to guarantee the voters' privacy, as typically the protocol publishes the list of the decrypted votes at the end to achieve verifiability. In such a protocol, any possibility to link a voter to his decrypted plaintext vote immediately breaks privacy. Voting protocols using Mix-Nets have been even employed in real political elections, for example in the Australian state of Victoria [18] or in Norway [28].

Since their introduction, many Mix-Net constructions have been proposed, analyzed and integrated into various cryptographic protocols. In [37], Park *et al.* presented the *Re-encryption Mix-Net*. These Mix-Nets rely on malleability properties of the encryption scheme, giving the possibility to re-encrypt a list of ciphertexts resulting in a new list of ciphertexts, without knowing or changing the associated plaintexts. In [30], Haenni *et al.* presented a different form of a Mix-Net, the so-called *Exponentiation Mix-Net*. These Mix-Nets create, from a list of ElGamal public keys [26], a new shuffled list of anonymized public keys, which can no longer be associated to individual parties, but can still be used to verify signed messages or encrypt data. Exponentiation Mix-Nets are used in various protocols, notably in electronic voting [30] and electronic exams [27].

The Remark! [27] exam protocol was analyzed and proven secure [23] using ProVerif [9], a tool for the formal analysis of cryptographic protocols in the symbolic model. In the symbolic model the algebraic properties of cryptographic primitives are usually modeled using equations, e.g., the equation $dec(enc(m,k),k) = m$ can be used to model a simple deterministic symmetric encryption scheme, where the functions *dec* and *enc* represent decryption and encryption, respectively. These equations can fail to take into account subtle behaviors of primitives which can lead to miss certain classes of attacks. For example, the model of Remark! in [23] abstracts away completely the implementation of the Mix-Nets. Hence,

they missed an attack on the Mix-Net described in [40] that exploits the details of the exponentiation process. This attack was found manually and works as follows: an attacker submits a modified version of the public key of a targeted user as their own key to the Mix-Net. This enables the attacker to link both keys after the mixing, breaking the anonymity of the targeted user.

Similar attacks on Mix-Nets had already been described in 1994 [39], long before exponentiation mixnets [30] where proposed in 2011. Still, it took a decade for [40] to (apparently independently) discover that these Mix-Nets were insecure.

The goal of this paper is to propose new symbolic models that capture sufficiently well the mathematical properties of cryptographic primitives used in Mix-Nets and to automatically find such attacks using automated tools such as ProVerif, thus helping protocol designers avoiding these and similar attacks in the future.

Contributions. We show that with the advances of protocol verification tools it is now possible to model Mix-Nets more precisely. This allows us to automatically (re-)discover previously missed (but known) attacks, to discover new attacks, or to prove verify properties of protocols against a more powerful attacker that can exploit weaknesses of the Mix-Net. Our contributions are the following:

- We propose a detailed model of Haenni's [30] exponentiation Mix-Net, taking into account details of the exponentiations.
- Our refined model includes a new, more precise model of ElGamal encryption and signatures, which includes the exponentiation operations and is of independent interest as it can be used to model more precisely protocols that use ElGamal encryption or signatures, but no exponentiation Mix-Nets. To the best of our knowledge, until now symbolic models of ElGamal encryption completely abstracted away the exponentiations, hence potentially missing attacks.
- We then show that this new model of the exponentiation Mix-Net and ElGamal can be used to automatically analyze protocols using this Mix-Net. For this, we model and analyze three protocols in ProVerif: an e-voting protocol [30], an e-exam protocol [27], and the Crypto Santa protocol [42].
  - We give a formal model and analysis of the e-voting protocol from [30]. Our analysis shows that it is vulnerable to a privacy attack (similar to the one from [40]) due to a weakness in the Mix-Net, and the lack of Zero-Knowledge Proofs by the voters.
  - We are able to automatically find the attack from [40] on the exam protocol. Interestingly, Amin et al. [40], despite identifying this attack manually, used a simple formal model in ProVerif which was incapable of detecting the vulnerability.
  - We provide the first formal model and analysis of the Crypto Santa protocol, which turns out to be not vulnerable due to use of appropriate ZKPs by the participants.
- To fix the identified attacks we add the lacking ZKPs to the voting and exam protocols. We check the protocols again, using the standard symbolic modeling of ZKPs, and show that the corrected protocols are secure.
- The standard symbolic modeling corresponds to ideal ZKPs. We propose a model for weaker Zero-Knowledge Proofs (which are common [19], although they are known to be vulnerable [7]), and can show that they are insufficient in this case, as all attacks persist. To the best of our knowledge, these concrete attacks have not been described in the literature. Even the Crypto Santa protocol becomes vulnerable when using these weak proofs, yet the protocol does not specify which ZKPs should be used. Again, the model of weak ZKPs is of independent interest, as it can be used for any protocol using ZKPs of ElGamal keys, even if there is no Mix-Net.
- We also propose a refined model for re-encryption Mix-Nets, and analyze the Estonian e-Vote protocol [1]. As the protocol does not use any ZKP by the voters, it is vulnerable to attacks on the Mix-Net, which we can automatically detect (similar attacks were found manually before, e.g., [36]). We verify the protocol with added weak or strong ZKPs, and are able to show that only the strong ZKPs are sufficient to avoid attacks.

Related work. There exist several automatic protocol verification tools handling equivalence properties, but we chose ProVerif as Deepsec [13] cannot handle our equational theory, and although Tamarin [6] supports Diffie-Hellman exponentiation, the built-in exponentiation operator cannot appear inside a user defined equation. In the case of exponentiation Mix-Nets we need to define encryption and signature schemes using the Diffie-Hellman keys, hence we need to re-use the exponentiation operator in the equations modeling encryption and signature. Previous work mostly focused on improving the modeling of exponentiation in isolation [17], but we need to connect exponentiation and encryption.

Computational tools such as EasyCrypt [5] or CryptoVerif [8] would be able to detect such attacks, they however provide a significantly lower level of automation. Instead, this paper follows a line of work which tries to refine the modeling of cryptographic primitives in symbolic models and thereby to reduce the gap to computational models, while keeping a high level of automation. Similar work has been done for other primitives, for example for digital signatures [32], Diffie-Hellman exponentiation in weak groups [17], hash functions [11] and authenticated encryption with additional data (AEAD) [16]. In all these papers, the authors proposed more detailed and more realistic models of cryptographic

primitives in the symbolic framework, to be able to identify protocol flaws exploiting weaknesses of the cryptographic primitives.

In [32], the authors refine the existing Tamarin models of signature schemes so they discover attacks exploiting for example the fact that in some schemes a signature potentially verifies against multiple different keys. In [17], the authors propose a novel extension of the symbolic model of Diffie-Hellman groups for Tamarin enabling them to capture a large family of attacks exploiting weak groups that were previously outside the symbolic model. In [11], they propose a methodology to systematically discover attacks using Tamarin and ProVerif that exploit weaknesses in widely deployed hash functions, such as length extension attacks. They automatically find known attacks, but also new variants of these attack on several protocols. In [16], the authors provide an automated analysis method in Tamarin for protocols that use AEAD. This method allows them to systematically find attacks that exploit the subtleties of the specific type of AEAD used, as different schemes have different weaknesses.

We propose a refined model for Mix-Nets in ProVerif. Our new models allow us to automatically re-discover known attacks on several protocols, but also to discover new attacks that could not be found using previous models.

Note that in symbolic models, used by the above works, all negligible probabilities are abstracted away. For example, if there is only a negligible probability to generate twice the same random value, or for the adversary to break an encryption scheme, in a symbolic model this will simply be impossible. It has been shown that under certain assumptions this can nevertheless give computational guarantees (an approach called "computational soundness", see e.g. [4, 34]). There are also works on symbolic models that allow non-negligible probabilities in the control flow, i.e., where agents can chose among different actions with given probabilities (e.g., [12]), however there is currently no tool support for this. As the goal of our work is to automatically identify attacks, we use standard symbolic models, where mature tools exist.

The first formal model of Mix-Nets was provided by Wolff *et al.* [46]. They formalized the Mix-Net and its components using the CSP process algebra and the FDR model-checker. The formal analysis was conducted considering a passive attacker, and the Mix-Net model was not specific to a particular type of Mix-Net, but rather general. At this time, this tool was only able to deal with simple dedicated equational theory.

In 2014, Stathakidis *et al.* [43] proposed a formal model for re-encryption Mix-Net suitable for automation based on CSP process algebra and the FDR model checker. They model and analyze the protocol in the presence of an intruder based on Roscoe and Goldsmith's perfect Spy [41]. The main security property analyzed was the robustness of the mix protocol, which is a functional property. Moreover, they do not model any mathematical properties of the Mix-Net.

Also in 2014, Küsters *et al.* [33] provided the first computational formal security analysis of Chaumian Mix-Net with random partial checking. In their paper, they focus on accountability, where misbehavior should be detectable and the responsible of the misbehavior should be blamed. Their analysis in the computational model is not automated. There are other works on the verification of Mix-Nets, e.g., in [31], where the authors provide a mostly manual proof of the Verificatum Mix-Net, but to the best of our knowledge there is none targeting exponentiation Mix-Nets.

Our work in the symbolic model using ProVerif allows us to automatically discover flaws or verify protocols using Mix-Nets. Compared to previous work in the symbolic model, we capture more precisely the exponentiation used in the Mix-Nets to achieve anonymity of the exchanged messages.

Outline. We start by recalling the symbolic models and the applied Π-Calculus in Section 2. In Section 3, we describe exponentiation Mix-Nets and detail known attacks against those types of Mix-Nets in Section 3.1. In Sections 3.2, 3.3, 3.4, and 3.5, we present our new formal models for exponentiation Mix-Nets, ElGamal encryption and ZKPs, respectively. In Section 3.6, we apply those models to three different protocols using exponentiation Mix-Nets to guarantee the privacy of the participants. In Section 4, we describe re-encryption Mix-Nets and detail known attacks against those types of Mix-Nets. In Section 4.2 we present our new formal model for re-encryption Mix-Nets. In Section 4.3, we apply those models to the Estonian e-voting protocol. We conclude and discuss future work in Section 5.

2 Preliminaries

We provide a formal analysis of re-encryption and exponentiation Mix-Nets in the symbolic model, also called Dolev-Yao model [22]. In this model, the cryptographic primitives are represented by function symbols and considered as black-boxes; the messages are terms built using these primitives, which may be read, modified, deleted or injected by the adversary who has total control over the network. Under the assumption of perfect cryptography, the attacker is only able to perform cryptographic operations when it is in possession of the right keys. We model Mix-Net protocols in the applied Π-Calculus [3] and check privacy properties in ProVerif [9].

The applied Π-Calculus is a language for modeling security protocols. We briefly recall its syntax, semantics and equivalence relation. For the full details, see [3].

Syntax. A finite *signature* Σ is a finite set of function symbols each with an associated arity. Given a signature Σ, an infinite set of names $\mathcal{N}$ and an infinite set of variables $\mathcal{V}$, the set of *terms* $\mathcal{T}$ is defined as names, variables and function symbols applied to other terms. Terms are equipped with an equational theory (a set of equations), which induces an equivalence relation between terms, denoted $=_E$.

The behavior of a probabilistic asymmetric encryption and

$P,Q,R ::=$	
$\mathbf{0}$	null process
$P \mid Q$	parallel composition
$!P$	replication
$\nu\, n \cdot P$	name restriction
if $M = N$ then P else Q	conditional
$in(c,x) \cdot P$	message input
$out(c,N)$	message output

Table 1: Grammar of Processes in the applied Π-Calculus.

$A,B,C ::=$	
P	plain process
$A \mid B$	parallel composition
$!A$	replication
$\nu\, n \cdot A$	name restriction
$\nu\, x \cdot A$	variable restriction
$\{^M/_x\}$	active substitution

Table 2: Grammar of extended processes.

decryption, for example, is usually modeled by:

$$dec(penc(m, pk(x), r), x) =_E m \tag{1}$$

where pk is a unary function symbol representing the public key corresponding to the secret key x, m is the plaintext and r represents a random variable.

Systems are described as *processes*. The grammar for processes is depicted in Table 1, where M and N are terms, n is a name, x is a variable and c is a channel name. The null process $\mathbf{0}$ does nothing; $P \mid Q$ is the parallel composition of P and Q; the replication $!P$ behaves as an infinite number of copies of P running in parallel. The process $\nu\, n \cdot P$ makes a new private name n then it runs P. Finally, $c(x)$ and $\overline{c}\langle N \rangle$ stand for an input and an output on the channel c respectively.

Processes are also extended with *active substitutions*. We write $\{^M/_x\}$ for the substitution that replaces the variable x with the term M. The grammar of extended processes is given in Table 2. $\{^M/_x\}$ is considered as a process and $\nu\, x \cdot (\{^M/_x\} | P)$ corresponds to let $x = M$ in P.

A *frame* is defined as an extended process built from 0 and active substitutions by parallel composition and restrictions. The *domain* of a frame is the set of variables for which the frame defines a substitution, and which are not under restriction. An extended process A is *closed* when its free variables are all defined by an active substitution.

A *context* $\mathcal{C}[\cdot]$ is defined as a process with a hole, that can be filled with any process. An evaluation context is a context whose hole is not under a replication, a condition, an input or an output. A context $\mathcal{C}[\cdot]$ closes A when $\mathcal{C}[A]$ is closed.

Semantics and Equivalences.

Internal reduction is the smallest relation on extended processes following the rules in Table 3.

COMM	$\overline{c}\langle x \rangle \cdot P \mid c(x) \cdot Q \to P \mid Q$
THEN	$if\ N =_E N\ then\ P\ else\ Q \to P$
ELSE	$if\ M =_E N\ then\ P\ else\ Q \to P$ for ground terms M,N where $M \neq_E N$

Table 3: Internal reduction in the applied Π-Calculus.

The applied Π-Calculus defines *observational equivalence* to model the indistinguishability of two processes by the adversary. We write $A \Downarrow a$ when A can send a message on channel a.

An *observational bisimulation* is a symmetric relation $\mathcal{R}$ between closed extended processes with the same domain such that $A\ \mathcal{R}\ B$ implies:

1. if $A \Downarrow a$, then $B \Downarrow a$;
2. if $A \to^* A'$ and A' is closed, then $B \to^* B'$ and $A'\ \mathcal{R}\ B'$ for some B';
3. $E[A]\ \mathcal{R}\ E[B]$ for all closing evaluation contexts $E[\ ]$.

Observational equivalence ($\approx$) is the largest such relation.

3 Exponentiation Mix-Nets

In [30], Haenni *et al.* have presented the so-called *Exponentiation Mix-Nets*, which create, from a list of ElGamal public keys, a new shuffled list of anonymized public keys, which can no longer be associated to individual parties.

Let us consider the usual ElGamal setup: a group G of large prime order q with generator g in which the discrete logarithm problem is hard. We have a list of n public keys $\langle pk_i \rangle = \langle pk_1, \ldots, pk_n \rangle$ such that $pk_i = g^{sk_i}$ and m mix servers M_j. The first mix server M_1 takes the original list of public keys $\langle pk_i \rangle$, generates a fresh random $r_1 \in \{0, \ldots, q-1\}$ and computes $\langle pk_i^{r_1} \rangle$. Then M_1 permutes the resulting terms with a secret shuffled order $\langle pk^{r_1}_{\pi_1(i)} \rangle$ where π_1 is the permutation of indexes applied by M_1. Then M_1 sends $\langle pk^{r_1}_{\pi_1(i)} \rangle$ to the next mix server along with g^{r_1}. The following mix servers repeat these same steps as required. The last mix server M_m outputs the list: $\langle g^{sk_{\pi(1)} \cdot r}, g^{sk_{\pi(2)} \cdot r}, \ldots, g^{sk_{\pi(n)} \cdot r} \rangle$ along with g^r where: $\pi = \prod_{i=1}^{m} \pi_i$ and $r = \prod_{i=1}^{m} r_i$. Each party in possession of their secret key sk_i should be the only one able to identify her pseudonym from the final list published by the last mix server by computing $(g^r)^{sk_i} = pk_i^r$.

3.1 Attacks against Exponentiation Mix-Nets

Although exponentiation Mix-Nets were designed by Haenni *et al.* [30] to preserve anonymity and unlinkability of voters in their e-Voting Protocol by attributing anonymous keys, there is an attack. An attacker $\mathcal{A}$ has access to the list of public keys

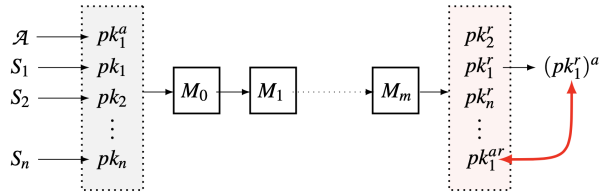

Figure 1: Attack against Exponentiation Mix-Nets.

$\langle pk_i \rangle$ of all participants. They want to learn the pseudonym generated by the mix servers for a specific public key pk_k. $\mathcal{A}$ can generate $a \in \{1,\ldots,q-1\}$, raise pk_k to the power a and append term $(pk_k)^a$ to the list of public keys as their own public key to be mixed. When the final list of pseudonyms is published, they raise each pseudonym to the power of a and look for a match. The attack, as illustrated in Figure 1 for a list of n public keys, exploits the commutative property of exponentiation: $((g^{sk_i})^a)^r = ((g^{sk_i})^r)^a$. This attack (a more specific variant of it) was described by Rakeei *et al.* [40], but it can be seen as a variant of an attack firstly described by Pfitzmann [39] in 1994.

3.2 Models of Exponentiation Mix-Nets

We give a formal specification of exponentiation Mix-Nets.

Definition 3.1 (Mix-Net) *A* Mix-Net *is a tuple* $(S,M,A,\tilde{n}_p)$ *where S is the process executed by the senders, M is the process executed by the Mix-Net servers, A is a process executed by an authority and* $\tilde{n}_p$ *is a set of private channel names, where A can be the null process whenever the protocol does not involve such an entity.*

Definition 3.2 (Exp-mixnet instance) *An* exp-mixnet instance *is a closed process* $EP = \nu\tilde{n} \cdot (S\sigma_{id_1}\sigma_{skS_1} | \ldots | S\sigma_{id_j}\sigma_{skS_j} | M\sigma_{m_1} | \ldots | M\sigma_{m_k})$ *where* $\tilde{n}$ *is the set of all restricted names, which includes the set of the protocol's private channels;* $S\sigma_{id_i}\sigma_{skS_i}$ *are the processes run by the senders with the substitutions specifying the identity and the secret key of the* i^{th} *sender respectively;* $M\sigma_{m_j}$ *is the process executed by the Mix-Net servers with the substitution specifying in particular their secret exponent.*

We write $MP_{\{id_1,id_2\}}[\cdot]$ for the Mix-Net instance MP without the processes for the senders id_1 and id_2.This allows us to define anonymity.

Definition 3.3 (Anonymous Shuffling) *A Mix-Net ensures* Anonymous Shuffling *if for any mixnet processes MP, any senders* id_1 *and* id_2 *and any private materials* p_1 *and* p_2 *(i.e., their keys or messages):*

$$MP_{\{id_1,id_2\}}[S\sigma_{id_1}\sigma_{p_1} \mid S\sigma_{id_2}\sigma_{p_2}] \approx MP_{\{id_1,id_2\}}[S\sigma_{id_1}\sigma_{p_2} \mid S\sigma_{id_2}\sigma_{p_1}]$$

In the case of exponentiation Mix-Nets, this definition requires that the process where id_1 has sk_1 and id_2 has sk_2 as their secret key, is equivalent to the process where id_2 has sk_1 and id_1 has sk_2. This prevents the attacker from obtaining information about the identity of the sender based on the outcome of the Mix-Net.

As stated above, we consider a Dolev-Yao attacker. They has complete control of the network, except the private channels: they can eavesdrop, remove, substitute, duplicate and delay messages that parties are sending to one another, and insert messages of their choice on the public channels. Depending on the properties, we also allow the attacker to corrupt parties. Such corrupted parties cooperate with the attacker by revealing their secret data and/or taking instructions from them. We model them using the definition given in [20]: if the process P is an honest party, then the process P^{c_1,c_2} is its corrupted version. The latter is a variant of the honest process sharing with the attacker channels c_1 and c_2. P^{c_1,c_2} sends all its inputs and freshly generated names to the attacker via channel c_1, and receives (via channel c_2) messages from the attacker that will determine its behavior.

Naturally, it is interesting to consider corrupted or dishonest senders, as they might be interested in obtaining a link between the outcome of a Mix-Net and the identity of some other users. We can do this by replacing honest senders with corrupted ones. For example, if we assume that candidate id_3 is dishonest, we obtain:

$$MP_{\{id_1,id_2,id_3\}}[S\sigma_{id_1}\sigma_{p_1} \mid S\sigma_{id_2}\sigma_{p_2} \mid (S\sigma_{id_3}\sigma_{p_3})^{c_1,c_2}] \approx MP_{\{id_1,id_2,p_3\}}[S\sigma_{id_1}\sigma_{p_2} \mid S\sigma_{id_2}\sigma_{p_1} \mid (S\sigma_{id_3}\sigma_{p_3})^{c_1,c_2}]$$

3.3 Model and analysis in ProVerif

Exponentiation Mix-Nets have been modeled previously, but only as part of other, bigger protocols, for example in the analysis of the E-exam protocol Remark! [23]. However, as the Mix-Net was only part of a bigger protocol, this model used a high-level abstraction of the Mix-Net's functionality, which completely abstracts the details of the computations. This explains why some attacks were missed. The following functions were used to model the Mix-Net's computations:

- $pk(sk)$ computes the public key associated to the private key sk,
- $pseudo\_pub(pk(sk), rce)$ is the function used by the Mix-Net servers to compute the public pseudonyms of the participants based on their public keys $pk(sk)$ and the random exponent rce,
- $pseudo\_priv(sk, exp(rce))$ is the function used by the participants to compute their pseudonym from their private key sk and the new generator $exp(rce)$ (representing g^{rce}) generated by the Mix-Net.

The equational theory also involves a function *checkpseudo* which is a binary function taking as argument two

pseudonyms and returns *true* when the first argument, representing the pseudonym computed by the Mix-Net, matches the second argument which represents the pseudonym recomputed by the candidate based on the new basis: $checkpseudo(pseudo\_pub(pk(sk),rce), pseudo\_priv(sk,exp(rce))) = true$.

This modeling is sufficient to represent the Mix-Net functionality, but it is clearly insufficient to capture the attack described above, as all exponentiations are hidden away by the functions *pseudo_pub* and *pseudo_priv*.

However, recent progress in ProVerif's development enables us to use a much more precise modeling, which we describe in the following.

Equational theory. Our new function consists of a single binary function *exp* which denotes the operation of exponentiation performed by the participants of the protocol. The properties of this primitive are captured by:

$$\begin{aligned} exp(exp(g,x),y) &= exp(exp(g,y),x) \\ exp(exp(exp(g,x),y),z) &= exp(exp(exp(g,x),z),y) \end{aligned} \tag{2}$$

This equational theory directly models exponentiation, enabling us to capture the attack when checking the protocol against Anonymous Shuffling. Note that in the equations g is a fixed generator and not a variable, as otherwise the pretreatment of equations by ProVerif does not terminate. The first equation takes into account the equation needed for the protocol to work but is insufficient to capture attacks against exponentiation Mix-Nets. This is the reason why we need to explicitly give an equation for three exponents, as the attack uses an additional exponentiation. Adding additional exponentiation (more than three) to the equational theory caused non-termination of ProVerif in our examples.

Model. The process for each Mix-Net server M is given in Figure 2, the honest sender process is: let S(sk_S) = out(ch, (exp(g, sk_S))). The sender simply outputs their public key. Each Mix-Net server inputs the list of all keys, checks that they are distinct, applies their random exponent to all keys and outputs the list of all keys in random order (modeled using parallel outputs on the same channel). We note that all keys should be different. Otherwise a trivial attack consists in copying the public key to track: the corresponding pseudonym is the one figuring twice in the list output by the Mix-Net.

In ProVerif, we add dedicated private channels between the two participants swapping their keys and the Mix-Net to ensure that both keys take part in the mixing. The keys are still published, and the attacker can still add a malicious key to the mixing.

Analysis. The result of the analysis of exponentiation Mix-Nets is given in Table 4. ProVerif concludes that *Anonymous Shuffling* property is not satisfied and finds the exact same attack depicted in Figure 1.

let $M(e_{N_j}) =$
1: $in(ch, pk_{S_1})$.
2: ⋮
3: $in(ch, pk_{S_k})$.
4: if $(pk_{S_1} <> pk_{S_2})\&\& \ldots \&\&(pk_{S_1} <> pk_{S_k})$ then
5: ⋮
6: if $(pk_{S_k} <> pk_{S_1})\&\& \ldots \&\&(pk_{S_k} <> pk_{S_{k-1}})$ then
7: $(out(ch, exp(pk_{S_1}, e_{N_j})) \mid\mid$
8: ⋮
9: $out(ch, exp(pk_{S_k}, e_{N_j}))$).

Figure 2: Mixnet process.

3.4 Refined Model of ElGamal

ElGamal asymmetric encryption is typically modeled the same way as any other public key encryption schemes: using a model for an abstract standard probabilistic asymmetric encryption scheme, as in Equation (1) (e.g., in [15, 24]).

However, when using our equational theory depicted in Equations (2) to model the Mix-Net operations, the public keys are of the form $exp(\cdot,\cdot)$ and not $pk(\cdot)$, so we need to modify the equational theory used to model ElGamal encryption, and also the equational theory used to model signatures.

An intuitive approach to modeling ElGamal encryption, where public keys are the result of the exponentiation operator, would be as follows: $dec(enc(m, exp(g,sk), r), sk) = m$ where g is a fixed generator. However, this equation only allows encryption under public keys with the form $exp(g,sk)$. The attack described in Section 3.6.3 would not be detectable using this equation as the attacker's key involves two exponentiations.

Another attempt at modeling ElGamal would be to replace the fixed generator g in the aforementioned equation with a variable to allow encryption with different generators: $dec(enc(m, exp(X,sk), r), sk) = m$. This equation is incorrect. Consider a dishonest party constructing their public key $D = exp(H,d)$ from an honest key $H = exp(g,h)$. When the dishonest party receive a message m encrypted with their public key $enc(m, exp(H,d), r)$, they should not be able to obtain m as when deciphering one should obtain $m \cdot ((g^h)^d)^r \cdot ((g^r)^d)^{-1} \neq m$. However, with the latter equation we have $dec(enc(m, exp(H,d), r), d) = m$. To avoid this issue, we include the generator used in the encryption in the equation, which is consistent with the real cryptographic primitive (the public key includes the generator as a parameter).

To that end, we use the following equations:

$$\begin{aligned} \text{dec(enc(m, X, exp(X, s), r), X, s)} &= \text{m} \\ \text{getmess(sign(m, X, s))} &= \text{m} \\ \text{checksign(sign(m, X, s), X, exp(X, s))} &= \text{m} \end{aligned} \tag{3}$$

The first equation models ElGamal probabilistic public key

encryption and decryption. To encrypt a message m one needs to generate a random r and to use the public parameters of the receiver: a basis X and the key $exp(X,s)$ such that s is the secret key of the receiver. For example, with respect to the notation given in the previous section, let $pk_S = exp(g, sk_S)$ be the public key of a sender and $exp(pk_S, e_N)$ be the pseudonym created by the Mix-Net. To encrypt a message m into the ciphertext c, we use the constructor enc with the following parameters m, $exp(g, e_N)$, $exp(pk_S, e_N)$ and r, respectively. This works because of the commutativity of the function exp defined in the first equation of the equational theory given in Equations (2). Thus, the only way to decrypt c is to apply the destructor dec using the secret key sk_S as parameter and specifying the basis $X = exp(g, e_N)$ used for the encryption.

The second and the third equations model a digital signature algorithm. To sign a message m, one needs to specify the basis X used in the public parameter $exp(X,s)$ and the secret exponent s. Then, $sign(m,X,s)$ is a digital signature for the message m. The second equation states that anyone can extract a message from a signature (we do not assume the signature scheme to be hiding). The third equation models the verification of a signature using the corresponding public key $exp(X,s)$ and the basis X with respect to the parameters used by the signer. This model of ElGamal probabilistic public key encryption is not bound to any protocol, and more precise than the usual models, as it inherits the algebraic properties of the exponentiation operation defined in the equational theory given in Equations (2). Obviously, it can also be used in protocols that do not include exponentiation Mix-Nets. Our model of the ElGamal encryption has allowed us to find a subtle attack described later in Section 3.6.3.

3.5 Refined Model of Zero Knowledge Proofs

A *Zero Knowledge Proof* (ZKP) allows a party to show to another party that a mathematical statement is true without revealing anything other than the truth of the statement itself. A specific class of ZKPs are proofs of knowledge, in which the prover demonstrates knowledge of the preimage $x \in X$ of a public value $y = \phi(x) \in Y$, where ϕ is supposed to be a one way function. These proofs are in particular used to prove knowledge of the discrete logarithm $y = g^x$ in a multiplicative finite group G_q with a generator g of order q. Moreover, interactive proofs between provers and verifiers can be turned into non-interactive ones using the Fiat-Shamir heuristic [25].

We enriched our model with a non-interactive knowledge proof (NIZKP) of the discrete logarithm. The sender is required to transmit its message along with a ZKP proving its possession of either the secret key sk_S for the exponentiation Mix-Nets or the randomness used for encryption for the re-encryption Mix-Net. Upon a valid verification of the proof given by the sender, the Mix-Net servers accept the entry. Otherwise, they reject the message.

Intuitively, adding a ZKP of the possession of the secret information along with the messages fixes the attack mentioned above. However, two variants of the Fiat-Shamir transformation appear in the literature. In [7], Bernhard *et al.* distinguish a weaker and a stronger variant. Both variants begin with the prover making a commitment. The stronger variant hashes both the commitment and the statement to be proved, while the weak variant hashes only the commitment.

The latter version is subject to an attack which allows a malicious party to "fake" a proof as follows [7]. To create a proof, an honest prover, having as public key $pk = g^{sk}$, picks a random $a \in \{1, \ldots, q-1\}$, computes $A = g^a$ and then, they hash A to create a challenge $c = \mathcal{H}(A)$. Finally, they compute $f = a + c \cdot sk$. The proof corresponds to the pair (c, f) and the verification procedure consists in checking whether c is equal to $\mathcal{H}(g^f \cdot (pk)^{-c})$ or not. For an honestly generated proof the verification procedure succeeds since we have $\mathcal{H}(g^f \cdot pk^{-c}) = \mathcal{H}(g^{a+c \cdot sk} \cdot g^{-sk \cdot c}) = \mathcal{H}(g^a) = c$.

However, a dishonest prover can fake a NIZKP as follows. They pick A' a random element from G_q, f' a random exponent, computes $c' = \mathcal{H}(A')$ and the verification of the proof (c', f') succeeds for $pk' = (g^{f'} \cdot A'^{-1})^{c'^{-1}}$ as $\mathcal{H}(g^{f'} \cdot pk'^{-c'}) = \mathcal{H}(g^{f'} \cdot ((g^{f'} \cdot A'^{-1})^{c'^{-1}})^{-c'}) = \mathcal{H}(A') = c'$. The public key depends on the faked proof, *i.e.,* the dishonest prover must compute the proof before choosing pk'.

Because of this attack, the use of the weak variant may invalidate the proof of knowledge. The authors of [7] stated that the weak Fiat-Shamir transformation can safely be used when the statement (in this example, the public key) is fixed first (as in the attack the public key depends on the proof). However, since exponentiation Mix-Net or re-encryption Mix-Net are carried on as part of other bigger protocols, the list of inputs is not a priori known. It is therefore interesting to investigate the impact of the weak variant in our context. Note also that the weak Fiat-Shamir transformation is widely used in practice when it comes to non-interactive proof systems: in [19] the authors examined over 75 different open-source implementations of proof systems that use the Fiat-Shamir heuristic and found 36 systems using the weak variant.

In the case of exponentiation Mix-Nets, the use of weak ZKPs allows for the following attack. Let $(c, f) = (\mathcal{H}(g^a), a + c \cdot sk)$ be the proof generated by an honest participant with public key $pk = g^{sk}$. An attacker computes $c' = \mathcal{H}(A^{c^{-1}})$, where $A = g^a$ is the commitment of the honest participant, chooses $pk' = pk^{c'^{-1}}$ as public key and computes $f' = c^{-1} \cdot f$. The attacker sends (c', f') as a proof along with their public key pk' to the Mix-Net. The verification procedure of the ZKP by the Mix-Net succeeds since we have $\mathcal{H}(g^{f'} \cdot (pk'^{c'})^{-1}) = \mathcal{H}(g^{c^{-1} \cdot a + sk} \cdot g^{-sk}) = c'$.

As the verification of the proof succeeds, the attacker can then perform the same attack as described in Figure 1 by raising pseudonyms to the power of c'^{-1} (instead of a).

Models and analysis. We use two different models, one

Protocol	ZKP	Result	Time
Exponentiation Mix-Nets	without	✗	2 s
	weak	✗	1 m 6 s
	strong	✓	3 s
Re-encryption Mix-Nets	without	✗	1 s
	weak	✗	2 s
	strong	✓	1 s

Table 4: Results of our analysis of Anonymous Shuffling, with and without the added ZKP.

modeling weak ZKPs and the other modeling strong ZKPs.

$$ck(szkp(A,g,x),g,exp(g,x),h(g,exp(g,x),A)) = true \quad (4)$$
$$ck(wzkp(A,X,x),X,exp(X,x),h(A)) = true \quad (5)$$

These equations state that the verification of a proof of knowledge of a secret key succeeds only if the proof was created genuinely: it needs to be checked using the same generator, public key and hash that was used to generate it. The first argument of both functions (*szkp* and *wzkp*) refers to the commitment used in the proof. The hash of the commitment is used by *ck* to check the adequacy of the challenge, and in the case of the strong variant the hash includes the public key. Moreover, in case of the strong ZKP, the proof is only valid when using the public generator g, as this is part of the statement. In the case of a weak ZKP, the hash only includes the commitment, and the generator is now a variable as it is no longer part of the statement. The latter allows the attacker to perform the attack described above, where the public key is $exp(exp(g,x),a)$ for some x and a. Note that in our ProVerif code, when the Mix-Net verifies a weak proof, we input the value X from the network – fixing g would prevent the attacker from using a public of the form $exp(exp(g,x),a)$, as in the first equation.

With the strong variant ProVerif concludes that Anonymous Shuffling is satisfied for exponentiation Mix-Nets (Table 4). When using the weak ZKP, ProVerif returns attack traces on the exponentiation Mix-Net. The ProVerif attack works in the same way as the one without a ZKP (Figure 3.1): an attacker builds a new key $pk' = pk^{\alpha}$ from their victim's key pk and bypasses the proof check due to Equation (5), since $ck(wzkp(A,pk,\alpha),pk,exp(pk,\alpha),h(A)) = true$. In reality, this attack does not work for any α, but for example choosing $\alpha = c'^{-1}$ results in a real attack as described above. Using this approach, we were able to instantiate all attack traces found by the tool with real attacks. In fact, ProVerif cannot find the real attack directly as our equational theory does not encompass inverses (and adding them is currently not possible in ProVerif). However, our equations do not induce false vulnerabilities in the modeled cryptographic primitives since they represent a real (albeit abstracted) behavior of the primitive, and the missing values are simple to instantiate.

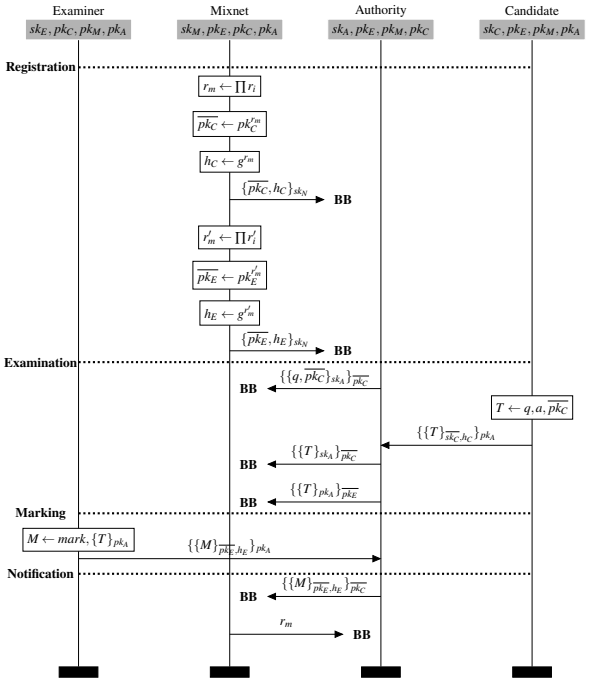

Figure 3: Remark! protocol diagram.

3.6 Applications

We perform formal analysis of three cryptographic protocols using Exponentiation Mix-Nets for different privacy purposes. A formal analysis of the electronic exam protocol has been presented in [23] where the protocol has been proved secure and no attacks have been found against privacy properties. Regarding the two other protocols, to the best of our knowledge, we present their first formal analysis. The timings for the results of the formal analysis given below were done on macOS with a M1 processor and 16 GB of RAM. All ProVerif files are available online [2]. We use a public Bulletin Board, denoted **BB**. A Bulletin Board is a public append-only (*i.e.*, nobody can delete) broadcast message channel. We also assume that the exponentiation Mix-Net behaves correctly. For simplicity, we have modeled the exponentiation Mix-Nets performed by all servers as a single honest Mix-Net server. All the aforementioned protocols are analyzed with and without the proposed fix described in Section 3.5.

3.6.1 Remark! Protocol

We first analyze the Remark! protocol, an electronic exam protocol, designed by Giustolisi *et. al* [27] and meant to achieve multiple privacy properties without relying on trusted parties. The following description of the protocol is based on [23, 27].

Protocol Description. The Remark! protocol involves four types of parties: Mix-Net servers, the candidate(s) sitting the exam, the examiner(s) correcting the answers and marking them, and an exam authority collecting the answers, dispatch-

ing them for the marking phase and delivering the final marks. It is assumed that each party is given a pair of public/private ElGamal keys with a common generator g, *i.e.,* the private key x and the public key $y = g^x$. The protocol runs in four phases: Registration, Examination, Marking and Notification. The protocol's sequence diagram is depicted in Figure 3.

Registration. The registration phase uses an exponentiation Mix-Net to generate pseudonyms $\overline{pk_C}$ and $\overline{pk_E}$ for both candidates C and examiners E based on their public keys pk_C and pk_E as described in Section 3. Let r_m and r'_m denote the Mix-Net's exponents related to candidates and examiners respectively, and let $(h_C = g^{r_m}, h_E = g^{r'_m})$ be the new generators.

Examination. The exam authority begins by signing (using its secret key sk_A) and encrypting (with the candidates' pseudonyms $\overline{pk_C}$) the questions q and publishes the result on the bulletin board **BB**. Then, the exam authority collects the candidates' answers a (which are signed with the candidates' pseudonym keys, and encrypted with the authority's key pk_A), verifies the signatures, resigns them, encrypts them using the corresponding candidates' pseudonyms and publishes them.

Marking. The exam authority encrypts the answers with examiners pseudonyms $\overline{pk_E}$ and publishes them. Each examiner marks the received tests with a mark *mark*, signs them using its pseudonym, encrypts them with the *pkA* and sends the marked tests back to the authority.

Notification. The authority receives the marks, verifies the signatures of the examiners and publishes the signed marks encrypted with the candidates' pseudonyms. Finally, the Mix-Net servers de-anonymize the candidates' pseudonyms by revealing the secret exponent r_m.

Formal Analysis. Dreier *et. al* [23] formalized privacy properties for electronic exams. Here we focus on *Anonymous Marking* and *Anonymous Examiner*'s informal definitions. An e-exam protocol ensures *Anonymous Marking* if a process where two candidates C_1 and C_2 answer a_1 and a_2 respectively, is indistinguishable from a process where the candidates switch their answers. Similarly, it ensures *Anonymous Examiner* if a process where two examiners E_1 and E_2 grade exam forms f_1 and f_2 respectively, is indistinguishable from a process where the examiners switch the forms.

The mentioned properties were proven satisfied with ProVerif on the model given in [23]. This model uses the abstract model for the Mix-Net described in the beginning of Section 3.3. We took the existing ProVerif files and replaced the abstract model of the Mix-Net with our refined model, and checked the same properties. Now, ProVerif finds attacks on Anonymous Examiner and Anonymous Marking. The results of the analysis are depicted in Table 5.

Anonymous Marking and Anonymous Examiner are not satisfied because candidates C_i sign their answer a_i with their pseudonyms $\overline{pk_{C_i}}$, and examiners sign their marks similarly; while pseudonyms generated by Mix-Net are linkable using the attack described in Section 3.1. Such vulnerabilities break the expected fairness of the marking procedure and also might make examiners vulnerable to coercion. The results of the analysis are depicted in Table 5.

Protocol	ZKP	Property	Result	Time

3.6.2 Crypto Santa Protocol

The second protocol we have analyzed is the Crypto Santa protocol. It is based on a Christmas tradition called Secret Santa. During this ceremony, the participants are randomly assigned a person to whom they give a gift. In particular, the identity of the gift giver is to remain a secret. The Crypto Santa protocol is a cryptographic protocol designed by P. Ryan [42] to cryptographically implement the Secret Santa tradition. The protocol is designed to protect the anonymity of the gift giver, and is essentially based on an Exponentiation Mix-Net.

Protocol Description. The participants are n players. Each player is assumed to have a pair of a public and secret keys (pk_i, sk_i) where $pk_i = g^{sk_i}$. The public keys are arranged into a list $\tilde{L} = (pk_1, \ldots, pk_n)$ such that the key pk_i belongs to the player P_i. Given a list L let $L[j]$ denote the j^{th} term of the list L. The players take the list of public keys in turns, and each player i performs an exponentiation with s_i and shuffling step.

The final output is the list $L_n = \Pi_n(L_{n-1}[1]^{s_n}, \ldots, L_{n-1}[n]^{s_n})$ along with the final generator $g^s = g^{s_1 s_2 \cdots s_n}$. Note that the position of each pseudonym in the final outputted list L_n is relevant, as it determines a player to whom the gift is offered. If $L_n[j] = pk_i^s$, then P_i presents their gift $gift_i$ to the player P_j.

To prevent a player from cheating, the protocol suggests that each player provides two different Zero-Knowledge Proofs: a proof that he has performed the shuffle correctly (based on the specifications from [45]), and a proof of knowledge of their secret key sk_i using a standard ZK proof of the discrete log [42]. We do not give further details about the proof of shuffle since in our model we assume that the shuffle procedure is performed correctly.

Formal Analysis. In [42] there is no formal definition of the security properties ensured by Crypto Santa proto-

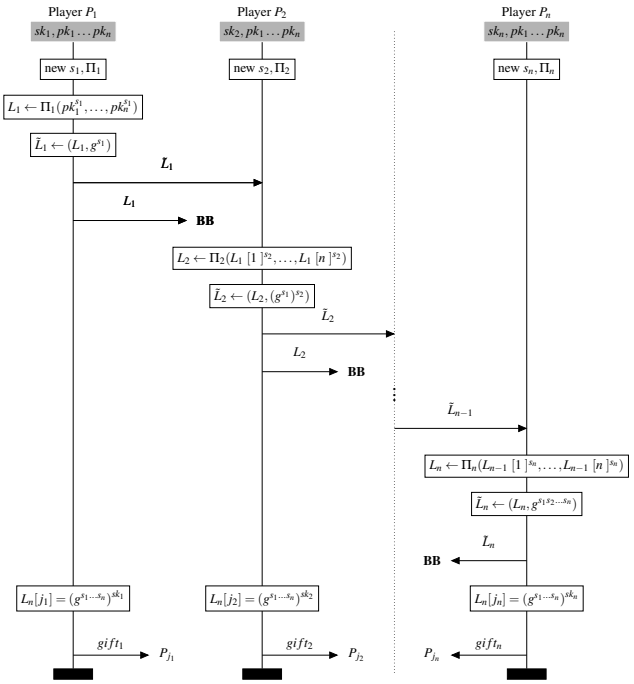

Figure 4: Crypto Santa Protocol

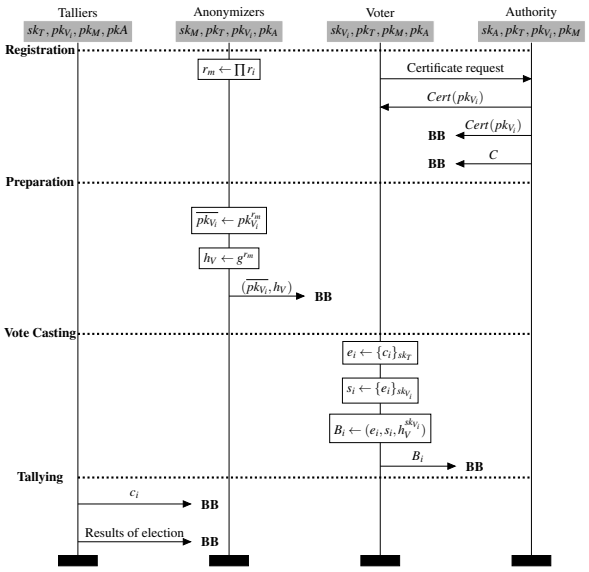

Figure 5: Haenni voting protocol sequence diagram.

col. Nevertheless, they emphasized the fact that the gift giver should be anonymous. Hence, in the final list, the players' pseudonyms should be anonymized. Thus, the Crypto Santa protocol should probably guarantee Anonymous Shuffling (Def. 3.3). The results of our analysis are depicted in Table 5: Anonymous Shuffling is satisfied in case of strong ZKPs, but broken in case of weak ZKPs. Note that the original paper [42] does not specify which ZKP is to be used, and weak ZKPs are widely used [19].

3.6.3 Haenni's Internet Vote Protocol

The next protocol we analyze is an internet vote protocol designed by Haenni *et. al* [30]. This paper also introduced the concept of exponentiation Mix-Nets. The security of this protocol relies on the anonymity obtained by shuffling the voters' public keys. Casting a vote consists in signing the encrypted candidate choice with the anonymized public key generated by the Mix-Net. To obtain the election result, votes carrying a valid signature are decrypted and counted.

Protocol Description. This voting protocol involves four types of parties: the anonymizers, which are the Mix-Net servers, the voters, the talliers and an election authority. The protocol runs in four phases: Registration, Preparation, Vote Casting and Tallying. We assume an anonymous channel $\mathcal{C}$ between the voters and the Bulletin Board. The protocol's sequence diagram is depicted in Figure 5.

Registration. The election authority begins by setting up a Public Key Infrastructure for the voters. Each voter id_{V_i} is therefore equipped with a key pair $(sk_i, pk_i = g^{sk_i})$ and a public certificate binding their public key pk_i to their identity id_{V_i}.

Election Preparation. During this phase the election authority publishes the set C of possible candidates. The authority has to publish all certificates corresponding to eligible voters. Let $Y = \{y_1, \dots, y_n\}$ be the list of voters' public keys. The anonymizers take as input Y and output the shuffled list $\tilde{Y} = \{\tilde{y_1}, \dots, \tilde{y_n}\}$ together with the new generator $\tilde{g}$. The talliers jointly generate a public key using a threshold encryption scheme. The talliers jointly generate a public key using a threshold encryption scheme.

Vote Casting. Let $c_i \in C$ be an eligible candidate. To vote for c_i, a voter v_i needs to encrypt c_i with the talliers' public key y, signs the encrypted vote e_i with their private key sk_i, computes their pseudonym based on the new generator $\tilde{g}$ created by the anonymizers, and submits the ballot $B_i = (e_i, s_i, \tilde{g_i}^{sk_i})$ such that s_i corresponds to the encrypted and signed vote.

Tallying. Let $B = (e, s, \tilde{y})$ be a ballot. For a vote to be considered in the tally, the following conditions have to be satisfied: $\tilde{y}$ is a valid pseudonym, s is a valid signature for e and B is the only valid entry for $\tilde{y}$ in **BB**. The talliers decrypt all valid votes individually, and determine the final election result by applying the counting function to the resulting plaintexts. They also provide proofs of correct decryption.

Formal Analysis. The main security property related to vote protocols is *Vote Privacy*. We informally recall the definition proposed by Delaune *et. al* [21]. In a nutshell, considering two voters V_1 and V_2 and their votes c_1 and c_2, respectively, a voting protocol respects vote privacy whenever a process where V_1 votes c_1 and V_2 votes c_2 is observationally equivalent to a process where V_1 votes c_2 and V_2 votes c_1. This

means that an attacker is not able to detect whether arbitrary honest voters V_1 and V_2 swapped their votes or not. The result for Vote Privacy is depicted in Table 5. Once again, in the absence or in the presence of weak ZKPs, there is an attack; in the presence of strong ZKPs, the property is verified.

The attack found by ProVerif linking the pseudonyms generated by Mix-Net (which is used by the voters to sign their votes) and the identities of the voters is quite interesting as it also relies on our refined model of ElGamal encryption and is slightly different from the attack described in Section 3. More precisely, let us consider two voters V_i and V_j with secret keys skV_i and skV_j with corresponding public keys $pkV_i = g^{skV_i}$ and $pkV_j = g^{skV_j}$ respectively. An attacker who wants to track V_i would choose as public key pkV_i^s. The outputted list of the pseudonyms generated by the Mix-Net contains ${pkV_i}^{r_m}$ (the pseudonym of V_i), ${pkV_j}^{r_m}$ (the pseudonym of V_j) and ${pkV_i}^{sr_m}$, the attacker's pseudonym. To test whether a pseudonym $\tilde{g}$ belongs to the voter V_i, the attacker generates a plaintext m and encrypts it using their pseudonym h as the public key and using $\tilde{g}$ as the basis. If the attacker succeeds in decrypting the ciphertext using their secret key, then the pseudonym used as the basis for ElGamal encryption corresponds to V_i's pseudonym. We can see as follows why this attack works. Let c be the ciphertext for the plaintext m. Then, $c = (c_1, c_2)$ such that $c_1 = \tilde{g}^r = ({pkV_k}^{r_m})^r$ and $c_2 = m \cdot h^r = m \cdot ({pkV_i}^{sr_m})^r$. Using their secret key s the attacker tries to decrypt c. If $k = i$ then $c_2 \cdot c_1^{-s} = m$. ProVerif was only able to find such an attack because of our refined model of ElGamal encryption.

4 Re-Encryption Mix-Nets

Re-Encryption Mix-Nets were proposed by Park *et al.* [37]. In re-encryption Mix-Nets, both the input and output lists are ciphertexts encrypted within the same public-key encryption scheme. These Mix-Nets rely on homomorphic operations that allow the servers to re-randomize ciphertexts, thereby re-encrypting the corresponding plaintexts. Consider the usual ElGamal setup. We have a list of n ciphertexts $\langle C_i \rangle = \langle C_1, \ldots, C_n \rangle$ such that $C_i = (g^{r_i'}, m_i h^{r_i'})$, where m_i a plaintext, and m mix servers M_j. The first mix server M_0 takes the original list of ciphertexts $\langle C_i \rangle$, and for each ciphertext C_i generates a fresh random coin $r_i \in \{0, \ldots, q-1\}$ and re-randomizes the ciphertext with r_i to obtain $C_i' = (g^{r_i'} g^{r_i}, m_i h^{r_i'} h^{r_i})$. Then M_0 permutes the resulting terms using a secret random order and sends the new list to the next mix server. The following mix servers repeat these same steps. The last mix server M_{m-1} outputs a list of ciphertexts which encrypt the permuted input messages, initially chosen by the senders, encrypted using different and secret random values.

4.1 Attacks against Re-Encryption Mix-Nets

Despite the fact that re-encryption Mix-Nets were specifically designed to guarantee anonymity, Pfitzmann [39] described

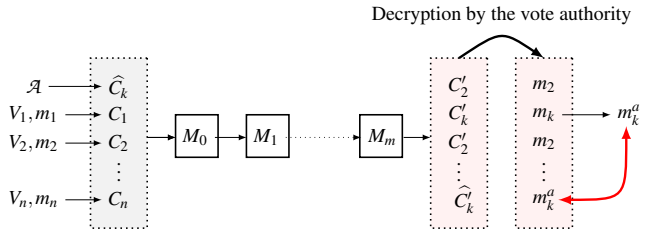

Figure 6: Attack against Re-encryption Mix-Nets, where $\widehat{C}_k = (g^{r_k a}, (m_k h^{r_k})^a)$.

the attack depicted in Figure 6 in the context of electronic voting. In this case encrypted ballots are sent to a Mix-Net. Once the ballots are mixed, the authority decrypts all the mixed encrypted ballots, and publishes the plaintext values in order to ensure verifiability properties. The attack considers a malicious voter $\mathcal{A}$ participating in the protocol. The attacker has access to the list of the Mix-Nets' input $\langle C_i \rangle$ of all participants. The attacker wants to learn the plaintext corresponding to a specific ciphertext $C_k \in \langle C_i \rangle$ such that $C_k = (g^{r_k}, m_k h^{r_k})$. $\mathcal{A}$ can generate $a \in \{1, \ldots, q-1\}$, raise both components of C_k to the power a, and send the ciphertext $\widehat{C}_k = (g^{r_k a}, (m_k h^{r_k})^a)$ to the Mix-Net as its vote. When the output list of encrypted messages is sent to the authority, all plaintexts m_i are published, and $\mathcal{A}$ knows that there is one output value m_i that is equal to m_j^a. Hence, $\mathcal{A}$ looks for this collision by raising each plaintexts to the power of a and looking for a match with the others. This way $\mathcal{A}$ can identify the plaintext m_i of the victim.

Adding zero knowledge proof of possessing the randomness would fix the attack described above, as the attacker only knows a, but not r_k. However, when the weak variant is used, since the first component of the honest ciphertext is g^{r_k} and $(g^{r_k})^a$ for the malicious one, the attacker can construct an invalid ZKP for a fixed a as it is shown in Section 3.5: let (c, f) be the ZKP for g^{r_k} with the commitment $B = g^b$, then he can compute $c' = \mathcal{H}(B^{c^{-1}})$ and $f' = c^{-1} f$, and choose $a = c'^{-1}$, and submit the ciphertext $((g^{r_k})^{c'^{-1}}, (m_k h^{r_k})^{c'^{-1}})$ with the proof (c', f'). This enables them to bypass the verification of the ZKP as $\mathcal{H}(g^{f'} \cdot ((g^{r_k})^{c'^{-1} c'})^{-1}) = \mathcal{H}(g^{c^{-1}(b+cr_k)} \cdot (g^{r_k})^{-1}) = \mathcal{H}(g^{c^{-1} \cdot b + r_k} \cdot g^{-r_k}) = c'$.

4.2 Formal model and analysis using ProVerif

For our formal mode of re-encryption mixnets, we define a Reenc-mixnet instance, analogous the exp-mixnet instance.

Definition 4.1 (Reenc-mixnet instance) *A* reenc-mixnet instance *is a closed process* $RP = \nu \tilde{n} \cdot (S\sigma_{id_1}\sigma_{m_1} \mid \ldots \mid S\sigma_{id_j}\sigma_{m_j} \mid M\sigma_{r_1} \mid \ldots \mid M\sigma_{r_k} \mid A\sigma_{sk_A})$ *where* $\tilde{n}$ *is the set of all restricted names, which includes the set of the protocol's private channels;* $S\sigma_{id_i}\sigma_{m_i}$ *are the processes run by the senders with the substitutions specifying*

the identity and the plaintext of the i^{th} sender respectively; $M\sigma_{m_j}$ is the process executed by the Mix-Net servers with the substitution specifying their secret random; A is the process run by the decryption authority and σ_{sk_A} specifies the decryption key.

This definition allows us to apply the same definition of *Anonymous Shuffling* (Def. 3.3). Applied to re-encryption Mix-Nets, Anonymous Shuffling requires that the process where id_1 encrypts m_1 and id_2 encrypts m_2, is equivalent to the process where id_2 encrypts m_1 and id_1 encrypts m_2. This prevents the attacker from having any information about which plaintext belongs to which sender.

Equational theory. Re-encryption Mix-Nets relies on the homomorphic properties of the encryption scheme since Mix-Net servers need to re-encrypt the list of the inputted ciphertexts. Therefore, in addition to the encryption equation, we require an additional equation that models a re-encryption operation. We use the following equational theory:

$$\begin{aligned} &dec(enc(m,X,exp(X,x),r),X,x) = m \\ &reenc(enc(m,X,exp(X,x),r),r',X,exp(X,x)) = \\ &\qquad enc(m,X,exp(X,x),sum(r,r')) \quad (6) \\ &EXP(enc(m,X,exp(X,x),r),a) = \\ &\qquad enc(exp(m,a),X,exp(X,x),mult(r,a)) \end{aligned}$$

The first equation corresponds to our refined model of ElGamal described in Section 3.4. Let $(c_1 = g^r, c_2 = m \cdot (g^x)^r)$ be an ElGamal ciphertext. Re-encrypting the latter ciphertext consists in generating a new random r' and multiplying c_1 with $g^{r'}$, and c_2 with $(g^x)^{r'}$. The resulting ciphertext is of the form $(g^{r+r'}, m \cdot (g^x)^{r+r'})$. To model the re-encryption operation, we introduce two function symbols *sum* and *reenc*. The binary function *sum* represents a sum of two exponents (albeit in a limited way, as *sum* has no further equations – ideally *sum* should be associative and commutative, but this is not possible in ProVerif). The function *reenc* takes as arguments a ciphertext $enc(m,X,exp(X,x),r)$, a coin r', a basis X and a public key $exp(X,x)$. It returns the ciphertext $enc(m,X,exp(X,x),sum(r,r'))$ with a coin representing the sum of r and r'. The first and the second equations are needed for the protocol to work as it uses encryption and re-encryption, but they are insufficient to capture attacks against re-encryption Mix-Nets. To capture the attack depicted in Figure 6, we need to augment our equational theory with an equation that allows for the exponentiation of the ciphertext with respect to the induced homomorphic properties on the corresponding plaintext. The third equation uses the binary function *EXP* (different from *exp*) to apply a known exponent a over the plaintext. We introduce the function *mult* to represent a multiplication between random coins (again, in a limited way). When analyzing re-encryption Mix-Nets using ZKPs to show knowledge of the randomness used for the encryption, we also added Equations (5) and (4) to the equational theory.

Model. The process for each Mix-Net server M is similar to the one defined for exponentiation Mix-Net (as depicted in Figure 2), but it uses different parameters. Each Mix-Net server inputs the list of all generated ciphertexts, checks they are distinct, applies a random coin to each ciphertext in order to re-randomize it and outputs the list of all new ciphertexts in random order. The sender simply outputs its ciphertext. Thus, the sender process is: let S(m_S, r_S, pk) = out(ch, (enc(m_S, g, pk, r_S))).

Analysis. The result of the analysis of re-encryption Mix-Nets is given in Table 4. ProVerif concludes that *Anonymous Shuffling* is not satisfied and finds the attack depicted in Figure 6 when the protocol is modeled without ZKP. In the case of the weak ZKP, ProVerif finds (nearly) the same attack, except that the attacker need to fake the ZKP as in the attack on the exponentiation Mix-Net with weak ZKP. In contrast, the property is verified when the strong ZKP is used instead.

4.3 Application: IVXV Internet Vote Protocol

In this section, we analyze the Estonian internet vote protocol which uses a re-encryption Mix-Nets [1]. It is used to conduct legally binding political elections in Estonia. We use the equational theory described in Equation (6). The description of the protocol is based on the one given by Müller in [36].

Protocol Description. The Voting System consists of the Election Organizer *EO*, the Vote Collector *VC*, the Registration Service *RS*, the I-Ballot Box Processor *IBBP*, the Talliers *T* and Mix-Nets *MS*. The protocol runs in four phases: *Registration*, *Vote Casting*, *Preparation* and *Tabulation*.

Registration. This scheme requires a Public Key Infrastructure. Each eligible voter v_i is therefore equipped with a key pair (sk_{v_i}, pk_{v_i}) and a public certificate $Cert_{v_i}$ binding their public key pk_{v_i} to their identity v_i. The *EO* publishes the set $C = \langle c_j \rangle$ of possible candidates. The talliers *T* jointly generate a public key pk_T using a threshold encryption scheme.

Vote Casting. To vote for a candidate c_j, a voter v_i encrypts first c_j with the Talliers' public key pk_T and a generated coin rv_i. The voter signs the encrypted ballot Bc_i with their private key skv_i and sends their signed encrypted ballot Bcs_i along with their certificate $cert_{v_i}$ and their identifier v_i to *VC*. Upon receiving a valid $(Bcs_i, cert_{v_i}, v_i)$, *VC* responds with a unique generated identifier vid_i and the *RS* confirmation reg_{vid_i}.

Preparing for Tabulation. After the online voting phase, the *VC* has a set of digitally signed votes and *RS* has the set of registration queries and responses. Both of these sets are transferred to the *IBBP* responsible for auditing the voting phase and pre-processing the votes for tabulation/ *IBBP* composes a new list of signed vote envelopes. This list only contains the latest vote for each voter v_i since the protocol allows voters to revote. *IBBP* then anonymizes the votes in the list by extracting only the encrypted ballots. *IBBP* can then pass the

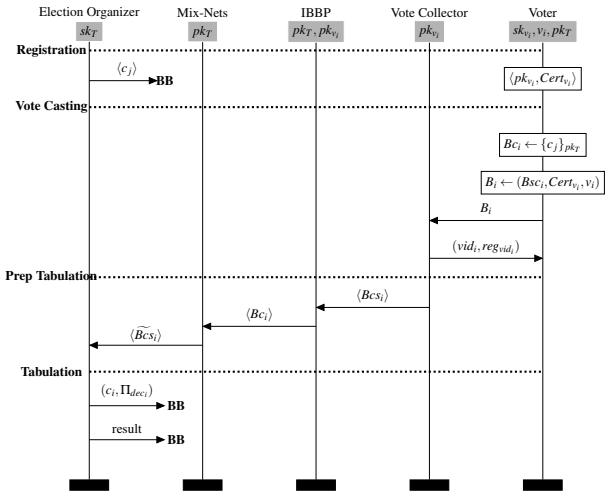

Figure 7: Estonian voting protocol sequence diagram.

list $\langle Bc_i \rangle$ to the re-encryption Mix-Nets MS. The output set of the Mix-Nets $\langle \widetilde{Bc_i} \rangle$ is then sent to EO for tabulation.

Tabulation. The EO uses the election private key to decrypt each choice c_i and to compute the result. EO also provides a proof of correct decryption Π_{dec_i} for every plaintext.

Formal Analysis. We analyze *Vote Privacy* as described in the previous protocol analysis. The input list to the Mix-Nets in IVXV protocol is not public, but is given to a third party performing audits. The re-encryption Mix-Net was added to the protocol to preserve the privacy of voters with respect to this third party performing audits. Hence, vote privacy in the IVXV protocol relies on the anonymity provided by the shuffling procedure performed by the re-encryption Mix-Net.

We verify vote privacy using our new refined model of the Mix-Net. The result of the analysis is depicted in Table 5: ProVerif finds an attack on Vote Privacy. Assuming a malicious third party, the attacker can retrieve the encrypted ballot Bc_i of his victim v_i from the ballot list and perform the attack described in Section 4.1. At the end of the election, when the results are published, the attacker knows to which candidate c_j the voter v_i voted. In [36], Müller found that the IVXV protocol is vulnerable to similar attacks exploiting the malleability of the ElGamal encryption when investigating the protocol manually. To fix this issue, he added ZKPs proving that the voter knows the randomness and the plaintext of the encrypted ballot. We also verified the protocol with an added weak or strong ZKP showing knowledge of the randomness (only), using the modeling described in Section 3.5. In the case of a weak ZKP the attack persists, whereas with a strong ZKP ProVerif succeeds in proving the property (Table 5).

5 Discussion and Conclusion

In this paper we propose a novel and more precise modeling of exponentiation Mix-Nets which includes the details of the exponentiation. Previous models used a high-level abstraction of the functionality, which lead them to miss attacks based on a weakness where a user can submit a modified version of a key of another participant in an attempt to trace them.

Using three case studies (including a voting and an exam protocol) we show that we can use our improved modeling to analyze protocols using exponentiation Mix-Nets. In particular, we are able to (re-)discover known and unknown attacks on these protocols. Fixing these attacks requires the use of zero-knowledge proofs. We propose two models: a novel model for weak ZKPs vulnerable to certain attacks, and a model for strong ZKPs. We can show automatically that in our examples the use of weak ZKPs is insufficient, as all attacks persist. The use of strong ZKPs however fixes the attacks, and we can verify the protocols.

Moreover, we propose a novel and more precise modeling of ElGamal encryption where keys are actually the result of exponentiation operations, which is of independent interest and can be applied to other protocols, even if they do not use Mix-Nets. We also propose a refined modeling of re-encryption Mix-Nets, which allows use to rediscover a known attack on the Estonian voting protocol. Again, we can automatically show that the attack persists when adding weak ZKPs, but disappears if strong ZKPs are used.

As future work, we would like to apply our ElGamal and ZKP models to other protocols using these primitives, such as other voting protocols, private set intersection protocols or password based authentication protocols. Essentially, all existing ProVerif models of protocols using these primitives could be extended using our new refined modeling. We hope that in the future such a modeling will become commonplace.

Moreover, we would like to get rid of some of the remaining limitations of the current model in ProVerif. For example, in the current equational theories, we use a fixed generator, which in particular limits the number of exponentiations, and some attacks need more than three exponentiations [38]. In general, there are results showing that a fixed number can be sufficient (e.g., [35]), which are however not directly applicable in this case.

We would also like to propose models capturing other attacks on weak zero-knowledge proofs.

Finally, we do not consider the scenario of corrupted Mix-Nets. To model one or more corrupted Mix-Nets, additional details have to be considered within the model. The assumption of having at least one single honest server among the ones in Mix-Nets is sufficient to have an honest mixing process, as stated for example in [27]. However, this assumption is not always true, as shown in [44]. The fifth and the second attack required that the first mix-server is corrupted whereas the third and the fourth ones required that both the first and

the last mix-servers are corrupted.

Abstract

We present Rabbit-Mix, a robust algebraic mixing-based anonymous broadcast protocol in the client-server model. Rabbit-Mix is the first practical sender-anonymous broadcast protocol satisfying both robustness and 100% message delivery assuming a (strong) honest majority of servers. It presents roughly 3× improvement in comparison to Blinder (CCS 2020), a previous anonymous broadcast protocol in the same model, in terms of the number of algebraic operations and communication, while at the same time eliminating the non-negligible failure probability of Blinder. To obtain these improvements, we combine the use of Newton's identities for mixing with a novel way of exploiting an algebraic structure in the powers of field elements, based on an *additive 2-basis*, to compactly encode and decode client messages. We also introduce a simple and efficient distributed protocol to verify the well-formedness of client input encodings, which should consist of shares of multiple arithmetic progressions tied together.

1 Introduction

Anonymous communication is one of the most central computer security goals, yet it is also among the most difficult to realize at scale. Anonymous communication should hide the identities of senders and recipients even against network surveillance and traffic analysis. Some of the best-known practical approaches for the problem include Tor [16] and anonymization proxies [19, 26, 30]. However, these approaches are vulnerable to adversaries with powerful traffic analysis capabilities, which potentially control a portion of anonymous network servers [24, 25, 37].

Leveraging MPC A cryptographic approach for overcoming traffic analysis leverages secure multiparty computation (MPC) [6, 11, 21] to build anonymous communication protocols. Chaum [10] introduced the *Dining Cryptographers* (DC) problem formalizing the cryptographic notion for anonymity, and proposed a seminal MPC-based solution for sender-anonymous broadcast (AB). In his approach, referred to as a DC-network (DC-net in short), a group of players can publish their messages without revealing the information of linkage between the players and their messages. The main advantage demonstrated by the DC-net approach was the strong anonymity guarantee even against adversaries using powerful adversarial traffic analysis as long as the players behave honestly and communicate over authenticated point-to-point (P2P) channels. A main drawback of the original DC-net approach is its poor scalability. Every player must have secure communication channels with all other players, and the number of players can be potentially large. A second drawback is that the system is easily disrupted by malicious players.

AB in the Client-Server Model To address both of the above limitations, a large number of of works considered scalable DC-net protocols in the so-called "client-server" model. In this model, a small set of N_s servers jointly provides a sender-anonymous virtual bulletin board to N_c clients[1], where $N_s \ll N_c$ [1, 2, 12–14, 17, 18, 27, 38, 40]. In particular, Dissent [13, 40], Verdict [14], and Riposte [12] proposed AB protocols with $O(N_c N_s)$ overall communication showing off better scalability than typical client-to-client DC-net protocols that have $O({N_c}^2)$ overall communication. Dissent built a DC-net in the client-server model and Verdict is built upon Dissent, and uses zero-knowledge proofs of knowledge to prevent disruption from malicious clients. Riposte and Express [18] rely on Function Secret Sharing (FSS) [8], which in turn only requires symmetric cryptography (e.g. AES). Sabre [38] inherits the structure of Riposte and Express and improves by employing fast secret-shared non-interactive proofs/arguments(of Knowledge) for more efficient audits on client messages. Indeed, Riposte presented a seminal blueprint for AB in which message shuffling is achieved via *private-writing* (PW). MCMix [2] presented a 3-server shuffling protocol

[1]Here, N_c is an upper-bound on the size of the anonymity set rather than the actual number of clients. See Section 1 for further discussion

with a different shuffling paradigm. Clarion [17] proposed a N_s-server shuffling protocol which improves over MCMix. We note that all protocols mentioned above do not guarantee resilience against malicious servers. Concretely, even a single misbehaving server can mount a Denial-of-Service attack by preventing output delivery, and can potentially weaken the security guarantee by disqualifying a subset of the clients, effectively reducing the size of the anonymity set.

Resisting Malicious Servers Lu et al. [27] pointed out that *fairness* of the underlying MPC protocol is essential to mitigate the leakage of information linking clients and their messages to corrupted servers. Fair MPC protocols guarantee that an adversary obtains protocol outputs only if honest clients receives their outputs. If an AB protocol is unfair, then an adversary may receive output messages and terminate the protocol forcing potentially some clients to participate again in the next epoch with the same messages.

Motivated by this security concern, Lu et al. [27] constructed the first practical AB protocols with *fair output delivery* in an asynchronous network by relying on honest-majority MPC based on Shamir's secret sharing. More concretely, they proposed two distinct mixing protocols: AsynchroMix and PowerMix. AsynchroMix uses honest-majority MPC to realize the butterfly sorting network for message shuffling. It has $O(1)$ client-to-server (c-to-s) communication and $O(N_s N_c \log^2 N_c)$ server-to-server (s-to-s) communication and computation with $O(\log^2 N_c)$ rounds. PowerMix is based on Newton's identities relating the sums of powers and symmetric polynomials, where the roots of the symmetric polynomial are the client messages [12, 27, 28, 33]. PowerMix is light on the client side: it has $O(1)$ c-to-s communication and client computation. However, it has $O({N_c}^3)$ server computation and $O({N_c}^2)$ (s-to-s) communication. It also requires an expensive offline protocol for securely generating a large amount of secret correlated randomness. AsynchroMix and PowerMix both do not guarantee resiliency against DoS attacks by corrupted servers since corrupted servers may choose to disrupt the mixing protocols at the cost of receiving no client message.

To address this limitation, Abraham, Pinkas, and Yanai [1] presented Blinder, the first practical AB protocol with full *robustness* (i.e., guaranteed output delivery). Following the blueprint of Riposte [12], Blinder also uses a PW-based approach to shuffle messages by writing them into random locations, but realizes this approach using an honest-majority MPC protocol based on Shamir's secret sharing. Due to the nature of the PW approach, Blinder requires communication and computation redundancy to (1) minimize the probability of severe collisions (e.g., messages will be lost if more than two clients write into the same location) and (2) recover messages from mild collisions if a collision involves two client messages. Similarly to Riposte, Blinder achieves the first goal by increasing the size of the PW database by some constant factor c and the second goal by using two database tables and a simple algebraic technique for recovering (at most) two colliding messages. As a result, it inherits Riposte's 95% message delivery success rate for $c = 2.75$, in contrast to PowerMix's 100% delivery success rate. Blinder has roughly $2c\sqrt{N_c}$ client-to-server communication and $O({N_c}^2)$ server computation/communication.

Technical Goal and Approach The goal of this work is to build a practical AB protocol that simultaneously achieves *robustness* (i.e., guaranteed output delivery) and *100%* message delivery success rate, while concretely improving both communication and computation complexities over the state-of-art MPC-based AB protocols.

This goal is achieved by a new robust AB protocol that we call Rabbit-Mix that we build upon authenticated point-to-point channels and broadcast channels. Our main technical approach is to combine Newton's identity based shuffling technique with novel techniques for re-balancing and optimizing communications and computations by exploiting the algebraic structure of powers of messages. As discussed above, AB protocols that follow a PW-based approach inherently require redundant blowups in their communications and computations in order to reduce their message delivery failure rates. We mitigate this redundancy while achieving perfect message delivery by using Newton's identities as a main building block, similarly to PowerMix. However, PowerMix's server computation requires $O({N_c}^3)$ algebraic operations to privately compute secret shares of N_c consecutive powers (e.g., $m, m^2, \cdots, m^{N_c}$) of each client's message m, where PowerMix clients submit a single secret-share of their messages to servers. Another major bottleneck of PowerMix is its reliance on an expensive offline protocol[2] for generating secret-shared powers of random secret field elements used to compute the powers of the actual messages.

In order to achieve the best of both worlds, we exploit the algebraic structure in powers. Our main observation is that the N_c sequential powers of field element m can be computed by evaluating a circuit of multiplication depth 1 (and algebraic degree 2) on a set of $2\sqrt{N_c} - 1$ elements that we call a square-root encoding of m. This kind of degree-2 quadratic expansion resembles protocols for private information retrieval/writing with square-root communication; however, instead of applying the expansion to sparse vectors, here we apply it to a dense vector consisting of distinct powers of a message. Employing this client message encoding results in a graceful tradeoff between server computation and client communication: servers only need $O(N_c)$ algebraic operations to compute the N_c powers of each message m and a client is now required to send the $O(\sqrt{N_c})$ secret-shares of its message m. Moreover, similarly to Blinder (and unlike PowerMix), we only require a simple

[2] In the MPC literature, an offline (sub)protocol is a protocol that is executed before the actual protocol inputs are known. See Section 2.1 for further discussion.

	t_s	Service Strength	Delivery Success	Offline Preprocess	Broadcast Required	C-to-S (Broadcast)	S-to-S (P2P)	Client (comp)	Server (comp)	Server Round
Switch-Network* [27]	$< \frac{N_s}{3}$	Fair	100%	Non-linear (MultTri)	Yes	1	$12N_sN_c\log^2 N_c$	1	$2N_cN_s\log^2 N_c$	$\log^2 N_c$
PowerMix* [27]	$< \frac{N_s}{3}$	Fair	100%	Non-linear (Powers)	Yes	1	$6{N_c}^2$	1	${N_c}^3/2$	2
Blinder [1]	$< \frac{N_s}{4}$	Robust	95%	Linear (DouRand)	Yes	$4.97\sqrt{N_c}$	$17N_c$	$4.97\sqrt{N_c}$	$5.5{N_c}^2$	4
Rabbit-Mix (This Work)	$< \frac{N_s}{4}$	Robust	$100-\varepsilon$%	Linear (DouRand)	Yes	$1.87\sqrt{N_c}$	$5.32N_c$	$1.87\sqrt{N_c}$	$1.43{N_c}^2$	4

Table 1: Comparison to Related Works: Let N_c and N_s be the numbers of clients and servers respectively. t_s = server corruption threshold. Service strength is either Fair or Robust. The offline communication column shows the types of correlated data required to be prepared during the offline phase. DouRand, MultTri, Powers denote double random sharing, multiplication triple sharing, powers of a random sharing respectively. Offline setup marked as "linear" can be generated non-interactively using pseudorandom secret sharing. All communication complexity is measured by the number of field elements. C-to-S (broadcast) indicates communication costs from a client to each server in the number of field elements to broadcast. S-to-S (P2P) indicates the communication cost per server to be transmitted via authenticated P2P channels. Client (comp) is a client's computational overhead in N_c and N_s so that actual complexity can be computed by multiplying it by the operations required for underlying secret-sharings. Similarly, Server (comp) is also a server's computational overhead in N_c and N_s. The total communication complexity can be calculated by multiplying by N_c. * indicates that these protocols are built to work over an asynchronous network. ε denotes a statistical delivery failure percentage which is negligible (e.g., probability $\ll 1/2^{\kappa}$) for any system configurations with at least 32-byte long primes.

constant-round offline setup protocol, which can further be made entirely non-interactive in some parameter regimes.

Finally, we observe that the above quadratic compression can be viewed as using a simple *additive 2-basis* of $\mathcal{S} = \{1,2,...,N_c\}$, namely a small set $\mathcal{S}'$ such that every number in $\mathcal{S}$ can be written as a sum of two numbers from $\mathcal{S}'$. Using a more sophisticated additive 2-basis [39], we reduce the size of encoding to roughly $1.87\sqrt{N_c}$. Hence, the client communication (and computation) is smaller than $2\sqrt{N_c}$, and the server computation per client is linear in N_c.

An additional difficulty is posed by the need to guarantee robustness against malicious clients. Indeed, even a single input encoding which is inconsistent with the underlying additive 2-basis format can lead to a corruption of *all* outputs. Therefore, it is imperative for the servers to verify that the received secret-shares of an encoded client message are consistent with the additive 2-basis. We present such an efficient distributed verification protocol to verify the well-formedness of the shares contributed by the clients.

Summary of Contributions Following is a summary of the main contributions of this work.

- We construct Rabbit-Mix, a 4-round robust AB protocol with *statistically negligible* delivery failure. Rabbit-Mix has better concrete efficiency than state-of-the-art AB protocols, including those with imperfect message delivery or those that only guarantee fairness. Our protocol is built upon the existence of reliable broadcast and authenticated point-to-point channels to achieve the desired guaranteed output property, similarly to the previous related works.
- We exploit an algebraic structure in sequential powers, using an additive 2-basis to improve concrete efficiency.
- We design a distributed verification protocol to verify the well-formedness of the encoded input shares provided by clients with respect to an additive 2-basis.

Comparison to Related Works Table 1 summarizes concrete in-depth comparisons between Rabbit-Mix and relevant AB protocols with fairness or robustness. Rabbit-Mix improves over the latest robust AB protocol Blinder in all categories in terms of concrete efficiencies in both the offline and online phases. In comparison to PowerMix, Rabbit-Mix also has better concrete server communication and computation efficiencies and only requires linear correlated randomness (double random shares). This is contrasted with PowerMix and Switch-Network, which require non-linear correlated randomness that is more expensive to generate and requires interaction. In contrast, Rabbit-Mix and Blinder can both make their offline computations non-interactive by using pseudorandom secret sharing (PRSS) (See Section 7 and Appendix 2.1). On the other hand, in contrast to Switch-Network and PowerMix, Rabbit-Mix has $O(\sqrt{N_c})$ client-to-server communication overhead which might be a bottleneck in some network settings especially considering that client-to-server communication relies on reliable broadcasts. Rabbit-Mix is less tolerant against malicious servers as it has smaller corruption threshold $\frac{N_s}{4}$ than PowerMix's $\frac{N_s}{3}$. Furthermore, Rabbit-Mix has a negligible probability of delivery failure. Due to space limitations, the complexity expressions in the table only include the leading terms. We refer to Section 8 for in-depth efficiency comparisons that include empirical benchmarks.

2 Preliminaries

Let λ be the security parameter. Let a and b be integers s.t. $a \leq b$. Then, we write $[a,b]$ to denote the set of all integers $\{c \in \mathbb{Z} | a \leq c \leq b\}$ and $[a]$ to denote the set of positive integers $\{1,\cdots,a\}$. We often abuse our notations for arithmetic operations over a set. For example, let S be an ordered set of n field elements as $S = \{s_1, s_2, \cdots, s_n\}$ and a be a field element. Then, we denote the ordered set of powers of a with exponents in an ordered set S by simply a^S which is $\{a^{s_1}, a^{s_2}, \cdots, a^{s_n}\}$.

2.1 Secure Multiparty Computation

In the following, we provide the brief overview on the secure multiparty computation (MPC) especially in the honest majority setting where the number of corrupted servers is strictly less than the number of honest servers.

Shamir's Secret Sharing Shamir's Secret Sharing (SS) [34] is a core cryptographic scheme that enables one to share its secret to multiple parties where the secret remains hidden as long as a certain fraction of the parties are not compromised. SS scheme is a pair of two algorithms $(\mathsf{Share}, \mathsf{Reconst})$ defined as follows: let n be a positive integer and q be a prime such that $q > n$.

1. **Algorithm** $\mathsf{Share}_{n,d,q}(s)$: To share a secret s in a finite prime field $\mathbb{F}_q$ to n parties P_i, sharing algorithm $\mathsf{Share}_{n,d,q}(s)$ will output n secret shares denoted by ${}^d[\![s]\!]_q$ defined as follows: $\mathsf{Share}_{n,d,q}(s)$ will choose a random degree d polynomial $f(x)$ in $\mathbb{F}_q[x]$ with $f(0) = s$. Then, the i-th share for party P_i is $f(i)$. We omit d and q as well when the context is clear. The computational cost is $O(d \log^2 d)$.

2. **Algorithm** $\mathsf{Reconst}_{n,d,q}([\![s]\!])$: To reconstruct a secret s, we need to interpolate a d-degree polynomial $f(x)$ such that $f(0) = s$ from ${}^d[\![s]\!]_q$ which is n distinct coordinates $\{(i, f(i))\}_{i\in[n]}$ with up to t errors. We abuse the notation and use $\mathsf{Reconst}_{n,d,q}([\![s]\!])$ for the sake of simpler notation when the context is clear. We use Reed-Solomon (RS) decoding algorithm to implement $\mathsf{Reconst}_{n,d,q}([\![s]\!])$ which will interpolate a polynomial $f(x)$ of degree at most d from n points correcting up to $t = \lfloor (n-d)/2 \rfloor$ errors. The most efficient known version of the decoding algorithm is based on FFTs which has $O(n \log^2 n)$ computation [36].

The d-sharing of secret s, ${}^d[\![s]\!]$ is said to be *d-consistent* if there exists a polynomial $f(x)$ of at most degree d such that every honest party P_i holds share $f(i)$.

Batched Robust Opening In order to publicly open secrets, we use a robust share opening protocol due to the works [4,15] which opens multiple secret sharings in a batched manner. The idea is to expand ℓ consistent d-sharings into N consistent d-sharings for $\ell = N - (2t+1)$ and $d \leq 2t$ by using a public Vandermonde matrix. Let $Van^{(N\times\ell)}$ (simply Van when the context is clear) be a Vandermonde matrix where the entry at the i-th row and j-th column of the matrix is i^j. Then to open ${}^d[\![x^{(1)}]\!]_q, \cdots, {}^d[\![x^{(\ell)}]\!]_q$, all parties locally compute the matrix multiplication of Van with the vector of $[\![x_1]\!], \cdots, [\![x_\ell]\!]$, which essentially computes consistent d-shares of secret degree-ℓ polynomial with shared coefficients $x_1, x_2, \cdots, x_\ell$. Then, all parties will reconstruct at least $(N-t)$ y_i's which can be consequently reconstructed to x_i's. We denote the batched robust opening protocol by Π^{robust}_{open} that takes inputs ℓ *d-consistent* sharings ${}^d[\![x^{(1)}]\!]_q, \cdots, {}^d[\![x^{(\ell)}]\!]_q$ and outputs $x^{(1)}, \cdots, x^{(\ell)}$.

Protocol 1: Robust Opening Protocol Π^{robust}_{open}

Parameters: N is the number of parties (servers), t is the corruption threshold.
Input: ℓ *d-consistent* secret-sharings ${}^d[\![x^{(1)}]\!]_q, \cdots, {}^d[\![x^{(\ell)}]\!]_q$.
Output: $x^{(1)}, \cdots, x^{(\ell)}$.

1: Each party P_i locally computes $Van^{N\times\ell}({}^d[\![x^{(1)}]\!]_q, \cdots, {}^d[\![x^{(\ell)}]\!]_q) \rightarrow {}^d[\![y^{(1)}]\!]_q, \cdots, {}^d[\![x^{(N)}]\!]_q$
2: Each party sends share ${}^d[\![y^{(i)}]\!]_q$ to party P_i for each $i \in [N]$.
3: Each party P_i reconstructs $y^{(i)}$ by running $\mathsf{Reconst}_{N,d,q}(\left\{{}^d[\![y^{(i)}]\!]_q\right\}_{i\in[N]})$.
4: Each party P_i sends $y^{(i)}$ to other parties.
5: Each party upon all $y^{(i)}$'s runs $\mathsf{Reconst}_{N,d,q}(\left\{y^{(i)}\right\}_{i\in[N]})$ that outputs a degree-$(\ell-1)$ polynomial with coefficients $x^{(1)}, \cdots, x^{(\ell)}$.

The concrete communication cost to open $\ell = (N_s - t_s)$ secret-shares is $2N_s$ elements by each server as $t_s < N_s/4$ in this work. The computational cost by each server is $\frac{3}{4}{N_s}^2$ field multiplications/additions and two instances of $\mathsf{Reconst}_{N_s,d,q}$.

Algebraic MPC over Shamir's Shares We use a MPC protocol of basic arithmetic operations secure against malicious adversary with corruption threshold $t_s < N_s/4$ where a point-to-point authenticated communication and a broadcast channels are available to the MPC servers [3,4,15]. Let x and y be two secret input values and z be a public input values over a prime field $\mathbb{F}_q$. Then, the following secure arithmetic computations will be used to build our anonymous broadcast protocol:

1. **Share addition:** Each party holds input secret-shares ${}^d[\![x]\!]_q$ and ${}^d[\![y]\!]_q$, then locally computes ${}^d[\![x]\!] + {}^d[\![y]\!] = {}^d[\![x+y]\!]$

2. **Share multiplication**: Each party holds input secret-shares ${}^d[\![x]\!]$ and ${}^d[\![y]\!]$, then locally computes ${}^d[\![x]\!] \cdot {}^d[\![y]\!] = {}^{2d}[\![x \cdot y]\!]$.

3. **Scalar multiplication:** Each party holds input secret-shares ${}^d[\![x]\!]$ and a publicly known scalar z, then locally computes ${}^d[\![x]\!] \cdot z = {}^d[\![x \cdot z]\!]$.

4. **Scalar addition:** Each party holds input secret-shares ${}^{d}[\![x]\!]$ and a publicly known scalar z, then locally computes ${}^{d}[\![x]\!]+z={}^{d}[\![x+z]\!]$.

In this work, we design our algebraic circuits to only have the maximum multiplication depth 1. Therefore, secure multiplications over two d-shares ${}^{d}[\![x]\!]_q$ and ${}^{d}[\![y]\!]_q$ in our work will be simply local multiplications as ${}^{2d}[\![xy]\!]_q={}^{d}[\![x]\!]_q{}^{d}[\![y]\!]_q$ resulting in a $2d$-share. Note that xy cannot be reconstructed by directly applying $\mathsf{Reconst}_{n,d,q}$ on the $2d$-shares due to non-trivial information being leaked about secrets x and y. Thus, we rerandomize the $2d$-shares output by local multiplications of two shares by employing preprocessed random double sharing [15] (see Section 2.1). A random double sharing is a pair of ${}^{d}[\![r]\!]_q$ and ${}^{2d}[\![R]\!]_q$ such that r is a uniformly random secret over $\mathbb{F}_q$ and $r=R$. With ${}^{d}[\![r]\!]_q$ and ${}^{2d}[\![R]\!]_q$, we rerandomize ${}^{2d}[\![xy]\!]_q$ by computing ${}^{2d}[\![xy]\!]_q+{}^{2d}[\![R]\!]_q-{}^{d}[\![r]\!]_q$.

Security of Algebraic MPC In this work, we rely on standard MPC components and protocols from secure MPC protocols [3, 4, 15, 20] that securely realizes necessary MPC functionalities such as additions, multiplications, coin flip, etc., in the honest-majority setting. Specifically, we use the MPC components to construct our AB protocol by designing algebraic circuits of our AB functionality and composing the standard MPC protocols to securely evaluate the algebraic circuits. The protocol is secure as long as the number of corrupted servers $t<\frac{N_s}{4}$ where the arbitrary composition of protocols preserves the security [4, 9, 15].We describe our protocols in the hybrid model following [9] where the security of protocol Π that runs a subprotocol Π_{sub} is guaranteed even if Π_{sub} is replaced with its ideal functionality $\mathcal{F}_{sub}$. In such case, we say that Π is a secure protocol in the $\mathcal{F}_{sub}$-hybrid model.

Coin Flip We use a coin flip functionality denoted by $\mathcal{F}_{coin}$ when invoked with parameters a prime number q and $\ell\in\mathbb{Z}^+$ produces a set of ℓ field elements uniformly sampled random from $\mathbb{F}_q$ to participating servers. We can realize the functionality with information theoretic security by using a random sharing protocol (described later in this section) where all parties preprocess ℓ random shares over $\mathbb{F}_q$ and open them when the coins are necessary.

Offline Functionalities/Protocols Our AB protocol executes standard offline MPC protocols to prepare (correlated) randomness information that it uses during the execution of the main MPC protocols. In the MPC literature, we call these protocols/functionalities *offline* computation/functionality so that MPC servers before getting their inputs execute these protocols to prepare randomness or correlated information to execute the main MPC protocol upon their inputs. We use the following offline functionalities and see [15] for more details:

1. **Random Sharing:** A random sharing functionality denoted by $\mathcal{F}_{rand}$ takes N, degree d, and $\ell\in\mathbb{Z}^+$ and outputs consistent d-sharings of ℓ random field elements from $\mathbb{F}_q$.

2. **Random Double Sharing:** A random double sharing functionality denoted by $\mathcal{F}_{DouRan}()$ takes parameters N, degree d, and $\ell\in\mathbb{Z}^+$ and outputs ℓ pairs of $({}^{d}[\![r_i]\!],{}^{2d}[\![R_i]\!])$ such that random $r_i=R_i$ for all $i\in[\ell]$.

We measure the offline efficiency of a protocol by the number of random double sharings required to execute its online phase protocol.

2.2 Anonymous Broadcast

An anonymous broadcast (AB) functionality is involved with N_s servers, denoted by $P_1,P_2,\cdots,P_{N_s}$, which jointly serve at maximum N_c clients[3], in an epoch such that $N_s\ll N_c$. An adversary $\mathcal{A}$ may corrupt at most t_s servers as well as at most t_c clients where we require $t_s<N_s/c$ for some constant at least 2 while $t_c<N_c$. Given these, we define the ideal robust AB functionality as follows.

Definition 1 (Robust AB Functionality $\mathcal{F}_{AB}$)**.** *Let $C_1,C_2,\cdots,C_{N_c}$ be participating clients where C_i has secret message m_i such that an adversary $\mathcal{A}$ controls at most t_c clients for some $t_c<N_c$. Let a client message be represented as a field element over a prime field $\mathbb{F}_q$ for some prime q. Then, the ideal AB functionality denoted by $\mathcal{F}_{AB}$ proceeds as follows:*

1. *Functionality $\mathcal{F}_{AB}$ initialize an empty set H and waits for a message $m_i\in\mathbb{F}_q$ from each client.*

2. *An adversary $\mathcal{A}$ may select and corrupt up to t_c clients and instruct these clients to send any message from $\mathbb{F}_q\cup\{\perp\}$ where $\perp$ is a special character indicating an invalid input message.*

3. *Upon each m_i's, $\mathcal{F}_{AB}$ checks if $m_i=\perp$. If so, drop it. Otherwise, add m_i to H.*

4. *Once all messages are received from all participating clients, $\mathcal{F}_{AB}$ shuffles m_i's in H and outputs the messages in a random order.*

We note that the above definition of functionality formalizes the *robust* anonymous broadcast functionality in the presence of malicious adversary. That is, regardless of the malicious activities orchestrated by an adversary $\mathcal{A}$, the functionality $\mathcal{F}_{AB}$ is guaranteed to receive, mix, and publish messages from all honestly behaving clients. The fair AB functionality will allow an adversary to terminate the protocol execution without delivering the messages to clients. Hence, the ideal

[3] In general, N_c is a public parameter that sets only the maximum number of messages per epoch, while not limiting the total number of clients.

functionality for fair AB can be defined by modifying Step 4 in the above definition as follows: Upon completion of shuffling messages in H, $\mathcal{F}_{AB}$ asks if $\mathcal{A}$ wishes to obtain the messages. Finally, if $\mathcal{A}$ responses with $\perp$, then $\mathcal{F}_{AB}$ outputs $\perp$ to all clients and $\mathcal{A}$. Otherwise, $\mathcal{F}_{AB}$ outputs all the messages to clients as well as $\mathcal{A}$. Finally, unfair AB functionality allows an adversary to obtain all messages from honest clients and to determine which messages from honest clients are published. For this definition, Step 4 is modified as follows: Upon completion of shuffling messages in H, $\mathcal{F}_{AB}$ sends all the shuffled messages to $\mathcal{A}$. Then, $\mathcal{A}$ returns to $\mathcal{F}_{AB}$ a subset of messages denoted by H'. $\mathcal{F}_{AB}$ then publishes messages in H'.

3 Warm-up Protocol

To provide the intuition behind the mixing protocol, we start with the most basic mixing protocol where all servers and clients are assumed to follow the protocol. The toy protocol can be seen as a variant of PowerMix [27] where the server computation and c-to-s communication are re-balanced so that server computation is minimized at the cost of high c-to-s communication.

Algebraic Mixing Protocol Consider that clients C_i want to send a message $m_i \in \mathbb{F}_q$. The algebraic mixing protocol is based on Newton's identities. The mixing protocol can be summarized as a three-step process. First, suppose that mixing committee servers have the shares of the j-th powers of each $[\![m_i]\!]$ for each $j \in [N_c]$, that is, $[\![{m_i}^1]\!]$, $[\![{m_i}^2]\!]$, $\cdots$, $[\![{m_i}^{N_c}]\!]$. Then, the servers jointly compute power sums $x_j = {m_1}^j + {m_2}^j + \cdots + {m_{N_c}}^j$ for each power j (i.e., by locally summing the shares of the same power and reconstructing the sums). Note that computing power sums is an essential step to achieve desired mixing property. This step converts all message power encodings into order-independent aggregate values due to commutativity of additions. The second step is to locally compute a degree-N_c polynomial $f(x) = x^{N_c} + c_{N_c-1}x^{N_c-1} + \cdots + c_0$ such that $f(x)$'s roots are $m_1, m_2, \cdots m_{N_c}$ by using Newton's identities [29, 41] on the power sums to recursively compute the coefficients as follows:

$$
\begin{aligned}
c_{N_c-1} &= -x_1 \\
c_{N_c-2} &= -(x_2 + c_{N_c-1}x_1)/2, \\
c_{N_c-3} &= -(x_3 + c_{N_c-1}x_2 + c_{N_c-2}x_1)/3, \\
&\cdots
\end{aligned}
$$

We denote this procedure by $\mathsf{NewtonId}(x_1, x_2, \cdots, x_{N_c})$. The computation of $\mathsf{NewtonId}$ takes ${N_c}^2/2$ additions and multiplications. See [29] for more details on Newton's identities.

Finally, the servers locally executes a root-finding algorithm $\mathsf{RootFind}$ on $f(x)$ which eventually outputs roots of $f(x)$ which are $m_1, m_2, \cdots, m_{N_c}$ in a random order.

We instantiate $\mathsf{RootFind}$ with a randomized algorithm by Grenet, Hoeven, and Lecerf (algorithm 11 in [23]) which finds roots of polynomial $f(x)$ of degree d over a prime field $\mathbb{F}_q$ with prime $q = M \cdot 2^m + 1$ where $d < q$ and $M = O(\log q)$, and 2^m is chosen to be much larger than the number of terms to be found. The average running time of the root finding algorithm is $O(d(\log^3 q \log d + \log^4 q))$.

Naive Client Message Encoding Suppose that a client wishes to broadcast message m, a field element in $\mathbb{F}_q$. A client first needs to encode m into an AM-friendly format. With N_c being the number of participating clients in an epoch, a naive AM-friendly encoding $\mathsf{E}^0 : \mathbb{F}_q \to (\mathbb{F}_q)^{N_c}$ is simply the ordered set $\mathsf{E}^0(m) = \mathsf{pkg}_m = \{m^1, m^2, \cdots, m^{N_c}\}$.

Warm-up Protocol Let N_c and N_s be the numbers of clients and servers respectively. First, each client with message m locally computes $\mathsf{E}^0(m)$, secret-shares pkg_m, and send the shares $[\![\mathsf{pkg}_m]\!]$ to appropriate servers. Each server wait for all client message submissions and then locally compute the shared sums of powers described above over secret-shares. Finally, servers will jointly open the sums of powers and locally computes a symmetric polynomial and run $\mathsf{RootFind}$ to output mixed client messages. As long as all clients and servers honestly follow the protocol, this warm-up protocol is immediately correct. The protocol is secure as only the sums of powers are opened whereas all individual powers of messages remain shared.

4 Compressing C-to-S Communication

In this section, we describe how to optimize the warm-up protocol so that client's computation and c-to-s communication per server are sub-linear in the number of clients.

The First Attempt We observe that a sequence of N_c powers of a field element can be encoded into a set of $2\sqrt{N_c} - 1$ field elements in a way that the original N_c powers can be recovered (decompressed) with multiplications of two elements from the encoding. In the further details, consider that N_c is a square of some integer and a client has a message m. Then, the client can encode m into $\left\{m^1, m^2, \cdots, m^{\sqrt{N_c}-1}, m^{\sqrt{N_c}}, m^{2\sqrt{N_c}}, \cdots, m^{(\sqrt{N_c}-1)\sqrt{N_c}}\right\}$ instead of the entire sequence of N_c powers. Given this subset of powers of m, it is easy to see that multiplications of two entries from the subset will give $\{m^1, m^2, \cdots, m^{N_c}\}$ where we call this computation *an input decompression*. The size of the naive encoding is $2\sqrt{N_c} - 1$.

Additive 2-basis Above, we observe that multiplications of two encodings to enumerate all N_c powers are essentially additions of two entries' exponents to enumerate all exponents

from 1 to N_c. In mathematics, the later is known as an additive 2-basis for set $[N_c]$. We adopt the classical optimization of the additive 2-basis due to Mrose [39]. We denote Mrose's additive 2-basis for a set $[N_c]$ by $\mathcal{B}_{N_c}$ defined as follows. Let N be $N = 14L^2 + 10L - 1$, then additive 2-bases $\mathcal{B}$ for set $[N]$ contains five distinct finite arithmetic progressions:

$$S_1 = \{1 + (i-1)1 \mid \forall i \in \mathbb{Z} \text{ s.t. } 1 \le i \le L\},$$
$$S_2 = \{2L + (i-1)L \mid \forall i \in \mathbb{Z} \text{ s.t. } 1 \le i \le 3L\},$$
$$S_3 = \{3L^2 + 2L + (i-1)(L+1) \mid \forall i \in \mathbb{Z} \text{ s.t. } 1 \le i \le L\},$$
$$S_4 = \{6L^2 + 4L + (i-1)1 \mid \forall i \in \mathbb{Z} \text{ s.t. } 1 \le i \le L+1\},$$
$$S_5 = \{10L^2 + 7L + (i-1)1 \mid \forall i \in \mathbb{Z} \text{ s.t. } 1 \le i \le L+1\}.$$

The sizes of arithmetic progressions are: $|S_1| = |S_3| = L$, $|S_2| = 3L$, and $|S_4| = |S_5| = L+1$ so that $|\mathcal{B}| = 7L+2$ in total. Approximately, $7N \approx 2|\mathcal{B}|^2$, so that the size of the additive 2-basis $|\mathcal{B}| \approx \sqrt{\frac{7N}{2}}$ which leads to $|\mathcal{B}| \approx 1.87\sqrt{N}$ and $L \approx 0.267\sqrt{N}$. See [32] and [31] for further details and another variant with the same asymptotic properties.

Decompressing $\mathcal{B}$ to set $[N]$ can be done by adding two entries from the basis in a certain way. Due to space restriction, we provide the additive 2-basis decompression circuit $\mathsf{Decomp}(\cdot)$ in Circuit 1 in Appendix A.

Client's Input Encoding/Submission Now we describe how a client with message $m \in \mathbb{F}_q$ submits its messages to servers. Let $N_c = 14L^2 + 10L - 1$ be *the maximum number* of participating clients in an epoch for some integer L.[4] Given the corresponding (precomputed) additive 2-basis $\mathcal{B}$, a client with message m simply encodes m by computing $m^{\mathcal{B}}$, denoted by pkg. Then, the client computes the secret-sharing ${}^{t_s}[\![\mathsf{pkg}]\!]_q$ by running $\mathsf{Share}_{N_s,t_s,q}(x_i)$ for each $x_i \in \mathsf{pkg}$ and send ${}^{t_s}[\![\mathsf{pkg}]\!]_q$ to servers accordingly. We denote this client input encoding submission protocol by Π_{submit} that takes a client input message m and servers outputs their shares of ${}^{t_s}[\![\mathsf{pkg}]\!]_q$ at the end of protocol.

Protocol 2: Client Message Submission Protocol Π_{submit}

Parameters: Prime q, the number of clients N_c, the number of servers N_s, the server corruption threshold t_s, and the additive 2-basis $\mathcal{B}$.
Input: Client C holds a message m defined over $\mathbb{F}_q$.
Output: Servers output the secret-shares of ${}^{t_s}[\![\mathsf{pkg}]\!]_q$.

1: C computes $\mathsf{pkg}_m \leftarrow m^{\mathcal{B}}$.
2: C computes ${}^{t_s}[\![\mathsf{pkg}]\!]_q \leftarrow \mathsf{Share}_{N_s,t_s,q}(\mathsf{pkg}_m)$.
3: C sends the i-share of ${}^{t_s}[\![\mathsf{pkg}]\!]_q$ to S_i.

Each client's communication complexity is $1.87\sqrt{N_c}$ field elements per server. The computational complexity is $1.87\sqrt{N_c}$ multiplications followed by the computational cost from $1.87\sqrt{N_c}$ instances of Shamir's secret-sharing. We note that both complexities of computing and transmitting a client message encoding based on the additive 2-basis offers roughly 10% improvement compared to the ones based on the first attempt encoding described above where the message encoding is of size $2\sqrt{N_c} - 1$.

[4] We remind that N_c is a public system parameter that upper-bounds the number of participating clients in an epoch and *does not require* the number of clients to be N_c in order for the AB protocol to work. That is, the RabbitMix's functionality works correctly even if the actual participating clients is smaller than N_c in an epoch.

Decompressing Client Input Shares Upon clients' shared input message encodings ${}^{d}[\![m^{\mathcal{B}}]\!]_q$, the servers locally decompress them to the secret-shares of $m^{[N_c]}$. Having the additive 2-basis $\mathcal{B}$ as exponents in the message encoding, the encoding decompression to shares of $m^{[N_c]}$ can be done by locally computing ${}^{2d}[\![m^i]\!]_q = [\![m^i]\!] \cdot [\![m^j]\!]$ from ${}^{d}[\![m^{\mathcal{B}}]\!]_q$, whenever the additive 2-basis decompression requires the addition of i and j from B. Note that the resulting output shares are the $2d$-secret-shares of N_c powers of message m that has degree at most $2d$ as the maximum multiplication depth is 1. We denote this decompression protocol by $\Pi_{Decomp}({}^{d}[\![m^{\mathcal{B}}]\!]_q)$ that takes as inputs secret-shares ${}^{d}[\![m^{\mathcal{B}}]\!]_q$ and outputs ${}^{2d}[\![m^{[N_c]}]\!]_q$. See Protocol 4 for the full description in Appendix B.

The correctness immediately follows from the property of additive 2-basis decompression described in Circuit 1 as the decompression here is carried out on the exponents via the secure multiplications. The computational costs of the decompression protocol is essentially $14L^2 + 9L \approx N_c - 0.267\sqrt{N_c}$ field multiplications.

5 Input Well-formedness Verification

Malicious clients may deviate in two distinct ways from the protocol instruction submitting shares of malformed message packages. The first deviation strategy is that a malicious client submits a t-consistent shares of an input message encoding but the encoding does not agree with (is not well-formed w.r.t.) the additive 2-basis format. The second is that a malicious client submits inconsistent shares of an input message encoding. In both cases, the AB protocol will fail to output messages. To defeat such DoS attacks, servers must ensure that input message packages are (1) well-formed according to the additive 2-basis for N_c and (2) t-consistent. In the section, we present an efficient input encoding verification protocol by devising an efficient distributed verification protocol to defeat the first adversarial strategy. Looking ahead, we will show how to defeat the second strategy in Section 7.

Verifiable Input Encoding Let $N_c = 14L^2 + 10L - 1$, $\mathcal{B} = \{S_1, S_2, \cdots, S_5\}$ be the additive 2-basis for N_c described in the previous section and finally m be a client message. Once a client completes the submission of message m, servers holds the secret-sharings of input package $\mathsf{pkg} = \{x_1, x_2, \cdots, x_{7L+2}\}$. Let sets $X_1, X_2, \cdots, X_5$ be the 5 partitions of pkg where each X_i corresponds to m^{S_i} with denoting the

elements of set X_i by $x_{i,1}, x_{i,2}, \cdots$. Then, servers must jointly verify that $\mathsf{pkg} = \{m^{\mathcal{B}}\}$ for some m. This essentially means that the servers must be able to verify that the linear relations of the arithmetic progressions S_1, S_2, $\cdots$, S_5 appear as exponents of m in the fixed order. We have two distinct types of conditions to verify:

- **(Inner-Progression)** This type, called inner-progression of X_i is about whether each set X_i have an arithmetic progression of S_i as exponents. We define b_i^0 to be a linear sketch which is 0 only if the inner progression of X_i is satisfied. If an input package pkg is well-formed according to $\mathcal{B}$, then all b_i^0's will be 0.
- **(Inter-Progression)** This condition type, called inter-progression of X_i for $i \in \{2, \cdots, 5\}$ is about whether X_i's first element is correctly formed in relation to two elements in X_j for $j < i$. We define b_i^1 to be a linear sketch which is 0 only if the first element of X_i is indeed the first element of m^{S_i}.

In order to verify these conditions, we essentially exploit an system of degree-2 verification to which a client message encoding of additive 2-basis is a unique solution.

Inner Progression Verification We outline how to compute linear sketches for inner-progression conditions. Recall $S_1 = \{1, 2, \cdots, L\}$ starting from 1. This implies $x_{1,1} = m$. Then, we can define linear sketch $b_1^0 = \sum_{i=1}^{L-1} c_i(x_{1,i+1} - x_{1,i} \cdot x_{1,1})$ for random coin c_i's such that $b_1^0 = 0$ if the inner condition holds for X_1. The random coin c_i is distributed uniformly and must be multiplied to $x_{1,i+1} - x_{1,i} \cdot x_{1,1}$ to prevent an adversary from maliciously choosing S_1 such that $0 = \sum_{i=1}^{L-1}(x_{1,i+1} - x_{1,i} \cdot x_{1,1})$. Linear sketches b_2^0, b_4^0, and b_5^0 for X_2, X_4, and X_5 can be similarly defined as b_1^0 relying on the existing entries in pkg.

Defining b_3^0 for X_3 requires adding an additional element to the client's input encoding for the verification purpose. S_3 is an arithmetic progression of difference $L+1$ which does not exist in S_1 nor S_2 and can only be computed from the addition of 1 and L from S_1 which creates an additional multiplication depth for the verification. We bypass this by introducing a new ordered set denoted by S_6 that contains $L+1$. Then, the input submission package of message m has additionally X_6 with $x_{6,1} = {x_{1,1}}^{L+1}$ which is supposedly m^{L+1} for message m. Given $x_{6,1}$, the linear sketch of inner progression for X_3 is defined as $b_3^0 = \sum_{i=1}^{L-1} c_i(x_{3,i+1} - x_{3,i} \cdot x_{6,1}) + c(x_{6,1} - x_{1,1} \cdot x_{1,L})$ for random coins c_i and c where the computation still has multiplication depth 1. Note that $b_3^0 = 0$ only if the inner progression condition for X_3 is satisfied and $x_{6,1}$ is ${x_{1,1}}^{L+1}$.

Inter Progression Verification Except for X_1, each X_i's first element needs to be verified to be correct. If the first element of X_i is incorrect, then it is possible for X_i to still satisfy its inner progression while not matching with the correct additive 2-basis. Specifically, for each $i \in \{2, \cdots, 5\}$, we want to ensure $x_{i,1} = {x_{1,1}}^{s_{i,1}}$.

The linear sketch of inter progression for X_2 can be simply computed as $b_2^1 = c(x_{1,L} \cdot x_{1,L} - x_{2,1})$ for fresh random coin c since $s_{2,1} = 2L$ and $s_{1,L} = L$. The inter progression linear sketch for X_3 is also simple to compute as $b_3^1 = c(x_{2,3L} \cdot x_{1,L} - x_{3,1})$ for fresh random coin c. Also, the inter progression linear sketch for X_4 is simply computed as for fresh random coin c, $b_4^1 = c(x_{4,1} - x_{3,1} \cdot x_{3,1})$.

Verifying inter progression for X_5 requires a special treatment. S_5's first element is $10L^2 + 7L$ that cannot be expressed as a product of two elements in X_1, X_2, X_3, or X_4. Therefore, to keep multiplication depth 1 in general, we introduce a new exponent $s_{6,2}$ into S_6 such that (1) $s_{6,2}$ is an addition of two elements in any of S_j for $j < 5$ and (2) the exponent of X_5's first element (which is $10L^2 + 7L$) is an addition of $x_{6,2}$ and another element x in any of S_j for $j < 5$. We choose $s_{6,2}$ to be $10L^2 + 7L - 1$ additionally introduced into S_6 which is (1) an addition of $s_{3,L} = 4L^2 + 2L - 1$ and $s_{4,L+1} = 6L^2 + 5L$ from X_3 and X_4 respectively and (2) satisfies that $s_{5,1}$ is an addition of $s_{6,2} + s_{1,1}$. Hence, the linear sketch of inter progression for X_5 is defined as $b_5^1 = c_1(x_{5,1} - x_{6,3} \cdot x_{1,1}) + c_2(x_{6,3} - x_{3,L} \cdot x_{4,L+1})$ for fresh random coins c_1 and c_2.

In fact, the additive 2-basis based client message encoding by itself is verifiable without requiring introduction of S_6. We defer this to the full version of the paper.

Verifiable Input Encoding/Submission Due to space restriction, we provide the full description of the client input submission protocol with well-formedness verfiability (Protocol 5) in Appendix D. The new protocol is identical to the encoding/submission protocol described in Section 4 except adding $S_6 = \{L+1, 10L^2 + 7L - 1\}$ to additive 2-basis $\mathcal{B}$. Thus, with two additional field elements, the c-to-s communication cost is $7L + 4$ field elements per server which is still approximately $1.87\sqrt{N_c}$. The new input submission protocol $\Pi_{Submit}(m)$ will have client with input message m computes and secret-shares m^{S_i} for $i \in [6]$ and finally send the shares to servers accordingly.

Input Well-formedness Verification Protocol For the well-formedness verification, servers proceed as follows. Once they receive a secret-shared client input package pkg, they run coin-flip protocol $\mathcal{F}_{coin}$ to generate $1.87\sqrt{N_c}$ random coins. Then, each server locally computes the secret-share of sum of all linear sketches ${}^{2t}[\![b]\!]_q = \sum_{i=0}^{1} \sum_{j=1}^{5} {}^{2t}[\![b_j^i]\!]_q$. Finally, servers jointly reconstruct and check b. If $b = 0$, servers will keep pkg, otherwise delete it. Note that it is possible that $b = 0$ with probability $1/|\mathbb{F}|$ while the input is malformed. Let κ be the statistical soundness parameter. The above verification needs to be executed $\kappa / \log q$ times with independent input challenge c_i's to achieve the desired soundness error probability $1/2^{\kappa}$. We denote the well-formedness verification protocol by $\Pi_{ver}()$ and see Protocol 6 in Appendix E.

6 Rabbit-Mix against Malicious Adversaries

We describe our secure Rabbit-Mix protocol secure against malicious clients and servers without fairness. Looking ahead, we transform this unfair AB protocol into a robust protocol with tools for robustness in Section 7. We put together all the pieces built so far into an anonymous broadcast protocol that securely realizes the functionality $\mathcal{F}_{AB}$ according to Definition 1. The complexity analysis will be provided in Section 8.

Protocol 3: Anonymous Broadcast Π_{AB}

Input Parameters: Let q be a prime. Let $N_c = 14L^2 + 10L - 1$ be the number of participating clients in the current epoch. Let N_s be the number of servers.

Preprocessed Information: $2N_c$ *consistent* random double sharings $({}^t[\![r_i]\!], {}^{2t}[\![R_i]\!])$ for $i \in [N_c]$ prepared by running $\mathcal{F}_{DouRan}(N_c)$ in the offline phase. In addition, μ sets of $(7L+3)$ random coins each denoted by $\left\{c^{(i)}\right\}_{j\in[7L+3]}$ prepared by invoking $\mathcal{F}_{coin}(\mu(7L+4))$ such that $\mu = \kappa/\log q$.

Input: All servers receive and hold message package shares ${}^t[\![\mathsf{pkg}^{(i)}]\!]_q$ from all clients C_i via Π_{submit} (Protocol 5 in Appendix D). A set of identified malicious clients $\mathcal{C}^*$ initialized to be an empty set.

Output: The servers output $m_1, m_2, \cdots, m_{N_c}$ in a randomly shuffled order.

1: **(Format Verification)**: repeat μ times with random coins.
2: Each server locally computes for each $i \in [N_c]$, ${}^{2t}[\![b^{(i)}]\!]_q \leftarrow \Pi_{ver}([\![\mathsf{pkg}^{(i)}]\!], \left\{c^{(i)}\right\})$.
3: All servers open all $b^{(i)}$'s as $\Pi^{robust}_{open}(\left\{{}^{2t}[\![b^{(i)}]\!]_q\right\})$.
4: Each server updates set $\mathcal{C}^*$: for every $i \in [N_c]$, do the followings:
   1. If any opening returns $\perp$, output $\perp$ and terminate.
   2. If $b^{(i)}$ is a non-zero value, add the client to $\mathcal{C}^*$.
5: Set $\mathcal{C}^H = \mathcal{C} \setminus \mathcal{C}^*$, a set of clients' indexes that submitted inputs of valid format.
6: **(Input Decompression and Mixing)**
7: Each server locally runs for each $i \in \mathcal{C}^H$, $\Pi_{Decomp}([\![\mathsf{pkg}^{(i)}]\!])$ to decompress the input shares into $\{[\![m_i{}^1]\!], [\![m_i{}^2]\!], \cdots, [\![m_i{}^{N_c}]\!]\}$.
8: Each server locally computes for each $j \in [N_c]$, $[\![x_j]\!] = \sum_{i\in\mathcal{C}^H}[\![m_i{}^j]\!]$.
9: All servers open all x_j's by running $\Pi^{robust}_{open}(\{[\![x_j]\!]\})$.
10: Locally apply Newton's identity to compute a symmetric polynomial $f(x)$ of degree N_c using x_j's.
11: Run the root finding algorithm RootFind on $f(x)$ which returns the set of $\{m_i\}_{i\in\mathcal{C}^H}$ in a shuffled order which is the protocol output.

Theorem 1. *For any malicious adversary corrupting some constant $t_c < N_c$ clients and $t_s < N_s/4$ servers and for any client messages $m_1, m_2, \cdots, m_{N_c}$, protocol Π_{AB} securely and statistically realizes unfair $\mathcal{F}_{AB}$ with anonymity set size at least $N_c - t_c$ as defined in Definition 1.*

Proof. Intuitively, our simulator (ideal world adversary) $\mathcal{S}$ simulates the view of adversary in the real execution with an access to the ideal functionality $\mathcal{F}_{AB}$. Let $\mathcal{A}$ be an adversary corrupting less than t_s servers. $\mathcal{S}$ starts simulating honest servers' computation by initiating C^* to be an empty set and invoking $\mathcal{F}_{AB}$. $\mathcal{S}$ locally computing verification circuit on corrupted clients' input shares given by $\mathcal{A}$. Then, $\mathcal{S}$ opens every verification bit b_i for the i-th submitted input message. If any reconstructions fail, $\mathcal{S}$ sends a termination signal to $\mathcal{F}_{AB}$ and ends the simulation. Otherwise, $\mathcal{S}$ updates C^* with i's such that $b_i \neq 0$. $\mathcal{S}$ simulates the rest: it obtains all corrupted clients' inputs $\{m_i\}$ such that $m_i = \perp$ for $i \in C^*$. $\mathcal{S}$ sends corrupted clients inputs to functionality $\mathcal{F}_{AB}$ which returns all messages $\{m_i\}$ including honest clients' messages. $\mathcal{S}$ simulates the rest of interaction to provide $\mathcal{A}$ with $\{m_i\}$ by simulating Π^{robust}_{open} where $\mathcal{S}$ possibly obtains a subset of $\{m_i\}$ as its output. Finally, $\mathcal{S}$ submits the returned subset of $\{m_i\}$ to $\mathbb{F}_{AB}$ and completes the simulation. The view of adversary in the real execution is identical to the simulated view in the ideal execution except with probability $t_c/2^\kappa$ where κ is a security parameter since two views are different when $\mathcal{A}$ in the real execution succeeds to pass input well-formedness verification with malformed message packages from corrupted clients. We note that the sender-anonymity is guaranteed regardless of adversary's strategy since messages from honest clients are reconstructed only at the end of protocol after the algebraic mixing is correctly completed. □

Handling Large Messages The above description assumes that the maximum message length of clients is upper-bounded by $\log|\mathbb{F}|$ bits. For larger messages, we let clients and servers do as follows: now clients and servers have an additional parameter for the maximum number of sub-messages per epoch, denoted by μ. Clients then partition their messages into μ sub-messages each attached with the same random tag τ of fixed length (e.g., statistical parameter $\kappa \geq 40$) so that m is partitioned into $m_1||\tau, \cdots, m_\mu||\tau$ where each $m_i||\tau$ can be encoded in $\mathbb{F}$. Then clients submit each sub-message to mixing servers. To avoid deanonymization by different message lengths, clients with shorter messages must pad their messages. Servers wait for all clients completing the submissions of all μ sub-messages (one sub-message for each AB protocol instance). Once all submissions are completed, servers execute the μ instances of AB protocol. Since servers don't execute AB protocols until all sub-messages arrive, corrupted servers/clients cannot corrupt messages with identical tags except with very small chance.

7 Rabbit-Mix with Robustness

We transform the AB protocol in Section 6 to provide the robustness as described in Section 2.2. The main technical problem is that bad shares can be dealt by malicious clients or

servers so that batch reconstruction fails to reconstruct secrets resulting in the abort of protocol execution. This means there are two places that should be upgraded for Protocol 3 to be robust according to Definition 1: (1) client message input submission protocol and (2) random double sharing protocol (including random sharing protocol). Obviously, using a verifiable secret sharing (VSS) protocol, for example [6], to deal every secret for both protocols will immediately resolve the entire technical issue, resulting in a robust AB protocol. However, VSS protocols are expensive, relying on the interactions of multiple rounds or other heavy cryptography tools. Hence, we rely on the combination of dispute control techniques as well as lightweight robust input protocol by [5, 15] discussed below.

Robust Input Submission Protocol The robust input submission protocol denoted by Π^{robust}_{Submit} must guarantee that all honest servers receive consistent secret-shares ${}^{t_s}[\![\mathsf{pkg}]\!]_q$. Such input submission protocol can be realized using offline and online phases [5, 15]. In the offline phase, recipient servers jointly computes $[\![r]\!]$ for a random value r (in the robust way, described in the next subsection) and sends the shares to a client and the client recovers r from the shares. In the online phase, the client now having secret input x to be shared computes $x-r$ and *broadcasts* it to servers. Here, a broadcast channel is a cryptographic broadcast channel where it is guaranteed for all receivers to received the same data. Then, the servers locally compute their shares $[\![x]\!] = (x-r) - [\![r]\!]$. We provide the analysis on the amount of data to be broadcasted and compare with other relevant works in Section 8. We note that Protocol 3 is a fair protocol if input message packages are submitted by Π^{robust}_{Submit} so that the input shares are guaranteed to be t_s-consistent.

Robust Double Random Protocol The robust double random functionality denoted by $\mathcal{F}^{Robust}_{DouRan}()$ takes as input a positive integer ℓ, and outputs ℓ pairs of double random sharings in a batched way regardless of an adversary's disruption strategy. In this work, we simply adopt a robust double random protocol that securely realizes $\mathcal{F}^{Robust}_{DouRan}()$ from [1, 20] which relies on an elegant non-interactive dispute control [5, 15]. Due to space restriction, we refer the reader to further discussion and protocol description in [1, 20].

For the case of small number of servers, $\mathcal{F}^{Robust}_{DouRan}()$ can realized in a non-interactive manner removing communication during the offline phase by using Pseudo-Random Secret Sharing (PRSS). In this way, servers generate double random sharings by relying only on local evaluations of pseudo-random functions on seeds pre-distributed only once at the initialization of servers [7]. We refer to Appendix F for the further discussion of corresponding parameters and efficiency.

With replacing Π_{Submit} with Π^{robust}_{Submit} and $\mathcal{F}_{DouRan}$ with $\mathcal{F}^{Robust}_{DouRan}$ in Protocol 3, we finally have our robust Rabbit-Mix protocol.

Theorem 2. *Define Π^{robust}_{AB} to be the protocol obtained from modifying Π_{AB} (Protocol 3) as follows: (1) clients submit their messages by using Π^{robust}_{submit} and (2) servers compute double random shares by running $\mathcal{F}^{Robust}_{DouRan}$. Then, for any malicious adversary corrupting up to $t_c < N_c$ clients and $t_s < N_s/4$ servers and for any client messages $m_1, m_2, \cdots, m_{N_c}$, protocol Π^{robust}_{AB} securely realizes robust anonymous broadcast functionality $\mathcal{F}_{AB}$ with the anonymity set size at least $N_c - t_c$ as defined in Definition 1.*

Proof. The security and correctness of Π^{robust}_{AB} follow from the security and correctness of Protocol 3 with the similar simulation strategy. Intuitively, the robustness is guaranteed as follows. By the robustness guarantees of $\mathcal{F}^{robust}_{DouRand}$, the preprocessed correlated randomness $({}^{t_s}[\![r_i]\!], {}^{2t_s}[\![R_i]\!])$ is guaranteed to be t_s-consistent such that all honest servers hold consistent shares. In addition, Π^{robust}_{submit} guarantees that client input shares ${}^{t_s}[\![\mathsf{pkg}^{(i)}]\!]_q$ are t_s-consistent as well. Therefore, all $[\![b^{(i)}]\!]$'s at Step 3 and all $[\![x_j]\!]$'s at Step 8 are $2t_s$-consistent regardless of an adversary's strategies so that Π^{robust}_{open} always succeeds to reconstruct all secret shares to honest servers. Therefore, Π^{robust}_{AB} always outputs honest clients' messages. □

8 Concrete Complexity Analysis

We present the in-depth communication and computation cost estimates and comparisons to relevant anonymous broadcast protocols with fairness at minimum, Blinder [1], Switch-Network and PowerMix [27].

Online Communication We present communication cost estimates: the first is the c-to-s communication cost is the number of field elements broadcast by a client to each server. Recall that the robust input submission protocol described in Section 7 requires a client to broadcast message package masked by random elements. Hence, we provide the number of field elements to be broadcast per client. The second is the per-client/per-server s-to-s communication cost which is the number of field elements to be transmitted over point-to-point authenticated (P2P) channels. See Table 2. We note that the server communication for Blinder and our protocol do not include the communication incurred by computing random coins. Random coins can be computed by either (1) opening as many random shares as required using the batch opening protocol or (2) opening a single random share and then applying a pseudo-random generator on the reconstructed randomness. We provide the required number of random coins and corresponding necessary offline resources in Table 5.

Communication vs. Blinder Note that Blinder's complexities are estimated based on the protocol with *95% message delivery success rate*. Blinder relies on the private writing (PW) paradigm similarly to Riposte [12] that employs redundancy. Blinder's server-to-server communication complexity

	t_s	Network Type	Service Strength	Delivery Success	Offline Preprocess	C-to-S (Broadcast)	S-to-S (P2P)	Server Round
Switch-Network [27]	$< \frac{N_s}{3}$	A	Fair	100%	Non-Linear (MultTri)	1	$12N_sN_c\log^2 N_c$	$\log^2 N_c$
PowerMix [27]	$< \frac{N_s}{3}$	A	Fair	100%	Non-Linear (Powers)	1	$6{N_c}^2$	2
Blinder [1]	$< \frac{N_s}{4}$	S	Robust	95%	Linear (DouRand)	$4.97\sqrt{N_c}$	$17N_c$	4
Rabbit-Mix (This Work)	$< \frac{N_s}{4}$	S	Robust	100−ε%	Linear (DouRand)	$1.87\sqrt{N_c}$	$5.32N_c$	4

Table 2: Online Communication Comparisons: Let N_c and N_s be the numbers of clients and servers respectively. t_s = server corruption threshold, Network Type is either S (Synchronous) or A (Asynchronous). Protocol Feature is either Fair or Robust. The offline communication column shows the types of information that needs to be prepared during the offline phase for a protocol execution of a single epoch. DouRan, MultTri, Powers mean double random sharing, multiplication triple sharing, powers of a random sharing. See Table 5 for more in-depth offline complexity comparisons. C-to-S (Broadcast) is the number of field elements for a client to reliably broadcast to all servers. S-to-S (P2P) is the number of field elements sent *by a server to each server* via authenticated P2P channels.

	Client Computation	Server Computation
Switch-Network [27] (Fair)	C_{ss}	$(2N_cN_s\log^2 N_c)C_m + (2N_cN_s\log^2 N_c)C_a + (12\frac{N_c}{N_s}\log^2 N_c)C^M_{rec}$
PowerMix [27] (Fair)	C_{ss}	$(\frac{{N_c}^3}{2} + N_cN_s)C_m + ({N_c}^3 + \frac{{N_c}^2}{2} + N_cN_s)C_a + 6\frac{N_c}{N_s}C^M_{rec} + C_{RF}(N_c)$
Blinder [1] (Robust)	$4.97\sqrt{N_c}C_{ss}$	$(5.5{N_c}^2 + 13.2N_c\sqrt{N_c} + 5.74N_cN_s)(C_m + C_a) + 15.3\frac{N_c}{N_s}C^M_{rec} + \alpha(\log q - 2)C_m$
Rabbit-Mix (Robust)	$1.87\sqrt{N_c}C_{ss}$	$(1.43{N_c}^2 + 6.15N_c\sqrt{N_c} + 2N_cN_s)C_m + (1.5{N_c}^2 + 2N_cN_s)C_a + 5.32\frac{N_c}{N_s}C^M_{rec} + C_{RF}(N_c)$

Table 3: Online Computation Complexities: Let N_c and N_s be the numbers of clients and servers respectively. The computational complexity is measured in terms of the numbers of field operations (multiplications and additions) and of invocations of secret-sharing or share-reconstruction. C_m and C_a denote the costs of field multiplication and addition respectively. C_{ss} denotes the cost of secret-sharing. C^M_{rec} denote the costs of Reed-Solomon-decoding. $C_{RF}(N_c)$ is the cost of root-finding for N_c roots. In the above, α is the expected number of locations in the Blinder's PW table with non-zero values.

is $(6+4\gamma)N_c$ with $\gamma = 2.75$ for 95% message delivery success rate[5]. With a target message delivery success rate similar to ours (e.g., 100%), γ needs to increase accordingly (See Table 4) resulting in the increase of the communication (as well as computation) in a linear fashion in γ. Specifically, Blinder with 99.9% delivery success rate has server-to-server communication of $96N_c$ field elements per server which is 17 times bigger than Rabbit-Mix while still expectedly dropping 10 messages out of 10000 messages.

Success Rate (%)	95	96	97	98	99	99.9
Expansion Rate γ	2.75	3.14	3.67	4.63	6.71	22.02

Table 4: Redundancy and Delivery Success Rate

Online Computation We present the concrete computational cost estimates of the related work in terms of the number of field operations, multiplications and additions as well as the number of calls to the secret-share reconstruction protocol (Table 3). Our implementation of Root-finding algorithm has expected computational cost $C_{FindRoot}(N_c) \approx 7N_c\log^2 N_c$ for a fixed q. Thus, we observe that the major computational bottleneck in common is the cost to decompress clients' input shares.

Offline Requirements The performance of a system also crucially depends on the offline complexity. If the online phase requires the offline phase to prepare huge amount of preprocessed data, then the system in general cannot provide a continuous and efficient service. Table 5 provides the offline computation estimates of relevant protocols. Rabbit-Mix requires to prepare $2N_c + 0.94\sqrt{N_c}$ double random shares in the offline phase which is approximately 30% of Blinder and asymptotically improves by factor of N_c over PowerMix and Switch-Network, mixing protocols with fairness that in turns use these double random shares to prepare non-linear random shares (Multiplication Triple and Powers of random shares).

Discussion Both C-to-S and S-to-S communication of our robust AB protocol are reduced by over 60% in comparison to the latest robust AB protocol Blinder [1] while our message

[5]We assume here that the choice of prime is large enough so that a single execution of verification satisfies its info-theoretic security requirement.

	Double Random	Random Coin	Multiplication Triple	Random Bit Share	N_c-Powers of A Random Share	Total # of Double Random's
Switch-Network [27]	0	0	$1.25N_c \log^2 N_c$	$\frac{1}{2}\log^2 N_c$	0	$1.75N_c \log^2 N_c$
PowerMix [27]	0	0	0	0	${2N_c}^2$	${2N_c}^2$
Blinder [1]	$5.75N_c$	$N_c + 2.49\sqrt{N_c}$	0	0	0	$6.75N_c + 2.49\sqrt{N_c}$
Rabbit-Mix (This Work)	$2N_c$	$0.94\sqrt{N_c}$	0	0	0	$2N_c + 0.94\sqrt{N_c}$

Table 5: Offline Requirement Comparisons: N_c is the number of clients. The middle five columns (Double Random, Random Coin, Multiplication Triple, Random Bit Share, N_c-Powers of Random Share) show the types of preprocessed material shares required to execute each protocol per epoch. The values represents the amount of each preprocessed materials measured by the necessary numbers of Double Random Shares. The last column shows the total required number of double random shares which is the sum of all values on the left columns. Computing a preprocessed shared random coin (e.g. random shares) only requires the half of the computational cost of a double random so that the values of the column represent the half number of double random shares for the sake of measuring convenience.

delivery success rate is 100% in contrast to Blinder's 95%. The server computation cost of our protocol also improves over Blinder by over 60% in terms of number of field operations. In comparison to PowerMix, our protocol provides further optimized mixing efficiency with stronger robustness of the protocol. Essentially, our optimization allows our robust AB protocol to have $O({N_c}^2)$ computational overhead with sublinear client computation and C-to-S communication overhead in contrast to $O({N_c}^3)$ computational overhead of PowerMix [27]. Our AB protocol also requires minimal offline resources compared to previous relevant works as our protocol's offline resource requires less than 30% of double random shares compared to robust Blinder and PowerMix which requires the quadratic number of double randoms in the number of clients.

9 Implementation and Benchmarks

We implemented the preliminary prototype[6] of Rabbit-Mix protocol described in Section 6 and Section 7. Specifically, we implemented all online-computation subprotocols of robust Rabbit-Mix protocol (Protocol 3) with mock-up communication. That is, broadcasts and P2P channels between servers and clients are performed by direct reads and writes to each others' memory. The simulation of the Rabbit-Mix protocol is synchronized and local where servers' state machines configured with the number of servers, clients, and prime numbers execute subprotocols one by one in the state-by-state manner with mock-up communication where clients and servers directly read data from their read memory and write data to other servers' read memory. Therefore, our experimentation and benchmarks have limitations in capturing network-induced latencies and exposing bandwidth bottlenecks.

[6]This will be open-sourced at the point of publication due to an administrative reason.

Our prototype is implemented in C++ using Number Theoretic Library [35] to implement the algebraic operations. We note that, as our prototype directly uses NTL's native classes, the prototype is not to claim the best performance but to provide the insights on the protocol asymptotic behavior depending on distinct settings and parameters.[7] We tested our prototype on a virtual machine running 64-bit Ubuntu equipped with Intel Xeon CPU E3-1505M 3.00GHz with 4 CPU cores and 32 GB memory. All the benchmarks are measured based on 10 trials with 5 servers.

Computation Latency with Distinct Primes and Numbers of Clients First, we measured the server computation latency of the robust Rabbit-Mix prototype. We tested our prototype with N_c clients and distinct FFT-friendly primes of 64-1664 bits where the number of clients N_c is selected to be $N_c = 14L^2 + 10L - 1$ according to the additive 2-basis encoding to encode client messages. Specifically, we chose $N_c = 399, 1223, 2135, \cdots$ so that the number of clients are spread approximately by 800. Figure 1 presents the per-server computation latency with distinct primes.

Figure 2 shows the server computation latencies per client depending on distinct settings of number of clients, servers and primes as in the previous. As the latency measurements are scaled by the number of clients, a linear (or close-to-linear) trend can be observed as server computation is $O({N_c}^2)$. In addition, we observe in Figure 3 that some primes yield larger throughput in comparison to other prime settings.

Indeed, Figure 3 shows that a group of primes leads to larger throughput in comparison to a 208-byte prime. Specifically, consider that clients wish to send a 208-byte message.

[7]For example, even though the Rabbit-Mix's input decompression protocol requires less than half of algebraic operations (for both multiplications and additions) that Blinder requires, our implementation has higher latency than Blinder implementation due to differences in experimentation systems and implementations. The more optimized implementation based on light-weight libraries such as GMP is a future work.

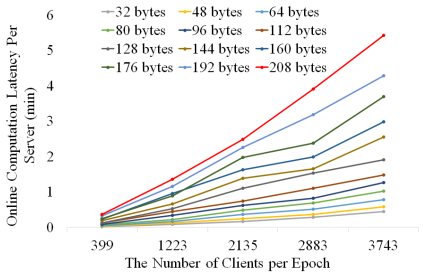

Figure 1: Per-Server Computation-Only Latency with Distinct Primes and Numbers of Clients.

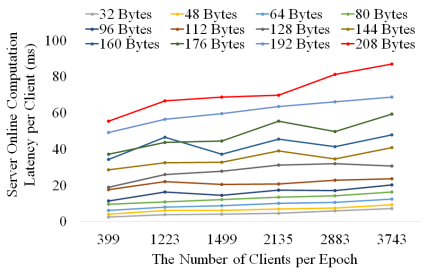

Figure 2: Per-Server Computation-Only Per-Client Latency with Distinct Primes and Numbers of Clients.

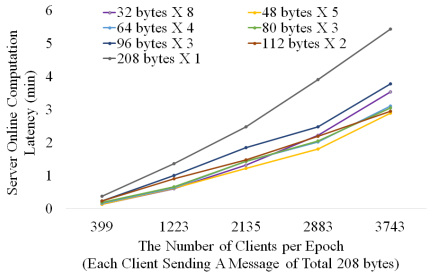

Figure 3: Per-Server Computation-Only Latency Delivering fixed-length Messages with the Distinct Prime Lengths.

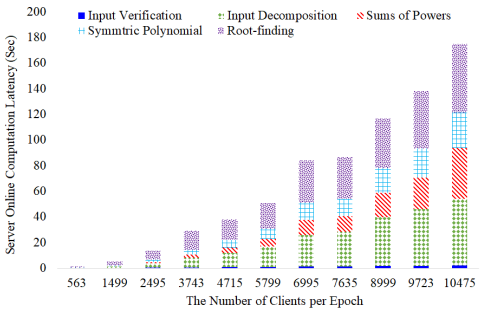

Figure 4: Server Computation Latency with Subprotocol Distribution in Logarithmic Scale: The benchmarks are measured with 5 servers executing the protocol over a 256 bit FFT-prime. Blue, orange, gray, yellow, purple colors corresponds to input format verification, input decompression, computing sum of powers, the symmetric polynomial, and the Graeffe-root finding algorithm to find roots from the symmetric protocol respectively.

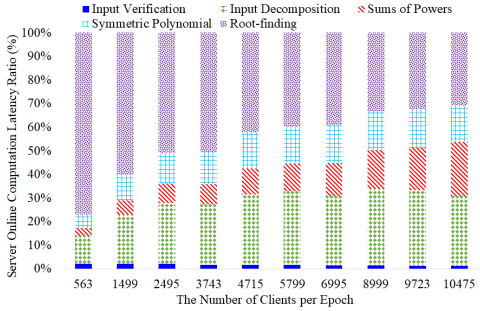

Figure 5: Server Subprotocol Computation Distribution Ratio: The ratio is based on the measurements in Figure 4.

In the first case, clients may submit a single 208-byte message to servers which run Rabbit-Mix with a 208-byte prime. In the second (and other) case(s), clients may partition its 208-byte messages into and submit μ messages of size $< 208/\mu$ to servers that in turns execute sequential Rabbit-Mix protocol μ-many times. For example, the gray line represents the total server computation latency of 8 sequential Rabbit-Mix executions with a 32-byte prime delivering a 208-byte message. Here, each message partition contains a 40-bit tag (See Section 6). Here, we set each partition to contain a 40-bit tag to reconstruct the whole messages at the end. Figure 3 essentially shows the selections of primes smaller than 208 bytes with which Rabbit-Mix delivers 208-byte messages with smaller server computation latency.

Server Computation Distribution In the following, we present the online computation latency distributions among the subprotocols of our robust ACB server. We first provide the server computation latency of Rabbit-Mix protocol depending on distinct numbers of clients spread by about 1000 up to over 10k clients per epoch with the settings of a 256-bit FFT-prime in Figure 4. Root-finding computation is observed to induce less computational time as the number of clients increases. However, it induces non-trivial computational latency due to the complexity of polynomial operations [23] for the smaller number of clients.

In Figure 5, we present the ratio between subprotocol computation latencies. We observe that the input decompression becomes the major computational bottleneck as expected when the number of clients grows. Recall that the overheads of subprotocols computing; input decompressions, sums of powers, and a symmetric polynomial is $O({N_c}^2)$, quadratic in the number of clients whereas the root-finding algorithm's overhead is $\tilde{O}(N_c)$ with a relatively large hidden constant. Therefore, when mixing larger volumes (e.g., 1 million) of client messages of relatively small sizes (e.g., 200 bytes), the computation latency from the root-finding is expected to be relatively tiny compared to the other subprotocols such as input decompression, the sums of powers, and symmetric polynomials. We note that Blinder's main computational bottleneck is also the input decompression where the Blinder protocol's input decompression requires at least 2 times more algebraic operations than ours.

Finally, Figure 6 presents concrete communication over-

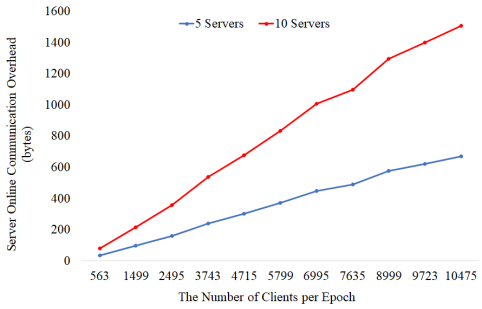

Figure 6: Server Communication Overhead in Bytes: Each server transmits the respective numbers of bytes to other servers during the online phase. The experimentation is taken with clients sending a single message of a 256-bit prime.

heads in bytes. Specifically, we measure the sizes of memory blocks (containing field elements) for each server to transmit to other servers via authenticated point-to-point channels during Rabbit-Mix's online phase. The experimentation is performed with two distinct number of servers (5 and 10 servers) with 256-bit FFT prime field.

Malicious Clients' Impact on Server Latency In the robust Rabbit-Mix protocol, clients are forced to submit consistent shares to honest servers by Π^{robust}_{submit}. Therefore, only a place that malicious clients may deviate is to submit the secret shares of a malformed message encoding that does not obey its additive-2 encoding format. In such cases, honest servers will detect those malformed encoding shares at the end of subprotocol Π_{ver} and simply drop those messages in the rest of execution with adding that client to the list of corrupted clients. Therefore, deviation by corrupted clients cannot degrade server computation latencies.

A Additive 2-basis Decompression Circuit

Let $N = 14L^2 + 10L - 1$ for a positive integer L and $\mathcal{B}$ be the additive 2-basis for $[N]$. Then the following circuit shows how to decompress $\mathcal{B}$ into $[N]$.

Circuit 1: Additive 2-basis Decompression Circuit $\mathsf{Decomp}(\beta)$

Input: Let $N = 14L^2 + 10L - 1$. The input is $\mathcal{B} = \{S_1, S_2, S_3, S_4, S_5\}$ as above.
Output: $[N] = \{1, 2, \cdots, N\}$.

1: **Elements from** 1 **to** $2L$**:** We already have elements from 1 to L. We can populate the rest by computing $i + L$ for each $i \in L$. This requires L additions in total.
2: **Elements from** $2L+1$ **to** $3L^2+2L$**:** These elements can be computed as $i + j$ for each $i \in S_1$ and $j \in S_2$. The total number of additions is $3L^2$.
3: **Elements from** $3L^2+2L+1$ **to** $4L^2+3L-1$**:** The elements in this range can be computed also by computing additions between S_1 and S_3 as $i + j$ for each $i \in S_1$ and $j \in S_3$. The total number of additions is L^2.
4: **Elements from** $4L^2+3L$ **to** $6L^2+4L-1$**:** These elements can be computed by computing additions of elements of $i \in S_3$ and $j \in S'_2 \subset S_2$ where the subset $S'_2 = \{L^2 + Li' - Lj' \mid i' \in [2L+1]$ and $j' \in \{0, 1, \cdots, L-1\}\}$. Let $s_{3,j}$ be the j-th number of S_3. Then, the circuit populates the elements in the range by adding for each $i \in [2L+1]$ and each $j \in [1, \cdots, L]$, $s_{3,j} + L^2 + Li - L(j-1)$. The total number of additions is $2L^2 + L$.
5: **Elements from** $6L^2+4L$ **to** $6L^2+5L$**:** S_4 trivially covers this range.
6: **Elements from** $6L^2+5L+1$ **to** $6L^2+6L$**:** The elements in the range can be computed by additions between S_1 and $6L^2+5L$, the last element of S_4, thus with L additions.
7: **Elements from** $6L^2+6L+1$ **to** $9L^2+6L$**:** The elements in this range can be computed by additions between S_2 and S_4 where the number of additions is $3L^2$.
8: **Elements from** $9L^2+6L+1$ **to** $10L^2+7L-1$**:** This interval can be computed by additions between S_3 and S_4 where the number of additions is $L^2 + L$.
9: **Elements from** $10L^2+7L$ **to** $10L^2+9L$**:** The elements up to $10L^2+8L$ in this interval is already covered by S_5 and the rest can be computed by additions between S_1 and $10L^2+9L$. Hence, the number of additions is L.
10: **Elements from** $10L^2+9L+1$ **to** $13L^2+9L$**:** The interval is computed by adding elements between S_2 and S_5. Hence, the number of additions is $3L(L+1)$.
11: **Elements from** $13L^2+9L+1$ **to** $14L^2+10L-1$**:** Finally, the interval can be computed by adding elements between S_3 and S_5 and the number of additions is $L^2 + L$.

B Client-Input Encoding Decompression

The following protocol shows how to decompress the secret-shares of client message package pkg into the secret-shares of N_c powers of a message. In the following, we have $N_c = 14L^2 + 10L - 1$ for some positive integer L and denote a t-consistent secret-shared encoding of client message m by ${}^t[\![\mathsf{pkg}]\!]_q$ where $\mathsf{pkg} = m^{\mathcal{B}}$.

Protocol 4: Client Input Decompression Protocol $\Pi_{Decomp}({}^t[\![\mathsf{pkg}^{(i)}]\!]_q)$

Parameters: N_c and L such that $N_c = 14L^2 + 10L - 1$. The number of servers is N_s. t is the threshold on the number of corrupted servers. q is a prime number.
Preprocessed Information: None
Input: A mixing server S_j has as inputs the j-th consistent t-sharings of input message encoding ${}^t[\![\mathsf{pkg}^{(i)}]\!]_q \in \mathbb{F}_q^{7L+2}$ received from client C_i with input message m_i such that ${}^t[\![\mathsf{pkg}^{(i)}]\!]_q = \left\{{}^t[\![S_1^{(i)}]\!]_q, {}^t[\![S_2^{(i)}]\!]_q, \cdots, {}^t[\![S_5^{(i)}]\!]_q\right\}$, where $\mathsf{pkg}^{(i)}$ is submitted via Protocol 2.

Output: An ordered set of N_c secret-shares $[\![x^{(i)}]\!]_q$ defined as

$$\{{}^{t}[\![x_1^{(i)}]\!]_q, \cdots, {}^{t}[\![x_L^{(i)}]\!]_q,$$
$${}^{2t}[\![x_{L+1}^{(i)}]\!]_q, \cdots, {}^{2t}[\![x_{6L^2+4L-1}^{(i)}]\!]_q,$$
$${}^{t}[\![x_{6L^2+4L}^{(i)}]\!]_q, \cdots, {}^{t}[\![x_{6L^2+5L}^{(i)}]\!]_q,$$
$${}^{2t}[\![x_{6L^2+5L+1}^{(i)}]\!]_q, \cdots, {}^{2t}[\![x_{10L^2+7L-1}^{(i)}]\!]_q,$$
$${}^{t}[\![x_{10L^2+7L}^{(i)}]\!]_q, \cdots, {}^{t}[\![x_{10L^2+8L}^{(i)}]\!]_q,$$
$${}^{2t}[\![x_{10L^2+8L+1}^{(i)}]\!]_q, \cdots, {}^{2t}[\![x_{N_c}^{(i)}]\!]_q\}.$$

Protocol: Each server locally computes the following:

1: **Every** j **from** 1 **to** $2L$**:** We already have output shares from 1 to L so that set $[\![x_j^{(i)}]\!] = [\![s_{1,j}^{(i)}]\!]$ where $[\![s_{1,j}^{(i)}]\!]$ is the j-th share in the input share set $[\![S_1^{(i)}]\!]$. Compute the rest ($j \in [L+1, \cdots, 2L]$) by computing ${}^{2t}[\![x_j^{(i)}]\!] = {}^{t}[\![s_{1,j-L}^{(i)}]\!] \cdot {}^{t}[\![s_{1,L}^{(i)}]\!]$.

2: **Every** j **from** $2L+1$ **to** $3L^2+2L$**:** Compute for each for $l \in [3L]$ and $k \in [L]$, ${}^{2t}[\![x_j^{(i)}]\!] = {}^{t}[\![s_{1,k}^{(i)}]\!] \cdot {}^{t}[\![s_{2,l}^{(i)}]\!]$.

3: **Every** j **from** $3L^2+2L+1$ **to** $4L^2+3L-1$**:** For each $k \in [L]$ and $l \in [L]$, compute ${}^{2t}[\![x_j^{(i)}]\!] = {}^{t}[\![s_{1,k}^{(i)}]\!] \cdot {}^{t}[\![s_{3,l}^{(i)}]\!]$.

4: **Every** j **from** $4L^2+3L$ **to** $6L^2+4L-1$**:** For each $k \in [2L+1]$ and each $l \in [L]$, compute ${}^{2t}[\![x_j^{(i)}]\!] = {}^{t}[\![s_{2,L+k-l}^{(i)}]\!] \cdot {}^{t}[\![s_{3,l}^{(i)}]\!]$.

5: **Every** j **from** $6L^2+4L$ **to** $6L^2+5L$**:** Set for each $k \in [L+1]$, ${}^{t}[\![x_j^{(i)}]\!] = {}^{t}[\![S_{4,k}^{(i)}]\!]$.

6: **Every** j **from** $6L^2+5L+1$ **to** $6L^2+6L$**:** For each $k \in [L]$, compute ${}^{2t}[\![x_j^{(i)}]\!] = {}^{t}[\![S_{1,k}^{(i)}]\!] \cdot {}^{t}[\![S_{4,L+1}^{(i)}]\!]$.

7: **Every** j **from** $6L^2+6L+1$ **to** $9L^2+6L$**:** For each $k \in [3L]$ and each $l \in [2, L+1]$, compute ${}^{2t}[\![x_j^{(i)}]\!] = {}^{t}[\![S_{2,k}^{(i)}]\!] \cdot {}^{t}[\![S_{4,l}^{(i)}]\!]$.

8: **Every** j **from** $9L^2+6L+1$ **to** $10L^2+7L-1$**:** For each $k \in [L]$ and each $l \in [L+1]$, skip the first computation ${}^{t}[\![S_{3,1}^{(i)}]\!] \cdot {}^{t}[\![S_{4,1}^{(i)}]\!]$ and then compute the rest as ${}^{2t}[\![x_j^{(i)}]\!] = {}^{t}[\![S_{3,k}^{(i)}]\!] \cdot {}^{t}[\![S_{4,l}^{(i)}]\!]$.

9: **Every** j **from** $10L^2+7L$ **to** $10L^2+9L$**:** For $k \in [L+1]$, set ${}^{t}[\![x_j^{(i)}]\!] = {}^{t}[\![s_{5,k}^{(i)}]\!]$. Then, compute for $k \in [L]$, compute ${}^{2t}[\![x_j^{(i)}]\!] = {}^{t}[\![s_{1,k}^{(i)}]\!] \cdot {}^{t}[\![s_{5,L+1}^{(i)}]\!]$.

10: **Every** j **from** $10L^2+9L+1$ **to** $13L^2+9L$**:** For each $k \in [3L]$ and $l \in [2, L+1]$, compute ${}^{2t}[\![x_j^{(i)}]\!] = {}^{t}[\![s_{2,k}^{(i)}]\!] \cdot {}^{t}[\![s_{5,l}^{(i)}]\!]$.

11: **Every** j **from** $13L^2+9L+1$ **to** $14L^2+10L-1$**:** For each $k \in [L]$ and $l \in [L+1]$, skip the first computation ${}^{t}[\![s_{3,1}^{(i)}]\!] \cdot {}^{t}[\![s_{5,1}^{(i)}]\!]$ and then compute the rest ${}^{2t}[\![x_j^{(i)}]\!] = {}^{t}[\![s_{3,k}^{(i)}]\!] \cdot {}^{t}[\![s_{5,l}^{(i)}]\!]$.

C Input Well-formedness Verification Circuit

The following circuit describes the algebraic circuit to compute a share of linear sketch predicate indicating whether a client's input message encoding is well-formed according to additive 2-basis for the number of clients N_c.

Circuit 2: Well-formedness Verification Circuit FormatVerify()

Input Parameters: Let q be a prime. Let $N_c = 14L^2+10L-1$ be the number of participating clients in the current epoch.
Input: A set of $7L+4$ field elements $X = \{x_1, \cdots, x_{7L+4}\}$ to be verified which can be partitioned into 6 ordered sets X_1, X_2, X_3, X_4, X_5 and X_6. A set of random field elements $\{c_i\}_{i\in[7L+3]}$ sampled independent of X.
Output: Output b where $b = 0$ if and only if pkg satisfies both the inner progression and inter progress conditions as defined above.

1: Parse the input set X into 6 ordered subsets $X_1, X_2, \cdots, X_6$ where $X_1, X_2, \cdots, X_5$ are ordered sets of elements having additive 2-basis S_1, S_2, $\cdots$, S_5 as exponents accordingly. We let X_6 contain the final two elements of X.
2: Compute $b_1^0 = \sum_{i=1}^{L-1} c_i(x_{1,i+1} - x_{1,i}x_{1,1})$
3: Compute $b_2^0 = \sum_{i=1}^{3L-1} c_{i+L-1}(x_{2,i+1} - x_{2,i}x_{1,L})$
4: $b_3^0 = \sum_{i=1}^{L-1} c_{i+4L-2}(x_{3,i+1} - x_{3,i}x_{6,1}) + c_{5L-2}(x_{6,1} - x_{1,1}x_{1,L})$
5: $b_4^0 = \sum_{i=1}^{L} c_{i+5L-2}(x_{4,i+1} - x_{4,i}x_{1,1})$
6: $b_5^0 = \sum_{i=1}^{L} c_{i+6L-2}(x_{5,i+1} - x_{5,i}x_{1,1})$
7: $b_1^1 = 0$
8: $b_2^1 = c_{7L-1}(x_{1,L}x_{1,L} - x_{2,1})$
9: $b_3^1 = c_{7L}(x_{2,3L}x_{1,L} - x_{3,1})$
10: $b_4^1 = c_{7L+1}(x_{4,1} - x_{3,1}x_{3,1})$
11: $b_5^1 = c_{7L+2}(x_{5,1} - x_{6,2}x_{1,1}) + c_{7L+3}(x_{6,2} - x_{3,L}x_{4,L+1})$
12: Compute and output $b = \sum_{i=0}^{1}\sum_{j=1}^{5} b_j^i$.

D Well-formedness Verifiable Client Input Submission

In order for (shared) client input encodings to be verifiable, an additive 2-basis $\mathcal{B}$ now modified to contain additional set of elements $S_6 = \{s_{6,1}, s_{6,2}\} = \{L+1, 10L^2+7L-1\}$ as described in Section 5. Hence, the new input submission protocol is identical a client with message m and the new $\mathcal{B} = \{S_1, S_2, \cdots, S_6\}$ creates $m^{\mathcal{B}}$ and secret-shares them towards servers. We will simply use the identical notation Π_{submit} for this input submission protocol.

Protocol 5: Well-formedness Verifiable Input Submission Protocol Π_{submit}

Parameters: Prime q, the number of clients N_c, the number of servers N_s, the server corruption threshold t_s, and the additive 2-basis $\mathcal{B} = \{S_1, S_2, \cdots, S_6\}$.
Input: Client C holds a message m defined over $\mathbb{F}_q$.
Output: Servers output the secret-shares of ${}^{t_s}[\![\mathsf{pkg}]\!]_q$.

1: C computes $\mathsf{pkg}_m \leftarrow m^{\mathcal{B}}$.
2: C computes ${}^{t_s}[\![\mathsf{pkg}]\!]_q \leftarrow \mathsf{Share}_{N_s,t_s,q}(\mathsf{pkg}_m)$.
3: C sends the i-share of ${}^{t_s}[\![\mathsf{pkg}]\!]_q$ to S_i.

E Input Well-formedness Verification Protocol

The following protocol describes the protocol that takes as inputs the t-consistent sharings of a client's input message encoding and outputs a $2t$-consistent sharing of a linear sketch that indicates the well-formedness of the input message encoding. The output sharing is re-randomized by using a random-double sharing. The protocol uses Circuit 2 as a sub-module.

Protocol 6: Well-formedness Verification Protocol $\Pi_{ver}()$

Parameters: Let q be a prime. Let $N_c = 14L^2 + 10L - 1$ be the number of participating clients in the current epoch.
Preprocessed Information: A pair of *consistent* random double sharings $({}^{t}[\![r]\!], {}^{2t}[\![R]\!])$.
Input: For each $i \in [N_c]$, Client C_i's degree-t sharing of input package ${}^{t}[\![\mathsf{pkg}^{(i)}]\!]_q = \left\{ [\![x_1^{(i)}]\!], \cdots, [\![x_{7L+5}^{(i)}]\!] \right\}$. Finally, a set of random challenge $\{c_i\}_{i\in[7L+4]}$ over $\mathbb{F}_q$.
Output: Output ${}^{2t}[\![b^{(i)}]\!]_q$.

1: Each server locally computes a linear sketch by evaluating $\mathsf{FormatVerify}([\![\mathsf{pkg}^{(i)}]\!], \{c_i\}) \to {}^{2t}[\![b^{(i)}]\!]_q$.
2: All servers rerandomize ${}^{2t}[\![b^{(i)}]\!]_q$ using the preprocessed random double sharing.

F Removing Offline Communication

As an alternative approach for generating robust random shares, we can make use of the recent improvements in pseudorandom secret sharing (PRSS) due to Benhamouda, Boyle, Gilboa, Halevi, Ishai, and Nof [7]. Using PRSS, participants can generate robust shares and robust double random shares locally after an initial setup step for distributing PRF seeds. This approach is worse asymptotically as N_s and the associated corruption threshold and polynomial degree grow, but it is likely to be more efficient in cases where a bounded number of servers N_s wish to perform a series of mixes for a large group of clients. For a fixed number of servers, using PRSS attains the Server-to-Server communication and round complexity in exchange for a $O(1)$ setup cost and a $O(N_c)$ computational cost.

More precisely, the online communication cost using the PRSS approach is always zero, while the associated setup time, memory costs, and online computational costs depend linearly on the minimum known size of a combinatorial object known as a (n,m,t) cover. When $t = \Theta(n)$, this minimum size is exponential in n, and so the approach is not feasible in the asymptotic case.

Nevertheless, for many concrete values of n, the resulting parameters are efficient, as we show in Table 6. For example, generating the $2N_c$ double shares required for our robust server requires around $81N_c$ PRF calls per server with 8 servers and $564N_c$ PRF calls per server with 12 servers, which are both likely to give a small increase in computation compared to the expression given in Table 3 for, say, $N_C = 100$. In many concrete settings, this increase in computation will be more than offset by the $2.7x$ improvement in communication from removing the interaction required to generate the robust shares.

N_s	d	t_s	PRSS seeds	Seed storage	PRF calls per double share
7	2	1	12.9	64.3	32.1
8	2	1	13.5	81.0	40.5
11	3	2	54.3	411.9	206.0
12	3	2	66.0	564.0	282.0
15	4	3	264.7	2785.3	1392.7
16	4	3	348.8	3975.0	1987.5
19	5	4	1686.9	22866.9	11433.5
20	5	4	2059.2	29867.4	14933.7
48	15	4	2746.4	86747.2	7228.9
72	23	4	5717.2	271813.5	13590.7

Table 6: The online and offline costs of generating packed double secret shares over polynomials of degree d and $2d$ for a given number of servers N_s and a corruption threshold t_s. All costs are given on a per-party basis. The offline costs are measured in PRSS seeds per party, which measures offline setup time, and PRSS seed storage per party, which measures memory cost. PRF calls per double share measures online computational time per party.

We require $2d + 2t_s < N_s$, and in all rows but the last two, choose t_s maximal subject to the condition $t_s < N_s/4$. The numbers in this table can be derived from Theorems 3.3 and 3.6 in [7] along with the list of covering designs maintained by Dan Gordon [22]. We include the last two rows of the table as a demonstration of how PRSS can continue to be efficient for much larger values of N_s when we set an even lower corruption threshold.

PerfOMR: Oblivious Message Retrieval with Reduced Communication and Computation

Zeyu Liu
Yale University

Eran Tromer
Boston University

Yunhao Wang
Yale University

Abstract

Anonymous message delivery, as in privacy-preserving blockchain and private messaging applications, needs to protect recipient metadata: eavesdroppers should not be able to link messages to their recipients. This raises the question: how can untrusted servers assist in delivering the pertinent messages to each recipient, without learning which messages are addressed to whom?

Recent work constructed Oblivious Message Retrieval (OMR) protocols that outsource the message detection and retrieval in a privacy-preserving way, using homomorphic encryption. Their construction exhibits significant costs in computation per message scanned ($\sim$0.1 second), as well as in the size of the associated messages ($\sim$1kB overhead) and public keys ($\sim$132kB).

This work constructs more efficient OMR schemes, by replacing the LWE-based clue encryption of prior works with a Ring-LWE variant, and utilizing the resulting flexibility to improve several components of the scheme. We thus devise, analyze, and benchmark two protocols:

The first protocol focuses on improving the detector runtime, using a new retrieval circuit that can be homomorphically evaluated 15x faster than the prior work.

The second protocol focuses on reducing the communication costs, by designing a different homomorphic decryption circuit that allows the parameter of the Ring-LWE encryption to be set such that the public key size is about 235x smaller than the prior work, and the message size is roughly 1.6x smaller. The runtime of this second construction is $\sim$40.0ms per message, still more than 2.5x faster than prior works.

1 Introduction

Protecting message contents in messaging applications has been extensively studied, with the wide usage of end-to-end encryption today. However, metadata (who sent and received messages, and when) can by itself disclose sensitive information. Therefore, protecting metadata is essential to anonymous message delivery systems like private messaging [2, 5, 10, 25, 40]. The importance is further amplified in privacy-preserving cryptocurrencies [3, 6, 18, 29], where the ledger containing all the messages is permissionless and widely replicated, making it easily accessible to everyone.

Among the various critical pieces of metadata, *recipient* privacy is a particularly challenging problem to efficiently solve. From a recipient's perspective, a transaction *pertinent* to them could be located anywhere on the ledger in the blockchain applications (or a queue in private messaging systems). Consequently, to find the messages pertinent to them, one simple way is for every recipient to scan the entire ledger. However, the imposed communication and computation costs may be too much of a burden for recipients with limited resources (e.g., wallet apps running on mobile devices). It is desirable to outsource this to a server in a privacy-preserving way.

Fuzzy Message Detection (FMD) [2, 36] is the first primitive proposed to address this issue. It adopts a decoy-based approach: the server detects and forwards a set of messages, including both the pertinent messages and random false positives. This is a weak, non-robust security guarantee [38].

Two primitives emerged after FMD enhanced the security guarantee to entirely hide the set of pertinent messages. Private Signaling (PS) [20,27] focuses on achieving this functionality by leveraging a trusted execution environment (TEE) or two communicating-but-non-colluding servers, while Oblivious Message Retrieval (OMR) [21, 22] realizes it via cryptographic assumptions on a single server. The state-of-the-art PS work [20] provides a very scalable solution; nonetheless, this line of work has a much stronger environmental assumption than OMR. Thus, in this work, we focus on OMR.

System Model. OMR works in the following model: in the systems, there are *senders* who send messages to the *recipients* without revealing who the recipients are. Each *message* contains a *payload* and a *clue* generated by the sender using the recipient's *clue key*. All the messages are placed on a *bulletin board*. When the recipients want to retrieve their messages, they send a *detection key* to an untrusted server, denoted the *detector*. The detector uses the board and the

detection key to generate a *digest* and sends it back to the recipients. The recipients decode the digest to obtain all the payloads pertinent to them.

Threat model. We consider an adversary that wishes to learn metadata about which messages are addressed to which user, and the identity of users that perform retrieval queries.

The adversary can read all public information (including all board messages and all public keys in the system), and all communication between detectors and the recipients. The adversary may control, or collude with, all the parties in the systems, except for the sender and recipient(s) of the message(s) whose privacy is to be protected. The adversary and its colluding parties may behave maliciously and send malformed messages and keys; but they are computationally bounded (i.e., cannot break the underlying computational assumptions).

Prior OMR schemes. Under these models, OMR [21] (and its extension to group setting [22]) offer a solution based on PVW encrpytion [34] and BFV homomorphic encryption [7, 13], However, there are several major practical concerns about the existing constructions:[1] (1) the detector is slow, taking ∼109 ms/msg (1-thread, and ∼51.7 ms/msg 4-thread) per processed message, i.e., approximately $17.6 per month for Bitcoin-scale application; (2) the clue key size is ∼132kB, which is awkward to senders as part of the recipient's public address/key; (3) the clue itself has a size of ∼956 bytes, which roughly doubles the total message size, e.g., for typical Zcash transactions.

In this paper, we address these practical issues by presenting two protocols that greatly outperform the prior works, and offer different tradeoffs between computation, clue sizes and key sizes.

1.1 Our Contribution

New constructions. We show two new constructions that provide different trade-offs. Both of the constructions are based on standard lattice hardness assumption (Ring-LWE) and are thus plausibly post-quantum secure.

- For our first construction, we tailor Ring-LWE encryption into a variant that suits our application. Combining this tailored scheme and a newly designed retrieval circuit (including a new decryption circuit and a new way to encode the digest), we obtain a construction that is both asymptotically and concretely faster in terms of the detector runtime.
- In the second construction, we show an alternative way to parametrize our Ring-LWE variant, together with a new decryption circuit. This alternative construction achieves a much smaller clue and clue key size, and a detector runtime that is still faster than prior work [21].

Implementation and evaluation. We implement our constructions in a (to-be-open-sourced) C++ library and measure the concrete improvement. Salient observations include:

- With the first construction, the detector runtime is about 15x faster, and the clue key size is about 60x smaller. The detector runtime is only ∼7.3 thread-ms/msg scanned (∼3.7 ms/msg 2-thread), thus only costs ∼$0.12 per million message scanned ($1.12/month for Bitcoin-scale applications).
- With the second construction, the detector runtime is about 2.7x faster than prior work (∼40.0ms/msg 1-thread, ∼20.2ms/msg 2-thread), while the clue key size is about 235x smaller. Furthermore, the clue size is about 1.6x smaller. These advantages allow the applications to have much less clue distribution and message size burdens.

We also discuss implications of these improvements on integration with a blockchain-based privacy-preserving cryptocurrency (exemplified by Zcash).

1.2 Related Works

Oblivious Message Retrieval. [21] proposes a message retrieval primitive with full recipient privacy and [22] extends it to the group setting. We recap how the construction of [21] works in § 4, and compare our schemes with it asymptotically in§ 2 and concretely in § 7.

Fuzzy Message Detection. FMD [2, 36] mainly focuses on decoy based security. While the construction is highly efficient, the security notion is relatively weak as analyzed in [38].

Private Signaling. Like OMR, PS [20,27] provides full security. However, prior works on private signaling have constructions using a Trusted Execution Environment (TEE). TEE is a strong environment assumption since a lot of work shows that the existing TEEs have side-channels that can leak secrets easily [39]. [27] also provides a solution assuming two communicating but non-colluding servers, which is also a very strong environment assumption. Moreover, this construction is concretely slower than [21] and thus our constructions.

PIR. Other related problems are *(batch) Private Information Retrieval (PIR)* [9] and its variant *(batch) Keyword PIR* [8]. Our setting differs in that recipients do not know the indices or labels of messages pertinent to them; rather, the clues are randomized and require nontrivial computation (rather than simple comparison) to detect.

Private Stream Search. In Private Stream Search (PSS) [4, 12, 14, 32], a client can prvately search a keyword over a database of documents and retrieve the ones with that keyword. As for Keyword PIR, this does not directly yield OMR.

See [21, 22] for further discussion.

2 Technical Overview

We follow the OMR framework introduced in [21] to build our improved constructions, and the requisite background is systematically recalled in § 3 and 4; then the improvements

[1] Benchmarked using the parameters of [22, Sec 9] and Google Cloud prices (instance type `e2-standard-4`), amortized.

	ClueToPackedPV		PVUnpack		ExpandedPVToDigest		Clue Size	Clue Key Size	Detection Key Size	Digest Size

Table 1: Asymptotic comparison with prior construction. N is the total number of messages. $\bar{k}$ is the upper bound of the number of pertinent messages provided by the recipient. ε_{p} is the false positive rate. n, ℓ, q, h are all PVW encryption or sRLWE scheme parameters (see § 3.1 and § 5.1). t is the BFV plaintext space. Practically $t \geq qh \gg \log(t)+h$, and D is the BFV ring dimension. P is the size of a payload (which can also be viewed as a constant). v is a tune-able parameter in our construction, which essentially means "gluing" v messages together and treating them as a single message in the later detection phases (see §§ 4.2.2 and 4.2.3).

are presented in detail in § 5 and § 6. For those readers already familiar with the approach of [21] and the encryption schemes it employs (PVW [34] and BFV [7, 13]), the following succinctly summarizes our approach to improvements.

Setup with tailored RLWE Encryption. Whereas [21] had clues which are PVW encryptions (based on LWE hardness), we instead use an encryption scheme based on Ring-LWE hardness. Our encryption scheme, sRLWE, is a variant of RLWE [26] but with sparse key, smaller decryption range, and smaller plaintext space. The encryption public key sRLWE.pk (included in the clue key) is much smaller than with PVW.

The sender generates $\mathsf{sRLWE.Enc}(\mathsf{sRLWE.pk}, 0) \in \mathbb{Z}_t^{n+1}$ as the clue (for some security parameter n, ciphertext modulus q)[2]. To perform a retrieval, the recipient uses the homomorphic encryption scheme BFV to compute $\mathsf{ct_{sk}} \leftarrow \mathsf{BFV.Enc}(\mathsf{BFV.pk}, \mathsf{sRLWE.sk})$ and send $(\mathsf{BFV.pk}, \mathsf{ct_{sk}})$ as the detection key to the detector.

A more efficient homomorphic decryption circuit. Given a detection key, the first step performed by the detector is to homomorphically decrypt each sRLWE ciphertext over $\mathbb{Z}_t$. Prior work relies on a degree-$(t-1)$ polynomial as in [21], which requires $t-1$ homomorphic operations. By exploiting the fact that sRLWE relies on sparse secret-key RLWE (using secrets with fixed hamming weight h), which implies that the sRLWE ciphertexts have noise $O(h)$, we design a more efficient decryption circuit that only takes $O(h+\log(t))$ operations. Since this circuit is evaluated using BFV, D (BFV ring dimension) clues are homomorphically decrypted simultaneously. For N clues, this process results in $d = \lceil N/D \rceil$ BFV ciphertexts, each of which encrypts a binary vector of size D (in its D slots) representing whether D corresponding messages are pertinent. We call this step ClueToPackedPV.

A new way to expand the BFV ciphertexts. The next step for the detector is to homomorphically expand these ciphertexts. Instead of one ciphertext encrypting D bits, the detector needs D ciphertexts each encrypting a single bit repeated D times (for more efficient digest encoding). To accomplish this goal, we first homomorphically decode the ciphertext via the SlotToCoeff procedure in [24]. Then, we perform OExpand introduced in [1] on the decoded ciphertexts to obtain the targeted result. This new expansion way requires only $O(D)$ operations for each ciphertext, compared to $O(D\log(D))$ operations in prior work [21]. We call this step PVUnpack.

Bundling v messages. With this new way of expansion, it still takes $O(N)$ homomorphic operations for N messages. A natural improvement is to bundle v messages to a single message. This can be done by adding up v ciphertexts obtained from ClueToPackedPV before expanding the ciphertexts.

A new encoding scheme. Despite the improved efficiency of the bundling technique, it introduces extra complexity. The major issue is that the encoding scheme in [21] does not work anymore, given that the ciphertexts output from PVUnpack now encrypts non-binary values (since we add v binary values together). To resolve this, we design a new encoding scheme for index encoding: we first expand each bit of the indices into $\log(\mathsf{v}+1)$ bits; then we use these expanded indices to encode and allow the recipient to decode all the pertinent indices. We call this last encoding step ExpandedPVToDigest

Putting all these three steps ClueToPackedPV,PVUnpack, ExpandedPVToDigest together, we obtain our first construction PerfOMR1, which is both asymptotically and concretely faster than the prior work OMRp2 in [21].

An alternative way to use sRLWE. Another way to use sRLWE is that instead of having its ciphertext modulus be t (the same as the BFV plaintext modulus, which relatively large for practicality), we can set sRLWE modulus to $q \ll t$. As our sRLWE relies on sparse keys (keys with hamming weight h), we set $qh < t/2$. This guarantees that decrypting the sRLWE ciphertext over $\mathbb{Z}_t$ is the same as over $\mathbb{Z}$ (no wrap-arounds). Therefore, we can instead design a polynomial with $O(qh)$ degree to perform the homomorphic decryption. While this makes the runtime worse, the clue key and clue of size $O(n\log(q))$ can be greatly reduced as q now is smaller.

Asymptotics. In Table 1, we compare the asymptotic behavior of our constructions, in terms of the cost metrics, with the prior construction in [21, 22]. As mentioned in above, our work mainly focuses on the improvement of the detector construction, which is composed of three main steps:

[2] In the actual construction, we encrypt 0^{ℓ} for some $\ell \geq 1$, to reduce false positive rate. We set $\ell = 1$ here for simplicity.

ClueToPackedPV, PVUnpack, ExpandedPVToDigest.

For our first construction, PerfOMR1, the detector runtime is strictly faster than the prior works by having much fewer homomorphic operations: in the step ClueToPackedPV, h is the hamming weight of the secret key which is normally viewed as $O(1)$ [15], and we thus have $\log(t)+h = o(t)$; in the step PVUnpack, we have $\mathsf{v} \geq 1$, thus reducing the number of homomorphic operations by a factor of v. Besides, the clue key size is smaller by reducing $\omega(n\log(n))$ to $O(n)$.

For our second construction PerfOMR2, we set $q \cdot h \leq t$. Therefore, the runtime is comparable with the prior work with slightly fewer homomorphic operations in the step ClueToPackedPV. The gain is that the clue size and the clue key size are both smaller since they now depend on $q < t$.

Note that the digest size of both of our constructions is parametrized by v. Concretely, the digest size is exactly the same as the prior work when $\mathsf{v} = 1$. Since v only affects the runtime of PVUnpack step, when PVUnpack is the runtime bottleneck, we set $\mathsf{v} > 1$ (e.g., for PerfOMR1); otherwise, we set $\mathsf{v} = 1$ (e.g., for PerfOMR2).

See § 7 for evaluation of concrete performance.

3 Preliminaries

Notation. Let $[n]$ denote the set $\{1,\ldots,n\}$. For a vector $\mathbf{v}$, $\mathbf{v}[i]$ indicates the i-th element of this vector. For a matrix A, $A[i][j]$ indicates the cell at the i-th row and j-th column. Let $\mathcal{R} = \mathbb{Z}[X]/(X^N+1)$ denote the $2N$-th cyclotomic ring where N is a power-of-two, and $\mathcal{R}_Q = \mathcal{R}/Q\mathcal{R}$ for some $Q \in \mathbb{Z}$. For matrices $A, B \in \mathbb{Z}_t^{n\times m}$, let $\circ$ denote the Hadamard product $C \leftarrow A \circ B$ satisfying $C[i][j] = A[i][j]\cdot B[i][j], \forall i \in [n], j \in [m]$. Drawing x uniformly at random from a set S is denoted $x \xleftarrow{\$} S$.

Definition 3.1 (Decisional ring learning with error problem)**.** [26, 35] Let $N, Q, \mathcal{D}, \chi$ be parameters dependent on λ and N being a power of two. Let $\mathcal{R} = \mathbb{Z}[X]/(X^N+1)$. The ring learning with error (RLWE) problem $\mathsf{RLWE}_{N,Q,\mathcal{D},\chi}$ is the following: distinguish $(a, a\cdot s+e)$ and (a,b) (with noticeable advantage), where $a \xleftarrow{\$} \mathcal{R}_Q, s \leftarrow \mathcal{D}, e \leftarrow \chi$ and $b \xleftarrow{\$} \mathcal{R}_Q$.

3.1 PVW Encryption

We adapt the PVW encryption from [34] and modify it according to [21].

- $\mathsf{pp} = (n,\ell,w,q,\sigma,r) \leftarrow \mathsf{PVW.GenParam}(1^\lambda,\ell,q,\sigma,\varepsilon_n)$: Choose a secret key dimension n, and $w = \omega(n\log(q))$ by ciphertext modulus q, plaintext size ℓ, and standard deviation σ for Gaussian distribution, as in [34]. Choose the noise bound r s.t. $\Pr[\mathsf{PVW.Dec}(\mathsf{sk}, \mathsf{PVW.Enc}(\mathsf{pk},\vec{m})) = \vec{m}] \geq 1-\varepsilon_n-\mathsf{negl}(\lambda)$.
- $(\mathsf{sk},\mathsf{pk}) \leftarrow \mathsf{PVW.KeyGen}(\mathsf{pp})$: Draw a secret key $\mathsf{sk} \xleftarrow{\$} \mathbb{Z}_q^{n\times\ell}$. Sample $A \xleftarrow{\$} \mathbb{Z}_q^{n\times w}$ and a noise matrix $X \in \mathbb{Z}_q^{\ell\times w}$ from the Gaussian distribution χ_σ, and compute $\mathsf{pk} = (A, P = \mathsf{sk}^T A + X)$.
- $\mathsf{ct} = (\vec{a},\vec{b}) \leftarrow \mathsf{PVW.Enc}(\mathsf{pp},\mathsf{pk}=(A,P),\vec{m})$: To encrypt a vector $\vec{m} \in \mathbb{Z}_2^\ell$, define the vector $\vec{t} = \frac{q}{2}\cdot\vec{m} \in \mathbb{Z}_q^\ell$, and draw $\vec{e} \xleftarrow{\$} \{0,1\}^w \in \mathbb{Z}_2^w$. The ciphertext is the pair $(\vec{a},\vec{b}) = (A\vec{e}, P\vec{e}+\vec{t}) \in \mathbb{Z}_q^n \times \mathbb{Z}_q^\ell$.
- $\vec{m} \leftarrow \mathsf{PVW.Dec}(\mathsf{pp},\mathsf{sk},\mathsf{ct}=(\vec{a},\vec{b}))$: $\vec{d} = \vec{b} - \mathsf{sk}^T\vec{a} \in \mathbb{Z}_q^\ell$, let $\vec{m} \in \mathbb{Z}_2^\ell$, and $\vec{m}[i] = 1$ iff $\vec{d}[i] + r/2 > r$ for all $i \in [\ell]$.

The scheme satisfies CPA security and tailored correctness: correct with probability $1-\varepsilon_n$ for some $0 < \varepsilon_n < 1$.

PVW also has two additional properties: key privacy (i.e., ciphertexts encrypted under different public keys are computationally indistinguishable); and zero-plaintext wrong-key decryption (i.e., given the wrong key, a PVW ciphertext is decrypted into a zero plaintext with small probability.) Since we later define these two properties for the PKE scheme we use in Thm 5.1, we skip the formal definition here for brevity.

3.2 Fully Homomorphic Encryption

Fully Homomorphic Encryption (FHE), introduced by Rivest et al. [37] and first constructed by Gentry [16], enables evaluation of a circuit on encrypted data.

BFV FHE scheme. We use the Brakerski/Fan-Vercauteran (BFV) homomorphic encryption scheme [7, 13].

BFV scheme consists of the following PPT algorithms: $\mathsf{GenParam}(1^\lambda), \mathsf{KeyGen}(\mathsf{pp_{BFV}}), \mathsf{Enc}(\mathsf{pp_{BFV}},\mathsf{pk},m)$, $\mathsf{Dec}(\mathsf{pp_{BFV}},\mathsf{sk},c)$ as normal PKE schemes. BFV is unconditionally correct and sound. Under the *RLWE* hardness assumption, it also fulfills CPA security.

Given a polynomial from the cyclotomic ring $R_t = \mathbb{Z}_t[X]/(X^D+1)$ (where D is a power-of-two, $t \equiv 1 \mod 2D$), the BFV scheme encrypts it into a ciphertext consisting of two polynomials, each of which in $R_Q = \mathbb{Z}_Q[X]/(X^D+1)$ for some $Q > t$. Here, t, Q, and D are called the plaintext modulus, the ciphertext modulus, and the ring dimension, respectively.

Plaintext encoding. In practice, instead of having a polynomial in $\mathcal{R}_t = \mathbb{Z}_t[X]/(X^D+1)$ directly as input, applications usually hold a vector of messages $\vec{m} = (m_1,\ldots,m_D) \in \mathbb{Z}_t^D$. Thus, to encrypt such input messages, BFV first encodes the messages into another polynomial $y(X) = \sum_{i\in[D]} y_i X^{i-1}$ such that $m_j = y(\zeta_j)$, $\zeta_j := \zeta^{3^j} \mod t$, and ζ is the $2N$-th primitive root of unity of t. Such encoding can be done using Inverse Number Theoretic Transform (INTT), which is a linear transformation represented as matrix multiplication. We say that a BFV ciphertext has D *slots*, each of which is a $\mathbb{Z}_t$ element.

For simplicity, we assume BFV.Enc takes a vector of form $\mathbb{Z}_t^D$ as an input, and BFV.Dec outputs a vector of form $\mathbb{Z}_t^D$, and will handle encode and decode implicitly. We use BFV.PartialDec to represent decryption without decoding. In other words, for a ciphertext ct, the output of $\mathsf{BFV.PartialDec}(\mathsf{sk},\mathsf{ct}) \in \mathcal{R}_t$ is the encoding of

$\mathsf{BFV.Dec}(\mathsf{sk},\mathsf{ct}) \in \mathbb{Z}_t^D$.

Operations. BFV supports the following operations.

- (Additions) For any two BFV ciphertexts $\mathsf{ct}_1, \mathsf{ct}_2$, and $\mathsf{ct} \leftarrow \mathsf{ct}_1 + \mathsf{ct}_2$, it holds that $\mathsf{BFV.Dec}(\mathsf{ct}) = \mathsf{BFV.Dec}(\mathsf{ct}_1) + \mathsf{BFV.Dec}(\mathsf{ct}_2)$ (element-wise).
- (Multiplication) For any two BFV ciphertexts $\mathsf{ct}_1, \mathsf{ct}_2$, and $\mathsf{ct} \leftarrow \mathsf{ct}_1 \times \mathsf{ct}_2$, it holds that $\mathsf{BFV.Dec}(\mathsf{ct}) = \mathsf{BFV.Dec}(\mathsf{ct}_1) \times \mathsf{BFV.Dec}(\mathsf{ct}_2)$ (element-wise).
- (Rotation) For any BFV ciphertexts ct, and $\mathsf{ct}' \leftarrow \mathsf{BFV.Rotate}(\mathsf{ct}, k)$ for some $k \in [D]$, let $\mathsf{BFV.Dec}(\mathsf{sk},\mathsf{ct})[i] = \mathsf{BFV.Dec}(\mathsf{sk},\mathsf{ct}')[i+k \mod D]$.
- (Substitution) For any BFV ciphertexts ct, and $\mathsf{ct}' \leftarrow \mathsf{BFV.Substitute}(\mathsf{ct}, k)$ for some odd number k, let $y(X) = \mathsf{BFV.PartialDec}(\mathsf{sk},\mathsf{ct})$ and $y'(X) = \mathsf{BFV.PartialDec}(\mathsf{sk},\mathsf{ct}')$, it holds that $y'(X) = y(X^k) \in \mathcal{R}_t$.

3.3 Oblivious Message Retrieval (Definition)

We adapt the definition of OMR from [21] by introducing a new parameter ν to relax the soundness and compactness as follows. At a high level, the scheme is allowed to include impertinent payloads, as long as the final output is still bounded by ν. For example, the scheme can bundle ν payloads together. If a bundle contains a pertinent message, the scheme can return all ν payloads in the bundle to the recipient. We discuss why this relaxation is reasonable in Remark 3.4.

Definition 3.2 (Oblivious Message Retrieval)**.** An Oblivious Message Retrieval scheme has the following PPT algorithms:

- $\mathsf{pp} \leftarrow \mathsf{GenParam}(1^\lambda, \varepsilon_\mathrm{p}, \varepsilon_\mathrm{n})$: takes a security parameter λ, a false positive rate ε_p, a false negative rate ε_n, and outputs a public parameter pp.
- $(\mathsf{sk}, \mathsf{pk} = (\mathsf{pk}_{\mathsf{clue}}, \mathsf{pk}_{\mathsf{detect}})) \leftarrow \mathsf{KeyGen}(\mathsf{pp})$: takes the public parameter pp; outputs a secret key sk and a public key pk consisting of a clue key $\mathsf{pk}_{\mathsf{clue}}$ and a detection key $\mathsf{pk}_{\mathsf{detect}}$.
- $c \leftarrow \mathsf{GenClue}(\mathsf{pp}, \mathsf{pk}_{\mathsf{clue}}, x)$: takes the public parameter pp, a clue key $\mathsf{pk}_{\mathsf{clue}}$, and a payload $x \in \mathcal{P}$ where $\mathcal{P} := \{0,1\}^P$ for some $P > 0$; outputs a clue $c \in \mathcal{C}$.
- $M \leftarrow \mathsf{Retrieve}(\mathsf{pp}, \mathsf{BB}, \mathsf{pk}_{\mathsf{detect}}, \bar{k})$: takes the public parameter pp, a bulletin board $\mathsf{BB} = \{(x_1,c_1), \ldots, (x_N,c_N)\}$ for size N, a detection key $\mathsf{pk}_{\mathsf{detect}}$, and an upper bound $\bar{k}$ on the number of pertinent messages addressed to that recipient; outputs a digest M.
- $\mathsf{PL} \leftarrow \mathsf{Decode}(\mathsf{pp}, M, \mathsf{sk})$: takes the public parameter pp, the digest M and the corresponding secret key sk; outputs either a decoded payload list $\mathsf{PL} \subset \mathcal{P}^k$ or an overflow indication $\mathsf{PL} = \mathsf{overflow}$.

To define soundness and completeness, we first define the notion of board generation:

Definition 3.3 (Board Generation)**.** Given pp, and the size of bulletin board N: arbitrarily choose the number of recipients $1 \le p \le N$, and a partition of set $[N]$ into p subsets $S_1, \ldots, S_p$ representing the indices of messages addressed to each party. Also arbitrarily choose unique payloads $(x_1, \ldots, x_N)$. For each recipient $i \in [p]$: generate keys $(\mathsf{sk}_i, \mathsf{pk}_i = (\mathsf{pk}_{\mathsf{clue}i}, \mathsf{pk}_{\mathsf{detect}i})) \leftarrow \mathsf{KeyGen}(\mathsf{pp})$, and for each $j \in S_i$, generate $c_j \leftarrow \mathsf{GenClue}(\mathsf{pk}_{\mathsf{clue}i}, x_j)$. Then, output the board $\mathsf{BB} = \{(x_1,c_1), \ldots, (x_N,c_N)\}$, the set S_1, and $(\mathsf{sk}_1, \mathsf{pk}_1 = (\mathsf{pk}_{\mathsf{clue}1}, \mathsf{pk}_{\mathsf{detect}1}))$.[3]

The scheme must satisfy the following properties:

- (Completeness) Let $\mathsf{pp} \leftarrow \mathsf{GenParam}(1^\lambda, \varepsilon_\mathrm{p}, \varepsilon_\mathrm{n}, \nu)$. Set any $N = \mathsf{poly}(\lambda)$, and $0 < \bar{k} \le N$. Let a board BB, a set S of pertinent messages, and a key pair $(\mathsf{sk}, \mathsf{pk} = (\mathsf{pk}_{\mathsf{clue}}, \mathsf{pk}_{\mathsf{detect}}))$ be generated as in Def 3.3 for any choice of p, partition and payloads therein. Let $M \leftarrow \mathsf{Retrieve}(\mathsf{BB}, \mathsf{pk}_{\mathsf{detect}}, \bar{k})$ and $\mathsf{PL} \leftarrow \mathsf{Decode}(M, \mathsf{sk})$. Let $k = |S|$ (the number of pertinent messages in S). Then either $k > \bar{k}$ and $\mathsf{PL} = \mathsf{overflow}$, or: $\Pr[x_j \in \mathsf{PL} \mid j \in S] \ge (1 - \varepsilon_\mathrm{n} - \mathsf{negl}(\lambda)) \quad \forall j \in [N]$.
- (ν-Soundness) For the same quantifiers as in Completeness: $|\mathsf{PL}| = \tilde{O}(\nu \cdot P \cdot (\bar{k} + \varepsilon_\mathrm{p} N))$
- (Computational privacy) For any PPT adversary $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$: let $\mathsf{pp} \leftarrow \mathsf{GenParam}(\varepsilon_\mathrm{p}, \varepsilon_\mathrm{n})$, $(\mathsf{sk}, \mathsf{pk} = (\mathsf{pk}_{\mathsf{clue}}, \mathsf{pk}_{\mathsf{detect}})) \leftarrow \mathsf{KeyGen}(\mathsf{pp})$ and $(\mathsf{sk}', \mathsf{pk}' = (\mathsf{pk}'_{\mathsf{clue}}, \mathsf{pk}'_{\mathsf{detect}})) \leftarrow \mathsf{KeyGen}(\mathsf{pp})$. Let the adversary choose a payload x and remember its state: $(x, \mathsf{st}) \leftarrow \mathcal{A}_1(\mathsf{pp}, \mathsf{pk}, \mathsf{pk}')$. Let $c \leftarrow \mathsf{GenClue}(\mathsf{pk}_{\mathsf{clue}}, x)$ and $c' \leftarrow \mathsf{GenClue}(\mathsf{pk}'_{\mathsf{clue}}, x)$. Then: $|\Pr[\mathcal{A}_2(\mathsf{st}, c) = 1] - \Pr[\mathcal{A}_2(\mathsf{st}, c') = 1]| \le \mathsf{negl}(\lambda)$.

An OMR scheme is ν-*compact* if it satisfies the following:

- (ν-Compactness) An OMR scheme is ν-compact if for $\mathsf{pp} \leftarrow \mathsf{GenParam}(1^\lambda, \varepsilon_\mathrm{p}, \varepsilon_\mathrm{n})$, $(\mathsf{sk}, \mathsf{pk} = (\mathsf{pk}_{\mathsf{clue}}, \mathsf{pk}_{\mathsf{detect}})) \leftarrow \mathsf{OMR.KeyGen}(\mathsf{pp})$, for any board $\mathsf{BB} = \{(x_1,c_1), \ldots, (x_N,c_N)\}$, letting $M \leftarrow \mathsf{Retrieve}(\mathsf{BB}, \mathsf{pk}_{\mathsf{detect}}, \bar{k})$, it always holds that: $|M| = \mathsf{poly}(\lambda, \log N) \cdot \log \varepsilon_\mathrm{p}^{-1} \cdot \tilde{O}(\bar{k} + \varepsilon_\mathrm{p} N) \cdot \nu$.

In the compactness definition, $\tilde{O}(\bar{k} + \varepsilon_\mathrm{p} N)$ (where $\tilde{O}(x) = x \cdot \mathsf{polylog}(x)$) accounts for the number of messages detected as pertinent, including false positives; and the remaining factors account for the cost of representing each such message, taking the payload size as constant.

Remark 3.4. Note that we have relaxed the "soundness" and "compactness" properties in [21, Def 4.3] special case to "ν-soundness" and "ν-compactness", allowing the digest and the decoded payloads to include more than just the pertinent messages, by a factor of ν. The scheme is thus allowed to bundle $O(\nu)$ messages as a single one and process them together (where each bundle may include pertinent messages and impertinent ones simultaneously).

In most applications of OMR, the recipients are able to find the single intended data payload from a bundle (e.g., the payloads are encrypted and using the wrong key to decrypt is detectable as a decryption failure). Therefore, in many cases, it is not an issue. See the full [23] version showing a general way to guarantee full soundness with a small cost.

[3] That is, S_1 is the indices of messages pertinent to the recipient whose keys are $\mathsf{sk}_1, \mathsf{pk}_1$, which wlog is the first recipient.

4 Revisiting the OMRp2 Construction

We first revisit and summarize the construction of OMR, OMRp2 in [21, Alg 8], which is the basis for improvements in later sections. Here, we abstract out each step of OMRp2 and provides modular analysis to each step to make the entire framework easier to understand.

4.1 Setup

OMRp2 mainly relies on the PVW encryption (see § 3.1) for clues and BFV FHE scheme (see § 3.2) for retrieval.

GenParam**.** Public parameter generation is straightforward. It outputs a public parameter pp including the PVW parameters $\mathsf{pp}_{\mathsf{PVW}} = (n, w, q, \ell, \mathcal{D}, \sigma)$, the BFV parameters $\mathsf{pp}_{\mathsf{BFV}} = (D, t, \dots)$,[4], false positive rate ε_{p} and false negative rate ε_{n}.

KeyGen**.** The recipient first generates a PVW key pair $(\mathsf{sk}_{\mathsf{pvw}}, \mathsf{pk}_{\mathsf{pvw}})$ and a BFV key pair $(\mathsf{sk}_{\mathsf{BFV}}, \mathsf{pk}_{\mathsf{BFV}})$. $\mathsf{pk}_{\mathsf{pvw}}$ will be the clue key. The recipient then generates $\mathsf{ct}_{\mathsf{sk}} \leftarrow \mathsf{BFV.Enc}(\mathsf{pp}_{\mathsf{BFV}}, \mathsf{pk}_{\mathsf{BFV}}, \mathsf{sk}_{\mathsf{pvw}})$, the encrypted $\mathsf{sk}_{\mathsf{pvw}}$ under $\mathsf{pk}_{\mathsf{BFV}}$. The tuple $(\mathsf{ct}_{\mathsf{sk}}, \mathsf{pk}_{\mathsf{BFV}})$ serves as the detection key.

GenClue**.** After fetching the recipient's $\mathsf{pk}_{\mathsf{clue}}$, the sender computes $c \leftarrow \mathsf{PVW.Enc}(\mathsf{pp}_{\mathsf{PVW}}, 1^{\ell})$. If a clue is decrypted to 1^{ℓ}, it indicates that the message is pertinent. Otherwise, there is at least one zero among the ℓ bits, and the message is impertinent. Based on the wrong-key decryption property, if a message is impertinent, the decrypted message will not be 1^{ℓ} with high probability.

4.2 Retrieval

To retrieve the pertinent messages for the recipients, the detector invokes OMRp2.Retrieve, which is composed of three main steps. We first define those steps and describe how OMRp2 in [21] realizes them. Looking ahead, our new construction rewrites these three with better efficiency, both asymptotically and concretely.

4.2.1 Step 1: From Bulletin Board to Pertinency Vector

The first step takes the detection key and all the clues on the bulletin board, and outputs a vector of BFV ciphertexts, each slot of which indicates whether a single message is pertinent (we call *pertinency vector*, PV). We visualize it in Fig. 1. The interface is defined as follows:

- $(\mathsf{ct}_1, \dots, \mathsf{ct}_d) \leftarrow \mathsf{ClueToPackedPV}(\mathsf{pp}, \mathsf{pk}_{\mathsf{detect}}, \mathsf{BB})$: takes public parameter pp, a detection key $\mathsf{pk}_{\mathsf{detect}}$, and a bulletin board BB of size N; outputs a vector of BFV ciphertexts $(\mathsf{ct}_1, \dots, \mathsf{ct}_d)$ where $d = \lceil N/D \rceil$.

[4]Technically, we should also set Q, the ciphertext modulus, to guarantee that there is enough noise budget to evaluate the entire circuit. However, it is not used in constructions explicitly, we leave it implicit for better readability.

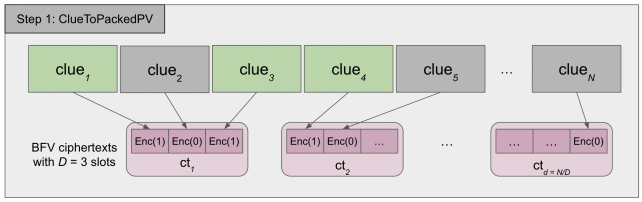

Figure 1: Visualization of Step 1 ClueToPackedPV. The green clues are for the pertinent messages and the gray ones are for the impertinent messages. Each BFV ciphertext in pale pink has $D = 3$ slots and each slot in dark pink encrypts the pertinency of a single message. For N messages, the output has $d = N/D = N/3$ ciphertexts.

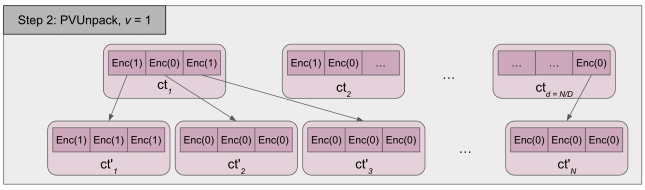
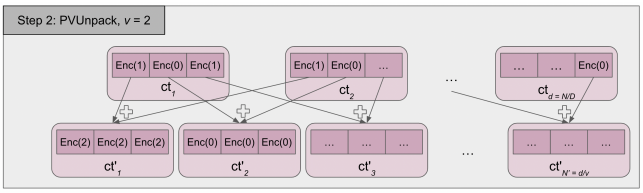


Recall that each BFV ciphertext contains D slots (i.e., encrypting a vector of $\mathbb{Z}_t^D$ for t being the plaintext modulus), where D is the ring dimension. If the i-th message is pertinent, the i-th slots should be 1; and 0 otherwise. Thus, there are in total of $\lceil N/D \rceil$ ciphertexts with $\geq N$ slots to encrypt the pertinency of each message. Correctness is defined as follows:

Definition 4.1 (Correctness of ClueToPackedPV)**.** Let $\mathsf{pp} \leftarrow \mathsf{GenParam}(1^{\lambda}, \varepsilon_{\mathrm{p}}, \varepsilon_{\mathrm{n}})$. For any $N = \mathsf{poly}(\lambda)$, and $0 < \bar{k} \leq N$, let a board BB, a set S of pertinent messages, and a key pair $(\mathsf{sk}, \mathsf{pk} = (\mathsf{pk}_{\mathsf{clue}}, \mathsf{pk}_{\mathsf{detect}}))$ be generated as in Def 3.3 for any choice of p, partition and payloads therein, let $(\mathsf{ct}_1, \dots, \mathsf{ct}_d) \leftarrow \mathsf{ClueToPackedPV}(\mathsf{pp}, \mathsf{pk}_{\mathsf{detect}}, \mathsf{BB})$, it holds that: (1) $\Pr[\mathsf{BFV.Dec}(\mathsf{sk}, \mathsf{ct}_j)[i] = 1 \mid j \cdot D + i \in S] \geq (1 - \varepsilon_{\mathrm{n}} - \mathsf{negl}(\lambda))$ for all $i \in [D], j \in [d]$.
and: (2) $\Pr[\mathsf{BFV.Dec}(\mathsf{sk}, \mathsf{ct}_j)[i] = 1 \mid j \cdot D + i \notin S] \leq (\varepsilon_{\mathrm{p}} + \mathsf{negl}(\lambda))$ for all $i \in [D], j \in [d]$.



ClueToPackedPV **Implementation.** In the construction of OMRp2, the detector uses $\mathsf{ct}_{\mathsf{sk}}$ to homomorphically decrypt each clue (where $\mathsf{ct}_{\mathsf{sk}}$ is the encryption of the PVW secret key and the clue is a PVW ciphertext). If a message is indeed pertinent, the homomorphic decryption yields 1^{ℓ} except with $\varepsilon_{\mathrm{n}} + \mathsf{negl}(\lambda)$ probability. Otherwise, the result would be 1^{ℓ} with probability $\leq \varepsilon_{\mathrm{p}} + \mathsf{negl}(\lambda)$. Lastly, the detector multiplies all the ℓ bits, and gets 1 if and only if the message is pertinent.

This homomorphic decryption circuit is evaluated under BFV, and D messages are processed simultaneously. As mentioned before, the ciphertext ct after the homomorphic decryption has D slots, where the i-th slot encrypts 1 if and only if the i-th message is pertinent (except with some small bounded probability), for $i \in [D]$. This decryption process is repeated $d = \lceil N/D \rceil$ times to obtain ciphertexts for all the N messages.

Essentially, let $\mathsf{sk}[i] \in \mathbb{Z}_q^n$ denote the i-th column of $\mathsf{sk} \in \mathbb{Z}_q^{n \times \ell}$, the PVW decryption circuit checks whether $|b[i] - \langle \vec{a}, \mathsf{sk}[i] \rangle| \leq r$ for $i \in [\ell]$, for each clue of form $(\vec{a}, \vec{b}) \in \mathbb{Z}_q^n \times \mathbb{Z}_q^{\ell}$. The evaluation of $b[i] - \langle \vec{a}, \mathsf{sk}[i] \rangle$ is easy. The hard part is the range check, as BFV operates over a finite field and only

(a) Step 2 with $\mathsf{v} = 1$ (i.e., for the original OMR construction in § 4.2.2)

(b) Step 2 with $\mathsf{v} = 2$ (i.e., for our new construction in § 5.2.2)

Figure 2: Visualization of step 2 PVUnpack. When $\mathsf{v} = 1$, each slot is expanded into a single BFV ciphertext, resulting in N ciphertexts. When $\mathsf{v} = 2$, two slots are added up and expanded into a single BFV ciphertext, thus N/v ciphertexts

supports additions and multiplications. Fortunately, one important observation in [21] is that any function over $\mathbb{Z}_t$ can be represented by a polynomial with degree-$(t-1)$. Therefore, the detector interpolates a degree-$(t-1)$ function to check the range and completes the step ClueToPackedPV.

4.2.2 Step 2: Unpack the Pertinency Vector

After obtaining the pertinency vector, to prepare for the third step, the framework in [21] unpacks those N slots (of the $\lceil N/D \rceil$ ciphertexts from last step) into N ciphertexts. If the i-th slot is 1, the i-th ciphertext after unpacking encrypts 1 in all of its D slots, and 0 in all D slots otherwise.

We further generalize this step to take a parameter called *bundle size* v to output N/v ciphertexts instead of N ciphertexts. For $\mathsf{v} = 1$, this procedure simply unpacks N slots into N separate ciphertexts. Looking ahead, in section § 5.2.2, we bundle $\mathsf{v} > 1$ messages into a single one for better efficiency: the i-th ciphertext after unpacking encrypts the number of slots encrypting 1's among all the v slots corresponding to the bundled messages. For simplicity, we require v to divide d. We visualize step 2 and the difference between $v = 1$ and $v > 1$ in Fig. 2. The interface is as follows:

- $(\mathsf{ct}'_1, \ldots, \mathsf{ct}'_{N'}) \leftarrow \mathsf{PVUnpack}(\mathsf{pp}, \mathsf{pk}_{\mathsf{detect}}, (\mathsf{ct}_1, \ldots, \mathsf{ct}_d), \mathsf{v})$: takes public parameter pp, a detect key $\mathsf{pk}_{\mathsf{detect}}$, a vector of BFV ciphertexts of length d, the bundle size v; outputs a vector of BFV ciphertexts of size $N' = d \cdot D/\mathsf{v}$ for D being the underlying BFV ring dimension.

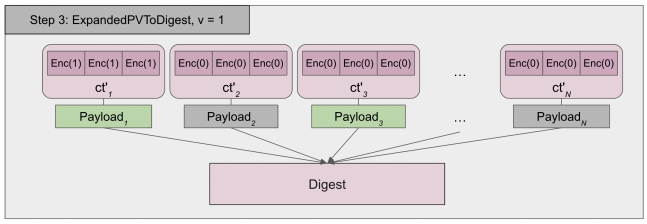
Definition 4.2 (Correctness of PVUnpack)**.** Let pp, $\mathsf{sk}, \mathsf{pk} = (\mathsf{pk}_{\mathsf{clue}}, \mathsf{pk}_{\mathsf{detect}})$ generated as in Def 4.1, for any vector of ciphertexts $(\mathsf{ct}_1, \ldots, \mathsf{ct}_d)$, let $(\mathsf{ct}'_1, \ldots, \mathsf{ct}'_{N'}) \leftarrow \mathsf{PVUnpack}(\mathsf{pp}, \mathsf{pk}_{\mathsf{detect}}, (\mathsf{ct}_1, \ldots, \mathsf{ct}_d), \mathsf{v})$, it holds that:$\forall i \in [D], j \in [0, \frac{d}{\mathsf{v}} - 1]$, $\Pr[\mathsf{BFV.Dec}(\mathsf{sk}, \mathsf{ct}'_{j \cdot D + i}) = (\sum_{w=0}^{\mathsf{v}-1} \mathsf{BFV.Dec}(\mathsf{sk}, \mathsf{ct}_{j \cdot \mathsf{v} + w})[i])^D] \geq 1 - \mathsf{negl}$

PVUnpack **Implementation (with** $\mathsf{v} = 1$**).** We explain detailed construction in [21] by giving a simplified example of unpacking a single ciphertext, i.e., given a BFV ciphertext ct encrypting $(b_1, \ldots, b_D)$ where b_i is the i-th encrypted bit, we eventually want D new ciphertexts where the i-th ciphertext encrypts $\vec{b_i} := (b_i, \ldots, b_i)$, which is a vector of D b_i's in all slots.

[21] first multiply ct with $(0, \ldots, 0, 1, 0, \ldots, 0) \in \mathbb{Z}_t^D$ where the i-th slot is 1 and other slots are 0, obtaining a ciphertext ct' encrypting $(0, \ldots, 0, b_i, 0, \ldots, 0)$, where b_i is the i-th element encrypted in ct. To fill all the D slots with the same value b_i, [21] uses the rotate-and-add method: for $j \in [\log(D)]$, it computes $\mathsf{ct}' \leftarrow \mathsf{ct}' + \mathsf{BFV.Rotate}(\mathsf{ct}', 2^{j-1})$. The final ciphertext ct' thus encrypts $\vec{b_i}$ as desired. This process is simply repeated D times for each input ciphertext.[5] This step requires D multiplications and $D\log(D)$ rotations in total.

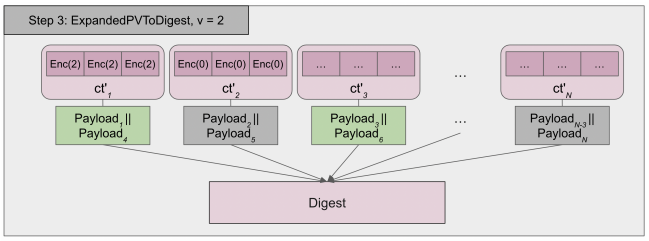
4.2.3 Step 3: Use PV to Construct the Digest

Lastly, with all these N' ciphertexts above encrypting either non-zero (if pertinent) or zero (if impertinent), the detector forms a compact digest using BFV: if the i-th ciphertext does not encrypt zero, message i should be included in the digest. In OMRp2, $N' = N$, and each ciphertext either encrypts 1 or 0. However, our optimization requires those ciphertexts to encrypt $\mathsf{v} > 1$ and $N' = N/\mathsf{v}$. We visualize step 3 in Fig. 3. The interface is as follows:



- $M \leftarrow \mathsf{ExpandedPVToDigest}(\mathsf{pp}, \mathsf{pk}_{\mathsf{detect}}, (\mathsf{ct}_1, \ldots, \mathsf{ct}_{N'}, \bar{k}), \mathsf{BB})$: takes public parameter pp, a detector key $\mathsf{pk}_{\mathsf{detect}}$, a vector of BFV ciphertexts of length N', a bulletin board BB of size $N \geq N'$, N divides N', and an upper bound $\bar{k}$ on the number of pertinent messages addressed to that recipient; outputs a digest M.

Definition 4.3 (Correctness of ExpandedPVToDigest)**.** There exists a PPT algorithm DecodeDigest taking a digest M and a secret key sk and outputing payloads PL such that: for the same quantifiers as in Def 4.1, for any $N' \leq N$, and any vector of ciphertexts $(\mathsf{ct}_1, \ldots, \mathsf{ct}_{N'})$ encrypted under $\mathsf{pk}_{\mathsf{detect}} = \mathsf{pk}_{\mathsf{BFV}}$, let $M \leftarrow \mathsf{ExpandedPVToDigest}(\mathsf{pp}, \mathsf{pk}_{\mathsf{detect}}, (\mathsf{ct}_1, \ldots, \mathsf{ct}_{N'}), \bar{k}, \mathsf{BB})$ and $\mathsf{PL} \leftarrow \mathsf{DecodeDigest}(M, \mathsf{sk})$; let $k = |S|$ (the number of pertinent messages in S), it holds that either $k > \bar{k}$ and $\mathsf{PL} = \mathsf{overflow}$, or: $\Pr[x_j \in \mathsf{PL} \mid \mathsf{BFV.Dec}(\mathsf{sk}, \mathsf{ct}_i) \neq 0^D] \geq (1 - \mathsf{negl}(\lambda))$, for all $j \in [N], i \leftarrow j \bmod N'$



ExpandedPVToDigest **Implementation (with** $N' = N$**).** To realize ExpandedPVToDigest, [21] first encodes all the per-

[4] Here $(\cdot)^D$ means a vector of D of $\cdot$ elements.

[5] In [22], the authors provide an optimization to this step at the cost of a deeper circuit. We omit the details here for simplicity.

(a) Step 3 with $\mathsf{v} = 1$ (i.e., for the original OMR construction in § 4.2.3)

(b) Step 3 with $\mathsf{v} = 2$ (i.e., for our new construction in § 5.2.3)

Figure 3: Visualization of step 3 ExpandedPVToDigest. When $\mathsf{v} = 1$, each ciphertext has one corresponding payload to be included in the digest. When $\mathsf{v} = 2$, since two messages are viewed as a single one, their payloads are concatenated.

tinent indices into the digest, and then the corresponding pertinent payloads.

We refer to the first part as "index encoding": OMRp2 first initialize $m > \bar{k}$ buckets, where $\bar{k}$ is the upper bound of the number of pertinent messages. Then, it randomly assigns all the N messages into m buckets, and let Y_i, represent the set of messages (represented by indices) assigned to bucket $i \in [m]$.

For each bucket $i \in [m]$, compute $\mathsf{Acc}_i \leftarrow \sum_{j \in Y_i} (\mathsf{ct}_j \cdot j)$. If there is no pertinent message assigned to bucket i, Acc_i encrypts 0. If there is only one pertinent message j assigned to bucket i, Acc_i encrypts j, and the recipient can easily decrypt j to be the index of that pertinent message. However, if more than one pertinent message gets assigned in bucket i, there is a collision. To inform recipients of such collisions, OMRp2 computes $\mathsf{ctr}_i \leftarrow \sum_{j \in Y_i} \mathsf{ct}_j$ for bucket i, which is the number of pertinent messages assigned to bucket i. [6] The process is repeated $C \geq 1$ times to allow the recipient to obtain all the pertinent indices except with negligible probability, even with non-negligible probability of collision.

After obtaining all the pertinent indices, obtaining the pertinent payloads is easier. We refer to this second part as "payload encoding". The detector first samples a uniform random matrix[7] $A \in \mathbb{Z}_t^{K \times N}$ for some $K > \bar{k}$, and computes $\mathsf{comb} \leftarrow (A \circ Z) \times (\mathsf{ct}_1, \ldots, \mathsf{ct}_N)$, where $Z = \begin{pmatrix} x_1, x_2, \ldots, x_N \\ \vdots \\ x_1, x_2, \ldots, x_N \end{pmatrix} \in \mathcal{P}^{K \times N}$,[8] for x_i being payload of message i (recall that $\circ$ is the Hadamard prodoct introduced in § 3). With the pertinent indices and A (sent to the recipient as a random seed), the recipient uses Gaussian elimination to solve for all the pertinent payloads except with negligible probability.[9]

The digest thus includes $B_j = ((\mathsf{Acc}_{i,j})_{i \in [m]}, (\mathsf{ctr}_{i,j})), \forall j \in [C]$, together with comb, and the seed s used to generate A.

4.3 Decoding

The last step is for the recipient to run Decode. The recipient first checks all the counters $\mathsf{ctr}_{i,j}$ ($i \in [m], j \in [C]$) and filters the ones that encrypt 1. The corresponding $\mathsf{Acc}_{i,j}$ then contain all the pertinent indices. After obtaining these indices, the recipient uses the seed s to recover A and uses comb to solve for all the pertinent payloads.

5 Improved OMR Construction

This section focuses on our new construction of OMR, containing a new setup phase (a different way to generate the clue keys and the clue) and a more efficient algorithm for each of the three steps forming the detector retrieval.

5.1 Reducing the Clue Key Size using RLWE

We start with the setup algorithms and keys in § 4.1. Recall that the setup for each recipient is essentially generating a PVW key pair, whose public part serves as the clue key. One major issue with the PVW scheme used in OMRp2 is that the public key size is $w\ell \log(q) = \omega(\ell n \log^2(q))$, and concretely, hundreds of kilobytes — which is awkward to distribute (e.g., it is too large for direct inclusion in a cryptocurrency wallet address). We introduce a tailored variant of RLWE encryption of [26] to resolve this issue.

The main contributor to the large PVW public key is the parameter w, which is the number of LWE samples it contains. $w = \omega(n \log(q))$ is required by the leftover-hash lemma to guarantee that $A\vec{e}, P\vec{e}$ are indistinguishable from uniformly random vectors over $\mathbb{Z}_q$.[10] However, instead of making $A\vec{e}, P\vec{e}$ statistically indistinguishable from randomly drawn vectors, the scheme can rely on computational assumptions.

In other words, for $w = n$, although $A\vec{e}, P\vec{e}$ by themselves are not statistically close to random vectors, by adding some noise and get $A\vec{e} + \vec{x}', P\vec{e} + \vec{x}''$, where $\vec{x}', \vec{x}''$ are noise vectors, we again have the resulting public key indistinguishable from

[6] Note that if there are $t+1$ pertinent messages, there is an overflow since the calculation is done over $\mathbb{Z}_t$. However, [21] parametrizes the construction such that it overflows with negligible probability.

[7] Note that in [21, 22], a sparse matrix is used instead. However, that requires additional explanation and is not useful for us, so we ignore that part. See Remark 5.5 for more discussion.

[8] W.o.l.g., assume $\mathcal{P} := \{0,1\}^P$ can be embedded to $\mathbb{Z}_t$ as if not, simply repeat this process for $P/\log(t)$ times.

[9] As in [21], $K = \bar{k} + \delta/\log(t)$ to achieve $O(2^{-\delta})$ failure probability.

[10] Recall that $A\vec{e}, P\vec{e}$ are computed during PVW.Enc for $A, P \in \mathbb{Z}_q^{n \times w} \times \mathbb{Z}_q^{n \times \ell}$ being the public key (§ 3.1).

random vectors based on LWE assumption; and thus greatly reduces the public key size with $w = n$.

To achieve even better efficiency, instead of relying on LWE, we rely on RLWE. In more detail, the key generation algorithm samples $\alpha \xleftarrow{\$} \mathcal{R}_q$, where $\mathcal{R} := \mathbb{Z}(X)/(X^n+1)$ for some security parameter n being a power-of-two. The secret key $s \in \mathcal{R}$ is sampled from some distribution $\mathcal{D}$, and the public key is $(\alpha, \beta = \alpha s + x)$ for some noise x sampled from noise distribution χ_σ. To encrypt, the sender simply samples $e \leftarrow \mathcal{D}$ and computes $a \leftarrow \alpha e + x', b \leftarrow \beta e + x''$ where $x', x'' \leftarrow \chi_\sigma$.

To make it more suitable for our use case, since we need to encrypt just $\ell \ll n$ bits, only the first ℓ coefficients of the ring element b are needed during decryption. In addition, to guarantee correctness with probability $1 - \varepsilon_n$, the scheme simply needs to choose a range parameter r used for decryption to guarantee that the noise of the ciphertexts is $\leq r$ except with ε_n probability. With all noises sampled from χ_σ, and a distribution $\mathcal{D}$ such that the Hamming weight of s, e drawn from $\mathcal{D}$ are both bounded by h and $|s|_\infty, |e|_\infty = 1$, the aggregated noise of $(as + b)$ can be viewed as sampled from distribution $\chi_{\sqrt{2h+1}\cdot\sigma}$ (since there are in total $2h+1$ independently sampled noise being summed up). We can thus set r according to $\chi_{\sqrt{2h+1}\cdot\sigma}$ to guarantee correctness.

Defining sRLWE **encryption.** Putting all these together, we get a tailored variant of the RLWE encryption formally stated as follows:

- $\mathsf{pp} = (n, \ell, q, \sigma, r, \mathcal{D}) \leftarrow \mathsf{sRLWE.GenParam}(1^\lambda, \ell, q, \sigma, \varepsilon_n)$: Choose a secret key dimension n and a distribution $\mathcal{D}$ where the distribution is sampling a random vector of form $\{-1, 0, 1\}^n$ with a fixed Hamming weight h, such that $\mathsf{RLWE}_{n,q,\mathcal{D},\sigma}$ holds. Set ciphertext modulus q, number of bits in plaintext $\ell \leq n$, and standard deviation σ for Gaussian distribution for ciphertext noise generation. Additionally, set minimum integer r such that $\mathsf{erf}(\frac{r}{\sqrt{2}\cdot\sqrt{2h+1}\cdot\sigma}) \leq \varepsilon_n/\ell$.
- $(\mathsf{sk}, \mathsf{pk}) \leftarrow \mathsf{sRLWE.KeyGen}(\mathsf{pp})$: Draw a secret key $s \leftarrow \mathcal{D}$. Sample $\alpha \xleftarrow{\$} \mathcal{R}_q$ and noise $x \leftarrow \chi_\sigma \in \mathcal{R}$, and compute $\mathsf{pk} = (\alpha, \alpha s + x) \in \mathcal{R}_q \times \mathcal{R}_q$, $\mathsf{sk} \leftarrow s$.
- $\mathsf{ct} = (a, \vec{b}) \leftarrow \mathsf{sRLWE.Enc}(\mathsf{pp}, \mathsf{pk}, \vec{m})$: To encrypt a vector $\vec{m} \in \mathbb{Z}_2^\ell$, define the ring element $t \leftarrow \sum_{i\in[\ell]} \frac{q}{2} \cdot \vec{m}[i] X^{i-1} \in \mathcal{R}_q$. Draw a ring element $e \leftarrow \mathcal{D} \in \mathcal{R}_q$ and noises $x', x'' \leftarrow \chi_\sigma$. Let $b \leftarrow t + x'' = \sum_{i\in[N]} b_i X^{i-1}$. The ciphertext is the pair $(a, \vec{b}) = (\alpha e + x', (b_i)_{i\in[\ell]}) \in \mathcal{R}_q \times \mathbb{Z}_q^\ell$.
- $\vec{m} \leftarrow \mathsf{sRLWE.Dec}(\mathsf{pp}, \mathsf{sk}, \mathsf{ct} = (a, \vec{b}))$: Let $a' \leftarrow a \cdot \mathsf{sk} := \sum_{i\in[n]} a'_i X^{i-1}$, $\vec{d} = \vec{b} - (a'_i)_{i\in[\ell]}$, $\vec{m} = \lfloor \frac{\vec{d} + q/2}{r} \rfloor \in \mathbb{Z}_2^\ell$.

We formalize the properties of sRLWE, including the (tailored) correctness, CPA security, key privacy (i.e., ciphertexts under different public keys are computationally indistinguishable) and zero-plaintext wrong-key decryption (i.e., given the wrong key, a PVW ciphertext is decrypted into a non-zero plaintext with high probability), as follows. These follow from the analysis above and RLWE.

Theorem 5.1. *Assuming the hardness of RLWE,* sRLWE *satisfies the following properties:*

- *(Correctness) For any* $\lambda > 0, q = \mathsf{poly}(\lambda), \sigma > 0, 1 > \varepsilon_n > 0$ *and* $\ell \leq n$ *for* n *chosen in* $\mathsf{pp}_{\mathsf{sRLWE}}$*, let* $\mathsf{pp}_{\mathsf{sRLWE}} \leftarrow \mathsf{sRLWE.KeyGen}(1^\lambda, \ell, q, \sigma, \varepsilon_n)$*,* $(\mathsf{sk}, \mathsf{pk}) \leftarrow \mathsf{sRLWE.KeyGen}(\mathsf{pp}_{\mathsf{sRLWE}})$*, for any message* $\vec{m} \in \{0,1\}^\ell$*, it holds that:* $\Pr[\mathsf{sRLWE.Dec}(\mathsf{sk}, \mathsf{sRLWE.Enc}(\mathsf{pk}, \vec{m})) = \vec{m}] \geq 1 - \varepsilon_n - \mathsf{negl}(\lambda)$.
- *(CPA security) For any PPT adversary* $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$*, for the same quantifiers above in correctness, let the adversary choose two messages* $(\vec{m}_1, \vec{m}_2, \mathsf{st}) \leftarrow \mathcal{A}_1(\mathsf{pp}_{\mathsf{sRLWE}}, \mathsf{pk})$*; let* $b \xleftarrow{\$} \{1,2\}, \mathsf{ct} \leftarrow \mathsf{sRLWE.Enc}(\mathsf{pp}_{\mathsf{sRLWE}}, \mathsf{pk}, \vec{m}_b)$*, it holds that:* $|\Pr[\mathcal{A}_2(\mathsf{st}, \mathsf{ct}) = b]| \leq \mathsf{negl}(\lambda)$.
- *(Key privacy) For the same quantifiers above in CPA security, let* $(\mathsf{sk}', \mathsf{pk}') \leftarrow \mathsf{sRLWE.KeyGen}(\mathsf{pp}_{\mathsf{sRLWE}})$*; let the adversary choose a message* $(\vec{m}, \mathsf{st}) \leftarrow \mathcal{A}_1(\mathsf{pp}_{\mathsf{sRLWE}}, \mathsf{pk}, \mathsf{pk}')$*; let* $\mathsf{ct} \leftarrow \mathsf{sRLWE.Enc}(\mathsf{pp}_{\mathsf{sRLWE}}, \mathsf{pk}, \vec{m})$*,* $\mathsf{ct}' \leftarrow \mathsf{sRLWE.Enc}(\mathsf{pp}_{\mathsf{sRLWE}}, \mathsf{pk}', \vec{m})$*, it holds that:* $|\Pr[\mathcal{A}_2(\mathsf{st}, \mathsf{ct}) = 1] - \Pr[\mathcal{A}_2(\mathsf{st}, \mathsf{ct}') = 1]| \leq \mathsf{negl}(\lambda)$.
- *(Zero-plaintext wrong-key decryption) For the same quantifiers above in correctness, let* $(\mathsf{sk}', \mathsf{pk}') \leftarrow \mathsf{sRLWE.KeyGen}(\mathsf{pp}_{\mathsf{sRLWE}})$*; it holds that:* $\Pr[\mathsf{sRLWE.Dec}(\mathsf{sk}', \mathsf{sRLWE.Enc}(\mathsf{pk}, 0^\ell)) = 0^\ell] \leq (\frac{r}{q})^\ell + \mathsf{negl}(\lambda)$.

Proof. • (Correctness) The noise of a ciphertext comes from x, x', x'' all sampled from χ_σ. Since $\mathcal{D}$ gives out a binary vector with hamming weight x, there are $2h$ Gaussian noise contributed by x, x', sampled independently. Additionally, x'' is one additional Gaussian noise. In total, there are $2h+1$ independently sampled noises from discrete Gaussian distribution $(0, \sigma)$. The resulting noise x_t is thus from discrete Gaussian distribution $(0, \sqrt{2h+1}\sigma)$. To satisfy $\Pr[r \geq x_t] \geq 1 - p$ for some probability $0 > p > 1$, it is required that $\mathsf{erf}(\frac{r}{\sqrt{2}\cdot\sqrt{2h+1}\cdot\sigma}) \leq p$. As required by sRLWE.GenParam, $\mathsf{erf}(\frac{r}{\sqrt{2}\cdot\sqrt{2h+1}\cdot\sigma}) \leq \varepsilon_n/\ell$. Thus, by union bound, all $\ell \geq 1$ noises together are bounded by r with probability ε_n. Thus, the correctness property follows straightforwardly.

• (CPA security) CPA security is the same as the original RLWE encryption in [26]. Then only change we make is that the ciphertext only contains $\vec{b} \in \mathbb{Z}_q^\ell$ instead of $b \in \mathcal{R}_q$. However, this does not affect the security guarantee (given that the RLWE assumption holds for our parameters).

• (Key privacy) We argue key privacy via a hybrid argument. We introduce the hybrid construction Π_1: the only difference between Π_1 and sRLWE is that instead of computing $a \leftarrow \alpha e + x, b \leftarrow \beta e + x'' + t$ as in Enc (where $t \leftarrow \sum_{i\in[\ell]} \frac{q}{2} \cdot \vec{m}[i] X^{i-1} \in \mathcal{R}_q$ for $\vec{m}$ being the input plaintext of ℓ bits), it first samples $a, b' \xleftarrow{\$} \mathcal{R}_q$ uniformly at random, and then compute $b \leftarrow b' + t$, and outputs (a, b') as the ciphertext. This is simple OTP and thus achieves key privacy trivially. Thus, if there exists an adversary that breaks sRLWE, since it cannot break Π_1, it must break the Ring-LWE assumption.

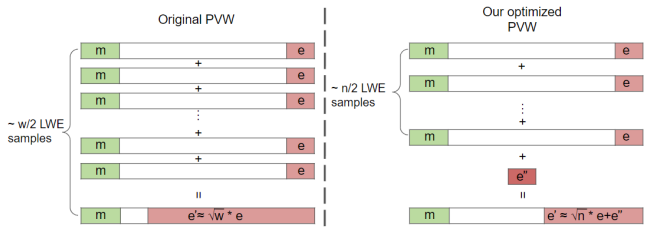


Figure 4: Visualization of the reduced noise of the ciphertexts from our RLWE encryption variant scheme compared to the original PVW scheme

- (Zero-plaintext wrong-key decryption) By RLWE, given a ciphertext $\mathsf{ct} = (a, \vec{b})$ encrypted under sk', $\vec{b}$ is indistinguishable from a random vector sampled from $\mathbb{Z}_q^\ell$ with respect to sk sampled independently from sk'. Therefore, $\vec{b} - a\mathsf{sk}$ results in a random vector sampled from $\mathbb{Z}_q^\ell$, which decrypts to 0^ℓ with probability $(\frac{2r+1}{q})^\ell + \mathsf{negl}(\lambda)$.

□

Efficiency. Since α can be represented as a random seed, and β has $n\log(q)$ bits, the public key size is now $n \cdot \log(q)$ bits, which is much smaller.

Setup for our OMR construction. Our very first step is to replace the underlying PVW scheme in OMRp2 with our RLWE encryption variant sRLWE. This reduces the clue key and sender runtime.

Smaller range r. One additional property of sRLWE compared to PVW is that the value r is much smaller than in § 3.1. sRLWE requires $\mathsf{erf}(\frac{r}{\sqrt{2}\cdot\sqrt{2h+1}\cdot\sigma}) \leq \varepsilon_n/\ell$, while the original PVW requires $\mathsf{erf}(\frac{r}{\sqrt{2}\cdot\sqrt{w}\cdot\sigma}) \leq \varepsilon_n/\ell$ as in [21]. Since $h = O(n)$ and $w = \omega(n\log(n))$, the new noise range is much smaller. We visualize the difference in Fig. 4.

5.2 A New Retrieval Circuit

Another major bottleneck of the prior OMR construction is the detector runtime. Therefore, we shift our focus to Retrieve and design a new and more efficient retrieval circuit.

5.2.1 A New Decryption Circuit for Step 1

Recall that in OMRp2 step 1 (§ 4.2.1), the detector homomorphically decrypts the PVW ciphertexts via a linear transformation followed by a degree-$(t-1)$ polynomial (where t is the plaintext modulus of BFV, $t = q$ for q being the PVW ciphertext modulus). The evaluation of the polynomial requires $O(t)$ homomorphic operations, which is costly for $t > 2D$, where D is the ring dimension of the underlying BFV.

Fortunately, since the new RLWE encryption variant has a much smaller range r, a new more efficient circuit can be designed as follows. The fundamental goal is to compute the following function using a polynomial function: $f(x) = \begin{cases} 0 & \text{if } t-r \leq x \leq r \\ 1 & \text{o.w.} \end{cases}$. While it has t distinct points, implying a degree-$(t-1)$ function, it can be evaluated more efficiently at the cost of having a higher degree, i.e., we represent $f(x) := (\prod_{i=-r}^{r}(x-i))^{t-1}$. This representation chiefly requires two steps of computation: $y = \prod_{i=-r}^{r}(x-i)$, checking whether $x \in [-r, r]$, if so, $y = 0$; otherwise, $y \neq 0$. By Fermat's Little Theorem, y^{t-1} returns 1 iff $y \neq 0$. Therefore, it is equivalent to the defined $f(x)$ above. Furthermore, we optimize the evaluation of y to be $y = \prod_{i=0}^{r}(x^2 - i^2)$, which is equivalent as before, but has $r+1$ multiplications instead of $2r$ multiplications, and thus can be evaluated more efficiently.

Algorithm 1 Our new ClueToPackedPV

procedure PerfOMR1.ClueToPackedPV($\mathsf{pp}, \mathsf{pk}_{\mathsf{detect}} = (\mathsf{pk}_{\mathsf{BFV}}, \mathsf{ct}_{\mathsf{sk}}, \mathsf{BB} = (x_i, c_i)_{i\in[N]})$
  ▷ $\mathsf{ct}_{\mathsf{sk}} = \mathsf{Enc}(\mathsf{sk}_{\mathsf{BFV}}, \mathsf{sk}_{\mathsf{pvw}})$)
  Parse $c_i = (a_i = \sum_j a_{i,j} X^{j-1}, \vec{b} = (b_{i,l})_{l\in[\ell]})$
  Let $d \leftarrow \lceil N/D \rceil$
  for $k \in [d]$ **do** ▷ D is the ring dimension of the BFV scheme
    for $l \in [\ell]$ **do**
      for $u \in [D]$ **do**
        Let $\vec{a}_u = (\ldots) \in \mathbb{Z}_q^{n\times 1}$
      Let $A \leftarrow (\vec{a}_1 || \ldots || \vec{a}_D) \in \mathbb{Z}_q^{N\times n}$
      Homomorphically compute $\mathsf{ct}_1 \leftarrow \mathsf{sk}_{\mathsf{pvw}} \times A^\intercal$
      Let $\vec{b}' \leftarrow b_{k\cdot d+1,l} || \ldots || b_{k\cdot d+D,l}$
      Homomorphically compute $\mathsf{ct}_{k,l} \leftarrow \vec{b}' - \mathsf{ct}_1$
      $\mathsf{BFV.Eval}(\mathsf{pk}_{\mathsf{BFV}}, \mathsf{ct}_{vkl}, h \circ g)$,
        where $g(x) = \prod_{i=0}^{r}(x^2 - i^2)$ and $h(x) = x^{t-1}$
    Homomorphically compute $\mathsf{ct}_v \leftarrow \prod_{l\in[\ell]} \mathsf{ct}_{k,l}$
  return $(\mathsf{ct}_k)_{k\in[d]}$

Efficiency. In total, to evaluate $f(x)$, only $r + 1 + \log(t-1)$ multiplications are needed.

This decrease in the number of multiplications comes at the cost of increasing the multiplicative degree from $\sim t$ to $\sim r \cdot t$. To evaluate a function of degree k, each multiplication takes $O(D\mathsf{polylog}(k))$ time. Therefore, our new representation takes $O((r + \log(t)) \cdot (\mathsf{polylog}(r) + \mathsf{polylog}(t)))$ time to evaluate, while the original degree-$(t-1)$ polynomial needs $O(t\mathsf{polylog}(t))$ time. As long as $r \ll t$, our method is more efficient. Concretely, with the parameters chosen in § 7, our new representation is $\sim$20x faster.

We formalize our new construction in Algorithm 1, and the correctness follows from the aforementioned analysis. The more detailed proof is deferred to the full version [23].

Theorem 5.2. ClueToPackedPV *in Algorithm 1 is correct (Def 4.1) given the correctness of the BFV scheme.*

5.2.2 An Efficient PV Unpacking Algorithm for Step 2

After step 1 (constructed above, defined in Def 4.1), we obtain $d = \lceil N/D \rceil$ ciphertexts, each of which encrypts D bits, indicating whether the N messages are pertinent or not. For step 2 (Def 4.2), we need to expand these into $N' = N/\mathsf{v}$ ciphertexts, each of which encrypts a single integer in all of its D slots.

Recall that v is the bundle size (i.e., we bundle v messages into a single one for efficiency). We first focus on $\mathsf{v} = 1$ as in OMRp2 (construction in prior work) for simplicity, and thus $N' = N$. OMRp2 achieves this by performing $O(N\log(D))$ homomorphic operations (or $O(\log(D))$ levels of multiplications but with $O(N)$ operations as in [22])[11]. In this section, we introduce an algorithm with $O(N)$ homomorphic operations and a single multiplication level.

Message Extraction. Let us start with a single ciphertext ct encrypting $(m_1, \ldots, m_N) \in \mathbb{Z}_t^N$. Recall that in BFV, the message vector is first encoded into a polynomial before encryption (see § 3.2). This encoding is to make the multiplications between messages easier over $\mathbb{Z}_t$, while our goal instead, is to unpack these messages into individual BFV ciphertexts. Thus, we first reverse this encoding and extract the message in each slot out to each coefficient of the encoded polynomial.

In other words, we homomorphically revert the encoding process by performing the SlotToCoeff step introduced in [24, Sec 4.4], formally presented in Algorithm 2.

Unpacking. After obtaining a ciphertext ct' encrypting a polynomial $m(X) = \sum_{i\in[D]} m_i X^{i-1}$, we want to obtain D ciphertexts $\mathsf{ct}'_1, \ldots, \mathsf{ct}'_D$, such that each ciphertext ct'_i is encrypts a constant polynomial $p_i(X) = m_i$ (recall that a constant polynomial encodes a vector $(m_i, \ldots, m_i) \in \mathbb{Z}_t^D$, i.e., $p_i(\eta) = m_i$ for all $\eta \in \mathbb{Z}_t$). To do so, the detector performs the oblivious expansion procedure introduced in [1]. This well-established procedure is recalled in Algorithm 2 OExpand.

Allowing $\mathsf{v} > 1$. Despite the great efficiency improvement with the unpacking technique above (both SlotToCoeff and OExpand take only $O(D)$ operations per ciphertext), fundamentally, this requires $O(N)$ homomorphic operations for N messages, which is still quite costly.

One natural idea is to bundle $\mathsf{v} \ll N$ messages as a single one (v to be fixed later), reducing N messages to $N' = N/\mathsf{v}$ messages before performing this PV unpacking process. The number of operations thus reduces to $O(N')$. In more detail, with d input ciphertexts $(\mathsf{ct}_1, \ldots, \mathsf{ct}_d)$ (assuming v divides d for simplicity), the detector first divides them into v chunks: $(\mathsf{ct}_1, \ldots, \mathsf{ct}_{d/\mathsf{v}}), (\mathsf{ct}_{d/\mathsf{v}+1}, \ldots, \mathsf{ct}_{2(d/\mathsf{v})}), \ldots$. Then, it adds up all the chunks ciphertext-wise, i.e. computing $\tilde{\mathsf{ct}}_i \leftarrow \sum_{j=0}^{\mathsf{v}-1} \mathsf{ct}_{j\cdot(d/\mathsf{v})+i}$ for $i \in [d/\mathsf{v}]$. This gives d/v ciphertexts, each with D slots, where each slot encrypts the summation of v slots of the input ciphertexts. After obtaining these d/v ciphertexts, everything proceeds as the unpacking procedure described above (expanding each slot into a single ciphertext).

[11] [22] gives a flexibility to trade off the number of operations vs. levels.

Putting everything together, we obtain our PVUnpack algorithm as in Algorithm 2. Correctness follows from SlotToCoeff and OExpand, and the proof is deferred to the full version [23].

Algorithm 2 Our new PVUnpack

procedure OExpand(ct) (Adapted from [1])

    $[\mathsf{ct}'_{i\cdot D+1}, \ldots, \mathsf{ct}'_{i\cdot D+D}] \leftarrow \mathsf{OExpand}(\mathsf{tmp}_i)$
  return $(\mathsf{ct}'_i)_{i\in[N']}$ (where $N' = d \cdot D/\mathsf{v}$)

Theorem 5.3. PVUnpack *in Algorithm 2 is correct (Def 4.2) given the correctness of the underlying BFV scheme.*

5.2.3 A General Encoding Procedure for Step 3

Lastly, we discuss digest encoding. As aforementioned, v messages are bundled as a single one for efficiency. Therefore, to deliver all the pertinent payloads, the payloads of these v messages bundled together should also be concatenated and viewed as a single large payload. In other words, we consider the concatenated payloads of the form $x'_i \leftarrow x_{i_1} || \ldots || x_{i_\mathsf{v}}$. The corresponding ciphertext ct'_i indicating whether x'_i is pertinent

(if ct'_i encrypts a value > 1, x'_i should be included in the digest and otherwise not)[12]. Hence, the detector performs digest encoding as if there were only N/v messages.

Overall, this speeds up the step 2 of the detector (nearly) v times. However, there are several issues to address:

Spurious payloads. The decoding algorithm will output all v messages in the bundle, some of which may be impertinent. This is allowed by v-soundness as defined in Def 3.2, and often the application using OMR can filter the bundled impertinent messages as discussed in Remark 3.4.

Alternatively, we can do a final filtering (and thus attain the original OMR soundness definition [21, Thm 4.1]) by a small addition to the scheme: the sender will encrypt the payloads to the recipient, using an encryption scheme with the property that decryption using the wrong key is detectable. See [23, Apd A.1] for details.

Intra-bundle collisions. A more serious issue is that the index encoding process would fail if using the realization in § 4.2.2. Recall that during the index encoding part of the original ExpandedPVToDigest step, each message is assigned to a bucket Y_j. Then, for each bucket Y_j, compute $\mathsf{Acc}_j \leftarrow \sum_{i\in Y_j} i \cdot \mathsf{ct}_i$ and $\mathsf{ctr}_j \leftarrow \sum_{i\in Y_j} \mathsf{ct}_i$. The decoding procedure views all the bucket j with ctr_j encrypting a value > 1 as having collisions and discards that bucket.

Now, when there is at most one pertinent message among each bundle of v messages, ct'_i indeed encrypts 0 or 1 and the original decoding procedure (§ 4.2.3) works. However, when there are multiple pertinent messages (either true or false positives) in the same bundle, the counter ctr in the associate bucket (i.e., sum of ct'_i for the bundled message i in the bucket) encrypts a number greater than 1, causing those buckets to be treated as a collision of different (bundled) messages and discarded.

To solve this, we use a different index encoding scheme, supporting pertinency vector entries that are greater than 1. Let $N' \leftarrow \lceil N/\mathsf{v} \rceil$ be the total number of bundled messages. At a high level, we expand each single bit of $i \in [N']$ into $\log(\mathsf{v}+1)$ bits and combine the expanded bits into a new index $i' \in [N' \cdot (\mathsf{v}+1)]$. In this way, when multiplying i' by v, no carrying occurs into the next expanded bit..

More formally, we process as follows. For any index $i \in [N']$, let $i[j]$ denotes the j-th bit of i. We define the following function to expand each bit into $\log(\mathsf{v}+1)$ bits: $i' \leftarrow \mathsf{BitExpand}(\mathsf{v}, i) := \sum_{j=1}^{\lceil \log(N'+1) \rceil} i[j](\mathsf{v}+1)^{j-1}$. In other words, this function represents a binary value using a $(\mathsf{v}+1)$-ary value: $0,1 \in \mathbb{Z}_2$ are encoded by $0,1 \in \mathbb{Z}_{\mathsf{v}+1}$.

Then, the index encoding process uses the new index i' instead of i. In more detail, the detector randomly assigns each bundled message i into a bucket j for $j \in [m]$ (where m is the number of buckets and $m > \bar{k}$ for $\bar{k}$ being the upper bound on the number of pertinent messages). Let Y_j represent the set of indices (of messages) assigned to bucket j. Then, as before, for bucket j, the detector computes $\mathsf{Acc}_j \leftarrow \sum_{i\in Y_i} \mathsf{ct}'_i \cdot i'$; and computes $\mathsf{ctr}_j \leftarrow \sum_{i\in Y_j} \mathsf{ct}'_i$ for bucket j.

The collision happens if and only if one of the following conditions happens: (1) $r_j > \mathsf{v}$ for $r_j \leftarrow \mathsf{Dec}(\mathsf{ctr}_j)$; (2) let $b_j \leftarrow \mathsf{Dec}(\mathsf{Acc}_j)$ and $b_j = \sum_i b_{j,i}(\mathsf{v}+1)^{i-1}$, there exists an i such that $b_{j,i} \neq 0 \wedge b_{j,i} \neq r_j$.

This process, again, is repeated for C times to guarantee that all the indices can be successfully recovered.

Toy example. We provide an example of this encoding method. Assume we have $N' = 32$ bundled messages, where bundle $15, 20, 25$ contain pertinent messages, and $\mathsf{v} = 7$. After buildling the messages accordingly, we obtain $\mathsf{ct}'_{15} = \mathsf{Enc}(1), \mathsf{ct}'_{20} = \mathsf{Enc}(5), \mathsf{ct}'_{25} = \mathsf{Enc}(7), \mathsf{ct}'_{i\notin\{15,20,25\}} = \mathsf{Enc}(0)$: We first get the binary representation of the indices: $15 = 001111, 20 = 010100, 25 = 011001$.

Then we encode all of them using BitExpand: $\mathsf{BitExpand}(15,7) = 000{,}000{,}001{,}001{,}001{,}001$,
$\mathsf{BitExpand}(20,7) = 000{,}001{,}000{,}001{,}000{,}000$, and
$\mathsf{BitExpand}(25,7) = 000{,}001{,}001{,}000{,}000{,}001$.

If there is no collision, i.e., if those three pertinent messages are assigned into different buckets, then these buckets' Acc encode $15 \cdot 1 = 000{,}000{,}001{,}001{,}001{,}001$, $20 \cdot 5 = 000{,}101{,}000{,}101{,}000{,}000$, and $25 \cdot 7 = 000{,}111{,}000{,}111{,}000{,}000$. The corresponding ctr's are $1 = 001, 5 = 101, 7 = 111$. If there is a collision, say 15 and 20 collide, then Acc for that colliding bucket would be decrypted to $000{,}101{,}001{,}110{,}001{,}001$ while the counter is $1+5 = 6 = 110$; mismatch happens: $110 \neq 001 \neq 101$ (where $001{,}101$ appears in the Acc decryption above). The recipient can identify such a collision. On the other hand, if 15 and 25 collide, ctr is $8 > \mathsf{v} = 7$, which is clearly a collision.

Decoding. Recipient decoding is then straightforward: first checks whether the counter encrypts a number $> \mathsf{v}$, and if so, there is a collision. Then, the recipient checks whether the Acc number matches the ctr number.

Again, after such index encoding, the payloads are encoded using the sparse matrix the same way as in § 4.2.3, so we omit the details. We formalize all these in Algorithm 3The correctness holds as the intuition discussed above, and the proof is deferred to the full version [23].

Theorem 5.4. ExpandedPVToDigest *in Algorithm 3 is correct (Def 4.3 with* DecodeDigest *defined in Algorithm 3) given the correctness of the underlying BFV scheme.*

Remark 5.5. As mentioned in § 4.2.3, we do not use sparse matrix A but instead a uniform random matrix (see line 9 in Algorithm 3) as the weights to compute the random linear combinations of the payloads. In [21], a sparse matrix is suggested to boost efficiency (as if a cell is 0, the corresponding multiplication can be skipped). However, in practice, this may not be the case. This is mainly because by the SIMD natural of BFV ciphertext, a single ciphertext can store $D \cdot \log(t)$

[12] Recall that ct'_i encrypts the summation of v slots in the input ciphertexts of PVUnpack corresponding to message $x_{i_1}, \ldots, x_{i_\mathsf{v}}$.

Algorithm 3 Our new ExpandedPVToDigest

procedure PerfOMR1.ExpandedPVToDigest($\mathsf{pp}, \mathsf{pk}_{\mathsf{detect}}$, $(\mathsf{ct}_1, \ldots, \mathsf{ct}_{N'}, \bar{k}), \mathsf{BB} = ((x_i, \cdot))_{i\in[N]}$)
  $\hat{k} \leftarrow \bar{k} + N\log(N)\varepsilon_{\mathsf{p}}$ ▷ Recall that ε_{p} is the false positive rate included in pp.
  Choose C, m s.t:
  (1) $C \cdot m$ is minimized
  (2) the index encoding fails with probability $\mathsf{negl}(\lambda)$ (i.e., decoding using eliminating the collisions fails with negligible probability)
    ▷ Failure probability is $1 - \prod_{i=1}^{\hat{k}-1}(1 - (\frac{i}{m})^C)$ per [21, Sec 6.1.2]
  (3) each bucket is assigned at most $t-1$ messages except with negligible probability
    ▷ Overflow probability is $m \cdot \exp(-\frac{(2m'-1)^2}{2m'+1}\frac{t/2}{m'})$ where $m' \leftarrow m/D$
  Choose K such that a random matrix in $\mathbb{Z}_t^{K\times\bar{k}}$ is full rank with $1 - \mathsf{negl}(\lambda)$ probability
    ▷ $K = O(\bar{k} + \lambda/\log(t))$ as discussed in [21].
  for $i \in [D], j \in [0, \frac{N'}{D} - 1]$ **do**
    $x'_{j\cdot D+i} \leftarrow x_{j\cdot \mathsf{v}+1} || \ldots || x_{j\cdot \mathsf{v}+\mathsf{v}}$
  for $i \in [C]$ **do**
    Initialize $\mathsf{Acc}_{i,u}, \mathsf{ctr}_{i,u}$ for $u \in [m]$
    for $j \in [d/\mathsf{v}]$ **do**
      $u \xleftarrow{\$} [m]$
      $\mathsf{Acc}_{i,u} \leftarrow \mathsf{Acc}_{i,j} + \mathsf{ct}_j \cdot \mathsf{BitExpand}(\mathsf{v}, \mathsf{binary}(j))$
        ▷ Note that for each accumulator Acc, the calculation needs to be split into multiple $\mathbb{Z}_t$ elements. Each $\mathbb{Z}_t$ element contain $t' = \lfloor \log(t)/\log((\mathsf{v}+1)) \rfloor$ bits, and thus totally need $\lceil \log(N/(\mathsf{v}+1))/t' \rceil$ $\mathbb{Z}_t$ elements.
      $\mathsf{ctr}_{i,u} \leftarrow \mathsf{Acc}_{i,j} + \mathsf{ct}_j$
  $A \xleftarrow{\$} \mathbb{Z}_t^{K\times N'}$
  Homomorphically computes $\mathsf{comb} \leftarrow (A \circ Z) \times (\mathsf{ct}'_i)_{i\in[N']}$ where $Z = \begin{pmatrix} x'_1, x'_2, \ldots, x'_{N'} \\ \vdots \\ x'_1, x'_2, \ldots, x'_{N'} \end{pmatrix} \in \mathcal{P}^{K\times N'}$
  return $M = (s, (\mathsf{Acc}_{i,u}, \mathsf{ctr}_{i,u})_{i\in[C],u\in[m]}, \mathsf{comb})$
procedure PerfOMR1.DecodeDigest(M, sk)
  $\hat{k} \leftarrow \bar{k} + N\log(N)\varepsilon_{\mathsf{p}}$
  Parse $M = (s, (\mathsf{Acc}_{i,j}, \mathsf{ctr}_{i,j})_{i\in[C],j\in[m]}, \mathsf{comb})$
  Initialize an empty set$P = \{\}$ to record all pertinent indices
  for $i = 1$ to C **do**
    for $j = 1$ to m **do**
      $a, c \leftarrow \mathsf{BFV.Dec}(\mathsf{sk}, (\mathsf{Acc}_{i,j}, \mathsf{ctr}_{i,j}))$
      If $c > \mathsf{v}$, skip this iteration
      Parse a into $(\mathsf{v}+1)$-ary numbers, i.e., $a = \sum_i a_i(\mathsf{v}+1)^i$
      If any $a_i \neq c$, skip this iteration
      Let $a' = \sum_i a'_i$ where $a'_i = 1$ if $a_i \neq 0$, and $a'_i = 0$ if $a_i = 0$.
      Add a' to P
  If $|P| > \hat{k}$, PL = overflow and skip the next step
  Use P, comb, s and Gaussian elimination to solve for all payloads PL
  If failed, PL = overflow
  return PL

bits of information, and thus can store $W = D \cdot \log(t)/P$ (for $\mathcal{P} = \{0,1\}^P$) linear combinations. In this case, as long as one of the W corresponding weights is non-zero for a particular payload, the whole ciphertext needs to be multiplied. Therefore, practically, a sparse matrix does not reduce the number of multiplications, unless $\mathcal{P}$ is large enough (e.g., such that $W = 1$). One can easily change this step to use a sparse matrix using the Sparse Random Linear Coding (SRLC) discussed in [21, Section 6]. To avoid extra complicity, we omit the details about SRLC.

5.3 Putting Everything Together

Putting everything above together yields a more efficient OMR construction. The pseudocode is presented in Algorithm 4The correctness, soundness, and compactness follow from the correctness of the three sub-procedures discussed above. Privacy holds by the key privacy of sRLWE. The proof is deferred to the full version [23].

Theorem 5.6. *The scheme* PerfOMR1 *is an* OMR *scheme (with* v*-soundness) for $N < D \cdot t/2$, assuming the hardness of* RLWE*, the correctness of* BFV *leveled HE. Moreover* PerfOMR1 *is also* v*-compact.*

5.4 Optimizations

Next, we introduce several implementation-level optimizations that further improve efficiency. Note that these optimizations are all implementation-level and compute the same algorithm proposed above, so all the properties trivially hold.

One-time rotation of sk**.** Originally in [21], there are ℓ secret key vectors independently sampled (forming an sk matrix). During homomorphic decryption (i.e., step ClueToPackedPV), when computing the vector-matrix multiplication $a \cdot \mathsf{sk}$, the ℓ secret key vectors need to be rotated for a total of $n \cdot \ell$ times (note that only a single encryption of sk and a single rotation key is sent to minimize the size of the detection key). However, with our use of sRLWE, we compute $a \cdot \mathsf{sk}$ over $\mathcal{R}_t$, where sk is a single $\mathbb{Z}_t^n$ vector and a is a (structured) matrix. This means that we only need to rotate sk n times. Furthermore, we rotate the sk once at the beginning of the retrieval and store them all in the memory. This implements $a \cdot \mathsf{sk}$ for all N messages using just n rotations, instead of nN/D rotations for a naive implementation.

Improved linear transformation. Recall that in step PVUnpack, we need to compute a linear transformation as in Algorithm 2 line 16, which takes N rotations and N homomorphic multiplications. We reduce this to just $2\sqrt{N}$ rotations using the Baby-step-giant-step algorithm of [17].

Two-level oblivious expansion. Recall that in OExpand in Algorithm 2, we expand a single ciphertext with D slots to D ciphertexts. However, a naive call of this function directly

Algorithm 4 PerfOMR1: Practical Oblivious Message Retrieval

Let $f_s(x)$ be a PRF. Let BFV and sRLWE be as defined above.

procedure PerfOMR1.GenParam($1^\lambda, \varepsilon_p, \varepsilon_n$)
  Choose $\mathsf{pp}_{\mathsf{BFV}} = (D, t, \dots)$ such that homomorphically evaluate Retrieve with all but negligible probability
  Choose $\ell, q = t, \sigma$ such that with the r generated below, it satisfies that $(\frac{2r+1}{q})^\ell \le \varepsilon_p$ [13]
  $\mathsf{pp}_{\mathsf{PVW}} = (n, \ell, q, \sigma, r, \mathcal{D}) \leftarrow$ sRLWE.GenParam($1^\lambda, \ell, q, \sigma, \varepsilon_n$)
  return $\mathsf{pp} = (\mathsf{pp}_{\mathsf{BFV}}, \mathsf{pp}_{\mathsf{PVW}}, \varepsilon_p, \varepsilon_n)$
procedure PerfOMR1.KeyGen(pp)
  $(\mathsf{sk}_{\mathsf{sRLWE}}, \mathsf{pk}_{\mathsf{sRLWE}}) \leftarrow$ sRLWE.KeyGen($\mathsf{pp}_{\mathsf{BFV}}$)
  $(\mathsf{sk}_{\mathsf{BFV}}, \mathsf{pk}_{\mathsf{BFV}}) \leftarrow$ BFV.KeyGen($\mathsf{pp}_{\mathsf{BFV}}$)
  $\mathsf{ct}_{\mathsf{sk}_{\mathsf{sRLWE}}} \leftarrow$ BFV.Enc($\mathsf{pk}_{\mathsf{BFV}}, \mathsf{sk}_{\mathsf{sRLWE}}$)
  return $(\mathsf{sk} = (\mathsf{sk}_{\mathsf{BFV}}), \mathsf{pk} = (\mathsf{pk}_{\mathsf{clue}} = \mathsf{pk}_{\mathsf{sRLWE}}, \mathsf{pk}_{\mathsf{detect}} = (\mathsf{pk}_{\mathsf{BFV}}, \mathsf{ct}_{\mathsf{sk}_{\mathsf{sRLWE}}})))$
procedure PerfOMR1.GenClue(pp, $\mathsf{pk}_{\mathsf{clue}}, x$)
  $\vec{b} \leftarrow (0, \dots, 0) \in \mathbb{Z}_2^\ell$
  $c \leftarrow$ sRLWE.Enc($\mathsf{pk}_{\mathsf{clue}}, \vec{b}$)
  return c ▷ $c \in \mathcal{R}_q \times \mathbb{Z}_q^\ell$
procedure PerfOMR1.Retrieve(pp, BB, $\mathsf{pk}_{\mathsf{detect}}, \bar{k}$)
  Select v such that the runtime of ClueToPackedPV and PVUnpack are similar and also v divides N/D
  $(\mathsf{ct}_i)_{i \in [N/D]} \leftarrow$ ClueToPackedPV(pp, $\mathsf{pk}_{\mathsf{detect}}$, BB)
  $(\mathsf{ct}'_i)_{i \in [N']} \leftarrow$ PVUnpack(pp, $\mathsf{pk}_{\mathsf{detect}}, (\mathsf{ct}_i)_{i \in [N/D]}$, v)
  $M \leftarrow$ ExpandedPVToDigest($\mathsf{pp} = (c, C, m)$, $\mathsf{pk}_{\mathsf{detect}}, (\mathsf{ct}'_1, \dots, \mathsf{ct}'_{N'}, \bar{k})$, BB)
  return M
procedure PerfOMR1.Decode(M, sk)
  return PerfOMR1.DecodeDigest(M, sk)

produces D ciphertexts. Concretely this is very costly: each ciphertext has a size ∼100kB, so with $D = 32768$ (cf. § 7), this takes 3.2GB of memory (and it gets worse for multi-thread). To reduce the memory cost, we first expand the input ciphertext to l_1 ciphertexts (to-be-fixed later), and then, for each expanded ciphertext, further expand it to $l_2 = D/l_1$ ciphertexts. In this way, we keep only $l_1 + l_2$ ciphertexts in memory and expand on the fly for each batch of l_2 ciphertext.

6 OMR with Further Reduced Key and Clue Sizes

While PerfOMR1 in § 5 greatly improves the detector runtime, which is indeed a major practical concern of deploying OMR in real-world applications, there are some other practical considerations.

Recall that in the previous construction, the clue size remains to be $\sim(n \cdot \log(q))$. However, since now sRLWE relies on sparse secret keys, practically, n needs to be larger than in [21] (relying on uniform keys) for the same security level. Therefore, the concrete clue size increases. Additionally, since the circuit for homomorphic decryption is deeper (§ 5.2.1), the detection key size (poly-logarithmically in the depth) is also larger. Lastly, while it has already been greatly reduced in PerfOMR1, the clue key size is always better to be smaller.

Taking these three costs into consideration, we propose an alternative construction that makes these reduce the size of the clue, the detection key, and the clue key, at the cost of making the detection time larger than our protocol in § 5, while still slightly smaller than in [21].

6.1 Reducing the Clue Field

In PerfOMR1 above (as in OMRp2 [21]), we use $q = t$ so that decryption of the clues' PVW ciphertexts (defined over $\mathbb{Z}_q$) can be done directly via BFV homomorphic operations (defined over $\mathbb{Z}_t$). This modulus matching provides the mod q reductions for free. However, it forces q to match the large t needed by BFV, and we pay for this in the size of clues and clue keys (both $O(n \cdot \log(q))$). Removing this constraint gives us the flexibility to reduce the clue size, and we indeed do so when sRLWE uses (sparse) short secrets, as follows.

We set $q \ll t$ (q to be even for simplicity) such that evaluating the PVW decryption in $\mathbb{Z}_t$ is the same as working in $\mathbb{Z}$ (i.e., no modular reductions). Then, when the PVW decryption performs its $\mathbb{Z}_q$ range test, we need to account for all the congruent values in $\mathbb{Z}$.

Formally, for clue $(a, \vec{b}) \in \mathcal{R}_q \times \mathbb{Z}_q^\ell$, by computing $\vec{b} - (a'_i)_{[\ell]}$ where $a' = a \cdot s$ over $\mathcal{R}$ (instead of $\mathcal{R}_q$), we obtain $(\mu_i + \kappa_i \cdot q)$ for some $\kappa_i \in \mathbb{Z}$ satisfying $||\mu_i + \kappa_i \cdot q|| \le t/2$ for all $i \in [\ell]$. If the message is pertinent, $\mu_i \in [-r, r]$ for the noise bound r. Otherwise, μ_i is indistinguishable from uniform in $[-q/2, q/2)$. Furthermore, since s has some fixed Hamming weight h, we bound $|\kappa_i|$'s by $B+1$, such that $\Pr[\kappa_i \ge B+1] \le \mathsf{negl}(\lambda)$ using h. The detailed analysis involving h is deferred to the full version [23].

A new homomorphic decryption circuit. The homomorphic decryption in $\mathbb{Z}_t$ can thus be realized as follows: first compute $c_i \leftarrow \vec{b}[i] - a'_i \in \mathbb{Z}_t$ for all $i \in [\ell]$ as before; then homomorphically evaluate the function f' over c_i:

$$f'(x) = \begin{cases} 0 & \text{if } x \in [\kappa \cdot q - r, \kappa \cdot q + r] \text{ for all } \kappa \in [-B, B] \\ 1 & \text{else if } x \in [-(B+1)q, (B+1)q] \end{cases}$$

This function has $2(B+1)q$ distinct points, and therefore degree $2(B+1)q - 1$ (requiring $O(Bq)$ operations). We can evaluate it as a polynomial using Lagrange interpolation.

Efficiency. The clue key and clue are both of size $O(n \cdot \log(q))$, and thus shrink now as we choose a smaller q. Fur-

[13] Such a choice exists since, given a fixed q, we can choose σ such that $r = \mathsf{poly}(\sigma)$ is small enough (e.g., $r = (q-1)/2$ and sufficiently large ℓ to satisfy the condition), then choose n sufficiently large to maintain the security level. Our implementation uses a choice that minimizes the cost of homomorphically evaluating the induced decryption circuit.

thermore, since q is smaller, we can maintain the noise distribution while reducing n as well.

On the other hand, the degree of the function is now $2(B+1)q-1$ instead of $r \cdot t - 1$. Thus, with careful parameter selection, the depth is greatly reduced as well. Therefore, the detection key size is also reduced.

The downside is that, evaluating f' homomorphically requires $O(Bq)$ homomorphic operations, compared to only $O(r+\log(t))$ operations before. Moreover, since the noise distribution remains the same, $\frac{2r+1}{q}$ becomes larger. Therefore, the guarantee the same wrong-key decryption probability (the false positive rate in OMR), ℓ needs to be larger. For the concrete results of this tradeoff, see § 7.

Since the construction is very similar to Algorithm 4, and only the homomorphic decryption circuit is changed, we defer the pseudocode and proof to the full version [23]

Theorem 6.1. *The scheme* PerfOMR2 *is an* OMR *scheme (with* v*-soundness) for $N < D \cdot t/2$, assuming the hardness of* RLWE*, the correctness of* BFV *leveled HE. Moreover,* OMRp2 *is also* v*-compact.*

7 Evaluation

We implemented the above PerfOMR1 and PerfOMR2 schemes in a C++ library (to be released as open source, with the optimizations introduced in § 5.4). Our code extends the OMR library [31] and uses the SEAL [28] and PALISADE [33] libraries. We then compare our constructions to an improved version of OMRp2 introduced in [22]. We run our implementation and the improved OMRp2 using Google Compute Cloud `e2-standard-4` with 16GB RAM for a fair comparison.

Parameters. We chose the number of messages to be $N = 2^{19}$, and let $\bar{k} = k = 50$ (i.e., the upper bound and the real total number of pertinent messages are both 50)[14].

For OMRp2, we reuse the parameters in [22] and guarantee > 120-bit of computational security. Therefore, for the sRLWE used in PerfOMR1 we choose $n = 1024, q = 65537, \sigma = 0.5, h = 32, \ell = 2$. For the BFV used in PerfOMR1, we choose $D = 32768, Q \approx 2^{905}, t = q = 65537$. For the sRLWE used in PerfOMR2, we choose $n = 512, q = 400, \sigma = 0.5, h = 32, \ell = 6$. For the BFV used in PerfOMR2, we choose $D = 32768, Q \approx 2^{808}, t = 65537$. All these parameter settings guarantee > 128-bit of security by [11]. Furthermore, same as in [21], we choose the false negative rate $\varepsilon_n = 2^{-30}$ and false positive rate $\varepsilon_p = 2^{-21}$, range $r = 19$, and the κ_i bound in § 6 as $B = 29$. We choose $\ell_1 = 1024, \ell_2 = 32$ for our two-level oblivious expansion (see § 5.4). We used $m = 400$ buckets and $C = 16$ trials. For the the random matrix A (line 9 in Algorithm 3), we choose $K = 53$.

[14] For simplicity, since $k = \bar{k}$, we set $\hat{k} = \bar{k}$ instead of $\hat{k} = \bar{k} + N\log(N)\varepsilon_p$. One can also alternatively view it as we choose $\bar{k} = 45$ and $\hat{k} = 50$.

Lastly, we choose $v = 8$ for PerfOMR1 and $v = 2$ for PerfOMR2 (discussed later).

7.1 Results

Representative costs. Table 2 summarizes the main cost metrics of all our schemes and the baseline (i.e., OMRp2 in [21] integrated with optimizations in [22]).

Our PerfOMR1 is about 15x faster than OMRp2 in terms of the detector runtime. Furthermore, the clue key size is reduced by roughly 60x. On the other hand, the clue size is about 2.2x worse (since sRLWE uses sparse keys, n for PerfOMR1 is larger than the n used for OMRp2). The detection key is also about 10% worse (due to the larger depth, we needed a larger Q). Lastly, since we choose $v = 8$, the digest size is also increased, but only by about 2.5x, since originally the digest contains 2 ciphertexts, one for index encoding and one for payload encoding. With the current parameter setting, we need 4 ciphertexts for payload encoding (the 8 concatenated payloads together have a size of 4896 bytes and one BFV ciphertext can encrypt at most 65536 bytes), but still only one ciphertext for index encoding. See below for how the runtime and digest size scale with v.

For PerfOMR2, the runtime is slightly better ($\sim$2.7x) than OMRp2 (mainly due to the improved PVUnpack step for $v = 1$ in § 4.2.2). The clue key size is drastically decreased: roughly 235x smaller than the clue key size of OMRp2. The clue is about 1.6x smaller. The detection key and digest size both remain roughly the same. Therefore, PerfOMR2 is strictly better than OMRp2, while having some complicated tradeoffs compared to PerfOMR1.

Improvement of each individual step. Fig. 5 shows the runtime breakdown for the three main steps of our schemes, compared to OMRp2 (all using $v = 1$ for fair comparison).

For PerfOMR1, our ClueToPackedPV is much faster than OMRp2 (about 15x faster); the bottleneck is PVUnpack, which is why we choose $v = 8$ for PerfOMR1 to optimize the runtime in the rest of our benchmarks. Conversely, for PerfOMR2, the runtime of ClueToPackedPV is roughly the same as OMRp2, which is thus the bottleneck. Therefore, we choose $v = 1$ for PerfOMR2. Moreover, our PVUnpack is about 5x faster than the PVUnpack in [21] even for $v = 1$.

Lastly, in both of our constructions, ExpandedPVToDigest remains similar to [21], while our encoding scheme requires slightly more operations.

How costs scale with v. As shown in Fig. 6, the costs of our two constructions changes with v: the runtime decreases as v increases. However, since it only boosts the PVUnpack step, enlarging v only works well when PVUnpack is a bottleneck. For example, for our PerfOMR1, the runtime with $v = 8$ is about 2x faster than the runtime with $v = 1$. Conversely, the runtime for PerfOMR2 is only about 20% faster when changing v from 1 to 8. Additionally, the digest size also grows with

	Detector Runtime (ms/msg)	Clue Key Size (kB)	Clue Size (Bytes)	Detector Key Size (MB)	Digest Size (Bytes/msg)	Recipient Runtime(ms)
OMRp2 [21,22]	1 thread: 109.5 2 thread: 54.7 4 thread: 51.7	132.81	956	139	1.08	20
PerfOMR1 § 5	**1 thread: 7.31** **2 thread: 3.65**	2.13	2181	171	2.57	37
PerfOMR2 § 6	1 thread: 39.64 2 thread: 19.84	**0.56**	**583**	140	1.03	20

Table 2: Comparison of cost metrics. Costs are per recipient. The bulletin contains $N = 2^{19}$ messages, of which $\bar{k} = k = 50$ are pertinent to the recipient. ms/msg and Bytes/msg are all amortized over N messages. Each message has 612 bytes of payload (as in [21,22]).

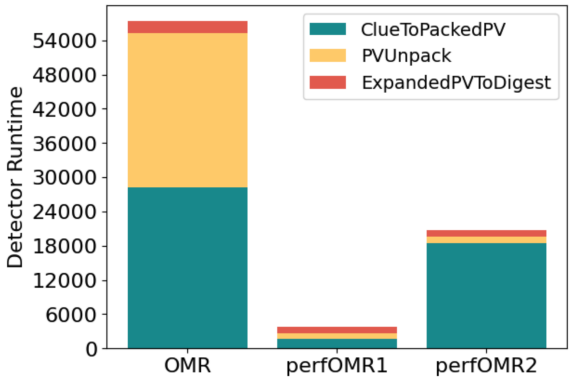

Figure 5: Comparison of runtime of each step for OMRp2 in [21], and our constructions PerfOMR1 and PerfOMR2 with $N = 2^{19}$ and $\bar{k} = k = 50$. We set $\mathsf{v} = 1$ for both of our constructions for fair comparison.

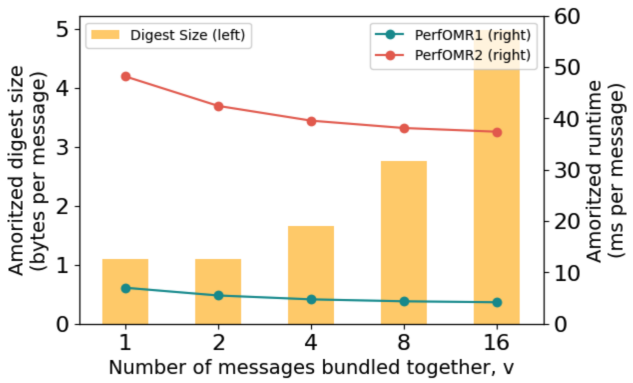

Figure 6: The runtime and digest size of our two schemes with respect to the value of v.

v linearly for both schemes (except for $v = 2$ which comes for free due to the SIMD nature of BFV, which can also improve the OMRp2 construction in [21,22] but not by much).

Larger N and $\bar{k}$. To show scalability, we also test $N = 2^{21}$ and $N = 2^{23}$ for $\bar{k} = k = 50$; and fixing $N = 2^{19}$, we also

		$k = \bar{k} = 50$			
	N	Amortized runtime (ms/msg)	Total runtime (s)	Amortized digest size (Bytes/msg)	Total digest size (MB)
PerfOMR1	2^{19}	7.31	3931.65	2.57	1.35
	2^{21}		15868.37	0.48	
	2^{23}		64701.09	0.12	
PerfOMR2	2^{19}	39.64	20953.45	1.03	0.54
	2^{21}		82826.57	0.26	
	2^{23}		330985.56	0.06	

		$N = 2^{19}$			
	$k = \bar{k}$	Amortized runtime (ms/msg)	Total runtime (s)	Amortized digest size (Bytes/msg)	Total digest size (MB)
PerfOMR1	50	7.31	3931.65	2.57	1.35
	100	9.29	4874.03	4.71	2.47
	150	11.15	5847.55	9.34	4.67
PerfOMR2	50	39.96	20953.45	1.03	0.54
	100	41.58	21797.76	1.63	0.81
	150	42.85	22465.38	2.16	1.08

Table 3: Performance when N and $k = \bar{k}$ varies.

test $\bar{k} = k = 100$ and $\bar{k} = k = 150$. As shown in Table 3, the total runtime scales linearly with N, and grows slightly with larger $\bar{k}$. Digest size is essentially independent of N and scales linearly with $\bar{k}$. The scaling behavior is essentially the same as the prior construction OMRp2 in [21,22] and matches the asymptotic analysis.[15]

Smaller $\varepsilon_n, \varepsilon_p$. To achieve even better $\varepsilon_n, \varepsilon_p$, we need to increase our parameters. For example, for $\varepsilon_n = 2^{-80}$ and $\varepsilon_p = 2^{-38}$ (which we believe is essentially enough for almost all real-world applications) for $\bar{k} = k = 45$ and $N = 2^{19}$, we need to make $r = 42$, $\ell = 4$, $C = 30$ for PerfOMR1 and other parameters remain unchanged.[16] The runtime, by our estimation, is only about 2x slower and other metrics remain roughly the same based on our test. PerfOMR2 and OMRp2 in [21,22] requires a similar parameter change and slow down.

[15] As discussed in Remark 5.5, only when the payload size is large enough, does the runtime benefit from having sparse encoding and depends only on polylog of k. Of course, if k is too large, one can simply concatenate multiple payloads together to form a payload as large as 65536 bytes and take advantage of the sparse coding.

[16] Note that $\bar{k}$ is reduced from 50 to 45 for simplicity. Otherwise, we need to increase K to 56 instead, which introduces another BFV ciphertext. This makes the runtime about 30% slower and the digest size 10% larger based on our estimation.

7.2 Integration Considerations

Lastly, we discuss some system aspect of integrating the improved OMR in real-world applications, exemplified by the Zcash cryptocurrency [18] as analyzed in [21] (for detection cost, we consider Bitcoin-scale applications).

Clue key distribution. To integrate OMR, senders need to obtain the prospective recipient's clue key to generate clues. As in [21], we consider Zcash' Unified Addresses mechanism [19] to include a clue key as an extension of the recipient's public address in a backward-compatible way, and extend the payment URIs similarly [30]. The clue key size of our PerfOMR1 is only 2.13KB, which can easily fit in a standard QR code that stores up to 3KB of data. Furthermore, our PerfOMR2 clue key size is only 0.59KB. Therefore, the clue key distribution is no longer as complicated as [21].

Clue embedding. For PerfOMR1, a clue of size 2181 bytes needs to be attached to every payload. This is larger than the 1.3kB of data on-chain per such payment. On the other hand, for PerfOMR2, the clue is only 583 bytes, much smaller than the one in OMRp2. This allows smaller on-chain data size. Including the clue in a transaction, we can simply use the `OP_RETURN` data that Zcash supports as discussed in [21].

Detection cost. The computational cost of detectors for OMRp2 is roughly $1.95 per million payments scanned (4-thread), using commodity could computing.[17] On the other hand, using our PerfOMR1, the cost is only $0.12 per million payments scanned (2-thread). Using our PerfOMR2, the cost is $0.88 per million payments scanned (2-thread). For Bitcoin-scale applications of roughly 300,000 payments per day,[18] our costs are $1.12/month and $7.88/month respectively, while prior work's cost is $17.56/month.

Fast RS-IOP Multivariate Polynomial Commitments and Verifiable Secret Sharing

Zongyang Zhang[*†] Weihan Li[*†] Yanpei Guo[*] Kexin Shi[*]
Sherman S. M. Chow[‡] Ximeng Liu[§] Jin Dong[¶]

Abstract

Supporting proofs of evaluations, polynomial commitment schemes (PCS) are crucial in secure distributed systems. Schemes based on fast *Reed–Solomon interactive oracle proofs* (RS-IOP) of proximity have recently emerged, offering transparent setup, plausible post-quantum security, efficient operations, and, notably, sublinear proof size and verification. Manifesting a new paradigm, PCS with one-to-many proof can enhance the performance of (asynchronous) verifiable secret sharing ((A)VSS), a cornerstone in distributed computing, for proving multiple evaluations to multiple verifiers. Current RS-IOP-based multivariate PCS, including HyperPlonk (Eurocrypt '23) and Virgo (S&P '20), however, only offer quasi-linear prover complexity in the polynomial size.

We propose PolyFRIM, a fast RS-IOP-based multivariate PCS with optimal linear prover complexity, 5-25× faster than prior arts while ensuring competent proof size and verification. Heeding the challenging absence of FFT circuits for multivariate evaluation, PolyFRIM surpasses Zhang et al.'s (Usenix Sec. '22) one-to-many univariate PCS, accelerating proving by 4-7× and verification by 2-4× with 25% shorter proof. Leveraging PolyFRIM, we propose an AVSS scheme FRISS with a better efficiency tradeoff than prior arts from multivariate PCS, including Bingo (Crypto '23) and Haven (FC '21).

1 Introduction

A *polynomial commitment scheme* (PCS) enables a prover to commit to a polynomial f defined over a field $\mathbb{F}$ with degree bound d and variable number μ. When given a point $\boldsymbol{x} \in \mathbb{F}^\mu$, the prover can convince a verifier via an evaluation proof that the committed polynomial f satisfies $f(\boldsymbol{x}) = y$ for a public $y \in \mathbb{F}$. A PCS is *succinct* if the size of the proof/transcript is sublinear in the polynomial size d^μ and is *efficient* if verification time is sublinear in d^μ. Succinct and efficient PCS is integral in recent zero-knowledge succinct non-interactive argument of knowledge (zk-SNARKs) [16,20,29] via integrating PCS with polynomial interactive oracle proofs (IOPs) [8].

A pioneer PCS of Kate–Zaverucha–Goldberg [24] (*KZG-PCS*) and its multivariate extension [28] feature constant communication and verifier complexity. However, their security relies on a *trusted setup* to generate a structured reference string, which poses challenges in deployment for blockchain or other distributed applications. Bulletproofs [11] only needs a *transparent* setup. Contrarily, it entails a linear number of exponentiations for both the prover and verifier. PCSs [25,32] from *fast Reed–Solomon* (RS) *IOP of proximity* (FRI) [5] stand out among succinct and efficient ones [12,27] for their efficient execution and plausible post-quantum security, gaining popularity in zk-rollup[1] and post-quantum signatures [9].

Adapting the first PCS from FRI [32] (*FRI-PC* henceforth), tailored for univariate polynomials, to multivariate PCS poses challenges without additive homomorphism [26]. HyperPlonk [16, §B] (only work for $d = 2$) and Virgo [37] represent the latest FRI-based multivariate PCSs. Their prover complexity is $O(\mu \cdot d^\mu \log d)$, in contrast to $O(d^\mu)$ FRI-PC (for $\mu = 1$). In Virgo, the prover needs to invoke the Goldwasser–Kalai–Rothblum (GKR) protocol [21] for fast Fourier transformation (FFT) with a statement size of $O(\mu \cdot d^\mu \log d)$, incurring a prover complexity quasi-linear to the polynomial size d^μ. HyperPlonk is simpler without needing the GKR composition.

A PCS with *one-to-many proofs* [31] allows a prover to open distinct evaluations of a single committed polynomial, where each evaluation corresponds to a unique verifier with a lower prover complexity than repeating single proof. Zhang *et al.* (ZXH+22) [36] propose a framework for one-to-many proof of transparent univariate polynomials, including

a polynomial interactive oracle proof and a (univariate) polynomial commitment. Zhang *et al.* instantiate this framework using Virgo, obtaining a one-to-many PCS with a prover complexity of $O(n \log n)$, as well as a verifier and communication complexity of $O(\log^2 n)$, for $n = O(d^\mu)$ produced proofs.

A natural application of one-to-many proofs is *verifiable secret sharing* (VSS) [31, 36] with low dealer complexity. VSS allows a dealer to distribute secret shares to parties so that enough honest parties could either recover the secret when the dealer is honest or identify a cheating dealer. *Asynchronous VSS* (AVSS) [4] operates without timing assumptions, and its resilience [1, 2] is integral for a wide array of applications, including Byzantine agreement [13], distributed key generation [19, 33], and proactive secret sharing [23, 35].

AVSS from PCS [1–3, 34] enjoys strong security guarantees (*e.g.*, termination [18]) and low communication complexity. They roughly fall into univariate or multivariate approaches [18]. The former [34] typically adapts an *encrypt-then-disperse* [18] strategy to remedy any fault due to message delay or malice. Encryption limits plaintext visibility, causing communication redundancy for sending multiple ciphertexts, and efficiency overhead for proving the well-formedness [18]. Utilizing multivariate (precisely, bivariate) PCS to build AVSS [2, 3] can achieve secret recovery and correction almost for free. A typical framework [3] involves the dealer distributing shares $f(x_i, Y)$ of polynomial $f(X, Y)$ to party P_i. P_i then delivers $f(x_i, y_j)$ to P_j, where $i, j \in \{1, 2, \ldots, n\}$. Upon receiving sufficient $f(x_i, y_j)$, P_j computes $f(X, y_j)$ and sends $f(x_k, y_j)$ to P_k, helping it to recover or correct its share $f(x_k, Y)$. One-to-many proofs fit in nicely: a dealer proves n^2 different evaluations of a bivariate polynomial to n^2 verifiers. Each $f(x_i, y_j)$ is given to a "combined" party of P_i and P_j.

AVSS schemes from bivariate PCS [2, 3] typically use PCS directly, leading to $O(n^3)$ dealer complexity for proving n^2 point evaluations on an $O(n)$-degree polynomial, each with $O(n)$ complexity. A recent work Bingo [1] reduces the dealer complexity by overloading every party with partial proof generation. The availability of one-to-many multivariate PCSs provides a potential route to lower dealer complexity. While univariate PCSs with one-to-many proofs [31, 36] exist, multivariate one-to-many proofs remain unknown. Virgo-PCS [37] (used by ZXH$^+$22 [36]) originally supports multivariate polynomials, but it is employed in a framework solely for univariate PCS, leading to only univariate one-to-many proof.

Amidst ample advantages, we tackle two open problems for advancing FRI-based multivariate polynomial commitments:

1. Can we build an FRI-based multivariate PCS with optimal linear proving, further with non-trivial one-to-many proof?
2. How far can we push the frontier of AVSS with the advancements in multivariate polynomial commitment?

1.1 Our Contribution

We solve these questions and bring the contributions below.

• **PolyFRIM: Polynomial Commitment Scheme from Fast Reed–Solomon Interactive Oracle Proofs of Proximity in the Multivariate Setting with Linear Prover Complexity.** Proving a μ-variate d-degree polynomial at least requires its evaluation, taking $O(d^\mu)$. We propose PolyFRIM with such optimal prover complexity. Its verifier and communication take $O(\mu^2 \log^2 d)$, living up to others [16, 37] in Table 1.

• **One-to-Many PolyFRIM.** Our new PCS design supports multivariate one-to-many proof, surpassing ZXH$^+$22 [36] in functionality. For $O(n^2)$ proofs on any $O(n)$-degree bivariate polynomial, the prover time is $O(n^2 \log n)$, which is optimal.[2] Per-verifier computation and communication costs stay at $O(\log^2 n)$ as the non-amortized case. Details are in Table 2.

• **FRISS: FRI AVSS from PolyFRIM.** FRISS, our new AVSS enabled by PolyFRIM (*cf.* [3]), exhibits a dealer complexity of $O(n^2 \log n)$ for party number n, the same as Bingo [1]. eAVSS [3] and HAVEN-1/2 [2] take $O(n^3)$. See Table 3.[3]

• **Implementation and Evaluation.** In terms of performance, we fully implement our schemes[4], which set new benchmarks. Our experiments show that PolyFRIM has 5-25× faster prover time than other transparent PCSs [11, 16, 37], with at most <30% (resp., <10%) worse verifier time (resp., proof size) compared with FRI-based PCSs. As there have been no one-to-many bivariate PCSs before, we only compare the performance of univariate one-to-many PCSs [36]. Ours reduces the prover time by 4-7× and improves the verifier time and proof size by 2-4× and 25%, respectively. For AVSS, FRISS has a 4-400× advantage for dealers on the cost of PCSs over existing schemes such as eAVSS [3] and HAVEN [2], and a 10× faster party computation than Bingo [1].

1.2 Technical Overview

Contribution-I: PolyFRIM from HyperPlonk. Succinctly, the core of HyperPlonk [16, §B] is that a μ-variate multilinear polynomial $\tilde{f}(X_1, X_2, \ldots, X_\mu)$ evaluated on $(x_1, x_2, \ldots, x_\mu)$ is the inner product between the coefficient vector of $\tilde{f}$ and the tensor product $(1, x_1) \otimes \cdots \otimes (1, x_\mu)$. HyperPlonk primarily involves committing μ univariate polynomials $\{\hat{f}_i\}_{i \in [0, \mu-1]}$ and running the FRI low-degree test [5] for μ times to check whether $\hat{f}_i$ have respective upper degree bounds $2^{\mu-i}$.

Motivated by the demand for multivariate polynomial commitments in AVSS, we generalize HyperPlonk to cover multivariate polynomials by our dedicated transformation. This stems from the observation that a μ-variable polynomial $\tilde{f}(X_1, \ldots, X_\mu)$ with variable degree d evaluated on $(x_1, \ldots, x_\mu)$ is equivalent to a multilinear polynomial $\tilde{g}(X_1, \ldots, X_{\mu \log d})$

[2] The prover needs to compute $O(n)$ univariate polynomials after determining the first variable with n values, taking $O(n^2)$ in total. Then, the FFT for evaluating these $O(n)$ polynomials takes $O(n) \cdot O(n \log n) = O(n^2 \log n)$.

[3] Our paper only instantiates one-to-many PolyFRIM with eAVSS. Future work includes using our (univariate and multivariate one-to-many) schemes to improve other AVSS schemes such as hbACSS and HAVEN.

Naïve [16, 37]	yes	Bi.	$O(n^3 \log n)$	$O(\log^2 n)$
PolyFRIM	yes	Bi.	$O(n^2 \log n)$	$O(\log^2 n)$

Table 3: Existing n-party AVSS from multivariate PCS

Scheme	PCS	Dealer	Party	Commun.
eAVSS [3]	q-SDH	$O(n^3)$	$O(n)$	$O(n^2)$
HAVEN-1 [2]	q-SDH	$O(n^3)$	$O(n)$	$O(n^2)$
Bingo [1]	q-SDH	$O(n^2 \log n)$	$O(n^2)$	$O(n^2)$
HAVEN-2 [2]	DLog	$O(n^3)$	$O(n^2)$	$O(n^2 \log n)$
FRISS	Ours	$O(n^2 \log n)$	$O(n \log^2 n)$	$O(n^2 \log^2 n)$

evaluated on $(x_1^{2^0},\ldots,x_1^{2^{\log d}-1},\ldots,x_\mu^{2^0},\ldots,x_\mu^{2^{\log d}-1})$. Such a transformation features an $O(d^\mu)$ prover, but verifier and communication complexities are both $O(\mu^3 \log^3 d)$ for verifying μ independent proof, worse than univariate FRI-PC [32] when μ reduces to 1. Ideally, a multivariate PCS scheme should maintain the same complexity as its univariate counterpart.

Conceivably, batch-FRI [6] over a random linear combination of the μ polynomials could reduce verifier and communication complexities to $O(\mu^2 \log^2 d)$. However, while each independent proof can be tailored to a small domain, the above direct aggregation requires a single domain of an enlarged size of $O(d^\mu)$ to accommodate the evaluations of all polynomials $\{\hat{f}_i\}_{i\in[0,\mu-1]}$. The prover now takes $O(\mu d^\mu \log d)$.

We propose a *rolling batch* approach to resolve the above complexity tension. It enables more efficient low-degree tests for $\{\hat{f}_i\}_{i\in[0,\mu-1]}$. The first round of FRI transforms $\hat{f}_0$ into polynomial $\hat{f}_0^{(1)}$ with a degree-bound of $2^{\mu-1}$, which is also the (upper) bound for the degree of $\hat{f}_1$. Generalizing our observation above, we can invoke FRI over $\hat{f}_1'$, a random linear combination of $\hat{f}_0^{(1)}$ and $\hat{f}_1$ (versus independent invocations for $\hat{f}_0^{(1)}$ and $\hat{f}_1$). Similarly, we can combine every $\hat{f}_i'^{(i)}$ with $\hat{f}_{i+1}$, effectively aggregating μ independent FRIs into one, yielding $O(d^\mu)$ prover and $O(\mu^2 \log^2 d)$ verifier/communication.

Contribution-II: One-to-many PolyFRIM. Simplistically, producing n^2 proofs for degree-n $f(X,Y)$ takes n^2 times the overhead. Merging proofs for many evaluations can be challenging. Checking the evaluation proof for bivariate $f(X,Y)$ on point (x_i,y_j) takes $2\log n = 2\cdot t$ rounds. In the k-th round ($k < \log n$), the prover and verifier handle a multilinear polynomial $\tilde{g}_k(x_i^{2^0},\ldots,x_i^{2^{k-1}},X_k,\ldots,X_t,Y_1,\ldots,Y_t)$ determined by $f(X,Y)$. They then transform $\tilde{g}_k$ into another multilinear polynomial $\tilde{g}_{k+1}(x_i^{2^0},\ldots,x_i^{2^{k-1}},x_i^{2^k},X_{k+1},\ldots,X_t,Y_1,\ldots,Y_t)$. The procedure for $k > \log n$ is similar and omitted. As every verifier has a unique evaluation pair $\{(x_i,y_j)\}_{i,j\in[n]}$, repeating the proof for n^2 evaluations seems necessary.

Methodically, we reduce the prover complexity by making evaluation pairs "repeatable" and reusing procedures in proofs even for different verifiers. First, we swap the order of the evaluation vector for each variable. Precisely, we see every $f(x_i,y_j)$ as the evaluation of a multilinear polynomial $\tilde{g}(X_1,\ldots,X_t,Y_1,\ldots,Y_t)$ on $(x_i^{2^t-1},\ldots,x_i^{2^0},y_j^{2^t-1},\ldots,y_j^0)$ instead of on $(x_i^{2^0},\ldots,x_i^{2^t-1},y_j^{2^0},\ldots,y_j^{2^t-1})$. Such a transformation yields equivalence. Second, we set $x_1,\ldots,x_n$ as the n-th roots of unity $w_1,\ldots,w_n$, respectively, *i.e.*, for every $i\in[n]$, $w_i^n = 1$, and similarly for $y_1,\ldots,y_n$.

Completing the whole evaluation proof can be done by constructing a binary tree of depth $2t$ as above. In the i-th round, the prover and verifiers would handle 2^i multilinear polynomials, each of size $O(n^2\cdot 2^{-i+1})$. The total prover complexity is reduced to $\sum_{i\in[2t]} O(2^i)\cdot O(n^2\cdot 2^{-i+1}) = O(n^2 \log n)$.

Contribution-III: FRISS from PolyFRIM. Synthesizing our new AVSS scheme FRISS from our one-to-many PolyFRIM is a non-trivial endeavor (*i.e.*, our FRISS is not derived from merely black-box calling PolyFRIM) even given existing frameworks like eAVSS [3] (instantiated with KZG [24]).

Meshing PolyFRIM into AVSS is hindered by the absence of PCS homomorphism. In a typical AVSS scheme, after the dealer sends a univariate polynomial $f(x_i,Y)$ to P_i, P_i would send $f(x_i,y_j)$ and corresponding evaluation proof $\pi_{i,j}$ to P_j. Some honest party P_k may fail to receive valid $f(x_k,Y)$ to

carry out secret reconstruction. To resolve this issue, after receiving sufficient evaluations and proofs, P_j would compute $f(X, y_j)$ and send $\{f(x_k, y_j), \pi_{k,j}\}$ to P_k to help it construct the valid $f(x_k, Y)$. Note that for such P_k, P_j has to construct $\pi_{k,j}$ using $\{\pi_{i,j}\}_{i \neq k}$. The homomorphism of KZG allows such adaption of proofs for evaluation at new points, given valid proofs for d evaluations of a d-degree univariate polynomial.

Currently, all FRI-based PCSs only use hash functions and lack homomorphism. Our solution is to let the dealer additionally send $\{f(x_j, y_i), \pi_{j,i}\}_{j \in [n]}$ to P_i apart from $f(x_i, Y)$. In the reconstruction phase, P_i sends $(f(x_j, y_i), \pi_{j,i})$ to P_j. Now, even with a message delay or a malicious dealer, any honest P_k can still construct valid $f(x_k, Y)$. Our solution increases the dealer-party communication from $O(n^2)$ to $O(n^2 \log^2 n)$ but does not affect the total complexity (as the party-party communication is already $O(n^2 \log^2 n)$). We leave it as an open problem to construct AVSS without such additional communication using bivariate PCSs without homomorphism.

1.3 Related Work

Polynomial commitment. KZG-PCS [24] achieves $O(1)$ communication and verifier complexity. It is later extended to multivariate [28]. They rely on the q-strong Diffie–Hellman (q-SDH) assumption on pairing groups and a trusted setup.

Bulletproofs [11] removes the trusted setup requirement and supports multivariate polynomials based only on the discrete-log (DLog) assumption. It uses the folding technique to achieve a proof size of $2 \log n$ group/field elements (several KBs) for polynomial size n. However, verification takes $O(n)$ exponentiations. Another PCS DARK [12] achieves logarithmic proof size and verification but relies on strong RSA and adaptive root assumptions. It is thus transparent only if (hence yes/no in Table 1) class groups (of a quadratic number field) are used, which are known for slower operation (*e.g.*, [33]).

FRI-PC [5, 32], an $O(\log n)$-round transparent PCS, features $O(n)$ prover and $O(\log^2 n)$ communication and verifier. It is concretely efficient, relying on field operations without exponentiation/pairings. However, without help from group structures, the prover uses Merkle trees to commit a vector in each round, and the verifier needs to open dozens to hundreds of leaves, leading to a concrete proof size of 50-100 KBs.

If $f(z) = y$ for an n-degree polynomial $f(X)$, $\frac{f(X)-f(z)}{X-z}$ is a degree-$(n-1)$ polynomial. This makes FRI-PC univariate, thereby complicating the generalization of the above fact, and hence FRI-PC, to multivariate polynomials. In particular, Virgo of Zhang *et al.* [37] treats a multivariate polynomial evaluation as a univariate sum-check protocol [7]. The verifier runs FFT for an $O(n)$-size random vector challenge to invoke the sum-check, resulting in $O(n \log n)$ verification. Virgo reduces it by FFT delegation using the GKR protocol [21], and both the sum-check and GKR cost $O(n \log n)$ prover complexity. Multivariate HyperPlonk [16] uses the tensor product [10] to transform a multilinear polynomial evaluation into evaluations of multiple univariate polynomials, then invokes FRI-PC for $\log n$ times to prove them, also incurring an $O(\log n) \cdot O(n) = O(n \log n)$ prover.

One-to-many proofs. Tomescu *et al.* [31] present AMT, a one-to-many proof for KZG-PCS. It constructs an authenticated multi-point evaluation tree to compute n^2 evaluation proofs of a degree $O(n)$ univariate polynomial in $O(n^2 \log n)$ time. However, both communication and per-verifier complexities increase from $O(1)$ to $O(\log n)$. Zhang *et al.* [36] achieve a one-to-many proof for KZG with the same prover complexity without any overhead on the proof size and verifier time. Its main idea is to set the evaluation points as n^2-th root of unity, enabling multiple evaluations via FFT.

For transparent one-to-many proofs, Zhang *et al.* [36] invoke an FFT circuit using the GKR protocol [21] with $O(n^2)$ outputs such that each output is an evaluation. Notably, they propose an elegant method to unify statements for all outputs and a new Fiat–Shamir transformation so the challenges can be used for multiple verifiers. The above procedure is a polynomial interactive oracle proof and can be instantiated with any univariate polynomial commitment, but it is non-trivial to be transformed into multivariate cases due to the difficulty of constructing FFT circuits for multivariate polynomials.

AVSS. Without a synchronous network, parties cannot always receive the message from the dealer in time and may not know when all honest parties have obtained their shares to allow successful reconstruction. One recent common approach for AVSS is to rely on a bivariate polynomial to share secrets. In the sharing phase, each party receives not only its share but also pieces of shares of other parties, *i.e.*, "share-of-share." Parties who have received valid messages can help other parties obtain their shares by sending the pieces of other parties' shares. eAVSS [3], employing bivariate polynomials, is the first AVSS with $O(n^2)$ communication complexity. It is also achieved by Bingo of Abraham *et al.* [1], an adaptively secure and optimally resilient packed AVSS. HAVEN [2] does not use bivariate polynomials but still follows the above idea using a univariate polynomial to share the secret and additional univariate polynomials to generate the pieces of parties' shares.

Encrypt-then-disperse is an alternative [30, 34] with amortized quasi-linear communication complexity. Via asynchronous verifiable information dispersal [14] or Byzantine reliable broadcast [17], the dealer distributes an encryption of each share under each party's key. Parties can eventually obtain their encrypted share accessible solely with their decryption key. Recently, Das *et al.* [18] give an AVSS with complaints, using univariate polynomials but requiring the dealer to stay online until sharing concludes.

2 Preliminaries

Notations. Let $\hat{f}(X)$ and $\tilde{f}(X_1, \ldots, X_\mu)$ represent univariate and multivariate polynomials, respectively. Given size-N $\tilde{f}$

with coefficients $(f_0,\ldots,f_{N-1})$ (low left), $\hat{f}(X)=\sum_{i=0}^{N-1} f_i X^i$ denotes its corresponding (implicitly converted) univariate polynomial (*e.g.*, $\tilde{\phi}$ and $\hat{\phi}$ in Figure 1). Let $\mathbb{F}$ be a prime finite field. Lowercase denotes $\mathbb{F}$-elements, and bold denotes vectors on $\mathbb{F}$. x_i denotes the i-th entry of $\boldsymbol{x}$. $\langle \boldsymbol{a},\boldsymbol{b}\rangle$ and $\boldsymbol{a}\otimes\boldsymbol{b}$ denote the inner and tensor product, respectively. Given a code rate $\rho\in(0,1)$ and $L=\{\eta_1,\ldots,\eta_{|L|}\}\in\mathbb{F}^{|L|}$, an RS code $\mathrm{RS}[L,\rho]\in\mathbb{F}^{|L|}$ means $\{\hat{f}(\eta_1),\ldots,\hat{f}(\eta_{|L|})|\deg(\hat{f})<\rho|L|\}$. Let $\hat{f}|_L$ be the evaluations of $\hat{f}$ on L.

We denote the security parameter by λ, and PPT means probabilistic polynomial time. $\mathsf{negl}(\cdot)$ denotes a negligible function, which means for all polynomials $\hat{f}$, $\mathsf{negl}(\lambda)<1/\hat{f}(\lambda)$ for sufficiently large integer λ. $y\leftarrow_\$ S$ denotes picking y from set S uniformly at random. $[n]$ denotes $\{1,2,\ldots,n\}$ and $[n,m]$ denotes $\{n,n+1,\ldots,m\}$ for positive integers $m>n$.

Merkle trees. Merkle tree is a vector commitment with linear prover time and logarithmic verifier time and proof size, all in the vector size. It consists of three algorithms [37]. $\mathsf{rt}\leftarrow\mathsf{MT.Commit}(\boldsymbol{v})$ outputs the Merkle tree root rt for vector $\boldsymbol{v}$. $(\{v_i\}_{i\in I},\mathsf{path})\leftarrow\mathsf{MT.Open}(I,\boldsymbol{v})$ outputs the query location set I and verification path path. Verification is done via $\mathsf{MT.Verify}(\mathsf{rt},I,\{v_i\}_{i\in I},\mathsf{path})$. This paper uses the Merkle tree from collision-resistant and non-invertible hash functions.

Interactive argument of knowledge (AoK). An interactive AoK for an NP relation $\mathcal{R}$ is a tuple of algorithms $(\mathcal{G},\mathcal{P},\mathcal{V})$. $\mathcal{G}$ is for public parameter (pp) generation. $\mathcal{P}$ and $\mathcal{V}$ represent a PPT prover and verifier, respectively. $\mathcal{P}$ tries to convince $\mathcal{V}$ that $\exists\mathtt{w}$ such that $(\mathtt{x},\mathtt{w})\in\mathcal{R}$ for a public statement $\mathtt{x}$ through rounds of interaction, and $\mathtt{w}$ is efficiently extractable by an extractor. Below, we adopt an existing definition [37].

Definition 2.1. *$(\mathcal{G},\mathcal{P},\mathcal{V})$ is an interactive argument of knowledge for an NP language $\mathcal{L}_\mathcal{R}$ if the following hold:*

- ***Completeness.*** *For every $\mathsf{pp}\leftarrow\mathcal{G}(1^\lambda)$, every $\mathtt{x}\in\mathcal{L}_\mathcal{R}$ and $(\mathtt{x},\mathtt{w})\in\mathcal{R}$, $\Pr[\langle\mathcal{P}(\mathtt{w}),\mathcal{V}\rangle(\mathsf{pp},\mathtt{x})=1]=1$.*
- ***Argument of knowledge.*** *For any PPT prover $\mathcal{P}^*$, any $\mathsf{pp}\leftarrow\mathcal{G}(1^\lambda)$ and any $\mathtt{x}$, there is a PPT extractor $\mathcal{E}$ s.t. $\Pr[\langle\mathcal{P}^*(),\mathcal{V}\rangle(\mathsf{pp},\mathtt{x})=1,(\mathtt{x},\mathtt{w})\notin\mathcal{R}|\mathtt{w}\leftarrow\mathcal{E}(\mathsf{pp},\mathtt{x})]\le\mathsf{negl}(\lambda)$.*

2.1 Polynomial Commitment

Definition 2.2. *A polynomial commitment scheme (PCS) [12, 22] for μ variables and degree bound d is defined as follows.*

- $\mathsf{pp}\leftarrow\mathsf{Gen}(1^\lambda,d,\mu)$*: Takes as input security parameter λ and bounds d and μ; generates public parameter pp.*
- $C\leftarrow\mathsf{Commit}(\mathsf{pp},\tilde{f})$*: Takes pp and polynomial $\tilde{f}$ as input; generates the commitment C.*
- $b\leftarrow\mathsf{VerPoly}(\mathsf{pp},C,\tilde{f})$*: Verifies the opening of commitment C to the polynomial $\tilde{f}$; outputs $b\in\{0,1\}$.*
- $b\leftarrow\mathsf{Eval}(\mathsf{pp},C,\boldsymbol{x},y,\tilde{f})$*: An interactive argument between a PPT prover $\mathcal{P}$ and verifier $\mathcal{V}$, which can be denoted as $b\leftarrow\langle\mathsf{Open}(\tilde{f}),\mathsf{Verify}\rangle(\mathsf{pp},C,\boldsymbol{x},y)$. $\mathcal{P}$ attempts to convince $\mathcal{V}$ that $\tilde{f}(\boldsymbol{x})=y$. $\mathcal{V}$ outputs $b\in\{0,1\}$ at the end.*

We call the prover, verifier, and communication complexity of PC the corresponding complexity of Eval, respectively.

Recent PCS definitions [22] consider completeness, polynomial binding, and knowledge soundness as necessary properties, but not zero knowledge. Zero-knowledge PCS is also not necessary for AVSS, as the secrecy only requires that parties less than the threshold cannot recover the secret instead of obtaining no additional information. Similar to HyperPlonk, our PCS is not zero knowledge, but we define a property called *t-bound knowledge leaking* weaker than zero knowledge (inspired by [15]), meaning that a verifier can only obtain polynomial evaluations bounded by t with no additional information. This suffices for AVSS, as shown in Section 4.

Definition 2.3. *A multivariate PCS [22] requires:*

- ***Completeness.*** *For any polynomial $\tilde{f}\in\mathbb{F}^d[X]$, every $\mathsf{pp}\leftarrow\mathsf{Gen}(1^\lambda,d,\mu)$, $C\leftarrow\mathsf{Commit}(\mathsf{pp},\tilde{f})$ and $\tilde{f}(\boldsymbol{x})=y$, $\Pr[\mathsf{Eval}(\mathsf{pp},C,r,y,\boldsymbol{x},\tilde{f})=1]=1$.*
- ***Polynomial binding.*** *For all $\mathsf{pp}\leftarrow\mathsf{Gen}(1^\lambda,d,\mu)$, any PPT adversary $\mathcal{A}$, the following probability is $\mathsf{negl}(\lambda)$.*

$$\Pr\left[\begin{array}{c}\mathsf{pp}\leftarrow\mathsf{Gen}(1^\lambda,d,\mu),(C,\tilde{f}_0,\tilde{f}_1)\leftarrow\mathcal{A}(\mathsf{pp})\\ b_0\leftarrow\mathsf{VerPoly}(\mathsf{pp},C,\tilde{f}_0)\\ b_1\leftarrow\mathsf{VerPoly}(\mathsf{pp},C,\tilde{f}_1)\\ (b_0=b_1=1)\wedge(\tilde{f}_0\neq\tilde{f}_1)\end{array}\right].$$

- ***Knowledge soundness.*** *Eval is an argument of knowledge given $\mathsf{pp}\leftarrow\mathsf{Gen}(1^\lambda,d,\mu)$.*
- ***t-bound knowledge leaking.*** *For all PPT adversaries $\mathcal{A}$, its random tape $r_\mathcal{A}$, $\mathsf{pp}\leftarrow\mathsf{Gen}(1^\lambda,d,\mu)$, and polynomial $\tilde{f}$, there exists a simulator $\mathcal{S}=(\mathcal{S}_1,\mathcal{S}_2)$ such that the experiments below are computationally indistinguishable, i.e., $|\Pr[\mathsf{Real}_{\mathcal{A},\tilde{f}}(\mathsf{pp})=1]-\Pr[\mathsf{Ideal}_{\mathcal{A},\mathcal{S}^\mathcal{A}}(\mathsf{pp})=1]|\le\mathsf{negl}(\lambda)$.*

$\mathsf{Real}_{\mathcal{A},\tilde{f}}(\mathsf{pp})$:	$\mathsf{Ideal}_{\mathcal{A},\mathcal{S}^\mathcal{A}}(\mathsf{pp})$:
1: $C\leftarrow\mathsf{Commit}(\hat{f},\mathsf{pp})$	1: $C\leftarrow\mathcal{S}_1(1^\lambda,\mathsf{pp},r_\mathcal{A})$, with oracle access to t evaluations on $\hat{f}$
2: $\boldsymbol{x}\leftarrow\mathcal{A}(C,\mathsf{pp})$	2: $\boldsymbol{x}\leftarrow\mathcal{A}(C,\mathsf{pp})$
3: $y\leftarrow\tilde{f}(\boldsymbol{x})$	3: $y\leftarrow\tilde{f}(\boldsymbol{x})$
4: $1\leftarrow\langle\mathcal{P}(\tilde{f}),\mathcal{A}\rangle(\mathsf{pp},C,\boldsymbol{x},y)$	4: $1\leftarrow\langle\mathcal{S}_2,\mathcal{A}\rangle(\mathsf{pp},C,\boldsymbol{x},y)$, with oracle access to $y=\hat{f}(\boldsymbol{x})$
5: $b\leftarrow\mathcal{A}$ and output b	5: $b\leftarrow\mathcal{A}$ and output b

2.2 FRI and FRI-based Schemes

FRI. Given a degree bound d and a committed vector, FRI [5] allows a prover to convince a verifier that the vector is δ-close to $\mathrm{RS}[L,d/|L|]$ in the meaning of relative Hamming distance, *i.e.*, the vector corresponds to $\hat{f}|_L$ such that $\deg(\hat{f})\le d$.

Theorem 2.1 ([5, 6])**.** *FRI is an argument with soundness error $\varepsilon_{\mathsf{FRI}}=O(|L|/|\mathbb{F}|)+\mathsf{negl}(q,d/|L|)$ where the verifier queries $q=O(\lambda)$ (query repetition number) entries of every*

prover's message. The prover complexity is $O(|L|)$ other than the $O(|L|\log|L|)$ commitment. The verifier complexity and the communication complexity are $O(\log^2|L|)$.

Batch-FRI enables proving efficiently that t committed vectors correspond to polynomials $\hat{f}_1,\ldots,\hat{f}_t$ with degree bounds $d_1,\ldots,d_t$. Specifically, $\mathcal{P}$ and $\mathcal{V}$ invoke an FRI to check whether $\hat{f}'|_L \in \mathrm{RS}[L, d_{\max}/|L|]$ for $\hat{f}'(X)=\sum_{i=1}^{t}\lambda^{i-1}\cdot\hat{f}_i(X)\cdot X^{d_{\max}-d_i}$, $d_{\max}=\max\{d_1,\ldots,d_t\}$ and random λ from $\mathcal{V}$.

FRI-PC [32]. FRI can be turned into a univariate PCS with no additional asymptotic overhead. We denote it by FRI-PC. Appendix A recalls the FRI protocol and FRI-PC.

HyperPlonk. HyperPlonk [16, §B], an FRI-based multilinear PCS, treats a multilinear $\tilde{f}(x_1,\ldots,x_\mu)$ as the inner product of the coefficient vector of $\tilde{f}$ and the tensor product $(1,x_1)\otimes\cdots\otimes(1,x_\mu)$. Theorem 2.2 (proven in Appendix B) asserts its security, which is missing in the original paper.

Theorem 2.2. *HyperPlonk is a PCS. Its computation complexity for* Commit *is $O(n\log n)$ for $n=d^\mu$. Other complexities can be divided into two cases according to the concrete algorithm. Prover: $O(n)$ or $O(n\log n)$; Verifier: $O(\log^3 n)$ or $O(\log^2 n)$; Communication: $O(\log^3 n)$ or $O(\log^2 n)$.*

2.3 Asynchronous Verifiable Secret Sharing

An AVSS scheme consists of two phases. In the Share phase, a distinguished party called the dealer P_d distributes shares of a secret s to all n parties $\{P_1,P_2,\ldots,P_n\}$ via Deal. When an honest party P_i receives a share s_i of s, it completes Share. In the Reconstruction phase, any $t+1$ honest parties invoke a reconstruction function to recover the secret s. Each party outputs s' or $\perp$ to indicate either the successful reconstruction of the secret s' or to claim that the dealer P_d is malicious, respectively. Each pair of parties is connected by an asynchronous channel that provides authenticity and privacy [3]. The dealer can broadcast messages to parties by *reliable broadcast* [17].

Any PPT adversary $\mathcal{A}$ can corrupt and coordinate the actions of at most t parties. A party is honest if not corrupted. AVSS assumes no upper bound on message delivery times. $\mathcal{A}$ could delay messages between any two honest parties, but these messages would eventually be delivered.

Definition 2.4 ([2, 3])**.** *(n,t)-AVSS with $n\geq 3t+1$ achieves:*

- ***Liveness.*** *If the dealer P_d is honest, all the honest parties complete the* Share *phase.*

3 PolyFRIM with a One-to-many Prover

We first propose an FRI variant called rolling batch FRI. Section 3.2 presents an improved multilinear PCS using the rolling batch FRI, which is asymptotically better than HyperPlonk. It is then generalized to our FRI-based multivariate PCS PolyFRIM in Section 3.3. Section 3.4 presents the one-to-many proofs for PolyFRIM, a key component of FRISS.

3.1 Rolling Batch FRI

A main overhead in HyperPlonk comes from running FRI to check every $\hat{f}_{i-1}|_{L_{i-1}}\in\mathrm{RS}[L_{i-1},n/|L_0|]$ for $i\in[\mu]$, where L_0 is an $O(n)$-size multiplicative coset and $L_i=\{x^2|x\in L_{i-1}\}$. One could run FRI for μ times separately to complete these low-degree tests. The prover complexity is $\sum_{i\in[\mu]}O(n/2^{i-1}\cdot\log(n/2^{i-1}))=O(n\log n)$. The verifier and communication complexities are $\sum_{i\in[\mu]}O(\log^2(n/2^{i-1}))=O(\log^3 n)$. Alternatively, a batch FRI evaluates all $\{\hat{f}_i\}_{i\in[\mu]}$ on L_0. It reduces verifier and communication complexities to $O(\log^2 n)$ but leads to a prover complexity of $\sum_{i\in[\mu]}O(n\cdot\log(n/2^{i-1}))=O(n^2\log n)$ due to polynomial evaluations using FFT.

We propose rolling batch FRI (Protocol 1) to perform these μ low-degree tests with $O(n\log n)$ prover complexity and $O(\log^2 n)$ verifier and communication complexities. Our high-level idea is to combine transformed polynomials during the FRI and new polynomials with the same degree to be tested. Specifically, in the i-th round of the rolling batch FRI, the current-round polynomial $\hat{f}^{(i-1)}$ is transformed to a new polynomial $\hat{p}^{(i)}$, which has both the same degree bound $n/2^i$ and evaluation domain L_i as $\hat{f}_i$. So, the prover could combine $\hat{p}^{(i)}$ and $\hat{f}_i$ using a random linear combination and run the FRI on a new combined polynomial. Recursively, for every $i\in[\mu-1]$, $\hat{p}^{(i)}$ can be combined with $\hat{f}_i$, and μ independent FRIs are aggregated into one. Theorem 3.1 asserts its security.

Theorem 3.1. *Protocol 1 is an AoK with a soundness error $\varepsilon_{\mathsf{FRI}}=|L_0|/|\mathbb{F}|+((1+\rho)/2)^q+\mathsf{negl}(\lambda)$ for $\delta\in(0,(1-\rho)/2]$.*

The soundness of FRI comes from the correlated agreement over lines of RS code [6]: if $\boldsymbol{u_0}+\lambda\boldsymbol{u_1}$ is close to an RS codeword $\boldsymbol{v}\in\mathbb{F}^{|L|}$, $\boldsymbol{u_0},\boldsymbol{u_1}\in\mathbb{F}^{|L|}$ are respectively close to two codewords with high probability for random λ. As for rolling batch FRI, the tested vector is a random linear combination of three vectors instead of two (Steps 5 and 9, Protocol 1). Now we rely on the generalized correlated agreement over span spaces [6]: if $\boldsymbol{u_0}+\lambda\boldsymbol{u_1}+\lambda^2\boldsymbol{u_2}$ is close to $\boldsymbol{v}$, then still with high probability $\boldsymbol{u_0},\boldsymbol{u_1},\boldsymbol{u_2}\in\mathbb{F}^{|L|}$ are close to three codewords, respectively. Appendix C gives the detailed proof.

Complexity. The prover complexity is $O(n\log n)$ due to the FFT and Merkle tree construction for $\hat{f}_0|_{L_0}$. The computation overhead other than this is caused by FRI, where in every round, the prover computation takes $\sum_{i\in[0,\log n-1]}O(n/2^i)=O(n)$. The proof size in the i-th round is $O(q)$ field elements and $O(\log(n/2^i))$ hashes for $q=O(\lambda)$. The consis-

Protocol 1 Rolling batch FRI

Inputs: $\big((\mathbb{F}, L_0, d_0); (\{\hat{f}_i\}_{i\in[0,\mu-1]})\big)$. For $i \in [0,\mu-1]$, let $d_i = d_0 \cdot 2^{-i}$ and $L_{i+1} = \{x^2 | x \in L_i\}$. Also, set $n = d_0 = 2^\mu$. The prover shows $\hat{f}_i|_{L_i} \in \mathrm{RS}[L_i, n/|L_0|]$.

1: For every $i \in [0,\mu-1]$, $\mathcal{P}$ computes $\hat{f}_i|_{L_i}$, executes $C_i \leftarrow \mathsf{MT.Commit}(\hat{f}_i|_{L_i})$, and sends C_i to $\mathcal{V}$. Set $\hat{f}^{(0)} \leftarrow \hat{f}_0$.
2: **for** $i = 1$ to μ **do**
3: $\quad\mathcal{P}$ decomposes $\hat{f}^{(i-1)}(X)$ into $\hat{g}_i(X^2) + X \cdot \hat{h}_i(X^2)$.
4: $\quad\mathcal{V}$ sends $\alpha_i \leftarrow_\$ \mathbb{F}$ to $\mathcal{P}$.
5: $\quad\mathcal{P}$ computes $\hat{p}^{(i)}(X) \leftarrow \hat{g}_i(X) + \alpha_i \cdot \hat{h}_i(X)$.
6: $\quad$**if** $i = \mu$ **then** $\mathcal{P}$ directly sends the coefficients of $\hat{p}^{(i)}$.
7: $\quad$**else** $\mathcal{P}$ computes $\hat{p}^{(i)}|_{L_i}$.
8: $\quad\quad\mathcal{P}$ sends $\mathsf{MT.Commit}(\hat{p}^{(i)}|_{L_i})$ to $\mathcal{V}$.
9: $\quad\quad\mathcal{P}$ computes $\hat{f}^{(i)}(X) \leftarrow \hat{p}^{(i)}(X) + \alpha_i^2 \cdot \hat{f}_i(X)$.
10: **for** $j = 1$ to q **do**
11: $\quad\mathcal{V}$ sends $\beta \leftarrow_\$ L_0$ to $\mathcal{P}$.
12: $\quad\mathcal{P}$ invokes $\mathsf{MT.Open}$ to open $\{\hat{f}_i(\pm\beta^{2^i})\}_{i\in[0,\mu-1]}$ and $\{\hat{p}^{(i)}(\pm\beta^{2^i})\}_{i\in[\mu-1]}$. $\mathcal{V}$ checks them by $\mathsf{MT.Verify}$.
13: $\quad$For each $i \in [\mu]$, $\mathcal{V}$ checks whether the three pairs of evaluations $(\pm\beta^{2^{i-1}}, \hat{f}^{(i-1)}(\pm\beta^{2^{i-1}}))$, $(\alpha_i, \hat{p}^{(i)}(\beta^{2^i}))$ are on a common line. Note that $\hat{f}^{(i)}(\pm\beta^{2^i})$ can be computed by $\hat{p}^{(i)}(\pm\beta^{2^i})$ and $\hat{f}_i(\pm\beta^{2^i})$.
14: Iff all the above checks pass, $\mathcal{V}$ outputs 1; 0 otherwise.

tency of $O(q)$ elements and Merkle trees can be checked in one go. Similarly, the verifier computation in the i-th round mainly comes from verifying the Merkle tree validity, which is $O(\log(n/2^i))$. Thus, the verifier and communication complexities are both $\sum_{i\in[0,\log n-1]} O(\log(n/2^i)) = O(\log^2 n)$.

3.2 An Improved Multilinear PCS

We rely on the rolling batch FRI to improve HyperPlonk. The main procedure of HyperPlonk includes: for every $i \in [\mu]$, (1) check $\hat{f}_{i-1}|_{L_{i-1}} \in \mathrm{RS}[L_{i-1}, n/|L_0|]$; (2) prove the validity of $\hat{f}_{i-1}(\pm\beta), \hat{f}_i(\beta^2)$ by FRI-PC for $\beta \leftarrow_\$ \mathbb{F}\setminus\{0\}$ from the verifier. Specifically, for each $i \in [\mu]$, the prover $\mathcal{P}$ proves that

$$\hat{f}_{i-1}\big|_{L_{i-1}} \in \mathrm{RS}[L_{i-1}, d_{i-1}/|L_{i-1}|], \tag{1}$$

$$\frac{\hat{f}_{i-1}(X) - \hat{f}_{i-1}(\pm\beta)}{X \mp \beta}\Big|_{L_{i-1}} \in \mathrm{RS}\left[L_{i-1}, (d_{i-1}-1)/|L_{i-1}|\right],$$

$$\frac{\hat{f}_{i-1}(X) - \hat{f}_{i-1}(\beta^2)}{X - \beta^2}\Big|_{L_{i-1}} \in \mathrm{RS}[L_{i-1}, (d_{i-1}-1)/|L_{i-1}|]\ (i \neq 1).$$

Here, $d_i = d_{i-1}/2$, $L_i = \{x^2 | x \in L_{i-1}\}$, $d_0 = n = 2^\mu$. To prove the above three equations, for each $i \in [\mu]$ $\mathcal{P}$ and $\mathcal{V}$ invoke a batch FRI to show that $\hat{p}_{i-1}|_{L_{i-1}} \in \mathrm{RS}[L_{i-1}, d_{i-1}/|L_{i-1}|]$, where $\hat{p}_{i-1}$ is a random linear combination of

$$\hat{f}_{i-1}, \quad X \cdot \frac{\hat{f}_{i-1}(X) - \hat{f}_{i-1}(\pm\beta)}{X \mp \beta}, \quad X \cdot \frac{\hat{f}_{i-1}(X) - \hat{f}_{i-1}(\beta^2)}{X - \beta^2}.$$

HyperPlonk achieves a succinct FRI-based multilinear PCS without proof composition (*cf.* [37]), but it has limitations:

(1) The soundness error is directly related to the field size due to the Schwartz–Zippel lemma. Attaining the desired security level needs a large field, yet it impacts efficiency.

(2) As shown in Theorem 2.2, there is a tension for HyperPlonk to achieve $O(n)$ prover complexity, $O(\log^2 n)$ verifier complexity, and $O(\log^2 n)$ communication complexity.

(3) The verifier may get additional knowledge from the multiple evaluations it opens on $\{\hat{f}_i\}_{i\in[0,\mu-1]}$, which is inapplicable to AVSS for secrecy violation, *i.e.*, parties less than the threshold may obtain extra information about the secret.

Our proposed PCS overcomes the above limitations.

(1) The verifier picks β from L_0 instead of $\mathbb{F}\setminus\{0\}$ and for $i \in [\mu]$, its queries change to $\hat{f}_{i-1}(\pm\beta^{2^{i-1}})$ instead of $\hat{f}_{i-1}(\pm\beta)$. Now, the verifier can obtain queries by directly opening the Merkle trees instead of invoking the FRI-PC. Consequently, the prover and verifier only need to invoke the FRI to prove Equation (1) other than the two equations below it. This avoids their computation of obtaining additional inverses of field elements and enlarging the polynomial degrees to the same. Besides, the soundness error originating from the Schwartz–Zippel lemma is no longer related to the field size.

(2) Based on the idea (1), the prover now needs to show $\hat{f}_{i-1}|_{L_{i-1}} \in \mathrm{RS}[L_{i-1}, d_{i-1}/|L_{i-1}|]$ for $i \in [\mu]$ instead of $\hat{p}_{i-1}$. This statement is exactly the same as that of rolling batch FRI in Section 3.1, and the prover and verifier can invoke the rolling batch FRI to complete these low-degree tests.

(3) To mask the evaluations on $\{\hat{f}_i\}_{i\in[\mu]}$, the prover chooses a random μ-variate multilinear polynomial $\tilde{r}(X_1,\ldots,X_\mu)$, and sets $\hat{f}_0$ to be the univariate polynomial determined by $\tilde{f} + \alpha\tilde{r}$ instead of $\tilde{f}$ itself for $\alpha \leftarrow_\$ \mathbb{F}$ from the verifier. Now, the evaluations $\{\hat{f}_i\}_{i\in[\mu]}$ are uniformly distributed because of $\tilde{r}$. Although the verifier may still obtain evaluations on $\hat{f}_0|_{L_0}$, the number of leaked evaluations is limited by an upper bound, and it suffices for AVSS (in Section 4).

Below, we present PC_m, our improved multilinear PCS.

- $\mathsf{pp} \leftarrow \mathsf{Gen}_m(1^\lambda, \mu)$: takes security parameter λ and the number of variable μ; outputs the public parameter $\mathsf{pp} = \{\mathbb{F}, L_0\}$.
- $C \leftarrow \mathsf{Commit}_m(\mathsf{pp}, \tilde{f}, \tilde{r})$: takes as inputs pp, $\tilde{f}$, and a random multilinear polynomial $\tilde{r}$; outputs $C = \{C_{\hat{f}}, C_{\hat{r}}\}$ for $C_{\hat{f}} \leftarrow \mathsf{MT.Commit}(\hat{f}|_{L_0})$ and $C_{\hat{r}} \leftarrow \mathsf{MT.Commit}(\hat{r}|_{L_0})$.
- $b \leftarrow \mathsf{VerPoly}_m(\mathsf{pp}, C, \hat{f}|_{L_0}, \hat{r}|_{L_0}, \tilde{f}, \tilde{r})$: receives $\hat{f}|_{L_0}$ and $\hat{r}|_{L_0}$ as openings of C, checks the validity using $\mathsf{MT.Verify}$. Then, decodes $\hat{f}|_L$ and $\hat{r}|_{L_0}$, and checks the consistency between the decoding of $\hat{f}|_L$, $\hat{r}|_{L_0}$ and $\tilde{f}$, $\tilde{r}$. Outputs 1 iff all checks pass.
- $b \leftarrow \mathsf{Eval}_m(\mathsf{pp}, C, \boldsymbol{x}, y, \{\tilde{f}, \tilde{r}\})$: Given evaluation point $\boldsymbol{x} = (x_1,\ldots,x_\mu)$, $y = \tilde{f}(\boldsymbol{x})$, $\tilde{f}$, and $\tilde{r}$, $\mathcal{P}$ and $\mathcal{V}$ run the following:
  1: $\mathcal{P}$ sends $y = \tilde{f}(\boldsymbol{x})$ and $y_r = \tilde{r}(\boldsymbol{x})$ to $\mathcal{V}$.
  2: $\mathcal{V}$ sends $\alpha \leftarrow_\$ \mathbb{F}$ to $\mathcal{P}$.
  3: $\mathcal{P}$ sets $\hat{f}_0(X) \leftarrow \hat{f}(X) + \alpha\cdot\hat{r}(X)$, and for $i \in [\mu]$, computes

$$\hat{f}_i(X) \leftarrow \hat{g}_{i-1}(X) + x_i \cdot \hat{h}_{i-1}(X) \tag{2}$$

by uniquely decomposing $\hat{f}_{i-1}(X)$ into $\hat{g}_{i-1}(X^2)+X\cdot\hat{h}_{i-1}(X^2)$. For every $i\in[\mu-1]$, $\mathcal{P}$ sets $L_i=\{x^2|x\in L_{i-1}\}$ and sends $C_i\leftarrow\mathsf{MT.Commit}(\hat{f}_i|_{L_i})$ to $\mathcal{V}$. When $i=\mu$, $\mathcal{V}$ can compute $\hat{f}_\mu=\tilde{f}(\boldsymbol{x})+\alpha\tilde{r}(\boldsymbol{x})$ locally.

4: Set $\hat{\varphi}_0(X)=\hat{f}_0(X)$. For each $i\in[\mu]$:
   a. $\mathcal{V}$ sends $\alpha_i\leftarrow_\$\mathbb{F}$ to $\mathcal{P}$.
   b. $\mathcal{P}$ derives $\hat{p}_i(X)\leftarrow\hat{g}_{i-1}(X)+\alpha_i\cdot\hat{h}_{i-1}(X)$ by uniquely decomposing $\hat{f}_{i-1}(X)$ into $\hat{g}_{i-1}(X^2)+X\cdot\hat{h}_{i-1}(X^2)$. When $i=\mu$, $\mathcal{P}$ sends the coefficients of $\hat{p}_\mu$ to $\mathcal{V}$; else, $\mathcal{P}$ computes $\hat{\varphi}_i(X)\leftarrow\hat{p}_i(X)+\alpha_i^2\cdot\hat{f}_i(X)$, and sends $\bar{C}_i\leftarrow\mathsf{MT.Commit}(\hat{p}_i|_{L_i})$ to $\mathcal{V}$. $\hat{\varphi}_i(X)$ represents the i-th round polynomial to be invoked in FRI.
5: Repeat the following $q=O(\lambda)$ times.
   a. $\mathcal{V}$ sends $\beta\leftarrow_\$ L_0$ to $\mathcal{P}$.
   b. $\mathcal{P}$ invokes $\mathsf{MT.Open}$ to open $\{\hat{f}_i(\pm\beta^{2^i})\}_{i\in[0,\mu-1]}$ and $\{\hat{p}_i(\pm\beta^{2^i})\}_{i\in[\mu-1]}$.
   c. $\mathcal{V}$ runs $\mathsf{MT.Verify}$ to check the Merkle trees and if, $\forall i\in[\mu]$, triples $(\pm\beta^{2^{i-1}},\pm\hat{f}_{i-1}(\beta^{2^{i-1}})),(x_i,\hat{f}_i(\beta^{2^i}))$ and $(\pm\beta^{2^{i-1}},\pm\hat{\varphi}_{i-1}(\beta^{2^{i-1}})),(\alpha_i,\hat{p}_i(\beta^{2^i}))$ (note the $+$ and $-$ points) are on two common lines, respectively.
6: Iff all above verifications pass, $\mathcal{V}$ outputs 1; 0 otherwise.

Theorem 3.2. *PC_m is a polynomial commitment scheme as described in Definition 2.3. PC_m also has $2q$-bound knowledge leaking property. (The proof is in Appendix D.)*

Complexity. The computation of Commit is $O(2^\mu\cdot\mu)$ due to the FFT and Merkle tree construction for $\hat{f}|_{L_0}$ and $\hat{r}|_{L_0}$. As the main procedure of Eval can be seen as a tensor product argument (as in [10] and HyperPlonk) and a rolling batch FRI, the complexity overhead comes from these two protocols. The prover complexity in each round is linear to the current polynomial degree and is $\sum_{i\in[0,\log(2^\mu)-1]}O(2^\mu/2^i)=O(2^\mu)$ in total. The verifier complexity and communication complexity in each round are both logarithmic to the current polynomial degree and are $\sum_{i\in[0,\log(2^\mu)-1]}O(\log(2^\mu/2^i))=O(\mu^2)$.

3.3 Construction of PolyFRIM

We present PolyFRIM, our multivariate PCS. Suppose $\tilde{f}(X_1,\ldots,X_\mu)$ is a μ-variate d-degree polynomial where $d=2^t-1$. Any evaluation $\tilde{f}(x_1,\ldots,x_\mu)$ is equivalent to the evaluation $\tilde{f}'(x_{1,1},\ldots,x_{1,t},\ldots,x_{\mu,1},\ldots,x_{\mu,t})$, where $\tilde{f}'$ is a $\mu\cdot t$-variate multilinear polynomial, and for every $i\in[\mu]$ and $j\in[t]$, $x_{i,j}=x_i^{2^{j-1}}$. So, the evaluation proof for $\tilde{f}$ can be transformed equivalently into that for $\tilde{f}'$, which can be proved by PC_m.

The algorithms of PolyFRIM are described below.

- $\mathsf{pp}\leftarrow\mathsf{Gen}_\mathsf{F}(1^\lambda,d,\mu)$: Takes as inputs security parameter λ, degree d, and variable number μ; outputs $\mathsf{pp}\leftarrow\mathsf{Gen}_m(1^\lambda,\mu\cdot t)$.
- $C\leftarrow\mathsf{Commit}_\mathsf{F}(\mathsf{pp},\tilde{f},\tilde{r})$: Takes as inputs pp, polynomials $\tilde{f}$ and $\tilde{r}$, and sets $\tilde{f}'$ and $\tilde{r}'$ be multilinear polynomials with $\mu\cdot\log(d+1)$ variables constructed by $\tilde{f}$ and $\tilde{r}$, respectively. The algorithm runs $C\leftarrow\mathsf{Commit}_m(\mathsf{pp},\tilde{f}',\tilde{r}')$.
- $b\leftarrow\mathsf{VerPoly}_\mathsf{F}(\mathsf{pp},C,\tilde{f},\tilde{r})$: Takes as inputs pp, C, $\tilde{f}$, and $\tilde{r}$, and sets $\tilde{f}'$ and $\tilde{r}'$ be multilinear polynomials as in $\mathsf{Commit}_\mathsf{F}$. The algorithm runs $\mathsf{VerPoly}_m(\mathsf{pp},C,\hat{f}'|_{L_0},\hat{r}'|_{L_0},\tilde{f}',\tilde{r}')$
- $b\leftarrow\mathsf{Eval}_\mathsf{F}(\mathsf{pp},C,\boldsymbol{x},y,\{\tilde{f},\tilde{r}\})$: Parse $\boldsymbol{x}=(x_1,\ldots,x_\mu)$. The prover and verifier invoke the interactive argument $\mathsf{Eval}_m(\mathsf{pp},C,\boldsymbol{x}',y,\{\tilde{f}',\tilde{r}'\})$ to prove $\tilde{f}'(\boldsymbol{x}')=\tilde{f}(\boldsymbol{x})$, where $\boldsymbol{x}'=(\boldsymbol{x}_1,\boldsymbol{x}_2,\ldots,\boldsymbol{x}_\mu)$ and for every $j\in[\mu]$, $\boldsymbol{x}_j=(x_j^{2^0},x_j^{2^1},\ldots,x_j^{2^{t-1}})$.

Complexity. The complexity of PolyFRIM is similar to PC_m, but substituting the term 2^μ as d^μ. The time complexity of Commit is $O(\mu d^\mu\log d)$, the prover complexity is $O(d^\mu)$, and the verifier and communication complexities are $O(\mu^2\log^2 d)$.

Theorem 3.3. PolyFRIM *is a polynomial commitment scheme with $2q$-bound knowledge leaking property.*

Due to the equivalence of transformation from $\tilde{f}$ to $\tilde{f}'$, Theorem 3.3 follows Theorem 3.2 directly.

3.4 Extending to One-to-many Proofs

We extend PolyFRIM for (n,n)-degree bivariate polynomials to one-to-many proofs with $O(n^2\log n)$ prover complexity.

We first explain why reducing the prover complexity is challenging. When invoking PolyFRIM to prove $f(x_i,y_j)$ for $i,j\in[n]$, the evaluation proof will be transformed into a proof for a multilinear polynomial on $(x_i^{2^0},\ldots,x_i^{2^{t-1}},y_j^{2^0},\ldots,y_j^{2^{t-1}})$, where $n=2^t-1$. Therefore, Equation (2) in each round is different for every verifier. Besides, the random challenges (α and α_i) in Steps 3 and 4 of Protocol 1 can also be different for every verifier. Hence, the prover has to repeat PolyFRIM for $O(n^2)$ times, leading to an $O(n^3\log n)$ prover complexity.

We reduce the prover complexity by making evaluation vectors "partially the same" and random challenges "sharable" even for different verifiers. This enables the prover to save the computation overhead by reusing procedures as much as possible. The details are described below.

Improvement for evaluation vectors. First, we transform the evaluation vector $(x^{2^0},\ldots,x^{2^{t-1}},y^{2^0},\ldots,y^{2^{t-1}})$ into its variable-inverse $(x^{2^{t-1}},\ldots,x^{2^0},y^{2^{t-1}},\ldots,y^{2^0})$. The outcome is equivalent after reversing the order of coefficient vector $\boldsymbol{f}$.

Second, we make evaluation vectors "partially the same" by picking special values for every pair (x_i,y_j). This is feasible as AVSS only requires no repetition between any two distinct pairs. Specifically, for every $i,j\in[n]$, we set $(x_i,y_j)=(w_N^i,w_N^j)$, where $N=n=2^t$ and w_N^z denotes the z-th root of unity. This results in only 2^k choices for $\{x_i^{2^k}\}_{i\in[n]}$ in the k-th round, *i.e.*, the prover only needs 2^k operations instead of $n=2^t$. The case with Y is alike. The prover computation overhead related to the evaluation vector becomes $O(2\cdot\sum_{k\in[t]}2^k)=O(n^2\log n)$.

Improvement for random challenges. We construct "shared random challenges" [34, 36] for different verifiers to make

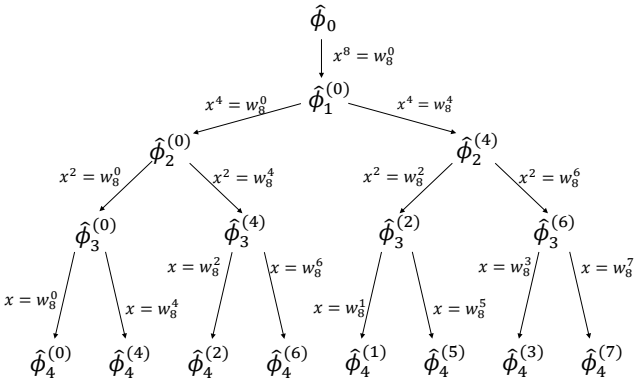

Figure 1: One-to-many proof for a 15-degree polynomial $\hat{\phi}(X)$. $\hat{\phi}(X)$ is firstly transformed into a multilinear polynomial $\tilde{\phi}_0(X_1,X_2,X_3,X_4)$ and then transformed into $\tilde{\phi}_1^{(0)}(w_8^0,X_2,X_3,X_4)$. For $k\in\{1,2,3\}$ and $\ell\in[0,2^{k-1}-1]$, $\tilde{\phi}_k^{(2^{3-k}\cdot\ell)}$ is converted into 2^k polynomials $\{\tilde{\phi}_{k+1}^{(2^{2-k}\cdot\ell)}\}_{\ell\in[0,2^k-1]}$.

PolyFRIM non-interactive. Let the set of random challenges in the ℓ-th round be $A_{r_\ell}=\{\alpha_{1,\ell},\ldots,\alpha_{n,\ell}\}$, where $\ell\in[2t]$ and $\alpha_{i,\ell}$ represents the random challenge from the i-th verifier. The prover computes $\alpha_\ell\leftarrow\mathsf{MT.Commit}(\{\alpha_{i,\ell}\}_{\ell\in[n]})$ and uses α_ℓ as the (final) challenge of the ℓ-th round. The verification path from the leaf $\alpha_{i,\ell}$ to α_ℓ is also sent to the i-th verifier. Figure 1 considers a univariate example, but the process naturally extends to any multivariate polynomial. Our non-interactive $\mathsf{Eval}_{\mathsf{otm}}$ algorithm consists of $\mathsf{Eval}_{\mathsf{otm}}.\mathsf{Open}$ and $\mathsf{Eval}_{\mathsf{otm}}.\mathsf{Verify}$, calling $\mathsf{Commit}_{\mathsf{F}}$ and $\mathsf{Eval}_{\mathsf{F}}$ of PolyFRIM.

• $\{(w_N^i,w_N^j),f(w_N^i,w_N^j),\pi_{i,j}\}\leftarrow\mathsf{Eval}_{\mathsf{otm}}.\mathsf{Open}(\mathsf{pp},f,r,V_{n,n})$: $\mathcal{P}$ computes proofs $\{\pi_{i,j}\}_{i,j\in[n]}$ for bivariate polynomials f,r and the evaluation-point set $V_{n,n}=\{(w_N^i,w_N^j)\}_{i,j\in[n]}$ as below.

1. For every $i,j\in[n]$, $\mathcal{P}$ computes

$$\alpha_{i,j}\leftarrow\mathsf{H}\big(C_f||C_r||(w_N^i,w_N^j)||f(w_N^i,w_N^j)||r(w_N^i,w_N^j)\big),$$

where $(C_f,C_r)\leftarrow\mathsf{Commit}_{\mathsf{F}}(\mathsf{pp},f,r)$. Then $\mathcal{P}$ computes $\alpha\leftarrow\mathsf{MT.Commit}(\{\alpha_{i,j}\}_{i,j\in[n]})$. Let $\mathsf{path}_{\alpha_{i,j}}$ be the verification path of $\alpha_{i,j}$. Set $\tilde{f}_0$ as the multilinear polynomial determined by $f+\alpha_0\cdot r$. Denote by $\hat{f}_0$ the univariate polynomial determined by vector $\boldsymbol{f}_0$. Set $n=N=2^t$.

2. Generate proofs about variable X. Let $\hat{f}_0^{(0)}=\hat{f}_0$. To avoid long superscripts, for every $k\in[t]$ and $\ell\in[0,2^{k-1}-1]$, let $\xi_{\ell,k}=\ell\cdot2^{t-k}$ and $-\xi_{\ell,k}=\ell\cdot2^{t-k}+2^{t-1}$. Polynomials with $-\xi_{\ell,k}$ go from the same upper-layer polynomials with $\xi_{\ell,k}$. Intuitively, $\xi_{\ell,k}$ covers $0,2,1,3$ in Figure 1, and $-\xi_{\ell,k}$ covers $4,5,6,7$. $\mathcal{P}$ then computes

$$\begin{aligned}\hat{f}_k^{(\xi_{\ell,k})}(X)&\leftarrow\hat{g}_{k-1}^{(2\cdot\xi_{\ell,k})}(X)+w_N^{\ell\cdot2^{t-k}}\cdot\hat{h}_{k-1}^{(2\cdot\xi_{\ell,k})}(X),\\ \hat{f}_k^{(-\xi_{\ell,k})}(X)&\leftarrow\hat{g}_{k-1}^{(2\cdot\xi_{\ell,k})}(X)-w_N^{\ell\cdot2^{t-k}}\cdot\hat{h}_{k-1}^{(2\cdot\xi_{\ell,k})}(X),\\ C_k^{(\xi_{\ell,k})}&\leftarrow\mathsf{MT.Commit}(\hat{f}_k^{(\xi_{\ell,k})}|_{L_k}),\\ C_k^{(-\xi_{\ell,k})}&\leftarrow\mathsf{MT.Commit}(\hat{f}_k^{(-\xi_{\ell,k})}|_{L_k}),\end{aligned}$$

by uniquely decomposing $\hat{f}_{k-1}^{(2\cdot\xi_{\ell,k})}$ as $\hat{g}_{k-1}^{(2\cdot\xi_{\ell,k})}(X^2)+X\cdot\hat{h}_{k-1}^{(2\cdot\xi_{\ell,k})}(X^2)$ to get $\hat{g}_{k-1}^{(2\cdot\xi_{\ell,k})}(X^2)$ and $\hat{h}_{k-1}^{(2\cdot\xi_{\ell,k})}(X^2)$ After the first t rounds, $\mathcal{P}$ will get polynomials $\hat{f}_t^{(1)},\ldots,\hat{f}_t^{(n)}$, corresponding to $w_N^1,w_N^2,\ldots,w_N^n$. Here, polynomials with $2\xi_{\ell,k}$ denote the decomposition of those with $\xi_{\ell,k}$.

3. The subsequent computation corresponding to variable Y is similar to Step 2. For every $i\in[n]$, let $\hat{f}_t^{(i,0)}=\hat{f}_t^{(i)}$. For every $k\in[t]$ and $\ell\in[0,2^{k-1}-1]$, $\mathcal{P}$ computes

$$\begin{aligned}\hat{f}_{k+t}^{(i,\xi_{\ell,k})}(X)&\leftarrow\hat{g}_{k+t-1}^{(i,2\cdot\xi_{\ell,k})}(X)+w_N^{\ell\cdot2^{t-k}}\cdot\hat{h}_{k+t-1}^{(i,2\cdot\xi_{\ell,k})}(X),\\ \hat{f}_{k+t}^{(i,-\xi_{\ell,k})}(X)&\leftarrow\hat{g}_{k+t-1}^{(i,2\cdot\xi_{\ell,k})}(X)-w_N^{\ell\cdot2^{t-k}}\cdot\hat{h}_{k+t-1}^{(i,2\cdot\xi_{\ell,k})}(X),\\ C_{k+t}^{(i,\xi_{\ell,k})}&\leftarrow\mathsf{MT.Commit}(\hat{f}_{k+t}^{(i,\xi_{\ell,k})}|_{L_{k+t}}),\\ C_{k+t}^{(i,-\xi_{\ell,k})}&\leftarrow\mathsf{MT.Commit}(\hat{f}_{k+t}^{(i,-\xi_{\ell,k})}|_{L_{k+t}}),\end{aligned}$$

by uniquely decomposing $\hat{f}_{k+t-1}^{(i,2\cdot\xi_{\ell,k})}$ as $\hat{g}_{k+t-1}^{(i,2\cdot\xi_{\ell,k})}(X^2)+X\cdot\hat{h}_{k+t-1}^{(i,2\cdot\xi_{\ell,k})}(X^2)$ to get $\hat{g}_{k+t-1}^{(i,2\cdot\xi_{\ell,k})}(X^2)$ and $\hat{h}_{k+t-1}^{(i,2\cdot\xi_{\ell,k})}(X^2)$. $\mathcal{P}$ will eventually get all paths reaching all evaluation points in $\{(w_N^i,w_N^j)\}_{i,j\in[n]}$, all forking from a single root of $\hat{f}_0$.

4. For every $i,j\in[n]$, we have commitments $\{C_k^{(i\cdot2^{t-k})}\}_{k\in[t]}$ and $\{C_{k+t}^{(i,j\cdot2^{t-k})}\}_{k\in[t]}$ in the path from the root for $\hat{f}_0$ to the evaluation point (w_N^i,w_N^j), where $C_k^{(x)}\leftarrow C_k^{(x\bmod 2^t)}$ and $C_{k+t}^{(x,y)}\leftarrow C_{k+t}^{(x\bmod 2^t,\,y\bmod 2^t)}$. $\mathcal{P}$ computes the challenge

$$\alpha_1^{(i,j)}\leftarrow\mathsf{H}\big(\alpha||\{C_k^{(i\cdot2^{t-k})}\}_{k\in[t]}||\{C_{k+t}^{(i,j\cdot2^{t-k})}\}_{k\in[t]}\big),$$

and $\alpha_1\leftarrow\mathsf{MT.Commit}(\{\alpha_1^{(i,j)}\}_{i,j\in[n]})$ in this step. Set $\hat{\varphi}_0^{(0)}=\hat{f}_0$. $\mathcal{P}$ computes polynomials for rolling batch FRI

$$\begin{aligned}q_1^{(\xi_{\ell,1})}(X)&\leftarrow g_0^{(2\cdot\xi_{\ell,1})}(X)+\alpha_1\cdot h_0^{(2\cdot\xi_{\ell,1})}(X),\\ \hat{\varphi}_1^{(\xi_{\ell,1})}(X)&\leftarrow q_1^{(\xi_{\ell,1})}(X)+\alpha_1^2\cdot\hat{f}_1^{(\xi_{\ell,1})}(X),\\ \bar{C}_1^{(\xi_{\ell,1})}&\leftarrow\mathsf{MT.Commit}(q_1^{(\xi_{\ell,1})}|_{L_1}),\end{aligned}$$

by uniquely decomposing $\hat{\varphi}_0^{(2\cdot\xi_{\ell,1})}(X)$ as $g_0^{(2\cdot\xi_{\ell,1})}(X^2)+Xh_0^{(2\cdot\xi_{\ell,1})}(X^2)$ to get $g_0^{(2\cdot\xi_{\ell,1})}(X^2)$ and $h_0^{(2\cdot\xi_{\ell,1})}(X^2)$. Let $(x)\leftarrow(x\bmod 2^t)$ for $x\in\mathbb{Z}$. Next, for $k\in[2,t]$ and $\ell\in[0,2^{k+1}-1]$, $\mathcal{P}$ computes the Fiat–Shamir challenges

$$\begin{aligned}\alpha_k^{(\xi_{\ell,k})}&\leftarrow\mathsf{H}\big(\alpha_{k-1}||\bar{C}_{k-1}^{(2\cdot\xi_{\ell,k-1})}\big),\\ \alpha_k&\leftarrow\mathsf{MT.Commit}\big(\{\alpha_k^{(\xi_{\ell,k})}\}_{\ell\in[0,2^{k-1}-1]}\big).\end{aligned}$$

Then for $\ell\in[0,2^k-1]$, $\mathcal{P}$ computes for rolling batch FRI

$$\begin{aligned}q_k^{(\xi_{\ell,k})}(X)&\leftarrow g_{k-1}^{(2\cdot\xi_{\ell,k})}(X)+\alpha_k\cdot h_{k-1}^{(2\cdot\xi_{\ell,k})}(X),\\ \hat{\varphi}_k^{(\xi_{\ell,k})}(X)&\leftarrow q_k^{(\xi_{\ell,k})}(X)+\alpha_k^2\cdot\hat{f}_k^{(\xi_{\ell,k})}(X),\\ \bar{C}_k^{(\xi_{\ell,k})}&\leftarrow\mathsf{MT.Commit}(q_k^{(\xi_{\ell,k})}|_{L_k}),\end{aligned}$$

by uniquely decomposing $\hat{\phi}_{k-1}^{(2\cdot\xi_{\ell,k})}(X)$ as $g_{k-1}^{(2\cdot\xi_{\ell,k})}(X^2)+X\cdot h_{k-1}^{(2\cdot\xi_{\ell,k})}(X^2)$ to get $g_{k-1}^{(2\cdot\xi_{\ell,k})}(X^2)$ and $h_{k-1}^{(2\cdot\xi_{\ell,k})}(X^2)$.

5. For $i\in[n]$, set $\hat{\phi}_t^{(i,0)}=\hat{\phi}_t^{(i)}$ and $\bar{C}_t^{(i,0)}=\bar{C}_t^{(i)}$. For $k\in[t],\ell\in[0,2^{k-1}-1]$, $\mathcal{P}$ computes the Fiat–Shamir challenges

$$\alpha_{k+t}^{(i,\xi_{\ell,k})}\leftarrow \mathsf{H}\big(\alpha_{k+t-1}||\bar{C}_{k+t-1}^{(i,2\cdot\xi_{\ell,k-1})}\big),$$
$$\alpha_{k+t}\leftarrow \mathsf{MT.Commit}\big(\{\alpha_{k+t}^{(i,\xi_{\ell,k})}\}_{\ell\in[0,2^{k+1}-1]}^{i\in[n]}\big).$$

Then for $\ell\in[0,2^k-1]$, $\mathcal{P}$ computes for rolling batch FRI

$$q_{k+t}^{(i,\xi_{\ell,k})}(X)\leftarrow g_{k+t-1}^{(i,2\cdot\xi_{\ell,k})}(X)+\alpha_{k+t}\cdot h_{k+t-1}^{(i,2\cdot\xi_{\ell,k})}(X),$$
$$\hat{\phi}_{k+t}^{(i,\xi_{\ell,k})}(X)\leftarrow q_{k+t}^{(i,\xi_{\ell,k})}(X)+\alpha_{k+t}^2\cdot \hat{f}_{k+t}^{(i,\xi_{\ell,k})}(X),$$
$$\bar{C}_{k+t}^{(i,\xi_{\ell,k})}\leftarrow \mathsf{MT.Commit}(q_{k+t}^{(i,\xi_{\ell,k})}|_{L_{k+t}}),$$

by uniquely decomposing $\hat{\phi}_{k+t-1}^{(i,2\cdot\xi_{\ell,k})}(X)$ as $g_{k+t-1}^{(i,2\cdot\xi_{\ell,k})}(X^2)+X\cdot h_{k+t-1}^{(i,2\cdot\xi_{\ell,k})}(X^2)$ to get $g_{k+t-1}^{(i,2\cdot\xi_{\ell,k})}(X^2)$ and $\cdot h_{k+t-1}^{(i,2\cdot\xi_{\ell,k})}(X^2)$.

6. For every $i,j\in[n]$, $\mathcal{P}$ gets $q_{i,j}\leftarrow \mathsf{H}(\alpha_{2t}||\bar{C}_{2t}^{(i,j)})$ and computes $q\leftarrow \mathsf{MT.Commit}\big(\{q_{i,j}\}_{i,j\in[n]}\big)$ as the random evaluation set, which $\mathcal{P}$ will open for all polynomials in Eval_m. Every proof $\pi_{i,j}$ includes all the Merkle tree commitments, opened evaluations and their verification paths, and all verification paths for aggregated random challenges.

• $b\leftarrow \mathsf{Eval}_{\mathsf{otm}}.\mathsf{Verify}(\mathsf{pp},\{(w_N^i,w_N^j),f(w_N^i,w_N^j),\pi_{i,j}\})$ for $i,j\in[n]$: $\mathcal{V}$ uses MT.Verify to check the consistency of the Merkle tree commitments against their verification paths. $\mathcal{V}$ outputs 0 if anyone fails. $\mathcal{V}$ then outputs $\mathsf{Eval}_{\mathsf{F}}.\mathsf{Verify}$.

Theorem 3.4. *The algorithm* $\mathsf{Eval}_{\mathsf{otm}}$ *is a non-interactive argument for the relation* $((C,\boldsymbol{x},\boldsymbol{y});\tilde{f})$.

From the standpoint of an individual verifier, the major distinction between $\mathsf{Eval}_{\mathsf{F}}$ and $\mathsf{Eval}_{\mathsf{otm}}$ is the random challenge generation. Instead of deriving it from the hash of preceding messages in $\mathsf{Eval}_{\mathsf{F}}$, $\mathsf{Eval}_{\mathsf{otm}}$ utilizes a Merkle tree root. This adaptation aligns with the equivalence of this mechanism to $\log N$ rounds of dummy messages [36]. The proof detailing this Fiat–Shamir transformation variant has been comprehensively addressed [36, Theorem 4].

Complexity. $\mathsf{Eval}_{\mathsf{otm}}$ computes and commits $O(2^k)$ polynomials of degree $O(2^{2t-k})$, $\forall k\in[2t]$, where the evaluations of a polynomial on L_k can be efficiently computed by the evaluations of polynomials on L_{k-1} within $O(2^{2t-k})$ computations. So, the prover complexity is $\sum_{k\in[2t]}O(2^k\cdot 2^{2t-k})=O(t\cdot 2^{2t})=O(n^2\log n)$. The communication and the verifier complexities per party are $O(\log^2 n)$, the same as PolyFRIM.

4 Construction of FRISS

Overview. For threshold t and n parties $\{P_1,P_2,\ldots,P_n\}$, FRISS uses a (t,t)-degree bivariate polynomial $f(X,Y)$ to share a secret $s=f(z,0)$ for a prescribed z. We set $V_{n,n}=\{(w_N^i,w_N^j)\}_{i,j\in[n]}$ as evaluation points, where $n=3t+1$ and $N=2^{\lceil\log n\rceil}$. On a high level, FRISS is similar with eAVSS [3] using PolyFRIM instead of KZG, where the dealer firstly sends $\hat{f}(x_i,Y)$ and its commitment as the share to party P_i, who then sends $f(x_i,y_j)$ and $\pi_{i,j}$ to party P_j. After receiving enough evaluations and proofs, P_j reconstructs $\hat{f}(X,y_j)$ and sends $\{f(x_i,y_j),\pi_{i,j}\}$ to P_i to help P_i obtain its share $\hat{f}(x_i,Y)$. However, trivially following the above idea poses challenges.

Firstly, eAVSS needs KZG to be zero-knowledge. FRISS achieves secrecy from PolyFRIM's $2q$-bound knowledge leaking by setting threshold $t=p+2q$ for p corrupted parties.

Secondly, without the homomorphism of KZG, generating $\pi_{k,j}$ for P_j to aid some honest party P_k to recover its share using proofs $\{\pi_{i,j}\}_{i\neq j}$ is not straightforward. As described in Section 1.2, this can be resolved by the dealer additionally sending $\{f(x_j,y_i),\pi_{j,i}\}_{j\in[n]}$ to P_i instead of only $\hat{f}(x_i,Y)$.

Thirdly, again facing the lack of homomorphism, it is unclear how to efficiently ensure the consistency among commitments to $\{\hat{f}(x_i,Y)\}_{i\in[n]}$ and $f(X,Y)$, which is necessary for the correctness of AVSS. In a KZG-based AVSS, the dealer just broadcasts $t+1$ commitments to $\hat{f}(x_1,Y),\ldots,\hat{f}(x_{t+1},Y)$, and every party P_i ($i\notin[t]$) can construct the commitment to $\hat{f}(x_i,Y)$ by homomorphism. Nevertheless, our unique construction of PolyFRIM allows an almost cost-free solution. Specifically, all commitments to $\hat{f}(x_i,Y)$ are generated from one commitment to $\hat{f}(X,Y)$, and this naturally guarantees commitment consistency. Each party needs only to use $\hat{f}(x_i,Y)$ for an extra validity check by invoking VerPoly of FRI-PC. It is unknown how to handle this problem using other FRI-based PCSs like Virgo without such special construction.

Below, we present FRISS, consisting of Algorithms 2-4.

Algorithm 2 $\mathsf{Deal}(s)$ for the dealer P_d

1: Sample (t,t)-degree polynomials $f(X,Y)$ and $r(X,Y)$ randomly, such that $f(z,0)=s$.
2: $C\leftarrow \mathsf{Commit}_{\mathsf{F}}(\mathsf{pp},f,r)$; $\mathsf{frv}\leftarrow(\mathsf{pp},f,r,V_{n,n})$.
3: $\{(w_N^i,w_N^j),f(w_N^i,w_N^j),\pi_{i,j}\}_{i,j\in[n]}\leftarrow \mathsf{Eval}_{\mathsf{otm}}.\mathsf{Open}(\mathsf{frv})$.
4: **for** $i=1$ to n **do** $\hat{f}_i\leftarrow\hat{f}(w_N^i,Y)$, $\hat{r}_i\leftarrow\hat{r}(w_N^i,Y)$.
5: Broadcast $\langle\mathsf{Commit},C,\{C_i^*\}_{i\in[n]}\rangle$.
6: **for** $i=1$ to n **do**
7: **for** $j=1$ to n **do** $f_{j,i}\leftarrow f(w_N^j,w_N^i)$, $r_{j,i}\leftarrow r(w_N^j,w_N^i)$.
8: Send $\langle\mathsf{Share},\hat{f}_i,\hat{r}_i,\{f_{j,i},r_{j,i},\pi_{j,i}\}_{j\in[n]}\rangle$ to P_i.

Dealing phase (Algorithm 2). Given the secret s, the dealer P_d randomly picks (t,t)-degree polynomials $f(X,Y)$ and $r(X,Y)$ where $f(z,0)=s$. P_d generates proofs of f,r on $V_{n,n}$ by $\mathsf{Eval}_{\mathsf{otm}}.\mathsf{Open}$. In this algorithm, P_d gets $\{C_i^*\}_{i\in[n]}$ where C_i^* is the commitment of $\hat{f}(w_N^i,Y)+\alpha\cdot\hat{r}(w_N^i,Y)$. Then P_d broadcasts all the commitments and sends the Share message to P_i for $i\in[n]$, which includes $\hat{f}(w_N^i,Y)$, $\hat{r}(w_N^i,Y)$, and evaluations/proofs of f and r on $\{(w_N^j,w_N^i)\}_{j\in[n]}$.

Algorithm 3 $\mathsf{Share}_i()$ for party P_i

1: $\mathsf{honest\_dealer} \leftarrow 0$, $\mathsf{share}_i \leftarrow \emptyset$, $\mathsf{echo\_set} \leftarrow \emptyset$.
2: **upon** receiving from P_d $\langle \mathsf{Commit}, C, \{C_i^*\}_{i\in[n]} \rangle$ and $\langle \mathsf{Share}, \hat{f}_i, \hat{r}_i, \{f_{j,i}, r_{j,i}, \pi_{j,i}\}_{j\in[n]} \rangle$ **do**
3: **if** $\mathsf{Commit}_{\mathsf{F}}(\mathsf{pp}, \hat{f}_i + \alpha\hat{r}_i) = C_i^*$ holds and $\forall j \in [n]$: $\mathsf{Eval}_{\mathsf{otm}}.\mathsf{Verify}(\mathsf{pp}, (w_N^j, w_N^i), \{f_{j,i}, r_{j,i}\}, \pi_{j,i}) = 1$ **then**
4: $\mathsf{honest\_dealer} \leftarrow 1$; $\mathsf{share}_i \leftarrow \hat{f}_i$.
5: Send $\mathsf{ec}_{j,i} = \langle \mathsf{Echo}, f_{j,i}, r_{j,i}, \pi_{j,i} \rangle$ to $P_j, \forall j \in [n]$.
6: **upon** receiving $\mathsf{ec}_{i,j}$ from P_j for the first time **do**
7: **if** $\mathsf{Eval}_{\mathsf{otm}}.\mathsf{Verify}(\mathsf{pp}, (w_N^i, w_N^j), \{f_{i,j}, r_{i,j}\}, \pi_{i,j})$ **then**
8: Mark Echo as valid.
9: $\mathsf{echo\_set} \leftarrow \mathsf{echo\_set} \cup \{(w_N^i, w_N^j), \{f_{i,j}, r_{i,j}\}\}$.
10: **upon** getting $2t+1$ valid Echo & $\mathsf{honest\_dealer} = 1$ **do**
11: Send $\langle \mathsf{Ready} \rangle$ to all parties.
12: **upon** receiving $t+1$ Ready and not yet sent Ready **do**
13: Send $\langle \mathsf{Ready} \rangle$ to all parties.
14: **upon** receiving $2t+1$ Ready **do**
15: Wait until $t+1$ valid Echo.
16: Interpolate $\hat{f}_i$ and $\hat{r}_i$ using the set echo_set.
17: **output** $\mathsf{share}_i \leftarrow \hat{f}_i$ and **terminate**

Sharing phase (Algorithm 3). Honest party P_i first checks the correctness of C_i^*, then checks if the received evaluations are valid by $\mathsf{Eval}_{\mathsf{otm}}.\mathsf{Verify}$. If all the verifications pass, P_i will set $\mathsf{honest\_dealer} = 1$, and send an Echo message with $f(w_N^j, w_N^i)$, its proof, and $r(w_N^j, w_N^i)$ to other parties. Through a typical "Echo + Ready" approach [3] (Steps 6-16, Algorithm 3), a party who has not received the Share message will get its share by $t+1$ valid Echo messages. When Share_i terminates, P_i gets $\hat{f}(w_N^i, Y)$ as its share.

At the end of the Share phase, every honest party receives at least $2t+1$ valid Echo messages. At least $t+1$ of them are sent by honest parties with $\mathsf{honest\_dealer} = 1$. Further, every such honest P_i has a valid commitment C_i^* and valid polynomial $\hat{f}(x_i, Y)$, so is able to generate a valid proof for $\hat{f}_i(0)$.

Reconstruction phase (Algorithm 4). Every (at least $t+1$) honest P_i with $\mathsf{honest\_dealer} = 1$ sending $\hat{f}_i(0)$ and corresponding proof to other parties would suffice to recover the secret. However, at most t honest parties with $\mathsf{honest\_dealer} = 0$ could not participate in the reconstruction as they cannot generate valid proofs. We propose an alternative to enable these "weaker" parties to contribute to the reconstruction.

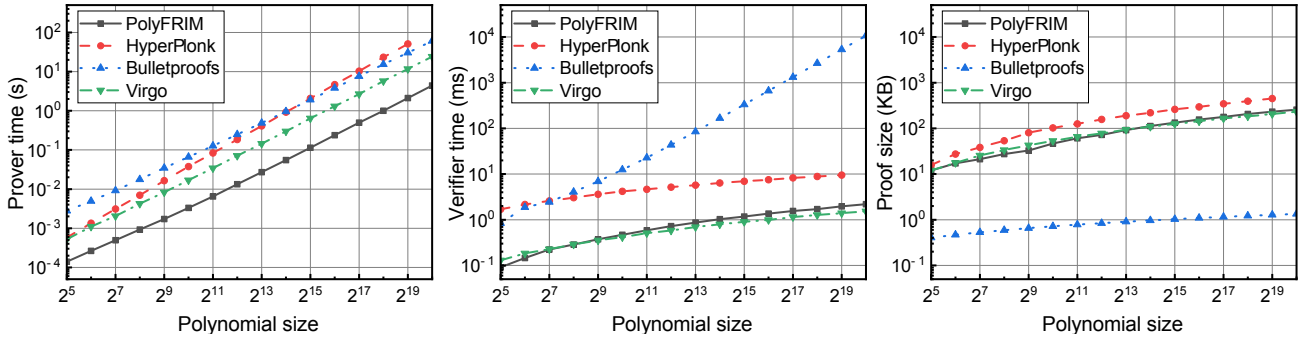
Specifically, if P_i is with $\mathsf{honest\_dealer} = 1$, it would send Rec_strong, evaluations, and corresponding proof to other parties. Otherwise, it just sends Rec_weak and evaluations. For another honest party P_j, if it receives at least $t+1$ proofs, it can verify the validity of evaluations and get its share directly by interpolation. If it receives sufficient evaluations (some with proofs but less than t and some without), it can still compute $f(X,0)$ by an efficient RS decoding algorithm such as Berlekamp–Welch, hence computing $f(z,0)$.

Algorithm 4 $\mathsf{Reconstruction}_i()$ for party P_i

1: $\mathsf{valid\_rec} \leftarrow \emptyset$, $\mathsf{decode\_set} \leftarrow \emptyset$.
2: **if** $\mathsf{honest\_dealer} = 1$ **then**
3: $\pi_i \leftarrow \mathsf{Eval.Open}(\mathsf{pp}, C_i^*, \hat{f}_i + \alpha\hat{r}_i, 0)$.
4: Send $\mathsf{rs}_i = \langle \mathsf{Rec\_strong}, \hat{f}_i(0), \hat{r}_i(0), \pi_i \rangle$ to all parties.
5: **if** $\mathsf{honest\_dealer} = 0$ **then**
6: Send $\mathsf{rw}_i = \langle \mathsf{Rec\_weak}, \hat{f}_i(0), \hat{r}_i(0) \rangle$ to all parties.
7: **upon** receiving rs_j for the first time **do**
8: **if** $\mathsf{Eval.Verify}(\mathsf{pp}, C_j^*, 0, \hat{f}_j(0) + \alpha\hat{r}_j(0), \pi_j) = 1$ **then**
9: $\mathsf{valid\_rec} \leftarrow \mathsf{valid\_rec} \cup \{\hat{f}_j(0)\}$.
10: $\mathsf{decode\_set} \leftarrow \mathsf{decode\_set} \cup \{\hat{f}_j(0)\}$.
11: **if** $|\mathsf{valid\_rec}| \geq t+1$ **then**
12: Get $\hat{f}(X,0)$ by interpolation and obtain $\hat{f}(z,0)$.
13: **terminate**
14: **upon** receiving rw_j from P_j for the first time **do**
15: $\mathsf{decode\_set} \leftarrow \mathsf{decode\_set} \cup \{\hat{f}_j(0)\}$.
16: **if** $|\mathsf{decode\_set}| + 2|\mathsf{valid\_rec}| \geq 3t+1$ **then**
17: Get $\hat{f}(X,0)$ by decoding and obtain $\hat{f}(z,0)$.
18: **terminate**

Theorem 4.1. FRISS *is an* (n,t)-AVSS *scheme as in Definition 2.4. Appendix E provides a formal proof.*

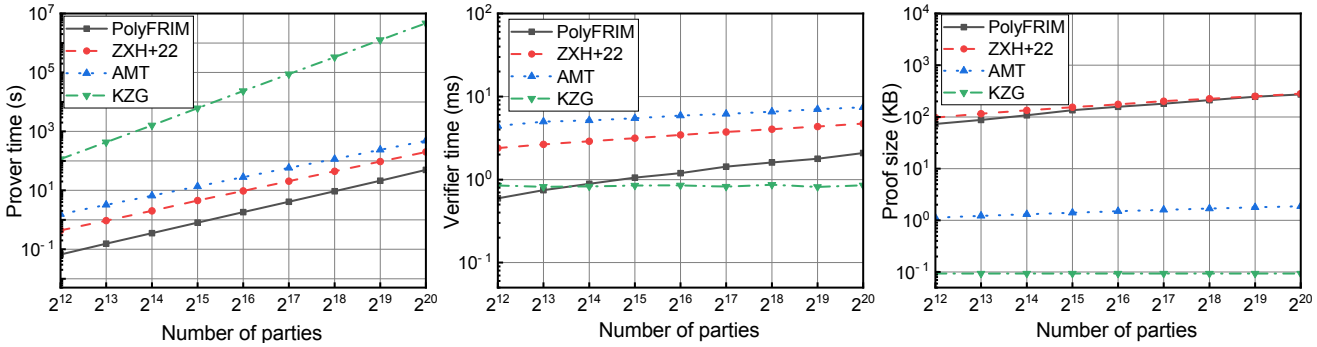
Complexity. The dealer complexity mainly comes from generating proofs in Step 3, Algorithm 2 using the one-to-many PolyFRIM, which is $O(n^2 \log n)$ as $t = O(n)$, $N = O(n)$.



The per-party computation overhead comes from:
(1) verifying proofs for $O(n)$ times using $\mathsf{Eval}_{\mathsf{otm}}.\mathsf{Verify}$ in Steps 3 and 7, Algorithm 3: $O(n) \cdot O(\log^2 n) = O(n \log^2 n)$;
(2) generating proofs using the FRI-PC Eval algorithm in Step 3, Algorithm 4: $O(n)$;
(3) verifying proofs for $O(n)$ times by the FRI-PC Verify algorithm in Step 8, Algorithm 4: $O(n) \cdot O(\log^2 n) = O(n \log^2 n)$.
So, the per-party computation overhead is $O(n \log^2 n)$.

The communication overhead comes from:
(1) the dealer sending shares and proofs in Step 8, Algorithm 2: $O(n) + O(n^2) + O(n^2) \cdot O(\log^2 n) = O(n^2 \log^2 n)$;
(2) the dealer broadcasting commitments in Step 5, Algorithm 2: $O(n^2)$ using reliable broadcast (*e.g.*, [14]);
(3) party sending shares and proofs in Step 5, Algorithm 3 and Step 4, Algorithm 4: $O(n^2) \cdot O(\log^2 n) = O(n^2 \log^2 n)$.
So, the total communication complexity is $O(n^2 \log^2 n)$.

5 Empirical Conclusion



We wrote $\sim$1,600 lines for PolyFRIM and $\sim$1,800 lines for FRISS in Rust. We ran all experiments on an AMD Ryzen 3900X processor with 80GB RAM and Ubuntu 22.04 LTS operating system. Reported figures are averages over 10 executions. We assume no parallelization.

We use $\mathbb{F}_{p^2}$ as our field, $p = 2^{61} - 1$ [37], with a multiplicative coset of size up to 2^{60}. For all FRI-based schemes (Virgo [37],

(a) prover time (b) verifier time (c) proof size

Figure 2: Comparison of transparent multivariate polynomial commitments

(a) prover time (b) per-verifier time (c) per-proof size

Figure 3: Comparison of one-to-many proofs of univariate polynomial commitments with the number of parties as the degree

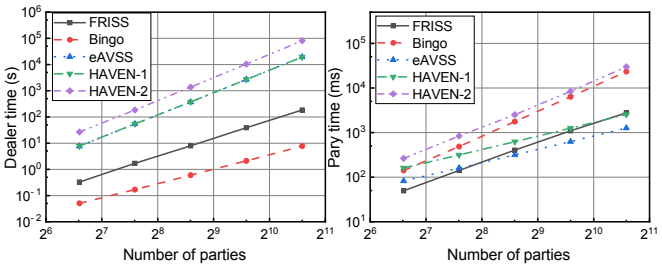
ZXH$^+$22 [36], HyperPlonk [16], and PolyFRIM), we set the code rate as $1/8$, and the query repetition number as 34, providing 100 bits of security [6, Conjecture 8.4]. Besides, we set the FRI reduction parameter as 2, reducing the polynomial degree by half in each round. Our hash function is blake3.[5]

5.1 Performance of PolyFRIM

We compare PolyFRIM with other transparent PCSs, including Bulletproofs [11][6], Virgo [37][7], and HyperPlonk [16]. As HyperPlonk is not open-sourced, we implement it ourselves.

Figure 2 shows their prover time, verifier time, and proof size. The size of the multivariate polynomial (number of monomials) varies from 2^5 to 2^{20} (as in [36]). We run out of memory for HyperPlonk when the polynomial size is 2^{19}. As shown, for size being 2^{20}, the prover time of PolyFRIM takes only 4.4s, which is 6×, 10×, and 25× faster than Virgo, HyperPlonk, and Bulletproofs, respectively.

PolyFRIM has a 4-10× faster verifier and a 2-3× smaller proof size than HyperPlonk. This speed stems from avoiding FRI-PC by changing the queries from the whole field to the committed domain. Its smaller proof size is due to the rolling batch FRI, which reduces Merkle tree depth and verification path size. The verifier time and proof size of PolyFRIM are competitive with Virgo (less than 50% and 10% worse, respectively). As for Bulletproofs, PolyFRIM has a 100-200× larger proof size but can be 1000× faster for verification.



5.2 Performance of One-to-Many PolyFRIM

PolyFRIM is the first multivariate PCS with one-to-many proof. Figure 3a shows the prover time. One-to-many PolyFRIM is 800-10^6× faster than its trivial repetition. It only takes 0.07s (resp., 49.4s) to generate 2^{12} (resp., 2^{20}) proofs for a 2^{12}-degree (resp., 2^{20}-degree) polynomial. Using only lightweight crypto operations (RS codes and hash), our prover time is 25-100× and 10^3-10^6× faster than AMT[8] and KZG, respectively. For one-to-many ZXH$^+$22[9], our prover time is 4-7× faster for eliminating the need for the GKR protocol [21, 36] (and PolyFRIM is faster than Virgo).

As in Figure 2b, our per-verifier time is 3-9× (resp., 2-4×) faster than AMT (resp., ZXH$^+$22). Even compared with constant-verifier KZG, ours is concretely faster for $n < 2^{14}$.

Figure 2c shows the proof size. Ours is larger than trusted-setup-based AMT and KZG. PolyFRIM features up to 20%

(a) dealer time (b) per-party time

Figure 4: Performance of PCSs in different AVSS schemes

smaller proof size than transparent ZXH+22, thanks to its avoidance of additional GKR protocol for delegation.

5.3 Performance of PolyFRIM in AVSS

Figure 4 compares the performance of PCSs in different AVSS schemes (eAVSS [3], HAVEN [2], and Bingo [1]) for varying numbers of parties $n = 3t+1$ and degree-t polynomials.

For FRISS, the dealer generates n^2 proofs for a (t,t)-degree polynomial using PolyFRIM, and each party verifies n proofs. In eAVSS and HAVEN, everything is the same except using different PCSs (KZG for eAVSS and HAVEN-1, and Bulletproofs for HAVEN-2). Following these works, we achieve a bivariate KZG by committing n t-degree univariate polynomials and generating n proofs for every polynomial. For Bingo, the dealer just commits $t+1$ $2t$-degree univariate polynomials, and every party generates n proofs for a $2t$-degree univariate polynomial using KZG.

Figure 4 shows the generation time of commitments and evaluation proofs for the dealer (Steps 2-3 in Algorithm 2) and verification time (Steps 3 and 7 in Algorithm 3) for per party. We omit PCS-irrelevant parts (*e.g.*, broadcast/encryption) to focus on how PCS improves AVSS. The dealer time of FRISS caused by the PCS is 4-800× faster than AVSS using a similar method (eAVSS and HAVEN-1/2). Our per-party time is 0.5-1.2× of eAVSS and HAVEN-1. In Bingo, proof generation is partially "shifted" from the dealer to the parties, so FRISS is 10× slower for the dealer but 10× faster for parties.

A The FRI Protocol and FRI-PC

Protocol 5 The FRI protocol to test if $\hat{f}|_L \in \mathrm{RS}[L,d/|L|]$

Inputs: $\big((\mathbb{F},L,d),(\hat{f})\big)$. L is a multiplicative coset. Without loss of generality, we assume $d = 2^{\mathsf{r}}$ for a positive integer r.

1: P sets $L_0 = L, \hat{f}_0 = \hat{f}$, computes $\hat{f}_0|_{L_0}$, executes $\mathsf{rt}_0 \leftarrow \mathsf{MT.Commit}(\hat{f}_0|_{L_0})$, and sends rt_0 to $\mathcal{V}$.
2: **for** $i = 1$ to $\mathsf{r}+1$ **do**
3: $\quad\mathcal{P}$ decomposes $\hat{f}_{i-1}$ as $\hat{g}_i(X^2) + X \cdot \hat{h}_i(X^2)$.
4: $\quad\mathcal{V}$ sends $\alpha_i \leftarrow_{\$} \mathbb{F}$ to $\mathcal{P}$.
5: $\quad\mathcal{P}$ computes $\hat{f}_i(X) \leftarrow \hat{g}_i(X) + \alpha_i \cdot \hat{h}_i(X)$.
6: $\quad$If $i \neq \mathsf{r}+1$, $\mathcal{P}$ computes $\hat{f}_i|_{L_i}$ where $L_i = \{x^2 | x \in L_{i-1}\}$, runs $\mathsf{rt}_i \leftarrow \mathsf{MT.Commit}(\hat{f}_i|_{L_i})$, and sends rt_i to $\mathcal{V}$.
7: $\quad$If $i = \mathsf{r}+1$, $\mathcal{P}$ directly sends $\hat{f}_i$ to $\mathcal{V}$.
8: **for** $j = 1$ to $q = O(\lambda)$ **do**
9: $\quad\mathcal{V}$ sends $\beta \leftarrow_{\$} L_0$ to $\mathcal{P}$.
10: $\quad$**for** $i = 1$ to $\mathsf{r}+1$ **do**
11: $\quad\quad\mathcal{P}$ uses $\mathsf{MT.Open}$ to open $\hat{f}_{i-1}(\pm\beta^{2^{i-1}})$, $\hat{f}_i(\beta^{2^i})$.
12: $\quad\quad\mathcal{V}$ checks the correctness by $\mathsf{MT.Verify}$.
13: $\quad\quad\mathcal{V}$ checks if the pairs $(\pm\beta^{2^{i-1}}, \hat{f}_{i-1}(\pm\beta^{2^{i-1}}))$ and $(\alpha_i, \hat{f}_i(\beta^{2^i}))$ are on a common line.
14: If all the above checks pass, $\mathcal{V}$ outputs 1; 0 otherwise.

We recall FRI in Protocol 5, and FRI-PC below.

• $\mathsf{pp} \leftarrow \mathsf{Gen}(1^\lambda, d)$: Takes as inputs the security parameter λ and the degree bound d; outputs public parameter pp, which includes the field $\mathbb{F}$ and a multiplicative coset L.

• $C \leftarrow \mathsf{Commit}(\mathsf{pp}, \hat{f})$: Executes $C \leftarrow \mathsf{MT.Commit}(\hat{f}|_L)$.

• $b \leftarrow \mathsf{VerPoly}(\mathsf{pp}, C, \hat{f}|_L, \hat{f})$: Receives $\hat{f}|_L$ as the opening of C; outputs 1 iff the decoding of $\hat{f}|_L$ and $\hat{f}$ are consistent.

• $b \leftarrow \mathsf{Eval}(\mathsf{pp}, C, y, x, \hat{f})$: $\mathcal{P}$ and $\mathcal{V}$ invoke the batch FRI on proving $\hat{f}|_L \in \mathrm{RS}[L, d/|L|] \wedge \hat{f}'|_L \in \mathrm{RS}[L, (d-1)/|L|]$, where $\hat{f}'(X) = (\hat{f}(X) - y)/(X - x)$. $\mathcal{V}$ outputs 1 iff FRI outputs 1.

The batch version of FRI-PC for multiple evaluation points on multiple polynomials can be obtained from the batch FRI.

B HyperPlonk

We recall HyperPlonk, which uses the FRI-PC algorithms $(\mathsf{Gen}_u, \mathsf{Commit}_u, \mathsf{VerPoly}_u, \mathsf{Eval}_u)$.

• $\mathsf{pp} \leftarrow \mathsf{Gen}(1^\lambda, \mu)$: Takes as inputs λ and a variable number μ, outputs public parameter $\mathsf{pp} \leftarrow \mathsf{Gen}_u(1^\lambda, n)$ where $n = 2^\mu$.

• $C \leftarrow \mathsf{Commit}(\mathsf{pp}, \tilde{f})$: Takes as inputs pp and $\tilde{f}$, outputs the commitment $C \leftarrow \mathsf{Commit}_u(\mathsf{pp}, \hat{f})$.

• $b \leftarrow \mathsf{VerPoly}(\mathsf{pp}, C, \hat{f}|_L, \tilde{f})$: Runs $\mathsf{VerPoly}_u(\mathsf{pp}, C, \hat{f}|_L, \hat{f})$.

• $b \leftarrow \mathsf{Eval}(\mathsf{pp}, C, \boldsymbol{x}, y, \tilde{f})$: Given pp, C, the evaluation point $\boldsymbol{x} = (x_1, \ldots, x_\mu)$, $y = \tilde{f}(\boldsymbol{x})$, and the multilinear polynomial $\tilde{f}$, $\mathcal{P}$ and $\mathcal{V}$ invoke the following argument:

1: Let $\hat{f}_0(X) = \hat{f}(X)$. For every $i \in [\mu]$, $\mathcal{P}$ first decomposes $\hat{f}_{i-1}(X)$ into $\hat{g}_i(X^2) + X \cdot \hat{h}_i(X^2)$, and then computes $\hat{f}_i(X) \leftarrow \hat{g}_i(X) + x_i \cdot \hat{h}_i(X)$. If $i < \mu$, $\mathcal{P}$ runs $C_i \leftarrow \mathsf{MT.Commit}(\hat{f}_i|_{L_i})$, and sends $\{C_i\}_{i \in [\mu]}$ to $\mathcal{V}$, where $L_i = \{x^2 | x \in L_{i-1}\}$. For $i = \mu$, $\mathcal{P}$ sends $\hat{f}_\mu$ directly to $\mathcal{V}$.

2: $\mathcal{V}$ picks $\beta \leftarrow_\$ \mathbb{F} \setminus \{0\}$ and sends it to $\mathcal{P}$.

3: For every $i \in [\mu]$, $\mathcal{P}$ computes $\hat{f}_{i-1}(\beta)$, $\hat{f}_{i-1}(-\beta)$, and $\hat{f}_i(\beta^2)$. Note that $\hat{f}_\mu$ is a constant polynomial and equals $\tilde{f}(\boldsymbol{x})$. $\mathcal{P}$ and $\mathcal{V}$ then invoke Eval_u to prove the validity of $\{\hat{f}_{i-1}(\beta), \hat{f}_{i-1}(-\beta), \hat{f}_i(\beta^2)\}_{i \in [\mu]}$ except $\hat{f}_\mu(\beta^2)$. If Eval_u outputs 0, $\mathcal{V}$ outputs 0 and aborts.

4: For every $i \in [\mu]$, $\mathcal{V}$ checks if $\hat{f}_i(\beta^2)$ equals $\big(\hat{f}_{i-1}(\beta) + \hat{f}_{i-1}(-\beta)\big)/2 + x_i \cdot \big(\hat{f}_{i-1}(\beta) - \hat{f}_{i-1}(-\beta)\big)/2\beta$. If so, $\mathcal{V}$ outputs 1; otherwise, $\mathcal{V}$ outputs 0 and aborts.

We give a detailed proof of Theorem 2.2 (inspired by [10]).

Proof. **Completeness.** Supposing $\tilde{f}(x_1, \ldots, x_\mu) = y$, we prove that the verifier $\mathcal{V}$ will output 1 in the interactive argument Eval. Setting $\boldsymbol{f} = (a_0, \ldots, a_{2^\mu - 1})$ as the coefficient vector of $\tilde{f}$, we first prove by induction that for all $i \in [0, \mu]$,

$$\hat{f}_i(X) = \sum_{\substack{j \in [0, 2^\mu - 1], \\ (j_1, \ldots, j_\mu)_2 \leftarrow j}} (a_j x_1^{j_1} \cdots x_i^{j_i})(X^{j_{i+1} + 2 \cdot j_{i+2} + \cdots + 2^{\mu - i - 1} \cdot j_\mu}). \tag{3}$$

In Equation (3) and below, $(j_1, \ldots, j_\mu)_2$ denotes the binary representation of j. When $i = 0$,

$$\hat{f}_i(X) = \sum_{j \in [0, 2^\mu - 1]} a_j X^j = \sum_{j \in [0, 2^\mu - 1]} a_j X^{j_1 + 2 \cdot j_2 + \cdots + 2^{\mu - 1} \cdot j_\mu}.$$

Suppose Equation (3) holds when $i = k$, and we next prove Equation (3) also holds when $i = k + 1$. Since $\hat{f}_k(X) = \hat{f}_E^{(k-1)}(X^2) + X \cdot \hat{f}_O^{(k-1)}(X^2)$, we have

$$\hat{f}_E^{(k-1)}(X^2) = \sum_{j \in [0, 2^\mu - 1], j_{k+1} = 0} a_j x_1^{j_1} \cdots x_k^{j_k} X^{2 \cdot j_{k+2} + \cdots + 2^{\mu - k - 1} \cdot j_\mu},$$

$$\hat{f}_O^{(k-1)}(X^2) = \sum_{j \in [0, 2^\mu - 1], j_{k+1} = 1} a_j x_1^{j_1} \cdots x_k^{j_k} X^{2 \cdot j_{k+2} + \cdots + 2^{\mu - k - 1} \cdot j_\mu}.$$

We thus have $\hat{f}_{k+1}(X) \leftarrow \hat{f}_E^{(k-1)}(X) + x_{k+1} \cdot \hat{f}_O^{(k-1)}(X)$ by the procedure of HyperPlonk, then we have $\hat{f}_{k+1}(X)$ equals to $\sum_{j \in [0, 2^\mu - 1]} a_j x_1^{j_1} \cdots x_k^{j_k} x_{k+1}^{j_{k+1}} X^{j_{(k+1)+1} + \cdots + 2^{\mu - (k+1) - 1} \cdot j_\mu}$. So, Equation (3) holds for all $i \in [0, \mu]$.

To see $\hat{f}_\mu(\pm\beta) = y$, we show by induction that $\hat{f}_\mu(X)$ equals to $\sum_{j \in [0, 2^\mu - 1]} a_j x_1^{j_1} \cdots x_\mu^{j_\mu} = \langle \boldsymbol{f}, (1, x_1) \otimes \cdots \otimes (1, x_\mu) \rangle = y$.

Besides, for every $i \in [\mu]$, $\hat{f}_i(X) \leftarrow \hat{f}_E^{(i-1)}(X) + x_i \cdot \hat{f}_O^{(i-1)}(X)$, where $\hat{f}_E^{(i-1)}(X^2) = \big(\hat{f}_{i-1}(X) + \hat{f}_{i-1}(-X)\big)/2$ and $\hat{f}_O^{(i-1)}(X^2) = \big(\hat{f}_{i-1}(X) - \hat{f}_{i-1}(-X)\big)/2X$, hence $\hat{f}_{i+1}(\beta^2) = \big(\hat{f}_i(\beta) + \hat{f}_i(-\beta)\big)/2 + x_i \cdot \big(\hat{f}_i(\beta) - \hat{f}_i(-\beta)\big)/2\beta$.

Polynomial binding. For proximity parameter $\delta \le (1 - \rho)/2$, by the soundness of batch FRI, if the verifier accepts in VerPoly, with probability $1 - \mathsf{negl}(\lambda)$ each opened vector of commitment binds to the encoding of a unique univariate polynomial. The polynomial binding property hence follows.

Soundness. Suppose that $\tilde{f}(x_1, \ldots, x_\mu) \neq y$, and $\hat{f}'_1, \ldots, \hat{f}'_\mu$ are actually committed polynomials. We argue by two cases:

• Case 1. There exists some $\hat{f}'_i$ for $i \in [0, \mu - 1]$ of degree at least $2^{\mu - i}$ or the evaluation proof for $\hat{f}'_i$ is invalid. According to Theorem 2.1, this probability is at most $\varepsilon_{\mathsf{FRI}}$.

• Case 2. Degrees of $\{\hat{f}'_i\}$ are less than $2^{\mu - i}$ for $i \in [0, \mu]$ and the evaluation proofs are all valid. Since $\tilde{f}(\boldsymbol{x}) \neq y$, there must be some i such that $\hat{f}'_i(X) \neq \hat{f}'^{(i-1)}_E(X) + x_i \hat{f}'^{(i-1)}_O(X)$ but it holds for all queries. Assume j is the smallest of such is. By definition, $\hat{f}'^{(j-1)}_E(X^2) = (\hat{f}_{j-1}(X) + \hat{f}_{j-1}(-X))/2$, and $\hat{f}'^{(j-1)}_O(X^2) = (\hat{f}_{j-1}(X) - \hat{f}_{j-1}(-X))/2X$. Set $\hat{g}(X)$ to be:

$$\hat{f}'_j(X^2) - \frac{\hat{f}_{j-1}(X) + \hat{f}_{j-1}(-X)}{2} - x_j \cdot \frac{\hat{f}_{j-1}(X) - \hat{f}_{j-1}(-X)}{2\beta}.$$

$\hat{g}(X)$ is a non-zero polynomial with a degree at most $2^{\mu - j + 1}$, so the soundness error is bounded by $2^{\mu - j + 1}/|\mathbb{F} \setminus \{0\}| \le 2^\mu/|\mathbb{F} \setminus \{0\}|$ according to the Schwartz–Zippel lemma.

Using the union bound argument, the total soundness error of HyperPlonk is $\varepsilon_{\mathsf{FRI}} + 2^\mu/|\mathbb{F} \setminus \{0\}|$. By appropriate parameter choices for $\mathbb{F}, L$, and q, the soundness error can be negligible.

Knowledge soundness. HyperPlonk is an argument of knowledge with extractability of Merkle trees proven in the random oracle model [8, 37]. Roughly, given the root and sufficiently many authentication paths, there exists an efficient extractor that reconstructs the leaves with high probability. Additionally, the leaves are RS codewords and can be efficiently decoded by decoding algorithms such as Berlekamp–Welch.

Specifically, for any PPT adversary $\mathcal{P}^*$ with Commit^* and Eval^*, there exists a PPT extractor $\mathcal{E}$ such that given the random access tape of $\mathcal{P}^*$, the following probability is $\mathsf{negl}(\lambda)$:

$$\Pr\begin{bmatrix} C^* \leftarrow \mathsf{Commit}^*(\mathsf{pp}, \tilde{f}^*) & \tilde{f}^* \leftarrow \mathcal{E}(\mathsf{pp}, C^*, \boldsymbol{x}, y^*) \\ 1 \leftarrow \mathsf{Eval}^*(\mathsf{pp}, C^*, \boldsymbol{x}, y^*, \tilde{f}^*) : & y^* \neq \tilde{f}^*(\boldsymbol{x}) \end{bmatrix}.$$

Suppose the Merkle tree is based on a random oracle $\mathcal{H}: \{0,1\}^{2\lambda} \to \{0,1\}^{\lambda}$. We then construct a PPT extractor $\mathcal{E}$ with the same random type of $\mathcal{P}^*$ working as follows:

1. $\mathcal{E}$ mirrors the process of $\mathcal{P}^*$ querying $\mathcal{H}$. Let the queries made by $\mathcal{P}^*$ to $\mathcal{H}$ be $(q_1, q_2, \ldots, q_{\max})$ in the order they are made with duplicates excluded, which implies that queries are not generated from parent nodes to child ones. Define $q_i \in \mathcal{H}(q_j)$ if the first λ bits or the last λ bits of q_i is $\mathcal{H}(q_j)$, *i.e.*, q_i could be the parent node of q_j. If there exists some $i \neq j$, $\mathcal{H}(q_i) = \mathcal{H}(q_j)$ or some $i \leq j$, $q_i \in \mathcal{H}(q_j)$, $\mathcal{E}$ outputs random polynomial $\tilde{f}$ and aborts.
2. $\mathcal{E}$ constructs a directed graph G according to the query set $Q = \{q_1, \ldots, q_{\max}\}$. There is an edge from q_i to q_j in G if and only if $q_i \in \mathcal{H}(q_j)$. The outdegree of each node is at most 2. When $\mathcal{P}^*$ generates C^* in the Commit^* algorithm, if C^* does not equal $\mathcal{H}(q)$ for some $q \in Q$ with depth $\lceil \mu \rceil$ of the binary tree, $\mathcal{E}$ outputs a random polynomial $\tilde{f}$ and aborts; otherwise we suppose that $\mathcal{H}(q_r) = C^*$ for some r. If any verification path is invalid, $\mathcal{E}$ outputs a random polynomial $\tilde{f}$ and aborts.
3. $\mathcal{E}$ reads all leaves from the root q_r. If there exists any missing leaf, $\mathcal{E}$ outputs a random $\tilde{f}$ and aborts; otherwise, it concatenates these leaf strings and decodes the string using an efficient RS decoding algorithm. Therefore, $\mathcal{E}$ could efficiently output the coefficients of $\tilde{f}$.

Let E_1 be the event $\mathcal{V}$ accepts, and E_2 be $y^* \neq \tilde{f}^*(\boldsymbol{x})$. Consider $\Pr[E_1 \wedge E_2]$. Suppose that $\mathcal{E}$ aborts before constructing the graph G. If for some $i \neq j$, $\mathcal{H}(q_i) = \mathcal{H}(q_j)$, $\mathcal{E}$ finds a collision. If for some $i \leq j$, $q_i \in \mathcal{H}(q_j)$, $\mathcal{E}$ could generate a Merkle tree violating the logical order. Either probability is $\mathsf{negl}(\lambda)$ since $\mathcal{H}$ is collision-resistant and non-invertible.

Otherwise, $\mathcal{E}$ has successfully constructed a graph G. If some node on a verification path does not lie in G, $\mathcal{P}^*$ has to guess the value to construct a valid verification path, and this probability is $\mathsf{negl}(\lambda)$ since $\mathcal{H}$ is non-invertible. Additionally, if any leaf is missing, $\mathcal{V}$ will be convinced with probability $\mathsf{negl}(\lambda)$ once it queries this leaf. The probability that this leaf is not queried by $\mathcal{V}$ is at most $(1-1/|L_0|)^q = \mathsf{negl}(\lambda)$ as the query repetition number of FRI-PC q satisfies $q = O(\lambda)$. If $\mathcal{E}$ does not abort, it could always efficiently extract the coefficient vector of $\tilde{f}$. In this case, $\mathcal{V}$ accepts the statement with probability $\mathsf{negl}(\lambda)$ with an appropriate choice of parameters according to the soundness. So, we can bound $\Pr[E_1 \wedge E_2]$:

$$\begin{aligned} &\Pr[E_1 \wedge E_2 \,|\, \mathcal{E} \text{ aborts}] + \Pr[E_1 \wedge E_2 \,|\, \mathcal{E} \text{ does not abort}] \\ \leq\ &\Pr[\mathcal{E} \text{ aborts}] + \Pr[E_1 \wedge E_2 \,|\, \mathcal{E} \text{ does not abort}] \leq \mathsf{negl}(\lambda). \end{aligned}$$

Complexity. Commit takes $O(n \log n)$, mainly caused by the FFT operation and the construction of the Merkle tree for $\hat{f}|_L$. The other complexities depend on the concrete algorithm.

• Case 1. The prover shows that $\{\hat{f}_i(\pm\beta),\ \hat{f}_i(\beta^2)\}_{i\in[0,\mu]}$ is valid round by round independently. The prover complexity is $\sum_{i\in[0,\log n]} O(n/2^i) = O(n)$. The verifier and communication complexities are both $\sum_{i\in[0,\log n]} O(\log^2(n/2^i)) = O(\log^3 n)$.

• Case 2. The prover invokes a batch FRI to prove the validity of all the evaluations, where all $\{\hat{f}_i\}_{i\in[\mu]}$ are computed and evaluated on the same multiplicative coset. The prover complexity is hence $O(n \log n)$ caused by constructing Merkle trees for $\log n$ n-length vectors. The verifier and communication complexities are both $O(\log^2 n)$ due to the batch FRI. □

C Proof of Theorem 3.1

Proof. The completeness comes directly from that of the FRI protocol. Similar to the proof in Appendix B, the argument of knowledge property holds according to the extractability of Merkle trees. We mainly prove the soundness property below from the following two cases.

• Case 1. If any of the Merkle tree commitments $\{\mathsf{rt}_i\}_{i\in[0,\mu]}$ is not valid, or the leaves are inconsistent with the roots, the verification passes with probability no more than $\mathsf{negl}(\lambda)$.

• Case 2. All the Merkle tree commitments are valid, and the leaves are consistent with corresponding roots. For this case, we first define functions $\{\mathrm{back}_i\}_{i\in[0,\mu]}$ and sets $\{\mathrm{err}_i\}_{i\in[0,\mu]}$.

Define $\mathrm{back}_0(A_0) = A_0$ for $A_0 \subseteq L_0$, and $\mathrm{back}_i(A_i) = \mathrm{back}_{i-1}(A_{i-1})$ for $A_i = \{x^2 | x \in A_{i-1}\}$ and $i \geq 1$.

Define $\mathrm{err}_0 = \emptyset$. For $i \in [\mu]$, let the set E be $\{x \in L_{i-1} : \hat{g}_i(x^2) + \alpha\hat{h}_i(x^2) + \alpha_i^2\hat{f}_i(x^2) \neq \hat{f}^{(i)}(x^2)\}$, where $\hat{f}^{(i-1)}(X) = \hat{g}_i(X^2) + X \cdot \hat{h}_i(X^2)$. Define $\mathrm{err}_i = \mathrm{err}_{i-1} \cup \mathrm{back}_{i-1}(E)$.

For $i \in [\mu]$, suppose that $\hat{h}^{(i)}|_{L_i} \in \mathrm{RS}[L_i, \rho]$ and set $A_i = \{x \in L_i | \hat{f}^{(i)}(x) = \hat{h}^{(i)}(x)\}$. Define $\varepsilon_i(\cdot) : L_i \to \{0,1\}$ such that $\varepsilon_i(A_i) = |\mathrm{back}_i(A_i) \cap \mathrm{err}_i|/|L_0| + (1 - |A_i|/|L_i|)$.

By definition, $|\mathrm{back}_i(A_i)| = 2^i|A_i|$, $A_i \subseteq L_i$, and $\mathrm{err}_i \subseteq L_i$. Further, $\varepsilon_\mu(A_\mu)$ means the probability that the verifier finds inconsistency and rejects with a single query in Step 13 of Protocol 1. Suppose:

$$\Pr[\varepsilon_\mu(A_\mu) \geq (1-\rho)/2] \geq 1 - |L_0|/|\mathbb{F}|. \tag{4}$$

That is, with probability at least $1 - |L_0|/|\mathbb{F}|$, the verifier can catch about $\delta = (1-\rho)/2$ inconsistency if it picks only one query. For q queries, the probability that a malicious prover cheats successfully will be $(1-\delta)^q = ((1+\rho)/2)^q$.

By the union bound argument, the total soundness error is $|L_0|/|\mathbb{F}| + ((1+\rho)/2)^q + \mathsf{negl}(\lambda)$. □

To prove Inequality (4), we first describe three lemmas.

Lemma C.1 ([6]). *For $\delta < (1-\rho)/2$, $\{\hat{f}\}_{i\in[n-1]}$ with degree bounds d and multiplicative coset L where $\rho = d/|L|$, if*

$$\Pr_{\alpha \leftarrow_\$ \mathbb{F}}[\Delta(\sum_{i=0}^{n-1} \alpha^i \cdot \hat{f}_i|_L, \mathrm{RS}[L,\rho]) \leq \delta] \geq |L|/|\mathbb{F}|,$$

where $\Delta(\boldsymbol{a},\boldsymbol{b})$ is the relative Hamming distance between $\boldsymbol{a}$ and $\boldsymbol{b}$, there exists $L' \subset L$ and $\hat{p}_0,\ldots,\hat{p}_{n-1}$ with degree bound d such that $|L'|/|L| \geq 1-\delta$ and $\hat{f}_i|_{L'} = \hat{p}_i|_{L'}$ for $i \in [0,n-1]$.

Lemma C.2. *For any $S_1 \subseteq S_2 \subseteq L_i$, $\varepsilon_i(S_1) \geq \varepsilon_i(S_2)$.*

Proof. By definition, $\varepsilon_i(S_1) - \varepsilon_i(S_2)$

$$= \frac{(|S_2| - |S_1|)}{|L_i|} - \frac{(|\text{back}_i(S_2) \cap \text{err}_i| - |\text{back}_i(S_1) \cap \text{err}_i|)}{|L_0|}$$
$$= |S_2 \backslash S_1|/|D_i| - |(\text{back}_i(S_2) \backslash \text{back}_i(S_1)) \cap \text{err}_i|/|\text{back}_i(L_i)|$$
$$= \frac{|\text{back}_i(S_2 \backslash S_1)|}{|\text{back}(L_i)|} - \frac{|\text{back}_i(S_2 \backslash S_1) \cap \text{err}_i|}{|\text{back}_i(L_i)|} \geq 0. \qquad \square$$

Lemma C.3. *For every $i \in [\mu]$ and $\hat{h}_{L_i}^{(i)} \in \text{RS}[L_i,\rho]$, if $\Delta(\hat{g}_i|_{L_i} + \alpha_i \hat{h}_i|_{L_i} + \alpha_i^2 \hat{f}_i|_{L_i}, \hat{h}^{(i)}|_{L_i}) \geq \theta$, then $\varepsilon_i(A_i) > \theta$.*

Proof. Let $\hat{f} \leftarrow \hat{f}_E^{(i)} + \alpha_i \hat{f}_O^{(i)} + \alpha_i^2 \hat{f}_i$. Define set $B = A_i \cup \{x_i \in L_i | \hat{f}(x) \neq \hat{f}^{(i)}(x)\}$. Define polynomial $\hat{f}'$ such that $\hat{f}'(x) = h^{(i)}(x)$ when $x \in B$ and $\hat{f}'(x) = f(x)$ when $x \notin B$.

For all $x \in B$, if $\hat{f}(x) \neq \hat{f}'(x)$, $\hat{f}(x) \neq \hat{h}^{(i)}(x)$. Besides, for all $x \notin B$, $\hat{f}(x) = \hat{h}^{(i)}(x)$. Thus, the number of inconsistency points in B is not less than the Hamming distance between $\hat{f}|_{L_i}$ and $\hat{f}'|_{L_i}$, *i.e.*, $|\text{back}_i(B) \cap \text{err}_i|/|L_0| \geq \Delta(\hat{f}|_{L_i}, \hat{f}'|_{L_i})$.

Also, as $\hat{f}'(x) = \hat{h}^{(i)}(x)$ holds for all $x \in B$, $1 - |B|/|L_i| \geq \Delta(\hat{f}'|_{L_i}, \hat{h}^{(i)}|_{L_i})$. So, $\varepsilon_i(B) \geq \Delta(\hat{f}|_{L_i}, \hat{f}'|_{L_i}) + \Delta(\hat{f}'|_{L_i}, \hat{h}^{(i)}|_{L_i}) \geq \Delta(\hat{f}|_{L_i}, \hat{h}^{(i)}|_{L_i}) \geq \delta$. As $A_i \subseteq B$, $\varepsilon_i(A_i) \geq \varepsilon_i(B) \geq \delta$. $\square$

Proof of Inequality (4). We prove by induction. When $\mu = 1$, Protocol 1 is a standard FRI, and soundness holds naturally. If Inequality (4) holds $\forall \mu \leq t$, we show it holds for $\mu = t+1$.

When $\mu = t$, the protocol can be seen as a partial protocol starting from $\hat{f}^{(1)}$ for $\mu = t+1$. Set $\delta = (1-\rho)/2$. By induction, when $\mu = t+1$, the following holds:

- If there exists $i \geq 1$, such that $\Delta(\hat{f}^{(i)}|_{L_i}, \text{RS}[L_i,\rho]) \geq \delta$, then $\Pr[\varepsilon_\mu(A_\mu) \geq \delta] \geq 1 - |L_i|/2|\mathbb{F}| > 1 - |L_0|/|\mathbb{F}|$.
- If there exists $i \geq 2$, such that $\Delta(\hat{f}_i|_{L_i}, \text{RS}[L_i,\rho]) \geq \delta$, then $\Pr[\varepsilon_\mu(A_\mu) \geq \delta] \geq 1 - |L_i|/2|\mathbb{F}| > 1 - |L_0|/|\mathbb{F}|$.

Therefore, we only need to prove Inequality (4) in the following case: (a) For all $i \geq 1$, $\Delta(\hat{f}^{(i)}|_{L_i}, \text{RS}[L_i,\rho]) \leq \delta$; (b) For all $i \geq 2$, $\Delta(\hat{f}_i|_{L_i}, \text{RS}[L_i,\rho]) \leq \delta$; (c) At least one of $\Delta(\hat{f}^{(0)}|_{L_0}, \text{RS}[L_0,\rho]) > \delta$ and $\Delta(\hat{f}_1|_{L_1}, \text{RS}[L_1,\rho]) > \delta$ holds.

As (3) holds, there does not exist $A_1' \subseteq L_1$ and $|A_1'|/|L_1| \geq 1-\delta$ such that $\hat{g}_1|_{L_1}, \hat{h}_1|_{L_1}, \hat{f}_1|_{L_1}$ are all δ-close to $\text{RS}[L_1,\rho]$, respectively. Otherwise, $\hat{f}^0|_{L_0}$ and $\hat{f}_1|_{L_0}$ are both close to some $\text{RS}[L_0,\rho]$ by the linearity of RS code, respectively. Therefore, by Lemma C.1, for random α_1 and codeword $\hat{h}^{(1)}|_{L_1} \in \text{RS}[L_1,\rho]$, with probability $1 - |L_0|/|\mathbb{F}|$, $\Delta\big((\hat{g}_1 + \alpha_1 \hat{h}_1 + \alpha_1^2 \hat{f}_1)|_{L_1}, \hat{h}^{(1)}|_{L_1}\big) \geq \delta$. Thus, by Lemma C.3,

$$\Pr[\varepsilon_1(A_1) \geq \delta] \geq 1 - |L_0|/|\mathbb{F}|. \tag{5}$$

Next, we prove that in the case mentioned above, it holds

$$\Pr[\varepsilon_{i+1}(A_{i+1}) \geq \min\{\varepsilon_i(A_i), \delta\}] \geq 1 - |L_i|/|\mathbb{F}|. \tag{6}$$

Note that if Inequalities (5) and (6) hold, Inequality (4) will hold. Below are two cases underlying Inequality (6).

On one hand, if there does not exist $B' \subseteq L_{i+1}$ and $|B'|/|L_{i+1}| \geq 1-\delta$, such that $\hat{f}_E^{(i+1)}|_{B'}, \hat{f}_O^{(i+1)}|_{B'}, \hat{f}_{i+1}|_{B'}$ are some RS codeword, respectively. By Lemma C.1, with probability $1 - |L_{i+1}|/|\mathbb{F}|$, the relative Hamming distance between $(\hat{g}_{i+1} + \alpha_{i+1}\hat{h}_{(i+1)} + \alpha_{i+1}^2 \hat{f}_{i+1})|_{L_{i+1}}$ and $\text{RS}[L_{i+1},\rho]$ is greater than δ. Then by Lemma C.3, $\varepsilon_{i+1}(A_{i+1}) \geq \delta$.

On the other hand, there exists such $B' \subseteq L_{i+1}$ and $|B'|/|L_{i+1}| \geq 1-\delta$. Set $\hat{h}_E^{(i+1)}|_{L_{i+1}}, \hat{h}_O^{(i+1)}|_{L_{i+1}}, \hat{h}_{i+1}|_{L_{i+1}} \in \text{RS}[L_{i+1},\rho]$, and suppose the following relation hold iff $x \in B'$:

$$\hat{g}_{(i+1)}(x) = \hat{h}_E^{(i+1)}(x), \hat{h}_{(i+1)}(x) = \hat{h}_O^{(i+1)}(x), \hat{f}_{i+1}(x) = \hat{h}_{i+1}(x).$$

By properties of random linear combination, with probability at least $1 - |L_{i+1}|/|\mathbb{F}|$, the relative Hamming distance between $(\hat{f}_E^{(i+1)} + \alpha_{i+1}\hat{f}_O^{(i+1)} + \alpha_{i+1}^2 \hat{f}_{i+1})|_{L_{i+1}}$ and $(\hat{h}_E^{(i+1)} + \alpha_{i+1}\hat{h}_O^{(i+1)} + \alpha_{i+1}^2 \hat{h}_{i+1})|_{L_{i+1}}$ equals $1 - |B'|/|L_{i+1}|$. If $\hat{h}^{(i+1)}|_{L_{i+1}} \neq (\hat{h}_E^{(i+1)} + \alpha_{i+1}\hat{h}_O^{(i+1)} + \alpha_{i+1}^2 \hat{h}_{i+1})|_{L_{i+1}}$; by the code distance of the RS code,

$$\Delta(\hat{f}_E^{(i+1)} + \alpha_{i+1}\hat{f}_O^{(i+1)} + \alpha_{i+1}^2 \hat{f}_{i+1})|_{L_{i+1}}, \hat{h}^{(i+1)}|_{L_{i+1}}) \geq \delta.$$

Hence, by Lemma C.3, $\varepsilon_{i+1}(A_{i+1}) \geq \delta$. Therefore, below, we only need to consider the following case:

$$\hat{h}^{(i+1)}|_{L_{i+1}} = (\hat{h}_E^{(i+1)} + \alpha_{i+1}\hat{h}_O^{(i+1)} + \alpha_{i+1}^2 \hat{h}_{i+1})|_{L_{i+1}}.$$

In this case, for $x \in D_{i+1} \backslash B$, with probability at least $1 - |L_{i+1}|/|\mathbb{F}|$, $\hat{h}^{(i+1)}(x) \neq \hat{f}_E^{(i+1)}(x) + \alpha \cdot \hat{f}_O^{(i+1)}(x) + \alpha^2 \hat{f}_{i+1}(x)$. Let $B = \{x \in L_i : x^2 \in B'\}$. By definition, $B \subseteq A_i$. Define set $C = A_{i+1} \cup B'$. To prove that $\varepsilon_{i+1}(A_{i+1}) \geq \varepsilon_i(A_i)$, it suffices to prove $\varepsilon_{i+1}(C) \geq \varepsilon_i(B)$ according to Lemma C.2 as $B \subseteq A_i$ and $A_{i+1} \subseteq C$. By the definition of B', for every $x \in A_{i+1} \backslash B'$,

$$\hat{f}^{(i+1)}(x) = \hat{h}^{(i+1)}(x) \neq \hat{g}_{(i+1)}(x) + \alpha \cdot \hat{g}_{(i+1)}(x) + \alpha^2 \hat{f}_{i+1}(x).$$

So, $\text{back}_{i+1}(A_{i+1} \backslash B') = \text{back}_{i+1}(C \backslash B') \subseteq \text{err}_{i+1}$. Define sets $M = \text{back}_i(B) \cap \text{err}_i$ and $N = \text{back}_{i+1}(C \backslash B')$. As $\text{err}_i \subseteq \text{err}_{i+1}$,

$$M \cup N \subseteq \text{err}_i \cup \text{back}_{i+1}(C \backslash B') \subseteq \text{err}_{i+1}. \tag{7}$$

Besides, as $B' \subseteq C$ and $\text{back}_i(B) = \text{back}_{i+1}(B')$, we have

$$M \cup N = (\text{back}_{i+1}(B') \cap \text{err}_i) \cup N \subseteq \text{back}_{i+1}(C). \tag{8}$$

By Relations (7) and (8),

$$M \cup N \subseteq \text{back}_{i+1}(C) \cap \text{err}_{i+1}. \tag{9}$$

Since $\text{back}_i(B) = \text{back}_{i+1}(B')$,

$$M \cap N \subseteq \text{back}_{i+1}(B') \cap \text{back}_{i+1}(C \backslash B') = \emptyset. \tag{10}$$

According to Relation (10), Relation (9) can be rewritten as

$$|\text{back}_{i+1}(C) \cap \text{err}_{i+1}| \geq |\text{back}_{i+1}(C \backslash B')| + |\text{back}_i(B) \cap \text{err}_i|.$$

Since $\frac{|\text{back}_{i+1}(C\backslash B')|}{|D|} = \frac{|C\backslash B'|}{|D_{i+1}|} = \frac{|C|}{|D_{i+1}|} - \frac{|B|}{|D_i|}$, we have

$$|\text{back}_{i+1}(C)\cap \text{err}_{i+1}| - \frac{|C|}{|D_{i+1}|} \geq |\text{back}_i(B)\cap \text{err}_i| - \frac{|B|}{|D_i|}.$$

So $\varepsilon_{i+1}(C) \geq \varepsilon_i(B)$, Inequalities (6) and (4) hold. □

D Proof of Theorem 3.2

Proof. **Completeness and polynomial binding.** Polynomial binding directly comes from HyperPlonk. The main differences between PC_m and HyperPlonk lie in the usage of rolling batch FRI and random polynomial $\tilde{r}$. The completeness of PC_m follows from that of HyperPlonk and rolling batch FRI.

Soundness. We bound the soundness error via two cases.

• Case 1. There exists some polynomial $\hat{f}_i$ for $i \in [0,\mu-1]$, which has a degree at least $2^{\mu-i}$. According to Theorem 3.1, the verification passes with a probability bounded by $\varepsilon_{\mathsf{FRI}}$.

• Case 2. For every $i \in [0,\mu-1]$, the degree of $\hat{f}_i$ is less than $2^{\mu-i}$. Suppose that $\tilde{f}(\boldsymbol{x}) \neq y$. We have $\hat{f}(\boldsymbol{x}) + \alpha\cdot\hat{r}(\boldsymbol{x}) = y + \alpha\cdot y_r$ holds with a probability bounded by $1/|\mathbb{F}|$ due to the randomness of α. Otherwise, there must exist some i such that $\hat{f}_i(X) \neq \hat{g}_{i-1}(X) + x_i\cdot\hat{h}_{i-1}(X)$ but for every query, the equation holds. Assume that j is the smallest of these i's. By definition, $\hat{g}_{j-1}(X^2) = \big(\hat{f}_{j-1}(X) + \hat{f}_{j-1}(-X)\big)/2$, and $\hat{h}_{j-1}(X^2) = \big(\hat{f}_{j-1}(X) - \hat{f}_{j-1}(-X)\big)/2X$. Set $\hat{\phi}(X)$ to be

$$\hat{f}_j(X^2) - \frac{\hat{f}_{j-1}(X)+\hat{f}_{j-1}(-X)}{2} - x_j\cdot\frac{\hat{f}_{j-1}(X)-\hat{f}_{j-1}(-X)}{2\beta}.$$

As $\hat{f}_j(X) \neq \hat{g}_{j-1}(X) + x_j\cdot\hat{h}_{j-1}(X)$, $\hat{\phi}$ is a non-zero polynomial of degree less than $2^{\mu-j}$. By the Schwartz–Zippel lemma, the verification passes with a probability of no more than $(2^{\mu-j}/|L_j|)^q \leq (2^\mu/|L_0|)^q$.

By the union bound argument, the total soundness error is less than $\varepsilon_{\mathsf{FRI}} + (2^\mu/|L_0|)^q + 1/|\mathbb{F}|$ for $\varepsilon_{\mathsf{FRI}}$ in Theorem 3.1.

Knowledge soundness. Similar to HyperPlonk, knowledge soundness comes from the extractability of Merkle trees and efficient decoding algorithms for RS code. We omit the proof.

$2q$-bound knowledge leaking. Figure 5 gives the simulator. In Step 3 of Eval_m, a random $\hat{f}'$ can always be found when $2q+m \leq 2^\mu - 1$. The consistency check in the first round always passes as only evaluations corresponding to $\{\pm\beta_i\}_{i\in Q}$ would be opened and $\hat{f}(\pm\beta_i) = \hat{f}'(\pm\beta_i)$. In addition, $\{\hat{f}'_i\}_{i\in[\mu]}$ are valid, so consistency checks in other rounds will pass. Due to random $\tilde{r}$, $\hat{f}'_i$ is uniformly distributed. So, no verifier can notice the simulation with non-negligible probability. □

E Proof of Theorem 4.1

Proof. **Liveness.** If the dealer P_d is honest, then every party will receive their share in the Share phase, so there will be at least $2t+1$ valid Echo messages sent by honest parties. Also, every honest party will send a Ready message, which means every honest party will complete the Share phase.

Agreement. Suppose an honest party P_i completes the Share phase; we consider the case for every other honest party P_j. We first prove that they will receive $2t+1$ Ready's. Completion means P_i must have received $2t+1$ Ready's according to Step 14 in Algorithm 3 with at least $t+1$ sent by honest parties. From Step 12, if an honest party who has not sent Ready receives $t+1$ Ready's, it will send Ready. Thus, every honest party will eventually receive at least $2t+1$ Ready's.

Next, we prove every honest party will receive $t+1$ Echo messages. An honest party sends Ready only via Step 10 or Step 12. If all honest parties send Ready by Step 12, there must be $t+1$ Ready's sent by dishonest parties, which is impossible. Thus, at least one honest party has sent Ready by Step 10. Consequently, at least $t+1$ honest parties have sent the Echo's. So, P_j will eventually receive $t+1$ valid Echo's. It can then obtain its share f_j and complete the Share phase.

Correctness. If the dealer P_d is honest, then $f(X,Y)$ only corresponds to a set of the same secret that $s = f(z,0)$, so honest parties will reconstruct the same secret. If an honest party P_i reconstructs z_i, every honest party receives at least $t+1$ valid Echo messages corresponding to a common commitment of a bivariate polynomial, so they reconstruct the same secret.

Secrecy. If the dealer P_d is honest and the corrupted set of $\mathcal{A}$ is $\{P_{c_i}\}_{i\in[t-\ell]}$, then $\mathcal{A}$ will get univariate polynomials $\hat{f}(w_N^{c_i}, Y)$ and $\hat{f}(X, w_N^{c_i})$ for all $i \in [t-\ell]$ along with the proof of these polynomials' evaluations. According to Theorem 3.2, the evaluation proof only leaks ℓ queried evaluations of $\hat{f}$. As the variable degree of X and Y are both t, $\mathcal{A}$ has no extra information about polynomial $\hat{f}(X,0)$ and the secret $s = f(z,0)$. □

• $C \leftarrow \mathcal{S}_1\left(1^\lambda, \mathsf{pp}, r_{\mathcal{A}}\right)$

1: Get $\{\pm\beta_i\}_{i\in Q}$ from $r_{\mathcal{A}}$ and $\{\hat{f}(\pm\beta_i)\}_{i\in[Q]}$ by the oracle access to $\hat{f}$, where Q is the set of all queries.
2: Construct a map $\hat{F}: L_0 \to \mathbb{F}$ such that $\hat{F}(\pm\beta_i) = \hat{f}(\pm\beta_i)$ for every $i \in Q$, and take random values on other points.
3: Randomly pick a multilinear polynomial $\tilde{r}'(X_1,\ldots,X_\mu)$.
4: Output $C'_f \leftarrow \mathsf{MT.Commit}(\hat{F}|_{L_0})$ and $C'_r \leftarrow \mathsf{MT.Commit}(\hat{r}'|_{L_0})$.

• $\mathcal{S}_2\big(\mathsf{pp}, \{C'_f, C'_r\}, \{\boldsymbol{x}_j = (x_1^{(j)},\ldots,x_\mu^{(j)})\}_{j\in[m]}\big)$

1: Send $\{y_j, \tilde{r}(\boldsymbol{x}_j)\}_{j\in[m]}$ to $\mathcal{V}$ given oracle access to $y_j = \tilde{f}(\boldsymbol{x}_j)$ for all $j \in [m]$.
2: Receive α from $\mathcal{V}$, and generate a random polynomial $\hat{f}'$ with coefficient vector $\boldsymbol{f}'$ such that for every $i \in Q$, $\hat{f}'(\pm\beta_i) = \hat{f}(\pm\beta_i)$ and for every $j \in [m]$, $\langle \boldsymbol{f}', (1, x_1^{(j)}) \otimes \cdots \otimes (1, x_\mu^{(j)})\rangle = \tilde{f}(\boldsymbol{x}_j)$. Let $\hat{f}'_0(X) = \hat{f}'(X) + \alpha\cdot\hat{r}'(X)$. $\mathcal{S}_2$ acts like an honest prover with input $\hat{f}'_0$.

Abuse Reporting for Metadata-Hiding Communication Based on Secret Sharing

Saba Eskandarian
University of North Carolina at Chapel Hill
saba@cs.unc.edu

Abstract

As interest in metadata-hiding communication grows in both research and practice, a need exists for stronger abuse reporting features on metadata-hiding platforms. While message franking has been deployed on major end-to-end encrypted platforms as a lightweight and effective abuse reporting feature, there is no comparable technique for metadata-hiding platforms. Existing efforts to support abuse reporting in this setting, such as asymmetric message franking or the Hecate scheme, require order of magnitude increases in client and server computation or fundamental changes to the architecture of messaging systems. As a result, while metadata-hiding communication inches closer to practice, critical content moderation concerns remain unaddressed.

This paper demonstrates that, for broad classes of metadata-hiding schemes, lightweight abuse reporting can be deployed with minimal changes to the overall architecture of the system. Our insight is that much of the structure needed to support abuse reporting already exists in these schemes. By taking a non-generic approach, we can reuse this structure to achieve abuse reporting with minimal overhead. In particular, we show how to modify schemes based on secret sharing user inputs to support a message franking-style protocol. Compared to prior work, our *shared franking* technique more than halves the time to prepare a franked message and gives order of magnitude reductions in server-side message processing times, as well as in the time to decrypt a message and verify a report.

1 Introduction

Public discussions on abuse reporting in messaging platforms primarily focus on content moderation policy questions regarding what kinds of messages should and should not be allowed. However, when it comes to reporting abuse on private messaging platforms that provide end-to-end encryption or hide metadata, important technical problems must be addressed before moderation policy decisions can be enforced.

In an unencrypted platform, a moderator can see the contents of all messages, as well as the identities of their senders, and can use this information to make decisions when a user reports a message. When messages are end-to-end encrypted, the moderator no longer sees the message contents, and a user making a report must be able to demonstrate to the moderator that the reported message actually corresponds to content sent through the platform. The metadata-hiding setting poses an even greater challenge, as the moderator sees neither message contents nor the identities of message senders.

Message franking, first introduced by Facebook and used in both WhatsApp and Messenger Secret Conversations, provides a lightweight solution to the problem of abuse reporting for end-to-end encrypted messages [29, 32, 25]. Unfortunately, message franking schemes used in practice do not work in the metadata-hiding setting. Proposals to handle abuse reporting for metadata-hiding platforms include asymmetric message franking (AMF) [44] and the Hecate scheme [33]. While these schemes provide strong security guarantees for abuse reporting in the challenging metadata-hiding setting, they come with performance overheads orders of magnitude higher than the message franking used in practice.

This work takes a new approach to abuse reporting for metadata-hiding communication. While previous solutions have been designed to work generically for any metadata-hiding platform, we take a non-generic approach that applies to a specific class of private messaging schemes: schemes based on additive secret sharing techniques. Given the large number of proposed messaging schemes that use secret sharing, as well as incipient deployments of other privacy preserving technologies based on secret sharing [19, 26, 5, 1, 2], this family of approaches merits special attention. We show how these schemes can use a message franking-style protocol with minimal performance overhead.

At a high level, our scheme involves secret sharing the message franking process. Message franking involves the platform MACing a compactly committing encryption of a message [29, 32], so we need to reproduce this efficiently in a setting where the server serving as the moderator does not have access to the whole message at the time a message is processed by the platform. Our solution has the moderator

compute a MAC over hashes of shares of the message, ensuring the moderator cannot recover the message itself, and has the message sender include the necessary information in the message to regenerate these shares at report verification time. Starting from this idea, we build a *shared franking* protocol that allows a moderator to authenticate messages sent through a platform and tie them to their senders, despite only ever seeing secret shares of the messages when they are initially sent.

In addition to designing the protocol itself, we introduce appropriate security definitions for abuse reporting in this setting and prove that our scheme satisfies security under these definitions. Our threat model allows all the servers except the moderator to be malicious, and ensures that misbehaving servers and users cannot violate confidentiality of messages, forge reports, or evade the reporting mechanism.

We show how to integrate our shared franking protocol with several families of existing metadata-hiding communication systems in the research literature. Our protocol is directly compatible with schemes based on computation over additive secret shares of messages [8, 35, 16, 27] and, in a limited sense, with schemes using threshold secret sharing [42, 6, 36]. We also describe how to adapt our scheme to support shared franking in schemes based on DC-nets [17, 21, 47], including works that augment a DC-net approach with distributed point functions [30, 14, 15, 20, 28, 39].

We implement our shared franking scheme and compare its performance to AMF, Hecate, and conventional message franking. We find that shared franking results in comparable or lower communication overhead than AMF and Hecate while dramatically lowering computation costs. In particular, for handling 1 KB messages in the two server setting and comparing to Hecate, we reduce the computation cost of sending a message by 2.6×, the overall computation for processing a message on the server(s) by 22.6×, the cost to read a message by 19×, and the cost to verify reported messages by 31×. Comparing to AMF, we achieve 1-2 order of magnitude performance improvements.

Overall, the performance of our scheme resembles that of deployed message franking more than it does previous abuse reporting schemes for metadata-hiding communication. These significant performance improvements are enabled by the fact that shared franking requires no public key cryptography, eliminating the need for signatures or zero knowledge proofs found in prior work. Our implementation and raw evaluation data are freely available and open source at https://github.com/SabaEskandarian/Shared_Franking.

In summary, we make the following contributions.

- Introduce the notion of shared franking and develop appropriate security definitions.
- Build a shared franking scheme compatible with metadata-hiding communication platforms based on additive secret sharing.

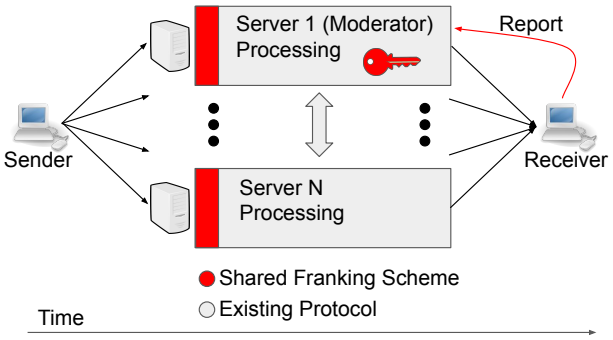

Figure 1: Shared franking augments a metadata-hiding communication scheme based on secret sharing. After receiving secret shares of a client's message, servers do some additional preprocessing before running the underlying protocol. This allows the moderator to later verify any messages reported by users. Only the moderator holds any new secrets, and security holds even if other servers collude with each other or with malicious users.

- Show how to integrate shared franking with existing metadata-hiding communication systems.
- Implement/evaluate our scheme, showing order of magnitude performance improvements and approaching the performance of conventional message franking used in practice.

2 Design Goals

A *shared franking* scheme builds on top of a metadata-hiding communication scheme based on secret sharing and allows users of the scheme to verifiably report abusive messages. This is achieved by augmenting the process of sending, processing, and receiving messages with additional information that can be sent to a moderator to report a message. The moderator runs a new verify() algorithm to authenticate reported messages and recover relevant metadata that it can use to make moderation decisions. In addition to satisfying various security requirements relating to authentication and verification of reports, a shared franking scheme must not compromise the privacy properties of the underlying communication system that it augments. Figure 1 abstractly illustrates how a shared franking scheme fits in with an existing metadata-hiding communication system.

We now briefly summarize the security properties we expect of a shared franking scheme before discussing them in greater detail below.

- **Confidentiality**: The shared franking scheme reveals nothing about who sent a message or what messages are sent. This property ensures that the security of the underlying scheme is not compromised by the addition of shared franking.

- **Accountability**: Every message delivered through the platform must be able to be reported to the moderator.

- **Unforgeability**: Users cannot be framed for sending messages they did not send.

- **Deniability**: Only the moderator can verify the authenticity of reported messages. If the contents of a report are leaked, it would be impossible for a third party to verify them.

As is the case in many metadata-hiding communication schemes, we will assume that the servers operating the communication system are trusted for *availability* but not for *security*. That is, correctness of outputs will assume that the servers cooperate with the protocol, but all our security definitions will require security against actively malicious servers. All our definitions additionally aim to protect against misbehavior by malicious or disruptive clients. In defining and achieving security, we will assume pairwise secure connections (encrypted and authenticated) between servers via TLS, which are generally already in use by the underlying communication protocol.

Accountability and anonymity. Before we move on, we emphasize that there are inherent tradeoffs between anonymity and accountability, and that, in addition to the technical considerations of how to build a shared franking scheme, it is also important to consider *whether* and *where* such schemes should be used. While our confidentiality definition will ensure that unreported messages enjoy the same privacy as in a scheme that does not support abuse reports, adding the ability to report a message to a moderator means that the moderator can learn the identity of a message sender and the contents of that message. Some metadata-hiding communication systems provide anonymity for the sender *even against the message recipient*. In these cases, shared franking would enable a message recipient to reveal information to the moderator that the recipient themself does not know, resulting in a greater cost to privacy than in standard message franking for end to end encrypted messaging. While this kind of disclosure may be desirable in certain limited settings, it does not seem suitable as a feature for general-purpose communication platforms. As such, examples of metadata-hiding schemes discussed in this paper provide *unlinkability* of message senders and receivers, but do not necessarily hide the identity of message senders from the receivers. This is not a technical limitation, but a reflection of our priorities in building better private communication technology. However, a relevant technical limitation of our scheme in the setting where the sender is anonymous to the receiver is that a malicious receiver could potentially collude with a malicious non-moderator server to reveal the sender's identity. This is not an issue in cases where the sender and receiver already know each other's identities.

2.1 Formalizing Shared Franking

Notation. Before formally stating the requirements of a shared franking scheme, we briefly summarize some notation used throughout the paper. We use $y \leftarrow f(x)$ to denote the assignment of the output of $f(x)$ to the variable y, and we use $x \xleftarrow{R} S$ to denote assigning to x a uniformly random element from the set S. The notation $\{\}$ represents the empty set. We use $\mathcal{A}^{O}$ to indicate that $\mathcal{A}$ has oracle access to O. A function $\mathsf{negl}(\lambda)$ is *negligible* if for all $c > 0$, there is an x_0 such that for all $x > x_0$, $\mathsf{negl}(x) < \frac{1}{x^c}$. We sometimes omit the security parameter λ when it is implicit from context.

We use $[x]$ to denote an additive secret sharing of x. For a message x split into N shares, we use $[x]_i, i \in \{1,...,N\}$ to denote each share. In particular, for an additive secret sharing $[x] = ([x]_1,...,[x]_N)$ it holds that $x = \Sigma_{i=1}^{N}[x]_i$. Finally, we use $\perp$ as a special character to indicate failure.

Throughout the paper, we use standard definitions of MACs, PRGs, CPA-secure encryption, collision-resistance, random oracles, and other widely used cryptographic primitives [13].

Syntax. A shared franking scheme consists of Send and Receive algorithms to be run by clients sending or receiving messages, a processing protocol run by servers $S_1,...,S_N$ who operate a metadata-hiding communication scheme, one of which also serves a content moderator, and a Verify algorithm used by the moderator to verify reports of abusive messages sent through the platform. For our scheme, we model the processing protocol with two functions, Process and ModProcess. The Process algorithm is the algorithm run by most of the servers participating in the protocol, and the ModProcess algorithm is a variant of Process run by the server serving as the platform's moderator.

We assume that the users in a shared franking scheme have access to a shared key k_U produced according to the protocol used in the underlying communication system, which they will use to encrypt messages. During the processing protocol, the moderator can include message *context* ctx with a message, to be revealed again if a user later reports the message. This is where the moderator can include information about the sender of the message or a timestamp indicating when the message was sent. Deployed message franking schemes use a similar mechanism to give moderators relevant information needed to judge reported messages [29].

We define the syntax of a shared franking scheme as follows.

Definition 2.1 (Shared Franking Scheme)**.** A *Shared Franking Scheme* consists of five algorithms $(\mathsf{Send}, \mathsf{Process}, \mathsf{ModProcess}, \mathsf{Read}, \mathsf{Verify})$. The syntax of a shared franking scheme is defined with respect to message space $\mathcal{M}$, *context space* $\mathcal{C}$, tag space $\mathcal{T}$, user key space $\mathcal{K}_U$, and server key space $\mathcal{K}_S$ as follows.

- $\mathsf{Send}(k_U, m, N) \rightarrow (w_1,...,w_N)$: This function takes a user secret $k_U \in \mathcal{K}_U$, a message $m \in \mathcal{M}$, and an integer

N indicating the number of servers to which the message will be sent. The function returns a series of *write requests* $w_1, ..., w_N$, each of which is sent to one of the servers.

- $\mathsf{Process}(N, i, w_i) \to (v_i, w_i')$: This function takes the total number of servers in the protocol, as well as the index of the server running the function and the input for that server. It returns the server's output value v_i as well as an output w_i' for the moderator server.
- $\mathsf{ModProcess}(N, k_S, w_1, \mathsf{ctx}, (w_2', ..., w_N')) \to v_1$: This function is a variant of the Process function that is run by the server serving as moderator. By convention, we set the moderator to be S_1. In addition to the number of users and the server's input, this function additionally takes the moderator's secret key $k_S \in \mathcal{K}_S$, the values w_i' for $i \in \{2, ..., N\}$ from the other servers, and a *context* input $\mathsf{ctx} \in \mathcal{C}$.
- $\mathsf{Read}(k_U, N, (v_1, ..., v_N)) \to (m, t)/\perp$: This function takes a user secret $k_U \in \mathcal{K}_U$, an integer N indicating the number of servers with which a message is shared, and a series of server output values $v_1, ..., v_N$. The function either recovers a message $m \in \mathcal{M}$ and tag $t \in \mathcal{T}$, or it outputs $\perp$ to indicate malformed server outputs.
- $\mathsf{Verify}(k_S, N, m, t) \to \mathsf{ctx}/\perp$: This function takes a server secret $k_S \in \mathcal{K}_S$, an integer N, a message $m \in \mathcal{M}$, and tag $t \in \mathcal{T}$. It outputs a context $\mathsf{ctx} \in \mathcal{C}$, or it outputs $\perp$ to indicate failed verification of the message/tag.

When a system uses shared franking, the user sending a message runs the Send algorithm to prepare messages rather than simply secret sharing – or encrypting and then secret sharing – their message. Once the servers receive the shares produced by Send, along with any other protocol-dependent information, they run the Process or ModProcess algorithms before doing any of the message processing used to deliver messages in the underlying communication system. When message shares are processed according to the design of the underlying system and delivered to a receiver, the receiver runs the Read algorithm to recover the message sent by the sender. If a message receiver decides to report a message, it sends the message m and tag t to the moderator, who runs Verify to check that the reported message is authentic and to recover relevant metadata.

A communication system compatible with shared franking is one that takes shares of (potentially encrypted) messages as inputs and then runs an interactive protocol between the servers offering the service to deliver messages. This protocol (called Deliver below), involves somehow shuffling the shares of messages in a way that the recipient of a message can identify it but the servers cannot link message senders and receivers. A simple example of such a scheme would be an MPC-based shuffle followed by anonymous broadcast of messages, where receivers do a linear scan of results to find their intended message. More sophisticated systems, such as MCMix [8], include mechanisms for senders and receivers to download only their intended messages after a shuffle, dramatically reducing communication and eliminating the need for trial decryptions. DC-net or DPF-based schemes [17, 30] can also rely on either anonymous broadcast or a mechanism for clients to privately determine where in a list of messages a given message will be delivered. In all cases, the correctness property provided by the underlying communication scheme must be that shares output by the scheme are shares of the same messages as the input shares, at least for the parts of the shares that correspond to the messages themselves. It is possible for additional protocol-dependent information to be appended by the servers during processing to aid in retrieval, but this is not relevant for the purposes of shared franking.

Correctness. The correctness definition for a shared franking scheme requires that messages sent via the scheme can be successfully read, and that the context the moderator retrieves when verifying a report matches the context used when the message was sent. Our definition of correctness, when restricted to the single-server case where $N = 1$, corresponds to a correctness definition for a conventional message franking scheme.

Our correctness definition also accounts for the possibility that the platform to which we add shared franking may do some computation on the shared franking outputs before they are returned to the user. For example, if the server outputs are secret shares of some messages and the underlying platform uses MPC to shuffle the messages before delivery, the final messages may be re-randomized versions of the shares output by the shared franking scheme.

We model the message delivery mechanism of the underlying protocol as an interactive protocol $\mathsf{Deliver}\langle\rangle$ between N servers, where each server S_i has a two-part input consisting of a share $[m]_i$ of the message being sent and some extra protocol-dependent data e_i,

$$\mathsf{Deliver}\langle S_1([m]_1, e_1), ..., S_N([m]_N, e_N)\rangle \to (([m']_1, e_1'), ..., ([m']_N, e_N')),$$

subject to the condition that the shared message m is preserved, i.e., $m = m'$. Although a real scheme acts on multiple messages at once, this description abstracts away other messages and routing logic but captures the impact on an individual message, which is the scope at which franking operations take place. A shared franking scheme modifies the shares $[m]$ of the message, replacing them with the processed outputs v_i of the shared franking protocol.

Definition 2.2 (Correctness)**.** We say that a shared franking scheme satisfies *correctness* if for any $\lambda, N \in \mathbb{N}, m \in \mathcal{M}, \mathsf{ctx} \in$

$\mathcal{C}, k_U \in \mathcal{K}_U, k_S \in \mathcal{K}_S$ and for some $e_1, ...e_N$, when we compute

$(w_1, ..., w_N) \leftarrow \mathsf{Send}(k_U, m, N)$
$v_i, w_i' \leftarrow \mathsf{Process}(N, i, w_i)$ for $i \in \{2, ..., N\}$
$v_1 \leftarrow \mathsf{ModProcess}(N, k_S, w_1, \mathsf{ctx}, (w_2', ..., w_N'))$
$((v_1', e_1'), ..., (v_N', e_N')) \leftarrow \mathsf{Deliver}\langle S_1(v_1, e_1), ..., S_N(v_N, e_N)\rangle$

we have that

$$(m', t) \leftarrow \mathsf{Read}(k_U, N, (v_1', ..., v_N'))$$

where $m' = m$, and

$$\mathsf{ctx}' \leftarrow \mathsf{Verify}(k_S, m, t)$$

where $\mathsf{ctx}' = \mathsf{ctx}$.

2.2 Defining Security

This section describes the various security properties we expect of a shared franking scheme. Following the discussion here, formal definitions for each property appear in Appendix A.

Confidentiality. The primary confidentiality property required of a shared franking scheme is that it does not compromise the privacy properties of the underlying metadata-hiding communication platform, except when revealing metadata stored in the context attached to a reported message. We use *metadata-hiding* to refer to systems that render message senders and receivers unlinkable to the platform. In secret sharing based schemes, message senders start by directly connecting to the servers to upload message shares, at which point the servers can identify the senders, as there is no need for anonymity in that connection. Only after receiving the messages do the servers process them in a way that breaks the link between message senders and message recipients. Our confidentiality definition is designed to ensure that the security of the message processing cannot be compromised by the addition of a tag to enable abuse reporting before messages are processed. This means that no server operating the platform, and no user other than the intended recipient of a message, can learn anything about the contents of a message sent through the platform or about who sent a given message through the platform. Since our work focuses on the case of secret-shared data, we will capture this requirement via an adversary who controls some strict subset of the N servers operating the service.

Our security definition allows an adversary to pick a set M of corrupted servers to control. In the security experiment, the adversary is allowed to adaptively ask an honest user to send the servers write requests for one of two messages m_0, m_1 of the adversary's choosing, and the adversary must determine which message is sent after seeing the resulting write requests w_i. We say that a scheme has confidentiality if no efficient adversary can distinguish between the two messages. This effectively means that the view of the adversary while processing messages for shared franking does not depend on the actual messages sent in any way. After the shared franking process is over, the security properties of the underlying messaging scheme will ensure that an adversary cannot see the contents of delivered messages or identify their senders. Our definition only requires that the additional message preprocessing required for shared franking does not expose information that could compromise users' privacy.

One could imagine other supplemental confidentiality requirements, such as requiring that a user's message remains confidential even against an adversary who controls all the servers, or that the context string ctx does not leak to servers other than the moderator. We do not formalize security definitions for these notions, but our scheme trivially satisfies both. To protect message contents against compromise of all servers, messages are encrypted via a CPA-secure encryption scheme before being secret shared. Our syntax prevents the message context ctx from being sent directly from the moderator to the other servers, and our scheme masks ctx with pseudorandom bits before the moderator outputs it to the underlying messaging protocol.

Accountability. Our accountability definition ensures that every message sent through the system can be successfully verified if reported, even in the presence of malicious clients and servers. In particular, an adversarial client or group of clients, even if they collude with all the servers except the moderator, cannot send a set of write requests where a message will be successfully decrypted by the recipient but verification of that message by the moderator will fail.

In our definition, the adversary is allowed to play the role of any number of malicious clients and servers, except for the moderator. The adversary controls the write requests, intermediate outputs, and context received by the moderator and gets the moderator's output share v_1 in response to inputs of the adversary's choosing. The adversary wins the game if, after its interactions with the moderator, it can produce a user key k_U^*, a context ctx^*, and write request w_1^*, and server outputs $v_2^*, ..., v_N^*, w_2', ...w_N'$, such that, after processing via $\mathsf{ModProcess}$, the Read algorithm can recover a non-$\perp$ message, but Verify either fails to verify or returns an incorrect $\mathsf{ctx}^{**} \neq \mathsf{ctx}^*$.

Unforgeability. Unforgeability requires that a malicious reporter cannot report messages or message contexts that were not actually sent through the platform. This property differs from accountability in that accountability protects against malicious *senders* who wish to send unreportable messages and abuse the platform without repercussions, whereas unforgeability protects against malicious *receivers* who wish to produce false reports that frame honest senders.

In this definition, similar to the accountability definition,

the adversary plays the role of any number of malicious clients and servers, except the moderator. After being allowed to interact with the moderator and receiving the moderator outputs for any successfully delivered/verified message, the adversary produces a new message and tag pair. The definition requires that the adversary cannot produce successfully verifying tags on new messages, and, moreover, the adversary cannot produce tags on already-sent messages that verify but return a context different from the context used when the message was originally sent.

Deniability. Deniability requires that only the moderator can verify the authenticity of reported messages. This property helps maintain the expectation that messages sent through private channels are largely ephemeral and cannot verifiably be exposed to third parties other than the moderator.

We do not formalize our own deniability definitions here, as notions of deniability from prior work extend to our setting in a straightforward way [44, 33, 40]. Instead, we briefly discuss some forms of deniability that a shared franking scheme must achieve and return to these in the security analysis of our scheme. See the asymmetric message franking work of Tyagi et al. [44] for an extensive discussion of the potential space of security definitions for deniability.

Following Tyagi et al., we consider three forms of deniability, all three of which should be satisfied: *receiver compromise deniability*, *moderator compromise deniability*, and *universal deniability*. Each definition requires that there exist a forgery algorithm that produces message, report pairs that are indistinguishable from real ones, thus allowing users to deny that they really sent or received a given message. The difference between the three definitions lies in what information the forgery algorithm can use in producing its forgery and in what information the distinguisher is allowed to see. Universal deniability gives the forger and distinguisher access to any public parameters of the system and the secret keys of all users uninvolved in the message being denied. In receiver compromise deniability, the forger and distinguisher additionally receive the user secret key that encrypts and decrypts the message being denied. In moderator compromise deniability, the forger and distinguisher additionally receive the moderator's secret key.

3 Franking for Secret-Shared Messages

This section introduces our shared franking scheme. We begin with background on conventional message franking. Our scheme can be seen as a way to lift standard, single-server message franking into the secret shared setting.

We will consider the message franking scheme used by Facebook [29] using the abstractions introduced by Grubbs et al. [32]. Roughly speaking, the scheme consists of two components: a *compactly committing* encryption scheme and a MAC. At its core, it consists of the platform MACing part of an appropriately formatted ciphertext from the user sending a message. This ciphertext, along with associated context information, is revealed later in the event that the receiving user reports the message. Verifying the MAC when a user reports a message allows the platform to record the context for each message without the need for extensive metadata collection and storage.

In this work, we will take advantage of the fact that, for metadata-hiding communication schemes based on secret sharing, the servers involved in the protocol can identify the sender of a message *at the time a message is sent*, even though they cannot identify the recipient or link senders and recipients for any message. In secret sharing based schemes, message senders start by directly connecting to the servers to upload message shares (without need for any intermediate anonymity layer), at which point the servers can identify the senders. Only *after* receiving shares of messages do the servers process them in a way that breaks the link between message senders and message recipients. This allows the server acting as the moderator to attach the necessary context, e.g., sender identity, at the time a message is sent.

Our approach is fundamentally different from prior work that extends content moderation to the metadata-hiding setting (e.g., [44]). Whereas prior works use cryptographic techniques to remove the involvement of the moderator from the message delivery process, we find ways to render the moderator's involvement harmless. This results in increased performance at the cost of only being applicable to schemes based on secret sharing.

3.1 Background: Message Franking and Compactly Committing Encryption

As mentioned above, a message franking scheme requires compactly committing encryption. This is an encryption where the ciphertext $c = (c_1, c_2)$ can be thought of as consisting of two components. Component c_1 is a conventional ciphertext, and c_2 functions as a commitment to the underlying message, which a moderator can verify in the event the message is reported. *Compactness* means that the size $|c_2|$ of the committing component of the ciphertext must be independent of the length $|m|$ of the underlying encrypted message m.

We restate the syntax for a compactly committing encryption scheme below. This is the same syntax introduced by Grubbs et al. [32], except whereas they presented their definitions in terms of compactly committing AEAD schemes, we present a syntax for compactly committing AE only. An AEAD scheme allows for additional authenticated, unencrypted data to be associated with a ciphertext [41], but we will not need this feature for our scheme. That said, although we do not use the AEAD syntax for simplicity of presentation, our scheme can easily be modified to accommodate additional associated data should it be necessary.

Definition 3.1 (Committing AE [32])**.** A committing AE scheme $\mathsf{CE} = (\mathsf{Kg}, \mathsf{Enc}, \mathsf{Dec}, \mathsf{Ver})$ is a four-tuple of algorithms with the syntax described below. Associated to a scheme is a key space $\mathcal{K}$, message space $\mathcal{M}$, ciphertext space $\mathcal{C}$, opening space $\mathcal{K}_o$, and franking tag space $\mathcal{T}$.

- $\mathsf{Kg}(1^\lambda) \to k$: This function takes a security parameter and generates a key for use in the ccAE. We omit calls to this function when the key is provided by the calling context.
- $\mathsf{Enc}(k, m) \to (c_1, c_2)$: This function takes in a key $k \in \mathcal{K}$ and message $m \in \mathcal{M}$, and it returns a two part ciphertext (c_1, c_2) where $c_1 \in \mathcal{C}$ and $c_2 \in \mathcal{T}$.
- $\mathsf{Dec}(k, (c_1, c_2)) \to (m, \mathsf{fo})/\perp$: This function takes a key $k \in \mathcal{K}$ and a two part ciphertext $(c_1, c_2) \in \mathcal{C} \times \mathcal{T}$, and it returns either $\perp$ or a message $m \in \mathcal{M}$ and a *franking opening* $\mathsf{fo} \in \mathcal{K}_o$.
- $\mathsf{Ver}(m, \mathsf{fo}, c_2) : 0/1$ This function takes a message $m \in \mathcal{M}$, an opening $\mathsf{fo} \in \mathcal{K}_o$, and a tag $c_2 \in \mathcal{T}$, and it outputs 1 or 0 to indicate acceptance or rejection of a message, respectively.

Our implementation uses the CtE1 scheme of Grubbs et al., which can be built entirely from standard primitives.

Grubbs et al. introduce sender and receiver binding security definitions for committing AE that go beyond the standard CPA-security and ciphertext integrity properties of authenticated encryption and ensure the security of the committing component of the ciphertext. See their work for a detailed description of these definitions [32]. In this work, we use SBadv and RBadv to denote the sender binding and receiver binding advantage of an adversary against a ccAE scheme.

3.2 Our Shared Franking Protocol

This section describes the intuition and design choices for our shared franking scheme. As a starting point, consider a scheme where the client computes a ccAE ciphertext (c_1, c_2) of the message it wishes to send, and secret shares it among the N servers. As an optimization, we set the shares w_i for $i \in \{2, ..., N\}$ to be short seeds which the servers can expand into message shares, and only the share sent to the moderator is a full-length message share. We now show how to build up from this starting point to a shared franking scheme.

Secret sharing a MAC. In order to apply the intuition of message franking to the secret shared setting, we need to compute a MAC on a ccAE ciphertext in a way that is amenable to computation on secret shared data.

One option for building a sharing-friendly MAC would be to adopt a Carter-Wegman MAC [46] or a homomorphic MAC [7]. Unlike widely used standard MACs like HMAC [12], the structure of these MACs allows efficient distributed computation of MACs over secret-shared data using MPC. Unfortunately, this is only the case if every party involved in the MAC computation holds the secret key for the MAC. In the shared franking setting, only the moderator holds the key, so a MAC cannot be computed by simply aggregating computations done by the servers processing a message. We can get around this by using a multiparty computation protocol over an arithmetic circuit that computes the MAC [31, 9, 24, 23], but this adds both communication and computation costs that we wish to avoid.

Instead, we have the moderator compute a MAC on the secret shares of the message rather than directly on the message itself. Since the shares, taken together, allow for reconstruction of the messages, this is equivalent to MACing the message directly. To avoid having the moderator see all the message shares directly, we have each server send the moderator a hash of its input share $w'_i \leftarrow H(w_i)$. The moderator computes a MAC over its own share $[c_2]_1$ of c_2, all the hashes it receives, and the context string ctx for the message being processed. Formally, the moderator computes

$$h \leftarrow (w'_2, ..., w'_N)$$
$$\sigma \leftarrow \mathsf{MAC.Sign}(k_S, ([c_2]_1, h, \mathsf{ctx})).$$

Note that, as is the case in standard message franking, appending a MAC means messages sent through the shared franking scheme will be longer than user-submitted ciphertexts. To accommodate this, other servers generate sufficiently long pseudorandom outputs from their write request seeds to match the length of the moderator's output. The moderator also masks these outputs with randomness generated from a seed provided by the user sending the message.

Reproducing shares. While MACing shares of a message suffices to serve as a MAC on that message, MACing *hashes* of shares of a message poses a problem for the correctness of our scheme. In order to verify this MAC, the recipient of a report needs the exact same shares that were used to generate the MAC tag. But the shares of a message delivered to the message recipient after passing through an MPC-based metadata-hiding communication scheme will almost certainly differ from the ones produced when a sender produces the message.

We get around this problem by ensuring the recipient of a message can reproduce the original shares used by the sender. When sending a message, the randomness for producing each share is generated from a seed r, and the sender includes r in the ciphertext delivered to the platform. Specifically, the sender computes

$$r \xleftarrow{R} \{0,1\}^\lambda$$
$$c = (c_1, c_2) \leftarrow \mathsf{ccAE.Enc}(k_U, (m, r))$$
$$\{s_i\}_{i \in \{1,...,N\}} \leftarrow G(r)$$
$$[c]_1 \leftarrow c \oplus G(s_2) \oplus ... \oplus G(s_N),$$

where G is a PRG with suitable output lengths. Since the message recipient can recover r, it can reproduce the original shares used when the message was sent. These can in turn be used to send the moderator the correct inputs to the MAC produced when it was processing the message, fixing the correctness problem introduced by MACing hashes of message shares instead of the message itself.

Adding accountability. The scheme as sketched thus far suffices to provide confidentiality and unforgeability (via the secret sharing and the MAC+ccAE combination), but accountability can easily be circumvented by a malicious user or server:

- A malicious user could include an incorrect value r' instead of r in the ccAE ciphertext.
- A malicious server could output a partially incorrect secret share so that the MAC σ is corrupted and fails to verify.

In order to achieve accountability, we need to ensure that these kinds of misbehavior can be caught by the receiving user in the Read algorithm, rather than only becoming apparent when Verify fails after a user reads and reports a message.

This problem can be resolved via additional integrity checks by receiving users to ensure messages can be verified by the moderator. In particular, we have the moderator compute a hash σ_c on the same message as the MAC σ, but with σ itself included at the end of the hash input. That is,

$$\sigma_c \leftarrow H'(k_r, [c_2]_1, h, \mathsf{ctx}, \sigma)$$

where the hash function H' is modeled as a random oracle. This serves as a checksum on the values that will be verified if a message is later reported.

The hash σ_c is masked and appended to the moderator's output, and the receiving user verifies σ_c when running Read on a received message. The fact that messages are secret shared means that σ_c is not visible to any party besides the moderator until a message is read.

Observe that when we instantiate this scheme with a MAC that also serves as a PRF, e.g., HMAC [12, 10, 11], the function H' has a pseudorandom input σ known only to the moderator. Since the values of σ and σ_c are secret shared among the servers, an adversary can only introduce additive offsets to them between the time σ_c is generated and checked. Since H' is modeled as a random oracle, an attacker has a negligible chance of offsetting both σ_c and its inputs in such a way that the checksum still verifies. Thus a receiving user can recompute σ_c to verify for itself that σ will be accepted during verification.

3.3 Formal Protocol Description

We formalize our protocol in Construction 3.2 below, including details on message lengths and masking/unmasking that were omitted in the explanation of the protocol above. We present our scheme assuming the servers operate over bit strings using the XOR operation, but the scheme generalizes to additive secret sharing in an arbitrary abelian group.

Construction 3.2. Our N party shared franking protocol Π appears in Figure 2 makes use of the following primitives to send messages of length ℓ.

- A ccAE scheme $\mathsf{ccAE}(\mathsf{Kg}, \mathsf{Enc}, \mathsf{Dec}, \mathsf{Ver})$ where $\mathsf{Enc} : \mathcal{K} \times \mathcal{M} \to \{0,1\}^{\ell+v_1} \times \{0,1\}^{v_2}$.
- A PRG $G : \{0,1\}^{\lambda} \to \{0,1\}^*$. We abuse notation and truncate $\{0,1\}^*$ to the needed length of the PRG output in each case where the PRG is used. We explicitly specify the length of the PRG output unless it's clear from context.
- Hash functions $H : \{0,1\}^{\lambda'} \to \{0,1\}^{\lambda''}$ and $H' : \{0,1\}^* \to \{0,1\}^{\lambda''}$ modeled as random oracles. The parameters $\lambda', \lambda'' = \mathsf{poly}(\lambda)$ are derived from the security parameter λ.
- A MAC scheme $(\mathsf{Sign}, \mathsf{Verify})$ with tag space $\{0,1\}^{v_3}$ where the Sign algorithm is also a PRF.

We assume that the input ctx to ModProcess has a fixed, publicly-known length denoted by $|\mathsf{ctx}|$.

The correctness of this scheme follows from the correctness of the underlying cryptographic tools used to build it, namely the ccAE encryption scheme and the MAC scheme, as well as the correctness of the underlying metadata-hiding communication scheme. Recall that correctness is defined (Definition 2.2) with respect to a scheme-dependent Deliver$\langle\rangle$ protocol. In many schemes, this will involve some kind of re-randomization or shuffling of the ciphertext shares sent to the servers [8, 36, 27]. Our scheme remains correct regardless of how this re-randomization happens because as long as the correct message is reconstructed at the end, the moderator can get the "original" shares the sender sent to the system by deriving them from r. This means that the correctness of the shared franking scheme only relies on the correctness of the underlying metadata-hiding communication scheme, not on the details of how it manipulates shares.

3.4 Security

We now briefly discuss the various security properties of our scheme. Due to space limitations, proofs for the theorems stated here appear in the full version of this paper.

Confidentiality. The confidentiality of our scheme relies on the fact that the view of any subset of the servers simply consists of secret shares of ciphertexts that the adversary, who does not control all the servers, cannot reconstruct. Since the secret shares are generated by several invocations of the PRG

$\underline{\mathsf{Send}(k_U, m, N):}$
$r \xleftarrow{R} \{0,1\}^\lambda$
$c = (c_1, c_2) \leftarrow \mathsf{ccAE.Enc}(k_U, (m, r))$
$\{s_i\}_{i\in\{1,...,N\}} \leftarrow G(r)$
where $|s_i| = \lambda$ for $i \in \{1,...,N\}$
$[c]_1 \leftarrow c \oplus G(s_2) \oplus ... \oplus G(s_N)$
$w_1 \leftarrow ([c]_1, s_1)$
$w_i \leftarrow s_i$ for $i \in \{2,...,N\}$
output $w_1, ..., w_N$

$\underline{\mathsf{Process}(N, i, w_i)}$
$v_i \leftarrow G(w_i)$
where $|v_i| = \ell + \nu_1 + \nu_2$
$\quad + |\mathsf{ctx}| + \nu_3 + \lambda''$
$w_i' \leftarrow H(w_i)$
output v_i, w_i'

$\underline{\mathsf{ModProcess}(N, k_S, w_1, \mathsf{ctx}, (w_2', ..., w_N')):}$
$([c]_1, s_1) \leftarrow w_1$
$([c_1]_1, [c_2]_1) \leftarrow [c]_1$
$h \leftarrow (w_2', ..., w_N')$
$\sigma \leftarrow \mathsf{MAC.Sign}(k_S, ([c_2]_1, h, \mathsf{ctx}))$

Figure 2: Our shared franking scheme (Construction 3.2).

G, security primarily reduces to the security of G. The only messages sent in the confidentiality experiment that are not secret shared are outputs of queries to H, so we additionally bound the probability that the adversary queries the random oracle at any point that overlaps with a query made by an honest server, ensuring that these random oracle outputs cannot help the adversary.

Theorem 3.3. *If we assume that G is a secure PRG and model H as a random oracle, then our shared franking scheme (Construction 3.2) satisfies sharing confidentiality (Definition A.1).*

In particular, for every confidentiality adversary $\mathcal{A}$ that attacks Π and makes at most Q_{RO} random oracle queries to H, there exists a PRG distinguishing adversary $\mathcal{B}$ such that for every λ, N, Q, and $N_M < N$,

$$\mathsf{CONFadv}(\mathcal{A}, \Pi, \lambda, N, Q, N_M) \leq 4Q \cdot \mathsf{PRGadv}(\mathcal{B}, G, \lambda) + 2Q \cdot (N - N_M) \cdot \frac{Q_{\mathsf{RO}}}{2^{\lambda'}}.$$

Accountability and unforgeability. The accountability of our scheme follows from the sender binding of the ccAE scheme and the hardness of forging a correct tag σ_c. Sender binding requires that an adversary cannot send a message (m, r) that successfully decrypts but does not pass ccAE.Ver. Modeling H' as a random oracle, an information-theoretic argument can be made that an adversary forges a valid σ_c with at most negligible probability in λ.

Unforgeability is ensured by the MAC σ and the ccAE verification checks in Verify. In order for a forged message to pass MAC verification, the adversary must either forge a new MAC tag, or find a collision in H, because an output of H is part of the message being MACed. If the adversary instead finds a new opening for the ccAE ciphertext, this would break the receiver binding of the ccAE scheme.

Theorem 3.4. *Assuming we model H' as a random oracle, that* MAC *is a correct MAC where* MAC.Sign *is also a PRF, and that* ccAE *satisfies sender binding, our shared*

franking scheme Π *(Construction 3.2) has accountability (Definition A.2).*

In particular, for every accountability adversary $\mathcal{A}$ *that attacks our protocol* Π*, there exists collision-finding adversary* $\mathcal{B}$*, a PRF adversary* $\mathcal{C}$*, and sender binding adversary* $\mathcal{D}$ *such that for every* λ, N, Q

$$\begin{aligned}&\mathsf{ACCTadv}(\mathcal{A},\Pi,\lambda,N,Q)\\&\quad\leq \mathsf{CRadv}(\mathcal{B},H',\lambda)+\mathsf{PRFadv}(\mathcal{C},\mathsf{MAC.Sign},\lambda)\\&\quad+\mathsf{SBadv}(\mathcal{D},\mathsf{ccAE},\lambda)+\mathsf{negl}(\lambda).\end{aligned}$$

Theorem 3.5. *Assuming that* MAC *is an existentially unforgeable MAC, that* H *is a collision-resistant hash function, and that* ccAE *satisfies receiver binding, our shared franking scheme* Π *(Construction 3.2) has unforgeability (Definition A.3).*

In particular, for every unforgeability adversary $\mathcal{A}$ *that attacks our protocol* Π*, there exist unforgeability, collision-finding, and receiver binding adversaries* $\mathcal{B}$*,* $\mathcal{C}$*, and* $\mathcal{D}$ *such that for every* λ, N

$$\begin{aligned}&\mathsf{FORGadv}(\mathcal{A},\Pi,\lambda,N)\leq\\&\mathsf{MACadv}(\mathcal{B},\mathsf{MAC},\lambda)+\mathsf{CRadv}(\mathcal{C},H,\lambda)+\mathsf{RBadv}(\mathcal{D},\mathsf{ccAE},\lambda).\end{aligned}$$

Deniability. As mentioned in Section 2.2, our scheme must achieve three kinds of deniability: universal deniability, receiver compromise deniability, and moderator compromise deniability. Since we do not formalize these notions in our setting, we sketch the forgery algorithms required to satisfy each definition. All three forms of deniability rely only on the deniability of the underlying ccAE encryption scheme and MAC to an adversary who does not know their secret keys. In particular, a formal proof would rely on an anonymity property of our encryption and MAC schemes – that two ciphertexts or MACs produced by different random keys should appear indistinguishable to an adversary who does not know the keys. Our implementation uses schemes (AES-GCM and HMAC-SHA256) that satisfy a pseudorandomness property that implies the required anonymity definition.

To produce a universal forgery – one that appears valid to a distinguisher who does not have the key k_U used to encrypt/read a message or the moderator key k_S – the forger can sample random keys k'_U and k'_S and use them to run the Send and Process, and ModProcess operations. The outputs of these operations will appear indistinguishable from the results of the same process using the real keys k_U and k_S to an adversary who does not know the keys. Receiver compromise deniability requires a forgery algorithm that has access to the key k_U used to send/receive a message but not the moderator key k_S. The forger for this definition behaves just like the universal forgery forger, but it uses the keys k_U, k'_S instead of generating a random k_U. Finally, the forger for moderator compromise deniability, who has access to k_S but not k_U, uses a random k'_U but the real k_S in generating its forgery.

4 Integration with Metadata-Hiding Communication Schemes

This section discusses how our protocol from Section 3 can be integrated into various kinds of metadata-hiding communication platforms that rely on secret sharing.

4.1 Schemes based on MPC

Our shared franking protocol integrates directly with metadata-hiding communication schemes based on MPC that use additive secret sharing. In an MPC-based scheme, users send shares of messages to the servers. The servers use MPC to shuffle the shares and prepare them for delivery to their intended recipients. To integrate shared franking into these schemes, users send messages to the servers via the Send algorithm of the shared franking scheme, incorporating any client-side preprocessing of the messages before secret sharing. Then the servers run the shared franking protocol *before* they run the underlying message processing and delivery algorithm. After a message's shares are made available to users, a message recipient retrieves the relevant shares according to the underlying messaging protocol and then recovers the message via our read algorithm. The report algorithm does not make use of the metadata-hiding communication functionality and therefore does not need to be integrated directly into the underlying messaging system. Recent schemes in this category that use additive secret sharing include MCMix [8], Ruffle [4], and Clarion [27], which is based on the secret shared shuffle work of Chase et al. [16].

Schemes based on threshold secret sharing. Our approach can be integrated with schemes that use threshold secret sharing [42], such as Asynchromix [36] or RPM [35], in a limited way. If a fixed subset of the servers processes each batch of messages, and this subset is known to the moderator and the message receiver, our scheme can be used. However, this means using shared franking would require giving up some of the security and robustness properties of these schemes. For example, Asynchromix aims to achieve robustness against malicious servers who may stop responding to messages or go offline during protocol execution. On the other hand, we assume that servers are trusted for availability but not for privacy. This means that while shared franking as described here can be useful for protocols that use threshold sharing to allow a subset of a potentially large number of servers to process user messages, further work is needed to strengthen the security guarantees of shared franking to handle robustness against malicious servers for availability in addition to privacy.

4.2 Schemes Based on DC-nets

A number of recent schemes combine a DC-net approach [17, 21, 47, 22], or a DC-net augmented with distributed point func-

tions (DPFs) [30, 14, 15] to improve scalability [20, 28, 39, 6]. Our shared franking scheme does not apply to these schemes directly, but we can adapt the scheme to work in this setting too. This results in higher computation and communication costs between servers, but not between users and the servers.

Background: Private writing with DC-nets and DPFs. Before describing our scheme, we briefly summarize aspects of DC-nets and DPFs that will be relevant for our purposes. We will be focusing on the setting where the work of the DC-net is outsourced to a small number of servers rather than the original DC-net setting where a number of clients run the DC-net among themselves [17]. Since the most widely-used and efficient DPF construction only applies for two servers, we focus on the two-server setting.

This family of schemes generally has servers maintain shares D_A and D_B of a database $D = D_A + D_B$, where the database is a vector of n elements of some finite abelian group $\mathbb{G}$, i.e., $D \in \mathbb{G}^n$. To privately write a message m to an entry j in the database, a client prepares secret shared vectors x_A, x_B such that $x = x_A + x_B = m \cdot e_j$, where e_j represents the jth standard basis vector: a length-n vector of all zeros except for a 1 in the jth position. To process a write, the servers compute

$$D_A \leftarrow D_A + x_A \qquad D_B \leftarrow D_B + x_B.$$

Since the shares x_A, x_B appear random to the servers, they cannot tell which entry of the shared database D is modified by a given write. After processing many messages, the servers merge their shares D_A and D_B to recover the modified database. This allows a number of clients to write messages into the database without the servers learning who wrote which message. To protect against denial of service attacks by malicious users, clients generally include lightweight proofs alongside their shares x_A, x_B to convince the servers that they are sending shares of a vector with only one non-zero entry [22, 20, 28].

The approach above is not efficient because it requires a client to send n group elements to each server to write a message. DPFs are a mechanism that "compress" the vectors x_A and x_B into a much more concise representation that takes advantage of the fact that most entries of these vectors are really shares of zero. A DPF allows a client to create two small *function shares* f_A and $f_B : \{1,...,n\} \to \mathbb{G}$ such that $f_A(j) = x_{A,j}$ and $f_B(j) = x_{B,j}$. Now clients can send a small function share to each server, and the servers can recover x_A, x_B on their own by evaluating $f_A(j), f_B(j)$ for $j \in \{1,...,n\}$. Importantly, the representations of the function shares f_A and f_B are concise, i.e., they require fewer bits to represent than x_A and x_B. Observe that this operation slightly *increases* computation costs on the servers, but it dramatically lowers the communication cost on the client, which is more likely to be a bottleneck in a communication-constrained setting.

Integration challenges. Let us see why we cannot integrate shared franking into DC-net schemes the same way we did with MPC. Shared franking involves a step where the servers append a share of additional data c_3 to the messages sent by users. But in a DC-net scheme, the servers do not know which entry of a database a user has modified. If the servers append shares of c_3 to every entry in the database every time a user sends a message, they will end up increasing the length of each entry until it is linear in the number of messages sent. This is clearly impermissible from a performance perspective, as it dramatically increases server storage costs and requires clients to download gigantic message shares when recovering a message.

In order to make shared franking compatible with a DC-net scheme, we need a way for the servers to *blindly* append shares of c_3 to the correct entry in D, while adding shares of 0 to other entries. We achieve this with a slight modification to the structure of messages sent by users and with the addition of a small MPC. In particular, the servers will compute a multiplication on secret-shared values for each entry in D.

Shared franking for DC-nets. First, if we are to use shared franking in the DC-net setting, we need to modify the behavior of Send so that instead of creating additive shares of c_1, c_2, it creates shares of an n-entry vector x such that every entry of x has the form (c_1, c_2, c_3) where $c_1 \in \{0,1\}^{\ell+\nu_1}$, $c_2 \in \{0,1\}^{\nu_2}$, and $c_3 \in \mathbb{F}_q$ where $\mathbb{F}_q$ is a prime order finite field. When the user wishes to write a message into the j^*th entry on the servers, the jth entry of x contains

$$(c_1, c_2, 1 \in \mathbb{F}_q) \text{ if } j = j^*, \text{ and}$$

$$(0^{\ell+\nu_1}, 0^{\nu_2}, 0 \in \mathbb{F}_q) \text{ otherwise.}$$

Note that c_1, c_2 remain bit strings, whereas the 0/1 values appended to each row are interpreted as elements of a finite field and are secret shared as elements of the field, not bit strings. Thus the shares of the jth entry in the secret shared vector x that are sent to the ith server have the form $[c_{1,j}]_i, [c_{2,j}]_i, [b_j]_i$, where $([c_{1,j}]_i, [c_{2,j}]_i) \in \{0,1\}^{\ell+\nu_1+\nu_2}$ and $[b_j]_i \in \mathbb{F}_q$ is a share of zero or one. As is the case in the standard shared franking scheme, all servers except the moderator can receive a single seed s_i. Seed s_i can in turn be expanded into seeds s_{ij}, $j \in \{1,...,n\}$, one for each entry $x_j \in x$.

Putting aside distinctions between bit strings and field elements for a moment, when servers process messages, they run Process and ModProcess separately for each entry x_j, $j \in \{1,...,n\}$. That is, ignoring the role of $[b_j]$ for now, the non-moderator servers run

$$\mathsf{Process}(N, i, s_{ij}) \text{ for each } j \in \{1,...,n\},$$

and the moderator runs

$$\mathsf{ModProcess}(N, k_S, s_{1j}, \mathsf{ctx}, (w'_{2j}, ..., w'_{Nj})) \text{ for each } j \in \{1,...,n\}.$$

The only change we need to make in the computation of these functions is that we expect the components the servers

append to the end of the shares of the ccAE ciphertext, which merge to form c_3 in Read, are an element of $\mathbb{F}_q$ instead of $\{0,1\}^{|\mathsf{ctx}|+\nu_3+\lambda''}$. This means that some portion of the output of the PRG G needs to be interpreted as an element of $\mathbb{F}_q$, as does the tuple $(\mathsf{ctx},\sigma,\sigma_c)$. This is easily accomplished if we set q close to a power of 2, as these values are random or random-looking values (ctx is not necessarily random but can be encrypted by the platform). This means both the relevant PRG outputs and $(\mathsf{ctx},\sigma,\sigma_c)$ will already be a valid representation of an integer mod q with all but negligible probability. If the string $(\mathsf{ctx},\sigma,\sigma_c)$ is too long for a single element of $\mathbb{F}_q$, we can either use a larger choice of q or, for performance reasons, represent it as multiple elements of $\mathbb{F}_q$.

Blindly appending shares. After processing each row in x as described above, the servers will hold shares

$$([c_{1,j}],[c_{2,j}],[c_{3,j}]) \text{ for each } j \in \{1,\ldots,n\}.$$

Since most of the entries of x are all zeros, we will have that

$$(c_{1,j},c_{2,j}) = 0^{\ell+\nu_1+\nu_2} \text{ for } j \neq j^*.$$

In order to append the correct tag c_{3,j^*} at the end of the j^*th entry and to not interfere with the tag at the end of other rows when updating the database D, we need to replace $[c_{3,j}]$ with $[c'_{3,j}]$, where $c'_{3,j} = c_{3,j}$ when $j = j^*$ and $c'_{3,j} = 0 \in \mathbb{F}_q$ otherwise. This is where we will use the shares $[b_j]$.

For each entry j, the servers will do a small MPC to compute the product $[c'_{3,j}] \leftarrow [b_j] \cdot [c_{3,j}]$, using *Beaver triples* [9] to multiply secret-shared values. Since $b_j = 1$ if and only if $j = j^*$, the products $c'_{3,j}$ will satisfy the requirement that $c'_{3,j} = c_{3,j}$ when $j = j^*$ and $c'_{3,j} = 0$ otherwise. After a message-independent preprocessing phase among the servers, each Beaver multiplication requires a small amount of communication and computation among the servers. The communication and computation for all the multiplications can be done in parallel. This increases costs on the servers but has no effect on client-side performance. We do not describe the widely-used Beaver multiplication technique here, but it is summarized in many excellent online resources, e.g., [43, 48].

5 Implementation and Evaluation

We implemented the shared franking construction described in Section 3. Our implementation is written in C and uses OpenSSL for standard cryptographic primitives.

We instantiate our PRG G with AES in CTR mode, and our MAC scheme with HMAC-SHA256. Our ccAE scheme, following the CtE1 scheme of Grubbs et al. [32], requires an AEAD scheme and a commitment scheme. We use AES-GCM for the AEAD scheme and HMAC-SHA256 for the commitment, where the commitment randomness serves as the HMAC key. Field operations are computed modulo $2^{256} - 189$, the largest 256-bit prime [3]. OpenSSL supports hardware acceleration for evaluating AES, so our implementation benefits from this feature by default. Finally, we instantiate our hash functions H, H' with SHA256. Since all the metadata-hiding communication systems we have discussed require sending fixed-length messages to avoid leaking size information about messages, SHA256 will be indifferentiable from a random oracle in this restricted setting [37, 18].

We evaluated our implementation using a machine with a 11th Gen Intel(R) Core(TM) i7-11700K @ 3.60G processor running Ubuntu 20.04. We evaluated our scheme on message lengths of up to 1,020 Bytes in 20 Byte increments, and we varied the number of servers from 2 to 10 for each message length. We fixed the length of the ctx string used by the moderator at 32 bytes for all our experiments. All reported results for our scheme are averages taken over 1,000 runs.

Appendix B briefly reports the results from repeating our evaluation on GCP to get performance numbers for a lower-end server. There, we also use GCP to confirm that the performance characteristics of our scheme remain similar when run in a networked setting.

Evaluation results. Figure 3 shows the running time of each operation in our shared franking scheme as the message size increases from 40 Bytes to 1,020 Bytes. All operations take under ten microseconds, with the Send and Read exhibiting the most rapid increase in computation time as the message length increases. Their cost comes primarily from producing the ccAE encryption of the message, which includes both encrypting the message and computing a commitment over it, both of which depend on the entire length of the message. Verification of messages also depends on the entire message length because the verifier needs to verify the ccAE tag on the message. Finally, the cost of processing a message, either for the moderator or for any other server, is extremely low and does not require any cryptographic or arithmetic operations that depend on the length of the message, other than expanding a PRG seed to the required length, which benefits from hardware acceleration.

Increasing the number of servers results in behavior similar to increasing the message length, as seen in Figure 4. Once again, Send and Read exhibit the highest costs and increase in costs because they primarily consist of operations that depend on the message length as well as the number of servers. Since processing a message on a non-moderating server is identical as the number of servers increases and processing a message as the moderator is almost identical (it only involves MACing a message 32 bytes longer for each server), these operations are largely unaffected by an increase in the number of servers.

We conclude that shared franking adds very little computational overhead to metadata-hiding communication schemes, with the majority of the cost incurred by clients or in the report verification process, neither of which affect the critical path of message delivery on the server side. The communication overhead is also small, increasing the data sent from the client to the moderator server by 124 Bytes, and requiring only 16

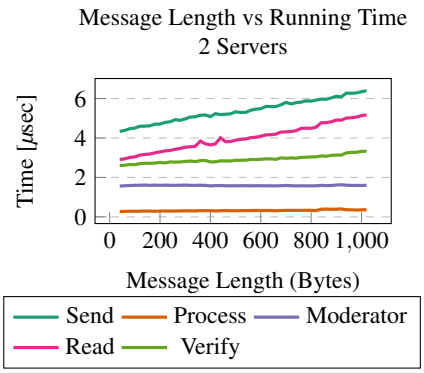

Figure 3: Running time as message length increases. Server-side operations on the critical path for message delivery run the fastest and do not noticeably increase in cost as message lengths increase.

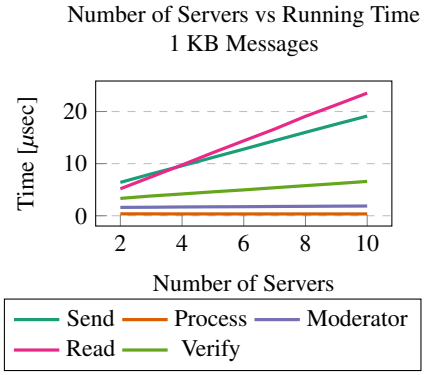

Figure 4: Running time of each operation as number of servers increases. Server-side operations on the critical path for message delivery run the fastest and do not noticeably increase in cost with the number of servers.

	Send	Read	Verify
AMF	489B	489B	489B
Hecate	380B	484B	380B
Our Work	124B	204B	144B
Plain Franking	92B	156B	128B

Figure 5: Comparison of communication costs for clients in AMF [44], Hecate [33], shared franking (our work), and plain message franking [29]. Communication costs are the overhead beyond the cost of sending the message itself. Costs for send/read in shared franking are the cost per server and do not include the additional 32 Byte hash sent from each processing server to the moderator. The additional communication cost for Send for each additional server in shared franking is 16B.

bytes sent to each other server, regardless of message length. The data retrieved from each server to read a message is the message length plus 204 Bytes, and a report consists of 144 Bytes in addition to the message itself.

We conclude the evaluation of our scheme by estimating the cost of the extension to DC-nets discussed in Section 4.2. This scheme adds a Beaver multiplication for each of the n elements of the DC-net. The Beaver multiplication adds one communication round to the protocol, as well as a preprocessing phase to generate the Beaver triples to aid in fast online multiplication. On our test machine, online evaluation of a single Beaver multiplication for 128 bits of data, which is more than sufficient for our scheme, takes 0.75μs (average of 1M runs, written in Go). Our scheme requires the cost of the Beaver multiplication and the normal processing protocol to be repeated n times to process each message. The small additional per-multiplication cost means that while shared franking remains an excellent choice for DC-net deployments with small anonymity sets – e.g., anonymous chat for participants in a class, seminar, or online community of limited size – large, general-purpose messaging platforms may opt for a different solution.

Comparison to prior work. We are aware of two prior works that extend message franking to the metadata-hiding setting: the asymmetric message franking (AMF) of Tyagi et al. [44], and the Hecate scheme of Issa et al. [33]. AMF can be added as a drop-in solution on top of *any* metadata-hiding messaging scheme where message delivery/retrieval only requires a single message from the client to the server(s), but it uses expensive proofs of knowledge to achieve this. Hecate achieves significantly improved performance, but requires an additional message-independent round trip between a user and the moderator before sending a message. AMF and Hecate both also allow for third-party moderation, which our scheme and plain message franking do not support. In the setting of secret-sharing based schemes, our solution is a drop-in approach similar to AMF, but it also outperforms both AMF and Hecate. We view the three works as exploring different areas in the design space of message franking, and quantitative comparisons between them are not necessarily apples-to-apples. AMF is the most general and the most costly. Hecate matches the generality of AMF and significantly improves performance while changing the model to add another round trip (which can be run in a message-independent preprocessing phase). Our performance improves on both prior schemes, but it is restricted to schemes based on secret sharing. We believe this is a valuable point in the design space given the large body of work that uses secret sharing approaches to hide metadata.

	Hecate	Shared Franking	Plain Franking
Preprocess	29.5μs	N/A	N/A
Send	16.4μs	6.4μs	3.7μs
Process	15.7μs	1.6μs or 0.4μs	1.1μs
Read	100.1μs	5.2μs	2.1μs
Verify	102.8μs	3.3μs	2.6μs

Figure 6: Computation time for various operations in Hecate [33], shared franking (our work), and plain message franking [29] on 1 KB messages. We report numbers for shared franking with two servers, and include the times for both the moderator and non-moderator servers to process messages.

To measure how shared franking compares quantitatively to prior work, we re-ran the benchmarks for Hecate and AMF (using the original Hecate implementation and a faster Rust implementation of AMF [38]) on our evaluation machine. We also implemented an instantiation of Facebook-style "plain" message franking [29] using the same cryptographic primitives and implementations as our scheme so we can compare to techniques deployed in practice.

Our instantiation of shared franking reduces the client communication overhead to process a message and report it compared to both AMF and Hecate, and approaches the report size of messages reported in a plain franking scheme. Figure 5 summarizes the communication costs of each scheme.

Figure 6 compares the performance of shared franking with Hecate and plain franking. Compared to Hecate, shared franking reduces the computation cost to send a message by 2.6× and the cost to read a message or verify a reported message by 19× and 31.0× respectively. The reduction in total time to process a message on the server, including time on both the servers in our implementation, is 22.6×. If we instantiate Hecate with a separate message-independent preprocessing phase per message, the online performance improvement of using our scheme is 7.9×. Our performance numbers are also more than an order of magnitude faster than those reported for AMF, which took about 230μs for each of sending, reading, and verifying a message.

Our performance improvements come from the fact that shared franking does not use any public key cryptography, whereas Hecate makes use of signatures and AMF uses zero knowledge proofs of knowledge. We can avoid these more expensive tools by taking advantage of the fact that, in the setting of secret-shared messages, the servers know the identity of message senders when they send a shared message. Thus we can use lightweight techniques more akin to those of standard message franking for E2EE messaging rather than the public key tools previously used in metadata-hiding schemes.

6 Conclusion and Future Work

We have shown how to add lightweight abuse reporting on top of metadata-hiding communication platforms based on secret sharing. Our scheme only requires symmetric cryptographic primitives and can be adapted to a broad family of communication platforms that use diverse underlying techniques. Our results show that relying on some existing structure provided by a communication platform – in this case the presence of secret sharing – can dramatically reduce the cost of adding support for abuse reporting functionality.

While this work focuses on building shared franking schemes to enable reporting abusive messages, the same technique can potentially be applied to build related private moderation capabilities as well. Recent works aimed at combating misinformation and disinformation on private messaging platforms have studied the problem of message *traceback* or *source tracking* [45, 40, 34, 33]. In these works, the goal of a report is not to identify the immediate sender of a message, but rather to find the the user who originated a piece of widely forwarded misinformation. An interesting opportunity for future work lies in extending our ideas to these kinds of schemes. In principle, our approach seems applicable to a broad class of protocols where the platform does not need to know the identity of the message recipient at the time it is processing a message. The path traceback scheme of Tyagi et al. [45] and the tree-linkable source tracking of Peale et al. [40] fall into this category, so it may be possible to efficiently extend these schemes to work in the secret shared setting as well.

Acknowledgments

I would like to thank the anonymous reviewers and shepherd for their helpful comments and suggestions that strengthened the results in this paper.

A Formal Security Definitions

Definition A.1 (Sharing Confidentiality)**.** We define the shared franking confidentiality experiment

$$\mathsf{CONF}[\mathcal{A},\Pi,\lambda,N,Q,N_M,b]$$

with respect to a stateful adversary $\mathcal{A}$ who makes at most Q queries to an oracle $\mathcal{O}_{\mathsf{honProcess}}$, shared franking scheme Π, security parameter λ, number of servers $N \in \mathbb{N}$, number of malicious servers N_M such that $N_M < N$, and a bit $b \in \{0,1\}$. The experiment proceeds as follows. We will use $\mathcal{M}$ to denote the message space for Send.

$\underline{\mathsf{CONF}[\mathcal{A},\Pi,\lambda,N,Q,N_M,b]:}$
$M \leftarrow \mathcal{A}(\lambda,N,N_M)$
where $M \subset \{1,...,N\}, |M| = N_M$(else output 0)
$b' \leftarrow \mathcal{A}^{\mathcal{O}_{\mathsf{honProcess}}}(\lambda,N,M)$
if $b' = b$: output 1; else : output 0
$\underline{\mathcal{O}_{\mathsf{honProcess}}(k_U,m_0,m_1):}$
if $b = 0$: $(w_1,...,w_N) \leftarrow \mathsf{Send}(k_U,m_0,N)$
else : $(w_1,...,w_N) \leftarrow \mathsf{Send}(k_U,m_1,N)$
$\mathsf{malw} \leftarrow (w_i)_{i\in M}$
if $1 \notin \mathsf{M}$: output $(\mathsf{malw},\perp)$
else :
  $v_i, w_i' \leftarrow \mathsf{Process}(N,i,w_i)$ for $i \in \{2,...,N\} \setminus M$
  $\mathsf{honw}' \leftarrow (w_i')_{i\in\{2,...,N\}\setminus M}$
  output $(\mathsf{malw},\mathsf{honw}')$

We define the *confidentiality advantage* of $\mathcal{A}$ as

$$\begin{aligned}\mathsf{CONFadv}(\mathcal{A},\Pi,\lambda,N,Q,N_M) &= \Big|\Pr\big[\mathsf{CONF}[\mathcal{A},\Pi,\lambda,N,Q,N_M,0]=1\big] \\ &\quad - \Pr\big[\mathsf{CONF}[\mathcal{A},\Pi,\lambda,N,Q,N_M,1]=1\big]\Big|.\end{aligned}$$

We say that a shared franking scheme Π satisfies $\varepsilon_{\mathsf{conf}}$-*confidentiality* if for all efficient adversaries $\mathcal{A}$, security parameters $\lambda \in \mathbb{N}$,and $N \in \mathbb{N}$, it holds that

$$\mathsf{CONFadv}(\mathcal{A},\Pi,\lambda,N,Q,N_M) \le \varepsilon_{\mathsf{conf}}(\lambda).$$

We say that Π has *confidentiality* if $\varepsilon_{\mathsf{conf}}(\lambda) \le \mathsf{negl}(\lambda)$.

Definition A.2 (Accountability)**.** We define the accountability experiment $\mathsf{ACCT}[\mathcal{A},\Pi,\lambda,N,Q]$ with respect to an adversary $\mathcal{A}$ who makes at most Q queries to an oracle $\mathcal{O}_{\mathsf{verification}}$, shared franking scheme Π, security parameter λ, and number of servers $N \in \mathbb{N}$. The experiment is defined as follows.

$\underline{\mathsf{ACCT}[\mathcal{A},\Pi,\lambda,N,Q]:}$
$\mathsf{win} \leftarrow 0$
$k_S \xleftarrow{R} \mathcal{K}_S$
$\mathcal{A}^{\mathcal{O}_{\mathsf{frank}},\mathcal{O}_{\mathsf{verification}}}(\lambda,N)$
output win
$\underline{\mathcal{O}_{\mathsf{frank}}(w_1,w_2',...,w_N',\mathsf{ctx}):}$
$v_1 \leftarrow \mathsf{ModProcess}(N,k_S,w_1,\mathsf{ctx},(w_2',...,w_N'))$
output v_1
$\underline{\mathcal{O}_{\mathsf{verification}}(k_U^*,w_1^*,v_2^*,...,v_N^*,w_2',...,w_N',\mathsf{ctx}^*):}$
$v_1^* \leftarrow \mathsf{ModProcess}(N,k_S,w_1^*,\mathsf{ctx}^*,(w_2',...,w_N'))$
$\mathsf{res} \leftarrow \mathsf{Read}(k_U^*,N,(v_1^*,...,v_N^*))$
output 0 if $\mathsf{res} = \perp$
$(m^*,t^*) \leftarrow \mathsf{res}$
$\mathsf{ctx}^{**} \leftarrow \mathsf{Verify}(k_S,m^*,t^*)$
$\mathsf{win} \leftarrow 1$ if $\mathsf{ctx}^{**} = \perp \vee \mathsf{ctx}^{**} \neq \mathsf{ctx}^*$
output win, res

We define the *accountability advantage* of $\mathcal{A}$ as

$$\mathsf{ACCTadv}(\mathcal{A},\Pi,\lambda,N,Q) = \Pr\big[\mathsf{ACCT}[\mathcal{A},\Pi,\lambda,N,Q]=1\big],$$

and we say that the shared franking scheme Π satisfies $\varepsilon_{\mathsf{acct}}-$*accountability* if for all efficient adversaries $\mathcal{A}$, security parameters $\lambda \in \mathbb{N}$, and $N \in \mathbb{N}$, it holds that

$$\mathsf{ACCTadv}(\mathcal{A},\Pi,\lambda,N,Q) \le \varepsilon_{\mathsf{acct}}(\lambda).$$

We say that Π has *accountability* if $\varepsilon_{\mathsf{acct}}(\lambda) \le \mathsf{negl}(\lambda)$.

Definition A.3 (Unforgeability)**.** We define the unforgeability experiment $\mathsf{FORG}[\mathcal{A},\Pi,\lambda,N]$ with respect to an adversary $\mathcal{A}$, shared franking scheme Π, security parameter λ, and number of servers $N \in \mathbb{N}$. The experiment is defined as follows.

$\underline{\mathsf{FORG}[\mathcal{A},\Pi,\lambda,N]:}$
$\mathsf{win} \leftarrow 0$
$k_S \xleftarrow{R} \mathcal{K}_S$
$T \leftarrow \{\}$
$\mathcal{A}^{\mathcal{O}_{\mathsf{send}},\mathcal{O}_{\mathsf{verification}}}(\lambda,N)$
output win
$\underline{\mathcal{O}_{\mathsf{send}}(k_U,w_1,v_2,...,v_N,w_2',...,w_N',\mathsf{ctx}):}$
$v_1 \leftarrow \mathsf{ModProcess}(N,k_S,w_1,\mathsf{ctx},(w_2',...,w_N'))$
$(m',t) \leftarrow \mathsf{Read}(k_U,N,(v_1,...,v_N))$
if $(m',t) = \perp$: output $\perp$
$\mathsf{ctx}' \leftarrow \mathsf{Verify}(k_S,m',t))$
if $\mathsf{ctx}' = \perp$: output $\perp$
$T \leftarrow T \cup \{(m',\mathsf{ctx}',t)\}$
output v_1
$\underline{\mathcal{O}_{\mathsf{verification}}(m^*,t^*):}$
$\mathsf{ctx}^* \leftarrow \mathsf{Verify}(k_S,m^*,t^*)$

	Hecate	Shared Franking	Plain Franking
Preprocess	61.3μs	N/A	N/A
Send	36.1μs	30.1μs	21.6μs
Process	32.0μs	15.7μs or 2.2μs	12.9μs
Read	215.8μs	27.7μs	17.6μs
Verify	222.9μs	31.2μs	27.8μs

Figure 7: Computation time for various operations in Hecate [33], shared franking (our work), and plain message franking [29] on 1 KB messages. We report numbers for shared franking with two servers, and include the times for both the moderator and non-moderator servers to process messages.

$$\mathsf{win} \leftarrow 1 \text{ if } \mathsf{ctx}^* \neq \perp \wedge (m^*, \mathsf{ctx}^*, t^*) \notin T$$
$$\text{output } \mathsf{win}, \mathsf{ctx}^*$$

We define the *unforgeability advantage* of $\mathcal{A}$ as

$$\mathsf{FORGadv}(\mathcal{A}, \Pi, \lambda, N) = \mathsf{Pr}\big[\mathsf{FORG}[\mathcal{A}, \Pi, \lambda, N] = 1\big],$$

and we say that the shared franking scheme Π satisfies $\varepsilon_{\mathsf{forg}}$ – *unforgeability* if for all efficient adversaries $\mathcal{A}$, security parameters $\lambda \in \mathbb{N}$, and $N \in \mathbb{N}$, it holds that

$$\mathsf{FORGadv}(\mathcal{A}, \Pi, \lambda, N) \leq \varepsilon_{\mathsf{forg}}(\lambda).$$

We say that Π has *unforgeability* if $\varepsilon_{\mathsf{forg}}(\lambda) \leq \mathsf{negl}(\lambda)$.

B Additional Evaluation Data

We repeated our evaluation on GCP, and Figure 7 shows a version of Figure 6 with data from the GCP evaluation. The GCP evaluation was run on a e2-standard-4 instance using Ubuntu 22.04.

On this instance, the cost of shared franking approaches that of plain franking, with all aspects of the protocol taking less than 1.6× the time of the corresponding plain franking operations. Repeating the evaluation on a lower-end server shows that, while the performance gap between the systems is reduced, a large gap remains between the time it takes for our scheme and Hecate to (pre-)process a message and verify reports to the moderator – the main server-side operations. Client-side sending time is much closer between the two schemes, but the gap in time to read messages remains large as well.

To verify that the performance characteristics of our scheme remain consistent when deployed in a networked setting, we also ran the processing phase of our scheme between servers located on the east and west coast. The server code for this evaluation is written in Go but uses our C implementation for the shared franking operations.

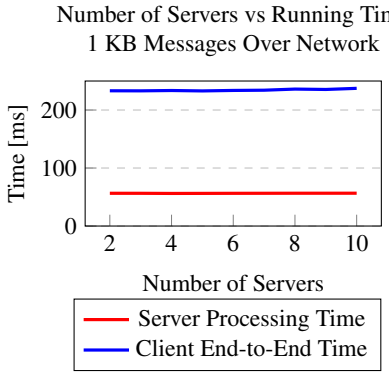

Figure 8: Processing time, including network costs, as number of servers increases. Since the primary latency bottleneck in this setting is the network, the server processing time is mostly flat around the ping time between the servers. The overall processing time from the client's perspective – including time spent setting up a TLS connection to the moderator, waiting for the servers to receive and process the message, and reading the result – are about 4.1-4.2× the ping time, reflecting the number of east/west network round trips in our evaluation setup. Times are averages of 10 runs of the protocol.

Our setup consists of one server on the east coast behaving as the moderator, a number of servers on the west coast (simulated by a single larger server) playing the role of the other servers, and another server on the west coast playing the role of the client. All messages from or to the client are sent to the moderator with the message encrypted under the receiving party's public key. This ensures that all the servers can receive their shares in the same order and also maximizes the communication cost between servers because all messages are sent between the east and west servers. There is no direct communication between the servers and client simulated on the west coast.

We had our e2-standard-4 GCP instance running in the us-east-4b zone simulating the moderator, an e2-standard-16 GCP instance running in the us-west1-c zone playing the role of the other servers, and an e2-standard-2 GCP instance in the us-west1-c zone playing the role of the client. The ping time between the east and west servers was 55.7ms. To isolate the performance characteristics of the shared franking scheme itself, our evaluation does not shuffle, mix, or otherwise run an anonymous message delivery process on the message shares sent to the servers. The servers only compute the processing stage of the shared franking protocol and send back the results to the moderator, who then runs the modProcess algorithm and returns the resulting shares to the client.

The results of this experiment, shown in Figure 8, demonstrate that, for unloaded servers, our scheme does not incur notable additional costs as the number of servers increases. The cost to the client increases very slightly due to the requirement that the client decrypt the messages it has received from each of the servers.

SOAP: A Social Authentication Protocol

Felix Linker
Department of Computer Science, ETH Zurich

David Basin
Department of Computer Science, ETH Zurich

Abstract

Social authentication has been suggested as a usable authentication ceremony to replace manual key authentication in messaging applications. Using social authentication, chat partners authenticate their peers using digital identities managed by identity providers. In this paper, we formally define social authentication, present a protocol called SOAP that largely automates social authentication, formally prove SOAP's security, and demonstrate SOAP's practicality in two prototypes. One prototype is web-based, and the other is implemented in the open-source Signal messaging application.

Using SOAP, users can significantly raise the bar for compromising their messaging accounts. In contrast to the default security provided by messaging applications such as Signal and WhatsApp, attackers must compromise both the messaging account and all identity provider-managed identities to attack a victim. In addition to its security and automation, SOAP is straightforward to adopt as it is built on top of the well-established OpenID Connect protocol.

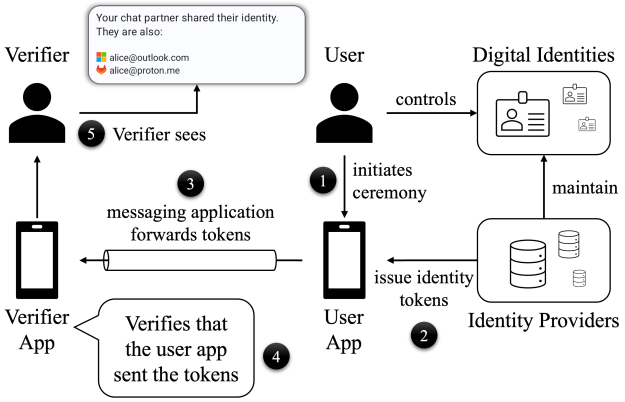

Figure 1: SOAP implements a social authentication ceremony. A user initiates the ceremony in their messaging application, which requests an identity token for each of the user's identities and forwards the tokens. The verifier's application verifies the token's sender. The verifier uses the identities to authenticate the user.

1 Introduction

Social authentication promises simple, usable, and remote key authentication for messaging applications [48] and was first implemented in the Keybase application [27]. Using Keybase, Alice can link her Keybase account to, for example, her Twitter account by tweeting a message signed with her Keybase account's key. This allows other users to *socially authenticate* Alice on Keybase via her Twitter account. More generally, when performing social authentication, users verify that their actual chat partner controls accounts at different identity providers (IdPs) which they know are controlled by their intended chat partner.

Authenticating chat partners is critical for user security: if not done properly, users risk that a Meddler-in-the-Middle (MITM) intercepts their messages. Existing authentication ceremonies do not sufficiently address this risk. Various studies have found that users are unwilling or unable to perform these authentication ceremonies [24, 41, 42, 49]. In particular, users are both challenged and constrained by the in-person comparison of safety numbers as implemented in the messaging applications Signal and WhatsApp. Not only must they understand how to perform this ceremony correctly, they must also be in close physical proximity with one another.

In contrast, automated social authentication was established as a usable authentication ceremony [48] that works remotely. Keybase was first to study social authentication beyond the idea, but Keybase requires manually posting key material, which requires non-trivial user effort. Moreover, the posting is public, which discloses account associations to everyone.

After Zoom acquired Keybase, Zoom published an end-to-end encryption whitepaper [7] which continued this line of work. In particular, it automated the authentication process using a modified version of the OpenID Connect protocol. Zoom's proposal, though, was designed in a setting where every account can be authenticated only by a single IdP and,

moreover, Zoom's design requires IdP adoption.

Finally, although past works have presented designs, social authentication has never been studied as an authentication protocol. No prior work defined what security guarantees social authentication should provide, let alone considered whether a given design correctly provides these guarantees.

In this paper, we address all these shortcomings and present SOAP, a formally verified social authentication protocol. We make the following contributions:

- We precisely define the security objectives of social authentication and argue that it should provide a novel security property that we call *sender correspondence*. This is a strong security property in that messaging sessions can only be compromised if all digital identities and the application's key servers are compromised. This raises the bar for the adversary and distributes trust amongst many providers. In contrast to Signal's and WhatsApp's default security, neither the cellular provider nor the key servers nor any of the IdPs involved can individually intercept messaging sessions.
- We formally relate sender correspondence to existing notions of authentication, and show how sender correspondence applies to designs beyond secure messaging.
- We present SOAP, a secure and practical protocol implementing social authentication. Our protocol can be seen as an extension of Zoom's design that works without IdP adoption and for multiple IdPs. SOAP automates the authentication ceremony and provides a straightforward and immediate means for adoption. Figure 1 provides an overview of our design.
- Using the Tamarin model checker [34], we formally prove that SOAP satisfies our novel security property and that SOAP respects user privacy. Users can decide to whom they disclose which identities, and SOAP leaks no information to IdPs beyond that one is using the messaging app in question, e.g., Signal. By employing a salt-and-hash scheme, we avoid revealing key material to IdPs and, thus, leaking one's contacts to providers.
- We show that SOAP is straightforward to adopt by implementing it in two fully functional prototypes: a web-based application and an extension of the Signal Android application.[1] The former requires some user interaction whereas the latter functions mostly automatically.

To the best of our knowledge, SOAP is the first formally verified authentication ceremony for messaging applications that works remotely and does not require users to work with cryptographic objects like keys or fingerprints. By leveraging an existing and widely used standard, SOAP is easy to implement and can be used immediately with any IdP that already supports OpenID Connect. Finally, SOAP allows for authentication in useful ways, that are impossible using conventional solutions, which we explicate in two further use cases.

Use Case 1: Social Authentication as a Second Factor One may question SOAP's value whenever users cannot authenticate their chat partner's identities because they have no relationship to these identities. For example, someone who has never received an e-mail from a given Outlook address would be unable to verify that e-mail address as truly belonging to the person in question without further interaction.

In such cases, SOAP is still valuable as it can serve as a second factor, raising the bar for compromise. If one of your contacts authenticated themselves as in control of two accounts, and you are prompted that this contact's public key changed, you can check whether the "new" contact still controls both these accounts. This information can help to distinguish a public key maliciously associated to your contact's profile from a legitimate, fresh public key after key-rollover.

Use Case 2: Native Digital Authentication For some online interactions, users do not base the identification of their chat partners in the physical world, but rather in the digital world. For example, in the physical world, I might like to authenticate my chat partner as "my colleague Alice, who I eat lunch with every day." In contrast, in the digital world, I might like to authenticate my chat partner as "the open-source maintainer Alice123 on GitHub, who I have never met in real life, but writes beautiful JavaScript." In the latter case, SOAP promises to seamlessly bootstrap a secure communication channel from such a pre-existing relationship.

Structure We proceed with additional problem motivation in Section 2. In Section 3, we present SOAP's design idea, define our security goal, and provide our threat model. Section 4 explains SOAP's design, Section 5 presents our security analysis, and Section 6 reports on our two prototypes. Finally, Section 7 compares SOAP to related work and sender correspondence to existing notions of authentication and designs.

Artifacts Our formal model and proofs (Sec. 5), and prototypes (Sec. 6) are available at: https://soap-wg.github.io/sources. Both prototypes come with source files and compiled versions, e.g., .apk files for the Signal prototype.

2 Problem Motivation

Both Signal and WhatsApp allow their users to communicate without authenticating their chat partners. By default, users rely on the authentication performed by the application provider during registration and that the application's key server correctly reports other users' public keys to them. When registering, users first register a public key at the key

[1] The web-based prototype is hosted at https://soap-proto.net, and a video demo of the Signal prototype can be viewed at https://youtu.be/Ip_RAF8PRrM.

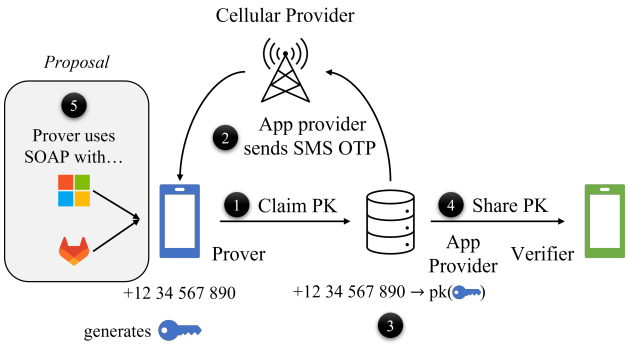

Figure 2: Steps of the prover to register at the messaging application and share their public key with other users. Our proposal is to additionally authenticate using multiple IdPs, here Microsoft and GitLab.

server (Step 1, Fig. 2). For that, they generate a public/private key pair locally and claim that the respective public key is associated with their phone number. The application then sends the user an SMS one-time password (OTP) to verify that the user controls the phone number (Step 2). When the user enters the correct OTP into the app, the key server associates the user's public key with their phone number (Step 3). Afterwards, the Signal server shares the user's public key with other users (Step 4).

This key distribution practice requires a high degree of trust in the security of SMSes and the application servers themselves. An adversary can eavesdrop or impersonate a user by compromising that user's cellular provider *or* the key server. More specifically, SMS-based attacks like SIM swaps [26] allow for impersonation, and by compromising a key server an adversary can eavesdrop on users as an MITM. Users must trust their messaging application and thus their messaging provider in general. But it is one thing to trust a provider to not implement a backdoor in a messaging application, and another to trust that their key servers are never compromised by insiders, attackers, or force by government authorities.

The breach of Signal's SMS OTP provider Twilio [46] calls into question whether the considerable trust placed in Signal's registration procedure is warranted. Through social engineering, attackers gained read access to SMS OTPs, and re-registered phone numbers, one of which belonged to a prominent journalist [20].

To prevent such attacks, Signal and WhatsApp users can compare *safety numbers* [36, 52] with their chat partners. Safety numbers are fingerprints of the two conversation participants' public keys. If two chat partners' safety numbers match, they are using the same public keys, and hence there is no MITM. To compare safety numbers though, users must rely on a trusted out-of-band channel, for example, the in-person scanning of the QR codes that encode these numbers.

In Signal's Android app, the screen for safety number verification displays the safety number as a QR code and numerically. Signal users have four options: (i) They can mark the conversation as verified. (ii) They can tap the QR code to scan their partner's QR code. (iii) They can share the safety number using a separate out-of-band channel. To do this, they click on the appropriate button, which launches the sharing menu of the phone's operating system. (iv) Finally, they can press on the safety number itself to either copy it to the clipboard or to compare it with the clipboard's contents.

Although safety numbers provide a secure authentication ceremony, their actual benefit is questionable. In incidents like the Twilio breach, users are unlikely to reauthenticate their session in a timely way by scanning QR codes. Signal notified the impersonated journalist's contacts when the attackers associated a malicious public key with the journalist's phone number. However, to successfully thwart this attack, users must (i) notice and understand this warning, and (ii) compare safety numbers in-person, which requires physical proximity, or (iii) compare safety numbers using an ad-hoc out of band channel, which must be first agreed upon – while possibly talking to an attacker. But even if users were to engage in these authentication ceremonies, various studies suggest that an attack is still very likely to succeed.

To start with, [24, 41, 49] reported that, lacking explicit instructions, only around 15%-25% of user study participants manage to successfully authenticate their chat partners in person or using phone calls. When receiving instructions, these numbers rise to 75%-80%. Remarkably, only around 50% of [24]'s participants indicated that they would perform the authentication ceremony again in the future, even after its importance was explained to them. Another study investigated the usability of SMS-based authentication ceremonies supported by Signal's share button in the safety screen's top right corner [42]. The authors found that in 40%-60% of the cases, a difference in safety numbers went unnoticed. Notably, the study considered a best-case scenario by recruiting educated, technology-savvy users who were explicitly instructed to compare safety numbers.

The aforementioned user studies show that many users cannot correctly compare safety numbers and, more critically, they do not want to. To make matters even worse, none of these studies accounts for how few users initiate these ceremonies in the first place. The share of authenticated messaging sessions is likely much lower than the above figures suggest.

Users can also protect their own accounts using a *registration lock*, provided by both WhatsApp and Signal [2, 43]. When activating the registration lock, users configure a PIN or password that must be entered when attempting to associate a new public key with a phone number. This, for the most part, rules out SMS-based attacks. If users (or attackers) cannot provide the PIN, an inactivity of 7 days is required to disable the registration lock. Registration locks, though, still require trust in the application's key server, and, more critically, users cannot verify whether their chat partners utilize them. I can

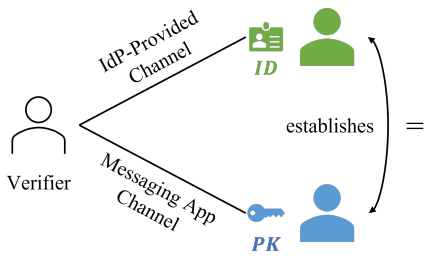

Figure 3: Social authentication establishes for a verifier that the digital identity *ID* and messaging application public key *PK* are controlled by the same person.

defend myself against impersonation attacks on my identity, but I cannot know whether my peers are impersonated or MITM-ed.

3 A Social Authentication Protocol

To address all aforementioned issues of modern messaging applications, we propose SOAP and present its security goals, its design idea, and our threat model.

3.1 Design Goals

The aim of social authentication is for a verifier to authenticate a prover (the verifier's chat partner) using one or more digital identities. Social authentication is appealing as: (i) many users have pre-existing relationships on social media, and (ii) by linking their social media presence to a different account, they can transfer the relationship from one medium to another. Note that these two notions are independent: even if you have no relationship with a given social media account, you could still be convinced that you are talking to the account holder. Formalizing this intuition, we define the security property of sender correspondence which, as we shall later see, is an authentication property.

Authentication Property (Sender correspondence)**.** A protocol *P* guarantees a verifier *sender correspondence* between two pseudonyms *A* and *B* if, whenever *P* successfully terminates, then all messages that appear to have been sent by *A* and all messages that appear to have been sent by *B* were sent by the same user.

Social authentication is simply an instantiation of sender correspondence, where the pseudonym *A* is the messaging application public key *PK* and *B* is an IdP-controlled digital identity *ID*. We define sender correspondence in more general terms than social authentication because sender correspondence finds application in other protocols, as we will discuss in Section 7.2. We illustrate social authentication's security guarantees in Figure 3.

In addition to social authentication, SOAP was also designed to provide privacy. For example, IdPs cannot learn with whom their users communicate. We define SOAP's privacy property in terms of the allowed leakage to an IdP. In particular, IdPs neither learn who the prover authenticates to nor which other IdPs the prover uses.

Privacy Property. IdPs can only learn that SOAP users (i) use SOAP, (ii) the messaging applications where they use it, and (iii) when they use it.

3.2 Design Idea

SOAP, our Social Authentication Protocol, works as follows. The prover requests an OpenID Connect identity token at an IdP and submits a hashed-and-salted conversation's safety number with that request. The IdP will then issue a token that includes a signature on the safety number and one of the prover's digital identities. At its core, this signature enables SOAP to provide social authentication and hashing-and-salting the safety number provides privacy. The prover forwards the token to the verifier, whose messaging application verifies it cryptographically and displays the prover's identity if all checks pass. In particular, this means that neither the verifier nor the prover must interact with cryptographic objects such as cryptographic keys or fingerprints thereof. In practice, users must run SOAP once per IdP to authenticate themselves to one contact, and only need to rerun SOAP should their long-term key material change.

We propose to run SOAP with multiple IdPs (as shown in Fig. 2), which substantially improves user security compared to Signal's and WhatsApp's default security. To the user, these multiple runs of SOAP (for multiple IdPs) will appear as one, which will become clear when we explain our prototypes in Section 6. Recall that, by default, a user's account can be attacked under the following condition: compromise the application's key server or compromise the cellular provider while the registration lock is not enabled (Sec. 2). Now suppose the prover runs SOAP (Step 5, Fig. 2), both with Microsoft and GitLab as the IdP. Both protocol runs are independent and, when completed successfully, the verifier's app will display both the prover's Microsoft and GitLab identity.

It is now much harder to impersonate or MITM the prover: the adversary must compromise both Microsoft *and* GitLab *and* either the prover's cellular provider *or* the application's key server. Critically, the compromise of the application's key server no longer suffices, and in contrast to the registration lock, users can authenticate their chat partners and need not rely on their chat partners activating the registration lock.

3.3 Threat Model

SOAP's security properties hold against two kinds of adversaries: We establish social authentication against an active network adversary and privacy against a malicious IdP. Whereas

the social authentication-adversary can read, intercept, reorder, and replay all messages, the malicious IdP can do the same but only with messages sent to it directly. For example, the malicious IdP cannot observe whether the prover forwards tokens to the verifier. We restrict our analysis of SOAP's privacy property to a malicious IdP as we wish to show that adding IdPs to the messaging application ecosystem does not threaten user privacy.

Our threat model permits the compromise of the messaging application's key server, the leaking of OpenID Connect requests to IdPs, and the compromise of some of the IdPs integrated into the messaging application. Notably, we make no assumptions on user-behavior other than that users do not leak their credentials. Users may click any link sent to them, whenever an IdP asks them for consent, they may provide it, and whenever an IdP asks them to log in, they may do so, even if the adversary triggered that query. We only limit our adversaries' capabilities in the following ways:

1. Adversaries are bound by the security properties of the cryptographic primitives used and the TLS and Signal protocols (both Signal and WhatsApp use the Signal protocol). For example, adversaries can neither invert cryptographic hash functions nor eavesdrop on a TLS session.
2. User credentials at IdPs are uncompromised.
3. Whenever a user authenticates via a given IdP, that IdP's signing keys and TLS certificates are uncompromised.
4. The messaging application and the user's web browser are uncompromised. In particular, the parameters of browser redirects to the messaging application remain confidential until they expire, and messaging application key material remains uncompromised.

The necessity for Assumptions 1-3 is self-evident. Regarding Assumption 4, it should be clear that we must require the messaging application and the user's browser to be uncompromised. We will discuss why we require the parameters of browser redirects to remain confidential later in Section 5.2.3 as this assumption requires a deeper understanding of SOAP's design. Finally, we require that messaging application key material remains uncompromised because an adversary could otherwise launch a trivial impersonation attack. They could run SOAP with a victim's safety number as a parameter and use an attacker-controlled account to log in. The adversary could then inject that token into the conversation between the victim and one of the victim's contacts as they compromised the key material. However, note that (i) messaging secret keys are stored on-device only, i.e., a compromise of these keys likely comes with a compromise of the messaging application, and that (ii) the Signal protocol offers strong security guarantees against such key compromise, namely forward secrecy and post-compromise security [9]. SOAP was not designed to defend against key compromise, but rather against impersonation by associating malicious keys with pseudonyms such as in the Twilio incident.

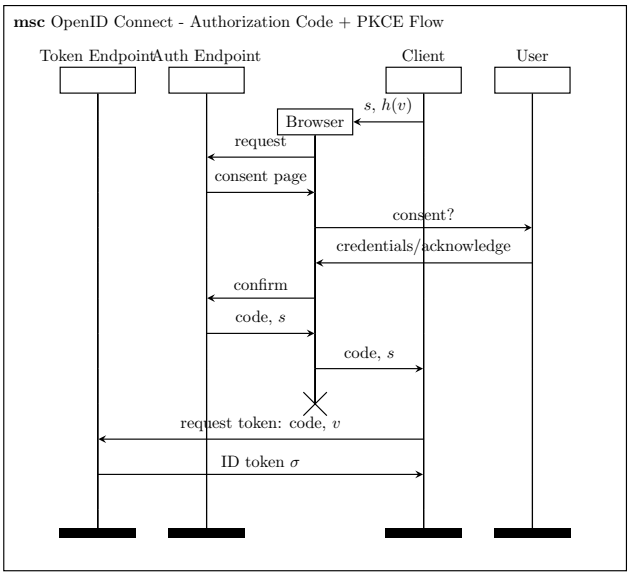

Figure 4: OpenID Connect authorization code flow with PKCE. $h(v)$ is the commitment to a random value v as specified by PKCE and s is the state parameter.

4 Protocol Design

In this section, we present SOAP's design in detail. SOAP utilizes the OpenID Connect protocol [38, 39] to facilitate adoption, which we explain first.

4.1 OpenID Connect

OpenID Connect [38, 39] is an authentication protocol that itself builds on the OAuth 2.0 authorization protocol [23]. OpenID Connect is used to implement the well-known *"Login with Google/Microsoft/Apple/..."* buttons. OpenID Connect involves three parties: a *user*, an *IdP* managing the user's identity, and a *relying party* seeking to authenticate the user. The OpenID Connect protocol is executed by a *client* operated by the relying party. At the end of a successful protocol run, the client receives an *ID token* through a browser redirect from the IdP. The ID token is a cryptographically signed message, proving that the IdP authenticated the respective user, and which the client can use to identify the user. Prior to issuing requests, relying parties must register at the respective IdP. During registration, relying parties whitelist redirect URLs, and IdPs issue *client IDs*.

OpenID Connect supports multiple *flows*, which are protocol variants aiming at specific types of software clients. We use the authorization code flow extended with the Proof Key for Code Exchange (PKCE) standard [40], which is currently recommended as best practice for clients such as mobile

applications [31]. The authorization code flow with PKCE implements a commitment reveal scheme, which we depict in Figure 4 and works as follows. The client first issues an authorization request by launching the device's browser at a specific URL called the *authorization endpoint*. The request encodes various parameters in the URL: a client ID, redirect URL, code challenge (the commitment, which is the hash of a random string), and optionally a state parameter and a nonce. The state parameter and nonce protect against replay and cross-side request forgery (CSRF) attacks.

After receiving an authorization request, the IdP verifies the redirect URL as whitelisted for the given client ID, authenticates the user, and asks the user for consent. Users usually authenticate by logging in, or through a session cookie already stored in their browser. Depending on the user's history with the IdP, the user may not need to grant consent.

Once a user consents to logging in, the IdP forwards the browser to the redirect URL given in the request. In the redirect URL, the IdP encodes an *authorization code* and the state parameter sent earlier. The client verifies that the state matches the state it previously issued, and exchanges the authorization code for an ID token. The client does this by sending a POST request to the IdP's *token endpoint*, including the authorization code and the *code verifier*. The code verifier opens the code challenge commitment sent earlier to the IdP. This allows the IdP to determine that the ID token is requested from the same client that issued the initial request.

The ID token is encoded as a JSON Web Signature (JWS), which is a signed object that maps keys to values. Amongst other values, the object includes the issuer, the audience (identifying the client), the subject (the user who was authenticated), the nonce, and a validity period. Usually, ID tokens are short-lived, with lifetimes typically ranging from two minutes to two hours. According to the OpenID Connect specification [38], ID tokens must only be accepted by the intended audience. This prevents a service to which a user logged in from using the ID token with another service.

4.2 Protocol Description

We next present SOAP, which provides an automated social authentication ceremony that requires no IdP adoption.[2] We suggest running SOAP with multiple IdPs (Section 3.2), and that applications provide a user experience where these multiple runs appear as one. Users are then only required to select IdPs and to provide consent. We base SOAP on the OpenID Connect authorization code flow with PKCE [38]. This makes its adoption straightforward, and it can be used immediately with any IdP that supports OpenID Connect.

The idea behind SOAP is to utilize the signed ID token to convince the verifier that the prover (i) authenticated to the IdP using the identity included in the token, and (ii) submitted their session's safety number when logging in. The verifier must only check that the token was intended for them by comparing the safety number included in the token to the safety number of the session through which they received the token. SOAP consists of three steps for the prover (request, validation, and forwarding) and one step for the verifier (validation). Figure 5 sketches our protocol.

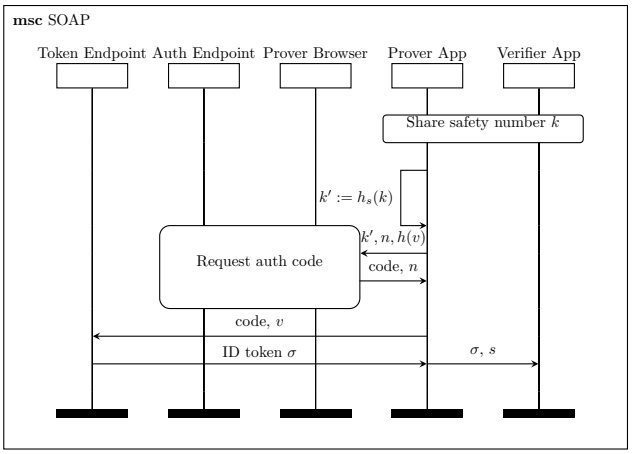

Figure 5: SOAP running between the prover, the IdP, and the verifier. Here, h_s is a password hashing algorithm using a salt s and h is SHA-256 as specified by PKCE. The application randomly samples a code verifier v, a salt s, and nonce n. Finally, σ is the OpenID Connect token, which is forwarded to the verifier and includes a signature on $h_s(k,s)$ and n.

To start a run of SOAP, the prover's messaging application prepares the request. It generates two random values: a code verifier and a nonce n. The application then uses a secure password-hashing algorithm to calculate a salted hash h of the safety number. This hash serves to blind the safety number to the IdP. To defend against CSRFs attacks, the application stores the nonce, the salt, the IdP's ID, and the code verifier as the most recently issued request. Then, the application launches the authorization code flow, passing n as the nonce and as the state, h, the code challenge, and a redirect URL. This redirect URL must be distinct for each IdP and should use the HTTPS scheme (preferred) or a custom scheme. The application then launches the system's browser with the request URL, which takes the prover to the consent/login page.

If the prover consents, the IdP redirects the browser back to the application. The redirect passes the application a state parameter and an authorization code, which can be exchanged for an ID token. Before the application uses the authorization code, it must verify that the state value it just received equals the nonce stored with the most recently issued request, and that the response originates from the expected IdP.

If both checks pass, the application uses the authorization code and stored code verifier to request the ID token from the IdP. It verifies the token's signature and fields, e.g., that it correctly encodes the hashed and salted safety number. Finally,

[2] For a technical description, see Appendix A.

the application clears its storage for the most recently issued request, and stores the nonce in a replay cache. Recording nonces defends against reflection attacks; the description of our web-based prototype in Section 6.1 illustrates this threat.

The application forwards the ID token and the salt to the verifier and the verifier applies the same checks. It also verifies that the safety number encoded in the ID token encodes the prover and verifier's keys, and that it did not request this token itself by looking up the stored nonces from runs where it was the prover. If these checks pass, the verifier can obtain the sender's identity from the token.

While Figure 5 may suggest that SOAP simply "calls OpenID Connect," previous work [31, 17, 19] highlighted many subtleties in implementing an OpenID Connect-based protocol securely. Hence, we next present our formal proof that SOAP indeed provides social authentication.

5 Security Analysis

SOAP is designed to implement social authentication and to protect user privacy, as defined in Section 3. In the following, we prove its security using the protocol-verifier Tamarin [34]. Tamarin has been used to verify many critical protocols, such as 5G-AKA, TLS 1.3, and the credit card protocol EMV [5, 10, 11]. We first introduce Tamarin, and then present the formal proofs of SOAP's social authentication and privacy property.

5.1 The Tamarin Prover

Tamarin [34] is an infinite-state protocol verifier that supports both fully automated and guided proof construction in the symbolic model. Tamarin models have three parts: rules modeling protocol steps, an equational theory modeling cryptographic primitives, and lemmas modeling protocol properties.

Rules have the form `l --lbl-> r`, where `l` reads from the current state, `r` updates the new state, and `lbl` labels this transition for reference in properties. Typically, `l` encodes reading incoming messages and parts of the participant's state and `r` encodes sending messages and updating the participant's state. For example, the rule below models that a participant receives a message, looks up a key, and sends the message symmetrically encrypted under the respective key. The label adds `Enc(m)` to the protocol trace for reference in properties.

```
[In(m),!K(k)] --[Enc(m)]-> [Out(senc(m,k))]
```

Equations model cryptographic primitives. For example, the equation `sdec(senc(m, k), k) = m` models that the symmetric decryption of a ciphertext using the correct key yields the respective plain text. Equational theories allow one to formalize a strong network adversary that can derive new knowledge from previously sent messages. For example, if a participant sent both a symmetrically encrypted message and the respective key, the aforementioned equation would allow the adversary to learn that message's content.

Tamarin supports two types of properties: universally quantified and existentially quantified trace properties. Tamarin verifies both kinds of properties similarly. Universally quantified properties are first negated, whereas existentially properties are left as is. Then, Tamarin tries to construct a trace that satisfies the resulting property using backwards constraint solving. For universally quantified properties, Tamarin hence tries to construct a counterexample, and for existentially quantified properties, Tamarin tries to construct a positive example.

5.2 Social Authentication

We next provide high-level intuition on why SOAP provides social authentication and then describe our formal proof.

5.2.1 Informal Analysis

We previously defined social authentication as an implication: "If the verifier associates an account A with the public key PK and received a message from each of these pseudonyms, then these messages were sent by the same party."

There are two ways to violate social authentication. Either, there is no send event for one of the messages or the send events have different senders. In our formal model, we modelled the message-exchange channels as authentic (i.e., given a receive event, there will be a send event) and thus focus on the latter case. Given SOAP's design, the attacker can achieve this by either making the prover send a malicious token through the messaging application, linking an attacker-chosen account to the prover's messaging channel (identity substitution), or making the prover authenticate in an attacker-controlled OpenID Connect flow, linking the prover's account to an attacker-chosen channel (impersonation).

Let us first focus on impersonation attacks, and presume Eve attempts to attack Alice. This means that Eve has a messaging session with Alice and wants to convince Alice that she, Eve, controls one or more of Bob's accounts at IdPs. To achieve this, Eve must send a token that includes a reference to Bob's account and the safety number of Eve's and Alice's public keys. As we assume that Bob's account is uncompromised (Assumption 2, Sec. 3.3), Eve must craft a malicious OpenID Connect request and forward it to Bob. This is straightforward as it requires nothing more than convincing Bob to click on a malicious link encoding such a request. However, Eve cannot obtain a token from this: Bob's application will discard the authorization response if it did not issue the request itself. Moreover, if it did issue the request itself, it would include one of Bob's safety number and not Alice and Eve's.

Similarly, Eve cannot launch an identity substitution attack. Eve would need to run SOAP herself, using a victim's safety number as parameter, log in with her own account, and then make the victim's application accept the resulting browser forward. However, the application would again discard that forward as it did not issue the corresponding request.

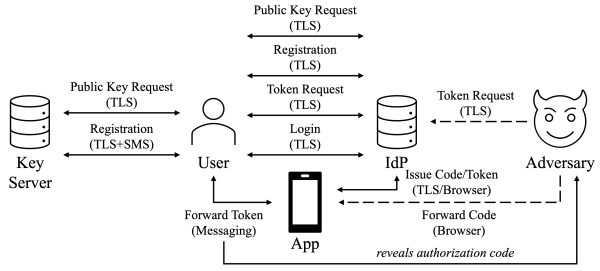

Figure 6: Sketch of our formal model of SOAP. Arrows indicate message exchanges, denoted with the respective channels used. Dashed arrows indicate that the adversary can initiate the respective request on the user's behalf. We omit the IdP-controlled bulletin board and the messaging channel.

This argument spells out the main idea behind SOAP's security. In reality, the security of protocols based on OAuth 2.0 and OpenID Connect is much more subtle. Attackers can in general access authorization code responses through other means than capturing the redirects. For example, [17] first described the IdP-mixup attack, in which applications leak an authorization code by sending it to the wrong IdP. Therefore, we formally evaluate SOAP's security next.

5.2.2 Formal Proofs

Our formal model comprehensively captures SOAP and its heterogeneous environment. Beyond the messaging application and TLS, we modelled all security-critical aspects and auxiliary protocols such as public key requests and distribution. Figure 6 depicts a sketch of what we modelled. Our model permits arbitrarily many participants to communicate with each other in arbitrarily many parallel protocol sessions. The adversary can corrupt any party in a fine-grained manner, e.g., a user's account could be compromised independently of their messaging long term keys, only constrained by our security assumptions from Section 3.3. For example, IdP corruption is possible for every IdP except the one with which the prover intends to authenticate themselves.

More specifically, our model includes channels for SMS, TLS, browser redirects, and messaging applications with different security properties and distinct keys. We also modelled communication associated with IdP-controlled pseudonyms (usernames) as a bulletin board where users can post messages associated with their pseudonym publicly after the IdP authenticates them using a password. We modelled SMSes as insecure and the messaging application as secure (confidential and authentic). We modelled TLS as a secure channel without client authentication, i.e., the adversary can always initiate new sessions with servers.

The adversary can compromise any TLS server, which allows it to read client queries and respond to them. TLS queries can have one of two methods, GET and POST, whereby GET requests can be initiated by the adversary on a user's behalf, modelling that the adversary can trick users into clicking any link. In practice, this allows the adversary to launch the OpenID Connect protocol at various points (e.g., initial request and code forwarding) for non-compromised clients. Browser redirects are modelled as GET requests using an existing session to connect to a new server, initiated by the previous server. This allows us to model, e.g., the redirect to a mobile application by modelling that application as a server.

We modelled the messaging provider, messaging application, end users, and IdPs as different parties. Our model includes SOAP itself, messaging application registration (including SMS OTP verification), IdP account registration, as well as messaging key server and IdP public key requests and responses. Moreover, we fully modelled OpenID Connect and we make no assumptions on this protocol's security.

Within this model, we prove that SOAP implements social authentication. Figure 7 shows our Tamarin specification formalizing social authentication as a trace property. It has three parts. Lines 2-7 formalize social authentication: If the verifier associates two pseudonyms with each other (`Correspond`), then all messages received from those two pseudonyms (`ReceiveMessaging`/`IdP`) originate from the same sender. We formalize the latter by showing that there exist two send events (`SendMessaging`/`IdP`) for which the sender (`Sender`) is the same party `s`.

Lines 8-15 formalize Assumptions 2-4 from our threat model (Sec. 3.3). Assumption 1 is covered implicitly as Tamarin operates in the symbolic model. There is just one subtle difference from social authentication as presented earlier. Namely, since the messaging channel is not just sender-authenticated, but also receiver-authenticated, we can include the recipient's pseudonym `rcvKey` in the receive and send event in lines 3 and 6. This means that our formalization of social authentication is stronger than sender correspondence.

The size and complexity of our model put its security properties out of reach for fully automated verification. For example, modelling that browser redirects remain confidential *until they expire* (Assumption 4) proved to be challenging. In part, we modelled this assumption by revealing authorization codes to the adversary after receiving the respective ID token. This led to infinite looping in Tamarin's proof construction, which we avoided by proving an inductive, auxiliary lemma showing that authorization codes can only be used once. In total, we verified nine auxiliary lemmas and programmed custom proof heuristics to aid Tamarin's proof construction.

5.2.3 Discussion of Threat Model

With our formal analysis of the authentication property completed, we briefly return to Assumption 4 of our threat model, where we require that the parameters of browser redirects to the messaging application remain confidential. Without this assumption, the adversary could easily obtain an identity to-

```
All v sendKey rcvKey m1 idp acc m2 #t #r1 #r2.
    ( Correspond(v, sendKey, idp, acc) @ #t
    & ReceiveMessaging(sendKey, rcvKey, m1) @ #r1
    & ReceiveIdP(idp, acc, m2) @ #r2)
==> ( (Ex s #x1 #x2.
       ( SendMessaging(sendKey, rcvKey, m1) @ #x1 & Sender(s) @ #x1 & #x1 < #r1
       & SendIdP(idp, acc, m2) @ #x2 & Sender(s) @ #x2 & #x2 < #r2))
    | (Ex p #x. CompromisedAccount(p, idp, acc) @ #x)
    | (Ex #x. CompromisedIdP(idp) @ #x)
    | (Ex #x. CompromisedDomain(idp) @ #x)
    | (Ex app redirectURL #x #y #z.
           IsMessagingApp(app) @ #x
         & IsRedirectURL(idp, app, redirectURL) @ #y
         & CompromisedDomain(redirectURL) @ #z)
    | (Ex p #x. CompromisedMessaging(p, sendKey) @ #x))
```

Figure 7: Formalization of social authentication (Sec. 3), also encoding the threat model (Sec. 3.3). Note that the two `Sender` facts are bound to the respective `SendMessaging` and `SendIdP` events, as they occur at the same time points (`x1` and `x2`).

ken that binds an attacker-chosen safety number to a victim's account. To achieve this, they would only need to trick their victim into clicking a SOAP-request link that includes a malicious safety number as parameter. As soon as the victim logs in and consents (which they will do under our liberal threat model), the adversary could learn the authorization code from the redirect URL and request the ID token themselves.

Users can theoretically protect themselves from this attack by only granting consent to requests they initiated themselves. However, (i) we find it unrealistic to assume users are resistant to social engineering, and (ii) we experienced during our prototype development that some IdPs immediately acknowledge requests without user involvement whenever the user was already logged in and had previously granted consent. In this case, users could be attacked easily, e.g., with malicious URLs obfuscated with a URL shortener.

In practice, though, capturing redirects requires the adversary to have access to a user's browsing history while an attack is launched. This requires the compromise of the user's browser, or the installation of a malicious application handler on the user's device. In case of a compromised browser, it is nigh impossible to protect the user's account credentials at the same time. To address malicious application handlers, we recommend that the application should use HTTPS redirect URLs as described in Section 4. With HTTPS URLs, application developers can utilize the security features provided by modern operating systems to ensure that authorization codes do not leak. For example, both Windows and Android support applications to handle HTTPS URLs, but only as long as these applications have been delegated to do so by the respective URL [22, 13]. This way, application developers can rely on the security features provided by the Web PKI to protect authorization responses. Without HTTPS URLs, an attacker would still need to install a malicious application handler and in turn a malicious application on their victim's device to capture redirects to custom schemes.

5.3 Privacy

SOAP protects users' privacy against the IdPs in that it only reveals that a prover is using SOAP, which messaging application is being used, and at what times SOAP is used. We formally proved SOAP's privacy as an observational equivalence property using Tamarin. Implementing our threat model (Sec. 3.3), we proved privacy in a simplified model (compared to the model presented in the previous section) that only includes communication between users and the IdP. We modeled the malicious IdP as the adversary and consequently replaced TLS with an insecure channel. Our observational equivalence property shows that IdPs cannot distinguish protocol runs where a user submits the correct salted-and-hashed prover/verifier safety number from runs where the user submits a different safety number. In the symbolic model, our privacy property is straightforward as we will lay out next.

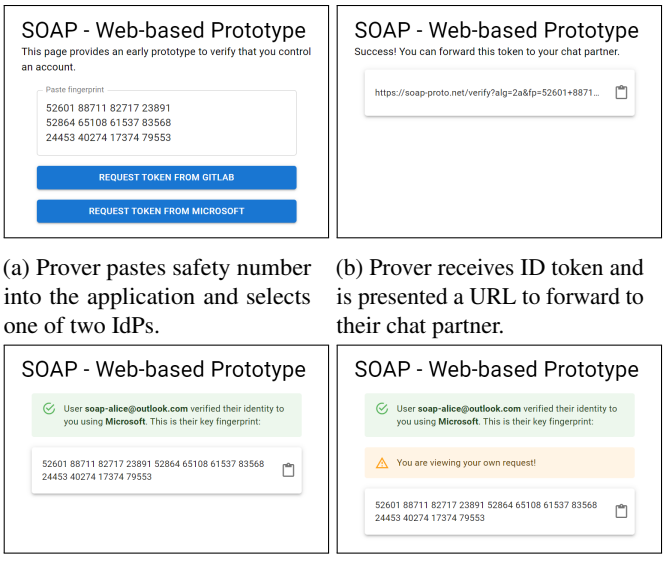
SOAP only includes two requests to the IdP's servers, and these requests include the following parameters: the messaging application ID with the IdP, a redirect URL, a nonce, the code challenge (the hashed code verifier), the code verifier, the authorization code, and the salted-and-hashed safety number. The messaging application's ID and redirect URL reveal the messaging application and that the prover is using SOAP. The nonce, the code challenge, and the code verifier are randomly generated values that change with every request, and hence, leak nothing about the prover. The authorization code is issued by the IdP and therefore allows the IdP to connect the initial authorization request with the token request. Finally, the salted-and-hashed safety number leaks nothing about the

prover under the assumption that the IdP cannot break cryptographic primitives such as salt-and-hashing, and because the salt is only shared with the verifier.

In theory, a verifier could share the salt with an IdP to reveal that the prover intended to communicate with the verifier. However, a verifier could leak this information even without SOAP. The IdP could also attempt to correlate public key requests with issued tokens. Fetching public keys, however, is not part of SOAP itself as applications will likely cache public keys. Additionally, the OpenID Connect specification [39] requires that IdPs distribute their public keys publicly and application-independently via HTTPS. For both of these reasons, we deem such a correlation to be practically infeasible. To summarize: SOAP prevents the surveillance by an IdP of its user's contact graphs in messaging applications.

6 Implementation

We implemented our proposal in two prototypes: as a stand-alone web application[3] and as a fork of the Signal open-source Android application. Both prototypes support GitLab and Microsoft as IdPs. The stand-alone version does not require messaging application adoption but requires more user interaction. In its current design, it can be used to associate arbitrary statements to a user's account.



Our prototypes demonstrate that social authentication can be realized practically, with provable security guarantees, and without OpenID Connect-IdP adoption. Our web-based prototype shows that social authentication can be implemented even without messaging application adoption. Library support for OpenID Connect is abundant and, hence, adoption is straightforward. One of the authors could implement an initial prototype within a day. With just a few clicks and in a couple of seconds, users can verifiably share their identity.

6.1 Web-based Prototype

Figure 8 depicts the interaction with our web-based prototype. When started, the application renders a text input and a list of IdPs to select from (Fig. 8a). After the prover selects an IdP, the application assumes that the input contains the safety number to authenticate, and initiates SOAP. After they complete the OpenID Connect flow (see Sec. 4.1), the prover is forwarded to our application, which requests the ID token (Fig. 8b). The web application verifies the ID token, and, if all checks pass, displays a success message. The prover can then copy a link to send to their chat partners.

This link encodes the ID token and everything needed to verify it. When the verifier clicks the link, the application verifies the token, and if all checks pass, displays the prover's identity, the IdP, and the safety number. The verifier can copy this safety number to their clipboard. The Signal Android

[3] The prototype is hosted at https://soap-proto.net.

(a) Prover pastes safety number into the application and selects one of two IdPs.

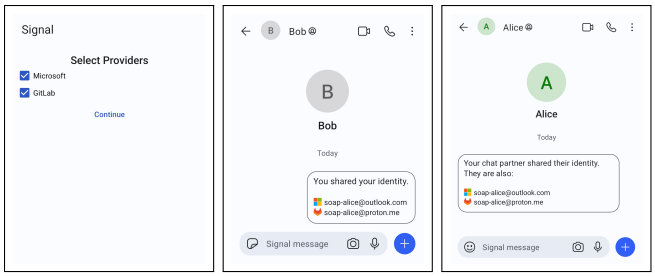
(b) Prover receives ID token and is presented a URL to forward to their chat partner.

(c) Verifier sees the prover's identity and safety number when clicking the link.

(d) Prover sees a warning when clicking a link generated within the same browser.

Figure 8: Screenshots depicting the web application prototype. The prover must initiate this flow for each IdP.

application offers its users to compare the safety number with the clipboard, giving the verifier an easy way to check the safety number (Sec. 2).



Note that the application will render a success message to anyone clicking a link containing an ID token. Only the user can determine whether the safety numbers match. This allows for social engineering attacks whenever users click links they earlier forwarded themselves. To mitigate this threat, the web application warns users that they issued this request themselves whenever they click a link that was issued within the same browser. Figure 8d shows the view after clicking on a URL that encodes an ID token.

6.2 Signal Prototype

Our Signal prototype, depicted in Figure 9, provides a more streamlined experience compared to the web-based prototype.[4] In particular, the Signal prototype requires significantly less interaction from the prover and no interaction from the verifier. Users need not actively examine and insert safety numbers, and flows need not be initiated for each IdP.

When a user wishes to authenticate themselves to their chat partner (becoming a prover), they must first select the new "Authenticate" option within the attachment menu. Next, the prover selects all the IdPs they wish to authenticate themselves with (Fig. 9a). When they press continue, they will run SOAP for each of the IdPs. The application verifies all tokens and

[4] A video demo of the Signal prototype can be viewed at https://youtu.be/Ip_RAF8PRrM.

(a) Prover selects the IdPs to authenticate with.

(b) Prover sees that they shared their identities.

(c) Verifier sees the prover's identities.

Figure 9: Screenshots depicting the Signal prototype. The interaction with our prototype is depicted from left to right.

displays a distinctly styled message to both the prover and verifier that shows the shared identities (Fig. 9b, 9c).

Our Signal prototype demonstrates that SOAP is a practical design that requires little user interaction. While it is adequate for a proof-of-concept, we suggest further enhancements before it is deployed in production. First, previously performed social authentications should be recorded as such in the application. The application could display a contact's identities within the chat header, rather than mark them as "Verified." This would additionally highlight that our proposal is intended to augment in-person safety number comparison, not supersede it. Second, the messaging application could compare the identities provided through SOAP with identities linked to the contact's address book entry on the smartphone to automatically combat impersonation attacks. Messaging applications are usually granted access to address books anyways, providing a straightforward means to automate social authentication further.

6.3 Development

The web-based prototype was written as a single-page JavaScript application in React [37], i.e., all code runs in the user's browser. The prototype consists of roughly 500 lines of code and the first version was developed within a day by one of this paper's authors. In contrast to the web-based prototype, the Signal prototype's development was more involved and required around three person weeks. Understanding the meagerly documented Signal Android codebase demanded most of the time. We changed 21 files and added around 1000 lines of Java and Kotlin code for the application logic, and also changed 17 files with around 200 additional lines of code for configuration changes, like layout and localization.

During prototype development, we noticed that not all IdPs support OpenID Connect ideally for our use case. Microsoft, for example, does not support HTTPS redirect URLs for Android applications. We tried working around this restriction by registering our Android application as a Single-Page Application, which permitted us to configure an HTTPS redirect URL. However, requesting the ID token failed as cross-origin request headers were missing.

GitLab supports HTTPS redirects and does not distinguish the types of applications upon registration. However, GitLab does not ask for consent again after the user consented once to log in. This causes HTTPS redirects to Android applications to fail. A Chrome policy requires user interaction in order to redirect users to Android applications through HTTPS URLs [3]. This left us with using custom schemes, e.g., `auth://`, in redirect URLs to support GitLab as an IdP.

Finally, Google neither allows one to configure a redirect URL nor lists a redirect URL when registering Android applications as an OpenID Connect client. In this way, Google hides their OpenID Connect API. We suspect this practice is intended to force developers to implement "Sign-In with Google" using Google's SDK [44]. This SDK need not be configured with a redirect URL to request ID tokens and does not allow one to specify a nonce.

These findings suggest that while SOAP does not require adapting the OpenID Connect specification, explicating our use case in the OpenID Connect specification could still benefit users and developers. Currently, users will only consent to log in, and developers have to use the nonce field outside its specified intent. If OpenID Connect were to recognize user-submitted claims as a request parameter, users could grant consent to show that they control the given account and developers could use APIs supporting user-submitted claims.

6.4 Performance

The performance of both prototypes is mainly constrained by the page load times of OpenID Connect authorization endpoints, consent screens, and HTTP redirects. We timed the prototypes with a user that was logged in and had authorized our application already. In the web-based prototype, running SOAP for a single IdP was nearly instantaneous (<1 second), and in the Signal prototype, running SOAP for two IdPs consistently took less than 10 seconds.

As we described in Section 4, SOAP requires local, persistent storage to protect against replay and CSRF attacks. SOAP stores the latest issued request, which only requires a small, constant amount of space, and the nonces generated by the application. The number of nonces stored is limited by the number of SOAP sessions initiated by the user, and the nonces can be discarded after a token expires, which in our experience happens within two hours.

7 Related Work

7.1 Key Authentication

In this section, we examine three research strands aimed at improving key authentication: key transparency, authentica-

tion ceremonies within messaging applications, and social authentication.

Key Transparency CONIKS, SEEMless, Parakeet, and KTACA [35, 8, 33, 53] implement *key transparency* as an alternative to key authentication. In key transparency, providers commit to a publicly auditable key directory, and users (or rather their messaging applications) both fetch their contacts' public keys from this directory and check that the public key associated with their pseudonym in the directory matches their actual public key. Key transparency aims to obviate the need for key authentication as other users can assume that their peers would have taken action should their application detect a malicious public key associated with their pseudonym. Recently, Meta announced that WhatsApp will deploy key transparency services and published an open-source key transparency service based on SEEMless and Parakeet [29, 14].

In contrast to SOAP, key transparency has the upside that it requires no user-interaction when there is no compromise, but this comes at the cost of a significant engineering effort and can require recruiting external auditors. Moreover, key transparency only aims to protect against malicious providers and not outside attackers, such as in the Twilio incident (Sec. 2), and key transparency cannot prevent compromise but only make it detectable. Finally, key transparency provides no notion of authentication, which is desirable in its own right, e.g., to verify that one chats with the person controlling a given account on a different platform. We see SOAP as complementing key transparency and not rivaling it. Moreover, SOAP is far less complex than key transparency and, thus, it is simpler to deploy SOAP, especially for smaller organizations.

Authentication Ceremonies for Messaging Applications We already extensively compared SOAP to numerous manual authentication ceremonies in Section 2. Other researchers additionally investigated how one could improve authentication ceremonies to increase success rates. [47] proposed UI changes, and [15] proposed new ceremonies altogether, but they did not consider whether those ceremonies were secure. Both [15, 47] focus on manual verification, where users compare two pieces of information. In contrast, SOAP lifts this burden from the user and instead asks them to authenticate a set of identities.

Social Authentication The idea of authenticating users using their profiles at IdPs was pioneered by Keybase [27]. There, users can bind their social media accounts, e.g., at Twitter, to their Keybase account using so-called *proofs* [28]. Users do this by posting a signed message on a social media platform. Other users can verify that a user linked their accounts by checking that the signature was generated using the key associated with the Keybase account, and posted by the claimed social media account.

[48] coined the term "social authentication," proposed its application to Signal, and conducted a user study. The authors found that users regard social authentication as understandable, easy to use, working asynchronously and remotely (in contrast to, e.g., in-person verification), and that it enhances their security when using multiple providers. However, users gave social authentication a lower trust score than in-person verification, partially stemming from their limited understanding of the mechanism. For example, users feared that a compromise of their social media accounts could lead to a compromise of their Signal account, and they distrusted social media providers in general. Users also mentioned the risk of social engineering with fake accounts.

The authors of [48] did not implement a working prototype for social authentication. They justified this decision with the complicated process of acquiring approval from the application providers to access social media accounts. Instead, they evaluated a mock-up prototype without designing or implementing any protocol. The prototype communicated with servers storing the association of social media profiles to Signal keys, simulating a perfectly secure world. Nonetheless, the authors note that safety numbers should be posted publicly on the social media platforms, thereby disclosing the association of keys with accounts. Through such public posts, users have no control over who can associate keys with accounts.

In contrast to both of the above works, SOAP is a privacy-preserving protocol that allows for the selective disclosure of key-to-account associations. Whereas the proposal of [48] requires users to authorize Signal to access the respective social media platform, SOAP neither requires Signal to access accounts at IdPs nor vice versa. Additionally, we demonstrated SOAP's feasibility with two fully functional prototypes, and we rigorously evaluated SOAP's security.

Key Authentication with OpenID Connect Zoom's cryptography whitepaper [7] proposes "Identity Provider Attestations," which authenticate Zoom's end-to-end encryption keys using OpenID Connect in conjunction with DNS. Organizations can delegate an IdP via DNS as eligible to authenticate that organization's users. The Zoom client can then (i) upload a commitment to a user's public key at the IdP on the user's behalf using OAuth and a custom API, and (ii) request an ID token that includes that commitment. Both these steps require adoption by the IdP, which is not the case for SOAP. Moreover, Zoom's design considers the case in which an account delegates authentication to a trusted IdP. In contrast, we propose to utilize multiple IdPs, which makes it strictly more difficult to compromise a messaging account.

7.2 Sender Correspondence

We next focus on sender correspondence, our formalization of social authentication. We show that this notion has application beyond secure messaging, and we relate it to existing

notions of authentication. Namely, we show that sender correspondence establishes non-injective agreement for each of the two associated pseudonyms.

7.2.1 Sender Correspondence in the Wild

To show that sender correspondence applies beyond social authentication as presented in this paper, consider the Automatic Certificate Management Environment (ACME) protocol [4, 1], powering the free certificate authority (CA) *Let's Encrypt*. ACME automates the certificate request and issuance procedure. Using ACME, CAs verify certificate requests using a challenge-response mechanism in three steps. First, a CA receives a certificate request for a given domain name, signed by a private key. Second, the CA sends a challenge to the respective public keyholder and asks them to return it using DNS or HTTP. Third, the CA verifies that they receive the signed challenge through the DNS or HTTP channel, at which point it issues a certificate for the respective public key.

The ACME protocol can be seen as establishing sender correspondence. Namely, the requesting public key is the pseudonym A and the domain name is the pseudonym B. Related literature [6, 25] verifying the ACME protocol only considered key establishment properties. Namely, they require that for any attack on ACME, the adversary must know the certificate's corresponding secret key. However, they do not consider identity misbinding attacks, where the adversary could provide the domain name that gets associated with an honest key. [4] analyzed ACME's domain validation algorithm and considered an authentication-style property. But as the authors only analyzed this one part of ACME, they did not consider ACME's overarching security goals.

In general, sender correspondence can be applied to any two channels that allow for information exchange associated to pseudonyms. An IdP-managed online version-control system like GitLab is a channel where users exchange information (commits, comments, etc.) associated with a pseudonym (usernames). Similarly, DNS is a channel where information (DNS records) is associated to pseudonyms (domain names).

7.2.2 Relationship to Other Authentication Properties

Non-Injective Agreement In his analysis of authentication properties [32], Lowe defined the notion of *non-injective agreement*, which we recast slightly as follows and formalize in Tamarin's property language below:[5]

Authentication Property (Non-injective agreement; adapted from [32])**.** A protocol guarantees a responder A *non-injective agreement* if whenever A receives a message m, apparently from initiator B, then B was previously running the protocol as the initiator, and the two agents agreed on m.

[5] [32] also requires that A and B agree on the intended recipient (A), which we drop so that we can also consider only sender-authenticated protocols.

```
1 All R S m #tr. Receive(R, S, m) @ #tr
2   ==> (Ex #ts. Send(S, m) @ #ts
3          & #ts < #tr)
```

Compare this to the following formalization of sender correspondence, a simplified variant of our formalization of social authentication (Sec. 5.2.2).

```
1  All V R1 R2 PX PY mx my #ta #trx #try.
2        ( Correspond(V, PX, PY) @ #ta
3        & ReceiveChX(R1, PX, mx) @ #trx
4        & ReceiveChY(R2, PY, my) @ #try)
5    ==> (Ex S #tsx #tsy.
6             SendChX(PX, mx) @ #tsx
7          & Sender(S) @ #tsx
8          & #tsx < #trx
9          & SendChY(PY, my) @ #tsy
10         & Sender(S) @ #tsy
11         & #tsy < #try)
```

`Receive[ChX/Y](R, S, m)` models that `R` received message `m` from `S` (on channel `X` or `Y`), `Send[ChX/Y](S, m)` that `S` sent message `m` (on channel `X` or `Y`). Note that `S` could be a pseudonym. `Correspond(V, PX, PY)` formalizes that the verifier `V` identifies pseudonyms `PX` and `PY` with the same party, and `Sender(S) @ #t` that the message sent at time point `t` was sent by agent `S`.

Intuitively, sender correspondence relates to non-injective agreement for two reasons: (i) Sender correspondence only works when the two associated pseudonyms can be used for authentic communication. Otherwise, it would make little sense to "tie" them together. (ii) The formalizations of both properties are very similar: lines 3, 6, 8 and lines 4, 9, 11 exactly match our formalization of non-injective agreement.

We can express (ii) formally. Namely, sender correspondence establishes non-injective agreement on channel `X` and `Y` for the pseudonyms `PX` and `PY`. Specifically, we show that whenever there is a successful run of a protocol providing sender correspondence between `PX` and `PY`, that trace also satisfies non-injective agreement for both of these pseudonyms (formalized using the respective `ChX` and `ChY` events). If such a trace were a counterexample to non-injective agreement, e.g., for channel `X` (the other case follows symmetrically), there must be an event `ReceiveChX(R, PX, m)` for which there is no corresponding `SendChX` event. In that case, since `R1` and `mx` in the formalization of sender correspondence are universally quantified, that trace would be a counterexample to sender correspondence as well. This contradicts our assumption that the protocol provides sender correspondence.

This relationship between sender correspondence and non-injective agreement highlights that sender correspondence is a desirable authentication property. When successfully running a protocol providing sender correspondence, we know that both pseudonyms can be used for authentic communication *and* that they are controlled by the same sender.

Sender Invariance In [12], the authors distinguish two notions of authentication that we conflate: *(non-injective) agreement* and *sender invariance*. Whereas non-injective agreement (in [12]) is defined for all kinds of agents, sender invariance is defined only for pseudonyms, capturing the security guarantees behind authenticated channels that use unauthenticated public keys. One does not know who one is connected with, but it must always be the same agent, provided their corresponding private key does not leak. The authors show that non-injective agreement implies sender invariance. Thus, in the formalism of [12], sender correspondence establishes both non-injective agreement and sender invariance.

7.3 Formal Analyses of OAuth Protocols

Our formal analysis of SOAP (Sec. 5.2.2) was influenced by the recommendations of *OAuth 2.0 Security Best Current Practice* standard [31] and the formal analyses of the OAuth 2.0 and OpenID Connect protocols conducted in [17, 19]. The latter works, [17, 19], conducted pen-and-paper proofs in the Web Infrastructure Model [18], which captures more details of the browser environment than our model, e.g., HTTP status codes and their semantics. In contrast, we utilize the Tamarin prover [34], generating machine-checked proofs and consider a strictly stronger adversary than both [17, 19] and the original specifications [23, 38, 30]. Neither of these considered the leakage of authorization requests.

Only [16], the formal analysis of the OpenID Financial-grade API, considers a stronger attacker model not requiring Assumption 4 (browser redirect parameters remain confidential). However, [16] analyzes a different profile of OAuth 2.0 that does not match our setting as it assumes that applications can protect secrets, which enables the IdP to authenticate clients. Dropping Assumption 4 for SOAP would allow the adversary to capture redirects and thus effectively allow them to run the protocol themselves altogether (see Sec. 5.2.3).

[21] proposed the Privacy-Preserving OpenID Connect (POIDC) protocol, which enhances OpenID Connect's privacy guarantees, and also analyzed the security of their proposal in Tamarin. While [21] models the process of users granting consent more explicitly (logging in and providing consent are two steps, which we model as one), they make stronger assumptions on user behavior. Namely, they require that users only log in and consent to OpenID Connect flows when they themselves launched the protocol. We do not make this assumption and it is unrealistically strong. Some IdPs neither require a login (given an existing session) nor require consent (given that consent has been granted in the past; see Sec. 4.1). Moreover, [21] does not model the authorization code flow with PKCE, which our design relies upon. Nevertheless, our design's privacy guarantees could be enhanced if designs such as POIDC were adopted.

8 Conclusion

Social authentication is an exciting authentication paradigm promising usable [48], remote, and automated authentication in messaging applications. In this paper, we precisely and formally defined social authentication (Sec. 3), we presented SOAP, a secure and practical protocol implementing social authentication (Sec. 4), we formally proved that SOAP implements social authentication even in the presence of a strong adversary (Sec. 5), and we demonstrated SOAP's practicality in two prototypes (Sec. 6).

Note that while we targeted Signal in our prototype development, and additionally WhatsApp in our problem motivation (Sec. 2), SOAP can be applied to any application to authenticate key material and, more generally, applied to any kind of pseudonyms. For example, the applications Telegram, Threema, and Viber [45, 51, 50] all provide contact verification mechanisms similar to Signal and WhatsApp. Hence, SOAP can also be applied to these applications.

SOAP is automated to a large degree and can immediately be adopted by IdPs (indeed, it may not require adoption at all) because it relies on the well-established OpenID Connect protocol. It implements a secure and complete in-application ceremony that requires nothing more of users than their consent. Widespread adoption in messaging applications would be a cost-effective measure to increase their robustness against impersonation attacks and eavesdropping.

Future Work. Our results suggest several next steps. First, we argue that social authentication should be supported by modern messaging applications. Improving our open-source Signal prototype such that it could be deployed in production is a promising first step in that direction. Second, social authentication should be applicable far beyond secure messaging. For example, it could be used to secure other communication such as e-mail, or video conferencing, or it could be used as a second factor. Third, we suggest amending the OpenID Connect specification to support user-submitted claims such that users can consent unambiguously and developers can use streamlined APIs. Finally, while [48] established social authentication as a usable authentication ceremony and our prototypes require little interaction, a user study would help to finalize our design, accounting for users' understanding and preferences regarding social authentication.

A Detailed Protocol Description

To run SOAP, applications must periodically load the IdPs's token and authorization endpoints, as well as signing keys as specified in [39]. The simplest option to do so is whenever a application engages in SOAP.

The prover's application starts SOAP by generating three random values: a code verifier *cv* as per the PKCE specification [40], a salt *s*, and a nonce *n*. We suggest generating each

of these random values with at least 256-bits of entropy, following [40]'s security requirements. The application then uses a secure password-hashing algorithm h to calculate a salted hash $h(k,s)$ of the safety number k. Next, the application uses these values to issue an OpenID Connect authentication request to the selected IdP with the following parameters:

scope: "openid email"; depending on the IdP, other scopes than "email" may be desirable.

response_type: "code"

nonce: $n \,||\, h(k,s)$; the application must ensure that it does not include the salt. $||$ denotes concatenation. The application must ensure the parsing is unambiguous, e.g., by adding a delimiter character.

state: n

code_challenge: S256(cv); S256 marks the SHA-256 hashing algorithm.

code_challenge_method: "S256"

Naturally, the application also includes its IdP-issued application ID, and an appropriate redirect URL. Redirect URLs must use the HTTPS scheme and must be distinct per IdP. The application stores the salted hash $h(k,s)$, the salt s, the nonce n, the redirect URL used, and the code verifier cv as the most recently issued request. Then, the application launches the system's browser with the request URL, which in turn takes the user to the consent and login page.

When the user consents, the IdP redirects the browser back to the application. The application verifies that it received the authorization code through the expected redirect URL and with the expected state by comparing these values to those stored as most recently issued request. If both checks pass, the application uses the authorization code and stored code verifier to request the ID token from the IdP as specified in [38], i.e., using a POST request. When receiving the token in the response, the application verifies the token as follows:

1. Verify that the issuer matches the redirect URL stored.
2. Verify that the token's audience matches the application ID.
3. Verify that the token's nonce includes the hash stored.
4. Verify that the token is not expired.
5. Verify the token's signature using a key loaded from the IdP's discovery document.

If all checks pass, the application clears its storage for the most recently issued request, stores the nonce as issued by itself, and forwards the token and salt to the verifier. The verifier's application applies checks 4 and 5 and makes the following additional checks:

1. Verify that the nonce encoded in the token has not been generated by itself, comparing it to the nonces stored locally.
2. Verify the safety number's hash encoded in the token by recomputing it, using the salt provided by the prover and the safety number of the channel through which it received the token, and comparing it for equality.

How WEIRD is Usable Privacy and Security Research?

Abstract

In human factor fields such as human-computer interaction (HCI) and psychology, researchers have been concerned that participants mostly come from WEIRD (Western, Educated, Industrialized, Rich, and Democratic) countries. This WEIRD skew may hinder understanding of diverse populations and their cultural differences. The usable privacy and security (UPS) field has inherited many research methodologies from research on human factor fields. We conducted a literature review to understand the extent to which participant samples in UPS papers were from WEIRD countries and the characteristics of the methodologies and research topics in each user study recruiting Western or non-Western participants. We found that the skew toward WEIRD countries in UPS is greater than that in HCI. Geographic and linguistic barriers in the study methods and recruitment methods may cause researchers to conduct user studies locally. In addition, many papers did not report participant demographics, which could hinder the replication of the reported studies, leading to low reproducibility. To improve geographic diversity, we provide the suggestions including facilitate replication studies, address geographic and linguistic issues of study/recruitment methods, and facilitate research on the topics for non-WEIRD populations.

1 Introduction

Usable privacy and security (UPS) research focuses on the perspective of those who use technology (i.e., humans), which has not been addressed in conventional security research. It contributes to solving security and privacy issues that arise in the gap between social requirements and technical feasibility, i.e., *social-technical gap* [4]. The UPS field has accumulated approximately a quarter of a century of research history. UPS papers have been published in various conferences and journals both inside and outside the field of security and privacy, and the number of published UPS papers is increasing every year. In 1996, Zurko and Simon introduced the concept of UPS, which was called *user-centered security* in their paper. Two pioneering UPS papers were subsequently published in 1999. Adams and Sasse advocated that human factors should be considered in the design of security mechanisms [6]. Further, Whitten and Tygar pointed out a lack of good user interface design for security and applied several usability testing approaches with signing and encrypting an email message [98].

The research methodologies, i.e., recruiting participants and conducting a user study, for UPS are often interdisciplinary. Many of these methodologies are drawn from human-computer interaction (HCI), psychology, and behavioral sciences. In these research fields, the majority of participants have been reported to be Western, which has caused the issue that many of the findings accumulated over several years may not generalize to other countries and cultures. Henrich et al. indicated that U.S. participants were common outliers on many psychological measures and this fact made these participants "WEIRD" (Western, Educated, Industrialized, Rich, and Democratic) [42]. Linxen et al. [59] published a paper in 2021 entitled "How WEIRD is CHI?" in which they conducted a literature review and quantitatively confirmed the WEIRD skew of participant samples at CHI, one of the top conferences in HCI. Because the residents of WEIRD countries are a minority of the world population, this fact is suggested to significantly impact the generalizability of HCI research. Although the WEIRD framework, which includes indicators based on national statistics or characteristics, has the limitation of assessing participant sampling (e.g., in the Global South individually wealthy people may be more accessible), it has been successful in providing a broad picture of the geographic diversity of the participants.

In UPS, some studies have also identified critical gaps concerning security and privacy between WEIRD and non-WEIRD societies/populations that stem from environmental aspects (e.g., IT resource usage, documentation, and laws/regulations) and personal aspects (e.g., (mis)conception, preference, and susceptibility) [7, 10, 18, 43, 53, 57, 58, 80]. We further assume that demographic skew may also influ-

ence *attack feasibility*. Researchers in UPS sometimes leverage user studies to demonstrate the feasibility of attacks, which is a unique approach to UPS. These observations suggest that threat assessment, design implications, interventions, and support technologies proposed based on the findings of conventional WEIRD-skewed studies may not be sufficiently beneficial to or actionable in diverse non-WEIRD societies/populations and may instead hinder facilitating security and privacy in such societies/populations. Even with the harms of the WEIRD skew to UPS research, the degree of geographic breadth and factors that impede geographic diversity have not been sufficiently investigated in UPS. Moreover, the methodologies used and topics addressed are still either unrevealed or overlooked from the WEIRD perspective. In this study, we conduct a systematic literature review in UPS to answer the following research questions (RQs).

RQ1: *To what extent are participant samples in UPS papers from WEIRD countries? How has this changed over time?*

RQ2: *What are the differences in the characteristics of the methodologies and research topics in each user study recruiting Western or non-Western participants?*

We reviewed 715 UPS papers, which recruited participants, from representative security and HCI conferences over a recent five-year period (2017–2021). We used the WEIRD framework for assessing the geographic diversity of participant samples on the basis of extracted participant information and analyzed the author affiliations, methodologies, and research topics. We found that a large majority of participant samples in UPS papers were skewed toward WEIRD countries and particularly involved Western participant samples (78.89%). This skew is higher than that in the results of Linxen et al.'s study, which reviewed CHI papers (73.13%). Linxen et al. reported that the percentage of non-Western participant samples in CHI papers largely increased (from 16.31% to 30.24%, 1.85x) in the past five years, whereas our results revealed that the percentage in UPS papers decreased (25.00% to 20.77%, 0.93x). Authors tend to recruit convenient participants from the countries of their affiliations, e.g., students of the local university who are easily accessible for university researchers. Because most authors are affiliated with institutions in Western countries, the participant samples are more likely to be skewed toward Westerners. Moreover, we identified that a non-negligible number of papers did not report participant demographics. This tendency was more pronounced in non-HCI and non-UPS-focused conferences. Such papers with low reproducibility may hinder replication studies. We confirmed that there is a large Western skew in every research topic. In particular, attack-feasibility studies are skewed heavily toward Western and suffered from demographic issues: the feasibility of the attacks can be affected by participant demographics due to relying on targets' English proficiency.

We provide the following recommendations for making UPS research less WEIRD. First, a replication study should be facilitated in UPS because most UPS papers have examined only WEIRD countries and not considered/discussed whether geographic diversity affects the results. Second, geographic issues of study and recruiting methods should be addressed. Third, researchers should also be diversified (e.g., non-Western researchers) to overcome linguistic barriers and communicate precisely and deeply with and understand non-WEIRD populations. Finally, we discuss UPS research topics to be addressed in the future.

2 Background and Related Work

2.1 Original Study: How WEIRD is CHI?

Linxen et al. published a paper titled "How WEIRD is CHI?" in 2021 (hereafter referred to as the Linxen study) [59]. The Linxen study was motivated by the issues raised in psychology: (1) most findings in psychology were based on U.S. undergraduate students [12] and (2) findings drawn from U.S. participants were frequently outliers when compared with those from other countries [42]. Then, Linxen et al. investigated the geographic diversity of participants recruited in 2,768 papers published between 2016–2020 at CHI, which is the most prestigious academic conference in the HCI field. They showed that the participant samples of the CHI papers were highly skewed toward WEIRD countries, e.g., 73.13% of the participant samples were from Western countries. However, encouragingly, they also showed that the percentage of non-Western participant samples had been increasing in recent years.

2.2 Harms of WEIRD skew to UPS Research

Some UPS studies have focused on non-WEIRD societies/populations and identified critical gaps concerning security and privacy between WEIRD and non-WEIRD societies/populations that stem from environmental and individual aspects. These results suggest actual and potential harms to UPS research; design implications, interventions, and support technologies that are proposed on the basis of the findings of conventional WEIRD-skewed studies may not be sufficiently beneficial to or actionable in non-WEIRD societies/populations.

Environmental aspects. Gaps have been reported between WEIRD and non-WEIRD societies/populations regarding environmental aspects, e.g., IT resource usage, documentation, and laws/regulations. The first one is the gap in IT resource usage. Whereas people in WEIRD societies usually own devices individually, cultural contexts such as economic constraints, social values, and social power relations drive shared device practices in non-WEIRD societies, which create new challenges to ensuring individual privacy [7]. In particular, several studies have reported that women who live in the

Global South, where gender inequality is greater than in Western countries, are likely to be vulnerable to privacy abuse, harassment, and fraud when they use IT resources [10, 80]. The second one is the gap in documentation. Security and privacy documents (e.g., advice, guidelines, and training materials) notably influence individuals' security and privacy practices [77, 101]. The U.S., for instance, has issued numerous critical security and privacy documents, e.g., NIST SP-800 series [67], which are referenced by other countries. However, these documents are much less widely available in non-English-speaking countries than in English-speaking countries due to lower English proficiency levels and the additional cost of translation [41, 53]. The third one is the gap in laws/regulations. Data privacy laws and regulations play a vital role in protecting individual privacy rights and promoting responsible data practices among service providers. Many studies have investigated whether services comply with laws and regulations, e.g., EU GDPR, and the usability of the law-compliant interfaces for user privacy [68, 91]. However, in addition to Europe and the U.S., many countries in regions such as Asia, South America, and Africa have already enacted numerous data privacy laws independently [24, 48], suggesting the anticipated divergence in the treatment of user privacy in services across different countries. Moreover, the countries where data privacy laws have not been established have usually been overlooked by the abovementioned study approaches based on existing privacy laws and regulations.

Individual aspects. Gaps have also been reported regarding individual aspects, e.g., (mis)conceptions, preference, and susceptibility. It is important to note that individuals and their surrounding environment are not mutually independent entities, as individuals are influenced by their environment [56, 85]. The first one is the gap in (mis)conceptions. Many studies have identified that misconceptions of security and privacy technologies lead to insecure behavior and increase users' risk of being harmed [3, 84]. However, Herbert et al. identified that one of the most important factors influencing user misconceptions is the country of residence, with greater differences between Western and non-Western countries [43]. This result suggests further investigation of the reasons for these differences and how to debunk misconceptions tailored to each country. The second one is the gap in preferences. Many studies have identified users' privacy preferences on willingness to share their data with companies and disclose their data on social media and have proposed techniques to recommend privacy settings on the basis of users' privacy preferences [54, 86, 97]. Some studies have reported that such privacy preferences vary among countries [20, 57, 58]. For example, Li et al. showed that when users were informed that third-party companies were accountable for data collection, users from collectivistic countries (e.g., China) were less likely to share their data, whereas users from individualistic countries (e.g., U.S) were more likely to share their data [58]. The third one is the gap in susceptibility. Many studies have identified attackers' phishing techniques and users' coping strategies and proposed interventions [33, 92, 95]. However, Butavicius et al. demonstrated that users from individualistic cultures were significantly less likely to be susceptible to phishing emails [18], suggesting that users in collectivistic countries may be more exposed to phishing threats. Moreover, Hasegawa et al. unveiled that non-native English speakers used different coping strategies for suspicious emails in English from suspicious emails in their native language [41].

Motivated by these observations, we focus on the WEIRD perspective in UPS. Ensuring security and privacy is not limited to WEIRD societies alone but rather a shared global challenge. To strive to equitably provide security and privacy globally, it is imperative to broaden the focus of UPS to include non-WEIRD societies; specifically, understanding the similarities and differences between WEIRD and non-WEIRD societies/populations is crucial for addressing this challenge.

2.3 Literature Reviews in UPS Research

Many researchers have conducted literature reviews in terms of "research topics" of UPS papers. Garfinkel and Lipford and [35] summarized the research topics of the whole UPS field. Other reviews focused on the research topics of specific subfields of UPS, such as privacy- and security-related decision-making [5], social cybersecurity [99], phishing interventions [33], at-risk users [94], sexual abuse [69], cross-cultural privacy issues in social media [90], and developer-centered security [87].

On the other hand, few researchers have conducted literature reviews in terms of the "methodology" of UPS papers. Distler et al. conducted a literature review to understand which methods researchers use and how researchers represent risks to participants [30]. Kaur et al. reviewed and compared the methods of UPS papers on experts and non-experts (end users) [52]. In addition to revealing current research practices, these authors identified methodological and ethical challenges in UPS papers, such as no definition of ethically-acceptable deceptions, lack of using theories for result interpretation, and lack of participant diversity.

Table 1 compares our study with the closely related literature reviews. Our study is a *quasi*-replication of the Linxen study [59], which focused on the WEIRD perspective on user study participants in the HCI field; we focus on the UPS field. Our study differs from the two closely related papers on UPS methodologies [30, 52] in the following points[1]:

- We collected papers from more diverse conferences to gain a comprehensive understanding of UPS papers.
- We review more recent papers (2017–2021).

[1] Note that this comparison is based on the simplified points and does not cover all the objectives of the papers.

Table 1: Comparison of our study with prior review literature on user studies.

Paper	Field	Population	Geographic Diversity	Research Topic	Conference	Period	# Papers*
Linxen et al. [59]	HCI	Any	Analyzed from WEIRD perspective	Not analyzed	CHI	2016–2020	2,768
Distler et al. [30]	UPS	Any	Not analyzed	Analyzed	S&P, SEC, CCS, SOUPS, CHI	2014–2018	284
Kaur et al. [52]	UPS	Experts	Analyzed from W perspective	Analyzed	Tier-1/2 in security [38], SOUPS, CHI	2008–2018	48 (+48)**
Our study	UPS	Any	Analyzed from WEIRD perspective	Analyzed	S&P, SEC, CCS, NDSS, PETS, CHI, CSCW, SOUPS, USEC, EuroUSEC	2017–2021	715

*The number of fully-reviewed papers. **They reviewed 48 papers on experts plus 48 papers on non-experts for comparison.

- We analyze not only the degree to which the participants' countries were Western but also the degrees to which they were Educated, Industrialized, Rich, and Democratic.
- We unveil the degrees of Western-skew in research topics, conferences, and author affiliations.
- We discuss the possible influence of participants' demographics on the results of UPS research and recommend future UPS research topics.

Note that, recently, Mathew et al. reported work-in-progress results of author diversity in security and privacy papers, partly including UPS [61]. Our study focuses on not only author diversity but also participant diversity.

3 Methodology

3.1 Review Process

We followed the review process of recent representative review papers in the UPS field [30, 69].

Criteria. Since we are interested in geographic diversity of participants recruited in UPS papers, we decided to review papers that meet three criteria: full-length papers (i) that addressed issues of human factors and computer security/privacy as the main research objectives, (ii) that recruited voluntary participants, and (iii) that reported the total number of participants. We removed the following papers because they did not meet criterion–(ii):

- The papers that analyzed online public data, such as online services design and social media posts.
- The papers that analyzed behavioral logs of employees (e.g., response to simulated phishing) or that of actual service users (e.g., response to warnings displayed on browser).
- The papers in which the authors conducted ethnographic observations.

Phase–1: Conference selection. We decided to review all conferences that were selected in either or both of the two recent representative papers that comprehensively reviewed UPS papers [30, 94]: S&P, USENIX Security (SEC), CCS, NDSS, and PETS (top and second tier conferences in security and privacy), CHI and CSCW (top-tier conferences in HCI), and SOUPS, EuroUSEC, and USEC (a conference and workshops that focus on UPS). The total number of full-length papers of the above 10 conferences between 2017–2021 was 7,587, as shown in Table 2.

Phase–2: Screening for potentially relevant papers. The dataset of Phase–1 included numerous non-UPS security papers (e.g., cryptography theory) and non-UPS HCI papers. To exclude the papers that did not meet the criteria, we filtered papers with the following search queries: *(security OR privacy) AND (recruit* OR participant* OR respondent*)*. Since we were especially interested in the UPS papers that recruited participants, we used the terms *recruit*, *participant*, and *respondent* instead of the terms relevant to all UPS papers such as *user* or *usability*. Whereas a prior study [30] conducted a similar search for titles or abstracts, we conducted it for full texts to prevent inappropriately excessive exclusion. We explain the detailed procedure in the extended version of this paper [40]. Our search query resulted in 3,226 potentially relevant papers.

Phase–3: Identifying relevant papers. The first author reviewed the titles, abstracts, and body text of the 3,226 papers and removed papers that did not meet our criteria. Every time the first author found a paper where it was unclear whether it met the criteria, the authors discussed and resolved the issue. The last author independently double-coded 323 randomly selected papers (10%). The inter-rater reliability was Cohen's kappa $k = .86$, which is considered to be an excellent level of agreement [32]. After this manual screening, we finally identified 715 relevant papers[2]. Table 3 lists the numbers of identified UPS papers in each publication year. The number of UPS papers noticeably increased in 2020–2021, which Distler et al. and Kaur et al. do not cover [30, 52].

Phase–4: Detailed review. The first author reviewed each paper in detail and extracted information about the publication, participant, author, and method/topic listed in Table 4. Note that we did not extract information of pilot studies. The coding items were based on the Linxen study [59], and some of them were newly added in this work for UPS papers. The newly added items are described below.

- **Participant type** is whether the participants are experts or non-experts (end users) [52].
- **Study method** and **recruitment method** consist of the classification listed in Table 5. We created this classification with reference to the existing classification [30, 52].

[2]The full list of papers is available in the extended version of this paper [40].

Table 2: The number of UPS papers in each phase of our review process.

Paper	S&P	SEC	CCS	NDSS	PETS	CHI	CSCW	SOUPS	EuroUSEC	USEC	Total
# Papers published for 5 years (Phase–1)	426	701	751	403	313	3,471	1,268	143	57	54	7,587
# Potentially relevant papers (Phase–2)	139	191	233	108	137	1,379	797	137	54	51	3,226
# Relevant papers (Phase–3)	45	81	48	28	53	177	63	125	48	47	715

Table 3: The number of papers for detailed review by publication year.

	2017	2018	2019	2020	2021	Total
# Papers	117	128	119	150	201	715

Table 4: Extracted information for each paper.

Category	Item
Publication	Title, conference, publication year
Participant	Number*, residence country*, education*, income*, participant type (experts/non-experts)*
Author	Affiliation, affiliation country
Method and Topic	Study method*, recruitment method*, research topic, design evaluation (y/n)*, attack feasibility evaluation (y/n)*

Asterisk marks mean the information that we extracted per user study rather than per paper. A single paper can conduct multiple user studies.

Table 5: Research methods and topics.

Item	Classification
Study method	Survey, interview, lab study, online field experiment, trial deployment, other
Recruitment method	Institution, crowdsourcing, social media, city, mailing list/personal contacts, conference/event, webpanel, source code repository, other, not mentioned
Research topic	Overall, access control and privacy preference, authentication, vulnerability/malware/incident response, privacy abuse, social engineering, privacy-enhancing technologies, other

- **Research topics** is the classification (seven distinct topics and "other") listed in Table 5. We improved an existing classification [30] by focusing on technology (details are described in the extended version of this paper [40]).
- **Design evaluation** is whether the authors experimented with technology or service design. For example, papers that compared multiple interfaces or framing with a between-group or within-group approach, or papers that clearly stated that usability evaluations have been performed are coded "yes."
- **Attack feasibility evaluation** is unique to UPS: whether the authors conducted a user study for only demonstrating the feasibility of their proposed attack and did not ask participants about their perceptions of security and privacy issues.

We extracted information per user study rather than per paper if a single paper recruited participants separately for multiple user studies with different study methods (e.g., a survey and interview) or with different purposes (e.g., one survey to identify user concerns and another to evaluate the proposed UI), as shown in Table 4.

Some papers were ambiguous in their description of the recruitment process and participant information. In addition, it is potentially difficult to classify research topics of each paper. To reduce coders' subjectivity, the first and last authors discussed many times to develop a codebook and resolve the discrepancies in their interpretations. The last author independently double-coded 72 randomly selected papers (10%). The Cohen's kappa of our review was $k = .85$–$.97$, which is considered to be an excellent level of agreement [32].

3.2 Analysis

We followed the analysis framework of the WEIRD acronym used in the Linxen study [59]. We used the same year's national statistics as the Linxen study to directly compare the results of the Linxen study (i.e., the HCI field) with our results (i.e., the UPS field)[3].

Participant sample. The number of participant samples refers to the number of countries from which there were participants who were recruited for a user study. A single paper can report multiple participant samples, i.e., a single paper can recruit participants from multiple countries.

WEIRD. The WEIRD acronym (Western, Educated, Industrialized, Rich, and Democratic) is the set of indicators for measuring the diversity of participants' countries. Just because a country is non-Western does not necessarily mean it is non-EIRD, i.e., there are certain non-W and EIRD countries such as Israel, Japan, and South Korea.

- **Western.** We classified participants' countries described in each paper into Western or non-Western using Huntington's classification [47]. This classification is based on civilizations in the post-Cold War era, and Western is centered in Europe and North America. Note that while we adopt this classification for our comparison, it has been criticized in the political science community [22, 34] and does not always agree with the general perception of Western.
  - Western (examples): U.S., Canada, UK, Germany, Netherlands, Switzerland, Sweden, and Australia.
  - Non-Western (examples): India, China, Japan, South Korea, Israel, Saudi Arabia, Russia, Pakistan, Bangladesh, Mexico, Brazil, and South Africa.

[3] The statistical data was provided from the authors of the Linxen study.

- **Educated.** We comprehensively explored participants' education levels by analyzing two indicators: (a) the mean years of schooling per country [73] and (b) specific educational levels of each participant if the information was provided in a paper.
- **Industrialized.** We used GDP (gross domestic product) per country, which is regarded as the most representative indicator for assessing the development and progress of a national economy [55]. To adjust for differences in purchasing power among countries, we used GDP based on PPP (purchasing power parity) [36].
- **Rich.** We comprehensively explored participants' wealth by analyzing two indicators: (a) the country's GNI (gross national income) based on PPP [37] and (b) specific income levels of each participant if the information was provided in a paper.
- **Democratic.** We used the political rights rating, which indicates countries' degrees of democracy and covers electoral process, political pluralism and participation, and functioning of government [46].

Normalization by country population. To address which countries are over- or under-represented in UPS papers relative to population, we normalized the number of participant samples and participants by the country's population [66]. Specifically, we calculated the normalized ratio of participant samples (ψ_s) and that of participants (ψ_p) as follows:

$$\psi = \frac{n_{samples} \text{ or } n_{participants} \text{ (country)} \ \cdot \ \text{population (world)}}{n_{samples} \text{ or } n_{participants} \text{ (total)} \ \cdot \ \text{population (country)}}$$

The values of ψ_s and ψ_p are at least 0. A value of $\psi_s < 1$ or $\psi_p < 1$ indicates the country is under-represented, while a value of $\psi_s > 1$ or $\psi_p > 1$ indicates that the country is over-represented corresponding to the country's population as a percentage of the world's population. For example, $\psi_s = 2$ indicates that the country was over-studied twice as much relative to its population size.

Correlation analysis. To understand to what extent participant samples tend to be from EIRD countries, we calculated the Kendall's tau rank correlations between ψ_s and each indicator of EIRD (e.g., mean schooling years and GDP). For instance, if there is a significantly positive correlation between ψ_s and the mean schooling years, we conclude that participant samples of UPS papers come from generally educated countries.

Author diversity. We identified the country of each author's affiliation on the basis of their affiliated institution listed first. Each paper was classified either as Western-affiliated authors only, both Western-affiliated and non-Western affiliated authors, or non-Western affiliated authors only.

Differences among conferences and research topics. To reveal the characteristics of conferences, we compared the percentage of papers that were published only by Western-affiliated authors, papers that recruited only Western participant samples and papers that reported the participants' countries across conferences. Similarly, we compared those percentages across research topics, participant type, design evaluation (y/n), and attack feasibility evaluation (y/n).

Table 6: The number of participant samples and participants.

Countries	$n_{samples}$		$n_{participants}$	
	Ours	[59]	Ours	[59][4]
Western	624	1,102	183,828	174,041
non-Western	167	405	38,208	75,068
Reported as "other"	–	–	4,836	n/a
% Western	78.89%	73.13%	82.79%	69.87%

4 Results

4.1 Western

Of our dataset, 51.89% (371/715) papers explicitly reported the participants' countries. In 15.94% (114/715) of papers, although the authors did not mention the participants' countries, we were able to infer them from the authors' affiliations (e.g., if authors mentioned that participants were recruited locally and all the authors were at institutions in the same country). For the remaining 32.17% (230/715) of papers, we were not able to confidently identify the participants' countries because the authors provided no or unclear descriptions. For example, there were papers (i) that described only that participants were recruited locally or a user study was conducted in person, but not all the authors were in the same country; (ii) that described only that participants were recruited thorough social media, crowdsourcing, or personal contacts (i.e., recruitment methods that may include people outside of the authors' country, especially for online studies); and (iii) that described only that participants were recruited at a security conference held in a specific country (some attendees may be from outside of the country). We provide a flowchart for coding in participants' countries in Appendix A.

Table 6 shows the number of participant samples and participants among 485 papers for which we were able to identify or infer the participants' countries. In terms of the number of participant samples, a large majority of UPS papers involved Western participant samples (78.89%, 624/791). This is higher than the results in the Linxen study [59] that reviewed studies in the HCI field (73.13%). In terms of the number of participants, 226,872 were involved in UPS user studies. Except for 4,836 participants who were reported as "and other" and whose details were not available, 82.79% (183,828/222,036) of participants were from Western countries. Although our analysis methods are the same as those

[4] This value was not mentioned in the Linxen study, but we compiled it using the artifact data published by the authors.

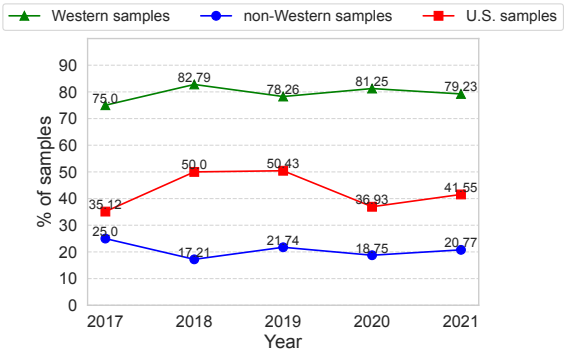

Figure 1: Temporal changes in participant samples.

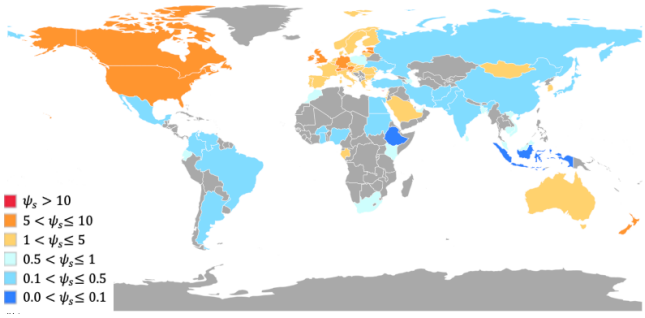

Figure 2: Distribution of normalized participant samples.

in the Linxen study [59], please note that this is a conservative estimate, given that we only included papers for which we were able to identify or infer participants' countries. If researchers recruited non-Westerners, they would probably have reported it because it is an uncommon practice. Thus, we are concerned that the true percentage of the Western participant samples is much higher.

Figure 1 shows the temporal changes in the percentages of Western, non-Western, and U.S. participant samples over the five-year period. Whereas the Linxen study reported that the percentage of non-Western participant samples in CHI papers largely increased (16.31% to 30.24%, 1.85x) between 2016–2020, our results unveiled that the percentage in UPS papers between 2017–2021 slightly decreased (25.00% to 20.77%, 0.83x).

Table 7 shows the top five countries by the number of participant samples, normalized ratio of participant samples by country population, and the number of participants, which enabled us to grasp over- and under-represented countries. Participant samples of UPS papers heavily skewed toward four Western countries: U.S. has been the most frequently studied, followed by Germany, United Kingdom, and Canada. Although these top four countries are the same as those for the CHI papers (the Linxen study), their shares are higher in the UPS papers (63.84%) than in the CHI papers (55.61%). Considering the U.S. population as a percentage of the world population, U.S. participant samples in the UPS field are over-represented by 9.79 times. Figure 2 shows the worldwide distribution of a normalized ratio of participant samples. Participants in the UPS papers between 2017 and 2021 were from only 79 countries, and many countries are completely missing from this map, especially African ones. South America, the Middle East, and Asia also have many countries that are missing or under-represented.

In the following two subsections, indicators of E, I, R, and D are analyzed independently. The percentage of participant samples that are from fully WEIRD (i.e., using AND as the logical operator) countries is presented in the extended version of this paper [40].

4.2 Educated

Table 8 indicates the correlation between countries' normalized ratio of participant samples and countries' mean years of schooling (see Analysis of Education-(a) in Section 3.2). We found a positive correlation ($r = .57$, $p < .001$), i.e., most participant samples of UPS papers come from countries with generally highly educated populations.

Next, we analyzed the participants' education levels on the basis of the detailed descriptions in each paper (see Analysis of Education-(b) in Section 3.2). In our dataset, only 34.69% (248/715) of papers explicitly reported their participants' education levels. Although 14.13% (101/715) of papers did not report their participants' education levels, we were able to infer the educational levels of participants because the authors mentioned that they recruited university students. In the remaining 51.19% (366/715) of papers, we were not able to find descriptions of their participants' education levels. Among the participants recruited in the 248 papers in which the authors explicitly reported their participants' education levels, 71.38% (79,539/111,436) of participants had a college-level or higher education, 20.89% (23,282/111,436) had a secondary or lower education, and the remaining 7.73% (8,615/111,436) were reported as "other" or "prefer not to answer." The participants of UPS papers (71.38% of the participants were college-educated) are as highly educated as the participants in CHI papers (69.93% of the participants were college-educated). We believe that the skew toward highly educated participants is related to the recruiting methods (described in Section 4.4): (1) many papers recruited participants within the authors' institutions including universities, (2) many papers recruited participants through crowdsourcing such as MTurk (e.g., MTurk workers tend to be more educated than the general U.S. population [75]), and (3) there is a certain percentage (14.96%) of papers that recruited experts (who are generally highly educated).

[5] The number of Japanese participant samples was small (N=6), but one user study recruited a very large number of participants (N=20,645).

Table 7: Top five countries by the number of participant samples (left), the normalized ratio of participant samples (middle), and the number of participants (right).

Top countries by $n_{samples}$				Top countries by ψ_s				Top countries by $n_{participants}$			
Country	$n_{samples}$	%	ψ_s	Country	$n_{samples}$	%	ψ_s	Country	$n_{participants}$	%	ψ_p
U.S.	329	41.59	9.79	Andorra	1	0.13	127.98	U.S.	142,908	62.99	14.83
Germany	76	9.61	8.94	Cyprus	2	0.25	16.33	Japan[5]	21,979	9.69	5.97
UK	67	8.47	9.73	Luxembourg	1	0.13	15.77	Germany	21,857	9.63	8.96
Canada	33	4.17	8.61	Austria	9	1.14	9.85	UK	9,297	4.10	4.71
India	26	3.29	0.19	U.S.	329	41.59	9.79	China	4,994	2.20	0.12

Table 8: Correlations of the normalized ratio of participant samples ψ_s with each indicator of Educated, Industrialized, Rich, and Democratic.

Indicators	r	r [59]
Educated (mean schooling year)	.57***	.46***
Industrialized (GDP)	.49***	.50***
Rich (GNI)	.52***	.50***
Democratic (political rights)	.44***	.50***

Significance levels: *$p < .05$, **$p < .01$, ***$p < .001$.

4.3 Industrialized, Rich, and Democratic

Table 8 shows the results of the correlations between countries' normalized ratios of participant samples and countries' GDP and GNI (see Analysis of Rich-(a) in Section 3.2). We found positive correlations for both GDP ($r = .49$, $p < .001$) and GNI ($r = .52$, $p < .001$), i.e., most participant samples of UPS papers come from industrialized and rich countries.

Next, we analyzed the participants' income on the basis of the detailed descriptions in each paper (see Analysis of Rich-(b) in Section 3.2). However, only 5.59% (40/715) reported the income levels of their participants. As in the Linxen study, we are also not able to directly establish whether the wealth of participants is representative of the general population.

Finally, as shown in Table 8, we found a positive correlation between countries' normalized ratio of participant samples and countries' political rights ($r = .44$, $p < .001$), i.e., most participant samples of UPS papers come from countries with a high degree of freedom in terms of political rights.

4.4 Author Diversity and Methodology

Of our dataset, 86.57% (619/715) of the papers consisted exclusively of authors affiliated with institutions in Western countries, which is slightly even more Western-skewed than the Linxen study (83.08%[6]). 9.93% (71/715) of the papers consisted of both Western-affiliated and non-Western affiliated authors, and the remaining 3.50% (25/715) of the papers consisted of only non-Western affiliated authors. The percentage of papers that included authors affiliated with institutions in non-Western countries remained roughly the same: from 14.53% (17/117) in 2017 to 13.43% (27/201) in 2021.

Table 9 shows the relationships of authors' affiliation countries, participants' countries, study methods, and recruitment methods. In 80.84% (464/574) of user studies, the authors recruited participants from only the countries of their affiliations. The possible reasons that participants samples are skewed towards Western countries as we presented in Section 4.1 include: (1) the countries of authors' affiliations in UPS papers are skewed toward Western ones and (2) authors tend to recruit participants in the countries of their affiliations.

In most user studies, surveys, interviews, or lab studies are conducted. As shown in Table 9, when authors recruited participants from other countries, they were more likely to conduct surveys than lab studies or interviews. Lab studies and interviews require researchers to communicate immediately/interactively with participants, and thus linguistic barriers are a serious problem. Moreover, geographic barriers also affect the choice of study method. While lab studies and interviews essentially require participants to physically come to a specific location, surveys are conducted online in most cases. Note that interviews can also be conducted online now thanks to video conferencing services.

For recruiting participants in the authors' country, authors tend to recruit within their institutions (which is a university in most user studies). We found crowdsourcing platforms are commonly used for recruiting participants both inside and outside of authors' countries. However, registered workers of commonly used crowdsourcing platforms such as Amazon Mechanical Turk (MTurk) and Prolific are skewed toward Westerners. Specifically, MTurk workers are mostly from the U.S., followed by India, whereas Prolific workers are primarily from the UK, followed by the U.S. and other Europe countries [70, 72]. Thus, such popular platforms contribute little to the recruitment of non-Westerners. Specifically, the Indian participant sample was the fifth largest in our dataset thanks to India's high numbers of MTurkers and English speakers as shown in Table 7, but non-Western countries except India are less likely to be studied by Western authors. We were interested in how Western-affiliated authors were reaching non-Western participants (excluding Indians, who are easily accessible via MTurk). In such user studies, the authors advertised their user study on social media, or one of the authors, who belonged to a Western affiliation but had a

[6] This value was not mentioned in the Linxen study, but we compiled it using the artifact data published by the authors.

Table 9: Author affiliations and study/recruitment method.

Authors	Participants	Study Method		Recruitment Method	
		Survey	Int/Lab	Top1	Top2
Western only	Only authors' countries (72.65%)	35.73%	55.88%	Institution (32.85%)	CS (27.58%)
	Other countries: Western only (7.84%)	57.78%	37.78%	CS (40.00%)	Social media (28.89%)
	Other countries: non-Western included (7.49%)	60.47%	32.56%	Social media (32.56%)	CS (30.23%)
non-Western included	Only authors' countries: Western only (2.79%)	62.50%	31.25%	CS (62.50%)	Institution (12.50%)
	Only authors' countries: non-Western included (5.40%)	25.81%	58.06%	Institution (51.61%)	ML/PC (22.58%)
	Other countries: Western only (1.22%)	85.71%	14.29%	CS (85.71%)	Institution (14.29%)
	Other countries: non-Western included (2.61%)	33.33%	53.33%	City (26.67%), ML/PC (26.67%)	

We show the percentages of user studies rather than that of papers because multiple user studies (e.g., interview and survey) can be conducted in a single paper. We focused on the user studies in which we were able to identify or infer the participants' countries. Figures represent the percentages of user studies within the sections separated by solid lines. "Int/Lab": interview or lab study. "CS": crowdsourcing. "ML/PC": mailing list or personal contacts.

Table 10: Characteristics of conferences.

Conference	% Country Reported	% Attack Feasibility	% W-only Authors	% W-only Samples
S&P field	56.08 (36.86)	18.82	81.96	85.31
HCI field	75.83 (61.25)	0.42	89.58	84.62
UPS-focused	72.73 (59.09)	0.45	88.64	86.25

"S&P field": S&P, SEC, CCS, NDSS, and PETS. "HCI field": CHI and CSCW. "UPS-focused": SOUPS, EuroUSEC, and USEC. "Country Reported" column: the percentage of the papers in which we were able to identify or infer the participants' countries (the figures in parentheses indicate the papers in which we were able to identify them).

non-Western background, was in charge of recruitment in the city or through the author's social network [7, 8].

4.5 Differences among Conferences

Table 10 shows the characteristics of authors and participant samples by conferences. Both authors' affiliations and participants were skewed toward Westerners at every conference. The percentages of the papers in which the authors explicitly reported their participants' countries are lower in S&P, SEC, CCS, NDSS, and PETS than in HCI conferences (CHI and CSCW) and UPS-focused conferences (SOUPS, EuroUSEC, and USEC). Those five conferences (S&P, SEC, CCS, NDSS, and PETS) have relatively higher percentages of the papers in which the authors recruited participants only for demonstrating the feasibility of their proposed attack.

4.6 Research Topics and Methodology

Table 11 shows the percentages of user studies that recruited only Western samples by participant type and study objectives. In terms of participant type (i.e., non-experts or experts), we found that the percentages of user studies that recruited only Western samples are higher among the user studies that focused on non-experts than among the user studies that focused on experts. This result was influenced by the fact that (1) more than 40% (40.48%) of user studies that focused on experts recruited "developers," and (2) for recruiting developers, Western-affiliated authors succeeded in accessing non-Western developers by using Freelancer.com (on which many non-Western developers are registered) and developer contacts published on source code repositories (e.g., GitHub), and app stores (e.g., Google's Play Store). However, if the user studies that recruited developers are excluded, the participants of the remaining user studies (e.g., user studies that recruited system/network administrators and security experts) skewed heavily towards Western participant samples (88.57%).

When comparing the user studies that conducted design evaluation (e.g., evaluated usability of the proposed prototype or effectiveness of the proposed nudges for security) with the user studies that did not conduct design evaluation, we found no difference in the degree of skewness toward Western

Table 11: Differences among participant type and study objectives.

	% Studies	% Country Reported	% W-only Samples
Participants – Non-experts	85.04	70.67 (53.07)	85.38
Participants – Experts	14.96	53.97 (38.10)	77.94
Design evaluation – Yes	39.55	68.47 (41.44)	83.78
Design evaluation – No	60.45	67.98 (56.97)	84.97
Attack feasibility – Yes	7.01	44.07 (15.25)	92.31
Attack feasibility – No	92.99	69.99 (53.51)	84.12

We show the percentages of user studies rather than those of papers because authors can conduct multiple user studies in a single paper (e.g., researchers recruit non-experts for the first study and experts for the second study).

Table 12: Differences among research topics.

Topic	% Papers	% Country Reported	% W-only Samples
Access control and privacy preference	31.47	75.11 (63.56)	90.53
Authentication	17.34	65.32 (33.06)	82.72
Vulnerability, malware, and incident response	13.43	56.25 (41.67)	77.78
Overall	11.33	77.78 (67.90)	85.71
Privacy-enhancing technologies	9.79	60.00 (45.71)	85.71
Social engineering	6.29	75.56 (64.44)	79.41
Privacy abuse	5.45	76.92 (66.67)	80.00
Other	4.90	34.29 (14.29)	91.67

We show the percentages of papers rather than those of user studies because research topics in a single paper can be classified into one code, even if the paper conducted multiple user studies.

participant samples.

The user studies conducted only for demonstrating the feasibility of the proposed attack account for 7.01% (59/842). Regarding such user studies, we found that (1) authors were less likely to report participants' countries explicitly (15.25%), and (2) authors were likely to recruit only Western samples (92.31%). The heavy Western skew of participant samples among attack-feasibility studies can be explained by the following fact: MTurk and lab studies, which are prone to demographic skew (e.g., the workers in MTurk are mostly from the U.S., and university researchers in Western countries are likely to recruit students at their universities for a lab study), were often used for demonstrating the feasibility of attacks. We further analyzed the studies of attack feasibility (56 papers including 59 user studies) and confirmed that attack feasibility can be influenced by participant demographics in the majority of studies (54.24%, 32/59). Two types of attack made up the majority: (i) targeting automatic speech recognition (15.25%, 9/59) and (ii) typing/keystroke inference (13.56%, 8/59). Because most such studies implicitly leveraged English audio or input in English, the attack feasibility may vary depending on the language used by the participants. For example, participants with low English proficiency may have difficulty recognizing malicious English audio. Additionally, for example, the keyboard layout and character input/conversion method used in each linguistic area can affect the feasibility of typing/keystroke inference. Therefore, authors who demonstrate attack feasibility should also properly report participants' demographic information such as their country of residence and language proficiency.

Table 12 shows the percentages of papers that recruited only Western participant samples by research topics. In UPS, "access control and privacy preference" was most frequently studied, followed by "authentication," "vulnerability, malware, and incident response," and "overall." The Western skew is pervasive in every topic. The degree of Western skew is relatively higher in "access control and privacy preference" and "other." On the other hand, in three research topics, the degree of Western skew is relatively lower: (i) for "vulnerability, malware, and incident response," researchers often recruited developers, and as mentioned above, researchers succeeded in accessing non-Western developers; (ii) regarding "social engineering", several researchers realized the importance of investigating the phishing susceptibility of non-Westerners (e.g., emerging market citizens [74] and non-native English speakers [41]); and (iii) regarding "privacy abuse," researchers often focus on privacy issues of minorities and demographic groups facing difficulties, one of which is non-Westerners (e.g., women in non-Western countries facing gender gaps [79]).

5 Discussion

Our literature-review results demonstrated that UPS has fewer non-Western participant samples than HCI and that the percentage of non-WEIRD participant samples has been slightly decreasing. This implies that more significant efforts should be made in UPS to address this geographic diversity issue. On the basis of our findings, we provide recommendations for further exploring UPS research with geographically diversified populations.

5.1 Summary of Main Findings

The main findings of our review and analysis as follows:

- Only 51.89% of UPS papers explicitly reported the participants' countries. In non-HCI and non-UPS-focused conferences, authors were less likely to report them. In papers from which we were able to identify or infer them, 78.89% of the participant samples were Western. The Western skew increased between 2017 and 2021. (RQ1, Sections 4.1 and 4.5)
- The participant samples tended to come from countries that were considered educated, industrialized, rich, and democratic on the basis of national statistics. The percentages of papers explicitly reporting their participants' education and/or income levels were not high. (RQ1, Sections 4.2 and 4.3)
- Most of the UPS papers (86.57%) exclusively comprised authors affiliated with institutions in Western countries. The authors tended to recruit participants from the countries of their affiliations. When authors recruited participants from other countries, they were more likely to conduct surveys than lab studies or interviews due to linguistic and geographic barriers. (RQ2, Section 4.4)
- Authors with a non-Western background, social media, and some recruitment methods for developers (e.g., source code repositories and app stores) contribute to the recruitment of non-Westerners. On the other hand, studies on experts excluding developers and studies for demonstrating attack feasibility were skewed heavily toward Western participant samples. (RQ2, Sections 4.4 and 4.6)

5.2 Replications for Non-WEIRD Populations

A replication study can be used to examine the generalizability of the findings of an existing study to a new population or to evaluate the robustness of the findings of an existing study when a new study design is used. Although several existing UPS papers have already shown that regional and cultural differences affect the results [43, 58, 81], we found that most UPS papers have examined only WEIRD countries

and not considered/discussed whether geographic diversity affects the results. Therefore, researchers should explore different insights from geographically diversified populations while pursuing generalizable results. Recognizing population differences is a promising path for addressing the issues faced by marginalized populations.

Replication studies are recognized to be important and are recommended by conferences dedicated to UPS, for example, SOUPS emphasizes their importance in the Call for Paper (CFP) [2], and USEC and EuroUSEC include them in their CFP topics. Seven replication papers are in our dataset [13, 16, 17, 19, 26, 82, 93][7]. However, the current replication studies did not sufficiently focus on non-WEIRD populations; some papers conducted a cross-cultural replication, but only in Western countries. Replication with an awareness of geographic diversity including non-WEIRD populations should be actively pursued and clearly recommended in the CFP.

The program committee (PC) needs to understand regional, cultural, and institutional differences arising from the geographic diversity to properly evaluate the value of research on non-WEIRD participants and replication studies for non-WEIRD participants. For this purpose, Western PC members alone may be insufficient to cover a broad knowledge base. In other words, more diversity of PC members is required. We additionally analyzed the PC diversity in UPS and found that the PC members also largely skewed towards researchers affiliated with institutions in Western countries: PC members were mostly Western-affiliated researchers (89.44%, 127/142) at UPS-focused conferences (SOUPS, USEC, and EuroUSEC) and research tracks ("Privacy and Security" subcommittee in CHI, "Security Usability and Measurement" track in CCS) in 2021. Soneji et al. shed light on the challenges of the review process by conducting interviews with PC members at the top-tier security conferences [83]. Although they mentioned the issue of PC members' expertise, they did not discuss the impact of the lack of geographic diversity of PC members. This implies that the Western skew of PC members is not currently well recognized as a major problem in top-tier security conferences. UPS-related conferences should be open for PC nominations and select PC members in accordance with geographic diversity. In addition, a complementary approach to enrich PC diversity is actively reaching out to research groups that study non-Western (non-WEIRD) populations and have expertise in cross-cultural/regional research. As a first step, such research groups need not necessarily have a background in non-WEIRD countries as long as they have expertise in cross-cultural/regional research and sufficient cultural knowledge.

[7] In our dataset, we identified papers with "Replication:" in the title as replication papers. SOUPS recommends this title naming rule.

5.3 Reproducibility and Participant Protection

Papers with low reproducibility may hinder replication studies. Through our review, we identified many papers with reproducibility problems, i.e., lacking basic demographic information of participants of a user study. For example, the percentage of papers for which we were able to identify the participants' countries was not sufficiently high (Section 4.1), nor was the percentage of papers that described the participant's education or income level (Sections 4.2 and 4.3). Moreover, most attack-feasibility studies did not report participant demographics, which is vital because many attacks used English audio or input, highlighting the impact of language proficiency (Section 4.6). Our recommendation that researchers appropriately report participant demographics can be helpful for researchers who conduct replication studies to analyze generalizability and population differences. Note that all participant demographics reported do not necessarily have to be linked to the study results one by one because such brute-force linking entails conducting numerous statistical tests to achieve the desired p-value and creates misleading interpretations (called p-hacking).

How and where participant demographic information was described were fragmented in many papers, so researchers (readers of these papers) may spend a lot of time searching for the relevant descriptions. Moreover, many papers provided some information but not clear and insufficient descriptions (please see frequent examples in Section 4.1). A straightforward approach for researchers to recognize the reporting of participant demographics is using a checklist or uniform format. For example, NeurIPS, one of the top AI conferences, has introduced a checklist for reproducibility of AI research [1]. In addition, Distler et al. suggested a self-check format for UPS researchers to provide a clear understanding of risk representation of user studies [30]. However, for recognizing and reporting participant demographics, such an approach needs a more careful discussion in the research community because it may (i) simplify sensitive issues in recognizing participant demographics or (ii) create a threat to the safety of at-risk populations. In the first case, researchers require careful consideration when recognizing certain demographics, e.g., asking transgender people about their recognized gender or asking people living in areas that cannot be clearly defined because of conflict zones or territorial disputes about their countries of residence. To avoid these issues, researchers should provide sufficient options for a broad range of individual expressions of identity. In the second case, researchers require measures to protect the physical/digital safety of at-risk populations (e.g., political activists and survivors of intimate partner abuse/violence). Bellini et al. summarized the practices of protecting at-risk populations' privacy and physical/digital safety against reidentification before, during, or after the research; representative practices include omitting details of research procedures and demographic information [15, 62]. Therefore,

the UPS community also needs to understand the reasons for not clarifying information associated with participants' identities when participants belong to at-risk populations.

5.4 Geographic Barriers

The skew toward Western participant samples in the UPS papers is related to the facts that the majority of authors are affiliated with institutions in Western countries and that authors tend to recruit participants from the countries of their affiliations as mentioned in Section 4.4. Geographic barriers may cause researchers to find the most *convenient sample* (e.g., students of the local university who are easy for university researchers to recruit). Online methods can be used as a promising approach to overcome geographic barriers. Our results demonstrated that crowdsourcing is the common method to recruit participants outside of authors' countries. However, note that there is also a skew in the participant pool in popular crowdsourcing platforms. Although crowdsourcing platforms such as MTurk, Prolific, and Clickworker are often used to recruit participants as end users, these platforms basically had Western workers, and researchers cannot reach people living in outside of the West, e.g., Asian countries as well as the Global South. Thus, to overcome the aforementioned geographic barriers of participant recruitment, researchers should consider using local (regional) crowdsourcing platforms used in the country of the target population. On the other hand, online methods have a major weakness: only people with Internet access and some familiarity with information technology can participate. This is a more serious problem in the Global South. As a complementary solution, we recommend improving the researcher diversity and collaboration with local researchers, as mentioned in Section 5.5.

Recruiting experts through crowdsourcing is generally more difficult than recruiting non-experts (end users). This is because most workers registered for crowdsourcing are non-experts. Even in this situation, software developers are often recruited online, e.g., Freelancer.com (a crowdsourcing platform for freelance developers), contact lists on source code repositories (e.g., GitHub), and app stores (e.g., Google's Play Store) as mentioned in Section 4.6. Unfortunately, however, the current methods of recruiting software developers have been reported to have several contractual and methodological issues. Danilova et al., whose study was published in 2021, admitted that Freelancer.com rejected their academic tasks of a user study for software developers [28]. This means a mismatch between researchers' "academic" objective and the platform's "business" objective. Furthermore, while some researchers started recruiting software developers by harvesting developers' emails from source code repositories, app stores, and social media, Tahaei et al. pointed out that there is no support for doing large-scale recruitment by harvesting those platforms (at least on GitHub, this harvesting is against the terms of service and privacy policy) [88]. In addition, Danilova et al. and Tahaei et al. pointed out the problem that online recruitment often includes software developers who do not have sufficient development skills to participate in the user study, and they evaluated screening methods to verify whether participants have sufficient development skills [25, 27, 88].

The majority of studies that recruited experts through online methods (e.g., crowdsourcing, source code repositories, app stores, and social media) focused on software developers. However, experts studied in UPS are more diverse and are not limited to software developers, but include system/network administrators, SOC analysts, security experts, and so on. Since such expert populations are hard to find in the current participant pool of crowdsourcing platforms, recruitment methods tend to rely on personal contacts. Although there is currently no groundbreaking method for recruiting experts other than software developers, a platform is desired that can be used without geographical or linguistic barriers and designed with incentives to attract professionals.

5.5 Linguistic Barriers

Whereas the online research mentioned in the previous section can (partially) resolve geographic barriers to recruiting, there are also linguistic barriers to studying non-WERID populations. We suggest approaches to reduce the linguistic barriers in UPS research include (1) enriching the geographic diversity of authors and (2) empowering non-Western researchers.

Although English is used as a national language in many countries, non-native English speakers account for the majority of the world's population, and there are many countries where English proficiency is not sufficiently high [31]. Linguistic barriers resulting from the use of different languages in various countries significantly impact the localization of research within a single linguistic community (Section 4.4). Linguistic barriers become apparent following two cases: when (1) participants and researchers and (2) documents and researchers have different native languages. For the first case of participants and researchers, especially in user studies that require immediate communication, the researchers have difficulty correctly communicating the intention of the study to the participants and to understanding the intended meanings of their responses. In fact, the results in Section 4.4 suggested that authors were more likely to conduct surveys than lab studies or interviews when they recruited participants from other countries. Dell et al. evaluated the difference in participants' response bias due to demand characteristics between a local interviewer and a foreign researcher with a translator [29]. Their results demonstrated that the bias towards the artifact of the foreign researcher was greater than that of the local interviewer. Therefore, the difficulty in conducting interviews with people speaking other languages can be a serious problem in human factor research including UPS. For the second case of documents and researchers, although understanding online public advice, policies (e.g., privacy

policies), and user posts on social media[8] is important work in the UPS field, such documents written in foreign languages are difficult for researchers to correctly analyze. Redmiles et al. suggested the key challenge in prioritizing security and privacy advice through their large-scale analysis of the advice on the Web [76], while the obtained results were inherently constrained to English-language advice owing to the advice collected from MTurkers, mainly consisting of workers from English-speaking countries, including the U.S. In their analysis of online phishing advice, Althobaiti et al. explicitly stated the linguistic limitation; they restricted their investigation to webpages from limited countries to avoid heavy reliance on automated translation [11]. When English-speaking researchers conducts a study in a non-English-speaking country, they should preferably work with a researcher who is a native speaker of the language of that country. From the viewpoint of studies in non-English speaking countries, especially in the Global South, researchers may incur additional costs to translate the participants' responses or documents into the publication language (i.e., English). To reduce these linguistic barriers, the UPS research community should facilitate cross-national authorship and consider linguistic support, including cost sharing.

The diversification of conference locations is expected to not only facilitate collaboration among researchers by increasing the number of diverse conference attendees [63] but also foster and strengthen local (e.g., non-Western) researchers by stimulating local research communities and technology transfers. In UPS, however, most conferences have been held in limited locations. S&P, NDSS, and SOUPS have never been held outside the U.S., USENIX Security has been held mostly in the U.S. and once in Canada, and CCS has been held almost exclusively in the U.S. and Europe (it was held in South Korea only in 2021).

5.6 Research Justice Considerations

Research justice is a concept and method that articulates and ensures fairness, equity, and ethical considerations in research, particularly in community-based collaborations, including non-WEIRD populations. It addresses power imbalances, promotes inclusivity, and respects marginalized populations' or individuals' rights and interests. Haelewaters et al. criticized "helicopter research," where Global North (i.e., richer globalized countries such as Western countries) researchers make roundtrips to the Global South to conduct their research with little to no involvement of local collaborators, highlighting it as a prime example of harming research justice [39]. Haelewaters et al. proposed rules for avoiding helicopter research for better, collaborative, and non-colonial science between the Global North and the Global South. The rules mainly include equal and synergistic collaborations with local researchers/collaborators/communities, being ethical and fair about publications and authorship, recognizing differences in work culture, and using local infrastructure. These rules are also related to our suggestions: improving researcher diversity and collaboration with local researchers (Sections 5.4 and 5.5), fostering and strengthening local researchers by stimulating local research communities and technology transfers (Section 5.5), increasing the diversity among PC members with knowledge of non-WEIRD societies/populations (Section 5.2), and using local crowdsourcing platforms (Section 5.4). When facilitating research on non-WEIRD societies/populations, the UPS community needs to embrace Haelewaters et al.'s rules as the principles of research.

[8] The papers that analyzed only online public data without a user study were out of the scope of our literature review.

5.7 Future Research

In Section 2.2, we presented how WEIRD skew would harm UPS research. Here, we discuss the promising areas of future research in USP, highlighting the undisclosed facts and unsolved challenges based on our literature reviews.

WEIRD perspective. Our results demonstrated that the participant samples were skewed toward Educated, Industrialized, Rich, and Democratic (EIRD) countries as well as Western. With respect to "Western," we found Western skew in UPS papers on any topic. Among these papers, participant samples that investigated experts (excluding developers) were particularly skewed toward Westerners. While the papers that focused on developers investigated non-Western participant samples to some extent as mentioned in Section 4.6, experts are more diverse, including system/network administrators, SOC analysts, and CSIRT engineers. In software development, organizational structures varied across countries and generated different organizational constraints [51]. This fact implies that organizational and cultural issues are a promising direction to study various types of experts in non-Western countries. With respect to "Educated," studying only educated countries is not sufficient because Global South countries face several challenges in the development of cybersecurity education. Cybersecurity education in the Global South is generally elementary [21], and individual participants' education level was found to be a significant factor influencing participants' security and privacy behaviors in general [71, 96, 102]. Researchers should clarify what kind of security and privacy education and advice people in the Global South are receiving and make efforts to narrow the digital divide regarding security and privacy education between the Global South and Global North. With respect to "Industrialized" and "Rich," some studies have already focused on the security and privacy concerns of people in the Global South, where people have limited IT resources, e.g., concerns regarding device sharing, and developed support technology for them [9, 14, 78]. Researchers should investigate whether support technology is actionable in other countries and regions with lower levels of industrialization and wealth. With respect to "Democratic,"

some studies indicated that people in countries with little political freedom perceive their privacy differently than people in other countries [100]. This democratic difference may affect the study result of the topic of "access control and privacy preferences": participant samples of this topic were particularly skewed toward Westerners as mentioned in Section 4.6. When conducting a user study with potential participants in politically repressive regimes, researchers should consider and overcome difficulties in recruiting methods and study methods, as well as the ethical issue of potentially putting participants at risk due to their criticism of the government. The research practices for protecting such at-risk participants are introduced in Section 5.3.

Design evaluation. Although some cross-cultural comparisons of user perceptions, concerns, and practices have been conducted in the UPS field, those of design evaluation have been insufficiently investigated. In the HCI and psychology fields, user preferences on interface design and framing are known to vary across countries [50, 60, 65]; therefore, more differences across countries in the usability of security/privacy interfaces and the effectiveness of framing, such as text and icons on the notification that encourage users to adopt a security technology, should be identified to design interfaces tailored to each country's users.

More diverse non-WEIRD societies/populations. Broadening geographic diversity is a vital factor in fostering UPS growth; nevertheless, there is a pitfall in the measure of the percentage of non-Western participant samples. If more papers studied India and China, which have already been studied to some extent (the fifth and sixth highest number of participant samples, respectively), the percentage of non-Western participant samples would increase; however, there are still many non-Western countries in Africa, South America, and Asia that have not been studied in the last five years (please see Section 4.1). The UPS research community should strive to understand more diverse countries.

5.8 Limitations

Measurement errors. While some measurement errors are inevitable in manual analysis, we have tried to make our literature-review procedure as clear as possible to ensure coding precision. Our dataset will be available to researchers upon request to improve reproducibility and facilitate replications of our study.

Conference coverage. Our dataset (ten conferences, N=715) is much larger than the recent representative literature-review papers in UPS (five conferences, N=284 in [30]). Our dataset covers top-tier and competitive conferences in which UPS papers are presented and that highly influence many researchers and societies globally. Understanding the WEIRD skew of such conferences would be a reasonable first step. Note that papers concerning non-WEIRD countries are also presented at region-focused conferences (e.g., AfriCHI), which are not included in our dataset.

Exclusion of papers that analyzed online public data. We focused on the UPS papers in which the authors recruited participants for user studies, and we did not focus on the UPS papers in which the authors analyzed online public data. We are concerned that such UPS papers are also skewed towards Western societies, i.e., researchers investigated design and policies implemented on Western online services and online content posted by Western users.

Limitation of WEIRD framework. Most indicators of the WEIRD framework[9] assume representative population demographics in each country. However, in general, individuals within the same country are diverse. For example, even if the participants are from poor countries, they may be personally wealthy. Moreover, online methods can easily recruit people with Internet access and some familiarity with information technology, as mentioned in Section 5.4. In addition, low-income people in Western countries remain valuable for the UPS community. However, we were unable to quantify the papers on such people because few papers reported their participants' income levels.

Other indicators of the diversity dimensions. The five indicators of WEIRD are just a subset of the diversity dimensions that are considered in human factor research [44]. UPS researchers should consider various kinds of diversities beyond WEIRD. For example, Hofstede's cultural dimensions framework includes promising indicators. We additionally analyzed our dataset in terms of that framework (please see Appendix B). Future research is needed to comprehensively capture the diversities that influence UPS research.

6 Conclusion

The goal of this study was to understand the geographic diversity of recruited participants in usable privacy and security (UPS) and the characteristics of the methodologies and research topics. Throughout our comprehensive literature review of 715 UPS papers, we unveiled that UPS papers are highly skewed towards Western participant samples (78.89%). Unfortunately, this skew is higher than that in human-computer interaction (HCI; 73.13%). Moreover, the percentage of non-Western participant samples in UPS papers between 2017–2021 decreased (25.00% to 20.77%, 0.83x). This implies that more significant efforts should be made in UPS to address this geographic diversity issue. We provided the recommendations for making UPS research less WEIRD (Western, Educated, Industrialized, Rich, and Democratic): facilitating replications, addressing geographic and linguistic issues of study and recruiting methods, and setting future research topics. We hope that our findings and recommendations encourage the growing UPS community to further diversify and become more inclusive.

[9] Indicators of E and I use both national averages and individual figures.

Acknowledgements

We would like to thank Sebastian Linxen, the author of the original study (the Linxen study) [59], for the advice on our replication efforts. We also thank the anonymous reviewers and shepherd for their insightful and invaluable feedback.

A Coding of Participants' Countries

Figure 3 presents a flowchart of for identifying the participants' countries. The participant sample in each user study was divided into "Identified," "Inferred," or "Not identified."

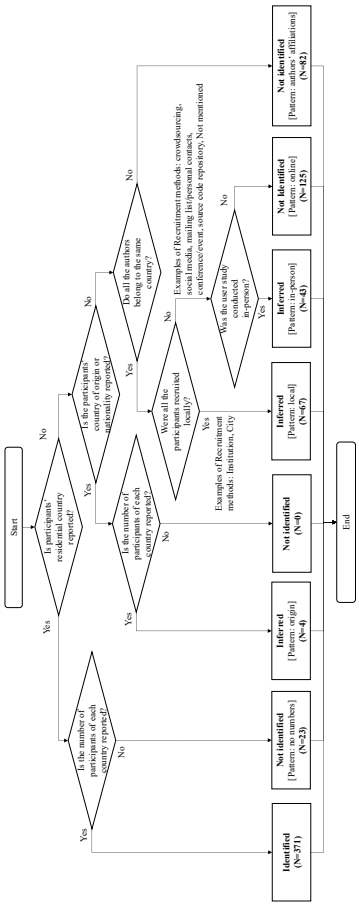

Figure 3: Flowchart to identify or infer participants' countries.

B Hofstede's Cultural Dimensions

We performed the additional analysis using Hofstede's cultural dimensions framework [45, 49]. This framework is used for understanding cultural differences and consists of six cultural dimensions, as shown in Table 13. Although the framework cannot explain all cultural differences, we believe that these dimensions are relevant to UPS research. For example, countries with higher power distance exhibited significantly higher levels of government involvement in regulating information privacy [23, 64]. As for information disclosure on social media, Trepte et al. [89] focused on the conflicting findings of the prior studies: (1) people from individualistic cultures are more likely to avoid privacy risks, and (2) people from collectivist cultures are more likely to avoid them. Their result supported the latter findings. As for phishing, Butavicius et al. demonstrated that users from individualistic cultures were significantly less likely to be susceptible to phishing emails [18].

We collected six dimension scores per country [49] and calculated the correlations between countries' $\psi_{samples}$ and each indicator of a cultural dimension. We found that $\psi_{samples}$ has a negative correlation (r =-.44, p <.001) with power distance and a positive correlation (r =.43, p <.001) with individualism. That is, most participant samples in UPS papers come from individualistic cultures that have equal distributions of power. Considering the findings of prior studies and our analysis, we highlighted that most UPS papers may have investigated people primarily from countries whose residents are more likely to disclose their information on social media and are less likely to be phished.

Table 13: Correlations of ψ_S with cultural dimensions.

Security and Privacy Software Creators' Perspectives on Unintended Consequences

Abstract

Security & Privacy (S&P) software is created to have positive impacts on people: to protect them from surveillance and attacks, enhance their privacy, and keep them safe. Despite these positive intentions, S&P software can have unintended consequences, such as enabling and protecting criminals, misleading people into using the software with a false sense of security, and being inaccessible to users without strong technical backgrounds or with specific accessibility needs. In this study, through 14 semi-structured expert interviews with S&P software creators, we explore whether and how S&P software creators foresee and mitigate unintended consequences. We find that unintended consequences are often overlooked and ignored. When addressed, they are done in unstructured ways—often ad hoc and just based on user feedback—thereby shifting the burden to users. To reduce this burden on users and more effectively create positive change, we recommend S&P software creators to proactively consider and mitigate unintended consequences through increasing awareness and education, promoting accountability at the organizational level to mitigate issues, and using systematic toolkits for anticipating impacts.

1 Introduction

Security and Privacy (S&P) software is created to protect users from attacks, guard their privacy, and keep their communication confidential. However, technology may have unintended consequences that harm users, non-users, or society [1]. *Unintended consequences* are unforeseen outcomes of purposeful actions—classified as unexpected drawbacks, perverse results, and/or unforeseen benefits [2]. For security and privacy software, unintended consequences can include propagating misinformation [3], using the software for criminal activities [4] such as the proliferation of child sexual exploitation [5], and excluding certain users. For example, a lack of accessibility can exclude or harm users with disabilities, children, older adults, activists, non-Western populations, victims of intimate partner abuse, and other vulnerable groups [6]; privacy browsers not considering the privacy needs of users requiring assistive technologies can inadvertently put these users at risk [7], [8]. Identifying unintended consequences of software can be very complicated [1], and software creators frequently struggle to address the diverse needs of their users [9]. Researchers and communities have been working to effectively anticipate unintended consequences since before the spread of computers [2].

While the Human-Computer Interaction (HCI) community studies unintended consequences and harms in the broad context of software [1], [10], there has only been limited focus on S&P software [11], [12]. We argue that it is worth studying the unintended consequences of security and privacy software, particularly for the following reasons: Users explicitly trust these tools to protect and handle sensitive information and data. Even minor unintended harms can majorly impact users' privacy and security, which may risk their lives and safety, or they might abandon the tools and their benefits—putting them at more risk. Developers of this software typically exhibit strong values and care deeply about their users' safety. Therefore, the criticality of considering unintended consequences in security and privacy software cannot be overstated.

Ethics frameworks [13], toolkits [14]–[16], and checklists [17] have been proposed to help software teams systematically anticipate and consider unintended consequences during software development: In particular, the HCI and Artificial Intelligence (AI) communities have explored assessing unintended consequences through toolkits [14], [15], [18], [19]. These toolkits categorize consequences that may emerge from the use of technology and are supposed to help organizations analyze the potential for unintentional consequences arising from their software. Aspects including misinformation, inequalities, biases, addiction, distraction, accessibility, surveillance, and risks through harmful actors are addressed in these frameworks [13], [16], [18], [20]–[22]. While these toolkits seem promising, it is unclear whether they are effectively used to mitigate unintended consequences in S&P software.

We address a gap in our understanding of whether and how S&P software creators identify and mitigate unintended consequences and systematically address issues during development. For this, we conduct an interview study with 14 creators (we use this term throughout to include developers, CEOs, designers, industry researchers, and maintainers) involved in the development of user-facing and developer-facing security and privacy software (such as, e.g., VPNs and secure messengers) to understand if and how they consider and mitigate unintended consequences of their software. Furthermore, we investigate the attitudes and perceptions of S&P software creators toward their software's purposes and unintended consequences. For this research, we define security and privacy software as software developed specifically for security and privacy purposes, with core values centered around security and privacy, and software developed to replace existing software in a more secure and privacy-preserving way.

The research questions that guide this study are as follows:

RQ1: *What are the attitudes and practices of S&P software creators concerning unintended consequences of their software?* We investigate motivations for developing S&P software, the software's purpose, the users it serves, and how the creators engage with users to understand their needs and expectations.

RQ2: *What unintended consequence of S&P software do S&P creators anticipate, how do they reason about them, and how do they mitigate them?* We explore unintended consequences creators of end user-facing security and privacy software anticipate. We investigate their reasoning for what they consider important, which unintended consequences they address and how, and which they do not address and why not.

RQ3: *What are facilitators and blockers in (systematically) considering and addressing unintended consequences?* We explore how systematic assessment can be facilitated and how (lack of) knowledge and collaboration can impact the consideration and resolution of unintended consequences.

We find that S&P software creators are motivated to create a positive impact on their users, but they do not systematically anticipate and mitigate unintended consequences. Their primary focus is on privacy and security-related aspects, while other consequences that can harm or exclude some users are considered anecdotally based on personal interests and experiences within the development team, if at all. Some significant challenges that limit considerations of unintended consequences include a lack of organizational support, a lack of awareness and knowledge, and a lack of formal roles and responsibilities to consider unintended consequences.

2 Related Work

We discuss related work in three key areas: (1) unintended consequences of S&P software, (2) frameworks and tools helpful in anticipating and mitigating unintended consequences, and (3) studies with developers and software professionals. While our research focuses on unintended consequences of S&P software, the concept of considering unintended consequences is often discussed and addressed in the related work as "ethics" or "ethical impacts" [10].

2.1 Unintended consequences of S&P software

S&P software is designed to provide useful solutions to security and privacy problems but may have drawbacks caused by oversights in issues like accessibility or usability factors or due to misuse by malicious actors. Below, we provide instances of harm that can be caused by S&P software.

Access barriers. Traditional anti-virus companies offer anti-stalkerware software, but their high costs, ranging from $5 to $100, and compatibility issues with different operating systems make them inaccessible to many users [23]. While VPNs are promoted to increase privacy online, low-cost ones suffer from low adoption rates among non-tech-savvy users, and others have high costs that make them inaccessible to a broader audience [24].

Misleading marketing and non-disclosure. In a 2022 study, Akgul *et al.* found that VPN companies use misleading marketing strategies with social media influencers to attract users [25]. Their ads included exaggerated claims about online safety beyond what VPNs are capable of, misleading novice users into choosing their services based on false promises. Fassl *et al.* found that anti-stalkerware apps did not detect all vulnerabilities users expected based on the apps' presentation and may, therefore, deceive users and leave them unprotected [23]. False marketing and not disclosing software capabilities can lead users to trust the software too much, which may result in compromised security.

Accessibility issues. Studies highlight that security solutions sometimes do not consider disabilities. In particular, people with visual impairments find it hard to access websites that require authentication technologies [7], [8]. People with dyslexia often struggle with creating and remembering unique passwords [26]. This issue can be exacerbated if the password manager is incompatible across devices, preventing them from saving passwords on different devices [27]. A lack of consideration of disabilities in security & privacy software design might push people with disabilities to resort to less secure alternatives [8].

Usability issues. Research shows that usability problems can prevent using security and privacy technology effectively. For example, unsolved or undetected usability issues can cause an increase in cognitive load, frustration, and even security vulnerabilities like password exposures [28] or unencrypted communication [29]. A 2021 Huaman *et al.* study illustrates usability problems with the compatibility of password managers across different websites and devices that may impede adoption [30]. Another 2021 study demonstrated that cryptographically secure technologies come with usability issues for

users who do not have the necessary knowledge to use them, which can lead to a lack of adoption of such technologies [5].

Stalking, abuse, and harassment. Anti-theft tracking and child tracking software that can be downloaded from the app stores can be used for harmful and abusive purposes like spying and stalking people [31]. Previous literature also shows how technology can be used to perpetuate Intimate Partner Violence (IPV) through surveillance [32], doxxing [33], cyberstalking [34], and other means. A common approach taken by abusers is to install stalkerware on their victims' phones [23] or use AirTags to track their victims' location [35]. Privacy Enhancing Technologies (PETs) are sometimes used to perpetrate crimes like the distribution of imagery of child sexual abuse [4]. Wei *et al.* identified instances of advice being circulated on social media that suggest ways to use technology, which is created with positive intentions such as accessibility features, to secretly monitor individuals without their consent, thereby violating their privacy and security [36].

Harms to vulnerable groups. In some cases, members of marginalized communities are disproportionately impacted due to S&P violations [6], [37], [38]. Research also highlights the importance of designing with the needs of marginalized groups in mind, for example, considering factors like language barriers, digital literacy, and access to technology [39]. A growing area of research in the S&P community focuses on identifying the needs of vulnerable and/or marginalized populations, like IPV survivors [40], refugees [39], activists [5], and sex workers [41].

2.2 Considering Unintended Consequences

Prior work explains that neglecting considerations of unintended consequences during development can cause tragic failures [9]. It suggests considering the worst possible impact of the software during the development phase to deliver ethically sound systems. In the following, we discuss how this might be accomplished.

Tools used to anticipate unintended consequences. Toolkits (also called "frameworks"; we use the term "toolkit" throughout this paper for consistency) are commonly suggested to anticipate and address unintended consequences systematically. In the privacy space, privacy frameworks such as Privacy by Design [42], Fair Information Practices [43], and Privacy Impact Assessment [44] primarily focus on preserving the privacy of individuals. They generally do not address other unintended consequences for security and privacy software. For instance, enhancing privacy for a single group can harm others, as in the case of refugees who had difficulty answering security questions due to cultural differences, which led them to create less secure answers [39]. Similarly, the very possession of privacy browsers or downloading certain end-to-end encryption messengers may incriminate people in some countries [45]. To gain a holistic view of harms that can arise as a result of software use, ethics frameworks [13], toolkits [13], [16], [18], [20]–[22], and datasheets [20]–[22] have been proposed. These assessment tools cover a more comprehensive range of issues that can occur due to software use, including biases, discrimination, lack of accessibility, and more. While there are also other methods like value sensitive design [46], speculative design [47], and inclusive cards [48], these methods have been criticized for overclaiming universal values and for undermining user voices due to the assumed authority of the development team over users [49]. Concurrent work analyzed 27 AI-ethics toolkits, criticizing their technology-centered design and the neglect of organizational and power dynamics [50]. Our interview guide is informed by topics we extract from nine toolkits to identify common software harms addressed in S&P software. While we hypothesize that these toolkits can expand awareness of unintended consequences beyond privacy issues, we are also interested in impediments to addressing the unintended consequences creators discuss in our interview study.

Navigating unintended consequences in software development. Several factors affect how unintended consequences and software harms are handled during the development process. Organizational climate plays a significant role in developers' ethical awareness and behavior [51], and organizations need to foster an environment to identify and address unintended impacts [52]. Technologists may show little enthusiasm towards ethics [53] (a finding that our study does not corroborate), and software issues are often only addressed on a legal compliance level [54]. Developers may lack expertise and knowledge in areas surrounding their field of expertise [54] due to insufficient awareness, time, and resources [55], which may also contribute to unintended consequences. Team diversity also affects how unintended impacts are assessed [56]. Previous research highlights the lack of diversity in the vulnerability discovery community, noting that it is predominantly dominated by white and Asian men [57]. The study uncovers unique challenges marginalized populations face, revealing the need for more inclusivity in security. Our work extends this conversation to the role of diversity and other factors that influence anticipating unintended consequences during the development of S&P software.

Previous studies have highlighted the importance of education and awareness in developing ethical software and protecting end users from unintended consequences [58], [59]. However, research shows that software developers receive little to no ethical training in classrooms [56]. In a study conducted with students studying AI, students were not inclined to think about the implications of AI technologies. When they considered the impacts, it was centered on personal experiences. This study suggests that it is vital to consider integrating ethics education into the computer science course curriculum to support their future considerations of ethics in AI learning [56]. Further, Do and Pang showed that computer science researchers tend to overlook unintended consequences of their research for many reasons, including the lack of for-

mal processes, fast-paced academic publishing process, and reliance on Institutional Review Boards (IRB) to point out issues [10]. In our study, our objective is to determine attitudes and processes that help or hinder anticipating and mitigating unintended consequences during the development of S&P software.

2.3 Expert Studies

Here, we examine previous research conducted with software professionals and our methodology is informed by best practices from prior work.

Interviews with software experts. Interview studies have been used in the past to gain deep insights into the work, processes, and mental models of experts [52], [60]–[63]. For instance, several studies illustrate that interviews are an effective method to understand the processes and challenges of developers [64]and organizations [65]. Similarly, we will use interviews to identify S&P creators' considerations of the impacts of their software during the software development process. We focus on creators of S&P software, like developers, designers, researchers, and executives involved in the development, as these experts share a vision to create positive impacts by improving security and privacy.

3 Methods

We conducted 14 semi-structured expert interviews with creators involved in the development of S&P software; interviews lasted just under one hour on average. In this section, we explain the methodology of our study, including the development of the interview guide, recruitment process, data collection, analysis, ethical considerations, and limitations.

3.1 Instrument development

Analysis of toolkits to anticipate unintended consequences of software. We developed our interview guide by analyzing nine toolkits that identify themes related to potential negative consequences and ethical impacts of technology, which we call *unintended consequences*. We used the Affinity Diagramming approach [66] to identify common aspects covered in these toolkits, which we draw from previous work discussed in Section 2. These toolkits are generally lists of questions or checklists to help technology developers anticipate unintended consequences, such as misuse of technology and broader ethical issues. We identified and analyzed ethical technology assessment toolkits from Human-Computer Interaction (HCI) literature [19] such as the *Ethical OS Toolkit* [14], the *Digital Impact Toolkit* [15], and *Ethics and Algorithms Toolkit* [16]. We also analyzed frameworks and datasheets for software development, including the *Data Ethics Framework* from the UK government [13], the *European Union Guidelines for Trustworthy AI* [20], *ACM Code of Software Ethics* [22], *World Economic Forum Ethics for Responsible AI* [21], and *Japanese Society for AI Ethics Guidelines* [67]. We stopped analyzing toolkits when we reached topic saturation [50], [68]; concurrent work by Wong *et al.*
The first part includes topics around *ethical and societal consequences* such as barriers to access, biases, accessibility issues, disempowerment, misinformation, addiction, distraction, physical and mental health, environmental impacts, and human rights violations. The second part addresses *data privacy and security risks* such as security measures, protection of user data, data governance, tracking, and surveillance. We used these aspects as probing questions to guide participants in considering potential unintended consequences and whether they addressed them during development.

Development of interview guide. Two authors crafted the interview guide's initial version based on our research questions and toolkit analysis. We went through several iterations and brainstorming sessions to improve the quality of the interview questions. After receiving feedback from a third author, we refined the guide before conducting pilot interviews. The complete interview guide is available in Appendix A.

The final interview guide consists of questions in four key areas: (1) *About the software, motivations, and vision*: Here, we focused on details about the software; we were particularly interested in the core values of the software and the key problems creators intended to solve. (2) *Users and non-users:* Here, we asked participants about their primary users, bystanders, unintentional users, and non-users and how the software was designed to suit users' needs. (3) *Unintended consequences:* they anticipate through the use of their software: here we were specifically interested to learn about how participants thought their software impacted their users and non-users. We started this section with open questions, where participants mentioned the consequences they thought of or had considered previously, both positive and negative. Later, we probed about the themes identified in our toolkit analysis to understand whether participants considered these aspects in their development process. In this section, we also asked about their security and data privacy considerations. (4) *Processes for mitigating consequences:* Here, we asked about the structure of the development team and their organization, and who is responsible for mitigating unintended consequences. We were also focused on the current processes, tools, and resources that support or hinder them in identifying and mitigating unintended consequences.

3.2 Interview procedure

For our study, we interviewed a total of 18 participants, of which 14 were eligible; two participants were removed, as we identified their software as out of scope after the conclusion of the interviews, two were obvious scammers. Valid interviews lasted an average of 57.35 minutes.

Pilot study. We piloted our interviews to evaluate the interview questions' validity, comprehensibility, and language. We conducted four pilots: two with professional colleagues not involved in this project and two with software creators from another industry. We used the feedback to add examples and details to questions that were unclear to our pilot participants.

Recruitment. For this study, we recruited participants involved in the creation of user-facing and developer-facing security and privacy software. For example, we included privacy-preserving browsers and secure messengers. Our recruitment process targeted diverse roles in the development process, such as CEOs, researchers, designers, front-end and back-end developers, and engineers. We recruited S&P software creators through personal and professional networks; we additionally used snowball sampling to recruit other experts that our participants knew in other relevant companies. Once we exhausted professional contacts, we resorted to social media. We posted a recruitment message on then-Twitter seeking potential participants. We also cold-emailed developers who contributed to S&P projects on GitHub and in S&P groups on Slack. For social media recruiting, we initially asked participants to fill out an eligibility survey, which can be found in Appendix A, and invited those who qualified for the actual interview; both scammers were recruited through social media.

Interview process. We conducted all except two interviews on Zoom; two interviewees preferred to use our self-hosted Jitsi instance instead. We generally conducted the interviews in lead-interviewer configuration, in some cases joined by a backup interviewer. Participants were given an option to opt-in for an $80 Amazon voucher as compensation for their participation in the interviews, unless they waived it. Interviews were all conducted in English. All interviews except one were recorded and transcribed by a GDPR-compliant service. For accessibility reasons, one of the participants preferred to switch between chat and voice call, so we transcribed one interview ourselves using the chat messages and the notes we took during the interview. Participants received informed consent forms before the interviews, and we also obtained verbal consent to record before starting the interviews.

Ethical Considerations. This study was approved by our university's IRB. We de-identified any personally identifying data of our participants as much as possible. We only collected their email addresses if they opted-in to receive an $80 gift voucher for their participation, or if they wanted to be mailed a copy of our results which they will receive if requested. Apart from optionally provided email addresses, all the other personal data is associated with random identifiers. We also ensured that we masked details about their companies, coworkers, or direct competitors they mentioned in our transcripts. Given that we probed participants to think about the negative consequences of their software during the interviews, we ensured that they could refrain from answering questions if they were uncomfortable to avoid reputational harm to their employers. We also made it clear to them that they could decline to answer questions or withdraw from the interview at any time.

3.3 Data Analysis

We used open coding to analyze interview transcripts qualitatively [69]. Two researchers independently coded all the transcripts, regularly met, and iteratively built a codebook by combining their interpretations of the data, the codebook is attached to Appendix C. We also regularly discussed the codes with the rest of the research team for feedback and consensus on naming conventions. By double-coding all transcripts, we actively resolved disagreements and, therefore, did not calculate the intercoder agreement [70]. Finally, the entire research team collaboratively worked together to identify clusters and generate themes within the coded data; themes are available in Appendix B. We use these themes to report our results and guide discussion points and future research directions. We fully developed themes using the first 12 interviews—these themes remained stable for the last two interviews—for major themes, we reached thematic saturation [71]. Due to the nature of the differing software and experiences, interesting insights emerged with every new interview but did not change major themes.

3.4 Limitations

This paper presents the results of a qualitative study and therefore shares limitations inherent to qualitative research, such as limited generalizability. Participants were mostly recruited by purposive sampling, using personal and professional contacts. As a result, most participants have a similar background and are mostly from the US and the EU. Once we exhausted our contacts, we resorted to recruiting on social media. Recruiting from then-Twitter and Slack resulted in many scammers signing up for the study. To filter out scammers, we only chose participants who signed up with their professional emails. We discarded the data of two participants who provided generic responses throughout the interview, identifying them as scammers. Generally, recruitment was difficult and drawn out, as we were focused on an expert population of creators of S&P software. As in any study, participants over-reporting their ethical considerations due to social desirability could bias their answers—and, consequently, our results.

4 Results

We find that participants do anticipate some unintended consequences but do not *systematically* anticipate or mitigate them. We report our findings in four areas: First, we provide an overview of participants, the S&P software they develop, and who they consider (non) users (Section 4.1). Second, we present participants' (lack of) practices and motivations for

Table 1: Participants' Roles and Type of Software.

P.No	Role	Software
P01	Lead Developer	Secure Messaging
P02	CEO	Password Manager
P03	Backend Developer	Encrypted Email
P04	Sole Developer	Software Release Signing Tool
P05	Researcher	Stalkerware Detection
P06	Maintainer	Social Network
P07	Executive Director	Anonymity Network
P08	Core developer	VPN
P09	Developer	VPN
P10	Researcher	Browser
P11	Privacy engineer	Browser
P12	Software/UI developer	Secure Translation
P13	Design Lead	Encrypted Office Suite
P14	UX Designer	File Sharing and Collaboration

Table 2: Participants' Gender, Experience, and Organization Size.

Gender		Years of Experience		Size of Organization	
Women	3	< 5 years	1	< 10	5
Men	9	5 - 10 years	3	10 - 100	7
Non-binary	2	10 + years	10	100 - 1000	1
				1000 +	1

anticipating unintended consequences (Section 4.2). Third, we explore which unintended consequences are (not) considered (Section 4.3). Finally, we present the factors that help or hinder development teams from anticipating and mitigating unintended consequences (Section 4.4).

4.1 Participants, S&P software, and their users

Here, we describe our study participants, the S&P software they create, and the user population they report.

Participants. We interviewed 14 valid participants involved in developing 13 different S&P software projects, including VPN, secure messaging, and security- or privacy-focused browsers. An overview of the roles and software types is in Table 1. We interviewed participants involved in the development team in technical roles like developers, designers, engineers, researchers, and those responsible for overseeing the product in roles like executive directors and CEO. We attached our screening criteria in Appendix A. Most participants were men, three were women, and two were non-binary. Participants had varying years of on-the-job experience ranging from three to 30 years.

Organization sizes ranged from one-person teams and people who do volunteer work to large organizations with over a thousand employees. An overview of demographics and bucketed organization sizes is in Table 2. Many participants reported that their teams were not diverse and said that their teams constituted predominantly white men. Only one developer stated they had a process to diversify their team: "*[. . .]it's a continuous effort. I wouldn't say we are there yet.*" (P01) A few participants saw their team as relatively diverse concerning ethnicity but not gender. "*Compared to most other development groups, we are pretty diverse in terms of country origins.*" (P01)

Primary, Secondary, and Unintended Users. Most software is marketed towards and adopted by privacy-conscious users. Participants described primary users as privacy-conscious users trying to protect their identities, including special populations like activists, journalists, and people targeted by governments. For instance, Participant P07, who works on the anonymity network stated that their user base included, "*human rights defenders, activists, lawyers, journalists to just a dad who wants the kids to not have the information about what they search online being collected by search engines or a doctor who wants to protect the privacy of their patients as they are browsing[. . .].*" (P07) Some participants revealed that they make special efforts to cater to specific demographics to strengthen their privacy, e.g., the secure messaging software (P01) and a VPN (P08) are primarily used in the global south. Participants P05, P10, and P11 stated they do not target special populations, and their predominant users are in the global north. The password manager's users were mostly corporate employees (P02), and the software release signing software was mostly targeted toward open source developers (P04).

Some participants acknowledged that harmful actors are also among their primary user base. P07 said that their software is used for "*[. . .]illegal content or for illegal activity by selling drugs or other things in that sense,*" and P06 mentioned that their social network "*did have attraction, for example, from ISIS [. . .]*" and "*anti-vax groups.*" We elaborate on this in Section 4.3.3. Bystanders and non-users can also be significantly impacted by software; participants noted that they had not considered the threat models of bystanders and non-users in the development process. For instance, the encrypted email service has cumbersome processes for recipients not on their server, and thus their users resort to sending unencrypted emails: "*[. . .] because then what happens is we create a temporary mailbox for the external user, and they have to log in with a pre-shared password, and then the user can see the email.*" (P03)

Given that S&P software caters to a wide spectrum of users, ranging from regular users to criminals, harm can proliferate via multiple modes, from adversarial actors using the software to non-tech-savvy users being unable to use the software. In the next section, we will look at how participants currently foresee unintended consequences.

4.2 Practices and motivations for anticipating unintended consequences

Participants are motivated to have a positive impact with their software, especially on security and privacy. Their strong fo-

cus on security and privacy can overshadow consideration for unintended consequences. The focus on the inherent positive impact of the software and user feedback can be limiting, especially without a structured process to identify unintended consequences. In this subsection, we discuss participants' attitudes and current practices for anticipating unintended consequences.

4.2.1 Motivations: privacy, usability, and "doing good"

Privacy-centered development process. Protecting people's privacy was the participants' major focus and the key problem their software is trying to solve; their thoughts on unintended consequences also revolved around privacy issues. In addition to "privacy", "anonymity", "end-to-end encryption", and "security" were also mentioned as core values. Participants highlighted that they specifically work on S&P software to make a positive impact, contributing to a world where people's information is protected and untrackable. For instance, the participants developing the browser and VPN services highlighted that their software solves issues related to tracking and surveillance: "*The key problem is surveillance. Corporations and states do tend to spy upon their customers and citizens*" (P09) and "*Our mission is to advance human rights by building privacy, security, and ordinary technology.*" (P07) Thus, participants indicated that they were motivated to contribute to protecting their users' privacy, but they had not meaningfully considered the unintended consequences of their software.

Creating usable products. Some participants indicated following user-centered processes during development to make security easier for their target users. While striving for usability, some actively involved vulnerable user groups to make products less harmful for them. Some participants acknowledge that security software can be very difficult to use correctly and strive to make it easy for users: Participant P02 stated, "*[. . .] in comparison to the competition, we try to be the easiest password manager.*" In order to achieve usability, participants specified using techniques like testing new features with beta users (P10), using personas for development (P01), co-designing and testing with the target population of their software: "*[. . .]the same is true with other Global South countries. We also try to do our development physically in these environments as much as we can.*" (P01) Participant P11, who reached out to IPV survivors during development, emphasized that not involving affected users can cause more harm than good: "*[. . .]we're trying to talk to folks who actually work in cases of domestic abuse, there are some centers. I want to make sure that the solutions that we're coming up with are in collaboration with them so that it actually helps and doesn't end up harming even more because we have some insight or some folks on our team have some insight, but we need more data.*" (P11)

Personal interests and experiences drive them to create a positive impact. In addition to the privacy-protecting values of the software, some participants stated that they were intrinsically motivated to develop ethically sound software, have a personal interest in ethics, and think about how their technology can harm people. Participants P02 and P11 stated they are interested and driven by a political interest to do good for people, wanting to provide good software for their users. Their personal interest motivated them to learn about ethics (P02) and reach out to marginalized user groups for feedback when designing new features (P11). Participant P05 brings up personal interest:

> "*I often take it upon myself to raise concerns, especially when people start thinking about solving a problem for parents, like: 'Oh, I want to help parents to protect or to monitor their kids', then I have to be like, 'They've got to be careful because that could be used to monitor people that are not kids or things like that'.*" — P05, Stalkerware Detection

Additionally, a few participants mentioned that they adhere to their *inner moral framework*, as P04 explains: "*It's not a scientific endeavor for me. I just want to do what is right in my eyes.*"

In the aforementioned themes, we find that participants were enthusiastic and wanted to contribute positively to their users, however, they inadvertently overlook other harms that may occur due to their focus on mostly privacy and usability. In the following section, we explore their current software development practices and how they lead to an oversight in anticipating unintended consequences.

4.2.2 Current practices: reactive and unstructured

Current practices that S&P software creators follow to avoid unintended consequences currently focus on usability issues and reacting to issues raised by their users. Additionally, there is a lack of formal processes to anticipate and mitigate unintended harms.

Reliance on user complaints rather than being proactive. Participants expected users to bring unintended consequences to their attention, for example, through GitHub issues, product reviews, and customer support. Some monitor product reviews and feedback surveys to identify problems their users encounter: "*[. . .]users continue to contact customer support, they leave reviews for our apps, and we monitor those to see if there are any issues with false positives or any complaints as we release the products and update them and things like that.*" (P05) Participant P04 also mentioned that if users encounter challenges, they can open issues on GitHub. Some participants mentioned monitoring social media channels that they use to interact with users to identify user problems. While user feedback is regularly monitored, sometimes issues may take a long time to fix or the feedback is obtained after harm has already occurred: "*through feedback collection, where*

like we learn about the main pain points our users have and we have. Sometimes they are not easy problems to fix. They may take like a year for us to get some solution out there." (P07) Participant P05 recalled a past incident where they received an uptake in user complaints after releasing a feature that provided warnings in their stalkerware detection software where, in some cases, perpetrators were potentially notified, and users deleted the software.

Fixing usability issues and bugs is the main focus. When talking about unintended consequences that can be detrimental to their users, participants stated that they have anticipated bugs in their code that might affect usability and are well-equipped to tackle usability issues. While usability is a critical aspect that can lead to issues with software adoption and in some cases abandonment, we think that participants overstated usability as the most critical negative impact. Participant P11, who works for a browser, mentioned that users might abandon the product if a website does not work on their browser, which may compromise their privacy: "*If you're browsing your favorite website and in Google Chrome, it works fine because Chrome lets the website fingerprint you and do whatever it wants with your data. But if that same website doesn't work in [browser] now, you will not use [browser], and then you lose out on a bunch of other additional privacy protection.*" Some had dedicated resources and processes to mitigate usability issues:

> "*Of course, there might be bugs in the software, like we might have bugs so that people cannot properly receive messages. We have some reports of those; this can be dangerous, like if you send a message that doesn't arrive on the other side for whatever reason.*" — P01, Decentralized Messenger

While usability was prioritized, unintended harms were sometimes overlooked, which was majorly due to lack of knowledge and resources to proactively consider them.

Lack of formal processes to anticipate and mitigate unintended consequences. A majority of the participants stated that their teams do not have formal processes or toolkits they follow to anticipate unintended consequences. The teams decide on processes depending on what fits them best, like involving collaborators and experts, allowing collaborators to open issues on GitHub, and facilitating discussions within teams. "*Other than us continuously discussing this, there's no procedure in place. Also, there's no checklist that we go through and so on.*" (P01) Participants mentioned that they take a reactive approach. They mitigate issues if users flag potential threats presented by harmful actors, "*[. . .]other than closing abusive accounts, we don't have any other processes in place.*" (P03) Participants mentioned that there were either no formalized processes in place or they were personally unaware of their existence, thereby not accounting for them in their work: "*We don't really use any kind of ethical framework. We don't think about the number of users impacted versus the harm or anything more formalized like that.*" (P11)

4.3 Reasons unintended consequences are or are not considered

4.3.1 Aspects that are ingrained in the software vision

Security. All participants specified that they followed processes to ensure security and keep their software free from vulnerabilities. Most participants stated that they have regular security reviews and follow industry standards to ensure security. Other security mechanisms were embedded in software development: P01 pointed out using Rust to develop the secure messenger and conducting usable security research regularly, P02 uses encryption in their password manager, and P04 also took additional security measures. Participant P03 highlighted that they use a threat model whenever developing a new feature.

Privacy & data protection practices. Most participants report collecting some sort of user data, few collect none. Participant P06 stated that users can use dummy information to signup on their social networking platform: "*if they ask them for like [sic] the name or we ask them for the location, if they want to enter dummy information, that's perfectly fine with us, you know, for the location, you don't do any validation there.*" (P06) Participant P03 mentioned that they allow anonymous signup so that the users need not use a phone number or email to sign up. However, they collect and store IP addresses for a short time. Few participants mentioned trying to collect only the bare minimum amount of data required to use their services. This included the password manager (P02) collecting metadata like "*how many people logged in today,*" a privacy browser (P11) collected minimal data on usage statistics: "*we try to collect the least amount of data and we are pretty good about updating our privacy policy to show all the kinds of data that we collect, so transparency is a goal.*" (P11) All participants mentioned a data protection practice; P02 mentioned that the password manager has a data deletion process, P02 and P10 mentioned they follow GDPR practices, four participants mentioned that they have a review process to ensure data governance procedures, and four participants also mentioned having data privacy officers and legal personnel to conduct reviews. The teams who did not follow constant review practices followed GDPR (2) and got in touch with external experts (1) to ensure good data protection practices.

Some software inherently has a positive impact on users' mental health. Many participants emphasized that their software positively impacts their users' physical and mental health. For instance, the password manager does not require people to remember complex passwords; encrypted email and secure messaging software help keep information secure, and VPNs make people feel "*less watched or surveilled, which can have a positive impact.*" (P09) Participant P11 mentioned

that their browser's ad-blocking could have a positive impact on their users' mental health by blocking disturbing ads: "*it benefits users' mental well-being positively is that we block all ads by default[...]I think users just don't have to see a bunch of really nasty ads across the web.*" (P11)

4.3.2 Prior awareness does not guarantee mitigation

Software is mostly not designed for non-western and non-technical users. While most participants could identify access barriers and biases of their software, many did not consider mitigating them during the development process, and only a few were working on actively making the software accessible to more audiences. Common barriers to access that participants pointed out were: "*low awareness*" (P01) of the product because these products are mostly marketed to the "*sphere of users who are already seeking privacy software or a Western audience,*" (P03) software being too "*technical for some users,*" (P02) high costs for certain populations, OS compatibility, lack of stable internet connections, and language barriers. Some participants were actively making the product available in more languages and/or countries and in more "*precarious situations than the well-resourced Western countries.*" (P01) Additionally, P12 remarked that mistranslations of some phrases in certain languages could harm users.

Making software accessible is not a priority. Few participants had processes in place to design for accessibility. On the lack of processes, they remarked that they either lack resources or have not considered prioritizing accessibility: "*It is not accessibility first in general. Mainly, I would say because of a lack of specific training in the developer community towards these needs.*" (P09) Participant P01 acknowledged that the desktop version of their decentralized messenger has accessibility issues and is not usable for users with visual impairments. A few participants pointed out that they followed best practices for accessibility, but they did not test whether the products worked well. For example, the privacy browser's interoperability with accessibility tools was not tested, e.g., whether the privacy browsers worked with accessibility tools. However, they cannot control how website developers operate. "*Then there are many limited things that we have there in that as a browser we could provide all of these properties that enhance accessibility, but is the responsibility of the website operators to actually use them.*" (P01) Only a few participants indicated that they have specific design teams responsible for accessibility: "*Internally, we have UX researchers and UX designers who are experts on accessibility.*" (P11)

Distraction and addiction are sometimes addressed through design. A few participants (browsers and communication tools) stated that their software was prone to maximizing users' attention. However, to mitigate this problem to a certain extent, the browser and the social network did not display ads, nor were their business models designed to maximize attention. Therefore, P06 mentioned that it depends on how users manage their time, and they "*have no incentive for maximizing your attention on the product*" because there are no ads on the platform.

The encrypted email, secure messaging, and browser participants indicated that their software could distract users. P10 had strategies to limit distractions by limiting ads on their browser. The secure messaging software limits distraction by allowing users to disable notifications. Participant P03, the encrypted email developer, mentioned that mitigation depends on users; however, they default to "non-intrusive defaults."

One participant mentioned that stalkerware warnings can make people anxious:

> "*[...]so if it's not giving any warnings, it gives them peace of mind, if there are warnings, though the warnings could make them more anxious but hopefully for a good reason.*" — P05, Stalkerware Detection

4.3.3 Aspects participants have no control over

Some issues may surface due to lack of control and missing content moderation. Participant P06 said that their social media platform could be used to share content that can violate human rights: "*[...]of course you can share content. Right? I guess you literally generate content and [sic] can be of course violation of human rights.*" (P06) Few participants mentioned that it was hard to mitigate the spread of misinformation through software because they do not monitor or control messages because "*it's difficult when you think about private messaging to have end-to-end encryption, and also the fact that we are not the mediators of the messages.*" (P01) Furthermore, participants P01, P10, and P07 mentioned that distinguishing misinformation is the responsibility of their users. Participant P07 additionally highlighted that their platform could be used to "*store, to distribute illegal content, or for illegal activity by selling drugs or other things,*" but it is difficult to "*control who uses it.*" Participant P04 mentioned that their software could be used to create fake signatures. However, a few participants were also actively working on mitigating misinformation; P01 enables marking messages as spam and blocking users in their messenger, and P11 mentioned their browser has strict guidelines to block problematic and misleading ads. Finally, two participants (P01, P07) mentioned that more research and strategies are required to handle misinformation on communication platforms.

Responsibility is shifted to administrators and moderators. Some participants mentioned that the software could be disempowering to their users: "*[...]the future of giving out the login without the password moves to power up in the hierarchy,*" (P02) if corporations enforce the code signing tool. Further, P02 mentioned that they will implement a feature that lets managers see which websites employees are logging into, and this may be misused: "*[...] it's not visible for us*

as a provider, but it will be visible for the project managers or CEOs. So that may be misused for surveillance of employees." (P02) Additionally, P14 stated that the responsibility of protecting the users shifts away from the people creating the tools to people who self-host instances, thus emphasizing challenges that come with autonomy granted to administrators:

> "*Again, there is a lot of responsibility and accountability taken away from the company itself building a tool that people can set up and use however they would like. If they choose to violate human rights with the tool, they can't do anything about it.*" — P14, File Sharing and Collaboration

Legal obligations versus user privacy. One participant highlighted a concern that they are compelled to surrender user data to law enforcement when they have a court order: "*We do have to provide the police with the data that they request, and they sometimes request data of specific users. Well, that has to be with a court order, but in case they are surveilled, and we have to deliver every information that we have about them, and that's mostly encrypted data.*" (P03)

Harmful actors and criminals can leverage the software. Participants said some consequences are inevitable and depend on how their users use the software, and they cannot control or moderate content on their software. A majority of them acknowledged that adversarial actors could use software to cause harm. Few participants (Browser, Stalkerware Detection) suggested that the use of their software might aggravate domestic abuse or IPV further. Because using the software "*may look like you're hiding something*" (P05) if the abuser finds the software installed on the victim's device. To mitigate this, they explained that they left the decision to delete an application to the users.

> "*It is possible, for example, someone gets a warning from our app, decides to remove the app, and then [sic] beaten or something right by an abusive partner, so our app doesn't automatically remove the app, it gives them the ability and the information that they need to make that decision.*" — P05, Stalkerware detection

P02 mentioned that the software could be used for employee surveillance. Cyberbullying was also mentioned by P03, who said that abusers and hackers use their encrypted E-mail service. These accounts can be reported through an abuse reporting channel and are disabled by the service. P03 also mentioned that since they enable "*anonymous signup*", a lot of spammers use their servers to send spam emails; therefore, they "*have several measures like a waiting period for people to be able to send emails; we collect and we maintain for some time the IP addresses that were used to register with the account. So we can detect suspicious activity there.*" Harmful actors use social networking sites to spread hateful messages; P06, a developer of a social networking site, stated, "*[. . .]being open source technology, privacy-first technology, it does attract certain groups which feel like anonymity gives them a space to do maybe not always lawful things right, so we did have attraction, for example, from ISIS, we do have the attraction from these groups.*" Similarly, P07 mentioned that software used to distribute illegal content or for illegal activities like selling drugs, and cyberwarfare. They further stated:

> "*I feel that it is a little difficult to pinpoint what exactly they are using it for. But it would be naive to think that it is not used in that (harmful) way.*" — P07, Anonymity Network and browser

Downloading the software can be harmful to users in hostile environments. Some participants mentioned that in some cases, the very use of their software or the download of it could be incriminating in certain countries and circumstances. Participant P01 emphasized this by stating the example of installing a secure messaging tool in Turkey: "*There have been cases in Istanbul and Ankara where people have been put into prison temporarily just for having installed a secure messaging tool, even without any content, so just the fact that you have it.*" Participant P09 who works for a VPN said "*I haven't directly, we haven't directly heard this*", but mentioned that they are aware that the use of VPN can be "*incriminating in some places.*" Participant P11 mentioned that using their browser might be banned on some networks and workplaces.

4.3.4 Aspects that do not affect all S&P software

Some aspects do not apply to all software. Addiction as a factor was discussed as irrelevant for many software types, including VPN, code signing, password manager, and secure translation. Many participants mentioned that their software could not be used to spread **misinformation**. These tools included VPN, translation, password manager, and stalkerware detection. This was because "*there's no way for people to communicate to our app or anything like that.*" (P05) Similarly, participants felt that software to accomplish very specific tasks like code signing tool and translation tool were **not distracting**. "*My products are not distracting. All you need to do is just get it on your phone and then tap on it whenever you want to use it and then just send a request to the software and it's going to respond to you, it's not going to distract you anyway.*" (P08) A majority of the participants mentioned that they see no difference in **negative environmental impacts** compared to any other software. Participants P02 and P03 mentioned that they try to have a positive impact by using renewable or green energy sources. Participants also could not think of how their software could **violate human rights**

and were unaware of **laws in different countries**. Participants P01 and P05 mentioned that their software contributes to strengthening human rights.

Most participants had at least considered **disempowerment** and the question of whether technology can impede users' decision-making. Conversely, a few participants mentioned that they had never considered disempowerment and how their technology can influence users' decision-making. The participants also indicated that it is quite hard to think about this question and had nothing to say about it: "*I couldn't say, I didn't have discussions about this. If I had to judge as much as any other communication platform, you will get challenges there.*" (P06) Participant P07 also never considered **physical and mental health** impacts of their technology on users.

4.4 Factors that help or hinder anticipating and mitigating consequences

4.4.1 Factors that hinder anticipating and mitigating unintended consequences

Shared accountability is assumed, and no one is accountable for anticipating unintended consequences. Many participants mentioned that there was no specific person in their team to look into unintended consequences. A few participants mentioned that the CEO, CTO, and leadership teams must be responsible for creating a product vision to lower negative impacts. Participant P11, who was from a larger organization, mentioned that there is no specific person assigned to look into it, "*[...]think it's not defined, to be very honest. The ethical impacts get rolled into privacy, so me and our DPO (Data Privacy Officer). But it's often quite tricky because that's not our mandate.*" (P11) Additionally, participants mentioned that everyone on the team should be held accountable. Participant P04, a volunteer one-person team, mentioned that they do not have the capacity to work on it and expect collaborators on GitHub to open issues. In addition, smaller teams faced more issues because they lacked the resources to conduct user research activities. Participant P13 mentioned that it is a collective responsibility of everyone on the team:

> "*I would say it's a very much a collective effort. Everyone does it. When we discuss features or how something is going to be implemented, there is always a high awareness of how it could be misused or how do we protect the users' data in a more secure way, etc.* " — P13, Encrypted Office Suite

Some participants believe that there are no negative consequences because their intentions are good. Participants stated that they did not observe any direct negative impacts due to the positive nature of their software. Participant P08 could not imagine any negative consequences of downloading the software and emphasized that they protected their users: "*No, no, no, not at all. What we're doing here is trying to protect your system. We're trying to protect your phone from harm.*" (P08) In addition, participants mentioned that their products positively impact people by empowering them and encrypting their messages. Some also mentioned that PETs like VPN could be incriminating, but in comparison, they have a positive impact:

> "*I think in comparison to other privacy-enhancing tools, it's a pretty small impact. I mean, basically [password manager] is a tool for being more productive. Saving time. Storing passwords.*" — P02, Password Manager

Participants also stated that certain consequences are not a direct consequence of downloading their software but the problem of third-party applications and providers. Participant P12, mentioned, "*[...]if some text offers offensive translations for certain languages, it is the fault of google translate and not my software.*"

Lack of awareness and knowledge at an individual and an organizational level. A lack of organizational support hindered participants from systematically anticipating unintended consequences. Participant P11 stated: "*I think it's more that we don't have the have the mandate to do it. We don't really have organizational buy-in to stop a feature from rolling out because of a perceived ethical risk. There is no one really who full-time has the job title to think about ethical issues.*" (P11) Furthermore, P11 specified that they should have an ethical overview similar to privacy overviews. Additionally, some participants did not receive formal training in ethics or unintended consequences of digital software. Few participants mentioned that they have read about ethics and try to educate themselves through books and other media. Few participants mentioned having some sort of ethics training via universities and company training. Additionally, the reported lack of team diversity may also hinder considerations of diverse users and their needs and unintended consequences in general [56].

Privacy trade-offs can impede the identification of certain unintended consequences. Prioritizing user privacy introduces challenges while identifying unintended consequences: S&P software creators are limited in collecting user feedback that might identify their users and also limited in their capacity to moderate content. This highlights challenges with balancing user autonomy and identifying issues that might harm them. For instance, when it comes to topics like misinformation and communication between their users, participants mentioned that since they are a "*privacy first technology*" (P06), they "*don't have central control*" (P14) to oversee conversations or content. Further, P01 stated that, since they are a private messaging software and their core value is end-to-end encryption, they are unsure how to solve the spread of

disinformation: "*to be honest, I think in the space of private messaging, how to prevent the spread of dubious information is difficult. I'm not sure that anyone has the answer to that.*" Participants reported that the privacy-first focus also interferes with collecting user input during development because they refrain from collecting any personal information about their users, which might reveal the demographics of their users: "*The first thing is that the feedback that we have or any kind of data that we get from the users is anonymous because we don't want to reveal, identify information that can pinpoint specific users.*" (P10) P11 also mentioned that though they can think of proactively involving users to get input through measurement studies, they still "*[. . .]don't want to just push for having as much measurements as we can because that will hit our core values, which is just preserving privacy.*"

4.4.2 Systematic assessments help to be proactive

When asked about what unintended consequences they anticipate without using systematic probing, participants initially had a narrow view of unintended consequences. Probing the aspects we extracted from toolkits helped them think through broader consequences, many of which they had not previously considered.

5 Discussion

In this paper, we explored how S&P software creators assess and mitigate unintended consequences through 14 semi-structured expert interviews. We also identified whether they use any toolkits and investigated their current processes. We found that these experts are highly motivated to create a positive impact by protecting people's privacy and security. However, they do not systematically anticipate and mitigate unintended consequences. Most participants mentioned that they hoped users would identify and report issues. We now discuss the implications of waiting for users to identify issues and provide recommendations for better impact assessment processes.

Relying on user feedback burdens them and puts them at risk. As discussed in Section 4.2.2, participants highlighted reliance on reactive approaches—acting upon user feedback or reports about issues they face. To receive feedback they use methods like tracking user feedback, and opening issues on GitHub. The term *technical debt* was coined by Ward Cunningham in 1992 [72], which describes the price software teams pay for prioritizing speedy delivery over perfect code. Similarly, *ethical debt* is the idea that when software development teams lack of oversight for the ethical and societal implications of their work, they may create harm that will have to be addressed later [73], [74]. While waiting for users to bring up and then resolving the issues works in some cases, this approach may be harmful, especially for vulnerable populations who might be experiencing threats of exacerbated quantities and qualities.

We think reactivity can be problematic because of the additional responsibility on marginalized users, expecting them to report issues they encounter during usage in addition to enduring partially usable tools. McDonald *et al*. state that there is too much onus on users in expecting them to *make do* with tools they have rather than soliciting users' feedback right at the beginning [75]. Negative experiences may be detrimental to users and put their privacy and security at risk, as they may abandon S&P tools and resort to less secure practices. Previous work has shown that negative experiences such as bad usability and inconvenience lead to the abandonment of privacy tools [76].

Proactively considering user threat models during the initial phases of software design can identify vulnerabilities quickly and thereby avoid adverse impacts on end users. We recommend technology designers be proactive in anticipating unintended consequences and negative impacts on users, during the initial stages of development. They may consider involving users and user input at the design stage.

Create incentives to avoid the shift of risk to users: a moral hazard problem. Chua *et al.* discuss the *moral hazard problem*, where software creators do not have an incentive to take action to avoid unintended harm because it does not affect them negatively [12]. Similar to our discussion above, they also emphasize that when harms are not addressed by software creators who have the power to do so, the risks are shifted to users who might be unprepared to bear the consequences. For instance, in case of negative experiences users might abandon the software, resorting to less secure means. Chua *et al.* further emphasize that software creators may not be incentivized to avoid unintended harms that do not directly impact them [12]. Therefore, creating incentives might be crucial. Software creators may consider making prevention of unintended harms a strategic priority. Harm prevention must be a fundamental part of the planning and designing of the software. Additionally, proactive harm mitigation strategies might incentivize software creators in attracting and retaining users, reinforcing trust of users, and maintaining a competitive advantage.

Systematic toolkits help in uniting the team and providing a more holistic view of potential unintended consequences. Participants had no systematic process to anticipate adverse outcomes; instead, they relied on user feedback or focused only on privacy and security aspects. Their current processes may not be sufficient to anticipate unintended consequences; systematic toolkits provide a comprehensive overview of possible harms. Currently, many participants reported not considering how their products may be misused in specific ways, as reported in Section 4.3. While previous work criticizes the limited view of systematic ethical toolkits and checklists [77]–[79], they can still serve as excellent probes and evocative heuristics that elicit thinking about harms that

may be otherwise overlooked [49], [70]. One major drawback of toolkits and checklists is that they are not prescriptive in how to mitigate harms [50]. We find them a good starting point to think about broader ethical and societal issues; due to the overwhelming number of available toolkits and checklists, their generality, and lack of prescriptive support, none seemed like in itself, it would effectively help mitigate harm. We implore that future studies explore effective preventative strategies for mitigating negative consequences of S&P software.

Anticipating harm is only a part of the solution; software professionals must be empowered to fix problems. Anticipating or identifying unintended consequences is required, but often insufficient to mitigate them. S&P software creators must be equipped to mitigate the problems they identify. We find that stakeholders not in leadership roles may not be empowered to bring up issues in their development process. A lack of resources and authority may result in an inability to mitigate unintended consequences. As discussed in Section 4.4.1, a majority of participants expected their management teams to take up the responsibility of mitigating unintended consequences. In this line, Widder *et al*. highlight that there is a disparity between anticipating and mitigating ethical issues [80]. Even if software creators have the knowledge and awareness to anticipate ethical issues, they often lack the power to act on them. We recommend that S&P organizations incorporate ethics into the core job responsibilities of their employees and foster an organizational culture that provides them with the resources and power to raise and mitigate unintended consequences.

Experts are more focused on their roles, and there is no accountability to address unintended consequences. Our study finds that participants are motivated to create a positive impact—within the confines of current knowledge and capacity—they fulfill the obligations of their official roles and responsibilities. Most often, they balance different roles and priorities. Even if they may recognize some ethical dilemmas, they may be prevented from addressing those consequences, not due to ignorance, but by the formal specifications of their roles (see Section 4.4.1). We found a lack of shared team or organizational goals to reduce or mitigate harm, as opposed to shared goals of privacy. Some participants mentioned that leadership should be responsible for making this a vision of the organization. We implore organizations to establish new roles or expand on formal role responsibilities and create a shared mission for the entire organization to uphold ethical values beyond privacy.

Without dedicated resources, accountability, and organizational backing, negative issues cannot be appropriately addressed through design changes. Organizations should actively play a role in dedicating resources to anticipating ethical impacts and issues right from the projects' inception and follow through with mitigating issues as they are identified. Furthermore, defining harm reduction and fixing ethical issues as business metrics like Objectives and Key Results (OKRs) might allow teams to do their due diligence in systematically anticipating and mitigating unintended consequences. Additionally, organizations should consider forming governance bodies for ethical review of software similar to privacy overviews; this would help to place equal significance on software impacts as other governance aspects, as discussed in Section 4.4.

Create resources and materials for smaller teams and teams where everyone volunteers. Large organizations may readily afford to invest time and resources into forming governance bodies and invest in large-scale efforts to look into unintended consequences. In contrast, smaller teams and individuals often lack the luxury to devote their time and resources to solving ethical issues. As these approaches can be time-consuming and resource-intensive, smaller organizations may look into building support communities with users and stakeholders in different organizations with aligned goals. Open source communities have historically helped foster support and faster iterations of products; therefore, similar communities can also be used to echo software impacts. The security community should also investigate ways to build software with ethics in mind and focus on unintended consequences within and outside the community. Importantly, when educators teach security, they should include teaching unintended consequences.

Develop formal guidelines and training to raise awareness. We also identified that most participants lacked formal education in ethics. While ethics frameworks, toolkits, and checklists are pervasive, they are not widely adopted or used in software development teams, likely due to the lack of ethics in technology education [81], [82]. As discussed in Section 4.4.1, S&P software organizations may want to consider creating a review process for examining ethical considerations and potential software harms before a feature is released to the broader public. Existing review processes for security and privacy may inform these review processes for software harms. Ethics discussions must be a priority and not an afterthought contingent on available time. Fiesler *et al.* suggest integrating ethics into technical classes beyond stand-alone ethics classes. McDonald *et al.* show that students' thinking about social justice improves over time if they are introduced to ethics over a longer time, therefore advocating for more time and exposure to ethics topics [83]. Kohno *et al.* emphasized using ethical scenarios to reason about security research implications [84]. Further, not everyone in software development has access to formal education; therefore, organizations should consider company training on ethics and software harm.

Privacy-moderation trade-off remains a constraint—posing many ethical dilemmas like user data collection and content moderation. Although collecting user feedback is essential, monitoring usage and gathering personal information or feedback can conflict with privacy principles. Since this remains inevitable, we recommend that future research develop guide-

lines and resources to balance the privacy-moderation trade-off.

Training and guidelines for self-hosters and moderators. As mentioned in Section 4.3.3, moderators and self-hosters often directly interact with end users. We find that developers usually create tools and hand over the responsibility of moderating to self-hosters, and they may most often encounter ethical dilemmas in the software instances they create and moderate. Moderators and self-hosters need to be empowered and provided with training, guidelines, and support on handling negative impacts and ethical dilemmas they may encounter. Further, future work can also look into how self-hosters deal with negative and challenging scenarios—identifying which resources should be provided to equip them better to mitigate harm or unintended consequences that cannot be prevented through software design or that clash with their privacy values.

6 Conclusion

We explored how developers of security and privacy software consider the unintended impacts their software can have, finding that participants want to create beneficial software but lack the resources to address unintended consequences systematically. We find that S&P projects often rely on user feedback to identify problems and mitigate risks and often also face ethical dilemmas due to conflicts stemming from balancing trade-offs between privacy values and moderation. We argue that systematically assessing risks, as we modeled in our interviews, can lessen the burden on users. We make recommendations for organizations, educators, and the S&P research community to take action to assess and mitigate unintended consequences of S&P software.

7 Acknowledgment

We want to express our deepest appreciation to Anna Lena Rotthaler, Kelly Almon Mumba, Anastassija Kostan, Marcel(le) Fourné, and Swar Joshi for their feedback and interest in this research. We thank our participants for participating in the study and providing valuable input. We also thank all the anonymous reviewers and shepherds for their thoughtful comments and feedback.

A Interview Guide and Screening Questions

Screening questions

1. Do you work on developing security and privacy-enhancing software like VPN, TOR, Password Managers, and Secure messaging?
2. Is the core Value or mission of your software or organization to enhance privacy and/or security?
3. Please describe the kind of software you work with. (VPN, Secure Messaging, TOR.. etc)
4. What gender do you identify as (Man, Woman, Non-binary, Prefer not to answer, Self- describe)
5. How many years of development experience do you have? (self-described)
6. What is your role within the development team or your role in the organization? (self-described)
7. Do you have previous experience with ethics? (Yes, No, Prefer not to answer, other(please specify))
8. Was ethics a part of your training or studies? (Yes, No, Prefer not to answer, other(please specify)
9. Do you wish to get a $80 gift card as a thank you for participating in this study?

Introductory questions

1. What product are you working on?

2. Could you describe the core value of your product? What is the key problem/ need you are trying to address?
3. What is your role within the development team?
4. Who are the primary users of your product? Who benefits from your product? And how?
5. Were users consulted or involved in the development process? If so, how was their feedback incorporated into the product development?
    (a) How did you ensure that a good representative sample of your users was involved in the development process?
    (b) Can you think of other secondary users, bystanders, or unintentional users who might also use your product?
    (c) How did you factor in primary, secondary, bystanders, and unintentional users within the development process?
6. How did you ensure that the product fits the problems/ needs of the users?
    (a) *Probe if needed:* How did you measure if the product fits the needs of the users? (eg. using metrics and user tests)
    (b) How have you communicated your understanding of the users' needs with them?

Negative and Unintended consequences
For each question, ask for mitigation strategies in place.

1. **Anticipated negative impacts:** Have you or your company observed your product having any negative impacts? *(negatively)*? *Who is impacted, for instance:* individuals, businesses, environment, groups of people, operators, etc.
2. **Potential harm:** Can you imagine people being harmed by using your software? (eg. issues with the government, partner abuse, etc.)
3. **Barriers to access:** Are there specific groups or communities who do not have access to the product? What are the different barriers to access?
4. **Biases:** How did you ensure that your software is unbiased and treats all your users fairly?
    (a) *If mitigation is not mentioned:* How were risks of biases identified and mitigated? (Selection bias, Historic Bias, Individual biases)
    (b) *Probe:* What about paid/ free users?
5. **Accessibility:** How do you design with the accessibility needs of people with disabilities in mind?
6. **Disempowerment:** Have you thought about disempowerment? Does the technology replace or weaken users' authority in decision-making? (eg. Blackbox AI Technology, Technology replacing people/ business)
7. **Misinformation:** Do you think your tech be used to generate or spread misinformation to create political distrust or social unrest?
    (a) *If they say no/ if it is a social tool then:* How do you think someone could use this technology to spread misinformation?
8. **Addiction:** How was addiction factored into the design of the software? Do you think your software could be addicting for users?
9. **Distraction:** Do you think your software fits into the natural workflow of your users? How do you think your software could be distracting to users?
10. **Physical and Mental health impact:** How does your software affect the physical and mental well-being of your users?
11. **Environment Impact:** What do you think are the environmental impacts of the solution?
12. **Human Rights Violation:** Do you think your software could violate the respect for the human rights of your users?

Data Privacy and Security Risks

1. **Security:** How did you assess potential forms of attacks and security threats to which the solution could be vulnerable?
2. **Data Protection:** How does your software protect users' personal data?
    (a) *Consent:* How did you communicate to your users about what data is collected and how it is used?
    (b) *If data is collected:* How do you minimize data collection?
    (c) Will the raw data be shared with additional external partners?
    (d) *Privacy impact:* How did you evaluate the privacy impact of the project? Does a Data Privacy Officer (DPO) or similar exist? Did you involve this person at an early stage in the process?
3. **Data Governance:** What protocols, processes, and procedures did you follow to manage and ensure proper data governance?
4. **Tracking and Surveillance:** How might your product be used for tracking and surveillance of targeted individuals?
    (a) Whom would they track, why, and do you want your tech to be used in this way?

Organizational factors, Ethics frameworks, and tools

1. What does your development team look like? What are the different roles of people within the development team? (e.g., are there designers, legal, etc.)
2. Is the development team a representative of the social and gender diversity of society?
3. Who takes the responsibility to assess ethical and societal impacts? Who do you think should be accountable?
4. How did you identify and address ethical risks? Are there any measures in place to assess and mitigate negative consequences?
    (a) *If frameworks are not mentioned:* Do you use any frameworks or tools to assess ethical risks?
    (b) *If not mentioned:* Have you engaged external domain experts in your project to assess the ethical considerations of your project (e.g., academics, ethicists, researchers)?
    (c) *If not done currently:* How do you think ethical risks can be mitigated in your software?
5. Did you have any training or education on ethics in creating digital tools?

B Themes

- **Theme 1: Current practices and attitudes for identifying unintended consequences** *privacy-first focus, create usable products, personal interest and moral compass, positive software can have no negative impacts, reactivity over proactivity, lack of formal processes and no frameworks/ responsible people*
- **Theme 2: Reasons unintended consequences considered and not considered** *unintended consequences ingrained in software vision, unintended consequences accounted through design, Inevitable Unintended consequences, unintended consequences that are not applicable, Software creators are unaware of unintended consequences*
- **Theme 3: Factors that hinder working on unintended consequences** *lack of accountability, good intentions have no negative consequences, lack of awareness individual level, lack of awareness organizational level, privacy vs collecting user feedback/ content moderation*
- **Theme 4: Systematic frameworks help with identifying unintended consequences**

C Codebook

Category	Code groups	Sub-codes
Primary users	Regular Users	Everyday users, regular unt-argetted users, un-specific
	Privacy Concerned users	Users avoiding ads, avoiding surveillance
	Special and Vulnerable populations	Journalists, Activists, IPV survivors
	Businesses	Mid-small sized businesses, corporates, employers
Un-intentional(non-users)	One time users	Out of necessity or crisis, downloaded by accident/ unaware of functions
	Unintentional(non-users)	People communication with users, users of product developed, employees
Anticipated negative impact	No direct harm	No consequences, only positive impacts
	Usability/ bugs	Bugs affecting usage
	Harmful actors	Spammers, abusers, spread misinformation
	Incriminating	downloading software can be incriminating, illegal in some countries
	Inevitable harms	Use by harmful actors, No moderation
Barriers to Access	Does not apply	-
	Applies - not mitigating	Skills needed (technology/ language), internet needed
	Applies - mitigating	Marketing to more users, reducing barriers (play store, language)
	Positive	Everyone can access
Biases	Does not apply	-
	Applies - not mitigating	Global north/ west, language
	Applies - mitigating	Global south, adding language
Accessibility	Does not apply	Just a library, no interface
	Applies - not mitigating	Not prioritized/ no process, no resources
	Applies - mitigating	Works with accessibility tools, designed with accessibility
Addiction	Does not apply	Possible in future with sufficient gamification
	Applies - not mitigating	Not considered, no incentive for maximizing attention
	Applies - mitigating	Working on mitigation: Offline capability
Distraction	Does not apply	Not distracting
	Applies - not mitigating	Difficult to integrate into workflow, users are responsible
	Applies - mitigating	Limit notifications through UI design, no ads
Disempowerment	Does not apply	No/No direct impact, empowering
	Applies - not mitigating	Disempowering when corporates force the use of this tool
	Applies - mitigating	Consent for data sharing
Environmental impacts	Does not apply	Not different from other software
	Applies - not mitigating	Software used by bitcoin, end device consumes energy
	Applies - mitigating	Use renewable engery
Human rights	Does not apply	no violation, strengthens human rights
	Applies - not mitigating	Social media content may be problematic, may have issues in future
	Applies - mitigating	-
Physical & mental health impacts	Does not apply	No/ No impact, positive impact
	Applies - not mitigating	Warnings from stalkerware can make people anxious
	Applies - mitigating	-
Misinformation	Does not apply	Not a communication/ content software
	Applies - not mitigating	Mitigation is with users, hard to mitigate, cannot moderate
	Applies - mitigating	Marking as spam/blocking strategies present
Security	Process	Security review, threat modeling, research
Data protection, surveillance & governance)	Processes	Minimize data collection, no sharing with external partners, consent processes
User involvement	Proactive practices	User research at the start, constant feedback, co-developing
	Reactive practices	Raise issues, fix issues/ react on feedback, impacts through feedback
	Challenges	No user data(privacy), small samples, lack of resources
Impact assessment	Current practices	Privacy & not ethical impacts, no processes, personal interest, Diversity
	Accountability	Leadership/bosses should be responsible, everyone in the team, no assigned person
	Framework/ Process followed	No framework used, user-centered design, Moral compass
	Training/ education ethics	No education, education in ethics (university/ company training), personal interest
	Own process	Proactive, reactive(git issues/reviews), experts(Legal, ethics, compliance)
Oganizational factors	Size of organization	Micro, Small, medium, large
	External Collaborations	lack of external collaborations (researchers/ ethicists)
	Diversity	No diversity (all white/ male), gender diversity, diversities of ethnicities

Engaging Company Developers in Security Research Studies: A Comprehensive Literature Review and Quantitative Survey

Raphael Serafini
Ruhr University Bochum

Stefan Albert Horstmann
Ruhr University Bochum

Alena Naiakshina
Ruhr University Bochum

Abstract

Previous research demonstrated that company developers excel compared to freelancers and computer science students, with the corporate environment significantly influencing security and privacy behavior. Still, the challenge of recruiting a substantial number of company developers persists, primarily due to a lack of knowledge on how to motivate their participation in empirical research studies. To bridge this gap, we performed a literature review and identified a conspicuous absence of information regarding compensation and study length in the domain of security developer studies. To support researchers struggling with the recruitment of company developers, we conducted an extensive quantitative survey with 340 professionals. Our study revealed that 62.5% of developers prioritize security tasks over software engineering tasks, and 96.5% are willing to participate in security studies. Developers consistently ranked security higher than other barriers and motivators. However, repeat participants perceived security tasks as more challenging than first-time participants despite having 40% more general experience and 50% more security-related experience. Further, we discuss Qualtrics as a potential recruitment channel for engaging company developers, acknowledging various challenges. Based on our findings, we provide recommendations for recruiting a high number of company developers.

1 Introduction

Including professional software developers from the industry in empirical research is imperative for studying factors influencing usable security and privacy within corporate settings. These factors encompass organizational processes, security culture, and communication between security and privacy experts and software developers [7, 8, 25, 39]. However, recruiting professionals for security studies poses a consistent challenge for researchers. This challenge is amplified by several factors, including the time constraints, the high cost of recruitment, the geographical dispersion of potential participants, and the relatively small size of this target population [2–4, 34, 37, 38, 62, 76]. These challenges are particularly pronounced in the context of quantitative studies or studies involving practical tasks such as evaluating software development tools [1, 21, 37, 47, 69].

To address recruitment issues, researchers explored the characteristics of participants, focusing on programming and security expertise, in various online recruitment platforms and samples [33, 69]. One strategy is to enlist computer science (CS) students as proxies or source appropriate participants from crowdsourcing or freelance platforms, which can help to investigate new development approaches [59] or study design parameters like security prompting [44]. However, CS students and freelancers showed a different security behavior in security developer studies compared to professionals employed by organizations [18, 44, 76]. Further issues, such as a lack of programming skills of crowdsourcing or freelance participants, required the usage of screening questions [15, 16, 33, 69].

To address these research challenges, we focused on the hard-to-reach population of professional software developers employed at least part-time by organizations and indicating software development as the main part of their job, henceforth referred to as *company developers* in this work, and explored the underlying reasons for existing recruitment challenges. Researchers lack established guidelines, consensus, and recommendations concerning appropriate compensation levels. Participation in some security studies with professional software developers is uncompensated [3, 12], while others provide monetary compensation [35, 44]. Expectations for monetary compensation may also vary depending on study type, task complexity, or study length. Additionally, study participants often perceive study length as a participation barrier [60]. Despite these challenges, recommendations for determining appropriate study lengths are lacking.

To provide foundational guidelines for participant recruitment, we conducted an extensive literature review of security developer studies, revealing that many studies omit crucial methodological details related to compensation, study

length, or participant recruitment. Consequently, researchers lack foundational knowledge to establish study parameters attracting company developers for security studies. However, keeping participants engaged in security studies is an essential researcher concern. To address this research gap, we investigated company developers' willingness to participate in empirical research and examined Qualtrics as a potential recruitment channel. We conducted a survey with 340 professional software developers employed in companies and explored the following research questions:

- **RQ 1:** What factors influence the security study participation of company developers?
- **RQ 2:** Are there differences in attitudes toward study participation between first-time and repeat participants?
- **RQ 3:** Compared to existing recruitment platforms concerning participants' programming and security experience, skills, and knowledge, is Qualtrics suitable for recruiting company developers?

Our research indicated 62.5% of developers favor security over software engineering tasks, with 96.5% willing to engage in security studies. Additionally, developers prioritized security over other barriers and motivators. We found that repeat participants perceived security as more challenging than first-time participants, although they had 40% more general and 50% more security experience than first-timers. Further, Qualtrics might be used as a recruitment channel for engaging company developers by acknowledging several challenges. Based on our findings, we provide study length and compensation guidelines for recruiting a high number of company developers.

2 Related Work

In the following, we discuss existing work on the recruitment of participants for software engineering and IT-security studies and factors affecting their participation.

Recruitment Guidelines: The current body of research on conducting software engineering studies provides researchers with guidance and case studies on conducting specific study tasks such as surveys [42], interviews [27], or experiments [66, 73]. Recruitment advice found in the literature tends to focus on recruiting a reliable and representative sample [55] and providing testimonials on specific issues and pitfalls during participant recruitment [20]. Although guidelines exist on how to recruit professionals for software engineering studies, they primarily focus on methodology [10], recruiting the right participants [56], or establishing cooperation between researchers and companies [58]. While these recommendations are useful for ensuring reliable data collection from recruited participants, they offer limited insights into how to effectively and efficiently motivate professional software developers employed in companies in significant numbers.

Recruitment Platforms: For participant recruitment, researchers can leverage personal and industrial contacts [25, 33, 44], rely on convenience samples such as CS students [9, 37, 47, 68, 69], or use crowdsourcing and freelancer platforms, such as Appen, Clickworker, MTurk, Prolific, Upwork, and Freelancer [16, 18, 24, 26, 33, 46]. However, these recruitment methods come with their own set of challenges, such as unreliable data [18, 51, 65], weak built-in tools [57], or contract limitations [24]. Thus, Kaur et al. [33] conducted a survey study with 706 participants and compared six recruitment platforms for software engineering and security studies. Their analysis was grounded in a literature survey of 59 developer studies in the field of usable security and privacy and revealed significant differences in programming and security experiences across participants from crowdsourcing platforms, Google Play, and universities. They suggested using MTurk for conducting quantitative studies that can tolerate a certain degree of fraudulent participation and use screening questions to detect and reject unsuitable participants. For smaller studies that require less noisy data, the authors suggested using Upwork for participant recruitment, a freelancer platform often used in previous research (e.g., [13, 25, 36, 41]). We based our survey on the work of Kaur et al. [33] to provide a comparable analysis of recruitment platforms and investigated the experiences, skills, and knowledge of software developers recruited with Qualtrics. Tahaei et al. [69] also compared different recruitment platforms, including four crowdsourcing platforms and a CS student mailing list. They found that MTurk participants exhibited the highest level of self-reported programming experience. However, they were also the least successful in solving programming skill screening questions developed by Danilova et al. [16]. No previous work presented recruitment insights into the sample of company developers or Qualtrics as a recruitment platform.

Motivation: Based on previous research on study design, persuasion, and the researchers' experience in conducting surveys, Smith et al. [63] analyzed survey invitation emails for factors associated with the recruitment of professional software developers. They found that most of the invitations did not include many persuasive factors. However, emails that addressed recipients directly contained similarity cues (e.g., belonging to the same company), compliments, scarcity cues (e.g., time limits or a maximum number of participants), rewards, and humor had higher response rates. Similarly, Brandt et al. [11] recommended highlighting the benefits for participants beyond monetary compensation (e.g., learning something new), personalizing communication, streamlining appointments (e.g., using a calendar service), and avoiding technical setups by providing an online environment. Additionally, they suggested appealing to different types of motivation, including fun, drive to produce knowledge, social connection, and self-improvement, to improve study participation rates

further [6]. The most related work on the motivational factors of participant recruitment was conducted by Serafini et al. [60], who investigated factors influencing the motivation of professional software developers from companies to participate in security studies. They conducted 30 semi-structured interviews on participants' perceptions of study factors related to study design, recruitment methods, and data collection. The results showed that study length, topic, monetary compensation, and trust were influential factors for participation in developer studies. However, participants were concerned about high effort and low performance in security tasks. Compared to [60], we conducted a quantitative analysis and focused on establishing a foundational guideline for participant recruitment.

3 Systematic Literature Review

To provide foundational guidelines based on recruitment strategies and study design used in previous security developer studies, we conducted a comprehensive literature review and selected papers from the most popular top-tier conferences in the field of Security and Privacy (S&P), Human-computer Interaction (HCI) and Software Engineering (SE) research: (1) Conference on Computer and Communications Security (CCS), (2) Conference on Human Factors in Computing Systems (CHI), (3) IEEE Symposium on Security and Privacy (IEEE S&P), (4) Network and Distributed System Security (NDSS), (5) USENIX Security Symposium (USENIX), (6) International Conference on Software Engineering (ICSE), and (7) Symposium on Usable Privacy and Security (SOUPS).

3.1 Paper Selection Process

The comprehensive literature review was conducted by two researchers R1 and R2. R1 reviewed titles, abstracts, and methodology sections of all papers published at the venues mentioned above and screened them according to the following inclusion criteria: (1) published in the years 2017-2022, (2) presented a study involving participants with programming skills, such as CS students, professional software developers employed in companies, freelancers, and crowdsourcing participants. We focused on recent studies and included CS students, freelancers, and crowdsourcing participants with programming skills, as they were often recruited as a convenience sample. R2 reviewed the resulting list of papers to ensure that all papers met the criteria. Both researchers extracted the following information from the resulting list of papers: year of publication, sample, recruitment channel, study type (online, lab, field), study task (survey, interview, practical), number of participants, compensation, study length, and IT-security focus. Any disagreements were resolved by reading the full paper.

In total, we identified 169 papers. We excluded one paper due to limited methodology (provided only information on the study task), another paper due to complex study design (included three different data collection methods)and four papers due to having different payment levels for the same task. The final list included 163 papers (see Replication Package [61]).

3.2 Systematic Literature Review Results

We identified five types of participants in the 163 papers; Software developers (100 paper), CS students (36 paper), security and IT experts (39 paper), admins (8 paper), and "other" (e.g., hackers and testers) (7 paper). In the following, we discuss the results of our systematic literature review analysis (see Replication Package [61]).

3.2.1 Recruitment Channels

The recruitment channels varied within the 163 papers, with social and regional contacts (75/163) being the most commonly used channels, often combined with unsolicited emailing (55/163). Other frequently used channels were social media (42/163), and university recruitment (36/163), especially for practical tasks that required a substantial number of participants while keeping costs and effort low. The least frequently used channels were snowball sampling (29/163), online forums/blogs (29/163), networking platforms (21/163) (e.g., LinkedIn), freelancer and crowdsourcing platforms (16/163) (e.g., Upwork, Clickworker), and security events (8/163). Additionally, some studies (4/163) used channels such as contacting an NGO to recruit participants. Twelve papers did not report the recruitment channels they used. While freelancer, crowdsourcing platforms and online forums/blogs were among the least used recruitment channels, they were often preferred for quantitative studies with many participants. On average, studies used2.06 (md: 2, σ: 1.2) recruitment channels. Universities, unsolicited email, and social and regional contacts were the most common recruitment channels, where no channel combination was reported.

3.2.2 Study Task and Type

Most papers (125/163) described an online study, usually a survey. While interview (72/163), practical (75/163), field (17/163), and laboratory (37/163) studies were less common than surveys (77/163), they often included additional surveys (e.g., entry or exit survey on demographics). For surveys, the highest number of participants were achieved (μ: 247.53, md: 102, σ: 416.81). Field (μ: 27.62, md: 24, σ: 19.12) and interview (μ: 18.33, md: 17, σ: 9.45) studies recruited the fewest number of participants. We identified 71 papers that focused on IT-security. However, we did not find significant differences in study design and recruitment compared to software engineering studies.

Table 1: Study Parameters.

Study Type	Online
Study Task	Survey
Study Language	English
Study Length	mean: 32.77 min (md: 28.5, σ: 18.85)
Recruitment Channel	Qualtrics Research Panels
Recruitment Duration	2.5 months
Participants	Company Developers (n = 340)
Compensation	$62.15 per participant (or Reward Points)

3.2.3 Study Length

Out of the 163 papers, 101 explicitly reported the study length, with an average of 77.75 (md: 52.5, σ: 93.76) minutes. Survey studies typically lasted about 16.58 (md: 14.4, σ: 17.52) minutes, interviews on average 50.93 (md: 45, σ: 25.65) minutes, and practical tasks had the longest length with 126.35 (md: 60, σ: 137.93) minutes. For practical tasks spanning multiple days or weeks, this information was often missing. 46 survey studies also lacked information on the study length.

3.2.4 Compensation

Out of the 163 papers, 77 did not mention any reward, 21 provided no compensation, 48 mentioned monetary compensation (μ: $60.09, md: $26.04, σ: 87.90), and 17 compensated participants with other incentives such as raffle participation, hardware products, charitable donations, or study credits. Of the 48 papers mentioning monetary compensation, 30 also reported the study length, which yielded a mean hourly wage of $41.07 (md: $31.91, σ: 54.77).

4 Methodology

To develop foundational guidelines for participant recruitment, we designed a survey based on our systematic literature analysis and related work. A Replication Package (RP) can be found in [61].

4.1 Study Parameters

Our literature analysis highlighted the importance of presenting detailed study information transparently and consistently. Thus, Table 1 provides an overview of our study parameters. We conducted a 30-minute online survey lasting 2.5 months (79 days) involving 340 company developers recruited through the Qualtrics service. The survey was conducted in English. The study incurred costs totaling €17,588.75 ($62.15 per participant). The Qualtrics service indicated compensation varied based on the research panel participants, including monetary compensation or points redeemable for services or products, such as video game currency. Qualtrics did not provide us with information on the detailed participant compensation plan.

4.2 Survey Design

Based on the systematic literature analysis, we designed questions concerning recruitment channels, study tasks and length, and the type and amount of compensation commonly used in recent research studies. We asked participants for previous experience with CS studies and explored their preferences and attitudes toward study topics, particularly in the area of IT-security and software engineering. We derived organizational and security-related statements Q3.1-Q3.20 for question Q3 from [8,45,46] (see Section D6 in RP) as well as time-related statements Q6.1-Q6.4 and trust-related statements Q6.22-Q6.25 for question Q6 from [16] and [5,19,23,75] accordingly (see Section D7 in RP). Based on [60], participants were asked about their willingness to participate in different types of studies and the factors that might influence their participation decisions. We further identified studies that lasted multiple days (e.g., [45, 49, 50, 64]) and thus considered longitudinal studies in our survey questions. Since code reviews were explored in the literature as an alternative approach to implementation tasks [17], we examined both in our survey. Finally, we collected developer and organizational backgrounds, coding experience, and participants' demographics. For this, we adopted coding and security experience questions from Kaur et al. [33], and included the SSD-SES scale from [74]. We used the exact wording and order of questions to provide consistency and allow comparison with previous research. The final survey consists of ten sections with 66 questions (see RP [61]).

4.3 Pilot Study

To test our questions' comprehensiveness and determine the survey length, we conducted a pilot study with eight participants involving two CS students, two professional software developers, and four researchers. Based on the pilot study results, we added an option allowing participants to indicate their expected monetary compensation with a familiar currency instead of using USD. Further, due to a mean completion time of 35.66 minutes in the pilot study, we reduced the number of items in our exploratory factor analysis (EFA) sets from 30 each to 26, 26, and 20 for the motivator, barrier, and security sets, respectively (see Section 4.6).

4.4 Recruitment

We used the Qualtrics research panel service to recruit participants for several reasons. First, we recruited a hard-to-reach population of company developers. As company developers, we consider professional software developers employed by organizations, at least part-time, who indicated software development as the main part of their job. We asked for 300 company developers evenly distributed across four major regions: Europe, Asia, Africa, and North America. Qualtrics

could not guarantee the recruitment of a high number of participants from other regions, such as Australia. The service reported primarily recruiting participants from traditional, actively managed, double-opt-in research panels; sometimes, they referred to social media.

Second, unlike most crowdsourcing and freelance platforms, Qualtrics managed the sampling and pre-screening of participants according to our specified inclusion criteria. To compare first-time with repeat participants' results, we specified that at least 40% of participants should be first-time and at least 40% repeat participants. We screened out participants if they indicated to work less than part-time in a company or reported software development is not part of their job. Previous research showed that participants claiming to be software developers recruited via Qualtrics failed a simple programming task [18]. Therefore, we additionally used a screening question recommended for the recruitment of participants with programming skills [15] (see Section D3 in RP [61]). With 1,556 of the 2,380 participants screened out, we experienced a high failing rate. In Section 5.3.2, we discuss potential concerns associated with participants of the Qualtrics pool.

Third, we were promised the recruitment time of 8 to 10 days, ensuring a predictable timeline for data collection. However, the recruitment process lasted 2.5 months (79 days). The delay was due to many participants being rejected by our built-in exclusion and quality checks. In addition, we reviewed the data set to check for inconsistencies in our participant's responses. This resulted in Qualtrics struggling to fulfill our quota in time (see Section 4.5). To compensate for the high time discrepancies, Qualtrics recruited 40 additional participants without increasing our compensation cost, resulting in a final recruitment sample of 340 participants.

4.5 Participants

Of the 3,240 participants who started the survey, 672 did not meet our inclusion criteria and 188 were from regions already covered. Of the remaining 2,380 participants, 1,556 failed the programming screening questions, and 247 failed our attention check or provided low-quality answers. Due to inconsistencies in their responses or survey completion time below 10 minutes, we excluded 237 additional participants, resulting in a final sample of 340.

An overview of our 340 participants' demographics can be found in Table 2. The average age of participants was 37 years. 265 (77.94%) were male and 73 were female. Most participants (92.65%) held academic degrees. They had 8.8 years of professional software development experience on average, working 37.9 hours weekly. They also had, on average, 12.8 total years of software development experience and 5.85 years in software security. Most participants worked in companies with 100 to 499 employees, with an average team size of 22. The majority of our participants worked in a security-related field for security-oriented companies. In addition, participants were more likely to be at least partially involved in security tasks than not involved at all. Almost all (98.82%) participants indicated they were at least somewhat comfortable completing our survey in English, with 295 (86.76%) being very comfortable.

4.6 Analysis

Quantitative Analysis: For statistical testing, we considered results with $p < .05$ significant. We used the independent t-test [67] to compare first-time and repeat participants for continuous data (e.g., EFA factor scores) and the Mann-Whitney U test [40] to examine differences in Likert type responses. We report results where the effect size exceeds the required effect size (Cohen's $d \geq 0.36$ with $\beta = 0.95$) of our power analysis. Unless otherwise noted, our results include responses from all 340 participants. Since we performed the Mann-Whitney U test on individual Likert items and the independent t-test on the mean of the overall factors of the EFA, we applied a correction factor of two. A significant right tail led to high standard deviations for questions about study length and compensation expectations. Therefore, we used the MAD (Median Absolute Deviation) method, as recommended in the literature [29], to exclude outliers exceeding 3.5 times the MAD. Using this approach, we removed at most 58 participants to calculate the mean, median, and standard deviation results of monetary compensation and study length expectations. We removed at most 21 participants while analyzing a subset of our participants. However, we did not remove outliers for statistical testing when comparing first-time and repeat participants due to a loss of statistical power. Outliers were also considered for statistical representation in Table 5. A detailed statistical analysis summary can be found in the RP [61].

Qualitative Analysis: Open-ended questions were analyzed by researchers R1 and R2 using inductive coding [70]. After two researchers independently coded answers, they merged their sets of codes. Due to the short and straightforward answers, all the discrepancies could be resolved by discussion. Although the main purpose of qualitative research is to explore a phenomenon in depth, we note how many participants stated specific themes to indicate their frequency and distribution.

Exploratory Factor Analysis: To explore the structure of participants' attitudes and concerns about study participation, we conducted an exploratory factor analysis [22]. Our study met several sample size guidelines for the EFA. A sample of at least 300 participants is considered satisfactory according to the literature [14]. A standard guideline is to have a minimum of 10 cases per item for analysis with $N \geq 300$. Following the recommendation, we retained variables with absolute factor loadings greater than 0.4 [22]. We used Kaiser-Meyer-Olkin (KMO) to ensure sampling adequacy [31, 32] and Bartlet's

Table 2: Demographics of the 340 participants.

Gender	Male: 265 (77.9%), Female: 73 (21.5%)	Non-binary: 1, NA: 1

test for sphericity to measure the correlation between our items. The KMO measure assesses the proportion of variance among variables that might be common variance. It indicates if the dataset is suitable for the Factor Analysis by showing if the variables share enough common variance to provide meaningful factors. Bartlett's test evaluates whether the variables are unrelated and hence unsuitable for structure detection, ensuring the data is not too dispersed to reveal any underlying patterns. For all three sets, Bartlett's test was statistically significant. Therefore, we used the oblimin rotation, a commonly used oblique rotation method for correlated variables [22]. The oblimin rotation allows factors to be correlated, reflecting the complex nature of attitudes and concerns by acknowledging that human behaviors and opinions are often interrelated rather than independent. As suggested by Field [22], we determined the maximum number of factors using Horn's parallel analysis, and considered only meaningful factors for which all variables fit the same theme. Horn's parallel analysis compares the actual data's eigenvalues against those from random data to accurately decide the number of factors to retain by preventing the retention of factors that do not significantly contribute to the understanding of the data structure.

4.7 Limitations

This study has several limitations that must be considered when interpreting the results. First, our literature review might not include all relevant work featuring developer studies. Second, other factors may influence the motivation and intention of company developers to participate in empirical research studies that are not considered in this study. Third, desirability bias might have affected participants' statements on their study preferences. Fourth, Qualtrics did not provide detailed compensation or response rate for participant recruitment. Finally, while we wanted to ensure participants genuinely represented company developers, the high number of drop-outs due to our strict screening procedure might have introduced selection bias. Thus, the results might not fully encompass company developers' diverse perspectives and experiences.

4.8 Ethics

The institutional review board (IRB) of our university approved our project. Participants were provided with a consent form outlining the scope of the study, the data use, and retention policies. We also complied with the General Data Protection Regulation (GDPR). Participants were informed about the practices used to process and store their data and that they could withdraw their data during or after the study without any consequences. We assured participants that we would only evaluate and publish anonymized data and quotes. Participants had to give their consent before completing the survey. They were also asked to download the consent form for their use.

5 Results

In this section, we present our participants' attitudes and expectations concerning different study factors, discuss first-time and repeat participation, and compare Qualtrics to existing recruitment platforms. Data comparison based on region can be found in the RP. The average survey completion time was 32.77 minutes (md: 28.5, σ: 18.85).

5.1 Exploring Factors Influencing Security Study Participation (RQ1)

5.1.1 Recruitment Channel

We asked participants through which recruitment channels they would accept a study invitation. Table 3 provides an overview of our participants' recruitment preferences. Most channels received a high acceptance rate except unsolicited emailing (μ: 2.67), flyers and posters (μ: 3.17). Targeted emailing (μ: 4.01), CS related mailing lists (μ: 4.33), and employer recommendations (μ: 4.48) were the most preferred channels. Interestingly, participants employed in Europe showed the lowest likelihood of responding to most recruitment channels, while participants in Asia showed higher acceptance rates. Par-

ticipants from security-focused companies (μ: 4.53), having a security focus in their current field of activity (μ: 4.61), or working on security-related tasks (μ: 4.59) had higher acceptance rates to recruitment through their employer compared to those without a security focus, with acceptance rates of (μ: 4.18), (μ: 4.24), (μ: 4.30), respectively. Asking about additional recruitment channels, 23 participants mentioned crowdsourcing and survey websites like Indeed [30], Naukri [48], or Mypoints [43]. Nine participants were willing to be contacted by phone, while seven preferred study invitations through social media or networks (e.g., YouTube, WhatsApp, Telegram, Instagram). Five participants explicitly mentioned LinkedIn as an appropriate channel for study recruitment. Less common responses included the participants' workplace, university, friends and family, or other third parties (e.g., "CS Global Network," "professional bodies").

5.1.2 Study Task and Type

Table 4 shows the proportion of participants willing to participate in different types of developer studies. While participants were interested in all study types, most (96.4%) indicated a willingness to participate in security studies. When given the option to choose between security and software engineering studies or indicate no preference, 62.5% specifically favored security studies. Participants in security-focused companies (67.0%), field of activity (75.2%), or who worked on security-related tasks (71.2%) preferred security over software engineering studies, compared to 54.5%, 56.8%, and 47.6% of their non-security counterparts, respectively. Almost all participants (95.8%) were willing to participate in implementation tasks. Field studies were the least preferred (80.5%).

5.1.3 Study Length

We asked participants how much time they would be willing to spend on different study tasks. Table 5 shows our participants' preferred study length. On average, participants were willing to spend 25.61 minutes on surveys (md: 20, σ: 15.77), 31.56 minutes on interviews (md: 30, σ: 20.68), 56.89 minutes on programming (md: 60, σ: 41.86) and 56.61 minutes on code review studies (md: 60, σ: 41.38). Participants from Africa were willing to spend more time on programming or code review studies, while participants from Asia were willing to spend more time on all study tasks except code. Most (81.18%) participants were willing to participate in studies lasting several days, weeks, or months. However, 93.48% of participants expected better hourly compensation than for one-day studies.

5.1.4 Compensation

We asked for participants' expected monetary compensation rates for different study types and tasks using their usual currency. The expected compensation rates for a 15-minute study are presented in Table 6.[1] Participants expected significantly less compensation for online ($6.50-$16.32), interview ($8.76-$15.64), and survey ($6.50-$12.34) studies for 15-minute studies than other study types and tasks. By contrast, implementation ($13.14-$20.12), code review ($16.32-$24.04), field ($12.34-$24.04) and laboratory ($11.29-$23.5) studies had the highest compensation rates expectations. Regarding regional differences, Africa, and North America generally had, on average, similar expectations. Europe excepted slightly lower compensation in most cases. By contrast, participants in Asia expected significantly lower compensation for all combinations, always expecting less than a third compared to other regions.

Table 7 shows the expected compensation rates for a 60-minute study. Compensation rates did not increase linearly with study length, with expectations almost always only two times higher for 60-minute studies compared to 15-minute studies. Participants' expected compensation rates were of-

[1] Participants' expected compensation rates were converted to USD by using exchange rates from January 25, 2023

ten based on previous study participation (41.2%), job salary (28.5%), or this study's compensation (25.6%). Regarding compensation alternatives, 282 participants selected Amazon vouchers, 145 chose hardware products, 60 might decide to reject the study compensation, and 56 indicated a preference for non-anonymous charitable donations. Participants suggested no alternative forms for non-monetary compensation but payment channels (e.g., PayPal) or cryptocurrency.

5.1.5 Barriers, Motivators and Security Attitudes

In this section, we present the results of our EFA on three sets of questions: attitudes toward participation motivators, barriers, and IT security. All overall and individual KMO scores were above 0.8 except for variable 20 in the security set, which had a score of 0.5401. Since this variable still exceeds the minimum threshold of 0.5, we retained this variable,

indicating that our three sets were suitable for the EFA. We report the individual factor loadings, the mean response of all, repeat and first-time participants, and the distribution of the Likert responses. Tables providing an overview of the resulting factors and their loadings and showing the distribution of the Likert responses for all, first-time and repeat participants can be found in the RP [61].

Motivators: We asked participants 26 questions about their attitudes toward study factors that could be perceived as motivators for study participation. We set the number of factors to five. We dropped five items iteratively due to items loading on factors that did not fit thematically until we obtained a sensible EFA output. The number of factors did not change. All factors had higher agreement rates than in the barrier set. Most participants agreed with the statements at least somewhat (μ: 3.93-4.29) suggesting participants placed more value on motivating than deterring factors. Altruism (μ: 4.14) and transparency (μ: 4.29) were the highest scoring factors, indicating that participants were interested in sharing their knowledge and experiences with the community. Still, they wanted to know how their data would be collected, stored, and processed.

Barriers: We asked participants 26 questions about their attitudes toward study factors that could be perceived as barriers to study participation. We set the number of factors to six. For most factors in this set, responses were equally distributed across the scale with a slight inclination towards agreement as evidenced by most means being close to or above three (μ: 2.81-3.65). Thus, only some participants perceived these factors as significant barriers to participation. Commitment (μ: 3.65), privacy concerns (μ: 3.32) and time-constraints (μ: 3.30) were the highest scoring factors. In contrast to the findings by [60], study participation uncertainty (μ: 2.81) was the lowest scoring factor in our analysis.

IT-Security: We asked participants 20 questions about their attitudes toward IT-security studies. We set the number of factors to five. There was a very high agreement for all factors (μ: 3.92-4.54), indicating that participants feel responsible for security and see a benefit for their company and themselves in improving their security knowledge and skills. Factors regarding security culture (μ: 4.54), responsibility (μ: 4.49) and risk awareness (μ: 4.43) were scored highest. While the agreement for task difficulty (μ: 3.92) was the lowest in this set, it was still very high compared to factors in the other sets.

RQ 1 – Summary

Almost all participants were willing to participate in security studies. Targeted emails and employer recommendations were the most accepted recruitment channels, whereas unsolicited emails were the least preferred. Participants were willing to invest about 30 minutes in surveys and interviews and 60 minutes in implementation and code review studies. The expected compensation was between $15.12 and $49.58, on average; however, it varied on the participants' country, type, and task of the study. Altruism and transparency were the highest-scoring motivators for participants. The highest-scoring barriers were commitment, privacy concerns, and time constraints.

5.2 Attitudes of First-Time vs. Repeat Participants in Research (RQ2)

e asked participants for CS-related study experience. 187 (55%) participated for the first time in a research study, while 153 (45%) indicated to have study experience, with an average number of participation of 8.81 (md: 8, σ: 8.91).

5.2.1 Recruitment Channel

First-time and repeat participants showed minor differences in recruitment channel acceptance rates. In particular, repeat participants were more receptive (μ: 4.23) to social media compared to first-time participants (μ: 3.46) (see Table 3).

5.2.2 Study Task and Type

Table 4 displays company developers' willingness to participate in research studies with different tasks and topics considering first-time and repeat participants. While first-time and repeat participants expressed their willingness to participate in studies with a focus on security, field studies were the least preferred study type (80.5%) for repeat participants (76.5%).

5.2.3 Study Length

We compared the results of first-time and repeat participants using the independent t-test. First-time participants were willing to spend more time on all tasks than repeat participants, with statistically significant differences ($p < 0.0005$) for interview (Cohen's $d = 0.42$) and implementation (Cohen's $d = 0.37$) tasks (see Table 5).

5.2.4 Compensation

Repeat participants expected higher compensation for most study types and task combinations for a 15-minute study than first-time participants, especially for code review and online studies (see Table 6). We used the t-test again to compare the results of first-time and repeat participants. However, no statistically significant results exceeded the effect size of our power analysis. For a 60-minute study, repeat participants aligned with first-time participants' expectations for all study combinations except for online studies (see Table 7). For online studies, they based their expectations more on the associated task than the type, resulting in higher expectations for online studies than first-time participants. Repeat participants mainly referenced past study compensation (55.5%), while first-time participants referred to their job salary (39%).

5.2.5 Barriers, Motivators and Security Attitudes

Motivators: Repeat participants placed more importance on motivational factors, as they had higher means for all factors and almost all items than first-time participants (see RP, Table 29). There were also statistical differences between first-time and repeat participants for personalization, self-interest, and personal development, indicating that repeat participants expected to be compensated for participation.

Barriers: For the privacy concerns and confidentiality factors, repeat participants scored statistically higher than first-time participants (see RP, Table 30). Repeat participants might be more critical in the context of privacy due to past experiences, with a significant difference in past negative experiences with data privacy (item 22) supporting this. First-time participants scored statistically higher on the commitment factor, indicating they were more concerned about time and conditional commitment (e.g., useful contribution).

IT-Security: We observed statistically significant differences between first-time and repeat participants for task difficulty and risk awareness. Repeat participants perceived security as a more challenging task, while first-time participants were more worried about their company's risks (see RP, Table 28).

5.2.6 Understanding Participation Motivations

First-Time Participants: We asked first-time participants why they chose to participate in our study. 67 expressed a general interest in the study topic or software development in general. Twenty-six participants wanted to gain new knowledge, while 25 each participated to share their expert opinion or to receive the compensation offered. Twenty-one participants felt this study was connected to their job, and 11 wanted to help. Another 21 participants did not indicate a specific reason beyond receiving an invitation. Participants indicated further reasons for study participation, such as having fun (4), relieving boredom (2), seeking variety (1), or challenging oneself (1). Only 27 (14.4%) first-time participants indicated to be regularly invited to CS studies. We asked first-time participants why they had not participated in the past. The majority (114) indicated they had never received invitations for this type of study. Thirty-one did not provide any reason, while 18 cited a general lack of time as the primary barrier to participation. Other less common reasons included lack of interest (3), studies already at full capacity (2), insufficient compensation (1) or relevance (1), COVID-related restrictions (1), or unclear requirements (1).

Repeat Participants: By contrast, 138 (90%) repeat participants indicated to be regularly invited to CS studies. We asked them for the type of studies they had previously participated in. Tables providing a summary of participants' previous study involvement can be found in the RP [61]. Most studies were conducted online (128) or at the participant's workplace (106). Participants frequently engaged in implementation (120), survey (103), or code review tasks (90). Only 43 participants participated in an interview study. General software development (125) was the most common study topic, followed by security (79) and privacy and data (77). Organization (44) and third-party libraries (39) were the least common study topics. We asked repeat participants if they had any negative experiences participating in CS studies in the past. We received 81 responses. Half of our participants (42) reported no negative experiences. Thirteen participants referred to less professional researchers or settings, such as poor preparation or moderation during group activities. Three participants cited technical problems or a less adequate environment. Others reported problems such as high task demands (3), long study length (2), use of deception (2), or low compensation (1).

RQ 2 – Summary

First-time participants were willing to spend more time on studies than repeat participants. They were also more likely to expect compensation based on their job salary than repeat participants who used previous studies as a baseline. First-time participants prioritized user security and were more aligned with organizational security policies, while repeat participants valued job recognition and perceived greater implementation challenges when working on security tasks.

5.3 Qualtrics for Company Developer Participation in Security Studies (RQ3)

We compared the characteristics of our sample recruited through Qualtrics with those investigated by Kaur et al. [33]. Tables providing an overview of the descriptive statistics can be found in the RP [61].

5.3.1 Sample Comparison

Programming Experience: While comparable to those recruited from platforms like MTurk or Google Play, our Qualtrics sample exhibited higher proficiency in software testing and reverse engineering, with a composition of software developers (72.35%), engineers (27.35%), data science/machine learning specialists (24.41%), and DevOps professionals (20.88%). Our participants had elevated proficiency levels in development areas, particularly in frontend (μ: 4.14) and backend (μ: 4.20) development, and showed substantial experience in software testing (78.24%), networking (40.29%), vulnerability research (38.53%), and reverse engineering (30.88%). In contrast to Kaur et al., our sample was more gender-diverse (21.5% female developers) and reported higher proficiency in the top 15 programming languages.

Security Experience: Our participants were more inclined to work in larger companies with security champions (49.7%) and made security-critical decisions collaboratively (77.4%). They were at least twice as likely to have security certifications, attend security events, engage in CTF contests, disclose

vulnerabilities, and submit bug reports compared to Kaur et al.'s samples. Further, they demonstrated extensive experience across security features, with higher usage reported in encryption/decryption (65.29%), authorization/authentication (59.41%), and API keys (58.53%), alongside more frequent application of security problem identification techniques. Finally, on the SSD-SES scale, our participants scored higher in vulnerability identification and mitigation (μ: 35.61), indicating stronger confidence in security-related tasks, with a moderate score in security communication (μ: 24.55), showcasing significant differences from all samples in Kaur et al.'s study.

5.3.2 Qualtrics as a Recruitment Platform for Company Developers

We tested Qualtrics as a promising recruitment platform for company developers. We opted for a comparable sample to [33]. For this, the Qualtrics service needed to conduct feasibility checks with individual panel providers in each country. With a recruitment duration of 2.5 month (79 days), Qualtrics required significantly more time than the promised 8 to 10 days for participant recruitment. However, our literature review suggested similar recruitment timeframes through alternative channels. Past work often recruited fewer participants (n = 45) within a similar time frame of 1.5 months with Upwork [28] or more participants (n = 333) over a longer period of 10 months with Prolific and Upwork [74]. Further, Tahaei et al. [69] recruited 613 participants across various platforms within 51 days.

Additionally, Kaur et al. [33] recommended using screening questions for recruitment on platforms such as MTurk. We also used screening questions recommended by Danilova et al. [15], resulting in 1556 participants being screened out of our study.

With 65.38%, the rate at which developers failed the screeners was notably higher than students' performance in previous studies. For example, in [69], freelancers recruited through Appen, Clickworker, MTurk, and Prolific failed screeners at rates of 100%, 36.8%, 91.6%, and 66.8%, respectively. However, the failure rate for students recruited through mailing lists was 10.8% [69]. This discrepancy raises concerns about the reliability and validity of participants recruited through the Qualtrics platform and suggests potential limitations in the screening process or participants' demographics within the pool. Thus, further investigation into the used screeners, screening criteria, and participant demographics is needed to assess and address potential quality issues associated with Qualtrics participants. The cost of using Qualtrics also needs to be considered, as the platform's per-participant charge of $62.15 for a 30-minute survey was significantly higher compared to alternative platforms like Upwork ($15-$120 per hour [71]), where participants could be compensated more flexibly based on the task complexity and duration.

RQ 3 – Summary

Compared to developer samples explored by Kaur et al. [33], our Qualtrics-recruited sample had higher proficiency in software testing and reverse engineering, focusing more on security-related tasks. Our participants reported greater proficiency in the top 15 programming languages, were more likely to work in teams involving security champions at larger companies, and demonstrated higher engagement in security-related activities and confidence in vulnerability identification and mitigation. Challenges with Qualtrics recruitment included longer-than-promised recruitment durations and a high screening rejection rate.

Table 8: Participant acceptance rates for different study lengths (in minutes).

Percentiles	Survey	Interview	Coding	Code Review
10%	60.00	60.00	120.00	120.00
25%	30.00	59.25	60.00	60.00
33%	30.00	30.00	60.00	60.00
50%	20.00	30.00	60.00	60.00
67%	15.00	20.00	30.00	30.00
75%	15.00	15.00	25.00	30.00
90%	10.00	10.00	15.00	15.00

6 Discussion and Recommendations

Improving the recruitment process of security studies with developers is critical for human-centered research's long-term success. This study serves as an initial step in guiding future research on recruitment strategies and establishing a foundational baseline for study design.

Security Studies: Our research indicated 62.5% of developers favor security over software engineering tasks, with 96.5% willing to engage in security studies. Additionally, developers prioritized security over other barriers and motivators. This preference is crucial for high numbers of participants and needs to be considered, e.g., in study design involving security deception. However, repeat participants perceived security as more challenging than first-time participants, although they had 40% more general and 50% more security experience than first-timers. Our results suggested these concerns might be mitigated by announcing security studies as a learning and development opportunity, aligning with corporate culture, and enhancing company reputation. Participants in security roles working for security companies predominantly preferred recruitment through their employers.

Study Length: Our results suggested that survey studies typically met participant expectations concerning study length, while interviews and practical tasks often exceeded them. First-time participants prioritized time flexibility, suggesting that emphasizing flexibility could attract more participants. Table 8 provides an overview for percentiles (10,

Table 9: Participant acceptance rates based on compensation rates for a 15-minute study.

90%	60.00	86.40	97.20	80.60	108.00	114.48

25, 33, 50, 66, 75, 90) describing how many percentages of our participants would accept a study invitation with the indicated length showing that 90% of participants would take a 15-minute programming task. Detailed percentile tables by region are available in the RP [61]. Participants from Africa and Asia generally showed a higher willingness to engage in longer tasks.

Compensation: Our literature review revealed significant inconsistencies in compensation practices that could introduce a recruitment bias affecting study samples' diversity and representativeness. Interviews and practical tasks showed a wider compensation range, with six out of 13 online interviews paid at least 50% above participant expectations. While a higher payment might affect participants' performance, researchers missed the opportunity to increase their sample size by reallocating research funds. Still, the most extended interview study out of these 13 studies offered the lowest hourly compensation of $20 for 2 hours. Additionally, compensation for online practical tasks often met or exceeded expectations, in contrast to lab-based studies, which tended to compensate less than our participants would have expected. This discrepancy is even more pronounced considering the limited data from field studies, where the only interview that provided an hourly compensation rate also reported the lowest rate. Table 9 and Table 10 provide an overview of compensation expectation percentiles (10, 25, 33, 50, 66, 75, 90) for a 15-minute and 60-minute study. Most participants expected compensation at least equivalent to their country's minimum wage. Repeat participants used previous studies as a baseline for compensation. While participants from Asia expected lower compensation, other regions typically requested higher rates. Additionally, participants expected higher compensation for long-term studies.

Recruitment Channel: Compared to platforms in previ-

ous work, where participants often indicated freelancing as their main profession, Qualtrics stated to have access to developers employed in organizations through panels and social media. Since past research found different security behaviors between freelancers and developers employed by organizations [18, 44, 76], we tested Qualtrics as a promising recruitment platform for company developers. We encountered challenges with Qualtrics recruitment due to a higher recruitment duration than promised and a high screening rejection rate that might be significant factors for researchers. However, our target demographic comprises professional software developers employed in companies, presenting a challenge in accessibility compared to freelance developers [33]. Therefore, Qualtrics' ability to recruit company developers in significant numbers might be promising in enhancing the ecological validity of study findings. Further research is required to explore the ecological validity of study results for both sample groups.

7 Call to Action

7.1 Research Transparency

Our literature review showed that many studies omitted factors such as study length and compensation. With only 30 of the 163 papers in our literature review explicitly mentioning hourly compensation, a lack of transparency poses a significant challenge for researchers to base their study design and recruitment decisions on prior research. This might affect the comparability and reproducibility of security studies. Additionally, even if this information is included, locating this "blink-and-you'll-miss-it piece of data" is often challenging. Hence, we advocate for establishing clear guidelines regarding the consistent reporting of such information in research.

To improve the transparency of research, we propose a dedicated section *Study Parameters* (see Section 4.1) supported by a table (see Table 1), including the following study details: (1) study type, (2) study task, (3) study language, (4) study length, (5) recruitment channel, (6) recruitment duration, (7) participants, (8) compensation (type, amount, currency, ethical considerations). Based on the conducted study, this information might be extended. Adopting such a standard procedure might be a critical step to enhance the clarity and efficiency of research design and process of future human-centered security research. Providing this information could further benefit the creation of a study design benchmark relevant to the security community.

7.2 Ethical Study Compensation

Our literature review revealed significant inconsistencies in compensation practices raising ethical concerns. For example, three out of four online surveys compensated participants less than our participants expected. This is particularly concerning considering studies that involve participants from different regions but do not adjust compensation to reflect regional economic realities. Most studies offered compensation rates below the average hourly wage of software developers in higher-income countries such as the U.S. ($59.71 [72]) while exceeding the average hourly compensation (assuming 40hr/week) in lower-income countries such as India ($1.56 to $11.73 [53]) and South Africa ($4.46 to $21.51 [54]). Wages in European countries (e.g., Germany $19.39 to $38.25 [52]) were more in line with the compensation offered in most studies. To mitigate these issues and improve the recruitment of participants for future security developer studies, we advocate the adoption of consistent compensation based on participants' expectations, the local minimum wage, and time requirements reflecting the effort associated with different study tasks and types. By implementing a respectful compensation approach based on these principles, the security community might further foster high-value human-centered research standards respecting the participant pool's global diversity.

8 Conclusion

Recruiting a high number of participants for software engineering and security studies is challenging. Many participants indicated not receiving study invitations regularly, even though they would accept most recruitment channels and strategies to be recruited through. Past studies have often used few recruitment channels, relied heavily on personal and professional contacts, and thus often struggled to reach enough potential participants. Diversifying the recruitment channels used is an essential first step. We investigated the attitudes and expectations of first-time and repeat study participants and provided recommendations on monetary compensation and study length for future developer studies. Software developers were motivated to participate in developer studies if they benefited from participation. Since there are significant differences in expected compensation based on employment region, we advise a careful setup of study setting and compensation level. Future research might investigate the effect of different payment levels on study performance and offering non-anonymous charity donations as an alternative form of compensation. Finally, we call to action to foster a transparency-friendly research environment by consistently reporting essential recruitment details such as channels employed, compensation provided, and study length. This practice would establish a fundamental benchmark for future research endeavors. Future research might also need to investigate how the results will replicate over time by considering the effect of currently popular AI assistants on developer security studies and their implications on compensation and study length.

"What Keeps People Secure is That They Met The Security Team": Deconstructing Drivers And Goals of Organizational Security Awareness

Jonas Hielscher
Human-Centred Security
Ruhr University Bochum, Germany

Simon Parkin
Cybersecurity (Technology, Policy, and Management)
Delft University of Technology, Netherlands

Abstract

Security awareness campaigns in organizations now collectively cost billions of dollars annually. There is increasing focus on ensuring certain security behaviors among employees. On the surface, this would imply a user-centered view of security in organizations. Despite this, the basis of what security awareness managers do and what decides this are unclear. We conducted $n = 15$ semi-structured interviews with full-time security awareness managers, with experience across various national and international companies in European countries, with thousands of employees. Through thematic analysis, we identify that success in awareness management is fragile while having the potential to improve; there are a range of restrictions, and mismatched drivers and goals for security awareness, affecting how it is structured, delivered, measured, and improved. We find that security awareness as a practice is underspecified, and split between messaging around secure behaviors and connecting to employees, with a lack of recognition for the measures that awareness managers regard as important. We discuss ways forward, including alternative indicators of success, and security usability advocacy for employees.

1 Introduction

Research has made great strides in informing security awareness practice and awareness campaigns [3, 13, 55, 57], in parallel with increased interest in the human factors of security over the past two decades and more. This has resulted in a greater understanding of awareness campaigns themselves, but not necessarily the drivers for how they are managed.

Recent research has evidenced that those managing employee security in organizations may have motives and measures outside of secure working itself [13,48], such as regulatory compliance. A disconnect may also exist between managers and the users they are looking after [10,11,27,48,49,73]. In 1999, Adams & Sasse characterized employees not using provisioned security apparatus in the way the organization had anticipated [2]. This raises questions as to the incentive structure and mechanisms of change, that would drive adoption of improved practices as derived in prior research. It is then natural that in recent years, guiding employees to behave securely has grown to be a business function in its own right – worth billions [77]. A heavy focus of work in this space has been on designing effective interventions focusing on secure behavior, but less on how these interventions are effectively positioned within the specific setting of an organization.

Prior work has illustrated how drivers and goals, especially relating to security, may differ between employees [16] and the managers of the system. Research up to now has focused on what the apparatus allows an awareness campaign to achieve – where it has been questioned whether security awareness campaigns in organizations exist only to achieve security awareness [13]. Less attention has been given to the decisions and drivers that shape what is possible for a Security Awareness Manager (SAM) to achieve in their role [29], though there has been work exploring the requirements for e. g., US local government awareness campaigns to succeed [40]. This prompts a need to determine if secure working behavior is the only driver influencing the activities of a SAM, and in turn, security awareness programs.

SAMs are those members of an organization tasked with managing the security awareness of employees, typically by conducting awareness campaigns or buying and managing awareness products (like phishing simulations) from external vendors. In most cases, regular members of the (technical) security teams, or Information Security Officers, are working as SAMs part-time [51,52]. In larger organizations full-time SAMs are becoming more common – like all participants in our study.

Here we study how security awareness activities are perceived by practitioners whose job it is to manage security awareness in (large) organizations – the SAMs. We explore their aims, how they demonstrate success, and – ultimately – how they sum their role with what is expected of employees in the same organizations. We identify the drivers and influences over their decisions, and to what extent this aligns with

the goals of behavior change and behavior support (such as smoothing the path to effective change [25,34]). To do so, we performed semi-structured interviews with $n = 15$ European SAMs, all working primarily in awareness and for large public and private organizations. SAMs are the primary gatekeepers for any change and improvement of real-world security awareness. Beyond a specific examination of US local government efforts to ensure employees are trained (see [40,54]), to the best of our knowledge, no previous in-depth research has studied this group's perception.

We formulate the following research questions:

- **RQ1**: What activities and topics do security awareness managers regard as being security awareness, within the remit of their role?
- **RQ2**: How do security awareness managers interact with employees?
- **RQ3**: How is success defined for security awareness managers, by them or others?

Looking at security awareness through the lens of SAMs and their perspective, we identify a range of critical outcomes. These include that, according to our participant SAMs, security awareness has a goal of ensuring active engagement with security; this is then not a direct measurement of increased security levels through behavior change. The positive feedback from employees is then used as a success indicator. Also, security awareness is both an underdefined and overstretched term, used to refer variously to training, communication, human factor principles, and usable security. Our suggestions to move forward include a clearer, modified mandate for SAMs (as employees' security advocates), the development of clear definitions around security awareness and related concepts, and research that takes into account the SAMs' struggle with raising engagement itself.

Contribution: (I) We study security awareness through the lens of practitioners from large European organizations, characterizing dependencies and drivers for their decisions around how security awareness appears for employees; (II) We identify barriers to improving awareness programs. We highlight how awareness is currently locked to a specific path, where usability is defined by vendors, and SAMs have limited tools for responding to engaged employees who cannot follow the training that the SAMs offer; (III) We address the under-specification of awareness activities in research, beyond an expectation of structured, regular training (where there are also ad-hoc advisories driven by technical teams, for instance).

2 Background & Related Work

Here we explore the definition of security awareness in literature (Section 2.1), what its goals are (Section 2.2), challenges related to how awareness happens in practice in organizations (Section 2.3), and the SAM role (Section 2.4).

2.1 What is Security Awareness

As a foundation, we refer to US NIST standards – NIST standard 800-12 defined employee-facing "awareness, training, and education" (ATE) for security, in the mid-nineties [39]; the what, how, and why of security behavior respectively. The NIST 800-50 standard appeared later in 2003, focusing on building a dedicated program for security awareness [79]. They define awareness as a process to focus attention, training to generate necessary skills, and education to integrate all skills. Here, learning is described as a continuum that starts with awareness. In reality, the three components of awareness, education, and training are often referred to collectively by the shorthand of "security awareness", and are considered to be hard to distinguish in security research [5].

Prominent issues covered by security awareness activities include the creation of secure passwords [31], and advice for how to detect phishing emails [21,23,60]. There have also been trends in the field, some of which are ongoing, such as e. g., "security culture" [28,74]. Looking ahead to our interviews, we observe that security awareness is more recently being referred to in practice as security behavior change – another trend in the field, also promoted by the US-based SANS institute.[1]

Regarding the positioning of security awareness activities within organizations, there will generally be computing devices and services provided by the IT team, complemented with a policy or declaration of expected ways to behave and use those provisions [58]. Employees are then expected to follow the rules and use the provided tools – to not do so has in the past been regarded as willing non-compliance [2], but in recent years there has been a growing body of research into users' knowledge and capacity to engage (or not) with security, e. g., with policy non-compliance [15], and employee motivations to use what is provided [18].

Informational and training materials may be deployed as e. g., online training and security alerts, but also instructor-led events and engaging artifacts such as posters and branded items [1,14] (as has also been advocated in prior NIST standards such as 800-50).

[1] Security Awareness Maturity Model - Promoting Change: https://www.sans.org/blog/security-awareness-maturity-model-promoting-change/, accessed March 6, 2024

2.2 Goals of Security Awareness

Looking broadly at what secure behavior is, there have been attempts to standardize what good behavior is and how to measure it, as with SeBIS [30], which focuses on general behaviors such as having a secure password and security checks when online. The HAIS-Q [70] instrument has a focus on organizations, including not only secure practices but awareness and alignment with IT provisions (including policies and compliance with them). The focus of these works is generally to determine how well individuals are engaging with and applying (provisioned) security solutions.

Looking at industry norms we see that, for example, ISO 27004 [53] explains that organizations should measure whether employees are prepared against social engineering through phishing simulation click-rates. The BSI basic protection [37] states that the goal of awareness campaigns would be to raise employees' awareness of security risks. In practice, awareness campaigns often require the recipient to already have a lot of existing security-related skills – in order for expected behaviors to take root [13] – and to also commit sizeable effort to engage. Further, progress is generally not adequately measured (in terms of relating awareness activities to what employees actually do in practice). Here we explore how restrictions in guidance influence SAM activities.

2.3 Awareness in Organizations

The influence of factors outside of security behavior has been explored elsewhere, for instance through the lens of policy creation [26], and how organizational factors influence what goes into those policies. Here we explore incentives and constraints imposed upon the SAM who must support the security behavior expectations that those factors inform. Pallas [67] applied an economics perspective to understand how security is managed in organizations, considering the pros and cons of using hard and soft controls and other related enforcement costs and resource needs (finding, for instance, that soft human-facing controls such as policies require comparatively costly, follow-up enforcement).

Focusing on employee-facing controls, specifically anti-phishing solutions, Brunken et al. [21] found that multiple stakeholders were involved, and that alignment between them all was difficult to find. Such a security solution could, for instance, create a clash between the security team and the helpdesk, if an increase in support queries is anticipated, triggered by anti-phishing measures. Taking a wider organization-level view, Moore et al. [64] examined the incentives and drivers for CISOs, finding that upper-management support and regulatory alignment were key influences, and with this, that the freedom to define the role and activities varied across security professionals and organizations.

The question, as to what exactly security awareness is in practice, has been asked before [50, 75]. We examine this further now, to understand how aspects of security awareness relate to security management efforts in organizations.

2.4 Security Awareness Managers

Security Awareness Managers (SAM) are tasked with raising security awareness among employees, regardless of their place in the organization. Typically this is done through the development or implementation of campaigns and training of different forms. However, no uniform definition for SAMs exists yet, all while e. g., the SANS institute or the German TUV offer training courses to become a certified SAM. Here the TUV envisions a SAM as someone who coordinates and strategically plans security awareness activities in their organizations.[2]

Typically, a SAM is an employee in the field of security who manages security awareness as one duty alongside another dedicated role [51, 52]; it may be that over 80% of security awareness professionals spend half or less of their time on awareness, given this model.

It was found that, among awareness managers in U.S. government agencies, approximately 90% manage awareness in a part-time capacity, with 55% managing awareness in less than 25% of their time [41]. In some cases, even a CISO, or an ISO27001 Information Security Officer [53] might act as a SAM. Especially in larger organizations, there might be multiple SAMs, working in an awareness team. There are few other studies directly focusing on the experiences of SAMs outside of the materials they produce: Haney et al. [40] studied U.S. governmental SAMs through focus groups and a survey. Among other things, they were interested in SAMs' collaborations, the importance of regulations for their work, and potential measurements. In an associated study, Jacobs et al. [54] found that effectiveness was measured through training engagement and event attendance, noting challenges in resourcing the materials needed for employees to know about secure practices. Blythe et al. [19] surveyed 98 security awareness professionals to understand their perception of sanctions for non-compliant behavior.

It is important to note that security and privacy awareness in organizations is not necessarily always managed centrally. So-called security and privacy champions/ambassadors/advocates – employees willing to voluntarily promote secure behavior in their teams, often without a direct formal mandate from the security managers – are spreading their knowledge to raise awareness among their colleagues [17, 36, 43–45, 63, 76]. Looking ahead to our findings, those champions were welcome allies for the work of our participants (see Section 4.6).

[2] Security-Awareness-Koordinator [German]: https://akademie.tuv.com/weiterbildungen/security-awareness-koordinator-tuev-473465, accessed March 6, 2024

3 Methodology

We conducted semi-structured online interviews with $n = 15$ security awareness managers (SAMs). The interviews were carried out from May to September 2023. Figure 1 summarizes our method.

3.1 Instrument Development

The development of our interview guide was informed by the literature review we performed on the practice of security awareness in organizations. The interview guide covered: (I) the SAM role; (II) activities related to this role; (III) goals of awareness for the SAMs and their organizations; (IV) awareness tools & techniques; (V) the role of employees in security awareness, and; (VI) an outro and debrief.

Regarding the management of awareness as a role, this informed questions regarding the availability (or scarcity) of resources to support the role (which can lead to trade-offs [69]), and decision-making drivers and influences (including whether the remit of the role or colleagues in the organization encourage particular decisions). We then have *role* questions and *role activities* questions.

Our position is that the majority of research focuses on behavior changes in isolation, and not how they are situated as a function of business, alongside other interests. Prior research has identified clashes between primary and secondary tasks in security [33, 46], and in organizations (e. g., [15]). In essence, managing awareness is a job, with pressures, and an activity that must sit alongside other non-security activities [47], that uses infrastructure provisioned by the organization.

For these reasons, we wanted to understand the *goals of awareness*, what *awareness tools & techniques* are available, and their suitability. It is only after establishing the empowerment of the role of a SAM, that we position this alongside the *role of employees in security awareness*. Prior research with CISOs [48] has identified a range of CISO perspectives, for instance, ranging from a view that employees simply have to find a way to do what is expected for security (because it is important), to the CISO struggling to find a way to support employees to work but be able to do so securely.

Our initial scope was to identify incentives, and perverse incentives [6] as well as misaligned incentives [7]; these mechanisms can help to explain observed (mis)alignment of drivers. Where a combination of economics with psychology generally points to behavioral economics [8], we took a step back to look at the infrastructure around behaviors, that defines and limits which behaviors are deemed acceptable – and not – within a system (in this case, an organization). From here we derived our research questions.

A pilot interview with a SAM of a German industrial organization led to further refinements of the interview guide, mainly in the form of a reduction of the question set to stay within time constraints. The results of this pilot interview were not included in the final analysis. The full interview guide can be found in Appendix A.

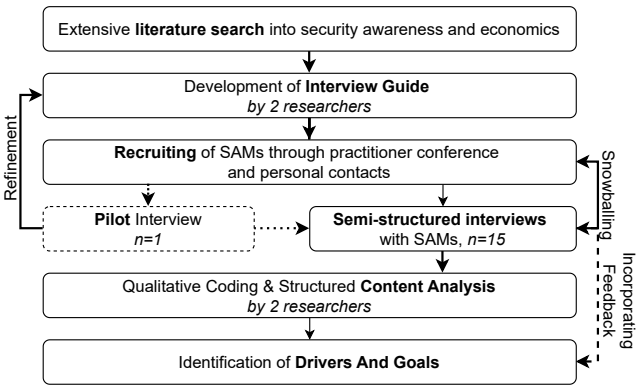

Figure 1: Our data collection and analysis methodology.

3.2 Recruitment

We only recruited SAMs that manage awareness as their primary job function. We hypothesized that organizations that have such dedicated SAMs implement *industry awareness best practices*. Hence, studying their SAMs can give insights into the state-of-the-art awareness implementations in practice that other, smaller organizations may assume to mimic for best results. Recruiting such a number of primary job SAMs was challenging and it took us from May till September 2023 to complete the recruiting. SAMs that are primarily employed for awareness tasks are a difficult-to-reach population (as with other security professionals such as CISOs [73]).

An initial recruitment channel was a security awareness practitioner conference held in Germany. Here one of the authors approached various participants of the conference and directly invited them to the interviews. This was combined with the recruitment of two SAMs via personal contacts, and snowballing to reach the remaining participants.

Three SAMs, who initially agreed to interviews, dropped out due to time constraints, resulting in 15 interviews in total (excluding the one pilot interview).

We did not compensate the participants financially, but instead offered each participant early sight of the study results before publication. When we sent out the results we also actively asked for participants' feedback on the content. Nine interviews were conducted in German, and six in English.

3.3 Analysis

The interviews were automatically transcribed with Open AI's whisper program[3] (offline, on the local machine, so no data

[3] Whisper: https://openai.com/research/whisper, accessed March 6, 2024

was sent OpenAI) and then manually corrected by one researcher. We used MaxQDA 2022 for the coding process. We applied Kuckartz' [59] process scheme of content-structuring analysis and followed Braun & Clarke's [20, 24] method of thematic analysis, where we implemented "codebook style" coding. Here we applied combining deductive and inductive coding strategies and a category-based evaluation along main codes.

Two researchers were involved in the analysis, with only one researcher directly coding in the interviews, due to only this researcher being able to understand German. We deemed this the better alternative, to coding translated documents, where meaning might have gotten lost. Following Braun & Clarke's [20, 24] guidelines, one coder is sufficient in the case of "codebook style" coding [61]. The second researcher shaped the coding in all steps through regular meetings (at a regularity of days rather than weeks) and direct discussion of the codes, resulting in adding/removing/updating of codes, toward the identified themes.

Additionally, both researchers created memos (summaries) after every interview session as an interim step before the systematic coding, which started after the first nine interviews were completed, where they would directly discuss the impression that the interviewer had on the interviews. Hence, the coding process had to be guided by multiple discussions (dozens of hours of joint sessions), where the main coder presented their coding strategy based on translated examples to coder two. Those discussions led to refinements in all steps of the coding process.

The coding happened in multiple steps: (I) A deductive codebook was created based on the interview guide and the research questions. (II) All interviews were coded deductively and inductively. (III) The code book was refined. (IV) All interviews were coded with the finalized codebook. During all steps, memos were created that guided the discussion. The codebook can be found in our replication package[4], with a mapping to where themes are discussed in the Results section.

3.4 Ethics and Data Privacy

Our study was reviewed and approved by the ethics committee at TU Delft. Ruhr University does not have an institutional review board (IRB) nor an ethics review board (ERB) for security research. We followed the Menlo Report principles [56] and GDPR requirements: all participants received a data privacy statement prior to the interviews. We informed the participants about their rights, especially that the interviews were voluntary and could be stopped at any time, and that we would only publish anonymous results of the interviews. All participants gave their explicit consent. We recorded the audio data of the interviews and ensured to delete this data after six months. The data was exclusively stored at our institutions, within the jurisdiction of the GDPR. Due to the small size of the SAMs community, we only report demographic data in an accumulated form to prevent identification.

[4] https://doi.org/10.4121/9dc01aa6-8274-43f4-b137-6d185e7008d1

3.5 Limitations

As with every study with human subjects, our research has limitations. Firstly, the participants might have held self-reporting and social desirability biases and might have kept information from us. This may reflect, for instance, how although our participants noted frustrations, they did not comment on any failure in their roles and activities.

The codebook reached saturation during the first 9 interviews (with all participants from central Europe) at which point we felt it conducive to explore other regions. Interviews with the UK SAMs brought new angles, e. g., a usable security perspective (see Section 4.6.1). In summary, we did not reach saturation. With a much larger set of participants from the same regions this would have been possible, but due to the nature of this hard-to-recruit population, which would have added considerably to the approximately six months required for the recruitment of the existing 15 participants, we refrained from further recruitment. Here we look only at large organizations employing someone in a 'security awareness' role. Smaller organizations face many challenges around security awareness centered around a lack of resources [12]. Our SAMs came exclusively from European countries.

4 Results

Here we first summarize the demographics of our participants, before we present the results of our content analysis.

4.1 Demographics

All participants worked in security awareness as their primary job function. Twelve participants were actively working as SAMs, and three SAMs transitioned from working inside of organizations to awareness consultant roles recently. The SAMs had diverse backgrounds like engineering, computer science, psychology, education, and marketing. Participants 1-9 worked in the *DACH-region* (Germany, Austria, Switzerland), P10 in Denmark (previously in the UK), and P11-15 in the UK. At least three SAMs have worked in different European countries in an awareness role. Table 1 summarizes key properties of the participants.

While our analysis did not aim to understand differences between regions, or industries, we identified a few systematic differences, namely: (I) the different interpretations of employees' roles between the DACH managers and all others (See Section 4.6), (II) the focus on sector-specific regulations (see Section 4.4.2).

Table 1: Background information of the SAMs.

Gender	#	%	**Sector**	#	%
Female	10	*66*	Energy	3	*20*
Male	5	*33*	Consulting	3	*20*
Education			Banking	3	*20*
Cyber & Inf. Sec	5	*33*	Industry	2	*13*
CS & Engineering	4	*26*	Retail	2	*13*
Comm. & Marketing	2	*13*	Public	1	*6*
Social Science	2	*13*	Automotive	1	*6*
Education	1	*6*	**Country**		
Psychology	1	*6*	UK	5	*33*
Number of Employees			Germany	4	*26*
Max: 400,000 & *Min*: 1,600			Switzerland	4	*26*
Median: 27,000			Austria	1	*6*
Average: 62,000			Denmark	1	*6*

4.2 Awareness in Organizational Practice

The concepts of awareness are shaped by the organizations they are carried out in [54], which we explore in this section.

4.2.1 Activities

Awareness is implemented as a multitude of activities for an organization's employees. For this, the SAMs combine e-learning, in-person events, simulations, and direct communication. Scalability of the activity was a prime argument for digital solutions, accepting that they might be less successful.

Phishing simulations were at the core of most SAMs' (P1,2,4-P10,12,15) awareness activities, as seen elsewhere [40]. Here we got an insight into why this might be the case: they are just best practices the SAMs see in other organizations (P8,15), regulations require them (P6,9,10), and they are scalable to reach most employees (P2,6,7). However, some SAMs (P3,9-11,15) were critical about it, often did not see the advantage, and some would even like to get rid of it: *"Phishing, I try to minimize it where I can, but must, so a regulatory default actually with us, must be made"* — [P9]. Others (P4-8,12) believed that phishing simulations would indeed bring a behavior change among employees.

Classical e-learning (*"very classic web-based training courses for security, data protection, and physical security."* — [P1]) was common in the SAMs' organizations (P1,2,4,5,7-10,12,15). Only a few SAMs sought personal face-to-face contact with employees (with the most important face-to-face meeting between employees and security being onboarding). P11 explained why this would be important: *"What keeps people secure will absolutely not be the cybersecurity awareness training they had to do on onboarding. What it will be is the fact that during that onboarding they met the cybersecurity team or somebody from it, or they had an onboarding before they were even in the company they were maybe taken through"* — [P11]. Gamification and serious games, as a way to improve the acceptance of security awareness activities and as a new promising trend, were exclusively brought into the discussion by the DACH-based SAMs (P1-5,7-9), e. g., *"we are still looking for it to be somehow interesting and interactive or to include gamification."* — [P4].

The third most important activity (P1,2,4-6,8,9) was described as active communication into the organization through intranet articles, blog posts, emails, and messenger platforms: *"The platforms that we serve both internally [are important], whether it's a social media channel, like Yammer or whether it's a SharePoint, where we sort of prepare all, yes, everything around cyber security."* — [P6]. P8 was critical about the range they can generate through such communication: *"often you can't necessarily reach the masses with videos, blog posts, and linking or advertising your own content."* — [P8].

Security Awareness Days, Live Hacking Events, and On-Site Training were mentioned by some SAMs (P1-4,8,12) but always with the exception that such activities would not scale up: *"The share of live training is by far not as large as the share that we try to bring to the people via online content, so to speak. Because we only do such live training courses on request."* — [P8]. Only P4, P5, and P7 talked about whole campaigns that would include material like posters, or flyers: *"They don't look at the intranet, but if there's a postcard lying around, they're much more likely to take it than something digital."* — [P7]. P4 was the only one that reported that they would try social engineering techniques on their colleagues on-site, e. g., by placing flash drives in the offices or checking the screen locks of Desktop computers.

4.2.2 Topics

Employees were trained on a mixture of threats, attack models, defense strategies, and concrete behavior. Topics were driven by a mix of 'basic' technologies such as passwords, and emerging concerns such as remote work and ransomware – focusing more on the explanation of attacks, than specific behavioral responses to threats. Password policies, social media security, the darknet, social engineering, tailgating, flash drive security, ransomware, security during mobile work, and data classification were some of the examples the SAMs gave, about what they trained the employees on. Regarding those mixtures of topics, P3 observed *"that people are actually always trained on strange topics. So there's usually a quick guide or a collection of topics on phishing, passwords, access, or something like that, i.e. clean desk, and then maybe remote work. But these are completely different categories. You have phishing, which is an attack technique. You have passwords, which are a security measure. You have remote work, that's a place. Clean Desk is another security measure."* — [P3].

Seven SAMs (P1,2,5,7,9-11) found it important to relate topics to the private lives of the employees since this would create much more attention for security, e. g., *"If I did a workshop on phishing, nobody will come. But if I want to do workshops on dating app security, using Grindr safely, you*

know, how to send nude photos correct, [...] they love it, you know." — [P11].

4.2.3 What Informs Awareness

The selection of topics, activities, and awareness strategies were influenced by multiple factors. The biggest influences came from within the organization of the SAMs, highlighting the necessity for awareness strategies tailored to specific organizational needs. Where Haney et al. note the involvement of the IT team [40], we find that this can result in sporadic content being created, and in a manner disjoint from regular training. New topics are then addressed in small ways by email at first, potentially long before they become part of regular, structured training. Addressing new threats becomes advisories, distinct from the established training, unless the SAM has resources to quickly make training for newer concerns.

Six SAMs (P4,5,7,8,12,15) stated that their organizational security policies would influence their activities and the content of learning materials: *"So 95% of the policies are integrated into this e-learning"* — [P5]. Some explicitly distinguished between their more sophisticated activities (like live hacking or gamified learning), and some mandatory e-learning only required to explain security policies.

Three SAMs (P1,6,7) explained that they would send out communication on short notice if topics would come up in the news: *"if incidents are picked up by the media, then it is often the case that we try to jump on it and, for example, pick up on a new fraud scheme such as multi-factor authentication phishing."* — [P6]. The SAMs reported that sometimes internal stakeholders influenced the activities, such as management (P1,2), the communications department (P1,9), the security team (P4,6,8,9), or the CISO (P4,10), e. g., *"With the Security Operations Center, we have a monthly appointment where we look, are there any points that we want to pass on [to the employees] each time"* — [P9]. Moore et al. [64] noted a similar phenomenon for CISOs, needing to respond to the concerns of higher-up managers.

P2 and P10 reported adapting their content to the wishes of employees. Only P4 and P8 would create content around technical updates. For P4, P7, and P8 the changing threat landscape leads to adaptation in their security awareness communication: *"At the moment there is a huge vishing campaign by some attackers, especially in our sector. And it's happening relatively quickly. So the topic came to me, too, but it also popped out at [the CISO]."* — [P4]. Only P7 reported that a previous incident at their organization influenced the awareness activities.

4.3 What is (Good) Security Awareness?

We explicitly asked the SAMs to define security awareness. What we found was that interpretations were as diverse as the background of the SAMs, covering all aspects of "Knowledge, Awareness, Training", with some SAMs explicitly negating some of those aspects. Others were hoping for a redefinition of the term and the whole field. For P2 it was important to distinguish awareness from training: *"But actually we are awareness and the awareness [team] does not execute training [in theory]"* — [P2].

For others (P1,3-6), training was equivalent to awareness or at least the core of it: *"When someone says 'I'm doing security awareness', [...] you train and you educate and you adapt processes."* — [P3]. P7 set awareness equal to phishing training and P10 reported having heard such from others: *"They thought phishing training was awareness. And I had to burst that bubble and basically say no like phishing is such a [...] small element of awareness."* — [P10]. P3 and P10 acknowledged that it is hard to actually state what awareness really means: *"when someone asks, 'Hey, do you do security awareness?' and the person says, 'Yes.' Then that can mean anything from, I wrote an email yesterday and next year I'm going to do this again, [...], to, I'm going to do it like company X [implementing a full security communication strategy]"* — [P3].

Multiple SAMs stated that they disliked the term security awareness for what they did, and would like to use alternatives, like security communication (P3), security training (P5), security behavior change (P10), security human factors (P11), security user experience (P13), security culture change (P14), and security engagement (P15). This is notable given that 'security awareness' as a term when unpacked typically represents awareness, education, and training. Those SAMs see a shift in the field of security awareness.

4.3.1 Goals of Awareness

One might assume that increased security levels would be the goal of any awareness activities. We found that this assumption might not be true. Awareness as practice seems for the majority of our participants to be about reaching employees and eliciting visible responses. Only a few SAMs (P3,5,9,10,12) stated that the actual behavior change of employees was indeed a goal of their work (e. g., *"the premier class: that the employees actually act securely in our interests."* — [P5]) or more generally that they wanted employees to become aware of security.

More important to the SAMs (P1-3,5-8,10) was that awareness itself reached the employees (e. g., *"if more than 10 percent of people have actually read the article or reacted in some way, then it's a success"* — [P1]) and that employees would start talking about security and the training they received. Most participants (P2,3,6,8-10,12,14) saw the creation of visibility for security at the core of awareness. In the interviews, the SAMs regularly came back to numbers that showed how they achieved greater reach with their activities, like the number of participants in training and live

hacking events, or the number of followers to the intranet: it was a prime topic they wanted to bring up. Haney et al. also remarked that US governmental awareness managers saw communication as important [42], but a complementary NIST report noted a challenge in reaching employees despite using a range of awareness formats similar to those we found here [40].

When SAMs (P2-4,6,7,9,15) reflected on the awareness goals of their organizations, the most common statement was that the security and risk strategies addressed some human factor, or some human risk and hence required awareness: *"So we have defined three main pillars in cyber security, including phishing, and that is the main goal in awareness, to have the human element as well under control as possible."* — [P2]. Only P9 directly connected their work with the actual protection of organizational assets: *"The goal is, of course, to be able to better protect our business data as well as our customer data. In other words, simply to meet the level of protection."* — [P9]. Some comments indicated that the goal of security awareness might be self-serving, aiming to find users to train, and not about evidencing secure behavior: *"Sometimes there is a campaign that just doesn't succeed. So we did spear phishing, we were too secure. So the emails didn't get in, my people were already too aware. [...] we paid so much money [for the campaign]."* — [P4].

4.3.2 Measuring Success

SAMs measure training response but are not sure if they are using the right measurements. They are then not directly measuring security behavior, but instead engagement, where if employees are engaged they are willing to invest themselves in security. Haney et al. noted dissatisfaction with measuring training completion and reliance on correlations with incident reports [40]. Awareness activities need confirmation – from the SAMs and other involved stakeholders. This is why all SAMs reported to have some form of measurement in place. Such measurements could be carried out before, during, or after an activity. The measurements were roughly aligned with the stated goals of awareness (see Section 4.3.1). However, the SAMs seemed to be uncertain whether the currently available measurements would indeed help with this.

The primary measures of success for the SAMs were (I) engagement- and click-rates on their content (P1-4,6,8,9, e. g., *"What are the access rates on the volunteer awareness blog? Yes, I measure that, how successful we are."* — [P4]); (II) the positive feedback they received (P1,2,5-9,12, e. g., *"What's also important with us is that after the sessions, that we then ask, 'What did you think of the talk?'"* — [P2]), and; (III) the reporting numbers from phishing simulations (P2,5-7,9,10,12,14,15) . P3, P6, and P14 also used classical metrics from marketing: *"An important indicator for us is the NPS, the Natural Promotor Score, where we have a number that indicates how satisfied our colleagues are with our formats."* — [P6]. Questionnaires to collect feedback were used by seven SAMs (P4-6,9,13-15).

Some participants (P1,4,8-10,11,15) were transparent that they did not know how to measure the success of their work in a meaningful way, or that their current measurements were limited: *"We have already had many discussions about how to measure security awareness, whether we can somehow measure that people are aware of it. But somehow we haven't found any good solutions yet."* — [P1]. Especially when it comes to the reporting rates from phishing simulations some SAMs (P9-11,15) were skeptical: *"How click-through rates change, I think that's what most people mention first. And where they also say, I'm measuring behavior like that, where I'm like, 'No, you're not.'"* — [P9]. Another problem identified by P3 and P10 was that measured results would not inform any decision about behavior, but instead about the success of the communication drive itself.

4.4 External Influences on Awareness

The SAMs' work was influenced by factors outside of their direct control, which we explore in the following.

4.4.1 Vendors

We highlight here that SAMs have something of a dependence on vendors, beyond interaction and collaboration as noted elsewhere [40]. Reflecting the trend of a growing market for security awareness, 13 of the SAMs reported working together with security awareness vendors. They were brought in to help with designing the material, providing e-learning platforms, and managing phishing simulations (e. g., *"with the phishing simulation, I also write the email myself and the format and everything [...] and the service provider takes it and builds it into their simulation and that's it. And then sends it out."* — [P5]), or even developing whole communication strategies. Vendors were either phishing simulation and security training vendors, marketing agencies, or consultants. Hence the influence of the vendors varied heavily from taking over parts of the SAMs' job of planning awareness strategies to being simply suppliers for content.

The primary reason to bring in a vendor was cost reduction, or better: a lack of human resources to do the job without the help of vendors, and hence a reduction of workload for the SAMs, e. g., *"We used to do that [content creation] ourselves, fortunately, we bought it from a vendor."* — [P2]. This seems unsurprising since our participants were responsible (solely, and in a few cases in small teams) for the awareness of thousands of employees. Doing their jobs without vendors might therefore be impossible.

However, a few SAMs questioned how helpful the vendors were in the end. P7 for example complained that international vendors were unable to adapt their content to the needs of a small country like Switzerland. For P5 it was quite

important that the concrete training content was created by themselves: *"I don't have a portfolio of service providers where I have [many] different measures that I put on a shelf, where I go into the shelf and pull them out, nope. We develop the measures"* — [P5]. For P4 the opposite was the case: *"My service provider usually still does some of the writing when I have a blog article"* — [P4]. Four SAMS (P3,10,11,13) stated that vendors are not worth their money: *"No it's not worth it. Make it yourself. There's plenty of educational apps, that you can use which are free or very cheap. And you can make something a lot more engaging and you're going to save yourself 75,000 pounds, you'll raise or whatever."* — [P11].

4.4.2 Regulations & Audits

We found that Regulations interfere with how SAMs are inclined to manage security awareness. Since multiple security regulations implicitly (e. g., ISO27001) or explicitly (e. g., BSI Basic Protection) require awareness and training for staff, we were interested in the SAMs' attitude towards regulations. We found differences in the way that some SAMs would come up with the topic themselves early in the interviews, while others would only talk about it after we brought it up. However, with few exceptions, regulations (and the subsequent audits) interfered with most SAMs (P1-6,9,10,12,15) activities. The SAMs talked about this rather abstractly and gave few concrete examples, e. g., *"It's actually a discussion I had with an awareness colleague in the community once who said, 'You don't have to phish.' And then when I looked at what FINMA [banking regulation] had written in our review, it explicitly says, 'You have to phish.'"* — [P9], or *"one of the biggest changes of the requirement for the new PCI [industry regulation] it specifically says that you have to teach them about social engineering and phishing."* — [P10].

The SAMs denied that regulations would be a primary driver of why they and their organizations do awareness, e. g., *"Audits is a necessary evil for everything, but I don't think that was the core point of why we implemented that, but we really want to be secure."* — [P4]. Some SAMs were proud that the auditors rated their awareness as positive (e. g., *"So the audit also always says, 'Our awareness is great.'"* — [P2]). However, no SAM described the regulations as helpful for their own work, e. g., for generating the necessary attention. Even more, the SAMs were critical of influence of regulations on security awareness. They would often demand a type of awareness that would not help their goals: *"one of the biggest changes of the requirement for the new [regulation] is that you have to teach them. [...] why am I teaching somebody in a retail store, who has no access to the computer and only a pay machine, why am I teaching them about phishing? They don't even have an email address."* — [P10].

4.5 Interactions and Frictions With Others

Interactions with several functions in the business act to limit or dictate SAM activities, namely regulators, and communications teams, which some SAMs felt negatively (e. g., *"the communication department is very obstructive anyway, I have to say quite honestly"* — [P1]), and their reports/managers, as well as technical teams.

Most SAMs were convinced that they had a lot of freedom in their decisions, when it comes e. g., to the content of training or the choice of an appropriate vendor. However, they noted that when their experiences and accounts of security in practice clashed with the expectations of the technical IT team, they would be overruled. Sources elsewhere note that most SAMs are part-time and otherwise in technical security roles [51, 52], whereas our participants are an exception.

4.5.1 Interactions With Technical Teams

The technical side of security played an important role in the SAMs' daily work, with most SAMs (P1-5,9,11,12,15) regularly working together with the technical security teams, e. g., security operation center teams, security infrastructure, or internal penetration testers. However, limitations were described in the relationship with technical teams by multiple participants (P3,8,10-12,14,15) when there were disagreements, as they reported that security awareness and SAMs are not acknowledged as equals by their counterparts in the more technical security teams, as *"they're the ones that will often say well you can just train people or you can just tell people"* — [P10], and *"the value of [the] security awareness and training team can get better no doubt."* — [P12].

Some SAMs also explained that if those teams tried to influence their work, they would often not consider updated threat models, e. g.for P10's organization when technical teams insist on teaching employees about secure WiFi networks, which is of less relevance when a VPN is always activated on all employee mobile devices, *"Just because it's written down doesn't make it true. [...] and of course, I'm just an awareness person. So what do I know about these things?"* — [P10]. This all points to a misalignment between the expectations of technical security teams and SAMs. SAMs are outnumbered and when there is doubt about topics, the technical side is more established and *"believed more."* — [P10]

There seems to be a disconnect in the mission of different teams. While our SAMs are in constant contact with the technical security teams, they do not interact and align their activities: awareness content is rarely adapted to technical security changes. Even more critical, the technical security teams want to decide on their own what to communicate to employees, and hence override the SAMs' awareness strategies.

4.6 Interactions with Employees

As the SAMs' efforts were in one form or another directed to employees, it is key to understand their perception of employees. Some form of relationship between the SAMs and the employees was key for every participant, but on different levels: for some (P1,7,10,11,14) it was at the core of their job to communicate with employees face-to-face or via email (e. g., *"The security awareness team has the fantastic opportunity to be the friendly face of security"* — [P14]), while others would like to reduce the number of questions they get from employees (P5,6). Almost all SAMs told us that customized training for different groups of employees is key for their work – that training needs to be adapted to the different job roles. Team leaders, blue-collar workers, software developers, and retail employees would need special attention – with the distinctive needs for e.g., developers and office-based workers being explored in previous research [15].

Four SAMs (P6,12,13,15) worked with Security Champions [17, 36, 43–45, 63, 76] or Security Ambassadors. Here, P13 described security champions as a way to close the (communication) gap between employees, security teams, and security awareness teams: *"And we're seeing success in that compliment that with the security champions or advocates that were people, you know, people on the ground, are able to cascade that information and give you feedback to be able to mature your program."* — [P13]. Looking back at the implemented awareness activities (see Section 4.2.1) we can see that for most SAMs a closer communication and tailored training would be desirable, but these do not scale up for thousands of employees.

4.6.1 Expected Effort, Security Friction, & Usable Security

The SAMs were well aware that security is only a secondary topic for most employees, and they often stated that security training should not take too much time from them (in contrast to many CISOs [48, 49]). There was, however, something of a contradiction, in that our participant SAMs sought ways to increase engagement and provide more training, and were looking to make training mandatory, simply to increase otherwise low engagement rates, e. g., *"Onboarding in particular is to be mandatory. The phishing simulations will soon be mandatory."* — [P7]. Hence, it was not that the secondary costs of security awareness were ignored, but were discounted when it came to making time for training. First and foremost the UK-based SAMs described their (desired) role as being aides for the employees. They looked beyond training and were more concerned about ineffective security processes that caused friction for employees and how they could help to tackle this. P15 explained how their task evolved over time and how they realized that security communication can not fix broken security processes: *"We now try and understand why it's happening and what's happened [...] what comes out of it is things like there's a process that is broken and there's no other way to do it [...] and comms would never fix. So we work quite closely with security operations on that to try and find those human risks rather than, you know, just putting up comms."* — [P15]. This was an outstanding example, and other UK-based SAMs described this as a task that they and other SAMs should look at, rather than as something that currently is within their job descriptions.

The DACH SAMs showed less thinking in this way. P2 even denied that it would be their task to consider the burden security creates for employees: *"as an awareness manager, I don't really care. So what you want to do with your data is a nice idea at first, but we have basic principles and rules. So we say, "Okay, these are the rules that exist in the company and that you have to follow.""* — [P2]. While all SAMs were aware that some security policies are hard to follow, they had few ideas on how to tackle these and did not describe it as within their roles. Some described the training as a solution for missing usability, e. g., *"At the same time, we try to train that e-mails should get encrypted. That works less well because, of course, that's something you have to do actively. But that's something we try to teach."* — [P1]. Here the SAMs showed the same thinking as CISOs, who see security training as a quick fix to unusable security procedures [48, 49]. P5 explained that their organization had a usability team that the head of IT and the CISO were part of, but their work was not related to his own. Similar disconnects between security, software, and usability teams have been documented elsewhere [22].

5 Discussion

Here, we discuss our findings, with regards to our research questions, followed by recommendations for research and industry.

5.1 RQ1 – The Definition of Awareness

Regarding RQ1, we found that awareness was regarded as a combination of tangible activities and material delivery (4.2.1), and ongoing engagement for visibility (4.3.1). The term "security awareness" can mean different things to different practitioners, be it about training engagement or pure dialogue with employees. This contrasts with an underspecification of what "awareness, education, and training" actually is in practice. This is not a new concern and has already been discussed at least as far back as 2005 [35]. We found that participants filled their role with work that they justified relative to security, but seemingly according to their own rationale. The role of the SAM also differed, sometimes including the creation of content, active communication, or more of a management role, navigating different stakeholders. This was informed by regulations (which were seen either as

a guide on content, or a hindrance in terms of being seen as overly prescriptive).

What we have found is that where existing research notes that training may be onboarding or regular (often annual) training, there is another activity of regular advisories on emergent threats. The tension here, noted by participants, is that technical teams may dictate these (fragmented) advisories and that senior managers and regulators may dictate very specific expectations which are not checked for whether they map to the organization's context.

There is then a "void of specification" as to what security awareness should be on a day-to-day basis, that our participants filled in a self-directed manner. SAMs are filling the void with seemingly good things, and what is considered state-of-the-art by their peers. There is then fragile success, that rests on technologies being usable and time being afforded for employees to enact security tasks, so that employees not knowing or doing the behaviors can be the only possible reason for non-secure behavior. This then presumes that awareness initiatives are the only solution needed to address the persistence of non-secure behaviors.

5.2 RQ2 – Managers and Employees

Based on our findings, it seems that employees do not complain about awareness activities (4.6), so SAMs (and CISOs [48]) can assume awareness must be working. Other scholars have already shown that support moves to self-help, resulting in invisible workarounds [58], and awareness is knowingly configured so that the influencer can claim success: most employees pass phishing tests over time (4.3.2).

What emerges is a kind of 'inverse usability' check, where it is not that SAMs check that security solutions are first usable, but instead make themselves available to hear about difficulties with security solutions. This is similar to providing an abundance of training materials, and being available if employees struggle. SAMs see engagement as important, so that employees can signal if they need information or extra help, but reliance on vendors and restrictions on resources mean that SAMs can only repeat or intensify the same assistance. The common approach is to ensure that employees know who to contact if there are problems, rather than investing upfront to ensure there are easier security solutions.

Ultimately the SAMs can define goals themselves and how to measure their success. NIST standard 800-50 [79] describes that awareness needs to fill a gap between existing security knowledge and identified needs. Reflecting on this gap, our results suggest that while SAMs consider specific content for different employee groups, there is little that moderates whether employees' specific needs are being met. Instead, a range of materials is communicated to employees coming from all groups and professions, rather than crafting content to specific needs. This is not necessarily the SAM alone – topics may be defined by regulations (4.4.2), internal technical teams, and 'market standard' approaches/products used. SAMs then communicate it and determine how employees engage with the content. This represents an approach of providing a maximum of content and seeing how it lands with the audience.

Missing Ownership Despite a thriving field of usable security research, in the organizations described here, no one feels responsible for implementing usable security, bringing awareness and technology together, and taking the burden security creates for employees into account: not the CISOs [48], nor security consultants [49], nor SAMs (4.6.1). No one has ownership of unusable security tools and policies. The remit – let alone the power – does not exist to put awareness and technology design together as advocated by prior research [16].

If the job of SAMs is to only get the message out, it relies heavily on technology already being usable, since this is not being tested and is not something in the power of the SAM to change (if they were to see it causing problems for users). In our study, guaranteeing secure employee behavior is costly to measure, but also does not seem to be within anyone's remit. This raises questions as to how 'usable' security solutions and associated training reach organizations in the first place. Studies aiming to quantify the costs of unusable security are rare [15, 46], but are needed to make a case for a usable security mandate within organizations.

Early research in Human-Centered Security [33] indicates that the research community was focused on building more usable tools; more recently, some 20 or so years later, in organizations, the concerns of (I) having secure tools and (II) effective use of secure tools now run in parallel rather than in tandem, and do not interact.

5.3 RQ3 – Success of Awareness

The SAMs are not relying on a direct measure of the practice of secure behaviors (4.3.2). Instead, awareness engagement itself, rather than the security of behaviors, is the typical measure; this has been seen in the past but in terms of e. g., how to automate away the effort of total coverage [4] (how to produce content efficiently to reach maximum engagement). We found that some SAMs were engaging in varied and nuanced ways, not just with training materials but also with a general openness to interactions that boosted engagement. A positive attitude to security was seen as an important measure, through any channel. SAMs then use the feedback of employees and reporting numbers in phishing simulations as proxy measures, to assess how the employees perceived their activities. Those activities are mainly built around some form of training & communication. The SAMs' job is about bringing messages out to the employees as much as it is about the message itself.

In this sense, the SAM's engagement activities prepare the ground, to be ready to capture feedback if something in the mix of materials is not landing well with employees.

Our SAM participants were watching for signals that: (I) the material was acknowledged, but also; (II) whether there were problems indicating that needs were not being met. This was epitomized by P7, who thought onboarding was just as important for making the cybersecurity team known in case there were issues down the road for new employees.

Awareness as a Proxy for Secure Behavior While security awareness is about getting employees to follow security rules – at least following norms like ISO27004 [53] or BSI Basic Protection [37] –, no one is actually measuring whether they are following the security rules. It is simply assumed that awareness will reinforce secure behavior; awareness then becomes a proxy for secure behavior. This works most aptly for anti-phishing, but anti-phishing measures are co-opted for a range of reasons including to measure a behavior [48] (but technically the simulated phishing emails, rather than actual malicious phishing emails).

What is dangerous about such an approach is that it risks assuming that if awareness or engagement is increased, secure behavior would increase. These efforts could be successful in increasing awareness alone, but do not resolve usability issues or inadequate policies. Awareness practice is driven as if technologies and policies are unquestioningly usable. This then has parallels to how the job of making software usable is treated as something 'part-time' [22].

We saw also in 4.3.1 that practitioners felt there would always be something that employees would need to learn; it is not completely clear how to separate this from awareness delivery being a person's job – being seen to deploy awareness materials as a measure that perpetuates a belief that employees will never know enough. It is then unclear if awareness as a discernible role means that SAMs are incentivized to treat employees like they never know enough; can a SAM expect to be paid if they declare that all staff know all the training?

This is all to say, that there is the unchecked provision of support materials into the organization, which satisfies the need to be seen to be meeting regulatory needs – what is checked is how well the materials are digested by the workforce. This also has the indirect benefits of: (I) the organization (including SAMs) (externally) looking like they are doing their job, and; (II) avoiding the cost of measuring the aforementioned gap defined by NIST 800-50. It is arguably cheaper to meet a complete set of needs than it is to identify a specific set of needs, hence over-communication, with parallels to advice over-production [65, 71, 72].

5.4 Lessons For Researchers

Here we present recommendations based on our outcomes, framing opportunities for further research.

The Not-So-Easy Task of Communication More research needs to focus on communication and this less tangible part of a SAM's job (4.3.1). Some research in security management has considered communication, through social marketing [9], dialogues between IT teams and employees [10], and advice construction [66]. The research community should make space for understanding how communication efforts link to security artifacts in organizations, such as policies and controls. More concretely, the metrics proposed by Ashenden and Lawrence in their 'Security Dialogues' work [10] could be adapted (as has been proposed for SME conversations with IT providers [68]), for instance not only recording how often help or a conversation is sought (as our SAMs already reported), but finding a formal mechanism for documenting this evidence. Going beyond the 'Security Dialogues' work, this could also include logging when user feedback influences a change in policy and training (as noted in other user engagements, e.g., [15]). Otherwise, the freedom of SAMs appears to rely on their drive and ability to convince others.

Capture the Splintered Nature of Security Awareness We argue that researchers using the term 'security awareness' – or indeed, any one term – in their own work need to specify what they mean by security awareness (4.3). Aside from the basic distinction between security education, training, and awareness, we found that SAMs deploy strategic campaigns, send emails to respond to new issues, reach out to employees, etc. We suggest distinguishing between (I) short-term *training or awareness-raising interventions* like phishing simulations, (II) long-term *strategic educational efforts* where different training modules are built on each other, over months or even years, and (III) *security communication*, where e. g., employees are simply informed about a new attack via a newsletter or email. This distinction reflects the categories of activities we identified among our participants. Without such distinction, it is more difficult to compare findings or categorize them across studies. This would require consideration of e. g., reactive alerts as part of the security sensitization and awareness activities of organizations, rather than focusing on assuming or focusing only on either a fixed regular training package, or an assumption that all security awareness in organizations is qualitatively the same.

Explore Alternative Success Indicators for Secure Behavior Our participants were generally split, between providing content, and focusing on communication. The former sets up a situation that disincentivizes ever stating that employees have enough information – otherwise the SAM risks not appearing to be doing anything. The latter was seen as having value but relies on the standing of the SAM to argue the case to non-SAMs (who are informed by the limited specification of what a SAM is expected to do).

The success of awareness is measured through indirect indicators, a common challenge in organization cyber-risk management [80]. Secure behavior measurement would require instrumentation of the entire digital estate, or at best

measurement of very narrow behavior definitions (which may be rigid and would need adaptation to particular contexts, as with e.g., SeBIS [30]). For some behaviors it would seem straightforward to measure a behavior change, e. g., the usage rates of password managers, MFA, or passkey, or the number of screen locks, the usage rates of cloud encryption tools, regularity of software updates, etc. However, these would require instrumentation of end-user machines (which is an issue if, as we have found, technical teams can 'over-ride' SAMs to dictate the importance of technical issues).

Regarding phishing simulations, it would be important to measure (I) whether employees reject legitimate e-mails out of fear (as a suggested negative side-effect [78]), and for larger organizations (II) whether the number of successful real-world phishing attempts is reduced after a phishing simulation. There is scope to explore the 'inverse usability' indicators noted earlier in this section, especially while the usability of security solutions is determined by vendors. This would require closer interactions with the helpdesk, but also could leverage suggestions from work on 'shadow security' [58], to have a team or middle managers log queries from staff.

5.5 Lessons for Industry and Policy

Here we summarize what organizations and policymakers could act on to explore improvements.

SAM as Advocate for Employees and Usable Security With security teams still having dysfunctional relationships with the rest of the organization [10, 27, 32, 62], SAMs – as self-described security communicators – can jump in and fill the gap. SAMs should be the employees' advocates: the friendly faces of the security team (P14). We advocate a general move to understand how more usable technologies enter an enterprise environment. SAMs could be involved in IT and security technology procurement processes, as advocates representing employees' needs – then, the representative of the 'user' (employee) has sight of products potentially entering the organization, more so than the 'user' (security manager) as a customer purchasing the products. A SAM can surface frictions that may appear once a product is deployed, based on their interactions with employees (as has already been hinted at with phishing product procurement [21]).

Surface Usability Within Assurance Measures If there is an underspecification of any measurable approach or goal for awareness, vendors can sell products to organizations without having to bear the cost of proving that they are effective; this shifts the risk and costs to the customer to make it work, as a 'negative externality' [6]. The revision of NIST 800-50 was open for comment around the time of writing [5]; similar efforts to gather experiences from the SAM community as a specification for awareness could help to avoid a market of 'silver bullets' [38] – where neither client nor their users know what works best – around security awareness, towards evidence-based security [48]. Our participants were dissatisfied with the increasing and prescriptive details of regulations requiring concrete content that risked not fitting the individual needs of their organization. This needs to be tempered, as P10 noted in response to our results, that organizations are too complex to directly measure security behaviors and the connection to security awareness. However, our participants did collect feedback through large-scale tools, where assurance expectations may lift the profile of those tool solutions, to ease the development of feedback mechanisms.

Give the SAM a Stronger Mandate We found SAMs were left to fight for what they believed needed to be done for employees to work securely. Regulations could be adjusted to add weight to the feedback that SAMs receive, as an assurance measure. This could be a regulatory mandate, similar to Data Protection Officers and privacy needs, to ensure that e. g., when an employee signals that they find a technical measure unusable, this does not get left unaddressed (for lack of either the employee or the SAM being able to push back against the expectations of technical and senior management teams). Linking to the previous recommendation, this then in turn gives organizations a mandate to match solutions to their specific context and reduces 'risk dumping' [6] upon employees to make security work. Vendors do not necessarily have this insight into organizations when they provide solutions (instead relying on what is told to them during procurement, typically by a technical manager).

6 Conclusion

Here we explored goals and drivers of security awareness in practice, through in-depth interviews with $n = 15$ European Security Awareness Managers. In the absence of well-defined, measurable, evidence-based security awareness – which would lead to secure behavior – those managers carry out awareness as what they perceive as successful: communication about security that reaches as many employees as possible. The managers were critical of the status quo (e. g., that phishing simulations might not work, but are required by some regulations), but they lacked a clear mandate for change.

We conclude that researchers need to clearly distinguish different aspects of the over-used term of security awareness, need to include the challenge of creating engagement in their work, and need to help identify clear measures of success for awareness activity – and hence move forward to evidenced-based security awareness. Organizations need a clear mandate for usable security processes over communication alone, with awareness managers being natural holders of such a mandate.

A Interview Guide

Intro + Role

1. Please describe your role
    - 1.1. Probe: Are you part of a team or are there others also responsible for managing Security Awareness?
    - 1.2. Probe: What are your duties and responsibilities in your current position?
    - 1.3. Probe: Is there anything in your role that is not Security Awareness?
2. How does Security Awareness fit with your role?
3. What to you is Security Awareness? What is not?
    - 3.1. Probe: are there any specific 'building blocks', such as Awareness, Education, Training, Policy?
4. Demographics (if not already covered): How many users does your work apply to in your current role?
5. Demographics (if not already covered): How many years of experience do you have, and how many organizations does this include?

Role Activities

1. What is done in your organization as Security Awareness?
    - 1.1. Probe: how well is it working?
2. How does a typical work week look for you?
3. What kinds of decisions do you have to make in your role?
4. What input/information informs those decisions?
5. Are there any regular barriers to your Security Awareness activities?
6. Does your work interact with more technical measures?

6.1. If yes, how do your job activities interact with the technical measures? Can you give an example?

6.2. If no, what is expected of technical measures that make them separate from your job activities?

Goals of Awareness

1. What is the demand for security in your organization?
   1.1. Probe: what do you see as the justification for your job activities?
   1.2. Probe: Are there points where your job activities are assessed by others? (within or outside of the organization)
   1.3. Probe: is there a predefined state of security awareness that the organization is seeking, or is it defined more by you?
2. What indicates success in your Security Awareness role, and how is your success measured/demonstrated?
3. What is the goal of Security Awareness for you and your organization?
   3.1. Probe: How much of your organization's security is reliant on what you do?
   3.2. Probe: What would happen in the organization if the Awareness did not happen?
4. How do the Awareness activities in your organization relate to the goals of the wider organization and other functions?
   4.1. Probe: core values, annual business objectives
   4.2. Probe: what is the relationship between what you do and the organization's security policies?
5. Are there any examples of where you need to react urgently to specific security issues, or is the pace of activities more planned out?
6. What would your work be if all employees were working securely and how would that differ from what you do now?

Awareness Tools & Techniques

1. What techniques, products, or services do you use?
   1.1. Probe: why these? (resources, recommendations, best practices)
   1.2. Probe: are there any which are more, or less, reliable than others for ensuring a successful outcome?
2. What do you produce that goes to employees? To others?
3. What characterizes a 'good' tool or technique for Security Awareness?
   3.1. Can you provide an example of a good solution, and explain why it is good?
   3.2. Is it good for you AND good for employees?
4. What resources do you have for Security Awareness? Do your resources change or stay the same over time?

Role of Employees in Security Awareness

1. What do employees do as security behaviors? (list main ones)
   1.1. Probe: how do these behaviors link to your Security Awareness activities?
   1.2. Probe: are there values, clear rules, or a policy? Or a mix?
2. How is the need to behave securely communicated to employees?
   2.1. Probe: explained/justified to employees in your organization?
   2.2. Probe: by its own importance, by it supporting other key org. goals, etc.
   2.3. Probe: what is the format?
3. Is there anything employees do that indicates that your Security Awareness efforts are effective? If so, what is that and how is it measured?
   3.1. Probe: do you know what employees do? How sure are you, and how sure do you want to be?
4. Do you interact with employees in your organization? What form and regularity do those interactions have?
   4.1. Can you recall any examples of good feedback?
   4.2. Can you recall any examples of bad feedback?
5. Would you say there are any differences in the Awareness/security needs of different employees in your organization?
   5.1. Probe: Any problems that particular users have?
6. Are there any aspects of your interactions with employees that are easier than others? If so, why?
7. If there was anything that would improve the way employees interact with your Security Awareness efforts, what would it be?
8. Is there anything outside of Security Awareness that would make Security Awareness easier to achieve or more reliable?
9. Is usable security considered in the security activities the employees have to carry out?
10. Is there any negative of the Security Awareness on employees you could think of?
11. As a hypothetical question: if you answered to employees, what do you think they would ask from you?

Outro

1. If you have any other thoughts or ideas, you can tell us now or write/ call us later. You know, a lot of thoughts come quite sometime after an interview happens.
2. Could you recommend any other Security Awareness Managers we may talk to?

Unveiling the Hunter-Gatherers: Exploring Threat Hunting Practices and Challenges in Cyber Defense

Priyanka Badva
University of Bristol

Kopo M. Ramokapane
University of Bristol

Eleonora Pantano
University of Bristol

Awais Rashid
University of Bristol

Abstract

The dynamic landscape of cyber threats constantly adapts its attack patterns, successfully evading traditional defense mechanisms and operating undetected until its objectives are fulfilled. In response to these elusive threats, threat hunting has become a crucial advanced defense technique against sophisticated and concealed cyber adversaries. However, despite its significance, there remains a lack of deep understanding of the best practices and challenges associated with effective threat hunting. To address this gap, we conducted semi-structured interviews with 22 experienced threat hunters to gain deeper insights into their daily practices, challenges, and strategies to overcome them. Our findings show that threat hunters deploy various approaches, often mixing them. They argue that flexibility in their approach helps them identify subtle threat indicators that might otherwise go undetected if using only one method. Their everyday challenges range from technical challenges to people and organizational culture challenges. Based on these findings, we provide empirical insights for improving threat-hunting best practices.

1 Introduction

Investigating a security breach can be daunting, complex, and time-consuming for security experts. In 2020, a security analyst at Mandiant[1] responded to what seemed like a routine security alert, unaware of what would unfold in the following weeks and months. Soon after, the team discovered that the hack had been active for weeks, undetected by the tools meant to raise alerts. While they could see the intruder's activities, they could not determine how the attack had occurred. But after weeks of intensive investigations, they traced the source to a tool supplied by SolarWinds [2] [49]. According to multiple sources [17, 29, 40, 49], the SolarWinds or *Sunburst attack* [3] is believed to be the biggest and most advanced attack to date. Its discovery was not straightforward; it was through trial and error and a series of separate and loosely connected activities.

Security attacks, e.g., *Sunburst attack*, require the expertise to proactively seek them out from an organization's networks or systems before they could cause significant damage or compromise sensitive data. However, their discovery highlights the complex nature of threat hunting and the challenges it poses to security experts. Despite an increasing number of threats being detected in the wild, the processes and practices of threat hunting remain poorly understood and undocumented. Prior research on threat hunting has largely focused on understanding attacks [18, 23, 31], improving detection [4, 14, 47] and mitigation techniques [20, 26, 33], improved policies around breach disclosures [41], and building effective tools [7, 13, 45], but very limited on the analyst who do the job. Another body of research [1, 3, 8, 32, 37–39, 42] has primarily focused on Security Operations Centers (SOCs) to improve their functioning and the well-being of experts within them. However, despite threat hunting largely falling under SOCs, there remains a significant lack of understanding of the daily practices and challenges threat hunters face.

Understanding these factors is essential for establishing best practices, streamlining threat-hunting procedures, enhancing tool usability, and identifying skill gaps and areas for improvement in the field. To bridge this gap, we interviewed twenty-two (22) threat hunters to gain deep insights into their daily practices, constraints, needs, and experiences with current processes and tools. We asked two primary questions:

RQ1: Who performs threat-hunting activities, and what methods and processes do they use? We aimed to understand the requirements for becoming a threat hunter, including the necessary skills and experience in the field. Moreover, we sought to understand the various approaches used for threat hunting and the factors influencing their adoption. This analysis would enable us to identify skill gaps and areas of focus

for recruitment while streamlining threat-hunting efforts by understanding the preferred methods.

RQ2: What challenges do threat hunters face, and what strategies do they employ as best practices to overcome them? Through RQ2, we aimed to explore the challenges faced by threat hunters, their resolutions, and the practices they found essential and effective. Addressing RQ2 will provide valuable insights into the areas where improvement efforts are needed and which practices should be standardized across the industry for effective threat hunting.

Our analysis suggests that threat hunting is performed by various experts with diverse skills and experiences. However, it also requires tacit knowledge, making training essential for new beginners. We unearthed three broad threat-hunting approaches commonly used in the field: use-case/hypothesis-based, intel-based, and random-based hunting. The innovation of threat hunting lies in seamlessly combining these methods to suit needs, available resources, skills, and organizational requirements. Though planning might vary, the core process remains constant - collecting data, identifying and validating threats, and instrument remediation and reporting. Threat hunters encounter various challenges, technical complexities, interpersonal dynamics, and organizational issues. For instance, they face difficulties in building hunting hypotheses due to the ever-evolving threat landscape, with new tactics emerging regularly. Consequently, adaptability is highly emphasized in their approach to address these unique challenges. Our results offer valuable insights into the specific daily experiences of threat hunters. In summary, our contributions to the field are as follows:

- **Comprehensive Understanding of Threat Hunters' Practices**: We provide the first empirical evidence on the daily practices of threat hunters in the wild. We highlight the prevalent methods and how they are used to tackle cyber threats. Additionally, we shed light on the required skills, qualifications, and experience needed for threat hunting.
- **Addressing Challenges and Suggesting Improvements**: Our study offers insights into the most common challenges in threat hunting and the strategies that threat hunters employ to overcome them. By doing so, we identified recommended practices for improving threat-hunting processes.

2 Background and Related work

The concept of threat hunting has evolved over the years, primarily driven by the growing sophistication of cyber threats and the realization that traditional security measures alone are insufficient to safeguard against these advanced threats. Threat hunting is typically classified as an essential element within Cyber Threat Monitoring and Analysis [33]. It can be defined as a proactive and iterative process aimed at searching for and identifying potential cyber threats and malicious activities within an organization's network or systems [28, 36]. Threat hunting can be broadly categorized into two main approaches: proactive and reactive. Proactive hunting involves the utilization of threat intelligence to formulate hypotheses or use cases, enabling security teams to actively search for potential threats before they can cause harm. On the other hand, reactive hunting focuses on conducting forensic investigations and responding to alerts indicating threats after they have been detected [33]. According to SANS 2018 threat hunting survey[4], 60% of respondents reported engaging in proactive threat hunting, with 43.2% conducting it continuously and 16.7% performing it at regular intervals. Our study aims to investigate this further and understand the threat hunting practices in the wild.

Threat hunting is widely recognized as a complex and cognitively demanding process. Consequently, ongoing efforts have been made to automate various aspects of the threat-hunting process. Previous works [3, 11, 33, 36] argue that automation in threat hunting can offer numerous benefits, such as reducing response times, resolving repetitive tasks, requiring less technical knowledge from analysts, and reducing their cognitive load. However, it is also acknowledged that complete automation may not be feasible, as certain aspects of the process require human analysts to make critical decisions. Most analysts rely on their domain knowledge and experience to make decisions, often without deeply considering specific cases [19, 22, 50]. Chen et al. [10] have argued that experts' critical knowledge is often lost and have advocated for tools that can retain expert knowledge to reduce their workload and address their blind spots. We expand this knowledge area by investigating the role of automation in threat hunting and hunters' experience influences their efforts.

While the consensus is that complete automation is not achievable, significant progress has been made in automating specific parts of the threat-hunting process. For example, hypothesis generation [36], data collection, threat detection [27, 48], data triaging [50], malware classification [6, 28], and other aspects of the process. Despite the advances in automation, prior studies have not focused on understanding how these tools impact threat-hunting investigations. In addition to tools, threat hunting heavily relies on intelligence (e.g., threat reports), analysts depend on it for investigations and to ensure the security of their systems. Threat reports are typically based on analyzed and remediated attacks, offering reactive advice [12, 34]. Outside academia, vendors such as Symantec, McAfee, Trend Micro, FireEye, Cyveillance, and Kaspersky regularly publish threat intelligence for multiple government and commercial organizations. Our current study provides valuable insights into how threat analysts use intelligence in their everyday hunting processes.

Other studies [1, 3, 8, 32, 35, 37–39, 42, 46] related to analysts focus on SOCs, primarily aiming to understand the well-being of security analysts. For instance, previous works [35, 37] investigated the factors contributing to analysts leaving the

[4] https://www.malwarebytes.com/pdf/white-papers/sans_report-the_hunter_strikes_back_2017.pdf

field. Another line of work on security workers has primarily focused on bug bounty hunters [2, 5, 43, 44]. For example, Votipka et al. [44] compared how testers and hackers discover software vulnerability techniques. They concluded that the discovery experience, knowledge of underlying systems, availability of access to the development process, and motivation play a crucial role in each step of vulnerability discovery. Our study builds upon these investigations by examining factors that are influential in identifying threats. Additionally, we provide insights about other security workers, specifically threat hunters.

3 Methodology

3.1 Study Design

To gain insight into the practices and challenges of threat hunters in real-world scenarios, we designed and conducted an online semi-structured interview study. Our interview script was divided the script into five sections: introduction, data collection, threat identification, threat analysis, and conclusion. The introductory section aimed to establish rapport and obtain information on participants' role and responsibilities. The subsequent sections, data collection, threat identification, and threat analysis, were designed to delve into the details of the threat hunting process. Lastly, the conclusion had questions that sought to gather suggestions from participants on improving the process and concluded the interview. Demographics were gathered using a separate form.

To validate the effectiveness of our interview script, we conducted pilot studies with two members of our research group who had experience working in SOC. The rationale behind this was twofold: to assess the clarity of our questions and whether they could elicit responses that addressed our research questions and ensure that the interview could be concluded within a reasonable time. Based on the outcomes of the pilot study, we refined our script by reducing the number of questions and supplementing follow-up questions in each phase of the threat hunting process. The pilot study data was excluded from the final analysis.

3.2 Ethics and Participant Recruitment

We obtained ethics clearance from our University of Bristol Ethics committee before beginning our study. Utilizing our personal, industrial, and academic connections, we recruited diverse participants through social media, word-of-mouth, Slack, and academic and industry conferences. Our objective was to identify and recruit professionals whose daily work could be described as threat hunting or involved some aspect of threat hunting and who had a minimum of 2.5 years of experience in the field. This was to ensure that our sample included the necessary expertise and familiarity with the problem space, particularly in identifying, analyzing, and managing cyber incidents. Once interested, we sent them the information sheet (PIS), the demographics form, and consent form. The PIS explained the purpose of the study, anonymization, what participation entailed and the withdrawal process. The consent form was seeking consent to participate, audio recording of the session. Respondents who completed and sent the consent form were further contacted for scheduling a session. We did not conduct any further screening of our respondents since our recruitment material explicitly requested participants with over 2 years of experience. However, to ensure suitability, we asked them to clarify their roles and daily activities during the interviews.

Similar to other works on security workers (e.g., [4]), targeting such a unique and specialized group presented a significant challenge. Some potential participants chose not to participate in the study due to concerns about being recorded and directly quoted or about disclosing their company's operational practices. Given the sensitive nature of the subject matter, participants were allowed to participate without sharing their cameras. Moreover, SOC personnel, for example, are typically occupied with responding to severe incidents, and their willingness to participate in academic studies may not be motivated by financial incentives. To overcome these challenges, we employed a snowball sampling technique to increase our sample size. We targeted professionals leading threat hunting teams and asked them to encourage their colleagues and other professionals they know to participate. We also encouraged those who participated in our study to share our research with their colleagues.

3.3 Participants

In the end, we successfully recruited 22 participants from various countries. The majority were from the UK (7) and the US (9), while the remaining six participants were from Qatar, Australia, Singapore, Germany, India and UAE. These participants were employed by leading multinational companies, five participants were from companies that provided in-house threat hunting services only, while eleven participants were from Managed Security Service Providers (MSSP). The remaining six were from companies that provided both in-house and external threat hunting services. While some participants shared the same company affiliation, most worked in different countries and states serving diverse clients around the world. Only P1 and P3 were based in the same office, while P4, P5, P9, P10, and P11 worked for the same company but across different offices in the US. As for their roles, participants held a variety of positions, including analysts, consultants, red team specialists, and security engineers. They also had diverse educational backgrounds and held various security certifications, such as the CISSP. Table 1 provides a summary of the demographics, a more detailed summary of our participants' demographic and professional backgrounds can be

Table 1: Participants demographics details "-" : Prefer not to answer

ID	Job Role	Country	Experience	Education	Company	Type of Service	Recruitment Method
P01	Senior Cybersecurity Analyst	UK	10-15 years	PhD	Company 1	In-house	Industry Connection
P02	Security Consultant	Australia	15-20 years	MSc	Company 2	MSSP	Industry Connection
P03	Threat Intelligence Analyst	UK	5-10 years	Bachelor	Company 1	In-house	Industry Connection

P22	Senior Incident Response Consultant	Qatar	10-15 years	MSc	Company 9	In-house + MSSP	Snowball

found in Table 2 in the Appendix 8.1.

3.4 Interview Procedure

At the beginning of each interview session, participants were reminded of the purpose of the study, their expected involvement, and the withdrawal process. They were also asked to confirm their willingness to participate. After obtaining consent, we initiated the audio recording and began the interview. Our first questions were about roles and responsibilities in their workplaces. We then proceeded to ask about their threat hunting practices, guided by their responses. While we had a script, we did not rigidly adhere to it in all cases, but we ensured that all relevant questions were covered by the end of each session. The interviews concluded with exploring potential areas for improvement in the threat hunting process. Participants were then thanked for voluntary participation in the study, and no financial compensation was provided. On average, each interview session took between 40 minutes to 1hr 15 minutes. Due to time differences with some participants, some interviews took place in the early hours or late evenings of our local time. Our complete interview protocol can be found in the Appendix 8.3.

3.5 Data Analysis

Once data collection was complete, we utilized a professional transcription service that adhered to our university policy and GDPR complaint to transcribe all our interview recordings. After transcribing all the audio files, we began the coding process. We inductively coded [9,30] the scripts using the conventional line-by-line method to identify key themes, methods, processes, tools, and attitudes relating to threat hunting. Two researchers independently coded the first two transcripts to identify key themes, methods, processes, tools, and attitudes related to threat hunting. Following this, they met and discussed their findings to create a codebook. Discrepancies between the coders were resolved using the "arguing to consensus" method [21]. The codebook was then shared with other researchers for review and validation before finalizing. After developing the codebook, two researchers proceeded to code an additional three transcripts and calculated the inter-coder reliability. The inter-coder reliability score using Cohen's Kappa Coefficient was 0.81, indicating substantial agreement in applying the codebook [24]. Then, the first author proceeded to code the rest of the scripts. High level codebook attached in Table 4 in the Appendix 8.4.

3.6 Limitations

While we attempted to diversify and enhance our sample using snowball sampling, we acknowledge some common limitations associated with studies that have employed this technique as a recruitment method. Firstly, snowballing can perpetuate power imbalances; some participants may have participated in the study because they were recruited by individuals in higher positions, feeling obligated to participate. To mitigate this, we emphasized to participants the voluntary nature of their involvement and their right to withdraw at any point, ensuring they felt no external pressure to participate. Secondly, samples recruited through snowballing often lack representativeness. For instance, our sample is biased towards participants from large companies that primarily offer managed security services. This bias may stem from participants sharing the study among their peers or personal networks limited to such companies. Moreover, some participants even

came from the same large corporations. However, while they may have been affiliated with the same large companies, they were situated in different countries, serving a diverse array of clients and dealing with various challenges and circumstances. This diversity instilled confidence in us that our sample has provided a broad spectrum of perspectives.

Other limitations of our study include lack of generalizability. As prior studies [3, 4] have reported, SOCs and organizations are unique, and other salient factors could influence the daily experiences of threat hunters that we may not have captured in our study. Moreover, our results may be skewed towards companies that provide managed security services than those with their own in-house dedicated threat hunting teams. We conducted recorded interviews, which might have influenced participants' responses. Some threat hunters declined to participate due to concerns about recording sessions, which could have led to under-reporting or giving answers that they believe are socially or professionally acceptable. To mitigate this social desirability bias, we emphasized that we were interested in their opinions on processes rather than specific sensitive issues. However, it remains essential for the security community to explore alternative methods that protect participants' identities or their organizations while still obtaining valuable insights.

4 Findings

4.1 Who performs threat hunting?

Our analysis suggests that threat hunting is performed by analysts with various skills and qualifications, who may either belong to dedicated teams or have other responsibilities within their organizations. Participants engage in threat hunting both for their own organizations and as consultants for external entities. From our sample, those who had dedicated teams performed threat hunting for their organizations and also provided external consultations: *"I have 9 staff working for me. We have staff in the US, India... It's a dedicated service, when a client signs up, we assign a dedicated analyst to that particular client."* P04

Teams are often formed randomly, with their structure and size depending on the organization's size and requirements. Threat hunting teams in some organizations can consist of one person or a team that leads the efforts and receives assistance from other teams or departments within the organization. For instance, P7 explained that their threat hunting is part of a SOC, where they have a monitoring team, and others perform threat investigations. *"I work around the SOC, which also has threat intel, threat hunting, [Incident] response, all of that. The organization is global in the sense that we have office in possibly every country on this planet. [...] We run our security operations centre from two geography's and do cover 24 [countries] across seven services. There is a threat intel function which works for big organizations, the other companies, the other big organizations in the United Nations family and so on."*

Regarding skills and qualifications, we found that threat hunting teams consisted of analysts with various skills and knowledge (captured in Table 1 and 2). However, many participants with teams explained that they either received or provided training for their new team members. For instance, one participant explained that their team comprised individuals with forensic and penetration testing backgrounds, but they had to provide training to cross-train the team members in threat hunting. P05 said *"I have a team of 8 people, most of them actually started on our forensic team, and I've kind of poached people from the forensic team... pentest team to form the threat hunt team. I had to cross-train the forensics guys and the pen-testers."*

This finding is further supported by the skills and qualifications of the participants in our sample. They have various skills and qualifications. Other teams started with one member, and later were joined by others. P10 explained: *"Our company had one dedicated threat hunter, [name]. He's also a science instructor. He kind of worked on threat hunting but he didn't work in the SOC doing the day-to-day job, [he did] informal type of threat hunting stuff. Me and a few others started doing threat hunting on our own and we proposed a threat hunting program."* P10

> **Take Away.** Threat hunting is carried out by analysts with diverse qualifications who may be part of dedicated teams or have other organizational responsibilities. Since there are no specific entry qualification requirements for threat hunting, organizations invest considerable time and resources in training their staff to excel in hunting for threats.

4.2 How do they perform threat hunting?

Our analysis revealed that threat hunters employ various methods when conducting threat hunting in the wild. These methods are often combined based on specific needs and available resources. For easy explanation, we have categorized them into three broad groups: use-case hunting, signature or intel hunting, and random hunting.

In the first approach, **use-case hunting (n=17)**, threat hunters use predefined scenarios or patterns of suspicious activities to identify and investigate known threats and attack patterns. These use cases are based on the threat hunters' knowledge of threat actors, the systems they own, and the typical attack patterns. The second category, **intel-based hunting (n=7)**, involves leveraging technical threat intelligence, such as known indicators of compromise/attacks (IoC/IoA), to guide the hunting process. This method relies on up-to-date threat intelligence to proactively detect potential threats. The difference between these two methods is that in use-case based hunting, hunters rely on pre-defined scenarios or cases to hunt for threats, while intel-based hunting relies on

the threat intelligence they receive to investigate and identify threats. For example, under intel-based hunting, hunters may use malware signatures they have received to search for threats. Under use-case based hunting, hunters formulate or create scenarios to guide their efforts, and sometimes these scenarios are informed by threat intel. For instance, a scenario may include the behavior of malware which was provided as intelligence. The third category, **random hunting (n=6)**, encompasses methods where participants conduct hunts without prior knowledge of specific indicators of compromise or a predefined plan. This approach involves being alert to potential threats during regular responsibilities or while conducting other specific hunts, such as onboarding new clients or responding to incidents initially considered benign.

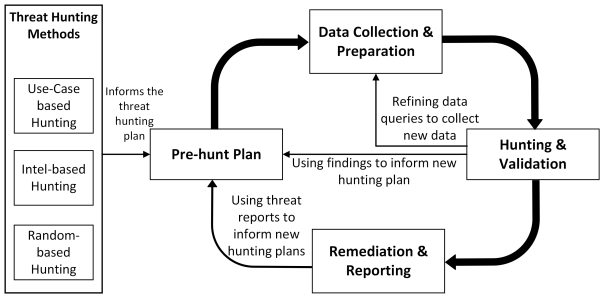

Figure 1: Threat Hunting Process

Our analysis indicated that the choice of approach is influenced by several factors, including available resources (e.g., malware lab), data availability (including external threat intelligence), the skills and experience of the hunter, and organizational requirements. Despite their differences, these methods share a similar approach involving planning, data preparation, threat identification, and remediating and reporting the findings. Figure 1 shows the relationship between various processes involved in threat hunting.

4.2.1 Pre-hunt Plan

Our analysis indicated that most threat-hunting activities begin with a dedicated planning phase. During this stage, hunters gather to formulate a plan that outlines the specific areas they intend to investigate. Participants emphasized that having a well-defined plan enables them to assume control over the exercise and effectively allocate resources. They also explained that having a plan helps keep the entire team involved. *"We try to plan all that stuff out at the beginning. It's planning, getting together in the beginning with everyone involved. And, then just let the system run, and then if something comes up later, you deal with it as a team."* P19

Pre-hunt plan for **use-case-based hunting** involved defining the scope of the hunt, determining the type of threat to pursue, and identifying the required data sources based on the use cases and hypotheses they have developed. Participants stated that they create use cases based on Tactics, Techniques, and Procedures (TTPs), particularly leveraging the MITRE ATT&CK framework, historical incidents, threat intelligence, their knowledge of the infrastructure in question, or the specific requirements of their organization. *"Using my experience of having worked in many environments and I look at how unlikely an attacker would target one of those individual systems. Then we build a threat mod el that goes from the outside in using info that is publicly available for the initial compromise. But then my experience comes in, how does a breach of [the] main frame look like, what data would they try to steal, what would they do if they got access to a PLC."* P18

Once the use case is finalized and the approach is outlined, participants explained that they would determine or compile a list of the necessary data for the hunt and identify the relevant sources. This is to ensure that the data is readily available when needed. *"It's really important that you identify the data sources before you do an investigation, so you can onboard them, normalize that data, so when you need to do any type of hunting activity, it's readily available."* P14

Participants who consulted for other organizations mentioned that the planning phase included assessing the client's infrastructure to understand normal behavior and whether their existing resources and methods could be applied to the client's case. P04 said: *"When a client signs up for our service, we assign a dedicated analyst specifically for that client. This allows the analyst to become familiar with the client's environment, understand what is considered normal in that context, and identify abnormalities."*

Intel-based planning is primarily influenced by the intelligence or indicators of compromise (IoCs) hunters receive. This intel may come as hash values, filenames, registry keys, IP addresses, domain names, malware, and host or network activities associated with malicious activities. Participants explained that detailed and specific planning begins when they receive such intel. Consequently, they rely on getting the latest threat intel. Participants received intel from various sources, primarily external sources such as mainstream vendors and open-source intelligence platforms. They shared that they also actively participate in various security communication groups on platforms such as Slack, LinkedIn, and Twitter, while others are public and private security exchange groups. *"We start by looking at what's available open source; blogs and reports that other vendors have produced, maybe where they have only mentioned a particular piece of malware or CnCs [Command&Control]. We then take those CnCs, analyze them further, and try to build a bigger picture. We also get intelligence from other partners in the community, closed intelligence exchanges, not open to the public, just between security vendors or other companies in that kind of space. We have our tracking as well. We've paid for services like VirusTotal, an online malware repository service, and we pay to put certain kinds of tracking in place on those sites, various services such as the known groups we track. We can say if it*

satisfies this rule, it will alert us, and we can stay on top of things that way as well." P16

Once intelligence is received, hunters review and try to understand it; its origins, the systems that can be affected, and how the threats can be identified and mitigated. P03 stated: *"The idea is that once we have that, we would then run that information through other data sources that we [have] purchased or have access to, and kind of enrich it."*

For **random hunting**, we observed that there is minimal planning involved. These hunts are more ad hoc, happening spontaneously and sometimes driven by curiosity or a hunch. For instance, a threat hunter may impulsively investigate old 'benign' logs without a predefined plan or specific objectives.

> **Take Away.** Threat hunters use various methods in their hunting activities, which they often combine based on their specific needs, skills, knowledge, and available resources. Most activities start with a dedicated plan, where hunters define the scope of the investigation, assess threat intelligence, generate hypotheses or use cases, identify relevant data sources, and allocate resources based on their chosen approach.

4.2.2 Data Collection and Preparation

Once the pre-hunt plan is complete, participants indicated they would collect and process the necessary data from various systems. Threat hunters collect data from various sources, including firewalls, antivirus, network systems, Endpoint Detection and Response tools (EDR), and proxy servers, and these data are based on specific time frames or behaviors of the systems. Participants emphasized the importance of selecting the hunting approach before initiating data collection. For example, P09 stated, *"Before you even get to data collection, you talk about the frame of where they are approaching it from. [...] People will see something on Twitter and say, 'That's a great idea; let me go and hunt for it,' but they don't really bring a rigorous approach to it."*

After gathering all the required data, they curate and prepared it for their hunts. The data preparation process involves cleaning, filtering, consolidating, and transforming the data into a usable format. This is often within a single location or system such as a SIEM (Security Information and Event Management) solution, which also aids in the hunting process. Other steps included normalizing, parsing, and restructuring the data. Filtering was typically performed to remove benign activities from suspicious events, based on time frames, patterns, and thresholds defined during the planning phase.

For participants using **use case hunting**, data collection was aligned with the goal of the hunt. They would determine what the hunt needed and then search for the logs supporting those detections. They would then build rules or triggers to detect threats, even those that may not be easily noticeable.

Participants who utilized the **intel-based approach** stated that once they understood the campaigns or the intel, they would plan how to implement or run the IoCs in their systems. This process involved collecting relevant data and preparing the testing environments such as malware labs, to handle the received indicators. Hunters also used the intel to develop new use cases or hypotheses for threat-hunting activities.

Those who engaged in **random hunting** used various data logs for their hunts, often selecting sources based on what was available or what they found interesting at the time.

We found that threat hunters generally prioritize gathering as much data as possible. Participants argued that it could significantly improve the quality of the hunt. For example, P04 stated, *"We collect as much data as we can because the more data you have, the better. Sometimes, you might search for an ID, which might appear on three different devices, allowing you to trace how it entered the network. The more we can do on the SIEM, the better, rather than having scattered devices."*

> **Take Away.** Threat hunters tailor their data collection to align with their hunting goals and collect as much data as possible to maximize their effectiveness in detecting and responding to security threats.

4.2.3 Hunting and Validating

Our analysis indicates that threat hunters hunt and validate threats through an interactive and connected process. Threat hunters move between hunting and validating as needed, often collecting more data/intel or creating new scenarios.

For **use case hunting**, hunters deploy the rules they have built on the collected and filtered data. When specific conditions related to threats are met, alarms are triggered, prompting the hunters to investigate further. P02 explained, *"We create use cases - if the rule is being triggered, we identify the specific behavior, whether that's coming from an IP address or a process."*

For **intel-based hunting**, IoCs are fed into relevant systems to trigger alerts and identify potential compromises. Hunters compare their own data or logs against signatures or patterns of known indicators of compromise associated with specific tactics, techniques, and procedures (TTPs). When a match is found, it suggests a potential compromise or the presence of a specific TTP. P22 elaborated, *"if our threat intelligence profile tells us that we need to look for a specific binary name in the Windows system32 folder, then we're going to search for that."*

On the other hand, **random hunts** tend to occur unplanned and are often initiated by hunches or when the hunter observes something that looks malicious. Participants described situations where, based on their knowledge of the normal state of the system, they occasionally discovered patterns of malicious behavior. P09 stated, *"I could be looking at something and think that looks weird. To me, that is an identification. An analyst looking at data and saying, 'That does not quite look right' is absolutely identification."*

After an investigation is triggered, threat hunters manually search for threats or use tools to understand the alarms. They employ tools such as Splunk, VirusTotal, or ReliaQuest/GreyMatter to validate whether they deal with threats or false alerts. Threat validation includes further investigations (using additional hypotheses) and may involve inviting other team members to confirm the findings. Threat identification is a process that requires knowledge and experience. P09 emphasized, *"I think it requires more knowledge and keeping up-to-date with stuff. We would discuss it as a team, 'Does this look suspicious? This doesn't seem quite right to me."'*

In addition to team discussions, participants mentioned that they refer back to previous incidents or notes to confirm whether the behavior is normal or if the suspicious pattern has been encountered before. P20 explained, *"The first thing I usually do is look back on my own notes and things and see if I recognize them. If it's a URL or a pattern, I look back on past incidents and any notes I have to see if it's familiar to me to jog my memory. If I can't recall it, then I usually go to open sources first, and secondly, I'll go to places like VirusTotal, input the domains, and see what comes back."*

Take Away. Threat identification and validation are interconnected processes. Threat hunters employ various tools and manually search and validate indicators of compromise. In most cases, validation is a team process.

4.2.4 Remediation and Reporting

Once threats are validated, the remediation and reporting process is initiated. Participants described these processes as interconnected and often addressed them together. Depending on the case, remediation can either be carried out by the threat hunting team or passed on to other teams in the SOC or the client to decide. *"If we do identify threats, and we prove our hypothesis to be correct, we'll inform the customer and move to emergency response."* P22

They emphasized the critical importance of severity and time in remediation and reporting. For severe issues, immediate action is taken, and relevant parties are contacted promptly on how to proceed. In cases where they have permission or authority to act on behalf of the client, they contain the situation. However, if authorization is needed, they would contact relevant people immediately suggesting some remediation steps. *"...depending on the severity, we contact the client; it could be a phone call or an email. Then we check with them and tell them some remediation steps they can take."* P02

Sometimes, the remediation process involves collaboration with other teams, requiring thorough communication. In such cases, participants emphasized the need for detailed reporting to ensure everyone understands what took place, what actions were taken, what was discovered, how the situation was contained, and any further recommendations to prevent future occurrences. *"For the breaches, the idea is pretty much that we wanna give a report, we want to tell a story, we want to be able to say this is how it actually started. So and so got a phishing email, they called the number on the phishing email..."* P05

The reporting process also includes lessons learned. Participants stated that this part of the report includes detailed information about how the detection mechanisms missed the threat or specific steps to configure a system properly. These lessons are valuable for future reference and can provide new intelligence on threats. P13 said, *"As I said, in the lessons learned part, we will be giving them more detailed information about how to enhance their detection analytics to fix where they failed to alert."*

Moreover, participants recognized the value of thorough reporting as it allows them to demonstrate the value of their hunt to the organization. By providing a detailed post-action report, they can show how they addressed deficient posture in the organization, helping prevent potential damage or further threats. *"For me, the hunt starts with that framework of a plan and post-action report to help capture the value because then we can show the organization we have this posture improvement report that came out of our hunt, and we helped to address deficient posture in the organization before it caused damage or allowed damage to occur."* P09

Take Away. Threat validation, remediation, and reporting are interconnected and vital stages of threat hunting. They are crucial for ensuring that threats are effectively addressed, lessons are learned, and necessary actions are taken to enhance the organization's security posture.

4.3 Threat Hunting Challenges

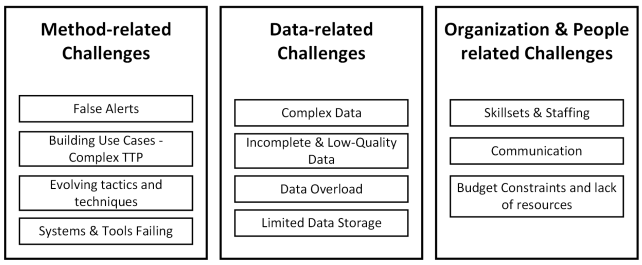

Figure 2: Threat Hunting Challenges regarding Method, Data, Organization and People

Participants revealed various challenges they face as threat hunters. We categorize and present these challenges in three groups as shown in Figure 2

Method-related challenges: These are participants' most common issues while attempting to identify, verify, and remediate threats.

False alerts One common challenge reported by all our participants is dealing with false alerts or false positives. They explained that many hunting activities are prone to trigger alerts that are non-malicious. However, despite being false, participants explained they cannot be ignored and require thorough investigations, which often takes time and need resources. Participants further indicated that several factors maybe contribute to false alerts, such as vague detection rules, new devices joining the network, and internal users using pirated or banned tools or accessing malicious sites. P08 mentioned, *"Yeah, there are many false positives, especially on the PowerShell side. We built a usecase to block PowerShell in the network, and it sometimes flagged it. When we ask about it, we received responses like, 'No, we're not using PowerShell,' but it turned out there's one admin who is very proficient with PowerShell and who used it. We thought, 'Oh, what's happening here?' The analysts said, 'No one's using PowerShell,' but there was a senior guy who was actually using it."*

Moreover, participants pointed out that verifying these anomalies can be particularly challenging, especially when users have flexible working conditions like working from home or during outside normal working hours. P19 further explained that it is even be more complex when the company operates globally; reaching an individual to verify alerts can be even more challenging: *"We're a global company and there are people working in different time zones. If people are working on a Sunday, and they've turned off their phones because they're not technically supposed to be working, trying to catch up, we may not be able to reach them when they've triggered the alerts. Sometimes that's a big challenge."*

Participants also discussed false alerts as a challenge when automating processes. They explained that automation sometimes results in false alerts or causes tools to miss out on detecting threats. They also pointed out that due to the speed at which threats constantly evolve, automation may struggle to keep up with newer threats, leading to countless false negatives. *"False negatives, that's a silent killer. Not understanding that, it's tough...There are dozens of cases that I can think of where I looked at something and was like, hey, I don't see anything and I go back to the business owner and we look at it together and then we're like, hey yes, these things right here, that should never happen. The system should never do that, even though to me they first looked benign."* P14

Building use cases - Complex TTP. Participants (n=5) also discussed building use cases or hypotheses for threat hunting as one of their biggest challenges. They explained that TTPs are complex, making it difficult to formulate and focus on specific usecases for each client. They also stated that the complexity arises from each usecase requiring its own unique data set, which limits the possibility of reusing certain use cases. Some participants specifically emphasized the challenges they face when using the MITRE ATT&CK Framework to build use cases, noting that its broad scope poses difficulties in application. *"The biggest challenge we have is going through all the tactics and identifying what we can look for in particular client's environments because the MITRE ATT&CK Matrix is very broad, there's so much data there that you have to go through and understand what data sources are needed for a particular techniques to focus on."* P08

Furthermore, some participants highlighted the difficulty in determining what to hunt for when they are not even a victim or aware of what is happening outside their companies. They find it challenging to identify what they should be monitoring without any leads, leading them to rely on information from other sources. *"If you are not a victim or an incident responder with access to active attacks, you have to rely on other people to say, 'Oh, we were just attacked by this. Here's the information,' that's different from a SOC where you're the one being attacked. You have the information. We wait on other people to present the information to us. That is a challenge. Trying to find things of interest is always a challenge, but fortunately, there's a lot of security researchers out there who are constantly blogging things, so we get by."* P16

Evolving tactics and techniques. Participants (n=10) mentioned that one challenge in the threat identification process is from the ever-changing threat landscape. They explained that from time to time they encounter evolving threats and actors as technologies change or advance, new threat actors and threats are discovered. Moreover, some participants explained that threat actors also adapt the way they operate, making threats increasingly challenging to understand. *"The biggest challenge would be changing TTPs, when you have groups that change the way they operate. You can't go in knowing that CONTI does this or APT28 does this ... you can't really be used to that much because they could change tactics... Groups change their tactics all the time so that's probably the biggest thing is involving tactics."* P05

Participants commonly described these tactics as a moving target, which some said it is overwhelming and hard to keep up with. They explained that the problem with these constant changes is that threat can sometimes evade their existing detection methods; actors refusing to comply with predictable patterns-*"not playing according to their wishes."* Evolving nature of threats demands continuous changes to approaches and budget to threat hunting. *"Big contenders of challenges, first of all, are adversaries are not rolling over and playing dead for us. They are specifically interested in evading detection. We are dealing with a moving target and that moving target has interest to succeed, the ability to evade our detections which means they are developing evasions."* P09

Systems and Tools failing. We also found that tool performance poses many challenges. Participants (n=7) described various situations in which the tools or system they were using failed to deal with their request. For instance, a tool crashing

because it is dealing with large amounts of data or queries. *"Because we do correlation, some searches take more time and CPUs than others, so we need to optimise so that one search does not crash all the system. We try to do that but the issue is, in the lab we only have few rules and only running when we want them to run, whereas for a big production you have a thousand of rules all running in parallel together. So, when we create a rule we have to make sure that it will fit in the big production without crashing everything else"* P02

> **Take Away.** Building relevant use cases or hypotheses is a big challenge because attacks constantly evolve. Dealing with false alerts, whether positive or negative, poses many challenges, including time and team effort. While tools play a significant role in hunting, they sometimes fall short.

Data-related challenges: These are the most common challenges threat hunters face concerning data for threat-hunting purposes.

Complex data. Participants (n=7) also highlighted that dealing with complex data poses various challenges. While having a lot of data available is considered a good thing, the task of getting these data into a usable format presents many challenges. They explained that logs of various systems come in various formats or containing different bits of information. Furthermore, technological advancements can also lead to changes in logs, which is challenging to keep up with. As P07 explained: *"it's very challenging to keep up with technology and available options, logs often change their format, the way they appear. The way they parse. So, what that mean is that the detection that we burn is based on what the logs looked like a year back. They're not really what it is today."*

To make use of this data effectively, participants explained that they must first get it into a standard and usable format. This involves filtering, normalizing, and transforming it into a format that is appropriate for analysis tools. But, in most cases, these processes require time and effort. P01 said: *"The challenge is to get the data in a good shape. For instance, if you have email logs where you have one that is odd, for this message ID, you have different indicators, the subject, sender, the recipients. Then you have another thing that says the file attachments are this big. You have all these logs, and they all intermingled, so you need to do a lot of work on the data just to get one line of the email. That's a challenge because you need to be like a data scientist and programmer just to get the information you need before you even do your analysis as a security person, so that's definitely a challenge."*

Incomplete and Low-Quality Data. Participants (n=11) also highlighted the significant challenges they face when dealing with incomplete or low-quality data; data lacking critical points or information required for threat-hunting investigations. They said data full of noise or data missing some information is of little value for effective threat hunting. We identified several factors contributing to data quality issues, including the lack of knowledge among data collectors, limited resources for long-term data storage, and excessive noise in the data. Participants noted that data collection decisions, particularly by external companies, can be ill-informed. This can result in unnecessary or incorrect event logging, which are common issues that lead to data not being useful for threat hunting. Moreover, storage limitations, where companies fail or do not have enough resources to retain logs for extended periods was commonly mentioned. Regarding the lack of visibility due to missing data points, P18 stated: *"Another thing that becomes apparent is when you expect the data to be there, but it's not. You should have had 30 days of logs, but when you check, there are only 7. What happened there? I think these are the basics for obtaining data, and some people would call this visibility. I need visibility into these things in order to do it."*

Other participants argued that the low visibility of devices or systems in the logs was sometimes caused by logs collected in various places rather than in one location. Some participants said this challenge is sometimes caused by not having access to relevant systems or devices to collect data. Example of P17 explaining that they had to revisit a device because it was missing from the logs: *"The data in the logs sometimes doesn't give us enough information to go on and hunt, what's presented in front of the analysts is quite hard to use to make a decision. You end up having to spend extra time actually going to the originated device to see what happened. So, we can't pull back PCAPs [Packet capture], things like that, we're solely based on what the logs present to us and they're defined by IS defenders so that can be quite tricky."*

Participants who cited noise in the data as a problem explained that it forces them to spend significant time filtering through irrelevant information. *"You're digging through large data sets you're always going to have limitations and time... You don't get instant results for any query or analysis that you're doing. Again the volume of data that you have to go through is so much data... it's overwhelming sometimes how much you have to dig through ... As you scale the data it just gets harder and longer and more difficult."* P04

Regardless of the specific cause of low data quality or visibility issues, all participants emphasized that missing data or data gaps create blind spots, making it difficult to identify threats (from benign events) or determine the duration of an ongoing attack.

Data overload. Participants(8) also reported that the sheer volume of data they have to deal with can sometimes pose challenges. They explained that going through all the data to identify threats takes time and is complex. Some highlighted that it can be an overwhelming experience which may affect the hunter's ability to spot obvious indicators of compromise. Another challenge mentioned concerning the abundance of

data was querying. Participants explained that having too much data makes querying difficult and time-consuming. We found that failing to promptly and effectively retrieve the necessary data slowed their efforts and made hunting challenging. *"To make sense of the data, we have a lot of it and to get something interesting from it is a big challenge. You end up with loads of results that are useless in the data set. It's hard to filter out new threats. It's very challenging and it takes time to adjust the query to get the right data."* P15

Limited data storage. Some (n=7) face challenges around data storage. They explained that they usually have limited storage capacity, which means they sometimes do not have sufficient data to conduct thorough investigations. Participants also explained that the issue of data storage is challenging because it is also hard to know how much data is needed to be stored just in case it needs to be used for investigations. The participants who conducted external threat hunting stated that most of their clients usually do not keep much data because they do not have the infrastructure to do so. They explained that this leads to challenges when investigating threats or understanding how long the systems have been compromised. *"Acquiring the data is the difficult part because they might not have storage for that stuff. It's ridiculous. The security solutions that are out there are not made to store data, they're basically made to do things with it and then remove it quickly. The problems I've seen, is that people don't think about what happens when you need the forensics? What happens when there's compromise? You need 30 days of logs or 60 days or 180"* P22

> **Take Away.** Threat hunting relies extensively on the availability, usability, and quality of data. However, this crucial aspect presents a significant challenge. The difficulty arises from (1) obtaining the required data for investigations due to poor logging (visibility) and storage practices within organizations, and (2) the complexity and overwhelming nature of the data, making it challenging to analyze with the available tools and/or knowledge.

People and Organizational-related Challenges These include issues around organizational culture and interpersonal skills of individuals. Participants reported facing significant challenges in identifying and recruiting skilled staff, establishing effective communication channels, and managing constraints around budget and resources.

Skillsets and staffing. Participants (n=11) highlighted various challenges related to their staffs' necessary skillset for effective hunting, including technical, communication, and analytical skills. They emphasized that threat hunting requires more than just technical expertise; it demands a specialized set of skills and critical thinking. As a result, they explained that they need to provide training to every new hunter to ensure they possess the right skills for the job, but this process takes time and requires resources. *"Our main challenge is that not a lot of IT people we encounter are well-versed in security and incident management, so we have to give them step-by-step instructions on what to do, and it takes time, and even if you do, sometimes they don't understand. 'Oh, what is happening? Why do we need to do this?' We have to let them understand it, otherwise they are going to make mistakes"* P08

In addition to skillsets, attracting and retaining skilled personnel emerged as another problem. Participants described the difficulty in finding individuals with skillsets that strike the right balance between broad enough for various threats and specific enough for effective threat hunting. Furthermore, retaining staff posed challenges as threat hunting can be demanding, making it crucial to maintain long-term commitment from employees. P02 elaborated on the staffing challenges, and said; *"Yeah. I will start with the people. People is finding people and retaining people especially with Level 1s because they work on shifts, they work at night, then when you work online looking at the logs, again it's a bit big. So, make sure they can see the end of the tunnel. We can keep them interested and they can move on to the next level of analyst."*

Communication. Participants (n=7) also reported that communication within teams, management and clients can sometimes be challenging. Some participants explained that some threat hunters have difficulty communicating threats or risks they find during hunts. Poor communication or unclear reporting protocols (or channels) may lead to other team members underestimating the impact of the threats or the management not understanding what is needed or how to respond. They emphasized the critical importance of communication, especially since they work with various teams (e.g., legal), some of which may not possess the technical expertise to understand and assess cyber attacks. P03 highlighted the significance of effective communication: *"There's no point having threat intelligence if you can't communicate it to someone in the proper way, so someone who is very skilled at reports who can create a lot of information. Communication is quite useful to the people that are working on the board and things like that and who don't understand cyber, presenting the threats to them in a way that they can understand it, that's useful."*

Budget constraints and lack of resources. Participants (n=9) also emphasized the significant challenge posed by budget constraints on security and threat-hunting efforts within organizations. They stated that the lack of budget affected several crucial aspects, including acquiring necessary resources, availability of skilled workforce, dedicated teams, and time allocation. Some participants argued that this is due to the management not understanding the importance of proactive security response. Most participants shared that threat hunting

and security are underfunded, making it difficult to acquire the right equipment for storage or analysis, as it is often expensive. *"Cost is one of the biggest issues because the technologies that companies need are expensive. I've been in threat hunting for almost 20 years one form or another as well as exploited all kinds of stuff, we have to do the best job possible with a lack of information and a lack of technology at the client."* P05

Some participants also associated operational issues like bad performance, time constraints, and lack of dedicated threat-hunting teams with insufficient budgets. The shortage of financial resources often forces threat hunters to perform other duties unrelated to threat hunting because the company does not have enough security personnel. This affected their threat identification performance, ability to learn and tune their threat detecting rules, and response time to alerts and investigations. *"Another [challenge] is having time, being able to dedicate – not just time, but continuous time, where you can continually tune the rules that we have, and actually go back and continually review the results of the rules that we have. So, I would say time is the biggest issue outside of data collection. Time and dedicated man hours to threat hunting. With respect to that, I guess having one person dedicated to threat hunting would definitely be useful but I always say there's a saying, if you give me six hours to cut down a tree I will spend four hours sharpening my axe"* P10

Furthermore, we found that budget constraints posed challenges in fostering a culture of innovation and continuous improvement among threat-hunting teams. Some participants were concerned that low or no budget could hinder analysts' exploration of new techniques and experimental approaches. The lack of allocated time and flexibility for hunting duties affected their ability to stay at the forefront of evolving threats and identify potential security risks effectively.*"The challenge is that our organizations are telling the analysts don't be smart, don't spend the time to learn new techniques, don't spend the time to experiment, don't spend the time to try things that might not work. That's exactly what the organization is telling people when they take away the time allocation from hunting and flexibility. That's the big pressure on us as to why we're not good at [threat] identification."* P09

Participants stated that budget constraints also their clients. They said budget constraints affected what they could do or recommend for their clients. For instance, P04 explained that their clients cannot collect all the necessary data they need due to budget constraints. *"I think the biggest challenge is usually client budgets because you know it's always kind of [affect] the amount of data that goes to the SIEM [because] that's how they get charged by EPS. The more data they send in there, the higher their bill. You know budget constraints seem to be the biggest barrier to collecting the data we really need in order to do the kind of threat hunting that they would want us to do."* P04

Take Away. Threat hunting's effectiveness is intricately tied to the skills and experience of the threat hunters. However, finding and retaining qualified staff in this field presents a significant challenge. Furthermore, threat hunting is frequently underfunded, exacerbating the challenges faced by security teams, like getting the right tools.

4.4 Best Practices Strategies

To address the various challenges, participants shared several strategies they used and practices they perceived to be the most effective in improving threat hunting processes. We only discuss the most reported strategies.

Strategy 1: Re-analysing, Re-tuning, and Collaborating. Firstly, to address false alerts participants emphasized conducting thorough analysis of the cases against historical data to identify patterns or common characteristic of previous attacks. This method helped them distinguish genuine threats from false positives more accurately. Secondly, some explained they constantly fine-tune their approaches; refine detection rules, use cases, and algorithms. Refining these approaches helps in reducing false positives. Participants also highlighted that relying only on rules for identifying threats might lead to false negatives, especially when dealing with new and emerging threats (e.g., zero-days). To overcome this, they randomly conduct further analysis on logs that may have initially passed without triggering alerts. This active approach helps them uncover potential threats that might have been missed by the existing rules or tools. Other participants emphasized the importance of collaboration and shared learning to mitigate false negatives. They explained that when an IoC is missed, and later found, they come together to discuss and understand the reasons behind the oversight. This collective effort helps them identify gaps in their detection capabilities and implement necessary changes to avoid similar false negatives in the future.

Strategy 2: Automating Repetitive Tasks. Other participants reported that automating certain activities helps to scale the search and improve its effectiveness. By streamlining repetitive tasks, they can free some time and focus on other strategic and analytical aspects of threat hunting. Moreover, they stated that automation also helps to ensure consistency and accuracy around data collection and analysis. We also found that automation also help reduce the burden on threat hunters; reduces the risk of errors that might result due to manual analysis of larger datasets.

Strategy 3: Refining data collection strategies. To mitigate issues around data collection, some participants reported that they work on their data collection strategies, identifying and collecting only info that is needed, and also using

efficient methods of collecting and storing logs. Other participants explained that they encourage best practices around data collection and also by following best policies. For instance, some argued for more centralization of data. They reasoned that having all the data in one place improves the overall visibility of the data and the infrastructure being investigated. While others stated that having centralised data was useful for use case generation; they explained that it made use case generation easier as one can clear visibility of what they have and what they do not have.

Strategy 4: Being flexible and Open minded. Participants said one way of making threat hunting easier is not following a rigid and repetitive process. They explained that, as threats constantly evolve, one needs to be creative and find new ways of hunting for threats. Being strict in approach or not adapting the process could lead to missing new or emerging threats. They explained that approaching threat hunting with an open mind however helps to break routines and norms that develop within teams over time. With an open-minded approach, threat hunting teams can promote an environment where fresh ideas and perspectives are valued which may eventually lead to new novel techniques to threat hunting.

Strategy 5: Keeping up with current threats. Some participants emphasized that staying informed about the latest threats is crucial for enhancing threat hunting practices. They recommended providing threat hunters with continuous learning opportunities to keep them updated on current threats and how to identify and respond to them. Other participants suggested that this could be achieved through training and research efforts. While some participants had specific suggestions like having frequent training, others stressed on enhancing the complexity of the training. In addition to training, other participants suggested documenting and reporting new threats as part of the learning and keeping up with new threats.

Strategy 6: Asking for better budget allocation. Almost all the participants discussed budget in one way or another particularly how it can improve threat hunting activities. For example, acquiring tools and organizing and conducting trainings. Participants suggested that having adequate budget allocation is critical to facilitate effective threat hunting activities and enable teams to have access to necessary resources and tools that can detect and mitigate threats.

5 Discussion

Humans, Machines, and Collaborations. Our findings reveal that threat hunting is a multifaceted process that demands creativity, attentiveness, and the utilization of appropriate tools. These results align with existing literature [15, 36, 48, 50], emphasizing the significance of human-machine interaction in hunting. From our results, it is clear that machines have a significant role to play in threat hunting, but alone, without humans, they are limited. For instance, they may struggle to detect zero-day attacks or other new and emerging attacks, which may require human involvement. Our findings also suggest that threat hunting requires dynamic reasoning, such as intuition, creativity, and strategic thinking, which cannot be fully replicated by tools alone. Moreover, like hackers and testers [44], we found that experience plays a significant role in threat hunting. Some threats have been discovered solely because of experience (Tacit knowledge). Also, some hunters have found threats due to their curiosity, personal creativity, and persistence. Future efforts could investigate how these workers could collaborate to build morale, exchange ideas, and bring creativity to the field.

In-House vs. Providing Services. Our sample represent various companies, with some conducting in-house hunting and others outsourcing their services. We observed significant similarities between both groups, particularly in how they apply each method. However, there were a few notable differences (Table 3), for example, reporting. Participants expressed frustrations about reporting while providing services to other companies, highlighting unclear reporting lines than in-house which they believe affect the remediation of identified issues. Regarding challenges, though they face similar issues, the manifested differently. For example, both groups faced challenges with data, but those offering services to outside companies emphasized issues such as unusable data and missing data points. This discrepancy is perhaps unsurprising, as companies typically have more control over their in-house operations compared to external entities.

Lack of standardization. While we categorized threat hunting methods in our paper, in practice, they are borderless, and not one size fits all. Hunters combine them for better output. While this flexibility may be beneficial in some cases, it could also lead to undesirable practices and outcomes. For example, hunters may choose to prioritize certain activities while neglecting others (e.g., skipping pre-planning), which may be critical in the entire threat hunting process. There is a need to standardize these methods to prevent the loss of critical processes and promoting best practices. Moreover, the establishment of industry standards outlining how each threat hunting approach should be executed may lead to greater consistency, and minimization of errors. Furthermore, this could lead to the development of specific training materials to assist practitioners, such as detailed case studies that could be used worldwide. Future work should look into these methods and identify which ones are prevalent in the wild and the activities that should form the base of threat hunting framework.

Beyond Traditional SOC Boundaries. Beyond Traditional SOC Boundaries: Our findings indicate that threat hunting is expanding beyond traditional SOC boundaries. Some participants reported that their threat hunting efforts began outside the SOC, while others mentioned that members of their threat hunting teams had additional responsibilities in their companies and conducted threat hunting outside the SOC. Hunting outside the SOC may have both positive and negative aspects. In some cases, it may democratize threat hunting and engage everyone. However, it may also introduce additional privacy and security risks or require extra measures to be put in place, which might increase costs. Also, during the pandemic, there were discussions about virtual SOCs (or metaverse SOCs), which would enable practitioners to connect to SOCs remotely or integrate several SOCs virtually in real-time. As spatial computing becomes more popular, virtual SOCs are feasible, and threat hunting outside physical SOCs might become common. We believe virtual threat hunting warrants further exploration to determine how it can be achieved securely. Moreover, research should further investigate current practices of threat hunting outside SOC settings and how it can be made effective and secure.

Budget and Staffing. Similar to other works on security workers (e.g., [5, 16, 25]), recruiting and retaining skilled personnel is also a challenge in threat hunting. This is a multifaceted problem, involving low budgets, lack of motivation, excessive responsibilities, and cognitive demands. We believe there is no single solution to these issues, but management should work on certain improvements. For example, removing additional non-hunting responsibilities, as they may indicate a lack of appreciation for proactive security measures. Moreover, this could maximize hunters' time and effort. We also acknowledge that hunters may take on other roles because they see no clear career progression in threat hunting. Consequently, there is a need for clear career paths in threat hunting, so hunters can envision themselves in these roles for the long term. Investing in threat hunting may also address some of these issues; for instance, providing training could ensure an adequate number of personnel and boost team motivation, which is crucial in this field, as highlighted in previous studies [2, 44] on bug hunters. The research community should also emphasize the importance of investing in proactive security rather than relying solely on reactive measures, as this is paramount to the success of threat-hunting initiatives.

6 Conclusion

In this work, we investigated threat hunters' practices in the wild, including who conducts the hunts, how they conduct them, the challenges they face, and the strategies they employ to address these challenges and improve hunting processes. We found that threat-hunting activities are not standardized; various security experts can perform threat-hunting and use different methods based on needs and resources. The challenges they encounter are not just technical but include organizational challenges. Our results not only provide empirical evidence on threat hunters' daily practices but also have the potential to strengthen Cyber Defense Strategies and improve decision-making in SOCs. Future studies could investigate the unique challenges and opportunities for threat hunting in specific areas, such as gaming.

7 Acknowledgement

We thank all the security experts who took part in our interviews, without their time and expertise, the publication of this paper would have not been possible. We would also like to thank the reviewers and shepherd for their valuable feedback to the paper. This work is supported in part by EPSRC CDT TIPS-at-Scale.

8.2 In-house Vs Outsourcing services

8.3 Interview Protocol

Q1. Please tell us about job role/position/level
Q2. Please tell us about your work responsibilities within the company?
Prompt: What do you have to do in your day-to-day job role?
Follow-up: Are you working in a team or individually?
Q3. Could you please tell me about your approach of threat hunting? Prompt: How do you perform threat hunting?

Study Intro: This study is divided into three parts:
1) Data collection 2) Threat Identification 3) Threat Analysis

Data\Log Collection

Aim: To identify and understand the data collection process, various sources of logs and address the challenges linked with the collected data.

Q1. How do you do data collection?
Follow up: Can you tell us about the types of information you collect?
Follow up: How often do you collect logs for analysis?
Q2. How do you get your logging information ? (event logs/ Cyber Threat Intelligence)
Follow up: What are the security devices or methods you use to collect logs? (Source of the logs: Where does the data come from?)
Q3. After collecting all your logs, what do you do next?
Follow up: Do you use any parser or tools for the analysis?
Follow up: How much data do you keep and for how long?
Q4. How do you do log aggregation?
Q5. What kind of challenges do you normally face during data collection?
Q6. How do you think the challenges can be mitigated?
Follow-up: Any suggestion for improvement of the current approach?

Threat Identification

Aim: Gain insight into the practical aspects of threat hunting and identify challenges when extracting threats from extensive event logs. Additionally, explore how analysts cope with uncovering advance threats while encountering the challenges in the data collection process.

Q1. What is your process of hunting the threats/IoCs out of the logs?
Follow-up: What procedure you follow for threat hunting? Is this process automated or manual, or reported?
Follow-up: What sort of tools and techniques do you use?
Follow-up: Do you use any specific tool or technique to identify thyreats?
Q2. How do you prioritise threat and threat validation?
Q3. How is the severity of incidents defined?
Follow-up: Who defines the severity of incidents?
Q4. What kind of challenges do you face during hunting process?
Q5. Threat hunting sometimes includes false alarms, do you also face such false positive alerts?
Follow-up: How do you deal with false positive?
Follow-up: What do you do in case false negative?
Q6. Based on your experience, What can be done to improve the process?

Analysis of Threats:

Aim: Now that you have cultivated a good amount of evidence indicating anomalies, the next step would be, analysis of threats or anomalies. We want to understand the challenges in the threat analysis part.
Note: The person identifying threats also analyzing the threats?

Q1. Once IoCs are identified, how do you analyse the threats?
Prompt: Is this automated or manually?
Follow-up: What challenges do you face while analysing threats?
Follow-up: Do you have labs or simulation environments to test out the particular executable behavior?
Follow-up: What challenges do you face when testing or simulating these behaviours?
Q2. How do you resolve the identified incidents?
Prompt: Once the incident source has been identified, what are actions taken to resolve it?
Follow-up: Is this process based on severity measurements?

Suggestion/Scope of improvement:

Q1. In general, as a person who works in SOCs or deal with identifying threats, what kind of challenges in terms of people, process and technology?
Follow-up: the processes involved in threat hunting?
Follow-up: the technologies used for threat hunting?
Q2. What would you like to change in this whole threat hunting process?
Q3. What tools and technologies do you think can benefit threat hunting process?

8.4 Codebook

Table 3: In-house Vs Outsourcing services

Threat Hunting Process	In-house	Outsourcing services
Pre-hunt Plan	Have deeper knowledge of the network, systems, and data being collected.	Cannot only rely on the client's in-house team, they must learn the systems themselves from scratch
	Have defined communication line so they know who to communicate with during planning about data and devices.	Communication is usually challenging because sometimes it is not clear who oversees what.
	Flexibility to adapt and refine planning	Services are for limited time, and they must follow standardize process.
	Priority issues (analysts may have other work responsibilities)	No priority issues, as this is a dedicated team
	Other local teams and management usually understand scope of the threat hunting	Keeping everyone on the same page as sometime client have different expectations.
Data Collection and Preparation	Have direct access to data/logs makes the process easy	Limited data access and availability because sometimes the logs are not even collected or have been collected but deleted.
	They are usually part of the team that decides which logs needs to be collected and retention period.	Lots of time can be spent on trying to understand logs. Data sometimes is missing
Hunting and Validating	Misunderstanding threats may lead to false negative alerts	Limited access to data and lack of data source results in false negative
Remediation and Reporting	Due to direct access to internal team can promptly respond to threats and start remediation actions	Must wait and be advised on how to respond to threats.
	Can communicate directly with other teams during remediation	Communication can be challenging which may delay the threat response process
	Reporting channels are clear	Reporting can be cumbersome

Table 4: Codebook

Theme	Code	Subcode	Description
Threat Hunting Practices	Threat Hunting Method	Use case-bases Hunting	Participants describing a process of threat hunting that involves building cases or scenarios on possible attack patterns, tactics, techniques, and behaviors that adversaries might employ.
		Intel-based Hunting	Participants explaining they leveraged threat intelligence feeds, open-source intelligence, or vendor-based intelligence for threat hunting.
		Random-based Hunting	Participants describing a method of hunting that is random, possible based on suspicion or knowledge from past events.
	Threat Hunting Process	Pre-hunt Plan	Participants describing a process in which they carefully plan for the hunting process. This includes defining the objectives, scope, choosing network or system logs to investigate, and determining the tools and techniques and who will carry out the search.
		Data Collection and Preparation	Participants describing an approach for collecting data from various sources such as network, tools, and other security devices deployed to collect data within the organizations.
		Hunting and Validating	Participants describing the hunting process and the validation process they follow to identify and verify threats.
		Remediation and Reporting	Participants explaining the process they follow when they have discovered and confirmed a threat or indicator of compromise including how they report it and to whom.
Threat Hunting Challenges	Method-related Challenges	False Alerts	Participants explaining sometimes they receive potential threat alerts that turn out to be false or benign.
		Building Usecases - Complex TTPs	Participants explaining that building use cases requires deep understanding of potential attacks tactic and technique, also highlighting that this is not easy.
		Evolving tactics and techniques	Participants explaining that because threat actors continually adapt and innovate their approaches to bypass security measures and avoid detection, then threat hunting is more challenging.
		System & Tools failing	Participants explaining that systems and tools sometimes fail to provide the services required.
	Data-related Challenges	Complex Data	Participants explaining that data being extracted can come in diverse formats, sometimes even challenging to understand.
		Incomplete & Low-Quality Data	Participants explaining that data is sometimes incomplete or of low quality leading to inaccurate assessments or provide insufficient insights on potential threats
		Data Overload	Participants explaining that identifying threats from large volume of data is complicated and challenging.
		Limited Data Storage	Participants explaining that their challenge is having limited storage which affects their threat hunting efforts.
	Organization & People related Challenges	Skillsets & Staffing	Participants discussing challenges around finding people with the right skills to perform threat hunting.
		Communication	Participants explaining that communication is one of their challenges in threat hunting.
		Budget Constrains & Lack of Resources	Participants explaining the constraints that they have in threat hunting due to lack of budget and having the right resources.
Threat Hunting Strategies	Best Practices Strategies	Re-analysing, Re-tuning, and Collaborating	Participants describing how they address false alerts.
		Automating Repetitive Tasks	Participants explaining how they use automation to address some of the challenges they face.
		Refining data collection strategies	Participants explaining that they continuously refine their data collection strategies to have useful data for threat hunting.
		Being flexible and Open minded	Participants explaining that they approach threat hunting with an open mind to ease the tasks.
		Keeping up with current threats	Participants describing the importance of continuous learning to keep up with threats.
		Asking for better budget allocation	Participants explaining how better budget would solve majority of their challenges.

Pixel Thief: Exploiting SVG Filter Leakage in Firefox and Chrome

Abstract

Web privacy is challenged by pixel-stealing attacks, which allow attackers to extract content from embedded `iframe`s and to detect visited links. To protect against multiple pixel-stealing attacks that exploited timing variations in SVG filters, browser vendors repeatedly adapted their implementations to eliminate timing variations. In this work we demonstrate that past efforts are still not sufficient.

We show how web-based attackers can mount cache-based side-channel attacks to monitor data-dependent memory accesses in filter rendering functions. We identify conditions under which browsers elect the non-default CPU implementation of SVG filters, and develop techniques for achieving access to the high-resolution timers required for cache attacks. We then develop efficient techniques to use the pixel-stealing attack for text recovery from embedded pages and to achieve high-speed history sniffing. To the best of our knowledge, our attack is the first to leak multiple bits per screen refresh, achieving an overall rate of 267 bits per second.

1 Introduction

In recent decades, the Internet has grown from a research-oriented network aimed for specialists into a communication network that encompasses all aspects of modern life. In typical use, a web browser accesses multiple websites, often concurrently. Each of these websites may process private, personal, and even sensitive information about their users. Even the fact that a user has merely accessed a specific website may reveal personal information about the user's beliefs, health, or social connections. Consequently, preventing information leaks within the browser is of paramount importance.

One of the main tools for preventing cross-site information leaks is the *same-origin policy (SOP)*, which prevents code of one website from accessing resources on other websites. This property holds even if the victim website and the attacker website appear together on the user's screen, through the use of the HTML `iframe` element.

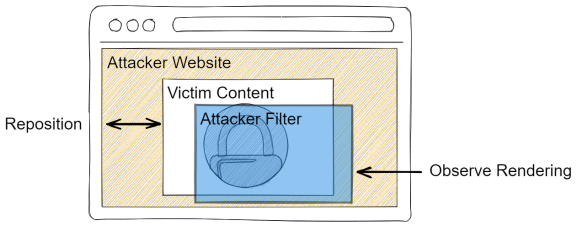

Figure 1: Overview of a pixel-stealing attack

Beyond code access, information can leak from websites through the way that they are displayed on the user's screen. This includes, for example, the rendering of inline `iframe`s, which embed content from one website into another website, and of links, which are rendered differently if the user has visited the linked site. To protect against such attacks, web browsers do not allow websites access even to their own rendered image. Browsers do, however, allow limited manipulation of the displayed contents through the use of *SVG filters*, which perform image transformations, such as recoloring, resizing, blurring, and more.

Past works have shown how to exploit minute data-dependent timing variations in SVG filters for pixel-stealing attacks [4, 36, 63]. Figure 1 shows the general structure of such filter-based pixel-stealing attacks. Here, the attacker lures the user to a malicious website that displays sensitive contents, e.g. in an `iframe`, applying SVG filters to the contents. By measuring the time it takes to render the page, the attacker can recover information about one of the pixels in the `iframe`. Changing the relative positions of the filters and the image, the attacker can target different pixels, eventually reconstructing the displayed contents.

A fundamental limitation of these attacks is their dependence on measuring the time it takes the browser to render a frame. This limits the leak to at most one bit per refresh, or no

* Equal contribution first author

more than 60 bits per second. Moreover, browser vendors are aware of the risks of timing-based pixel-stealing attacks, and have modified their filter rendering code to remove observable, content-dependent timing differences in filter execution time [12, 13, 14, 46]. Recent works have demonstrated the feasibility of exploiting CPU and GPU frequency scaling for pixel-stealing attacks [64, 68]. These attacks, however, have even lower leakage rates. Thus, we ask: *Are high-capacity pixel-stealing attacks on modern browsers feasible?*

1.1 Our Contribution

In this work we abuse SVG filters to send information through a cache-based side channel. We identify content-dependent memory access patterns in the CPU implementation of the `feComponentTransfer` filter. Because browsers default to GPU implementations, we first identify conditions under which the browsers elect to use this CPU version. We find that Chrome lacks support for many system configurations, forcing CPU execution on unsupported systems. For Firefox, we identify sequences of filters that force CPU execution even on otherwise supported systems.

To exploit the filter, we develop techniques to amplify the signal, allowing capture by a realistic side-channel attacker. We then design a communication protocol that allows the attacker to identify the cache location that the filter uses, and to transmit data through the channel. Our protocol allows us to overcome the limit of one pixel per frame, which affects all prior pixel-stealing attacks.

As an additional contribution, we show how to overcome cross-origin-isolation policies in web browsers. These policies allow websites to either use high-resolution timers or to embed contents of third-party websites, but not both. We note that the attacker can use two websites, one to embed the victim contents and the other to perform the cache attack. The attacker can therefore use high-resolution timers in the browser, without the need to resort to alternative timers [34, 59] or amplification techniques [29, 31, 54, 55].

We present two attacks that demonstrate the effectiveness of our technique. The first attack uses pixel stealing to observe text in the victim page. For that, we develop techniques for identifying a small number of regions that allow us to easily distinguish between letters, and show how to use these regions to accurately identify the displayed letters. We further show that the technique can be used as an end-to-end attack that leaks the Wikipedia identity of the victim.

Our second attack exploits pixel stealing for a history-sniffing attack. We first show a straightforward approach that leaks a limited number of links at a time. We then adapt the technique of Stone [63] for detecting whether any site in a given list has been visited. Finally, we devise an adaptive approach that further increases the speed of history sniffing under the assumption that the number of visited sites is substantially smaller than the total number of sites queried.

In summary, our contributions are as follows.

- We develop a simple approach to overcome cross-origin policies, allowing us to have access to high-resolution timers, while embedding third-party contents (Section 4).
- We show how to exploit the content-dependent memory access patterns of the `feComponentTransfer` SVG filter for pixel stealing. We design a transmitter (Section 5) and a protocol (Section 6), demonstrating the first faster-than-refresh-rate pixel-stealing attack.
- We show how to use our pixel-stealing attack to recover text from the victim page (Section 7).
- We demonstrate a fast history-sniffing attack on a modern browser (Section 8).

2 Background

2.1 Cache Attacks

Caches. To reduce the average latency of memory accesses, modern processors exploit program locality by introducing caches that store recently accessed memory locations. Modern x86 processors provide several levels of caches, where each core has private L1 and L2 caches, and all cores share access to a common last level cache (LLC). The caches in x86 processors are *set associative*, that is, the caches are organized as a collection of sets, each containing multiple *ways*, and each way in turn can store a single fixed-sized block of memory known as a *cache line*.

Cache Timing Attacks. Because the state of the cache depends on prior computation and, at the same time, affects code execution time, sharing caches can lead to information leaks [19], leading to a large number of attacks [21, 23, 40, 50, 51, 52, 53, 60, 61, 72]. Attacks typically detect the difference in access time, depending on whether the memory location is cached (a cache *hit*) or not (a cache *miss*).

In a Prime+Probe attack [40, 51, 52], the attacker first fills a cache set to be monitored with data. After waiting a while, the attacker accesses the previously cached data. A short access time indicates that the data is still cached, implying that the victim has not accessed data that maps to the monitored cache set. Conversely, a longer access time indicates that some of the attacker's data has been evicted from the cache set, presumably due to victim access.

Cache Attacks on Browsers. Cache attacks have been applied in browsers for website fingerprinting [50, 60, 61], keystroke timing [39], leaking cryptographic keys [20], and as a step in other attacks, such as Rowhammer [22] or transient execution attacks [1, 33, 41, 55].

2.2 Pixel Stealing

SVG Filters. Webpages often visually present sensitive information, such as cross-domain embedded content or links, which change visual appearance based on whether the link

was previously visited by the user. To protect this information, browsers isolate JavaScript executing on a webpage from the rendered appearance of that webpage. Pixel-stealing attacks break this isolation – they allow malicious webpages to recover their rendered appearance, and therefore to recover any rendered sensitive content.

In this work we exploit SVG filters, which are small functions that operate on web page elements after the elements are rendered, but before they are displayed [70]. Filters are composed of several *filter elements*, primitive operations that are parameterized and combined to form the complete filter, and are specified in XML markup. The possible list of filter elements is specified by the SVG standard, and includes several standard image-filtering operations such as color mapping and convolutions. Filters are used to apply artistic effects that may be difficult or impossible to achieve otherwise, such as blurring, to parts of the webpage.

Abusing Filters. Stone [63] showed that data-dependent code paths in filter implementations cause timing variations that can be used to leak pixel data. In response, browser vendors removed all data-dependent branching from their SVG filter implementations [12, 46], as is now required in the formal W3C documentation [70].

More recent works demonstrated that it is possible to leak data due to variations in the processing time of floating point instructions, even in the absence of data-dependent branches [4, 35]. To mitigate this threat, browser vendors now enable CPU flags that ensure these floating-point instructions no longer exhibit excessive slowdown when operating on specific floating-point values [13, 47]. Andrysco et al. [5] has since suggested the use of cryptographic constant-time programming in SVG filters to ensure that the execution time remains constant-time, although no vendor seems to have employed such an approach.

Two recent works show that execution of SVG filters constrain GPU power or thermal budgets, causing data-dependent voltage and frequency scaling that can be observed through timing [68] or via a counting thread [64].

2.3 History Sniffing.

The threat of recovering which websites a user has visited is well established [27, 28, 69]. To protect against attacks that query the `:visited` CSS selector [8, 16, 56] browsers limit the styles that can be applied to a link using this selector, avoiding styles that change the page layout, access external resources, or require significant computation [44, 48].

Other techniques for executing history-sniffing attacks have been proposed, such as measuring various browser caches [7, 17, 25, 62], tricking users into exposing their history by interacting with the webpage [32, 49], or by measuring the time taken for a request to be processed by the server [58].

Stone [63] showed that pixel-stealing attacks can be used to execute history-sniffing attacks by observing whether a link is rendered as visited or unvisited. Several follow up works [4, 35, 36, 63, 64, 68] have found various other mechanisms for pixel stealing. They all, however, suffer from an inherent limitation – they can extract at most one bit of information per rendering of the screen.

2.4 Cross-Origin Isolation

The Cross-Origin Opener Policy and Cross-Origin Embedder Policy (COOP/COEP) along with the `frame-ancestors` directive of the `Content-Security-Policy` header are three related policies that can be configured by web developers to control how their pages can be embedded into other websites. Unlike `X-Frame-Options`, which only allow developers to block all embedding or to restrict embedding to pages from the same origin, these policies provide more fine-grained control over embedding. In particular, COOP/COEP requires that the embedder and the embedded website mutually trust each other – signalled by the use of these policies. That is, in order for a website to embed another website while using these policies, both websites must opt-in to these policies, and both websites must add each other to an allow-list.

In addition, vendors have recently started to use COOP/COEP to signal whether it is safe to allow the website to access two sensitive APIs: high-precision timers and `SharedArrayBuffer`s. Websites that do not enable COOP/COEP are allowed to use `iframe` elements to embed other websites, excluding those that enable COOP/COEP or `X-Frame-Options`, but are restricted from accessing high-precision timers and `SharedArrayBuffer`s. Conversely, websites that enable COOP/COEP have access to high-precision timers and `SharedArrayBuffer`s, but can only embed websites according to the rules specified earlier.

3 Attack Model

We consider an adversarial model used by so-called *click-jacking* attacks [26]. Specifically, we assume that the victim visits a webpage which allows an attacker to execute JavaScript, for example the attacker lures the victim to visit a malicious webpage or the attacker masquerades their attack as an advertisement and embeds it into another otherwise benign webpage. We further assume that the attacker can entice the victim into interacting with the malicious website at least once, for example by clicking on a button to accept cookies. Finally, we assume that cross-origin content embedded by the attacker is not protected with `X-Frame-Options`, `frame-ancestors`, or COOP/COEP headers.

The requirement for interaction is not strictly necessary to recover same-origin content, such as the history stealing attack presented in Section 8, and removing the requirement would result in a model similar to previous pixel-stealing works, however for simplicity of explanation we treat all attacks under the stricter *click-jacking* model.

Hardware and Software. We assume that the victim is using a machine equipped with an Intel processor featuring an inclusive cache, that the user uses either Firefox V92 (or later) or Chrome V92 (or later). Section 7 assumes a version of Firefox that does not feature the Total Cookie Protection or that the feature has been disabled. For Chrome, we were unable to find a method to force the use of the CPU to render filters. We therefore assume that the user uses a device that is on the software rendering list [15]. This includes devices using Linux with open-source drivers and devices that use Mac OS with hardware that has not been added to an allow list.

Experimental Setup. Our experiments are performed on a machine equipped with an Intel i7-6700K CPU with 8 GiB of RAM, running at 2133 MT/s. Measurements throughout the paper are collected using Firefox V102. We have confirmed that the pixel-stealing attack primitive works on both Firefox V108 and V112, enabling the history-sniffing attack to be carried out. We note that in these versions of Firefox an unrelated open bug prevents cross-site filtering from working altogether, inadvertently preventing our cross-site pixel-stealing attack as well. On Chromium V113, we use the --disable-gpu flag to emulate the device being included in the Software Rendering List thereby causing filters to be rendered on the CPU. The attack code can be found at https://github.com/0xADE1A1DE/PixelThief

4 Overcoming Cross-Origin Isolation

Recall that for a website to access high-resolution timers or `SharedArrayBuffers`, the website must use COOP/COEP headers. If that website is to embed or be embedded within a cross-origin website, then that cross-origin website must also use COOP/COEP. Further, both websites must mutually add each other to allow-lists for embedding.

To mount an attack in such a setting, the victim website is not only required to use COOP/COEP, but the victim website must also add the malicious website to an allow-list. While wildcards are allowed, and it may be plausible that overly permissive allow-lists exist in the wild, this still prevents an attacker from mounting attacks on the plethora of websites that do not use COOP/COEP. For these reasons, we consider a setting in which the victim website does not use COOP/COEP.

Such a setting seems to imply a mutually exclusive scenario for the attacker: either they can access high-resolution timers and `SharedArrayBuffers`, or they can embed victim websites, but not both at the same time.

We note that several recent works have investigated the setting of reduced-precision timers, and there are now several advanced techniques that use transient execution to allow high temporal accuracy side-channel attacks to be mounted with reduced-precision timers [29, 31], but before we deploy such advanced techniques, we first ask: *Does the mutual exclusion implied by COOP/COEP actually exist?*

Throughout the rest of this section, we show that the answer is no, provided that we are willing to swap the standard pixel-stealing adversarial model with the stricter *click-jacking* [26] model. The key difference between the two models is the requirement of interaction from the victim.

Bypassing COOP/COEP. We use this interaction to open up a second tab in the browser. The first tab loads a page served with COOP/COEP headers. This page can thus access high-resolution timers and *SharedArrayBuffer*s, but it cannot embed any cross-origin content. The second tab loads a page that is not served with COOP/COEP headers. In this page the opposite holds – cross-origin content can be embedded with `iframe` elements, but high-resolution timers and *SharedArrayBuffer*s cannot be accessed.

We then split our attack between these two pages. Any part of the attack that needs to access high-resolution timers or *SharedArrayBuffer*s is placed on the first page, and any part of the attack that needs to interact with cross-origin content is placed on the second page. The two pages cannot directly communicate with each other because of the COOP/COEP headers. They can both, however, send messages to a server using `WebSockets`, and the server can relay the messages between the two pages, as we demonstrate in this work.

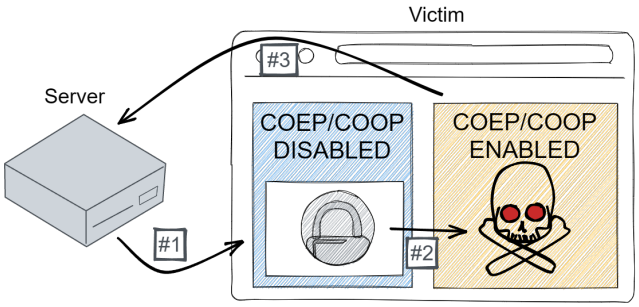

Figure 2: Achieving a high resolution timer. The server sends two pages to the victim operating under different security models, the first embeds the victim page (blue webpage, left) the second mounts the cache attack.

Figure 2 gives an overview of this approach. The server serves two pages to the victim: the first page operates under the old security model, and can therefore embed the victim page (blue webpage on the left), while the second page operates under the COOP/COEP security model, and is therefore able to mount the cache attack (orange webpage on the right). (#1) The server sends a command to the first page to manipulate the victim page into leaking data. (#2) Data leaks through the cache from the victim to the second page. (#3) The second page recovers the leaked data and sends it back to the server.

Same-Origin Content. In cases where the attack interacts with same-origin content, such as the history-sniffing attack presented in Section 8, the two-page architecture is not necessary because same-origin content is allowed to be embedded

into the page while COOP/COEP headers are present.

Measurements throughout the paper use the single-page architecture for same-origin content and the two-page architecture for cross-origin content.

5 Leaking Pixels

In this section we describe the pixel-stealing attack that forms the basis for the other attacks we present in this work. Our pixel-stealing attack reveals sensitive data displayed in parts of rendered webpages by exploiting input-dependent memory accesses in SVG filters.

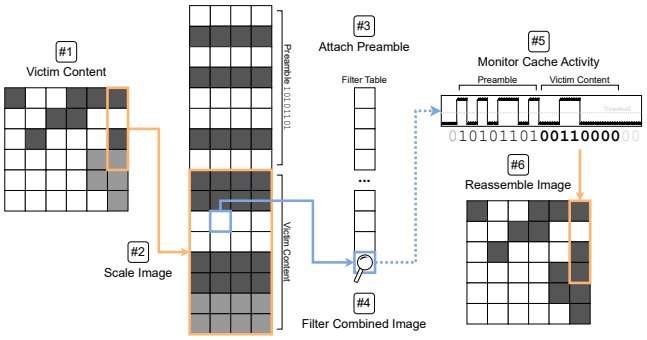

Figure 3: An overview of our attack. (#1) Embed victim content. (#2) Isolate pixels in victim content. (#3) Embed attacker content. (#4) Apply filter to both images. (#5) Record memory accesses. (#6) Find memory accesses correlating to attacker content then recover victim content.

Figure 3 presents an overview of how our attack functions. The attacker embeds the victim image into their page (#1) and uses CSS to isolate and scale chosen pixels (#2). The attacker then inserts their own image above these pixels (#3) to cause the filter to produce a predetermined sequence of memory accesses. When the browser later renders the page, the filter is applied to both images. The filter uses the value of each of the pixels as an offset into a table (#4). In parallel, the attacker mounts a cache attack to record memory accesses to this table over time (#5). Finally, the attacker analyzes the recorded memory accesses to find the predetermined sequence of memory accesses that correlates with their own image. Memory accesses after this sequence are attributed to the victim image and can be recovered and rearranged with other recovered pixels to reconstruct the full victim image (#6).

While the attack functions in both Chrome and Firefox, Firefox's implementation of the relevant filters is significantly easier to describe. We therefore focus on Firefox for the remainder of this section. We begin with a description of the vulnerable SVG filter. Then, we introduce and overcome the browser's use of GPU-based implementations. Finally, we end the section with a discussion of measurement frequency and how it affects the performance of the attack.

5.1 The feComponentTransfer Filter

`feComponentTransfer` is an SVG filter element that allows designers to remap the colors of their webpages. It can be used to implement various recoloring effects, such as sepia or greyscale. To that aim, the filter element operates over each pixel in the input image individually. First, it splits each pixel into its component red, green and blue values. It then maps each of the components' values, in addition to its alpha value, to target values based on functions defined by the designer. Finally, it merges the components back together to form the pixel color in the output image. Listing 1 (Lines 2–6) shows an example of how such a filter is defined.

```
1 <filter id="filter_id">
2     <feComponentTransfer>
3         <feFuncR type="discrete" tableValues="0
          ↪  1"></feFuncR>
4         <feFuncG type="discrete" tableValues="1
          ↪  0"></feFuncG>
5         <feFuncB type="discrete" tableValues="0.3
          ↪  0.6 0.9"></feFuncB>
6     </feComponentTransfer>
7 <feGaussianBlur stdDeviation="0" />
8 </filter>
```

Listing 1: A filter that executes feComponentTransfer and then uses feGaussianBlur to blur the result.

```
1  void TransferComponents(uint8_t input[N],
2   uint8_t output[N],
3   uint8_t tables[3][256]
4   ) {
5       for (int32_t i = 0; i < N; i += 3) {
6          for (uint32_t c = 0; c < 3; c++) {
7              output[i + c] = tables[c][input[i + c]];
8          }
9       }
10    }
```

Listing 2: Firefox's Implementation of feComponentTransfer.

Firefox's feComponentTransfer Implementation. The `feComponentTransfer` specification allows for several ways of defining the mapping of each channel to its target color, including identity mapping, linear and gamma maps, and interpolated and discrete tables [43]. Regardless of the definition chosen, internally Firefox uses a 256-entry lookup table for implementing each of the mappings. These tables are filled in during a precomputation phase, in which the values in the filter definition are mapped from floating point numbers between 0 and 1 into integers between 0 and 255, and the rest of the values of the table are interpolated according to the SVG filter specification. Listing 2 shows a simplification of Firefox's implementation for `feComponentTransfer` in C-like pseudo-code. Lines 1–4 define the function and its parameters.

The `input` and `output` parameters are the filter's input and output images, represented as interleaved 8-bit red, green, and blue values. The last parameter, `tables`, holds precomputed tables obtained by computing the functions defined in Listing 1. Line 5 iterates over each pixel in the input and output images. Line 6 iterates over each of the component values for each pixel. Finally, Line 7 applies the filter by performing a lookup in the appropriate table.

Analysing `feComponentTransfer` Cache Access Patterns. We now proceed to analyze the cache access patterns of Listing 2. Throughout the analysis we assume that each data element cached in the LLC, commonly referred to as a *line*, is 64 bytes long. To increase cache efficiency, the cache mapping function of the CPU aims to assign consecutive lines in memory to different sets in the cache [42]. Assuming that the data structure holding the tables is stored on a 4K page boundary, each 256-byte table will therefore span four different cache sets.

Consider a picture with two pixels, where the first pixel is black $(0,0,0)$ and the second pixel is white $(255,255,255)$. As before Lines 6 and 7 of Listing 2 iterate over each component of each pixel, with Line 8 performing table lookups. A side effect of accessing the table entries during lookup is that accessed entries are cached within the CPU cache hierarchy. That is, applying the filter to the black pixel causes the first 64 entries of the table to be loaded into the cache. Similarly, processing the white pixel causes the last 64 entries of each table to be cached. Consequently, an attacker who can tell apart accesses to the cache set holding the first 64 entries from the last can detect whether the pixel was black or white.

5.2 Executing `feComponentTransfer` on the CPU

To improve rendering performance, Firefox version 92.0 and newer attempt to offload image rendering to the GPU. This poses a challenge to adversaries that attempt to exploit vulnerabilities in CPU implementations of filter elements, simply because the vulnerable implementations do not get executed. We now describe how to overcome this issue, forcing Firefox to execute any filter element on the CPU.

Filter Elements without GPU Implementations. Although Firefox includes GPU-based implementations for many filter elements, some filters are still only supported through CPU-based implementation, see Appendix B for a complete list. One such example is `feGaussianBlur`, which applies Gaussian blur [67] to an image. We observe that none of the CPU-only filters are suitable for performing a side-channel attack. Most of these filters, including `feGaussianBlur`, achieve their effect through a convolution of the image and, as such, do not exhibit data-dependent memory access patterns that leak image data through the cache.

Forcing CPU Computation. Being unable to construct an attack using filters with only CPU-based implementations, we searched for methods for forcing Firefox to fall back to executing `feComponentTransfer` on the CPU. To that aim, we investigated Firefox's behavior when combining filter elements, especially when mixing CPU- and GPU- based filters. More specifically, when we combine `feComponentTransfer` with `feGaussianBlur`, we discover that both filters are executed on the machine's CPU (Firefox still computes `feComponentTransfer` on the GPU if the filters are combined in the opposite order). We notice that this observation holds true for all CPU- and GPU-based implementations: in the case that the last filter is CPU-based, the entire filter stack will be executed on the CPU, regardless of the number of GPU-based filters present.[1]

Our Filter Stack. To exploit this behavior, we use the filter shown in Listing 1. It consists of an `feComponentTransfer` filter element (Lines 2–6), connected to the inputs of an `feGaussianBlur` filter element (Line 7). As Firefox does not provide a GPU implementation for `feGaussianBlur`, it uses the CPU implementation for this filter. Moreover, as observed, this also results in using the CPU-based implementation showed in Listing 1 for `feComponentTransfer`. We note that the choice to use `feGaussianBlur` is arbitrary. We can use any other CPU-only filter to force execution of `feComponentTransfer` on the CPU.

Chrome. Chrome exhibits similar behavior to Firefox, in which Chrome will prefer to execute `feComponentTransfer` on the GPU. While we were unable to find an analogous method to force Chrome to execute `feComponentTransfer` on the CPU, we note that Chrome has an extensive GPU block-list that disables various aspects of GPU acceleration for specific hardware configurations. This includes devices with outdated drivers, devices running Windows Vista or earlier, devices running Linux with third-party drivers, and devices running MacOS X without a GPU on the allow-list [15]. An attacker would therefore be limited to attacking a victim with a device operating in one of these configurations. In our experiments, we emulate this scenario using the --disable-gpu flag, which disables GPU support in Chrome.

Signal Amplification. Cache attacks have a limited measurement frequency, which affects their ability to distinguish between events that occur rapidly [3, 53]. Recall that our goal is to perform a cache attack on the implementation of `feComponentTransfer` in Listing 2. To recover the image, we want to monitor each table lookup performed by the filter. The filter, however, is too fast – it performs an access every few cycles, whereas a typical cache attack requires hundreds or even thousands of cycles per measurement [3, 40, 53, 72].

Past works have explored methods for reducing the execution speed of the transmitter [2, 3, 23, 45, 65], but these rely on features that are not available from JavaScript, hence we cannot use them. Instead, we build on past works [4, 36, 63]

[1] We note that explicit linking of filter-elements using `in` attributes interferes with this behavior and prevents GPU-based filters from executing on the CPU.

that stretch the image such that the filter must perform repeated filter table accesses with identically colored pixels. As Firefox breaks up the screen into 256×256 px tiles, we stretch each pixel horizontally 256 times and vertically 256 times, divided by the number of pixels we want to measure in every attack iteration, as described below.

6 Recovering Pixels

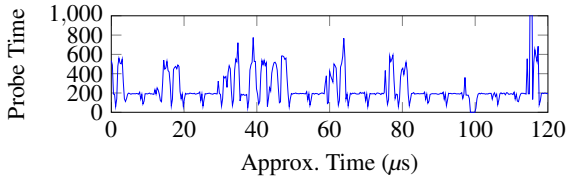
In Section 5, we construct the transmitter side of our pixel-stealing attack. We now turn our attention to the receiver side. We first explain how we prepare for mounting a cache attack. We then describe the cache attack we use. Our aim is to construct a fast attack that allows a high transfer rate. We selected the Prime+Probe [40, 51, 52] attack for this purpose. As discussed in Appendix A, we also evaluated the window-less Prime+Scope method of Purnal et al. [53], but discovered that it is less appropriate for our setting. We now discuss how we synchronize the transmitter and the receiver, then we evaluate our pixel-stealing setup described in Section 3.

6.1 Detecting Transmitter Communications

Recall that unlike other attacks mounted on filters [4, 36, 63], we measure leakage in parallel to filter execution, in order to perform multiple measurements and leak multiple bits of sensitive information from a single filter execution. The attacker, however, does not know if its cache measurement occurred while the browser filtered the webpage, or while the browser was performing some other tasks. Throughout this section, we describe how we detect whether cache measurements are transmitter communications or noise from other processes, and how we leverage the ability to detect transmitter communications to establish the communication channel. We first assume that the cache sets to be monitored are known to the attacker, and then show how these sets can be discovered.

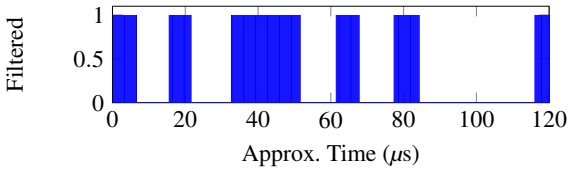
Adding a Preamble. To detect the beginning of a transmission, we follow a standard technique in communications and introduce a packet preamble. The preamble serves two functions – first, it allows the receiver to detect the start of transmission. Second, because its contents are known, it allows the receiver to match its clock rate, which is based on a free-running counting thread, to the rate of the sender. Recall that the signal is encoded into cache activity by moving an attacker-controller filter over a page containing victim content. We insert the preamble into the signal by prepending a known image into the page, just before the victim content, such that the filter will operate over the preamble first, and then process the sensitive information.

Listing 3 shows how the preamble is placed onto the attacker webpage. Lines 1 and 6 apply the filter to the preamble and the sensitive content. Line 2 displays the preamble as an image on the screen. Lines 3–5 display the sensitive content



```
1 <div style="filter: url(#filter_id);">
2     <img src="preamble.png" />
3     <div>
4         <!-- sensitive content -->
5     </div>
6 </div>
```

Listing 3: Preamble construction



on the screen. Since the filter goes over the image first horizontally and then vertically, the filter will first process the preamble image, and then the sensitive content.

Detecting a Preamble. With the transmitter equipped to send a preamble, we move to preamble detection in the receiver. Recall that the exact rate of the receiver's counting thread is not known to the attacker, and may even change over time. Thus, it is not possible to simply search the side-channel trace for the preamble, since it is stretched in time by an unknown factor. Instead, we search for the preamble at multiple different possible stretching factors. We speed up this process by first processing both the preamble and the trace using run-length encoding. In this representation, stretching in time is equivalent to multiplying by a constant. Once the preamble is found, the attacker knows both when the frame starts, and what is the appropriate data rate at which it should be sampled.

We implement the detector in the following manner. Input first passes in to a low-pass filter to remove high-frequency noise, then samples are compared to a threshold to classify them into cache hits and cache misses, then the recorded trace is run-length encoded, and finally, a substring search is performed to find the preamble. An example of cache activity measured by our attack before and after filtering the signal can be seen in figure Figure 4.

(a) Raw Data

(b) After Filtering

Figure 4: Cache Access Pattern Corresponding to a Preamble of '101011101010001', as Recorded using Prime+Probe.

Packet Payload. As mentioned in Section 5.2, our attack can be configured to leak different amounts of pixels per filter in-

vocation, depending on the chosen tradeoff between speed and error rate. Each invocation of the filter essentially transmits a "packet" of side-channel data, starting with the preamble and following with the sensitive payload. After the packet preamble has been detected using the method described above, and the scaling factor has been determined, the receiver can apply the same factor to the payload and read out the sensitive data.

Finding The Target Set. Until this point, we assumed the attacker already knows which cache set will be used by the filter processing code, and the only needs to detect when the data is actually being transmitted. To detect which cache set is being used by the filter processing code, the attacker begins by constructing an eviction set for each cache set, using the technique of Vila et al. [66]. After all eviction sets have been constructed, the attacker repeatedly applies the filter to a known image containing only the preamble, thus encoding the preamble into the cache. Next, the attacker goes over each possible set, recording a trace which is guaranteed to be long enough to include at least one screen drawing operation (practically, a little over 16 milliseconds), and searches for the preamble in this trace. If the attacker detects the preamble, they record the eviction set, so that future measurements do not need to perform this calibration step. If the attacker does not detect the preamble, they move to the next possible set.

6.2 Evaluation

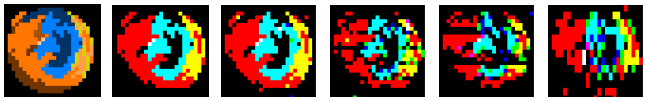


Figure 5: A pixel-art Firefox logo leaked using our pixel-stealing attack. From left to right: original image, ideal leakage, and actual leakage with payloads of one, four, eight, and 32 pixels.

In the previous section we described the final steps to detect cache leakage from `feComponentTransfer`. In this section we evaluate the effect of varying the payload size, the time required to identify the target set, and the effect of noise on the leakage rate and accuracy of the attack.

Throughout this section we mount our pixel-stealing attack on an image of a pixel-art Firefox logo in Figure 5 (First from the left). We serve a webpage that contains both the image and the pixel-stealing attack code from a local HTTP server. In Section 6.2.1, we evaluate the speed and accuracy trade off in selecting the payload size. In Section 6.2.2, we evaluate the capability of the attack to identify the correct target set. Finally, in Section 6.2.3, we evaluate the attack in a more realistic setting, with an additional concurrent workload.

We mount Prime+Probe only on the final entry in the `feComponentTransfer` filter table, which corresponds to indexes 192–256 of the table, and ignore accesses to any other

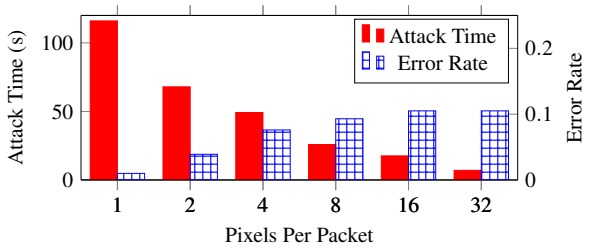

Figure 6: Attack time and error rates per packet sizes.

index. For each pixel, if an access to this cache line is observed, then we assume that index 256 of the table was accessed. Otherwise, we assume that index 0 of the table was accessed. Under these assumptions Figure 5 (Second from the left) is what the image would look like if there were no errors in the cache channel.

6.2.1 Varying Payload Size

First, we conduct an experiment to explore the trade off between speed and accuracy when selecting the payload size. We measure the time requried to recover the entire image after the attack setup has completed (i.e. setup times are excluded from the measurement). We recover an image with 1, 4, 8, and 32 pixels per packet. We recover the image 100 times at each packet size, and report the median elapsed time and the median error rate. Figure 5 (Third to sixth from the left) shows representative recovered images at each packet size.

The main type of error introduced is a skewing of the location of pixels in the image, since we leak a vertical column of pixels, with as many pixels as can fit in a single packet, all at once. Thus, if the attack incorrectly gauges the length of a pixel in the signal, a pixel may be inserted or excluded during recovery. Then, all following pixels in the column will be incorrectly offset. The effects of these errors are more visually apparent as the packet size increases.

Figure 6 shows quantitative results. We apply the Levenshtein distance [38] to measure the rate of errors, and then select the median value from the 100 measurements. The median runtime to leak the entire 25px by 25px image in three separate color channels (red, green, and blue) is 116s (16px per second) at the slowest speed to 7s (267px per second) at the fastest speed. As expected, the median error rate increases as the speed increases, starting at 1% at the slowest speed and increasing to 10% at the highest speed.

6.2.2 Finding the Target Set

Thus far, our evaluation has assumed an attacker that is ready to leak an arbitrary number of pixels. We now move to measuring the time taken to identify sets containing filter tables.

Work	Side-Channel	Measurement Target	Mitigated	Speed (b/s)
Stone [63]	Filter Optimizations	Page Rendering	✓	10
Kotcher et al. [36]	Filter Optimizations	Page Rendering	✓	<1
Andrysco et al. [4]	Subnormal Floats	Page Rendering	✓	16
Kohlbrenner and Shacham [35]	Subnormal Floats	Page Rendering	✓	60
Wang et al. [68]	Power Consumption	Page Rendering	✗	3
Taneja et al. [64]	Power Consumption	Page Rendering	✗	<1
This Work	Memory Accesses	Memory Accesses	✗	267

Table 1: Comparison of pixel-stealing attacks. We report which channel pixels are leaked through, how each work extract information from that channel, whether the presented attack has been mitigated, and the speed of the attack in pixels per second (roughly).

Setup. To identify the set, we use the technique described in Section 6.1. To validate our results, we used a patched version of Firefox that prints the virtual address of the cache set that holds the table. We use the methods of Maurice et al. [42] to infer the ground-truth set index in the cache, and compare it to the found index.

method. Since we may incorrectly detect a transmitted preamble, we record several traces and if we detect a preamble at least once while recording a set then we consider the set to be a candidate. We then record the same number of traces from the candidate again and if we detect preambles in at least three of the traces then we consider the set to be the target set. We repeat this process 21 times for each number of recorded traces and report the median time to identify the target set and the accuracy in Table 2. The median time to identify the target set is 372–1257 seconds and 48–77% of the runs identify the target set correctly on the first iteration of all eviction sets.

samples	Time (s)	Accuracy
40	1257.59±169	77%
30	999.56±152	67%
20	644.57±115	56%
10	372.39±60	48%

Table 2: Median time of identifying a target set and accuracy of the first iteration.

6.2.3 System Noise

Finally, we evaluate our attack in a more realistic setting in which the victim has other tabs open in the browser. We continue to use the same experimental setup as in Section 6.2.1, but now we open a new tab in the browser and have that tab play a video from YouTube. Figure 7 shows a representative qualitative result, where we can see slight degradation in the quality of the recovered image. With 100 runs of the experiment and comparing to the results from Section 6.2.1, the median runtime of the attack is 476s (4.09×) with a median error rate of 2.72% (+2.68×).

Figure 7: Left to right: Original, recovered image with zero errors, recovered image without system noise, recovered image with system noise.

6.3 Comparisons to Existing Works

Table 1 compares the speed of our work with other works that mount cross-origin pixel stealing attacks. All listed works mount timing side-channel attacks on filters to extract cross-origin pixels. We compare the channel that is used to leak pixels, how each work extracts information from that channel, whether the presented attack has been mitigated, and the speed of the attack in pixels per second.

Earlier works exploit optimizations in the filters themselves while later works, including our own, exploit leakage through microarchitectural side-channels.

All previous works extract side-channel information by measuring the time taken to render the page, indirectly measuring the execution time of the filter. In contrast, our attack extracts side-chanel information via measuring the execution time of victim memory accesses, indirectly measuring memory behavior of the victim. This difference is what allows us to achieve speeds that exceed the refresh rate of the display.

As with recent pixel stealing attacks, our work is yet to be mitigated. Fortunately, generic countermeasures for cross-origin pixel stealing attacks have been proposed, which would mitigate all attacks, including our own. We discuss these countermeasures in more detail in Section 9.

7 From Pixel Stealing to Text Stealing

We now show how to build upon our basic pixel-stealing attack to create a text-stealing attack that can recover sensitive text content from third-party websites. Unlike previous works [63] which mount pixel stealing attacks on monospaced fonts that can be easily pixelated, our work deals with text rendered with vector-based graphics using proportional fonts that feature kerning. In this section we describe the challenges that this introduces and how to overcome them.

Figure 8: Pixel-based content continues to stay pixellated after stretching (Left), whereas vector-based content is resampled after stretching (Right). Both regions in the original images are the same 3×3px size.

Text Rasterization. Our pixel-stealing attack scales the image to select individual pixels and amplify them. Pixel-based content can be scaled in such a way that it preserves the discrete pixels of the original image. (Figure 8 Left). In contrast, vector-based content, such as text, is represented using mathematical expressions, which are sampled to produce an image. When a vector-based image is scaled, scaling is applied to the mathematical expressions, and then the image is sampled at the display resolution (Figure 8 Right). Due to this difference, using transformations to isolate the color of a single pixel is simply not as effective for text.

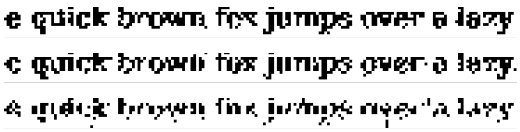

Figure 9: Naive Text Stealing at 1, 2, and 4 Pixels per Packet

Pixel Stealing on Vector-Based Content. To illustrate the problem, we perform our pixel-stealing attack on a classic pangram, and present the recovered text in Figure 9.

Compared to pixel-based content there is greater visual degradation, even when recovering one pixel at a time. Despite the visual degradation, there is sufficient redundancy within this pangram to be able to easily read it. While this is often the case for large pieces of text written in natural languages, this is often not the case for data of interest to attackers: victim's names, identification numbers, and passwords are all examples of sensitive data that is short and often contains very little redundant information.

A natural solution to this problem is to sample the image at a higher resolution to minimize this effect. However to double the resolution requires four times the samples, because grows with the square of the side length, and therefore we ask whether there is a better technique to extract text?

Stone's Method. We answer the question in the affirmative and present a solution that adapts Stone [63] binary-lookup technique. Stone's technique is based on the observation that given an image of an unknown character, if we discover the color of a carefully chosen pixel, we can exclude roughly half of the possible characters. However, Stone applied their tecnique to rasterized monospaced fonts, not proportional-width fonts that are more commonly used to display text.

Figure 10: An example region in the letters 'A' through 'F' in the MS Sans Serif font. The region is entirely inside or outside each letter.

Choosing a 'Pixel'. We begin by resolving the problem of identifying the color of 'pixels' with vectorized content. The observation that underlies the ability to adapt Stone's method to vectorized content is that we can isolate and arbitrarily scale any rectangular region of a character. Further, we can select regions that lie entirely inside or entirely outside the shaded part of a character, which guarantees the region only contains a single color, and therefore we do not observe any measurement artefacts. Figure 10 illustrates such a region for the letters 'A' through 'F'.

Finding Regions. We find such regions in an offline step, we randomly choose `x` and `y` coordinates and use a fixed width and height – these values are on the scale of one millionth of a pixel. We use the Selenium browser automation framework[2] to verify that the region lies entirely inside or entirely outside all characters we want to distinguish.

After collecting enough of these regions, we can distinguish each character but we will have redundant regions. We construct a minimized set of these regions using a greedy search algorithm – we find which region provides the most information and add it to a new set. This is repeated until every symbol can be distinguished. While this approach does not guarantee the theoretical minimum number of regions, we find that it builds a set very close to the theoretical minimum.

Kerning. Next we resolve the primary problem that proportional width fonts pose to the attack: kerning – the practice of changing the spacing between letters to achieve a better visual effect. With kerning, the position of a letter depends

[2] https://www.selenium.dev/

on the one or two letters that precede it. While kerning can happen between three or more letters, we limit ourselves to the common case of two letter kerning.

During region collection, we select a character at random (including no character) and prepend it to all characters we want to distinguish, we then continue with region collection as normal. This results in a set of regions for every starting character, which we then apply the minimization procedure to.

7.1 Text Stealing Results

We now move to evaluate our text stealing technique. We conduct two experiments. The first experiment measures the rate at which we can recover random characters of text. The second experiment we perform a proof-of-concept attack on Wikipedia, recovering the username of a logged in user.

Measuring Data Rate. First, we measure the rate at which our technique can steal randomly generated characters. We use the technique as described in the previous section, starting with the offline region collection on the default browser font over the set of all letters. We then select the letters *N*, *a*, and 1 and leak each one ten times. To reduce the effects of noise we sample the cache twelve times and perform a majority vote. The median time to leak a letter is 56 seconds with an accuracy of 93.3%.

Proof-of-Concept. We now move to show a proof-of-concept attack on cross-origin content, specifically we recover the username from a logged in Wikipedia account. We start by creating a new Wikipedia account and logging into it. Since we are performing a cross-origin attack, we deploy our two-page architecture as explained in Section 4 to bypass COOP/COEP. For this experiment, we manually interact with the page so that the second page is opened in a second tab.

Identifying Username Location. In order to steal the username, we first need to identify where the username is. We were able to side-step this in the previous experiment because we could simply apply the filter directly to the element containing the text. However, when we apply the filter to cross-origin content we must apply the filter to the `iframe` which in turn applies the filter to the entire page.

We manually use `getBoundingClientRect` to roughly guess where the username begins then refine this guess through the use of a Selenium script. This script slightly adjusts the starting position and then simulates the attack using screenshots. This step is performed once as an offline preparation step and once the script identifies the location of the text, we hardcode it directly into the attack.

Stealing the Username. Finally, we perform the attack to validate that we are able to steal text in a cross-origin setting and recover the username of the account.

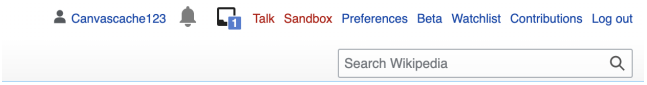

Figure 11: Layout of a Wikipedia User Name

```
.leak {
  display: inline-block;
  width: 1px;
  height: 1px;
  background-color: black;
  font-size: 0;
}

.leak:visited {
  background-color: white;
}
```

Listing 4: CSS Style for History Sniffing

8 History Sniffing

In this section, we show how to utilize our pixel-stealing attack for history sniffing. We first describe a straightforward approach that tests one or a small number of URLs at a time. We then show how to use batch testing to improve sampling rate when the number of visited URLs is expected to be low compared to the total amount of possible URLs.

8.1 Straightforward History Sniffing

Several prior history-sniffing attacks rely on the observation that the color of a link indicates whether it was visited or not [4, 25, 36, 49, 63] We build on the same observation.

To implement the history-sniffing attack, we first create a pixel whose color depends on whether a URL has been visited. For that, the attacker page includes a CSS style similar to Listing 4. The first set of rules in the code specifies that elements of class `leak` are rendered as colored boxes whose size is 1×1 pixels and whose color is black. The second rule changes the background of such elements to white if they have the property `:visited`, i.e. if they are a link to a URL that the user has visited in the past. When the class is applied to a link, e.g. using the HTML code `<a href="https://example.com" class="leak">`, the browser renders a 1×1 pixel whose color is white or black depending on whether the URL (in this example `https://example.com`) has been visited or not.

Having created a pixel that shows whether a URL has been visited, we can use the techniques of Section 5 and Section 6 to recover the color of the pixel, and therefore recover whether the URL has been visited by the victim.

To sniff multiple URLs we repeat these steps to produce several pixels for several different URLs, such that the color of each pixel indicates whether its corresponding URL was

visited. We then apply the technique of Section 6 to leak the color of each pixel simultaneously. After we have leaked the color of the pixel, we replace the URL for each link which causes the browser to recalculate the appearance of the link which in turn updates the color of the pixel to reflect whether the new URL has been visited or not.

8.2 Overview

Recall that history-sniffing attacks do not directly reveal victim browsing history, rather the browser is used as an oracle to reveal whether a given URL has been previously visited by the victim. Our attack is no different, we create a link with a specific URL such as *example.com* and apply a style so that the color of the link depends on whether the user has previously visited the URL. We then use our pixel-stealing attack to leak the color of the link which reveals whether that specific URL has been visited. We call this the *simple* method.

In addition to the *simple* method, we use a second method that exploits the behavior of the cache to query over a thousand URLs in parallel. This variation of the technique varies from other history-sniffing attacks. Typically the information revealed is whether a specific URL has been visited or not. Instead, this method uses the browser as an oracle to reveal if *any* of the URLs in a given set have been visited but does not reveal which. We call this the *set query* method.

The advantage of the set query method is that if none of the URLs are visited then $O(1)$ queries are sufficient to reveal this information and if one URL is visited then a binary search can be performed and $O(\log n)$ queries are sufficient to reveal which one of n URLs has been visited. In contrast, the *simple* method would require $O(n)$ queries to reveal the information.

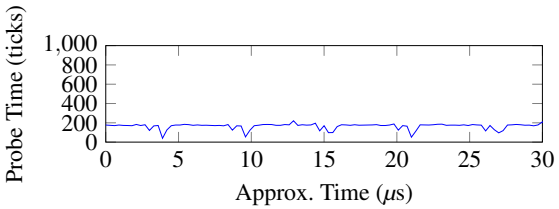
The set query method requires vastly less queries when the number of visited URLs is small. However, as the number of visited URLs increases, the number of required queries using the set query method approaches $O(n \log n)$. For this reason, our attack employs both the *simple* and the set query methods, and switches between the two depending on which is likely to reveal the information with the least queries.

8.3 Set Query

In this section we describe the set query optimisation.

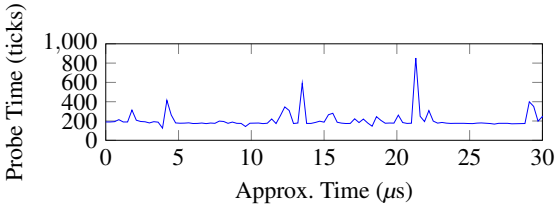
Recall that our pixel-stealing attack crafts an SVG filter with memory accesses that correlate to pixel values and these memory accesses are measured through the use of Prime+Probe. However, because memory accesses can be executed much faster than Prime+Probe the SVG filter can perform several memory accesses that correlate to different pixels between each measurement. The effect is that memory accesses are 'blurred' together as the first access to a given piece of memory brings it to the cache but any additional accesses do not have any effect since the memory is already cached.

Avoiding Blurring. Such behavior is generally undesirable in the pixel-stealing attack since the attack does not know which pixels correspond to which memory accesses. For example, a set of pixels containing exactly one white pixel has the same cache behavior as a set of pixels containing multiple white pixels since they are 'blurred' together. In the pixel-stealing attack we completely remove blurring by stretching the image, duplicating pixels, to such an extent that between any two cache measurements, the majority of memory accesses by the SVG filter correspond to one pixel value.



Behavior of Cache. In contrast, the set query method embraces this behavior to achieve much higher data rates. The high-level idea is that while we do not know the precise pixel values when they are 'blurred' together, we do know if all of the pixels share the same value. For example, when all of the pixels are black, only one location in memory will be accessed, the location of black in the lookup table. Similarly if all pixels are white only the location of the white color in the lookup table will be accessed. However, when some pixels are black and others are white, both the black and white color in the lookup table are accessed.

Set Query. The set query method exploits this property. It encodes unvisited links as black and visited links as white and observes the cache. If it only observes memory accesses to the black color in the lookup table, then it concludes that none of the links have been visited. *Detecting visited Links* As we did in Section 6.1 we construct a packet including the preamble and a payload, this time the *expanded* payload will include only one pixel of each website mapping to one access to the filters table. We also use the same method of payload detection in order to know the location and size of the payload cache activity. An example of the cache activity on what we detected as the payload part of the packet using the set query method can be seen in Figure 12. As can be seen the activity of one table access make the table line stay in the cache until our Prime+Probe measurement evicts it and thus we get at least one sample that it took longer time to retrieve.



Performance Problems. This can be extremely powerful when we expect few URLs in a set to be visited. In the ideal case we observe that none of the URLs have been visited after only $O(1)$ samples. Otherwise we observe that some of the URLs have been visited. We determine which URLs by splitting the set into two and sampling each, if we observe that a subset has at least one visited URL we repeat this process for the subset. In the event that precisely one URL has been visited, we can perform a binary search and find which URL is visited after $O(\log n)$ samples. However, as the number of visited URLs increases the number of samples required approaches $O(n \log n)$ and it can be faster to simply use the *simple* method which always determines which URLs are visited with $O(n)$ samples.

Method Selection. We resolve this problem by dynamically switching between the *simple* and the set query methods depending on whether the website is in the Alexa Top 1,000. If

the website is in the top 1,000 websites, the attack assumes there is a high probability of visiting the URL and uses the *simple* method. Otherwise, the set query method is used.

(a) No Visited Links

(b) Some Visited Links

Figure 12: Access Patterns for the Set-Query Attack.

8.4 Experiment Description

In this section we describe the experiments we perform to characterize the performance of our history-sniffing attack.

Fabricating History. We begin the experiment by fabricating browsing history. We first sample the Alexa Top 50,000 websites, such that popular websites are more likely to be included in the fabricated history.[3] We populate the browser history using Selenium. Our script opens each website and then verifies that the website was correctly loaded into the history by reading the contents of the screen. We use this as the ground truth when evaluating the attack.

History Sniffing. The history-sniffing attack runs over the top 50,000 websites. As described above, we are ignoring the top 1,000 websites and split the remaining 49,000 into 49 sets of 1,000 URLs, queried using the set query method.

8.5 Results

In this section we investigate the effect the number of samples has on the attack runtime and attack accuracy. We record several samples and use majority-voting to select the result. We vary the number of samples and measure the execution time, the recall (proportion of websites that the attack was able to recover from the victim history), and the precision (proportion of websites the attack claimed to be in the victim history that were actually in the victim history). In each experiment we use Selenium to fabricate a browsing history that is then recovered by the attack. Table 3 summarizes the results. As expected the attack accuracy and attack execution time both increase as the number of samples increases.

Fixed Sample Count

Samples	Runtime (s)	Recall	Precision
1	26.27	10%	3%
2	22.75	0%	0%
3	91.21	32%	26%
4	81.62	36%	9%
5	158.26	42%	42%
6	165.71	47%	26%
7	286.61	40%	60%
8	254.34	55%	47%
9	354.77	52%	59%
10	354.62	52%	56%
11	441.97	47%	57%
12	420.86	64%	65%
13	525.45	47%	80%
14	477.48	68%	73%

Table 3: Accuracy of the set query method using different measurements counts and a majority vote. Recall is the proportion of websites that the attack was able to recover from the victim history. Precision is the proportion of websites claimed by the attack to be in the victim history that were actually in the victim history. The time excludes the search for the victim eviction set.

9 Countermeasures

Total Cookie Protection. Total Cookie Protection is a new feature that enforces protection on HTTP cookies by validating that each requested cookie was requested from the domain that set it. Otherwise, the request is blocked. Mozilla enabled total cookie protection worldwide for all users on 14.6.2022. Practically, the update applies for Firefox versions starting from Firefox 101, all versions of Firefox Nightly, and none of the versions of Firefox ESR. Although this feature mitigates all cross-origin pixel stealing attacks, it does not affect the history-sniffing attack because the way links are rendered as visited or not is independent of any cookies. Safari features a countermeasure called Intelligent Tracking Protection that prevents cross-origin pixel stealing attacks in a similar manner.

Constant Time Programming. is a programming style that aims to prevent the use of known-leaky constructs with program secrets [9, 10, 51]. In particular, secrets cannot be used in the condition of control flow statements, as the address of a memory access, or as an argument for a variable time

[3] We include websites in the history with a probability of roughly $\frac{1}{n}$ where n is the position of the website in the Top 50,000.

instruction (e.g. division). These constraints have been shown to be highly successful at preventing side-channel leakage but often cause significant program overhead and it can often be unclear how to adhere to such constraints in high level languages, such as the SVG filter language. For these reasons, we only recommend this solution to browser vendors for any fallback filters that are executed on the CPU.

frame-ancestors. The `frame-ancestors` directive of the `Content-Security-Policy` is a widely supported feature that provides developers the ability to deny loading from within an `iframe` to prevent malicious embedding. While this solution does not address leakage from a webpage, it prevents a malicious webpage from embedding and then leaking content from an otherwise safe victim webpage. Considering that this technique also protects against other attacks, such as Click-Jacking [26, 57], we recommend this for all website operators. For website operators that need to support embedding within arbitrary webpages, consider removing sensitive information when embedding content.

10 Limitations & Future Work

Pixel Stealing. Our attack is limited to environments in which SVG filters are executed on the CPU rather than on the GPU. If the user uses Firefox, then any environment is applicable. If the user uses Chrome, then the user must have an environment on the Software Rendering List [15]. Our attack is limited to Intel CPUs featuring inclusive caches. In principle, the attack could likely be extended to CPUs that feature non-inclusive caches, for example by mounting an attack on coherence directories [71], but we leave such extension to future work.

Text Stealing. Our attack is limited to scenarios in which the attacker is able to guess the font used by the user. In cases where this is not possible, for example if the user changes the font, the user is not vulnerable. Moreover, while the technique extends to languages with very large alphabets, such as Mandarin, in practice as the alphabet size increases the attack becomes less practical especially compared to simply sampling each pixel multiple times.

Cross-Origin Content. Our attack assumes that cross-origin content does not use COOP/COEP, `X-Frame-Options`, or `frame-ancestors`. Unfortunately, the majority of websites still do not use these features and are therefore vulnerable to our attack [6, 11, 18, 24, 30, 37]. In addition, we assume that the browser does not support or does not enable `Total Cookie Protection` or similar countermeasures.

Theoretical Maximum Bitrate. Our pixel stealing attack in its maximum pixels-per-packet configuration has a theoretical maximum throughput of $32 \times 60 = 1920$ bits per second. In practice our attack achieves a maximum speed of 267 bits per second, while our attack is the fastest side-channel based pixel stealing attack it is roughly 14% of the theoretical maximum.

This is in part because the attack cannot spend all of its time recording cache activity, it must also spend some time analysing recorded traces to identify and extract packets. We measure the amount of time the attack spends analysing recorded cache traces and find that it spends roughly half of its time analysing traces.

In principle, we could offload analysing traces to a separate thread in order to allow the attack to record a greater portion of cache activity. We found naive attempts at doing this simply moved the problem from analysis to message passing overhead between threads. We leave a more thorough investigation of efficient methods to implement multi-threaded collection and analysis to future work.

While this shrinks the gap between the theoretical maximum and the actual throughput by half, there is still a significant gap remaining. We find that this is due to the attack missing on average a quarter of the packets – after accounting for the packets that would be missed while analysing. We believe this is due to system noise obscuring the preamble such that it is no longer recognized by our signal processing chain. While we could deploy a more robust signal processing chain that features more advanced signal processing techniques, it is unclear if the additional captured packets would outweigh the packets lost due to the additional analysis time. We leave a more thorough investigation of this trade off to future works.

11 Conclusions

In this work we present a cache-based pixel-stealing primitive that targets Firefox's SVG filtering engine. Despite several efforts to mitigate leakage, we show that pixel stealing is not only possible but is highly practical. To that aim, we develop an asynchronous attack architecture where the attacker measures cache leakage in parallel to SVG filter execution. This allows us to increase the total data rate, overcoming the previous hard limit of 60 pixels per second. It also allows the attack to completely bypass the Cross Origin Resource Sharing (CORS) policies of the browser and avoid its side-channel countermeasures. To the best of our knowledge, our attack is the first attack on SVG filters to leak data faster than the screen refresh rate, and is the first side-channel attack mounted on browsers that shows a generic method for bypassing CORS. The move from the timing side channel to a high-resolution cache side channel significantly expands the attack landscape for pixel-stealing attacks in particular, and for browser-borne privacy attacks in general. Browser vendors should ensure their filter code is resistant to cache side-channel attacks, not just traditional timing attacks.

A Modelling Prime+Scope False-Negatives

In this appendix we analyze Prime+Scope as a primitive to measure cache activity in our pixel stealing attacks. We find that Prime+Scope is significantly more sensitive to some kinds of noise than Prime+Probe. Specifically, Prime+Scope is sensitive to noise which causes a cache miss to be incorrectly classified as a cache hit. Such a situation can leave Prime+Scope in a state where it is unable to detect cache events until the next time the cache state is refreshed by a *prime* operation.

Prime+Scope. The prime operation of Prime+Scope performs two functions on a target cache set. First, similar to Prime+Probe, it clears victim cache lines from the set. Second, it sets a so-called *scope* line as the next line to be evicted from the target set. That is, if some other line needs to be cached in the set, then the scope line is evicted. Prime+Scope abuses this fact to detect victim memory accesses by only measuring access times to the scope line. If a cache hit to the scope line is detected, then the state of the cache remains unchanged and the attack can measure the access time to the scope line again. On the other hand, if a cache miss is detected, then this indicates a victim memory access. In this case, the state of the cache has changed and another prime operation is required to refresh the desired cache state.

However, if a cache miss is incorrectly categorized as a cache hit, then the prime operation will not be performed and Prime+Scope will not be able to detect any future victim memory accesses.

Model Description. To investigate this behavior, we model Prime+Scope as an abstract cache attack that detects cache events without disrupting the cache state. If the attack performs the prime operation, then the cache transitions to the *primed* state. If a victim accesses memory, then the cache transitions to the *dirty* state. The attack can only detect victim memory accesses by detecting the transition from the primed state to the dirty state. If the cache is in the dirty state when a victim memory access occurs, then the attack will not be able to detect it. After each detected victim memory access, or after w samples, the attack performs the prime operation setting the cache back to the primed state.

We limit ourselves to the following outcomes for each measurement: *false negative* or *some other outcome*. We do this so that we can model the attack using a weighted coin with finite trials and ignoring all other outcomes has no effect on measuring the effect of false negatives. We calculate the probability of flipping tails, the probability of a *false negative*, in the following way. Let d be the probability to incorrectly measure a victim memory access and v be the probability that the victim accesses memory on any given sample. The false negative rate is then dv, the probability that both events happen, the victim accesses memory and the attack incorrectly measures it. In the coin flipping model dv is the probability to flip tails.

Analytical Solution. Next we ask *What is the average number of coin flips until we flip tails?* this corresponds to *What is the average number of samples until we have a false negative?*. We answer these questions using a geometric distribution given x the number of trials and dv the probability of a false negative we find n_x the average number of coin flips (samples) until we flip tails (have a false negative). The portion of samples that are observed on average is $\frac{n_x}{x}$.

$$n_x = \sum_{i=1}^{x} (1-dv)^i = \frac{(dv-1)((1-dv)^x - 1)}{dv}$$

.

We extend this solution to attacks that prime the cache every w samples by noting that it is possible to break any run of s samples into $\lfloor \frac{s}{w} \rfloor$ identical runs of length w and one run of length $s \mod w$. We can calculate the average number of samples that can be observed by substituting w and $s \mod w$ into the equation above to yield n_w and $n_{s \mod w}$. These values are then combined to find n_s the average number of observed samples $n_s = \lfloor \frac{s}{w} \rfloor n_w + n_{s \mod w}$.

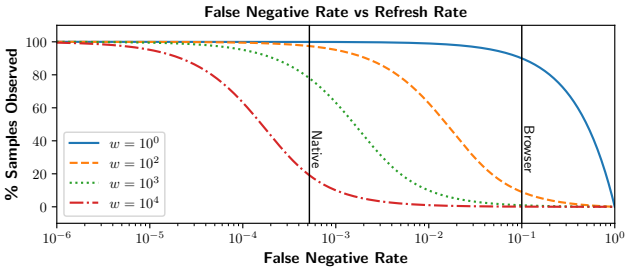

Figure 13: Comparison between False Negative Rate and Refresh Rate. Refresh Rate is defined as w the number of samples until the state of the cache is refreshed by the attack. False Negative Rate is defined as dv the probability that the attack fails to detect a victim memory access. captured.

Results. Figure 13 compares the refresh rate w with the probability of a false negative dv. The vertical lines marked *Native* and *Browser* show measured values for d in the two respective environments. Note that we do not know v and as

such these lines show the maximum expected false negative rate for these environments.

The figure shows that a false negative rate that is $10\times$ larger requires a refresh interval that is $10\times$ smaller to achieve a similar accuracy. The opposite is also true if the false negative rate is $10\times$ smaller than a refresh interval that is $10\times$ larger can achieve a similar accuracy. Importantly, this property holds for d and v independently. If the victim accesses memory $10\times$ more frequently, then the refresh interval must be $10\times$ smaller to achieve a similar accuracy.

Finally, the figure also provides a comparison to attacks that prime the cache for each sample ($w = 1$) such as Prime+Probe. Note that in this case the probability to observe a sample is simply the probability to not observe a false negative ie. The portion of samples observed is $1 - dv$.

B GPU Filters

Sync+Sync: A Covert Channel Built on `fsync` with Storage

Qisheng Jiang Chundong Wang*
School of Information Science and Technology
ShanghaiTech University, Shanghai, China

Abstract

Scientists have built a variety of covert channels for secretive information transmission with CPU cache and main memory. In this paper, we turn to a lower level in the memory hierarchy, i.e., persistent storage. Most programs store intermediate or eventual results in the form of files and some of them call `fsync` to synchronously persist a file with storage device for orderly persistence. Our quantitative study shows that one program would undergo significantly longer response time for `fsync` call if the other program is concurrently calling `fsync`, although they do not share any data. We further find that, concurrent `fsync` calls contend at multiple levels of storage stack due to sharing software structures (e.g., Ext4's journal) and hardware resources (e.g., disk's I/O dispatch queue).

We accordingly build a covert channel named Sync+Sync. Sync+Sync delivers a transmission bandwidth of 20,000 bits per second at an error rate of about 0.40% with an ordinary solid-state drive. Sync+Sync can be conducted in cross-disk partition, cross-file system, cross-container, cross-virtual machine, and even cross-disk drive fashions, without sharing data between programs. Next, we launch side-channel attacks with Sync+Sync and manage to precisely detect operations of a victim database (e.g., insert/update and B-Tree node split). We also leverage Sync+Sync to distinguish applications and websites with high accuracy by detecting and analyzing their `fsync` frequencies and flushed data volumes. These attacks are useful to support further fine-grained information leakage.

1 Introduction

Computer scientists have explored a variety of covert channels to leak information. CPU cache and memory are main building blocks for many existing covert channels, as programs share them when concurrently running. In this paper, we study a lower layer in the memory hierarchy, i.e., persistent storage and file system, to discover a new covert channel.

*C. Wang is the corresponding author (cd_wang@outlook.com). Readers can refer to [38] for the full version of this paper. Sample code of Sync+Sync covert channel is available at https://github.com/toast-lab/Sync-Sync.

The file is the most general form in which programs persistently store their intermediate or eventual execution results. There are different I/O models for programs to consider, including buffered I/O, direct I/O, and synchronous I/O with `fsync` [45, 53, 54, 61, 80]. We focus on synchronous I/O with `fsync` for two reasons. Firstly, many applications employ `fsync` for orderly durability and consistency, such as databases and mail services [57, 61]. Secondly, compared to buffered I/O and direct I/O that write data to the page cache of operating system (OS) and internal device cache of storage device, respectively, `fsync` has a more deterministic and constant timing. In short, when a program calls `fsync` on a particular file, file system (e.g., Ext4) flushes dirty data buffered in memory pages as well as file metadata (e.g., `inode`), for the file through the block I/O (bio) layer to underlying block device, such as a hard disk drive (HDD) or solid-state drive (SSD). To forcefully persist the file, `fsync` carries bio flags (i.e., `REQ_PREFLUSH` and `REQ_FUA`) to instruct storage device to flush the internal cache. Different file systems have different implementations for `fsync`. Take the widely-used Ext4 for example. Ext4 is a journaling file system generally mounted in the default `data=ordered` mode. Upon an `fsync`, it persistently commits file metadata to an on-disk journal after persisting file data [57]. Also, a storage device has mechanisms to guarantee orderly persistence for each `fsync` [13, 80].

With regard to the increasingly large capacity of terabytes or even more per disk drive, multiple programs are likely to run and share the same disk in a local machine or cloud dedicated server [27]. We find that, whenever two programs stay in the same disk partition with the same file system or different disk partitions with different file systems, one of them (*receiver*/*attacker*) would undergo much longer response time to wait for the return of `fsync` if the other program (*sender*/*victim*) is concurrently calling `fsync`. For example, with Ext4 mounted on an ordinary SSD, program X has to wait more than twice the time ($\frac{43.13\mu s}{21.39\mu s}$) for the completion of `fsync` when the other program Y is simultaneously calling `fsync`. Note that X and Y operate with absolutely unrelated files, without any on-disk file or in-memory data being shared.

The significant impact of `fsync` is due to contention at multiple levels in the storage stack. When two programs are running within the same file system, they share structures of both file system and storage device. For example, the aforementioned journal of Ext4 is a globally shared structure Ext4 uses to record changes of files in the unit of transactions. The journal is an on-disk circular buffer and transactions must be sequentially committed to it [42, 57, 71]. By default, Ext4 maintains one running transaction to take in modified metadata blocks for files. An `fsync` targeting a file explicitly commits to the journal the current running transaction where the file's `inode` block is placed. The `fsync` may need to wait for the completion of committing previous transaction and also hinder the progress of subsequent transactions. As a result, Ext4 forcefully serializes `fsync`s and each `fsync` must stall until Ext4 commits the transaction for current one. Although researchers have proposed the fast commit to optimize `fsync` [57, 64], our study shows that the introduction of it does not alleviate the substantial interference between `fsync`s. Worse, concurrent `fsync`s also share and compete on other limited software and hardware resources for storage. The bio and disk drivers need to serialize and write down metadata and data for each `fsync` through queues. Consequently, programs running in different disk partitions mounted with different file systems severely suffer from each other's `fsync`s.

These observations motivate us to propose a new covert channel named Sync+Sync for secretive communication. With Sync+Sync, the sender transmits a bit by calling `fsync` or not while the receiver receives the bit by calling `fsync`. For instance, the receiver gets '1' after undergoing a significantly longer response time and receives '0' otherwise. As mentioned, cross-file system and cross-partition Sync+Sync channels are effectual. We also find that receiver and sender staying in different containers and virtual machines (VM) can efficiently communicate with Sync+Sync in cross-container and -VM fashions. To establish a reliable and efficient covert channel, we only need both sides co-located in the same storage device. In addition, Sync+Sync does not demand sender and receiver to share on-disk or in-memory data. Both just call `fsync`s on absolutely unrelated files in the user space, as `fsync` is an unprivileged system call. Our further exploration shows that cross-disk Sync+Sync is also functional. This enables Sync+Sync to gain high flexibility and viability.

In practical, databases widely employ `fsync`s for durability and consistency. Many applications also use `fsync`s to store data. We hence use Sync+Sync to figure out sensitive information from a victim that calls `fsync` over time. For example, we leverage Sync+Sync to identify the runtime operations, such as insert, update, and B-Tree node split, for SQLite [16]. We also differentiate access patterns between common applications and websites with Sync+Sync. One example is that an attacker can leverage Sync+Sync side channel to distinguish Facebook and Twitter with 100% accuracy by analyzing their I/O traces. Sync+Sync hence provides an effective tool to observe a victim's I/O characteristics. Finally, we perform a keystroke attack with Sync+Sync to explore the sensitivity to user inputs with an accuracy of about 99.2%.

Because of the necessity and prevalence of `fsync`s, attackers calling `fsync`s with Sync+Sync are difficult to be discovered. The defense against Sync+Sync is also not straightforward. The performance cost and interference of `fsync` is a classic issue and it is impossible to avoid `fsync`s regarding critical persistence needs of applications. Also, existing techniques to reduce interference for `fsync` such as the aforementioned fast commit for Ext4 are still vulnerable to Sync+Sync. Though, we have given few suggestions to mitigate the impact of Sync+Sync attacks.

To sum up, we make the following contributions.

- We reveal and build a timing-based covert channel named Sync+Sync at the persistent storage with `fsync` system call. To our best knowledge, Sync+Sync is the first covert channel that makes use of `fsync` at the persistent storage without sharing any data between sender and receiver.
- We quantitatively demonstrate that the covert channel of Sync+Sync achieves a transmission bandwidth of 20,000 bits per second (bps) with about 0.40% error rate. Sync+Sync covert channel effectively works in cross-partition, cross-file system, cross-container, cross-VM, and cross-disk fashions. We also introduce various noise to test and justify the robustness of Sync+Sync.
- We perform side-channel attacks to target real-world application programs that use `fsync`s in their implementations. Sync+Sync is able to classify and identify database operations such as insert, update, and B-Tree node split with SQLite. It further differentiates applications and websites from their behaviors of calling `fsync`s with varying frequencies, timings, and data volumes. A keystroke attack is also practicable. Sync+Sync accomplishes all these attacks with high accuracy.

The rest of this paper is organized as follows. We study related works and background knowledge for side-channel attacks in Section 2. We illustrate why `fsync` makes an effectual covert channel in Section 3. We present the attack model and effectiveness of Sync+Sync in communicating between sender and receiver in Section 4. In Section 5, we detail how Sync+Sync is used to perform concrete attacks for information leakage. We show discussions and defenses for Sync+Sync in Section 6. We conclude the paper in Section 7.

2 Background and Related Work

2.1 Side-Channel Attacks

Side-channel attacks pose a significant threat to computer systems and software security. They exploit information leakage through various channels, including shared hardware

resources, system software and hardware, applications, and other observations. In this section, we discuss notable side-channel attacks that are both general and contention-related.

1) Shared Hardware Resources: Shared hardware resources, such as the CPU cache [33, 43, 46, 56, 59, 86], translation lookaside buffer (TLB) [30], branch predictor [21, 22], persistent memory [47, 78], and GPU [1, 51], are common targets for side-channel attacks. Researchers have developed numerous attacks that exploit contention by leveraging these resources. For instance, Prime+Probe [46, 56], Flush+Reload [86], and Prime+Scope [59] utilize cache sets or specific cache lines shared among running programs. Besides CPU cache contention, side channels utilizing other shared resources, such as the directory for cache coherency, cache bandwidth, and coherency states, have also been employed to leak information [84, 85, 87].

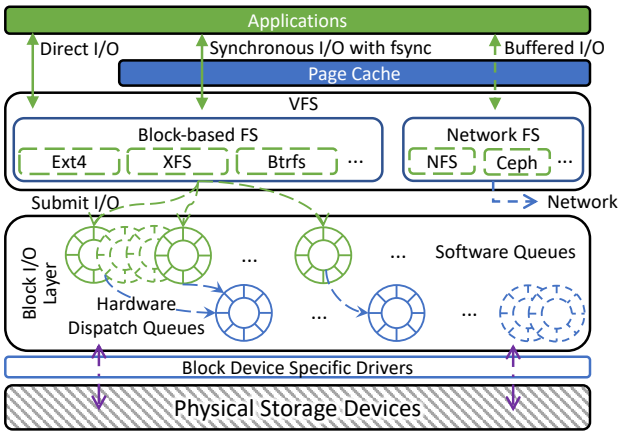
2) System Software and Hardware: Side-channel attacks can also target system software and hardware. Lower-level main memory components, such as the OS's page cache and shared page mapping with and without page faults, have been observed to imply side channels [32, 69, 74, 77, 83]. Page cache [27], file systems [6], page walker [89], just-in-time compilation [60], and database queries [31, 39, 44, 67] have been exploited for side-channel attacks too. For example, Gao et al. [27] demonstrated a covert channel across containers by utilizing `sync` to write back all dirty pages in the OS's page cache. Bacs et al. [6] introduced a timing-based side channel called DupeFS that utilized inline file system deduplication. Their observation is that if data an attacker writes have been deduplicated due to a previous write done by the victim, the attacker would observe a shorter response latency.

3) Applications: Web browsers and other applications are also susceptible to side-channel attacks. Researchers have developed attacks that target web browsers by exploiting various vulnerabilities [41, 70, 81]. For example, Kim et al. [41] utilized the interactions between websites and the disk space quota for different websites to infer visited websites, access history, and login status with a particular website.

4) Other Observations: Side-channel attacks have also been launched in other dimensions, such as power consumption analysis [15, 40, 79]. For example, Chen et al. [15] proposed a side channel based on the idle power management for CPUs. By observing the power consumption pattern of a victim, attackers can analyze and deduce sensitive information.

2.2 I/O Stack in OS

Most applications store data in the form of files with file system and underlying persistent storage device, such as SSD or HDD. Without loss of generality, we follow Linux I/O stack shown in Figure 1 to illustrate how OS handles and stores data into block I/O device. The main layers in Linux's storage stack include virtual file system (VFS), file systems, generic block I/O layer, and drivers for specific storage devices.



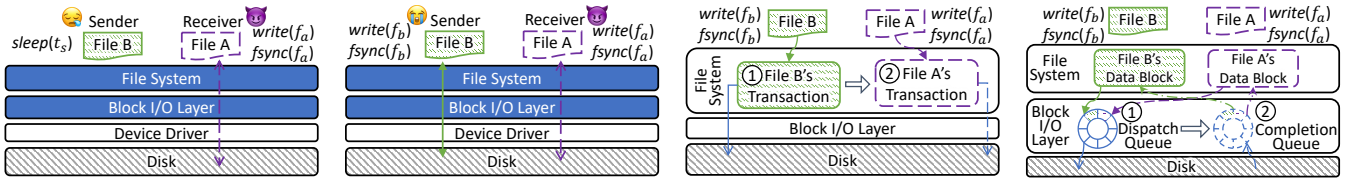


Figure 1: An Overview of Linux I/O Stack.

VFS and File Systems. VFS provides high-level abstractions of file operations for applications to utilize, such as `open`, `close`, `write`, `read`, and `fsync` interfaces. A particular file system (e.g., Ext4 or XFS) handles file operations with underlying storage device. File system is also responsible for organizing and managing storage space and guarantees essential properties like consistency and durability for files. Occasionally, OS may crash due to unexpected events, such as software bugs (e.g., kernel panic) or power outage. File system shall ensure that the modifications onto file metadata and/or data are crash-recoverable in line with a consistency level configured on mounting the file system. Journaling (logging) [42, 57, 71], copy-on-write (CoW) [63], and soft updates [26] are main techniques that file systems adopt to guarantee crash consistency for file metadata (e.g., `inode`) and data. Let us take Ext4 with journaling for illustration because of the wide deployment of it. Ext4 maintains an on-disk journal as a ring buffer. When Ext4 is mounted in the default `data=ordered` mode, only modified file metadata are written to the journal. Ext4 composes a *transaction* in memory with multiple metadata blocks and commits the transaction as a unit to the journal.

Ext4 writes file data and metadata into OS's page cache to handle a write request via buffered I/O. It triggers a write-back of these dirty pages with regard to several conditions. The first one is a periodical flush that occurs every five seconds by default. The second one is that dirty memory pages take more than a proportion of total memory (10% by default) [62]. The third one is an explicit `fsync` received from applications. In the `data=ordered` mode, Ext4 strictly writes file data to on-disk blocks allocated to a file before it commits the file's metadata block to the journal. Later, Ext4 checkpoints metadata blocks in place. The `inode` is the most important metadata for a file and contains the file's length, access time, and access permissions. Once an `inode` block is committed to the journal before a crash happens, Ext4 can recover the file since both file data and metadata have been made durable and retrievable. In addition, Ext4 maintains only one running

(a) `fsync` without Contention. (b) `fsync` with Contention. (c) Contention in File System. (d) Contention in Block I/O Layer.

Figure 2: An Illustration of Contention Caused by `fsync`.

transaction at runtime. Hence all files concurrently share one transaction. The aforementioned three conditions transform a running transaction to be committing transaction and Ext4 generates the next running transaction. It orderly commits consecutive transactions to the journal.

Block I/O Layer. Block I/O (bio) layer connects a particular file system and underlying storage device. As shown in the middle of Figure 1, Linux maintains multiple software queues (`blk-mq`) for bio [8]. Each block device contains per-core software staging queues and hardware dispatch queue(s) depending on the device's hardware and driver. File system submits a bio request to software staging queues and waits for I/O scheduler to dispatch. Then the device driver interacts with device to complete the I/O request. Although multiple software queues mitigate competitions between I/O requests at the bio layer, the limited number of hardware queues installed in a block device restricts the device's capability [80]. Thus, concurrent I/O requests issued to a storage device interfere with each other, especially for devices with one single hardware dispatch queue, such as ordinary HDDs and SSDs.

3 The Contention Caused by `fsync`

OS provides multiple unprivileged system calls, such as `fsync`, `fdatasync`, and `msync`, for user-space programs to synchronously flush data to storage device for orderly persistence. `fdatasync` and `msync` are variants of `fsync`. They either do not flush file metadata or specifically synchronize a memory-mapped file, respectively [53, 58]. On receiving an `fsync` call for a file, file system transfers all modified in-core data and metadata (i.e., dirty pages in OS's page cache) of the file to storage device and issues an ending bio request with two flags (`REQ_PREFLUSH` and `REQ_FUA`) set. Then the file's metadata and data are to be forcefully persisted into storage. File system returns a success or fail to the caller program according to the device's returned signal. A successful `fsync` means that the file's durability is achieved and all changed metadata and data become retrievable even if OS suddenly crashes. Because of the explicit and synchronous persistence of `fsync`, many applications, particularly ones like databases that are highly concerned with data consistency and durability, widely employ `fsync`s in their implementations.

In addition, there is a `sync` system call that flushes *all* dirty pages in the OS's page cache to storage device and applications do not need to specify a file [27]. Therefore, `sync` and `fsync` are like instructions of flushing all cache lines and one particular cache line, i.e., `wbinvd` and `clflush` in the x86 instruction set architecture (ISA), respectively. Since `sync` causes significantly longer time than `fsync` and is much easier to be perceived, we focus on `fsync` in this paper.

3.1 Contention within File System

As shown in Figure 2a and Figure 2b, two programs that call `fsync`s interfere each other. Let us use Ext4 for illustration. When a program calls `fsync` on a particular file, Ext4 flushes data pages and commits the transaction in which the file stays to the journal. As Ext4 maintains only one running transaction and the journal is organized in a ring buffer, the `fsync` may need to wait for the completion of committing previous transaction. Thus, at the Ext4 file system level, the shared global journal and serialization of committing transactions make one `fsync` undergo much longer response latency in the presence of another concurrent `fsync`.

We use the following notations to decompose the `fsync` latency for a certain file A with and without contention.

T^A_{fsync} := total `fsync` latency for the file A.
T^A_{data} := latency to flush file A' dirty data pages (blocks).
T_{flush} := latency to flush device cache with flush command.
$T_{meta}(\cdot)$:= latency to commit a metadata block.
Υ_{prev} := latency to finish previous committing transaction if applicable.

Assuming that the metadata block of file A is the block τ_n in current transaction, and blocks τ_0 to τ_{n-1} are prior elements for τ_n in the transaction, we have

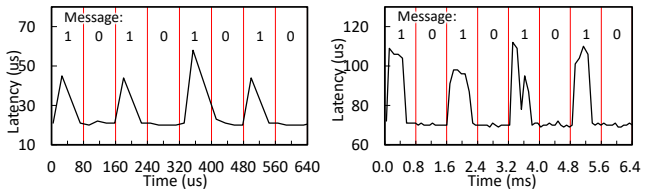
$$\tau_0 \succeq \tau_1 \succeq ... \succeq \tau_{n-1} \succeq \tau_n, \quad (1)$$

in which $\tau_i \succeq \tau_{i+1}$ means τ_i *happens before* τ_{i+1} (i.e., τ_i has entered the transaction earlier than τ_{i+1}). According to Ext4's `fsync` behavior, the `fsync` latency of file A, T^A_{fsync}, is contributed by the following parts,

$$T^A_{fsync} = T^A_{data} + \Sigma^{\tau_n}_{i=\tau_0} T_{meta}(i) + T_{flush} + \Upsilon_{prev}. \quad (2)$$

Table 1: `fsync` Latencies with and without Contention.

Operation for Measurement	Standalone Latency (*ns*)	Standard Deviation	Standard Error	Operation for Competitor	Contention Latency (*ns*)	Standard Deviation	Standard Error
`ftruncate+fsync`	124725.81	5067.66	506.77	`ftruncate+fsync`	186635.09	4035.34	403.53
				`write+fsync`	165046.60	20210.83	2021.08
				`fsync-only`	165989.67	17878.06	1787.81
`write+fsync`	55707.18	21756.38	2175.64	`ftruncate+fsync`	104521.34	24380.61	2438.06
				`write+fsync`	84345.38	27756.34	2775.63
				`fsync-only`	102094.32	26968.84	2696.88
`fsync-only`	21390.42	2478.57	247.86	`ftruncate+fsync`	47428.24	21527.58	2152.76
				`write+fsync`	51112.34	9088.28	908.83
				`fsync-only`	43133.73	2521.81	252.18



Concurrent `fsync`s cause dramatic impact on `fsync` latencies. For example, we write data to file A without any other program issuing `fsync` and measure the latency as T^A_{fsync1}. Next, we do the same `fsync` on file A but, in the meantime, we make the other program perform `fsync` on a different file B. We denote the second latency for flushing file A as T^A_{fsync2}. As shown in Figure 2c, two programs orderly proceed with Ext4's journaling (① $\succeq$ ②). Our quantitative tests confirm that T^A_{fsync2} is much greater than T^A_{fsync1}, which is mainly because Υ_{prev} emerges with the interference of syncing file B.

3.2 Contention within Storage Device

`fsync` demands underlying storage device to synchronously write data down and forcefully drain the device cache for eventual persistence. Because of the limited hardware resources of a storage device, further contention occurs at the device level between concurrent `fsync`s. Each `fsync` is transformed to bio requests that orderly flush data and metadata into disk. When an I/O request is submitted to the bio layer, it mainly goes through three stages [5, 8, 80]. **1) Q2I**: The submitted I/O request is preprocessed (e.g., request split and address remapping) and then inserted or merged into a request queue. **2) I2D**: The I/O request waits in the request queue, staying idle until the I/O scheduler dispatches and puts it in the dispatch queue (see ① in Figure 2d). **3) D2C**: The I/O request is issued to corresponding device driver for the device to handle and the bio layer waits at the completion queue for I/O completion (see ② in Figure 2d).

In each stage, I/O requests issued for different files compete for resources against each other. The contention at the D2C stage is even worse due to the limited capability of storage device, as overwhelming synchronous I/O requests are likely to engage I/O scheduler in spending increasingly longer time in dispatching next ones. As shown in Figure 2d, there is a high likelihood of contention for `fsync`s at the device level.

Each `fsync` generates bio requests with `REQ_PREFLUSH` and `REQ_FUA` flags, which are eventually translated to device flush commands to drain the internal device cache. This makes one more contention point between `fsync`s at the device level. For some file system, such as Ext4 or XFS, `fsync`s that do not follow any change of file data or metadata, e.g., with `write` `ftruncate` operations, still interfere with each other, because Ext4 and XFS always issue the device flush command for `fsync` regardless of a modification received or not onto files.

(a) `fsync`-only. (b) `ftruncate+fsync`.

Figure 3: Raw Traces of Cross-file Sync+Sync Channels within Ext4.

3.3 The Viability of `fsync` Channel

In order to empirically understand `fsync`, we test it with and without contention. We make a program X and measure the `fsync` latency without contention under following settings when program X synchronizes a file with Ext4 mounted on an ordinary SSD (SAMSUNG PM883 SATA SSD).

- The `ftruncate` + `fsync` stands for synchronizing a file after truncating the file to a random size, which triggers the commit of file metadata into Ext4's journal.
- The `write` + `fsync` represents that we call `fsync` on a file after overwriting the file for 1KB with data contents.
- The `fsync`-only means that we measure the latency of `fsync` without any modification of file data or metadata.

We only record the latency of `fsync` while the time of writing data or truncating a file is not counted. Next, we keep the other program Y running with the three settings on a different file co-located in the same disk for contention. We measure latencies of program X under different configurations and repeat each configuration for 100 times.

Table 1 captures the average latency for each configuration after 100 executions. It is evident that the latency of `fsync` that program X observes increases significantly when program Y is simultaneously calling `fsync`. For example, the latency of `fsync`-only jumps by 2.2×, 2.4×, and 2.0× when program Y is concurrently doing `ftruncate` + `fsync`, `write` + `fsync`, and `fsync`-only, respectively. As also shown by Table 1, in spite of dramatic increase for latencies, the standard deviation and standard error generally fluctuate in an acceptable and observable range. Among three settings, `write` + `fsync` needs to flush file data to disk, which causes more contention than both `ftruncate` + `fsync` that flushes metadata only and `fsync`-only that aims to retain a file's durability. These three settings are commonly I/O behaviors found in today's applications. Assuming that we make program X probe by calling and measuring `fsync` latency, it can detect whether applications like program Y are calling `fsync`s due to the substantial difference with and without contention. Figure 3 shows two raw traces of varying `fsync` latencies when 1) both programs X and Y are doing with `fsync`-only and 2) both

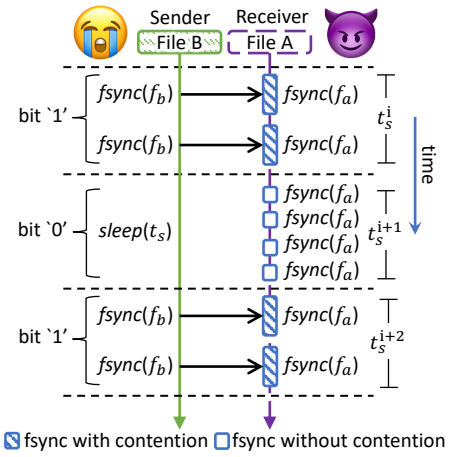


Figure 4: An Illustrative Example of '1' and '0' Transmission Protocol between Sender and Receiver with Sync+Sync.

are doing with `ftruncate` + `fsync`, respectively. It is evident that the latency sensed by program X largely fluctuates due to the impact of concurrent `fsync`s, thereby enabling a clear and reliable channel to transmit data. In all, these qualitative and quantitative observations indicate the viability of building a covert channel with `fsync` at the persistent storage.

4 Sync+Sync Covert Channel

Modern OS utilizes file systems and access control mechanisms to isolate files for users and store data with secrecy and privacy. Cloud vendors enforce further isolation of files for multi-tenants to secretly share a physical machine between containers and VMs. In this section, we focus on leveraging `fsync`s between two entities co-located in a storage device for secretive and reliable communication, regardless of whether they are running in the same OS, different containers, or VMs. As both sides call `fsync` to interact through file system and storage device, we name our new covert channel 'Sync+Sync'. Sync+Sync is timing-based since it transmits information by measuring response time at runtime.

4.1 Attack Model

We assume that there are two co-located entities in a Sync+Sync attack. The receiver (attacker or sink) and the sender (victim or source) concurrently run as user-space programs. Both sides use files to store data. We categorize Sync+Sync attack cases into three classes by their isolation environments. **1) Cross-file**: Sender and receiver access their respective files with exclusive access permissions. These files share the same storage device, residing either in the same disk partition mounted with the same file system (e.g., Ext4) or different partitions mounted with the same or different file systems (e.g., Ext4 and XFS). **2) Cross-container**: Sender and receiver stay in two containers sharing the same device for their overlay file systems. This is common for hosting multiple containers in a physical machine. For example, by default the Docker [18] stores all containers' overlay data in one directory `/var/lib/docker/overlay2/`. Sender and receiver can also use different directories with different file systems mounted on different partitions. **3) Cross-VM**: Sender and receiver are running in their respective VMs with independent disk images. Again, their image files need to be co-located in one storage device but can stay in different partitions.

With any channel, both sender and receiver can update file size via `ftruncate` + `fsync`, modify their own files via `write` + `fsync`, or keep file synchronized to storage device via `fsync`-only (see Section 3.3). However, by referring to Table 1 and Figure 3, we mainly leverage `fsync`-only to build Sync+Sync channel, because it incurs the shortest latency and implies the highest bandwidth for information transmission.

4.2 Communication Design

To transmit data via any aforementioned channel, the sender conveys bits by calling `fsync`s on a file or not. The receiver continually synchronizes the other file via `fsync` and measures the latency of `fsync` to decide the values of received bits. Figure 4 shows how sender and receiver transmit a bit with the protocol provided by Sync+Sync covert channel. Their pseudocode is shown in Appendix C of the full version [38].

The sender transmits bits via some purposeful file operations. As shown by the left part of Figure 4, in order to transmit a bit '1', the sender synchronizes a file in order to continuously submit I/O requests to disk for a predefined time period t_s named *symbol duration*. Otherwise, the sender sleeps for t_s to transmit a bit '0'. A stream of continuously transmitted bits form a meaningful data frame that is composed of two parts, i.e., header and payload. The header consists of a fixed number of bits with a distinct pattern, used to accurately distinguish the start (boundary) of a frame. The payload is a bit stream with a fixed length and stores actual data that is useful for the receiver.

The receiver receives a bit by measuring `fsync` latencies to detect whether contention happens or not. Before transmission, the sender constantly samples the uninterrupted `fsync` latency to profile a threshold for reference. In a symbol duration during transmission, the receiver checks if `fsync` latency is greater than the profiled threshold. If so, the bit is '1'; otherwise, the bit is '0'. The receiver tracks whether a frame of bits is received by comparing against the header pattern for calibration and synchronization. In case of a match, the receiver extracts payload from the frame.

The threshold to decide '1' or '0' is set empirically, depending on underlying machine's configurations and runtime environmental factors. For example, file system and storage device are being used by many programs which may cause noise with file operations, especially `fsync`s, to affect Sync+Sync. We

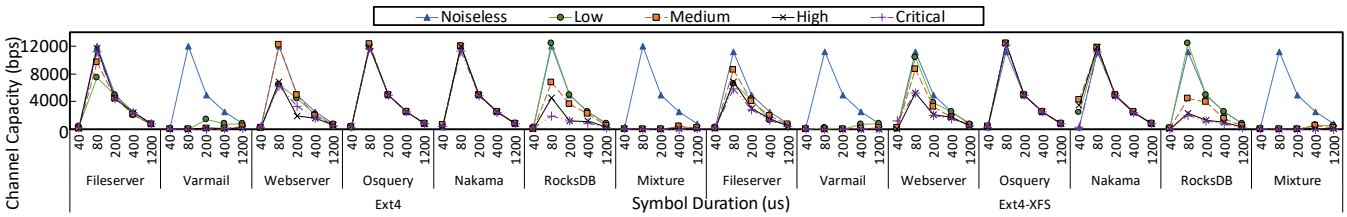

Figure 5: The Capacity of Cross-file Sync+Sync Channel (with and without Noise from Multiple Workloads).

Table 2: Noisy Workloads with Different Settings.

Degree	Filebench (Number of threads)			Osquery	Nakama	RocksDB
	Fileserver	Varmail	Webserver			
Low	1	1	1	Every 60s	0.1 QPS	100:0
Medium	2	2	2	Every 30s	1 QPS	80:20
High	4	4	4	Every 10s	10 QPS	50:50
Critical	8	8	8	Every 1s	100 QPS	20:80

take into account such noise and select a proper threshold in a heuristic approach [15]. In short, we firstly smooth the samples within a symbol duration based on their average. Then, we jointly consider polished latencies from numerous continuous symbol durations to determine the current threshold and periodically update it.

4.3 Performance Evaluation

4.3.1 Evaluation Setup

In order to thoroughly evaluate Sync+Sync channel, we test it on a server with Intel Xeon Gold 6342 CPU and 960GB SAMSUNG PM883 SATA SSD. The OS is Ubuntu 21.04 with kernel 5.15.0-48-generic while the compiler is GCC/G++ 10.3.0. We divide SSD space into few partitions and make different file systems on them, including Ext4, XFS, and Btrfs. We use Docker 20.10.14 to manage containers for which the base image is Ubuntu 21.04. As for cross-VM testing, the guest OS is Ubuntu 21.04 with Ext4 as file system, running with QEMU and Linux Kernel-based Virtual Machine (KVM) version 4.2.1. VM disk images are set in the RAW format with virtio enabled. We use the default writeback cache policy. Each VM is with 8GB DRAM and two vCPUs. Sender and receiver programs are respectively running in two isolated containers (resp. VMs). In all tests, both of them are normal user-space programs and access ordinary files without any privileged permission.

We evaluate three covert channel types, i.e., cross-file, cross-container, and cross-VM, built on different file systems, such as Ext4, XFS, and Btrfs. Due to space limitation, we place a part of results and raw traces in Appendix A of [38]. In the following contexts, the sender and receiver programs only synchronize their respective files using `fsync`, without modifying the files in the cross-file and -container channels. In the case of the cross-VM channel, both the sender and receiver modify the file data before invoking `fsync` on their files.

Table 3: Raw Bit Error Rate for Cross-file Covert Channel (Ext4, with and without Noise from Fileserver and Varmail).

Symbol	Noiseless		Fileserver, 8 Threads		Varmail, 8 Threads	
Duration (μs)	1⟶0	0⟶1	1⟶0	0⟶1	1⟶0	0⟶1
40	43.24%	43.24%	44.80%	44.81%	74.12%	74.12%
50	0.40%	0.43%	1.84%	1.87%	67.38%	67.34%
80	0.38%	0.38%	1.40%	1.39%	66.39%	66.37%
200	0.03%	0.03%	1.53%	1.43%	47.63%	47.62%
400	0.00%	0.00%	0.34%	0.34%	41.01%	41.02%
1200	0.00%	0.00%	0.89%	0.89%	37.73%	37.74%

Besides the noiseless environment, we employ workloads running alongside Sync+Sync to quantitatively assess the robustness of it. As shown in Table 2, we configure each workload with different settings to cause environmental noise at varying degrees. We adopt 1) Filebench [24] to generate Fileserver, Varmail, and Webserver workloads with varying threads, 2) an audit server Osquery [73] with different auditing frequencies, 3) Tsung [52] that simulates 1000 users concurrently sending various requests to a multi-player gaming server Nakama [36] with different Queries Per Second (QPS), and 4) YCSB [17] that issues requests to a prevalent NoSQL database RocksDB [50] with varying Read/Write ratios. Furthermore, we conduct experiments by running all foregoing applications simultaneously (denoted as Mixture).

4.3.2 Channel Capacity

We use the channel capacity to measure the bandwidth of Sync+Sync in bps, which is a theoretical upper bound for Sync+Sync's communication capability. We regard the Sync+Sync channel as a binary symmetric channel for measurement, following the methodology in [28]. The capacity of Sync+Sync (denoted as C) is determined as follows.

$$C = B \times \left[1 - p\log_2(\frac{1}{p}) - (1-p)\log_2(\frac{1}{1-p})\right] \quad (3)$$

where $B = \frac{1}{t_s}$ is the bandwidth and p is the symbol error rate (bit error rate) [68] [1]. We empirically estimate the bit error rate of Sync+Sync channel every ten frames transmitted, each of which carries 8,000 bits. We also vary the symbol duration t_s for each one of three aforementioned covert channels.

[1] Sometimes the error rate might be greater 50%, and we still regard channel capacity as 0, since channel with high bit error rate cannot transmit data correctly in our cases.

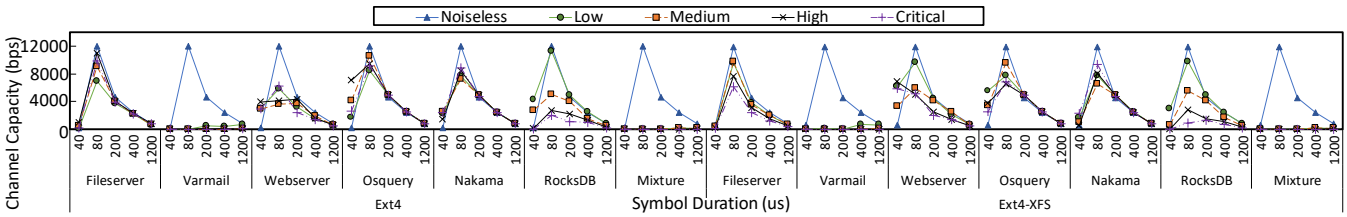

Figure 6: The Capacity of Cross-container Sync+Sync Channel (with and without Noise from Multiple Workloads).

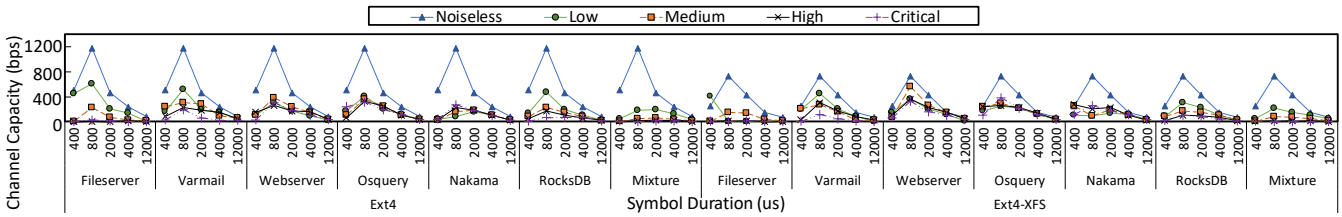

Figure 7: The Capacity of Cross-VM Sync+Sync Channel (with and without Noise from Multiple Workloads).

Intra-partition without noise. Figure 5, Figure 6, and Figure 7 show the capacities of all cross-file, -container, and -VM channels, respectively. To conduct a comprehensive study, we have performed experiments where the sender and receiver are located within the same partition (represented as Ext4 under the X-axis) and different partitions (represented as Ext4-XFS under the X-axis) mounted with different file systems. The cross-file channel, operating within one Ext4 partition, achieves a transmission rate of one bit every 50μs with an error rate of approximately 0.40% as shown in Table 3. Therefore, Sync+Sync achieves 20,000bps bandwidth without noise. The capacity of the cross-container channel, with two containers co-located in a disk partition with Ext4, is similar to that of the cross-file channel. This can be attributed to the weak isolation provided by the container and overlay file system that heavily rely on the underlying file system. Meanwhile, the capacity of the cross-VM channel is lower, with a maximum bandwidth of about 1200bps. The reason is that the sender and receiver modify their files before invoking `fsync` in the guest OS to trigger stable contention at the host OS and underlying storage device.

Inter-partition without noise. In all three channels, the receiver is placed in a partition with Ext4, while the sender operates with XFS or Btrfs mounted on another partition of the same SSD. The channels using Ext4 and Btrfs (see Appendix A of [38]) cannot be established with an acceptable bit error rate ($\leq$ 40%). This limitation arises because Btrfs does not flush the device cache for `fsync` unless there is concrete data modification to the files. In contrast, Ext4 and XFS flush the cache on every `fsync`, regardless of file modifications. Thus, the capacities of cross-file and -container covert channels based on inter-partition with Ext4-XFS exhibit similar observations with Ext4 in one partition. However, due to the influence of the VM hypervisor, the cross-container channel gains a much higher transmission frequency (every 80μs) compared to the cross-VM channel (every 12ms). Additionally, the inter-partition cross-VM covert channel experiences higher error rates and lower capacities than the intra-partition channel, mainly due to the impact of partitions. For instance, the capacity with an 800μs symbol duration of the inter-partition channel is 38.1% lower than that of the intra-partition channel.

4.3.3 Impact of Noisy Workloads

Next, we investigate the influence of different workloads on the Sync+Sync channel in the presence of noise. Our evaluation reveals that most of the workloads introduce noise to all types of Sync+Sync channels with varying degrees, thereby resulting in reduced capacities. For example, the bit error rate shown in Table 3 for cross-file covert channel with 50μs duration increases to about 1.84% and 67.34% when running Fileserver and Varmail with 8 threads, respectively. As shown in Figure 5, Varmail and RocksDB have the most significant impact on Sync+Sync. This is because both of them frequently invoke `fsync`s to ensure the durability of data, especially for Varmail. Fileserver and Webserver also affect the channel capacity, even without `fsync`s, particularly with shorter symbol durations. This is due to their consistent file operations (e.g., create and delete) and data writes to multiple files, leading to the accumulation of dirty pages in the OS's page cache and triggering page write-back. Conversely, Osquery and Nakama have limited impact on Sync+Sync, indicating that Sync+Sync is not highly sensitive to auditing activities and network traffic. The capacity under mixed applications (Mixture) is similar to that under Varmail, because Varmail frequently calls `fsync`s. In order to mitigate the impact of such noise, we can prolong the channel's symbol duration and adopt `fsync` with modifying file data to build a more reliable channel. As indicated by Table 3, a longer

symbol duration dramatically decreases the error rate. The results with cross-container channel are similar to those with the cross-file channel (see Figure 6).

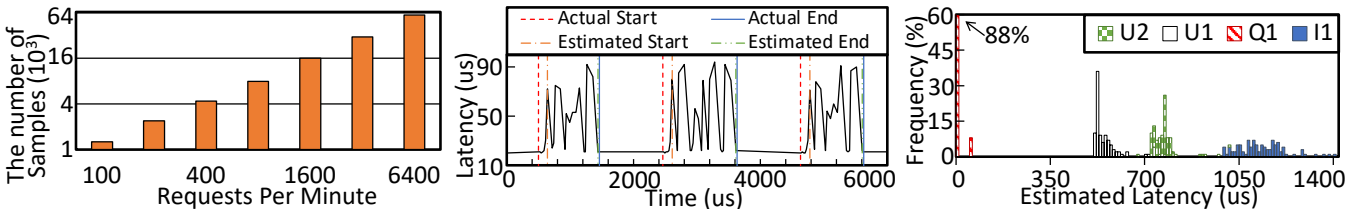
As illustrated by Figure 7, the cross-VM covert channel is more susceptible to noise compared to the cross-file and -container channels, even for workloads without `fsync`s. For example, Fileserver introduces severer noise than Varmail. The bit error rate for the cross-VM channel with a symbol duration of 12ms increases from around 0.07% to an average of 33.0% and 16.4% when running Fileserver and Varmail with 8 threads, respectively. We run Fileserver and Varmail in the same disk image under the same guest OS with the sender. Updating multiple files for Fileserver in the guest OS is actually updating the disk image in the host OS, and updated data might not reach the real disk unless calling `fsync`. Once the sender calls `fsync` in the guest OS, the host OS would synchronize the entire disk image file. Therefore, dirty data written by Fileserver are flushed alongside into disk with sender's `fsync`, which causes more difficulties with longer `fsync` latency for receiver to detect due to a larger volume of dirty data. As to Varmail that frequently calls `fsync` to flush every modified email file, each `fsync` is converted to synchronizing the disk image and does not aggregate a lot of dirty data like Fileserver when the sender calls `fsync`s. As a result, the impact of noise caused by Varmail on bit error rate for Sync+Sync is evidently lower than that of Fileserver.

5 Side-Channel Attacks with Sync+Sync

5.1 Database Operations Speculation

Attack Model. In order to perform database operating speculation, we consider a scenario where the victim is a database that stores and accesses data using a disk. The attacker, who is located on the same disk with the victim, operates as an independent process within the same OS, separate container, or VM. Particularly, the attacker does not have permission to access the victim's in-memory data or on-disk files. To infect the victim's environment, the attacker can exploit vulnerabilities via image pollution or social engineering. Due to the compactness of the attacker's code, it is possible for the attacker to inject the victim gadget into useful applications without perception. The attacker has full control over the attacker's program, container, or VM. She/he can manipulate containers or VMs to share the same disk with the victim, similar to co-located allocation [34, 75]. Additionally, the attacker can control multiple containers or VMs located on different disks and passively wait for a victim to use those disks. Once both parties share a device, the attacker initiates spying and stealing of sensitive information from the victim using the Sync+Sync channel.

Attack Design. On a disk, we set up isolated files in which a group of them belong to the victim database for data storage while and one file is used by the attacker to detect `fsync` latencies. We utilize SQLite as the victim database, which is widely used and has been exploited for security purposes [54, 67, 78]. We configure SQLite in the `journal_mode=DELETE` mode and perform various database operations to simulate requests received by the victim. Simultaneously, the attacker invokes `fsync` with three objectives. Firstly, the attacker aims to monitor the rate of insert and update requests in the victim database (Section 5.1.1). Secondly, the attacker aims to detect internal structural changes in the victim database, such as a node split in the B-Tree used for indexing (Section 5.1.2). Thirdly, the attacker aims to identify and resemble a sequence of database operations executed by the victim, thereby extracting more fine-grained information (Section 5.1.3).



5.1.1 Insert/Update Ratio over Time

Insert and update requests are tightly correlated to the `fsync` latency, because when handling such requests, databases such as SQLite utilize redo or undo logging with `fsync`s to ensure consistency and durability. We adopt Mobibench [20, 37] to repeatedly insert or update primary keys and corresponding data into the database, with the idle period adjusted for each insert to demonstrate different request frequencies. By leveraging the Sync+Sync side channel, the attacker detects longer `fsync` latencies when the victim database synchronizes files. The attacker counts latency samples above a threshold (50μs in our evaluation) that has been determined through profiling. The attacker accordingly estimates the victim's insert and update activities and calculates the rate of insert/update over time. We repeat this attack for ten times, each in 30 minutes.

Figure 8a depicts the relation between the number of insert requests per minute for SQLite and the number of samples above the threshold, using a logarithmic scale for the Y-axis. The number of samples above the threshold is approximately ten times higher than the number of requests per minute. The reason for such an order of magnitude difference is twofold. Firstly, SQLite requires multiple `fsync`s to flush log and data files in order to commit a single transaction. Secondly, the attacker's `fsync` latency is shorter than that of the victim because the victim flushes both data and metadata for database files to complete a database transaction. The attacker needs to call `fsync` for multiple times to cover the entire course of a database transaction. Consequently, the attacker is able to identify when the victim handles an insert or update request and thus calculate the rate of such requests over time. In a long run, the attacker can figure out the victim's workload characteristics, such as the insert/update frequency, modified data per request, and peak/non-peak periods in a day.

5.1.2 B-Tree Split Detection

SQLite utilizes an on-disk B-Tree for indexing keys. Each B-Tree node has a limited size. A fully filled node triggers a split that results in two nodes. SQLite calls `fsync`s to persist

(a) SQLite Insert Requests Estimation. (b) Raw Trace for Insert with or without Split. (c) Estimated Latency Distribution of SQL.

Figure 8: An Illustration of Sync+Sync Side Channel for Databases.

both new nodes to ensure consistency and durability. Under a relatively consistent workload, a node split leads to a longer committing latency for an insert into the B-Tree compared to inserts without node splits. Hence, the attacker can detect such structural changes in the SQLite database via Sync+Sync side channel. For example, the raw trace in Figure 8b demonstrates three different insert requests. The latency of middle one experiences longer than latencies of others due to the occurrence of a node split, while the other two have not involved two nodes to be persisted via `fsync`s. Additionally, researchers have mentioned that sensitive data stored in a B-Tree-based database could be leaked by exploiting node splits [25].

The attacker does not have knowledge of when an insert request starts or ends but can only determine when the corresponding `fsync` latencies spike and return to normal. Consequently, the attacker has introduced an estimated committing latency to speculate whether an insert with a node split has occurred. The attacker considers the first sample time with an `fsync` latency greater than a threshold as the estimated start timestamp for an insert request. The attacker detects the last sample that exceeds the threshold and estimates an end time, which is calculated by adding the measured `fsync` latency to the timestamp of the last sample. Note that the idle period before the next insert request is expected to be sufficient for the attacker to determine if a detected `fsync` belongs to the current insert or not. Furthermore, recent studies have shown that typical workloads in commercial environments are dominated by inserting small values (less than 1KB or 100B), which are unlikely to flush more than a 4KB block [10, 82]. Therefore, the impact of a B-Tree node split on two 4KB blocks with `fsync`s is realistically substantial.

The estimated start time and end time for an insert are exemplified in Figure 8b. The estimated committing latency for the victim database exhibits an identical observation to the actual committing latency. We insert 400 different primary keys and data into SQLite and cause 49 node splits in all. We set the threshold at 70μs to estimate the latency for each insert, and empirically classify an insert with an estimated committing latency greater than 1000μs as one causing a split. The attacker successfully detects 43 node splits, achieving an accuracy of 87.8%, and the F1-score is 0.84. By leveraging more sophisticated algorithms such as learning-based methods, the attacker may have even higher capability to differentiate inserts with node splits from normal inserts. This is yet not the focus of building Sync+Sync side channel in this paper.

5.1.3 Database Operation Leakage

By utilizing `fsync` latency as a probe, we can further categorize various database operations to discover and learn about the operations executed by the victim. In this study, we create database tables from the NPPES dataset [11, 78] containing two tables. One table is a `basic` that records users' basic information (e.g., their full names), using the National Provider Identifiers (NPI) as primary keys. The other table named `location` stores users' addresses, including city and state, with the NPI serving as a foreign key for the `basic` table.

Listing 1 provides examples of four database operations that the attacker can classify using the Sync+Sync side channel. `I1` represents the insertion of 1000 records, while `Q1` performs queries to count records. `U1` updates a single record in the `basic` table. Comparatively, `U2` updates 1000 records in the `location` table. We repeat the U1 and U2 operations for 100 times and estimate their `fsync` latencies using a similar way as presented in Section 5.1.2, with a threshold of 50μs based on profiling. Figure 8c shows the distribution of estimated latencies for each database operation. For the `Q1` operations, the majority of estimated latencies are close to 0 because queries do not involve `fsync` to flush data. As to update operations (`U1` and `U2`), the different numbers of records being modified result in varying data volumes for `fsync`s, leading to different distributions of estimated latencies. Whereas, the insert operations (`I1`) exhibit latencies that are consistently higher than other operations, even though `I1` and `U2` involve the same number of records. The reason is that, in contrast to an update that modifies one node only, some insert may cause node split that leads to longer latency.

Taking estimated latency for each operation as its feature, we employ the classic k-nearest neighbors (k-NN) algorithm [4] for classification. We calculate the Euclidean distances between a newly detected operation and each of known operations. Then, we assign a type to the new operation based on the majority of the k nearest neighbors. We randomly choose 70% samples for each operation as training set and the rest 30% samples are used as the testing set

to evaluate the k-NN algorithm. In the end, 115 out of 120 operations are correctly classified, resulting in an accuracy of 95.8% for the Sync+Sync side channel. The F1-scores for `I1`, `Q1`, `U1`, and `U2` are 0.98, 0.98, 0.93, and 0.95, respectively.

```
-- I1: Insert 1000 records in 'basic' table
INSERT INTO basic values (...), (...);
-- Q1: Count records in 'location' table
SELECT COUNT(*) FROM location WHERE lower(city)=
  'Anaheim';
-- U1: Update 1 record in 'basic' table
UPDATE basic SET name = 'new name' WHERE npi ==
  20230809;
-- U2: Update 1000 records in 'location' table
UPDATE location SET city = 'new city' WHERE npi
  == 20230809;
```

Listing 1: Classified SQL examples.

5.1.4 Comparison

The way Sync+Sync leaks information is not only effectual and portable, but also difficult to be perceived. For instance, Chen et al. [15] proposed a side channel based on idle power management for CPUs, allowing them to spy on a victim's network traffic, such as HTTP traffic load measured in requests per minute. However, the information they obtain is more coarse-grained compared to what is achieved with Sync+Sync that provides a detailed trace of the victim database's operations (insert/query/update). Moreover, Sync+Sync is built on `fsync`, which is commonly and frequently used by applications on various platforms. By contrast, the side channel presented by Chen et al. [15] relies on the prerequisite condition that CPU enters an energy-saving mode and switches back. The ND2DB attack [25] detects B-Tree node splits by measuring the response time of an insert request. However, the response time can be easily influenced by user software overhead and network latency. In our empirical study, using a threshold of 1300μs, the ND2DB attack detects only 75.5% of node splits with an F1-score of 0.65. Whereas Sync+Sync detects 87.8% of node splits with an F1-score of 0.84. The NVLeak attack [78] can figure out the database operations like Sync+Sync and achieves an 84% classification accuracy, which is yet much lower than the 95.8% accuracy of Sync+Sync. Furthermore, the NVLeak attack only works with Optane memory that Intel has winded down [3, 90]. Additionally, Sync+Sync can distinguish different database operations and may jointly make use of other techniques to inflict more fine-grained leakage with the victim database [31, 39, 44, 67]. In all, the prevalence of `fsync` entitles high efficacy, portability, and unnoticeability to Sync+Sync.

5.2 Application Information Leakage

Attack Model. We assume a scenario where the victim is an application (e.g., Linux/Android application or web browser [65, 66]) that accesses files in a disk which the attacker shares with the victim when running in the other process, container, or VM. Again the attacker neither has access permission with the victim's files nor shares data with the victim. To leak information from the application, the attacker synchronizes her/his file to record `fsync` latencies every 40μs based on profiling and spies on the victim's I/O behaviors.

Table 4: Classification Accuracy of Sync+Sync for Websites.

Website	Average # `fsync`	Accuracy	F1-score	Website	Average # `fsync`	Accuracy	F1-score
360.cn	10.6	3.3%	0.04	imdb.com	16.1	13.3%	0.19
adobe.com	11.5	0.0%	0.00	jd.com	14.9	56.7%	0.65
amazon.com	16.2	13.3%	0.08	live.com	10.6	13.3%	0.14
apple.com	11.5	16.7%	0.17	microsoft.com	12.1	3.3%	0.04
baidu.com	14.4	6.7%	0.03	**qq.com**	**264.6**	**100.0%**	**1.00**
bing.com	15.0	6.7%	0.08	**sina.com.cn**	**40.8**	**96.7%**	**0.98**
booking.com	15.9	0.0%	0.00	sohu.com	14.4	46.7%	0.44
cnn.com	15.2	6.7%	0.10	taobao.com	10.6	23.3%	0.16
detik.com	10.1	10.0%	0.13	tmall.com	11.4	3.3%	0.03
github.com	12.1	13.3%	0.18	yahoo.co.jp	11.4	6.7%	0.06

Attack Design. To perform information leakage for applications, we utilize Mobibench [20] to replay I/O traces for victim applications. Each I/O trace consists of a series of I/O-related system calls such as `read`, `write`, and `fsync`. We execute an I/O trace to simulate the corresponding application's behaviors while the attacker is simultaneously calling `fsync`s. In practical, different applications exhibit varying calling patterns of `fsync`s in terms of frequency and data volume to be flushed. These variations result in different `fsync` latencies sensed by the attacker. Sync+Sync is thus able to distinguish different applications. It also manages to fingerprint websites with web browsers under certain conditions.

Application Fingerprinting. We firstly run I/O traces of Twitter and Facebook Android applications, provided by Mobibench, as two victims separately for 100 times. We record and show the attacker's `fsync` latency distribution in Figure 9. It is evident that Twitter and Facebook exhibit distinctly different curves in each of their 100 runs. For instance, the number of samples between 50μs to 100μs for Facebook is significantly higher than that of Twitter. To accurately classify I/O traces for different applications, we utilize the latency distribution and Euclidean distances as features and metrics, respectively, for the k-NN algorithm. Similar to the k-NN mentioned in Section 5.1.3, we consider the majority of the k nearest neighbors for an application trace as the application's type. We randomly divide each application trace into 70% and 30% samples for training and testing, respectively. In the evaluation, we have 60 test cases (100 $\times$ 30% for each application), and Sync+Sync correctly categorizes all of them.

Website Fingerprinting. Next, to check if Sync+Sync can distinguish different websites based on their `fsync` usage patterns, we create an evaluation dataset as follows. Firstly, we randomly select 20 websites from the Alexa Top 100 websites. Then, with the Chrome web browser (Version 113 with default settings) [29] running on a computer installed with Ubuntu 22.04, we visit the front page of each website as the victim. Simultaneously, we capture the I/O trace of each

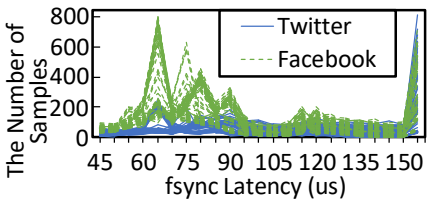


Figure 9: `fsync` Latency Distribution for I/O Traces of Twitter and Facebook in Application Fingerprinting.

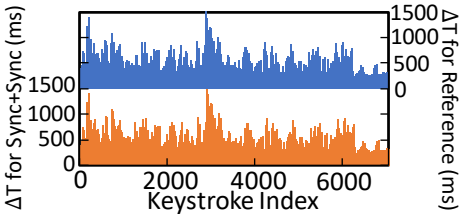

Figure 10: The Inter-keystroke Timings (ΔT) from the Reference Typer (Top, Right Y axis) and the Sync+Sync (Bottom, Left Y axis).

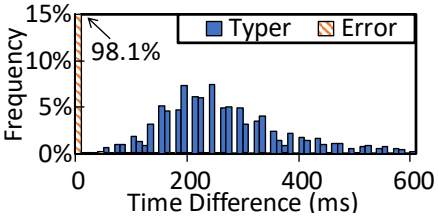

Figure 11: The Time Distribution of the Reference Typers Compared to the Error Distribution of the Sync+Sync.

website using strace [14] for 5 seconds, which is sufficient for loading a webpage. We repeat this procedure for 100 times with each website and overall collect 2000 I/O traces.

With these I/O traces, we record the attacker's `fsync` latency distribution when replaying each I/O trace and classify them using the k-NN algorithm with the same setup as application fingerprinting. Table 4 shows the classification accuracy and F1-score for each website, as well as the average number of `fsync`s invoked by each website. Most websites do not commonly use `fsync` and hence have similar `fsync` usage patterns. As a result, it is challenging for Sync+Sync to distinguish them from each other. However, some websites, such as qq.com and sina.com.cn, invoke `fsync` more frequently and exhibit different I/O behaviors. Therefore, Sync+Sync recognizes these websites at high accuracies of, for example, 100% and 96.7% for qq.com and sina.com.cn, respectively. Our analysis shows that, to persistently store data, both websites use the Indexed Database [2] that most of the browsers provides [7, 23, 49, 55]. As mentioned, database relies on `fsync` to ensure data consistency and durability. This explains why Sync+Sync successfully fingerprints websites that frequently synchronizes data with the Indexed Database.

Comparison. Distinguishing (fingerprinting) applications and websites enables an attacker to infer which application a victim is using or what website a browser is displaying, causing serious breach of user privacy [9, 35, 41, 76]. Sync+Sync shares similarities with the attack proposed by Kim et al. [41], as they both exploit storage to fingerprint victims. However, they differ in the explored observations. Kim et al. [41] use the disk space quota demanded by a web browser for each website's temporary storage, while Sync+Sync is based on different `fsync` usage patterns. Website fingerprinting attack conducted by Kim et al. [41] achieves a 97.3% inference accuracy, whereas Sync+Sync's accuracy varies depending on the characteristics of websites. Additionally, the side channel studied by Kim et al. [41] only applies to browsers, while Sync+Sync is widely applicable to applications that call `fsync`.

5.3 Keystroke Attack

Attack Model. We assume that the victim is entering user input either locally or remotely through a network connection. Each keystroke is then transmitted to a service program, which stores the input on an SSD similar to the attack studied by Liu et al. [47]. For every keystroke typed by the victim, the service program auto-commits the user input by storing it in a file with an `fsync`, in order to persistently track the user's latest input. The attacker and the service program are co-located to be sharing the same disk. However, due to OS-level isolation, any direct communication between them is not possible. Also the attacker has no access permission to the victim's and the service program's files or share any data with the latter two.

Attack Design. To conduct a keystroke attack, we utilize the Keystroke100 dataset [48]. It contains inter-keystroke latencies from 100 different typers who entered the same eight-letter password, 'try4-mbs', ten times each, resulting in a total of 7,000 inter-keystroke timings. In our attack scenario, the victim sends keystrokes to the service program with the corresponding delays of inter-keystroke timings prerecorded in [48]. The service program receives the user input and stores it using `fsync`. In the meantime, the attacker performs the Sync+Sync attack by continuously invoking `fsync` to infer whether a user input is stored by measuring the attacker's `fsync` latency. Given a stored user input, the attacker can detect an increased `fsync` latency. Conversely, if the `fsync` latency remains low, the attacker deduces with a high probability that no user input has been sent to the service program. In our evaluation, we set a threshold of 54μs through profiling to distinguish if a user input is received and stored.

To assess the accuracy of Sync+Sync, we calculate the timing difference between the ground-truth latencies from the prerecorded dataset and detected ones. Figure 10 illustrates a back-to-back comparison of the inter-keystroke timings between the reference typers and Sync+Sync attack. The difference is negligible, as Sync+Sync successfully detects keystrokes with an accuracy of 99.2%. Sync+Sync may misjudge keystrokes due to noise and less intense contention. Figure 11 presents the error distribution of Sync+Sync side channel in comparison to the timing distributions of the ground

Table 5: Raw Bit Error Rate with and without Fast Commit.

Symbol Duration (μs)	Sender: `ftruncate` + `fsync` Receiver: `fsync`-only		Sender: `ftruncate` + `fsync` Receiver: `ftruncate` + `fsync`	
	Fast Commit	Normal Commit	Fast Commit	Normal Commit
200	0.09%	0.15%	15.93%	23.75%
400	0.06%	0.07%	2.65%	2.59%
800	0.01%	0.17%	0.16%	0.12%
1600	0.06%	0.03%	0.03%	0.10%
2400	0.04%	0.10%	0.14%	0.06%

truth. On average, the error in received timings for Sync+Sync side channel is 2.5ms, with 98.1% of errors being less than 10ms. This further justifies the capability of Sync+Sync since an inter-keystroke latency is generally no less than 100ms.

Comparison. Inter-keystroke timing has been widely considered in software-based side-channel attacks. It allows attackers to reveal sensitive information through simple statistical techniques using keystroke timings [15, 72]. For instance, Song et al. [72] demonstrate that attackers can uncover information about the keys typed by analyzing users' typing patterns to recover passwords entered during SSH connections. Unlike Gruss et al. [32] that detect a keystroke when the OS's page cache loads related pages upon a key input issued by the user, Sync+Sync functions at the persistent storage with a hypothesis that `fsync` operations are needed to store user input keys. Sync+Sync is hence infeasible for applications that do not auto-commit and invoke `fsync` on the arrival of user input. With precise keystroke timings, Sync+Sync can jointly work with techniques like machine learning to guess passwords or infer written characters [15, 19, 47, 72, 88].

Recently Chen et al. [15] performed a keystroke attack by measuring the uncore power status, as the network traffic and encryption stack of SSH connections affect a system's uncore power. They achieved an F1-score of 0.93 with an error rate of 4.9%. Later Liu et al. [47] did a similar keystroke attack on Intel Optane persistent memory (PMEM). They persistently store the user input to a key-value store on PMEM after every keystroke typed by the victim and detect inter-keystroke timings by probing the Read-Modify-Write (RMW) buffer of PMEM to distinguish RMW hits from misses. They achieved an F1-score of 0.99 with an error rate of 1.04%. Comparatively, Sync+Sync achieves not only an F1-score of 0.996, but also with a lower error rate of 0.81%.

6 Discussions

In this section, we further study the impact of fast commit in Ext4, DoS attack, and the defense mechanisms about Sync+Sync. In Appendix B of [38], we also explore the cross-disk Sync+Sync channel, the channel on other platforms and NVMe SSD, and the impact of Pass-through Disk in VM.

The Impact of Fast Commit in Ext4. Fast commit is a new feature introduced in Ext4 to eliminate unrelated data when invoking `fsync` so as to reduce contention for `fsync`s [57, 64]. We test if Sync+Sync still functions with fast commit or not. To trigger Ext4 journaling every `fsync`, sender utilizes `ftruncate` to change file size randomly and invokes `fsync` to enable Sync+Sync channel, i.e., `ftruncate`+`fsync`. Receiver works with `ftruncate`+`fsync` or `fsync`-only. Table 5 presents bit error rates for Sync+Sync channel with and without fast commit. Evidently fast commit does not affect Sync+Sync, since at the same symbol duration Sync+Sync yields identical bit error rate despite the use of fast commit.

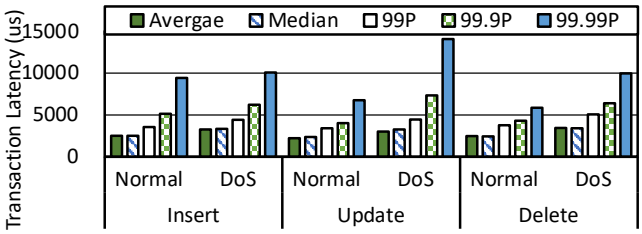

Figure 12: Transaction Average and Tail Latencies for SQLite in VM with and without DoS Attack.

DoS Attack. The interference between `fsync`s impairs performance and implies the potential of DoS attack for Sync+Sync. As VMs isolate programs with hypervisor handling I/Os for them, the difficulty of launching DoS attacks is higher than doing so with programs co-located in the same OS. We run two VMs with independent disk images. The attacker in malicious VM continually writes its file and invokes `fsync`s. We utilize Mobibench to issue Insert/Update/Delete workloads with SQLite for 100,000 times in the victim VM. As shown in Figure 12, the throughput of SQLite degrades by 22.5%, 25.9%, and 28.4% with Insert, Update, and Deletion requests, respectively. The 99.9P (99.9th percentile) tail latency increases by 20.8%, 82.2%, and 47.7%, respectively. These justify Sync+Sync's capability in making DoS attacks.

Defense Mechanisms. It is impracticable for applications to avoid using `fsync`s. One straightforward way to defend against Sync+Sync attacks is to prevent applications from being co-located with other users/applications in the same machine, especially on the same storage device. Yet such hardware isolation increases the operating cost with extra devices or even machines and causes waste of disk space.

Using network-based distributed file systems (e.g., Ceph [12]), to host applications remotely helps to mitigate the effect of Sync+Sync, as `fsync` operations become more sophisticated. Firstly, `fsync` latency is not only influenced by the storage devices, but also affected by the network. Secondly, distributed file systems often deploy replica in different physical machines to provide data consistency and durability, which increases difficulty of generating contention for adversaries to detect. However, this may not be feasible for some applications that are sensitive to network delay and need local storage to provide high performance. Such applications can consider utilizing a background thread that randomly calls `fsync`s to create noise for Sync+Sync, since Sync+Sync is

sensitive to noise. However, to blur `fsync` latencies by introducing extra `fsync`s may incur performance penalty.

7 Conclusion

In this paper, we build a new Sync+Sync side channel that entails a practical concern for programs that are co-located in persistent storage and call `fsync`s for durability. For example, Sync+Sync on Ext4 and an ordinary SSD establishes a covert channel with 20,000bps bandwidth at about 0.40% error rate. Sync+Sync is made effectual by the contention between concurrent `fsync`s on sharing file system's structures and storage device's hardware resources. Extensive experiments show that, leveraging Sync+Sync we manage to launch concrete attacks, such as precisely detecting operations of victim database, distinguishing applications, and fingerprinting websites. We have verified the viability of Sync+Sync on various platforms including Linux, Windows, and MacOS, and responsibly disclosed Sync+Sync to the security teams of Linux, Microsoft, and Apple. We hope Sync+Sync could encourage researchers to further study side-channel information leakage at the persistent storage.

Abstract

AI assistants are becoming an integral part of society, used for asking advice or help in personal and confidential issues. In this paper, we unveil a novel side-channel that can be used to read encrypted responses from AI Assistants over the web: the token-length side-channel. The side-channel reveals the character-lengths of a response's tokens (akin to word lengths). We found that many vendors, including OpenAI and Microsoft, had this side-channel prior to our disclosure.

However, inferring a response's content with this side-channel is challenging. This is because, even with knowledge of token-lengths, a response can have hundreds of words resulting in millions of grammatically correct sentences. In this paper, we show how this can be overcome by (1) utilizing the power of a large language model (LLM) to translate these token-length sequences, (2) providing the LLM with inter-sentence context to narrow the search space and (3) performing a known-plaintext attack by fine-tuning the model on the target model's writing style.

Using these methods, we were able to accurately reconstruct 27% of an AI assistant's responses and successfully infer the topic from 53% of them. To demonstrate the threat, we performed the attack on OpenAI's ChatGPT-4 and Microsoft's Copilot on both browser and API traffic.

1 Introduction

The proliferation of Large Language Models (LLMs) and Chat-based AI services, such as ChatGPT, marks a significant evolution in the digital landscape. These technologies have not only captured the imagination of the public but have also become integral to various aspects of society. Their utility spans from answering simple queries to assisting in complex decision-making processes, highlighting their importance and the trust placed in them by users worldwide.

As the use of AI assistants becomes increasingly commonplace, so too does the sensitivity of the information shared with them. Users frequently turn to these assistants for discussions on personal matters, such as health and hygiene, or for help with confidential tasks, including editing sensitive emails or seeking business advice. This trend underscores the critical need for robust security measures to protect the privacy of these interactions [2, 35].

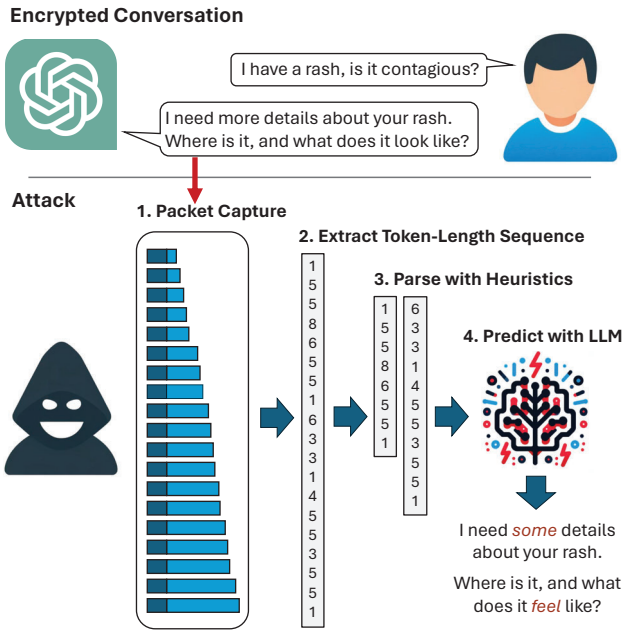

Figure 1: Overview of the attack. A packet capture of an AI assistant's real-time response reveals a token-length side-channel. The side-channel is parsed to find text segments which are then reconstructed using sentence-level context and knowledge of the target LLM's writing style.

However, our research has uncovered a significant vulnerability in the way LLM services, including the popular ChatGPT-4 [1], handle data transmission. LLMs generate and send responses as a series of tokens (akin to words), with each token transmitted from the server to the user as it is generated. While this traffic is encrypted, the sequential token

[1] Corresponding author

transmission exposes a new side-channel: the token-length side-channel. Despite encryption, the size of the packets can reveal the character length of each token, potentially allowing attackers on the network to infer sensitive and confidential information shared in private AI assistant conversations. The challenge for attackers in exploiting the token-length side-channel lies in the inherent complexity of accurately inferring text from a sequence of token-lengths. This difficulty is primarily due to the fact that the tokens from a single sentence can correspond to a multitude of grammatically correct sentences. Moreover, this task becomes exponentially more challenging when the goal is to decipher entire paragraphs, vastly increasing the potential combinations and interpretations.

Previous studies on remote keyloggers have leveraged additional side-channels, such as keystroke timings, to reveal information on which characters have been typed. However, such approaches are not applicable in our setting because LLMs generate whole words at a time and therefore do not leak any character-level information. This presents a unique challenge to traditional side-channel analysis. A complete discussion of related works can be found in section 8.

To overcome this challenge, we propose a *token inference attack* that is extremely effective at deciphering responses in encrypted traffic. The approach is to train a state-of-the-art LLM to translate a token-length sequences back into legible sentences. Furthermore, by providing the LLM with the context of previously inferred sentences, the LLM can narrow down the possible sentences further, thereby reducing the entropy involved in inferring entire paragraphs. Finally, we show how an adversary can exploit the predictable response style and phrase repetition of LLMs like ChatGPT to refine the model's accuracy even further. This is achieved by training the attack model with sample chats from the target AI assistant, effectively creating a known-plaintext attack scenario that enhances the model's ability to infer the sequence of tokens. These sample chats can be readily obtained from public repositories (e.g., [8]) or by accessing the AI assistant service directly as a paying user.

Our investigation into the network traffic of several prominent AI assistant services uncovered this vulnerability across multiple platforms, including Microsoft Bing AI (Copilot) and OpenAI's ChatGPT-4. We conducted a thorough evaluation of our inference attack on GPT-4 and validated the attack by successfully deciphering responses from four different services from OpenAI and Microsoft.

In summary, the contributions of our paper are as follows:

- **Novel side-channel**: We identify a novel side-channel inherent in all LLM models, affecting any LLM-based service that sends responses in real-time.
- **Token Extraction Method**: We provide framework for extracting token-length sequences from encrypted LLM response traffic, and identifying text segments (e.g., sentences) within the sequences.
- **Single Sentence token inference Attack**: We propose the first ever token inference attack. We train an LLM to translate token-length sequences into plaintext sentences. To the best of our knowledge, this is the first work that uses generative AI to *perform* a side-channel attack.
- **Multi-sentence token inference Attack**: We introduce a technique for inferring entire paragraphs by considering inter-sentence context. By doing so, we are able to significantly narrow the scope of possible sentences and enhance the accuracy of the inferred information.
- **Known-Plaintext Attack on LLMs**: We expose a novel attack vector which can be used to improve token inference attacks. By collecting and analyzing example responses from the target LLM (i.e., AI assistant) we can exploit the predictable style of LLMs, and tendency of LLM's to repeat training data, to better infer plaintexts.
- **Exposure & Demonstration** We identify several major vendors vulnerable to this attack and demonstrate the significance of the attack by demonstrating it on encrypted network traffic from OpenAI's ChatGPT-4 and Microsoft's Copilot.

This paper not only sheds light on a critical security flaw in current AI assistant services but also offers a comprehensive framework for understanding and mitigating the risks associated with the token-length side-channel.

2 Background

In this section, we outline the fundamental concepts needed to understand the token-length side-channel. We start by defining tokens and the tokenization process. Next, we briefly describe how Large Language Models (LLMs) use and generate token sequences. Finally, we examine the deployment of LLMs in online AI assistants and chatbots, highlighting how the streaming of tokens can expose their lengths to potential eavesdroppers.

2.1 Tokens & Tokenizers

In Natural Language Processing (NLP), a token is the smallest unit of text that carries meaning. The set of all tokens K is predetermined based on the content being processed. When a sentence is tokenized, it is divided into a series of tokens represented as $S = (k_1, k_2, ..., k_n)$, where S is the entire sentence, and $k_i \in K$ is an individual token.

For instance, consider the sentence "*I have an itchy rash*." The tokenization of this sentence could be represented as $S = (k_1, k_2, k_3, k_4, k_5)$, where the tokens are $k_1 = I$, $k_2 = have$, $k_3 = an$, $k_4 = itchy$, and $k_5 = rash$. In some cases, particularly with complex words, tokenization might result in a word being divided into multiple tokens. For example, the word "*tokenize*"

could be tokenized as $S = (k_1, k_2)$ with $k_1 = token$ and $k_2 = ize$. Furthermore, spaces and punctuation in tokenization are handled distinctively. Spaces are often included in the token, while punctuation like commas and periods are typically separate tokens. For example, consider the text "*Oh no! I'm sorry to hear that. Try applying some cream.*" The tokenizer of GPT-3.5 and 4 would tokenize it as

Oh no! I'm sorry to hear that. Try applying some cream.

and the tokenizer of LLAMA-1 and 2 would tokenize it as

Oh no! I'm sorry to hear that. Try applying some cream.

Note how the apostrophe and the letter following it can sometimes form a separate token, and that spaces are added as prefixes to words. Tokenizers used by different LLM models are fundamentally similar as they all follow the principle of breaking down text into manageable units. Also, it is important to note that major vendors do not keep their tokenizers secret since they are an important part of their API services.

In summary, although tokens are akin to words, they do not have a one-to-one mapping. They also include spacing and reserve tokens for punctuation.

2.2 LLMs in AI Assistants

AI chatbots, like ChatGPT, are sophisticated LLMs designed for engaging in human language interactions. Key to their functionality are prompts and responses:

Prompt (P): A prompt is the user's input, typically a question or statement, initiating interaction with the LLM. It is represented as a token sequence $P = [p_1, p_2, ..., p_m]$ for $p_i \in K$.

Response (R): In reply to the prompt, the LLM generates a response, also a sequence of tokens, denoted as $R = [r_1, r_2, ..., r_n]$ for $r_i \in K$.

Chat-based LLMs manage conversations through these alternating prompts and responses, maintaining context to ensure relevance and coherence. The model tracks the dialogue's history, allowing it to contextualize each response within the ongoing conversation.

LLMs use tokens both in training and execution. They are trained on vast datasets of tokenized text (e.g. The Pile [10]) to learn the probability of a token following a given sequence, which enables them to predict the next token in a response.

During execution, the LLM generates response tokens **sequentially**. Starting from the prompt, it predicts each subsequent token r_i based on both the prompt and the preceding response tokens $[r_1, r_2, ..., r_{i-1}]$. This method, $p(r_i|P, r_1, r_2, ..., r_{i-1})$, allows the LLM to produce contextually relevant and coherent responses, considering the entire conversational history.

2.3 The Deployment of AI Assistants

AI assistants are typically deployed in cloud-based environments. This setup allows for scalable and efficient access to the computational resources required to run these sophisticated models. A user session with an AI assistant generally follows a straightforward process:

1. **Connection**: The user connects to a server hosted in the cloud via a web app in a browser or via an API (e.g., using a 3rd-party app). The user starts or resumes a chat session (conversation) to set the context of the prompts.

2. **Prompting**: The user submits a prompt P (a query or statement) and it is transmitted to the server as a single message. The server forwards the prompt to an instance of the LLM model for processing.

3. **Response Generation**: The LLM generates a response R to the prompt and the response tokens are sent back as text to the user **sequentially** and **in real time** for visualizing the response as it's created. This operational approach enhances user experience by allowing users to see the AI's responses form in real-time, ensuring a dynamic and engaging conversation. This is especially important given that state-of-the-art LLMs are slow due to their complexity.

We observed that most vendors use either the QUIC protocol over UDP or web sockets over TCP to transmit responses. As of the time of writing, these vendors do not pad, compress, or encode the traffic before it is encrypted. For more details, see Table 1.

3 Side-channel Definition & Attack Model

3.1 Token-length side-channel

In a real-time communication setting, AI services transmit the next token r_i as text immediately after it is generated. Our observations of several AI assistant services (referenced in Table 1) indicate that the token r_i is sent either as an individual message or as part of a cumulative message (e.g., $[r_1, r_2, ..., r_i]$). Crucially, in both scenarios, the packet's payload length is directly correlated to the number of characters in r_i's text. In the case of cumulative messages, the length of each token can be inferred by calculating the difference in payload length between successive packets. Consequently, for each response message, it is possible to discern the lengths of every single token, even when the traffic is encrypted.

Let the token-length sequence for a response be denoted as $T = [t_1, t_2, ..., t_n]$, where t_i represents the **character length** of the token r_i's text. The relationship between the token r_i and its character length t_i can be expressed as $t_i = |r_i|$.

This token-length sequence L can be exploited to infer the original tokens, thereby breaching the privacy of the conversation by revealing every AI response. These responses can also be used to deduce the prompts themselves, either indirectly through context or directly in cases where the AI repeats the question before proceeding.

3.2 Attack Model

In our scenario, we have three entities: Bob, the user; Alice, the AI assistant; and Eve, the attacker. Bob interacts with Alice for various tasks such as seeking personal advice, looking up facts, or editing documents. Alice, the AI assistant, responds to Bob's prompts over an encrypted communication channel. We assume that all plaintext messages exchanged are in English and that no additional padding is added to these messages, as is common practice with several major vendors (see Table 1).

Eve, positioned as the adversary in this model, aims to read the encrypted responses sent by Alice. She is capable of observing the encrypted network packets, either within the Local Area Network (LAN) of Bob or somewhere in the internet infrastructure between Alice and Bob. By monitoring these packets, Eve intends to extract the token-length sequence T from each response and use it to infer the original plaintext R. With R, Eve can access not only private and personal information about Bob but also potentially sensitive data related to the company Bob works for. For instance, this could occur if Bob asks Alice for assistance in editing a work-related email.

It is important to note that Eve cannot use Alice's model to perform the inference attack using next-token probabilities. This is because AI assistant vendors, such as OpenAI and Microsoft, do not provide their model's next token probabilities in their chat services. We also assume that Alice has no knowledge of the prompt that elicited the response since the prompt is usually sent as one single encrypted message. Although we don't require it, we assume that Eve has access to publicly available datasets of example prompts and responses from the target AI service, or that she can register as a free or paid user to create her own dataset.

3.3 Problem Statement

The fundamental challenge for the attacker in this scenario is to accurately reconstruct the original response R from the observed token-length sequence T.
This can be formally stated as follows:

Given a sequence of token-lengths $T = [t_1, t_2, ..., t_n]$ extracted from encrypted traffic, infer the original token sequence $R = [r_1, r_2, ..., r_n]$ from T, where $t_i = |r_i|$ represents the length of token r_i.

Solving this problem is non-trivial due to the absence of additional character-level information that can help narrow down the options for each word. This lack of information significantly increases the number of possible grammatically correct sentences for even a single sentence structure.

For example, consider the sentence "She has a ___ and a ___," with blanks to be filled by 4-letter and 5-letter nouns respectively. There are at least 880 nouns with 4 letters and 905 nouns with 5 letters, so the total number of grammatically correct solutions for the sentence is $880 \times 905 = 795,600$. This example shows that even with just two unknown tokens, brute-forcing all possible *correct* sentences that can be mapped to T leads to too many results for the attacker to consider. This issue is compounded when considering entire paragraphs.

However, there are at least two sources that can be used to reduce the entropy of this task: long-distance language structure across sentences and paragraphs, and style-specific language structure exhibited by AI assistants. Therefore, we address this challenge by combining three strategies:

1. **Inference with Modern LLMs**: We harness the capabilities of state-of-the-art language models. By fine-tuning a pre-trained LLM for our task, we can capitalize on the common language structures and patterns prevalent in the English language to reduce sentence entropy. Unlike previous works that relied on Markovian models for exploiting similar side-channels (e.g., [21]), LLMs are more adept at this task due to their proficiency in considering long-distance relationships between tokens [31]. Additionally, we employ self-supervised learning for fine-tuning, which greatly simplifies dataset curation by eliminating the need for manual labeling.

2. **Forward Context**: Inferring the content of a token sequence is much easier if we know what the previous response was. For example, if R_{i-1} is a sentence about '*how to apply itch cream*,' it's likely that R_i will pertain to the application of itch cream. Formally, $p(R_i|T_i, \hat{R}_{i-1})$

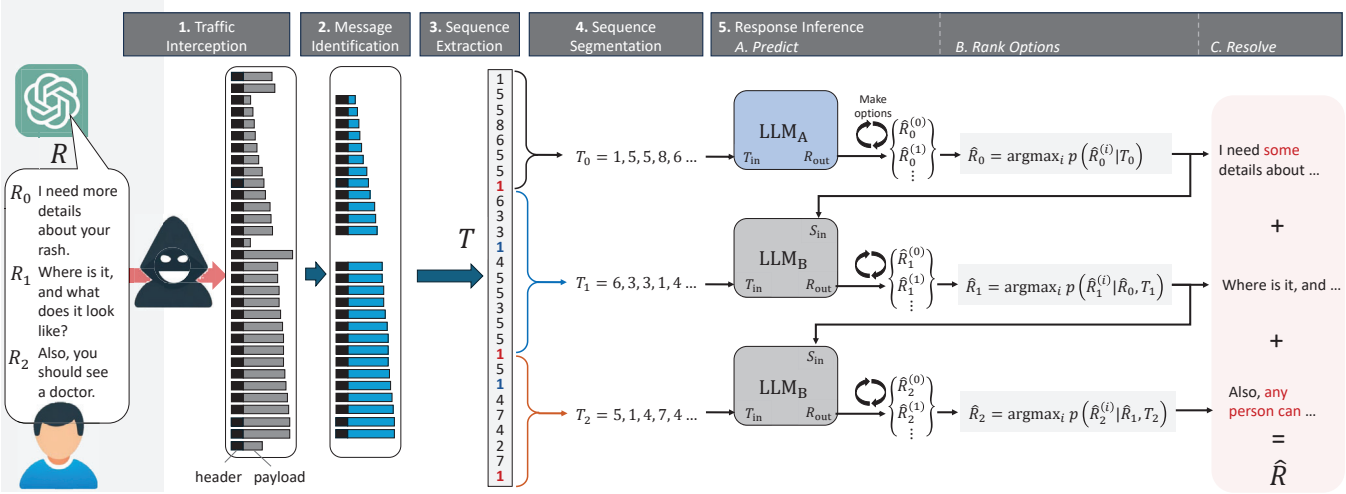

Figure 2: An overview of the attack framework: (1) Encrypted traffic is intercepted and then (2) the start of the response is identified. Then (3) the token-length sequence T is extracted and (4) a heuristic is used to partition T into ordered segments $(T_0, T_1, \ldots)$. Finally, (5) each segment is used to infer the text of the response. This is done by (A) using two specialized LLMs to predict each segment sequentially based on prior outputs, (B) generating multiple options for each segment and selecting the best (most confident) result, and (C) resolving the predicted response $\hat{R}$ by concatenating the best segments together.

where $\hat{R}_{i-1}$ is the inferred response from T_{i-1}. Therefore, by providing the adversary's LLM with $\hat{R}_{i-1}$ we can greatly reduce paragraph entropy.

Solving for T is hard. However, if T is part of a long sequence (i.e., a sentence in a paragraph) then the context of the prior resolved sentence can help us infer the words in the current sentence better. For example, if the last sentence was about 'how to apply itch cream,' then the next sentence may be about 'how often to use it.' This context can help an LLM model reduce paragraphs even further.

3. **Known-plaintext Attack**: We observed that LLMs used in AI assistant services exhibit distinct writing styles and sometimes repeat phrases from their training data, a notion echoed by other researchers as well [4,23]. Recognizing this characteristic enables us to conduct an attack similar to a *known-plaintext attack*. The method involves compiling a dataset of responses from the target LLM using public datasets or via sending prompts as a paid user. The dataset can then be used to further fine-tune the inference model. As a result, the inference model is able to reduce entropy significantly, and sometimes even predict the response R from T perfectly, word for word.

4 Token Inference Attack

In this section, we describe how we implement the *token inference attack* that exploits the *token-length side-channel* exhibited by major vendors. Our attack is structured into a series of steps, as depicted in Fig. 2:

1. **Traffic Interception**: The first step involves intercepting the encrypted traffic between the user and the AI assistant. This can be done by eavesdropping on the traffic sent through public networks or by malicious actors within an internet service provider (ISP).

2. **Message Identification**: Once the traffic is intercepted, the next step is to extract the message sizes. A message m is a communication that contains the latest token and other metadata. To do this, we must first identify the first message packet. This involves (1) removing all packets that do not contain messages and (2) combining packets that were split because they were too long. The result is a sequence of message sizes.

3. **Sequence Extraction**: With the sequence of message sizes, the token-length sequence T is extracted by observing the change of the stream's message sizes over time. Depending on the server's approach to token transmission — whether it includes all preceding tokens with each new token or not — two distinct strategies can be employed to extract the token-length sequence T.

4. **Sequence Segmentation**: The extracted token-length sequence T is then partitioned into ordered segments $T_0, T_1, \ldots$, where T_i roughly corresponds to a sentence. This is accomplished by using a heuristic that exploits the tokenizer's behavior.

5. **Response Inference**: The sequence of segments is then passed to a model consisting of two LLMs (LLM_A and LLM_B) which are used to infer the text of R. LLM_A is designed to reconstruct the first segment from T_0 and

LLM_B is designed to reconstruct the subsequent segments from T_1, T_2, and so on using the inferred text of the preceding segment as context. We employ two LLMs because the initial sentence of an AI assistant's response typically follows a unique distribution. By tailoring a dedicated model specifically for these first sentences, we enhance the accuracy at the paragraph's outset, which in turn significantly improves the inference quality for all subsequent sentences within the paragraph.

Given the stochastic nature of LLM outputs, for each T_i, we generate multiple outputs and select the most probable one as the predicted response segment $\hat{R}_i$. These segments, $\hat{R}_0, \hat{R}_1, ...$, are then concatenated to construct the complete inferred response $\hat{R}$.

We will now provide more details on each of these steps.

4.1 Traffic Interception

The initial step of the attack involves eavesdropping on encrypted communications, as detailed in Section 3.2. The adversary can be positioned within the same LAN, connected to the same WiFi, or anywhere on the internet, provided they can observe the packets. Moreover, there exist techniques that allow traffic to be rerouted through the adversary for observation, even if they are not directly on the communication path [6], enhancing the feasibility of eavesdropping.

To perform the attack, we must find the response. To accomplish this, we filter the traffic based on (1) the server's known IP addresses and (2) the protocol used by the vendor. For example, to target ChatGPT, we search for UDP traffic carrying QUIC, and for Bing Copilot we search for TCP traffic carrying TLS.

4.2 Message Identification

As mentioned in section 3.1, the server sends the client token r_i in a message m_i containing all previous tokens $r_1, r_2, ..., r_i$ along with fixed length session metadata. Our goal here is to extract message sizes from traffic. We start by identifying the first and last packets of a response and then extract the message lengths.

To detect the first and last packets, we analyze bandwidth patterns from the server to the client. The start and end of a response have a deterministic pattern specific to the service (e.g., OpenAI-GPT vs Microsoft-Copilot). This can be done by: (1) connecting to the service and observing the plaintext with our own TLS key, (2) sending a prompt to the service and recording the response traffic, and (3) creating rules that capture the bandwidth patterns for the start and end of the response. For instance, OpenAI's ChatGPT uses a fixed-size preamble of 4200 bytes and a jump in message size of 71 bytes at the end.

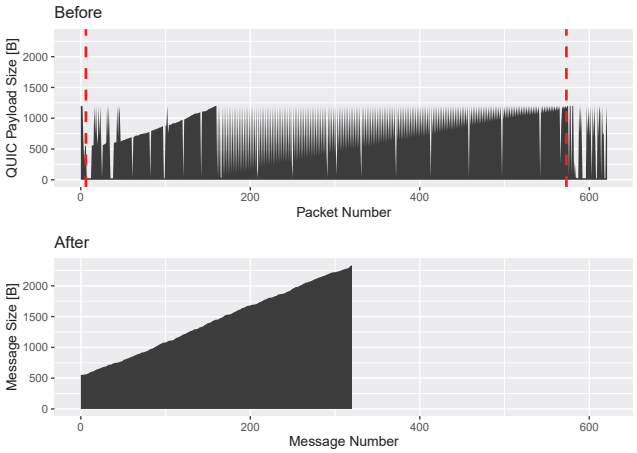

Figure 3: An example showing the trends in the encrypted traffic traffic before and after performing message identification. This example is taken from a response sent from OpenAI's ChatGPT-4 web app. Red bars indicate the start and end of the messages.

To extract message lengths, we use a straightforward method: since a given m_i typically fits into one packet, the sequence of $|R|$ packets will have payload sizes that are strictly increasing (see Fig. 3). To find the first packet (containing m_0), we look for this trend and then backtrack. The length of m_0 is the size of that packet, excluding the header length. Some vendors use protocols that send bursts of control packets; we filter these by ensuring continuity in the increasing payload lengths.

For vendors using QUIC, messages are split over multiple packets when they exceed a certain size. For example, ChatGPT-4's web app has a maximum QUIC payload size of 1200 bytes. When an HTTP3 packet exceeds this, it splits into multiple QUIC packets, each with a 28-byte HTTP3 header, creating a 'saw tooth' pattern in QUIC payload sizes for messages over 1172 bytes. This pattern is deterministic: if $|m| > 1172$ bytes, there will be $\lfloor \frac{|m|}{1172} \rfloor$ packets with the maximum payload size and one packet with a payload size of $|m| \mod 1172 + 28$ bytes.

4.3 Sequence Extraction

Now that we have extracted a sequence of message sizes, we can derive the token-length sequence as follows:

$$T = \left\{ t_i \,\middle|\, |m_i| - |m_{i-1}| \right\} \tag{1}$$

This method is feasible because, as outlined in section 2.3, vendors typically do not apply padding, compression, or encoding to tokens prior to encryption, enabling the straightforward extraction of T. It's important to highlight that while all major vendors currently transmit tokens in this manner, future services might opt to send each token independently without including the previous tokens. In such scenarios, one can

deduce the overhead and calculate T as $T = \{t_i || |\text{packet}_i| - h\}$, where h is the fixed-length message metadata. The value of h can be determined either by connecting as a legitimate user and inspecting the packets or heuristically by identifying the smallest packet likely containing a single-character token.

We note that even if a vendor encodes or compresses the data, it may not completely mitigate the side-channel, as shown in [21].

4.4 Sequence Segmentation

The token-sequence T encapsulates one or more paragraphs of text. Before we can use it with our model, we must segment it into meaningful chunks. Fortunately, it is possible to identify punctuation marks within T. This is due to two key observations: (1) tokenizers are designed not to include a space character with a punctuation mark, and (2) the smallest word, such as 'a', always comes with a leading space, making it at least two characters long. Consequently, tokens of length 1 are almost certainly punctuation marks.

Naturally, for our model to effectively infer text, we aim to segment T into units that closely resemble complete sentences. However, distinguishing between different types of punctuation marks (periods, commas, etc.) is not feasible directly. Thus, we employ a heuristic to approximate sentence boundaries.

Segmentation Process. The process begins by splitting T at every instance where $t_i = 1$, which likely indicates a punctuation mark. If a segment contains fewer than 10 tokens (~7 words), it is merged with the following segment. This step is iterated until we compile a list of token-length sequences $(T_0, T_1, ...)$, each approximating a sentence or meaningful textual segment. There are some edge cases that can also be considered to refine the results. For example, responses that contain an enumerated list always have the pattern ":\n\n1." which is the sequence (3,1,1) since the colon and newlines are joined. Therefore, we add this sub-string to the start of the next segment so that each item will start with its enumeration token and reduce the chance of error on the former segment.

While our heuristic for segmentation is not flawless, the model compensates for these inaccuracies by learning from numerous examples during training. For the sake of reproducibility, we have made our segmentation code, inclusive of all its edge cases, and the entire model training pipeline available online.[1]

4.5 Response Inference

Our attack model is predicated on the observation that the first segment in a response from an AI assistant typically exhibits a distinct format and style compared to its subsequent segments. For instance, an initial response might begin with "*Sure, I can provide information on the legality of abortion in a particular state*:..." or "*Here are some common mindfulness practices for managing stress*:..." where an inner segment would be more informational.

Given this intuition, our attack model optimizes effectiveness by employing two separate Large Language Models (LLMs) for generating complete paragraphs. The first model, denoted as LLM_A, is tasked with generating the initial segment using T_0 without relying on any additional context. The second model, LLM_B, generates all following segments, utilizing T_i and incorporating the context from the last predicted segment's text $\hat{R}_{i-1}$. This bifurcated approach allows us to tailor the generation process to the unique characteristics of both the opening and the inner segments of a response.

Due to the inherently stochastic nature of LLM outputs, a single execution of an LLM for a given input might not yield the correct answer. To address this, we execute each LLM multiple times for each input and employ the LLM's confidence scores across these samples to rank the results. We then select the best outcome as the actual prediction, leveraging the models' ability to evaluate their own output.

Later in section 5.2, we explore the effectiveness of this ranking mechanism and the performance of the LLMs.

Model Architecture. Our task of inferring R from T is similar to the task of translation. LLMs are designed for this task, thus making them excellent models for our purpose. In particular, the base model which we build on is the pre-trained T5 model [28]; a transformer-based encoder-decoder neural network, trained to perform multiple sequence-to-sequence tasks including translation.

As with other LLMs, the T5 models make use of a language model (LM) head in their decoder, which contains a final output layer consisting of the same output units as the model's vocabulary size, each representing the probability of that token. When used to create a new segment (known as generation), each new token is selected by sampling from the perceived probability distribution consisting of all the output units. The complete generation procedure operates in an autoregressive manner: tokens are sampled one at a time and are appended to the input sequence.

New Vocabulary. Unfortunately, LLMs are trained to associate words with their corresponding lengths, and not tokens, which also include partial words and special signs. Thus plainly prompting an LLM with a sequence of token lengths (e.g., 2, 5, 4, 1, ...) will yield an inaccurate result. We have confirmed this in our baseline evaluations where we show that ChatGPT-4 is unable to perform our task effectively (see section 5.2). Therefore, we decided to fine-tune the weights of the T5 model with an expanded token vocabulary, as commonly performed when adapting a pre-trained language for a specific domain [18]. In this vocabulary, each new token represents some t_i; the length of a token. For example, tokens with 5 and 8 characters are represented in the models' vocabulary by the new tokens _5 and _8 respectively. As the tokens in the expanded vocabulary are initialized from a natural starting

[1] https://github.com/royweiss1/GPT_Keylogger

point, relearning the meaning of the original number tokens is avoided, leading to an efficient training process.

Training. The training of T5 models mirrors the auto-regressive generation process. During training, a sequence of tokens is fed into the model, followed by a gradient update step aimed at refining the model weights. The objective is to adjust the LM head's output distribution to maximize the probability of correctly predicting the subsequent token in the sequence.

The objective of LLM_A is to predict $p(R_i|T_i)$ which can be achieved through standard T5 model training using cross-entropy loss. However, LLM_B is slightly more complicated since its objective it to predict $p(R_i|T_i, R_{i-1})$ where R_i is the corresponding response text for T_i. To add this secondary input sequence, we employ a scheme commonly used in the instruction tuning of language models [39]. The method is to prompt the model to perform translation but to append both the target tokens T_i and the context tokens R_{i-1} to the prompt.

For example, a prompt to train LLM_A on R_0 = "*I need more details about your rash.*" would be:

LLM_A Training Prompt

Translate the Special Tokens to English.
Special Tokens: _1 _5 _5 _8 _6 _5 _5 _1

However, a prompt to train LLM_B on R_1 = "*Where is it, and what does it look like?*" take the form of:

LLM_B Training Prompt

Translate the Special Tokens to English, given the context.
Context: I need more details about your rash.
Special Tokens: _5 _3 _3 _1 _4 _5 _5 _3 _5 _5 _1

The models are trained with a self-supervised training procedure. First, a set of responses is collected as the ground truth. Then, each response is segmented using the segmentation algorithm in section 4.4. These segmented plaint-text responses serve as the ground truth dataset $\mathcal{D}_y$. Finally, we generate the token-length sequences for each response segment in $\mathcal{D}_y$ as $\mathcal{D}_x$. Model LLM_A is trained on the first segment for each response in $(\mathcal{D}_x, \mathcal{D}_y)$ and LLM_B is trained on all *other* segments.

Ranking. During execution, an LLM (such as T5) will make different predictions for each time it is executed. This is because the model introduces some randomness in the selection of the next token to help the model explore better solutions. However, in the context of our problem, we want to generate the most likely solution. Therefore, when executing either of our models, we execute them k times and select the result with the highest probability: $p(R_i|T_0)$ for LLM_A and $p(R_i|R_{i-1}, T_0)$ for LLM_B. The probability is obtained by measuring the respective model's confidence on the given prediction.

Inference. To infer R from a given T, we perform the following process (illustrated in Fig. 2). First T is segmented using the segmentation algorithm. Then the first segment T_0 is passed through LLM_A k times and the result with the highest confidence is selected as $\hat{R}_0$. Next, the second segment T_1 is passed through LLM_B with $\hat{R}_0$. The result with the highest confidence is selected as $\hat{R}_1$. This process repeats over LLM_B until the last segment is processed. Finally, $\hat{R}$ is created by concatenating the predicted segments in order such that $\hat{R} = \hat{R}_0||\hat{R}_1||...||\hat{R}_{|R|}$.

5 Evaluation

In this section, we evaluate the threat of the token-length side-channel by demonstrating how effective our LLM-based inference model is at performing a token inference attack. Our evaluation is performed on services provided by major vendors, such as OpenAI and Microsoft. A demo video of the attack[2] and the source code for this research[3] can be found online.

5.1 Experiment Setup

Datasets & Training. We used the UltraChat dataset [8] which encompasses 1.5 million multi-turn dialogues using the GPT-4 Turbo API. Of these dialogues, 570,000 are general inquiries, and the rest focus on creative writing, summarization, and editing. For our purpose, we used the general inquiries section. From each dialogue, we used the first response only to form our dataset. After segmentation, the dataset had on average 12.57 sentences per response and 17.5 tokens per sentence. The entire dataset was used for training *except* for 10k which was used for validation and 10k which was used for testing. To prevent contamination of the test set with training samples, we removed any test set prompts that either contained all the same words as a prompt in the training set or shared at least the first eight words with a prompt in the training set.

The initial segment model was trained for 50 epochs, while the model dedicated to middle segments underwent training for 40 epochs, both utilizing an NVIDIA RTX 6000. The training duration for the first model was approximately 2 days, while the second model required about 10 days to complete its training phase.

Metrics. In our evaluation, we employed two distinct metrics for assessing the fidelity of our reconstructions at different granularities: edit distance (ED) at the character level and ROUGE at the word level. ROUGE measures the overlap of n-grams between the generated text and the reference text, focusing on the aspects of recall and precision. Specifically, we utilized precision ROUGE-1 (R1) and ROUGE-L (RL

[2] https://www.youtube.com/watch?v=UfenH7xKO1s&t
[3] https://github.com/royweiss1/GPT_Keylogger

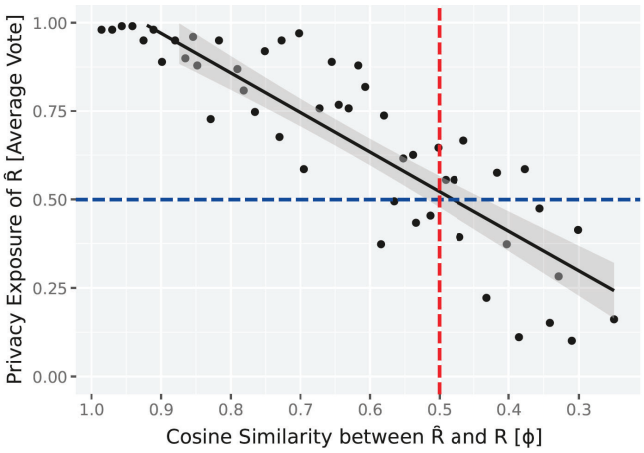

Figure 4: The relationship between cosine similarity and objective privacy exposure (average vote from 100 participants). Each point represents an evaluated tuple (a sentence R and its reconstruction $\hat{R}$). The black line shows the linear relationship with its 0.95 confidence interval. Most participants (above blue line) perceived a privacy exposure for reconstructed sentences with cosine similarity $\phi > 0.5$ (left of red line).

-longest sub-sequence), with the understanding that higher ROUGE scores, ranging from 0 to 1, indicate better performance, where 1 signifies a perfect match.

However, reconstruction accuracy alone does not ascertain whether the confidentiality of the responses, specifically their topics, has been compromised. To address this, our evaluation primarily hinges on cosine similarity [5, 22]. Utilizing a pre-trained sentence transformer [29] from the MiniLM architecture [33], we compute the embeddings for the original response R and its reconstruction $\hat{R}$, and then assess their similarity through by computing their cosine similarity (denoted ϕ), which ranges from -1 to +1 ($\phi = -1$ implies a complete divergence in the topic and $\phi = 1$ indicates perfect alignment). For examples of how this score correlates with actual reconstructions, we direct the reader to Fig. 5, which showcases successful and unsuccessful attacks on OpenAI's ChatGPT-4.

To determine objectively what value of ϕ indicates a successful attack (that the underlying topic is indeed captured in the inferred text), we performed a survey: Using the test set, we sampled 50 sentences uniformly at across $\phi = [0.3, 1.0]$. Then, 100 random people on Prolific were asked to vote on whether or not a reconstructed sentence captures the content or topic of the original sentence.[4] Fig. 4 plots the 50 sentences according to their survey score and ϕ values. The linear relationship shows that the majority of the participants found that ϕ values above approximately 0.5 indeed compromise the privacy of the message. Using this observation, we measure the attack success rate (ASR) of a model as the percent of samples that have a ϕ greater than 0.5.

Experiments. Our experiments were designed with two primary objectives: to evaluate our model's performance and to analyze the effectiveness of our attack under realistic conditions. Initially, we assessed the model's capability using a test set of 10,000 responses generated by GPT-4, focusing on its accuracy and reliability in reconstructing text from token-length sequences. Following this, we conducted an analysis of the attack's performance using captured network traffic, where the token-length sequences were subject to additional noise such as errors and buffering. We evaluated the attack performance on OpenAI's ChatGPT-4 services (browser application, GPT marketplace, and API) and Microsoft's Copilot.

To understand our model better, we also performed a baseline evaluation and an ablation study on the impact of the model's training data.

[4]The survey text can be found in the appendix.

5.2 Attack Evaluation

First, we will explore the performance of the attack on the first segment. This is because (1) often the first segment reveals the confidential topic entirely and (2) the quality of $\hat{R}_0$ directly impacts the subsequent segments.

First Segment Inference. As mentioned earlier, we subjectively set our attack success threshold to $\phi > 0.5$ as reflected in 5. Among the 10k test-set responses from GPT-4, we achieved an attack success rate of over 52.7% on the first segment. This is a significant finding because it indicates that over half of a user's conversations can be exposed. Furthermore, the model was able to reconstruct 27% of the first segments with very high accuracy ($\phi > 0.9$).

The top row of Table 2 summarizes the results. In the table, the cosine similarity and Rouge metrics reflect positive outcomes, suggesting successful results. Conversely, the ED metric presents a more conservative evaluation. This is because the cosine and Rouge metrics are considering more abstract measures (topic similarity and word accuracy) than ED (character accuracy). This result highlights a few insights into our model:

- Our attack model uses nearby tokens as context to maintain the expected topic of the segment. For instance, the second sample in Fig. 5 shows where the word "potential" was used instead of "important". Another example is the difference between the phrases "recent advancements" and "recent developments". In these cases, cosine and Rouge will be higher than ED.
- The model weighs the importance of token patterns in the segment and will 'cheat' at times by altering tokens in T_i to stay on topic while ensuring proper grammar. For example, in the third sample of Fig. 5, "language and" is used instead of "transferable". This results in a higher cosine but lower Rouge and ED.

Consequently, LLM_A can effectively reveal the topic of a token sequence, despite not precisely reconstructing the original wording. This outcome aligns with our primary objective,

Table 2: Inference performance on ChatGPT-4. Each row indicates how many leading segments are considered. Results are reported in percent [%].

as our main concern is the exposure of T in terms of confidentiality, emphasizing the importance of understanding the content's nature over its exact phrasing.

Topic Exposure. To discern which topics are more susceptible to exposure, we utilized ChatGPT-4 to categorize sentences by their privacy level and subject matter. Figure 7 displays the attack success rates ($\phi > 0.5$) across these categories. The results demonstrate a relatively uniform topic exposure, suggesting that (1) any topics can be exposed to a certain extent, and (2) the model does not exhibit a marked preference for reconstructing any specific subject over others. However, we acknowledge that this result is likely due to the diversity and relative uniformity of the topics in the UltraChat dataset.

Ranking. Recall that for each LLM we generate k samples, rank them, and select the top result. Choosing the optimal result for $\hat{R}_0$ is crucial as it sets the context for subsequent sentences. To evaluate our ranking method, we examined what would happen to the performance if we took the *ideal* sample from the top n results. In Fig. 6 we present this experiment by plotting the performance distribution for several selections of n. The red line shows the performance of our method where $n = 1$. The figure shows that while the top is not ideal, it is not far from it. We leave refining the ranking strategy to future work.

Inner Segment Inference. On average, the attack success rate for entire responses was 38% (see Table 2). This is noticeably lower than the success rate on the first segment (52.7%), but still meaningful. The reason for this drop is that the first segments typically contain common phrases and styles of the AI assistant more so than the inner segments (see section 4.5 for examples). However, the forward context from LLM_A has a significant impact on the success rate of the entire response and correlates directly to the quality of $\hat{R}_0$ (see appendix Fig. 12). Moreover, we found the model to work well at identifying and generating responses containing lists, likely due to the \n structure. Overall, we found that if the first segment receives $\phi > 0.6$ then the attack on the entire response will be successful.

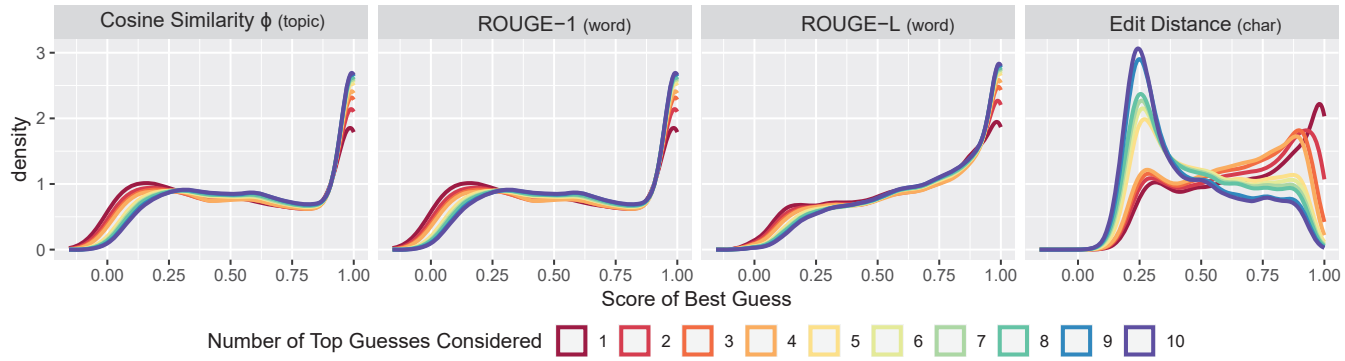

Figure 6: The performance distribution for 10k first segments. Red indicates the case where top ranked result is selected as $\hat{R}_0$. Other colors indicate what the performance *could* have been when selecting the 'ideal' sample from among the top results.

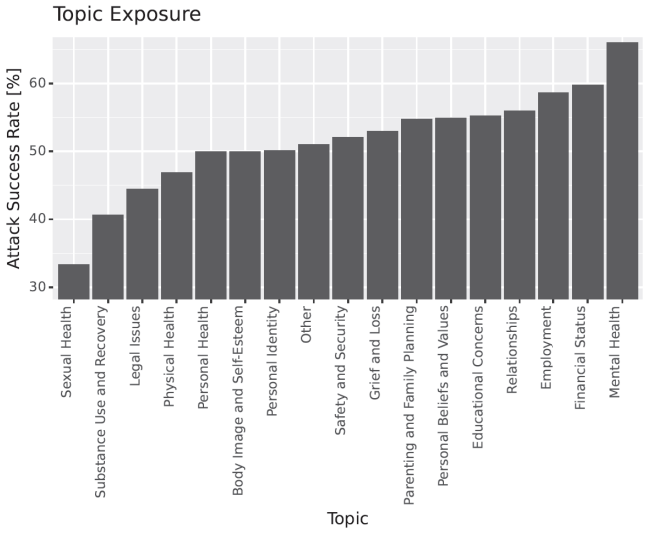

Figure 7: Attack success rates for sentences grouped by their topic of confidential exposure. Sentence classification and categorization was performed by ChatGPT-4 Turbo.

Baseline Analysis. While the performance of LLM_A demonstrates the legitimacy of the token-length side-channel, it is not clear whether the proposed model is better than other state of the art. We first considered using a Markovian model similar to [21] as well as using a hidden Markov model (HMM). However, these models did not scale well due to the enormous vocabulary of our dataset which includes names, dates, and so on. This is especially an issue in cases where tokens can be buffered or batched int eh network (see section 5.3). Markovian models are also memoryless which makes them a poor match compared to modern LLMs that consider long distance patterns.

Instead, we compared our model using two different approaches based on LLMs:

Direct Approach We used the ChatGPT-4 Turbo (0125-preview) API to solve for T_0 by writing prompts that included (1) a definition of the puzzle, (2) an example puzzle with solution and (3) T_0 itself as a list of integers.[5]

Progressive Approach We used a pre-trained Flan-T5-xl model to generate $\hat{R}$: (1) The model was given the same prompt as the *direct approach* and then (2) we generated each token by taking the next most probable token with the correct length. For example, to generate token r_i, we ranked the probability of the tokens in K according to the model and then selected the most likely token with the character length of t_i (observed in the traffic).

Fig. 8 shows that our model significantly outperforms both baselines. This finding reinforces our discussion in section 4.5, that it is necessary to train the model on new tokens that represent token lengths for the attack to be effective.

Ablation Study. We further explored the influence of training data on the efficacy of our attack. As outlined in Section 3.2, an adversary has the option to utilize either historical responses from the target AI assistant or alternative sources. In Fig. 8 we compare the performance of our model trained on ChatGPT-4 responses (victim) to the case where it is trained on a regular text corpus; the C4 dataset [27]. The C4-trained model performs significantly worse than the GPT4-trained model but still outperforms the baseline (an attack success rate of 5% vs 0.07%). Therefore, while it is clear that training on the victim's data gives the attacker a large advantage, preventing access to historical chats does not prevent the attack. Moreover, later in 5.3 we will show that this attack is even transferable, where a model trained on OpenAI's GPT-4 can be used to attack Microsoft Copilot.

Out of Distribution Prompts. The UltraChat dataset, which our model was trained on, was designed to captures specific set of topics. The question is whether our model will be able to generalize to topics not found in this dataset. To evaluate this, we gave GPT-4-Turbo a large sample of the UltraChat dataset and asked it to generate new prompts on different topics. These prompts were then sent to GPT-4-Turbo, under separate contexts, to generate the responses.

[5]The exact query language and additional results can be found in the appendix.

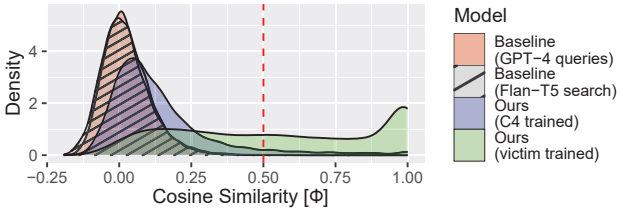

Figure 8: Comparative performance evaluation (1st segments). Green indicates our model trained on the victim's response distribution, blue represents our model trained on a generic text dataset, and red denotes the baseline model (GPT-4).

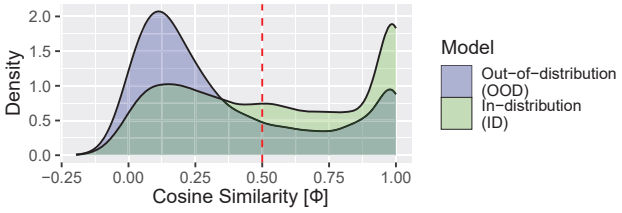

Figure 9: Performance of our model when attacking in-distribution (ID) prompts and out-of-distribution (OOD) prompts.

Figure 9 illustrates the performance of our model on both in-distribution and out-of-distribution (OOD) test sets. When inferring responses from OOD prompts, the accuracy of the ASR decreases from 53% to 28%. Despite this drop, the ability to compromise over a quarter of the messages remains notable. Regardless, this highlights the importance for adversaries to strategically prepare their attacks by incorporating prompts related to the targeted topics during training.

5.3 Framework Evaluation

In the previous section, we evaluated our model's effectiveness in ideal conditions with all tokens intact and unaltered. This section shifts focus towards validating the threat in practical scenarios, examining how our attack performs under imperfect network conditions. We examine four services from Microsoft and OpenAI. From OpenAI we looked at their in-browser assistant, GPT Marketplace, and their API. For Microsoft, we considered their in-browser assistant called Copilot. When analyzing traffic captured from these services, we noticed three consistent behaviors.

Preamble. We found that Microsoft includes a variable length preamble with the first token. The preamble includes metadata such as relevant URLs. As a result, we cannot infer the size of the first two tokens. To counter this, we trained a new version of our model where the ground truth R is complete but T would be missing the first two tokens.

	Vendor	Model	Service	ASR	$\phi > 0.9$	$\phi = 1.0$	R1 >= 0.9	R1 = 1.0	ED <= 0.1	ED = 0.0
No Buff.	OpenAI	GPT-4	in-browser	38.21	15.64	4.57	12.94	5.75	16.20	3.68
	OpenAI	GPT-4	marketplace	53.01	25.80	13.01	28.09	17.02	27.29	10.21
	OpenAI	GPT-4	API	17.69	5.06	0.82	2.65	0.99	2.40	0.57
	Microsoft	Copilot	in-browser	40.87	17.42	7.96	17.96	10.80	17.11	0.51
Buffering	OpenAI	GPT-4	in-browser	35.55	13.70	3.60	10.98	4.79	13.88	2.97
	OpenAI	GPT-4	marketplace	50.28	22.89	10.84	24.03	14.47	23.52	8.56
	OpenAI	GPT-4	API	17.69	5.06	0.82	2.65	0.99	2.40	0.57
	Microsoft	Copilot	in-browser	30.15	5.93	0.16	6.73	0.19	5.18	0.00

Table 3: Performance evaluation on vendor traffic, for best case (no groupings) and the average case. All values are reported as percent [%].

Buffering. Some services buffer tokens and send them grouped as a single message. As a result, these tokens are viewed as a single larger token during the sequence extraction step. This rarely occurs by Microsoft but frequently occurs by OpenAI depending on the time of day (see Fig. 10 in appendix). We found that the first two tokens are grouped 80% of the time, while groupings later within the response are rare. To handle this, we trained another model on an augmented dataset where tokens in T are grouped probabilistically according to statistics collected from OpenAI's traffic over a 24-hour period.

Pairing. When the GPT-4 API is set to `stream=true`, every pair of tokens is grouped together. For this, we trained model on a similarly augmented dataset.

For all four services, each message contained the current token and all prior tokens as well. For more information on other vendors, see the right side of Table 1.

We evaluated each of the services using token streams which capture the network traffic. We examined two times of day: night when there is no buffering and day when there is buffering. The results in Table 3 present the performance of the first segments. The results show that even with lost tokens, grouped tokens and paired tokens, we can still infer the content from the vendors' token-length side-channels. On the browser and marketplace assistants, we achieve an ASR of 30%-53%. On the API, where every two tokens are paired, we obtain an ASR of 17.7%.

There are two interesting takeaways from these results: (1) even if the token-stream side-channel is noisy, compressed, or incomplete, it is still possible to infer its content and (2) there is transferability between AI assistants. The latter insight is drawn from the fact that our models were trained on GPT-4 responses only, yet we still succeed when targeting Microsoft's Copilot. For examples of reconstructed prompts achieved on network traffic, please see GitHub repository. [6]

6 Discussion

Our investigation leads to two significant observations: first, our model is capable of making high-quality ($\phi > 0.9$) inferences on the initial response segment, and second, it exhibits a notable degree of success in applying the learnings from one AI assistant's responses to another. These points highlight an essential characteristic of the AI assistants: their responses are marked by a degree of predictability in style and a tendency to reuse phrases, especially noticeable in the first segment of the response, facilitating effective content inference by our model.

We observed four patterns that our model was particularly good at identifying:

Warnings. These are openings to responses that warn the user about the reliability of the response. For example, when personal questions, responses such as "*I don't have personal beliefs or interests, but...*" are common. Another example is when the model is asked about current events, the response is often in the form of "*As an AI language model, I do not have access to current data... However, ...*"

Templates. These are styles used by the assistant to frame the response and are often topic-specific. For example, if a user asks GPT-4 for a recipe it will get a response with the form "*Certainly! Here's a simple and classic recipe for...*", or when asking about travel: "*Certainly! Here are some lesser-known cultural attractions...*"

Unique Token Sequences. These are sequences of tokens that are unique in terms of n-gram frequency. For example, phrases and names such as 'Yellowstone National Park', 'The Road Not Taken', and 'renewable energy sources' are predicted perfectly quite often regardless of context.

Structure. These are formats that are included as tokens. For example, the structure of a list includes many newline tokens in a row and enumerated numbers. These patterns help the model scope and structure the inferred response.

Although this does not exist in our dataset, there are other frequent patterns that can be used to infer content. For example, AI safeguards are used to prevent users from asking illegal or unethical questions. They almost always result in a response declining the prompt but also include the context. E.g., "*I'm sorry, but I can't assist with creating content that could be used for phishing...*" Also, we note that while identifying these patterns helps the model infer them, our model is agnostic to them. For example, our model was able to perfectly infer the following segment although the training set does not include this topic at all: "*The recent economic crisis in Greece has had a severe impact on small businesses in Athens.*"

Lastly, from our evaluation in section 5.3, we note success in model transferability across different AI assistants. This points to consistency in their construction of responses, drawing a subtle comparison to transfer attacks in adversarial examples. This phenomenon not only sheds light on the potential uniformity in AI assistants' linguistic strategies but also raises questions about LLM security, hinting that their predictable patterns and phrase repetition may present other transferable vulnerabilities.

For future work, we recommend integrating other side-channel information, such as previous prompts from the same conversation, to improve context.

7 Ethics, Disclosure and Guidance

Disclosure Timeline. The side-channel attack introduced in this paper represents a practical and perilous threat that could potentially compromise the privacy of millions of individuals. Recognizing the severity of this vulnerability, we proactively reached out to all the vendors listed in Table 1 in parallel to this paper's submission (Feb. 1st 2024). Contact was made either through their bug bounty programs or through other confidential channels. Within the first month, the contacted vendors acknowledged the vulnerability and patched their systems.[7] Several vendors asked us for advice on how to fix the problem (discussed below). We also confirmed for them whether their defence was effective. We received bug bounties from OpenAI, CloudFlare and Quora as well as bug bounty recognition from Microsoft and Notion. After confirming with the vendors that their systems were protected, we made a public disclosure (March 14th) on Ars Technica[8] in parallel with a coordinated disclosure by CloudFlare.[9]

Countermeasures. To counteract the side-channel vulnerability, several mitigation strategies can be implemented:

1. **Adding Random Padding:** Incorporating random padding to each message can obscure the actual length of tokens, thereby complicating attempts to infer information based on packet size. However, this approach would inevitably lead to increased bandwidth consumption, as the padded messages consume additional network resources.

2. **Grouping Tokens:** Another effective measure is to transmit tokens in larger groups rather than individually. This method reduces the granularity of information that can be gleaned from observing the communication, thereby mitigating the risk. However, it's important to note that this could impact the real-time responsiveness that users expect from such services.

3. **Batching Responses:** Sending complete responses at once, instead of in a real-time, token-by-token manner,

[7] The exception was Perplexity, WriteSonic, CKSource and Anthropic who we repeatedly sent messages to for six weeks, but did not respond.

[8] https://arstechnica.com/security/2024/03/hackers-can-read-private-ai-assistant-chats-even-though-theyre-encrypted/

[9] https://blog.cloudflare.com/ai-side-channel-attack-mitigated

can significantly reduce the vulnerability to side-channel attacks. This approach eliminates the possibility of inferring token lengths from the packet sizes.

Despite the effectiveness of these mitigation strategies, they come with notable caveats. Specifically, the introduction of padding and the batching of responses would increase bandwidth usage, which could be a concern for services operating at scale. Moreover, grouping tokens or sending responses in batches could detract from the user experience. The real-time feedback provided by AI assistants is a key feature of their appeal and utility, especially given the inherent latency in processing large language models. Balancing security with usability and performance presents a complex challenge that requires careful consideration.

8 Related Works

Length-Based side-channels. The study of length-based side-channels reveals two primary methodologies: high-level inference, which deduces general information from a set of packets (e.g., website fingerprinting) and low-level inference, which explicitly infers plaintext from individual packets.

An example of a low-level inference attack was CRIME [30], which was revealed in 2012. The attack exploited information leakage in the LZ77 compression algorithm enabling attackers to infer plaintext in HTTPS traffic by interacting with the session. In 2015, the BICYCLE attack demonstrated the feasibility of inferring content without the need for interacting with the victim's session [12]. In this attack, a victim's password length is inferred by subtracting the size of the traffic's overhead from the traffic carrying the password.

The exploration of side-channels for plaintext inference on network traffic gained momentum in 2017 when it was shown that statistics, such as packet times and sizes, could reveal information about a query sent to a search engine on the web [24]. By employing classical ML models, the authors of [24] were able to detect the presence of specific keywords within a query but they could not decipher complete texts. However, this was solved in 2019 when the authors of [21] proposed KREEP. In their work, the authors noticed that the autocomplete feature of search websites was sending a single packet for every typed character. By measuring the victim's keystroke timings, the authors were able to infer entire search queries with an ED of about 0.4 for queries containing 7-12 words.

In contrast to the works of [21,24], our problem is different since (1) we cannot use keystroke timing to reduce character entropy, and (2) we are trying to predict sequences of tokens (~words) to the length of entire paragraphs. This distinction underlines the novelty of our approach in inferring content solely based on the length of tokens, presenting a pioneering effort in the analysis of extended texts via side-channels. Moreover, regarding the sequence prediction method, in [21] the authors used a memory-less Markovian model which only considers the previous word. However, we leverage long-distance linguistic relationships and inter-sentence context by using a modified LLM.

Side-channel Attacks using LLMs. The utility of using deep neural networks to *perform* side-channel analysis (SCA) has been well documented [3, 17, 20, 25, 26]. The primary application of deep learning in SCA is to classify (detect) known patterns in noisy and complex physical signals. Some works have used generative AI, specifically generative adversarial networks (GANs), to help create better training sets for the model to learn from [32]. To the best of our understanding, our study introduces two novel contributions to the field: it is the first instance where generative AI has been explicitly applied to reconstruct hidden information, and uniquely, it marks the first occasion where plaintext has been successfully extracted from encrypted network traffic utilizing a generative AI approach.

The risk of attackers using LLMs for malicious use cases is a growing concern. Our study aligns with the observations made in [37] which highlights the potential for malicious use of LLMs in side-channel attacks. This work not only confirms these hypotheses but also presents a concrete example of such an application.

Side-channel Attacks on LLMs. Recent studies have highlighted the vulnerability of deep neural networks to side-channel attacks, revealing that attackers can extract a model's architecture and parameters by observing behaviors in cache [13, 14, 19, 36], timing [9, 11], memory access [16] and physical signals [15, 34, 38]. Recent research by Debenedetti et al. [7] further highlights the presence of side-channels capable of revealing information about a model's training data, including the extraction of LLM vocabularies and inferring details through membership inference attacks. Our work, however, diverges significantly from these approaches. We discuss a novel side-channel attack that targets model predictions, distinct from past works which targets model parameters or training data.

9 Conclusion

This study exposes a critical vulnerability in AI assistants like OpenAI's ChatGPT-4 and Microsoft's Copilot through a novel token-length side-channel attack, achieving significant success in reconstructing and inferring encrypted responses. By leveraging large language model capabilities, context integration, and known-plaintext attack techniques, we are able to perform a token-inference attack that can expose over half of the responses sent back from these assistants. The research underscores the importance of addressing this security flaw and highlights the broader security implications for large language models, pointing to a need for enhanced privacy measures in AI-powered digital services.

Appendix

A Details on Experiment Setup

Setup of Baseline Model (GPT-4) The following is an example of the prompt template used to ask GPT-4 to infer R from T:

GPT-4 Inference Prompt

> Transform the given sequence of numbers into a coherent sentence where each number represents the length of a word in the sentence. For example, the sequence '7, 10, 10, 9, 3, 4, 5, 3, 2, 5, 1' could be transformed into 'Contact allergies typically manifest on the skin as a rash,'
>
> Please use the following sequence to generate a new sentence: **<encoding>**.
>
> Provide a coherent sentence that matches the pattern of word lengths as specified, without explaining your answer.

Setup of Framework Evaluations (Groupings) Here we present how many tokens are grouped by OpenAI's ChatGPT in-browser service over a 24 hour period. The statistics from this data where used to augment the datasets with groupings.

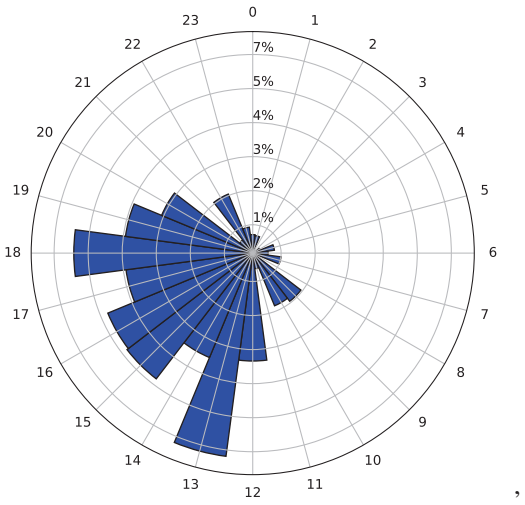

Figure 10: Percentage of grouped tokens in R by OpenAI across various times of the day.

B Additional Results

In Fig. 11 we provide another view of topic exposure among the first segments. Here, we asked ChatGPT-4 Turbo to classify the segments into 15 categories based on subject alone.

In Fig. 12 we show the relationship between the first segment's performance and its performance with its subsequent segments. As described in the paper, we can see that the performance of the paragraph is largely dependent on the performance of the first segment. However, interestingly, we see that for poor starts ($\phi < 0.4$), letting the model see more sentences improves paragraph performance. This indicates that the model can use long term patterns to help resolve local patterns in T.

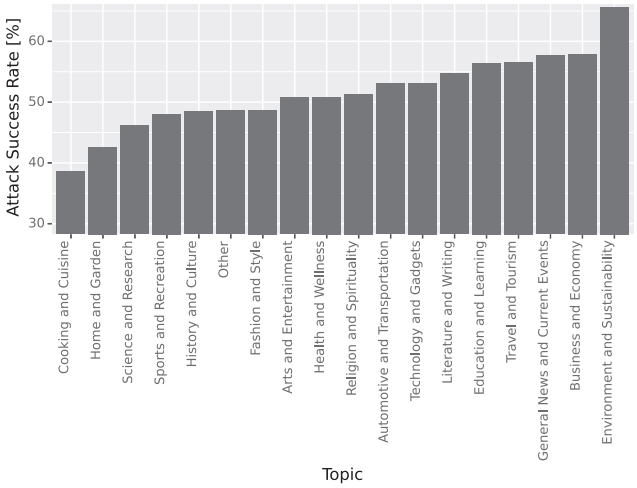

Figure 11: Attack success rates on first segments, grouped by subject material by GPT-4 Turbo.

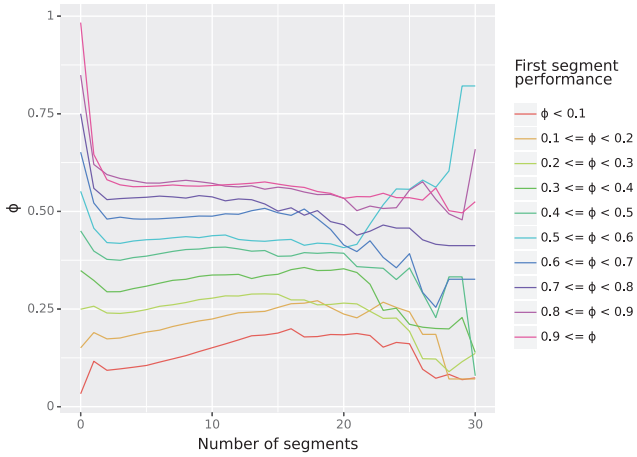

Figure 12: Performance of paragraph reconstruction by paragraph length, with each color indicating the performance when the first segment has a specific ϕ value. The initial segment's performance influences the accuracy of subsequent sentences in a paragraph.

The following is a random sample of full paragraphs inferred from ChatGPT-4:

Paragraph Reconstruction Examples

ϕ : 0.93 ROUGE-1: 0.75 Edit Distance: 0.26

Original: As an AI language model, I don't have personal experience or emotions, but below are some strategies that can help in developing a self-compassionate attitude:
1. Practice mindfulness - Mindfulness can help you identify and observe your thoughts and emotions without judging or reacting to them. This can help you develop a more compassionate attitude towards yourself.
2. Treat yourself with kindness - In stressful situations, treat yourself the way you would treat a friend or loved one. Do something kind for yourself, such as taking a break, self-care activities, or giving yourself a compliment.
3. Change your self-talk - Instead of being self-critical or negative, try to reframe your self-talk in a positive and supportive manner.
4. Accept your imperfections - Acknowledge that everyone makes mistakes and has flaws, including yourself. Learn to accept yourself for who you are, imperfections and all.
5. Be patient with yourself - Give yourself time to process and bounce back from stressful situations. Remember that healing and growth take time.
6. Seek support - Reach out to friends, family, or a mental health professional for support, guidance,
Prediction: As an AI language model, I don't have personal experience or emotions, but below are some strategies that can help in developing a self-compassion attitude:
1. Practice mindfulness - Mindfulness can help you identify and process your emotions and thoughts without judging or reacting to them. This can help you develop a more compassionate attitude towards yourself.
4. Treat yourself with kindness - By embracing compassion,treat yourself the way you would treat a friend or loved one. By accepting your own mistakes, such as taking a break,resuming activities, or simply avoiding a temptation.
4. Change your self-talk - Instead of going into a battle or argument,try to reframe your self-talk in a positive and supportive manner.
3. Accept your imperfections - Acknowledge that everyone makes mistakes and has flaws. Challenge yourself, learn to accept yourself for who you are, treat oneself kindly.
5. Be patient with yourself - Your personal life is complex and unique with many different challenges. Practice self-control and manage your time.
6. Seek support - Reach out to friends,family, or a mental health professional for support, guidance,

C Volunteer Survey

To objectively find an ϕ cutoff value for our ASR, we performed a survey described in section 5.1. The following is the text used in the survey:

Introduction

When sending messages across the Internet, we expect that no one except the intended party will be able to read them. In this survey, we are trying to assess how much one's privacy is violated when a message is partially revealed.

In this questionnaire, you will be given two messages: **A** and **B**.

- '**A**' is a private message sent over the Internet.
- '**B**' is what an attacker sees.

You will be asked whether the topic of message '**A**' is revealed by '**B**'. In other words, was there a breach of privacy?

Example Question:

(**A**) Message: In order to register as a political party in New Zealand,

(**B**) Attacker View: In order to function as a political party in New Zealand,

Is the content or topic of (**A**) revealed in any way in (**B**)?
YES NO

NetShaper: A Differentially Private Network Side-Channel Mitigation System

Amir Sabzi, Rut Vora, Swati Goswami, Margo Seltzer, Mathias Lécuyer, Aastha Mehta
The University of British Columbia

Abstract

The widespread adoption of encryption in network protocols has significantly improved the overall security of many Internet applications. However, these protocols cannot prevent *network side-channel leaks*—leaks of sensitive information through the sizes and timing of network packets. We present NetShaper, a system that mitigates such leaks based on the principle of traffic shaping. NetShaper's traffic shaping provides differential privacy guarantees while adapting to the prevailing workload and congestion condition, and allows configuring a tradeoff between privacy guarantees, bandwidth and latency overheads. Furthermore, NetShaper provides a modular and portable tunnel endpoint design that can support diverse applications. We present a middlebox-based implementation of NetShaper and demonstrate its applicability in a video streaming and a web service application.

1 Introduction

With the proliferation of TLS and VPN, traffic encryption has become the de facto standard for securing data in transit in Internet applications. Traffic can be encrypted at various layers, such as HTTPS, QUIC, and IPSec. While these protocols prevent *direct* data breaches on the Internet, they cannot prevent leaks through *indirect* observations of the encrypted traffic.

Indeed, encryption cannot conceal the shape of an application's traffic, i.e., the sizes, timing, and number of packets sent and received by an application. In many applications, these parameters strongly correlate with sensitive information. For instance, traffic shape can reveal video streams [55], website visits [14, 66], the content of VoIP conversations [69], and even users' medical and financial secrets [19].

In such *network side-channel leaks*, an adversary (e.g., a malicious or a compromised ISP) observes the shape of an application's traffic as it passes through a link under its control and infers the application's sensitive data from this shape.

Obfuscation techniques, which add ad hoc noise [44] or adversarial noise [6, 30, 34, 49, 51, 56] in an application's network traces, do not provide comprehensive protection against network side-channel attacks [73]. In fact, recent advances in machine learning (ML) have greatly improved the ability to filter out noise due to congestion or path variations and infer secrets from noisy data [14, 31, 55, 58]. For instance, our own novel classifier based on Temporal Convolution Networks (TCN) [9] can infer video streams even from short bursts of noisy measurements over the Internet (see §2 for details). Alternatively, a sensitive application could try to improve side-channel resilience by splitting traffic over multiple network paths [22, 65] or by using dedicated physical links that are not controlled by the adversary. However, such solutions are inadequate against a powerful adversary that can monitor a large fraction of the Internet [13] and may incur prohibitive network administration costs for small users on the Internet.

In contrast, a principled and practical approach to mitigating network side-channel leaks is *traffic shaping*. It involves modifying the victim's packet sizes and timing to make the resultant shape independent of secrets, so that an adversary cannot infer the secrets despite observing the (shaped) traffic.

Constant shaping involves sending fixed-sized packets at a constant rate, which is secure but incurs non-trivial bandwidth and/or latency overhead for applications with variable or bursty workloads [54]. Variable shaping strategies attempt to adapt traffic shapes to reduce the overhead at the cost of some privacy. However, the state-of-the-art (SOTA) variable shaping strategies rely on ad hoc heuristics that yield weak privacy guarantees [50, 66, 67] or unbounded privacy leaks [16, 17, 29, 36, 43]. Some techniques provide strong guarantees but require extensive a priori profiling of an applications' traffic to compute shapes [45, 73].

In addition to a shaping strategy, network side-channel mitigation also requires a robust implementation of packet padding and transmit scheduling. Many solutions attempt to protect traffic by controlling shaping from only one end of a communication (i.e., either a client or a server) and provide only best-effort protection [20, 44, 59]. Other solutions rely on trusting third-party mediators (e.g., Tor bridges), which implement shaping between the clients and mediators and between the servers and mediators [48, 70]. In Pacer [45], both applica-

tion endpoints integrate a shaping system to comprehensively mitigate network side channels. However, Pacer encumbers application end hosts with non-trivial changes in the network stack to implement shaping, thus deterring adoption.

In this work, we address two main questions. First, is there a variable traffic shaping strategy that provides quantifiable and tunable privacy guarantees at runtime without requiring extensive pre-profiling of application traffic? Second, can traffic shaping be provided as a generic, portable, and efficient solution that can be integrated in different network settings and can support diverse applications?

We present NetShaper, a network side-channel mitigation system that answers both questions in the affirmative. First, NetShaper relies on a differential privacy (DP) based traffic shaping strategy, which provides quantifiable and tunable privacy guarantees. NetShaper specifies the privacy parameters for a configurable window of transmission. Moreover, it can configure the parameters independently for each direction of traffic on a communication link. The DP guarantees can be composed based on these parameters to achieve bounded privacy leaks for arbitrary bidirectional traffic. Overall, applications can tune the shaping based only on the privacy guarantees they desire and the overheads they can afford, without the need for profiling their traffic. While strong privacy guarantees require DP parameters that incur large overheads, in practice, NetShaper can defeat SOTA attacks with even small amounts of DP noise, thus incurring low overheads.

Secondly, we present a traffic shaping tunnel with a modular endpoint design that can conceptually be integrated with any network stack and within any node. The tunnel implements padding and transmit scheduling of packets while adhering to the DP guarantees *by design*. By placing the tunnel endpoint in a middlebox at the edge of the private network, NetShaper can simultaneously protect the traffic of multiple applications. Moreover, the middlebox can amortize the shaping overheads among multiple flows without compromising the privacy for individual flows.

Together, the DP shaping strategy and NetShaper's tunnel provide effective network side-channel mitigation for diverse applications, such as video streaming and web services, with modest overheads. To the best of our knowledge, NetShaper is the first system to provide dynamic traffic shaping with quantifiable and tunable privacy guarantees based on DP.

Contributions. (i) We design a new attack classifier based on a Temporal Convolution Network (TCN) [9] and demonstrate its ability to infer videos streams from traffic shapes under noisy network traffic measurements in the Internet (§2). (ii) We model network side-channel mitigations as a differential privacy problem and provide a traffic shaping strategy that offers (ε,δ)-differential privacy guarantees (§3). (iii) We design a QUIC-based traffic shaping tunnel and present a middlebox-based implementation of the tunnel, which supports traffic shaping while adhering to DP guarantees (§4). (iv) We demonstrate NetShaper's efficacy in defeating a SOTA classifier [55] and our new TCN classifier. We empirically evaluate the tradeoffs between NetShaper's privacy guarantees and performance overheads while mitigating network side-channel leaks in two classes of applications that have already been used in prior work, namely video streaming and web service (§5). (vi) We present a formal proof of NetShaper's differential privacy guarantees (§C).

2 Background, Motivation, and Overview

2.1 Network Side-Channel Attacks

We start by explaining the workings of a network side-channel attack with an example application. Consider MedFlix, a fictitious medical video service that offers videos on symptoms, treatment procedures, and post-operative care. The goal of an adversary is to infer the videos streamed by users visiting the service. ISPs can aggregate such information to build per-user profiles and subsequently monetize them. Additionally, competitors might exploit network side channels to acquire corporate intelligence without detection.

The adversary performs the attack in two stages. First, the adversary requests each video from the medical service as a client and collects traces of the bidirectional network traffic generated while streaming each video. The adversary may collect multiple traces for each video stream to account for network variations in the traffic. The adversary then builds a classifier over the captured traces to identify the video streams. Prior work has used several features for classification, such as packet sizes, inter-packet timing, total bytes transferred in a burst of packets, the burst duration and inter-burst interval, and the direction of packets or bursts [55].

We reproduce the Beauty and the Burst (BB) classifier [55], a state-of-the-art CNN classifier for classifying video streams from network traces. Furthermore, we present a new TCN classifier [9], which is an improvement over the BB classifier. We describe the classifiers in §A. Here, we evaluate the efficacy of the two classifiers for a network side-channel attack.

We set up a video service and a video client as two Amazon AWS VMs placed in Oregon and Montreal, respectively. The video server hosts a dataset of 100 YouTube videos at 720p resolution with MPEG-DASH encoding [68]. The client streams the first 5 min of each video over HTTPS and collects the resulting network packet traces using tcpdump. We stream each video 100 times, thus collecting a total of 10,000 traces.

The classifiers' goal is to predict the video from a network trace. For each classifier, we transform each packet trace into a sequence of burst sizes transmitted within 1s windows and normalize the sequence by dividing each burst size by the total size of all bursts. We evaluate the performance of both classifiers with three datasets: a small dataset consisting of 20 videos with their 100 traces each (i.e., total 2000 traces), a medium dataset with 40 videos (4000 traces), and a large dataset comprising all 100 videos (10000 traces). We train the

classifiers for 1000 epochs with an 80-20 train-test split. BB's classification accuracy, recall, and precision with the small dataset are 0.85, 0.85, and 0.78, respectively, which drop to 0.61, 0.63, and 0.49, respectively, with the medium dataset, and further drop to 0.01 each for the large dataset. TCN's accuracy, recall, and precision are above 0.99 for all datasets. TCN performs better than BB because it is a complex model with residual layers and, hence, is robust to noise in the traces.

Similarly, advanced ML classifiers are capable of identifying web traffic [14, 58]. In general, classifiers will continue to evolve, increasing the adversary's capabilities to make inferences from noisy measurements. Hence, we need principled mitigations that address current SOTA attacks and achieve quantifiable leakage, which can be configured based on privacy requirements and overhead tolerance.

2.2 Key Ideas

A secure and practical network side-channel mitigation system must satisfy the following design goals: **G1.** Mitigate leaks through all aspects of the shape of transmitted traffic, **G2.** Provide quantifiable and tunable privacy guarantees for the communication parties, **G3.** Minimize overheads incurred while guaranteeing privacy, **G4.** Support a broad class of applications, and **G5.** Require minimal changes to applications.

NetShaper's shaping prevents leaks of the traffic content through sizes and timing of packets transmitted along each direction between application nodes (G1). In addition, NetShaper relies on the following three key ideas.

Differentially private shaping. Unlike constant shaping, variable shaping can adapt traffic shape, potentially based on runtime workload patterns, and thus significantly reduce shaping overheads. Unfortunately, existing variable shaping techniques either have unbounded privacy leaks, offer only weak privacy guarantees, or require extensive profiling of an application's network traces. NetShaper's novel differential privacy (DP) based shaping strategy provides quantifiable and tunable bounds on privacy leaks, without relying on profiling of application traffic (G2). NetShaper shapes an application's traffic in periodic, fixed-length *shaping intervals* and provides DP in the length of the application byte stream (burst) accumulated within each interval. The DP guarantees compose over a sequence of multiple intervals and, thus, for streams of arbitrary length (albeit with degraded guarantees).

Shaping in a middlebox. NetShaper uses a tunnel abstraction to implement traffic shaping. The tunnel shapes application traffic such that an adversary observing the tunnel traffic cannot infer application secrets. In principle, a tunnel endpoint could be integrated with the application host (e.g., in a VM isolated from the end-host application) or in a separate node through which the application's traffic passes. NetShaper relies on the second approach and implements the tunnel endpoint as a middlebox, which could be integrated with an existing network element, such as a router, a VPN gateway, or a firewall. The middlebox implementation enables securing multiple applications without requiring modifications on individual end hosts (G4). Furthermore, it allows pooling multiple flows with the same privacy requirements in the same tunnel, which helps to amortize the per-flow overhead (G3).

Minimal modifications to end applications. By default, NetShaper shapes all traffic through a tunnel with a fixed differential privacy guarantee. However, an application can explicitly specify different DP parameters to adapt the privacy guarantee enforced for its traffic, as well as bandwidth and latency constraints and any prioritization preferences on a per-flow basis. This requires only a small modification in the application; it must transmit a shaping configuration message to the middlebox. Thus, NetShaper offers a balance between being fully application-agnostic and optimizing for privacy or overhead with minimal support from applications (G2, G5).

2.3 Threat Model

NetShaper's goal is to hide the content of an application's network traffic. Hiding the type of traffic [57], the communication protocol [70], or the application identity [21, 27] are non-goals, although NetShaper can adapt its shaping strategy to address these goals. The applications are non-malicious and do not leak their own secrets.

We assume that the application endpoints are inside separate trusted private networks (e.g., each node is behind a VPN gateway node) and the adversary cannot infiltrate the private network, or the clients and servers within it. (Thus, we exclude covert attacks [72] and colocation-based attacks [45, 55]). The adversary controls network links in the public Internet (e.g., ISPs) and can record, measure, and tamper with the victim application's traffic as it traverses the links under the adversary's control. The adversary can precisely record the traffic shape – the sizes, timing, and direction of packets – between the gateway nodes. In particular, it may have access to observations of arbitrary known streams to train its attack. It may also have knowledge about NetShaper, including its shaping strategy and privacy configurations.

We do not consider threats due to observing the IP addresses of packets [32], although NetShaper can hide IP addresses of applications behind a shared traffic shaping tunnel.

NetShaper does not address leaks of one application's sensitive data through the traffic shape of colocated benign applications. Such leaks can arise, for instance, due to microarchitectural interference among applications colocated on a host or among their flows if they pass through shared links. End hosts could implement orthogonal mitigations against colocated applications [15, 39, 45, 63] and combine NetShaper's shaping with TDMA scheduling on network links [12, 64].

We present a middlebox-based NetShaper implementation that can be integrated with an organization's trusted gateway router. NetShaper's trusted computing base (TCB) includes all components in the organization's private network and the

middleboxes. Bugs, vulnerabilities or side channels in the middleboxes that threaten traffic confidentiality could be mitigated using orthogonal techniques, such as software fault isolation [61], resource partitioning [42], and constant-time implementation techniques [7].

Under these assumptions, NetShaper prevents leaks of application secrets through the sizes and timing of packets transmitted in either direction between the application endpoints.

2.4 A Primer on Differential Privacy

Finally, we provide a brief primer on DP, the steps involved in building a DP mechanism, and the key properties of DP that are relevant in the context of traffic shaping (§3).

Developed originally for databases, DP is a technique to provide aggregate results without revealing information about individual database records. Formally, a randomized algorithm $\mathcal{M}$ is (ε,δ)-DP if, for all $\mathcal{R} \subseteq \text{Range}(\mathcal{M})$ and for all *neighboring* databases d, d' that differ in only one element:

$$P[\mathcal{M}(d) \in \mathcal{R}] \leq e^{\varepsilon} P[\mathcal{M}(d') \in \mathcal{R}] + \delta \qquad (1)$$

The parameter ε represents the *privacy loss* of algorithm $\mathcal{M}$, i.e., given a result of $\mathcal{M}$, the information gain for any adversary on learning whether the input database is d or d' is at most e^{ε} [37]. The δ is the probability with which $\mathcal{M}$ fails to bound the privacy loss to e^{ε}.

Building such a randomized DP algorithm $\mathcal{M}$ involves three main steps: (i) defining neighboring database states, (ii) defining a database query and determining the sensitivity of the query to changes in neighboring databases, and (iii) adding noise to the query. Neighboring databases d and d', as mentioned above, are characterized by the *distance* between the databases, which quantifies the granularity at which the DP guarantee applies. Traditionally, this distance is defined as the number of records that differ between d and d'. However, DP also extends to other neighboring definitions and distance metrics used in specific settings [18, 41].

Given a database query q, the sensitivity of the query Δq is the max difference in the result achieved when the query is executed on the neighboring databases d and d'. Intuitively, a larger Δq implies higher probability of an adversary inferring from a result the database on which the query was executed, thus incurring higher privacy loss. To mitigate this privacy loss, a DP mechanism therefore adds noise to the query result to hide the true result and the underlying database. Popular noise mechanisms are Laplace [26, §3.3] and Gaussian [23].

DP provides three properties. As we will show in §3.2, these are also of relevance to NetShaper's DP traffic shaping. First, DP is resilient to post-processing: given the result r of any (ε,δ)-DP mechanism $\mathcal{M}$, any function $f(r)$ of the result is also (ε,δ)-DP. As a result, any computation or decision made on a DP result is still DP with the same guarantees. Second, DP is closed under adaptive sequential *composition*: the combined result of two DP mechanisms $\mathcal{M}_1$ and $\mathcal{M}_2$ is also DP, though with higher losses (ε and δ). We use the Rényi-DP definition [47] to achieve simple but strong composition results and subsequently convert the results back to the standard DP definition. Third, DP is robust to auxiliary information: the guarantee from Equation 1 holds regardless of any side information known to an attacker. Therefore, the attacker's knowledge of the shaping mechanism does not affect its privacy guarantees. That is, an attacker knowing or controlling part of the database cannot extract more knowledge from a DP result than without this side information.

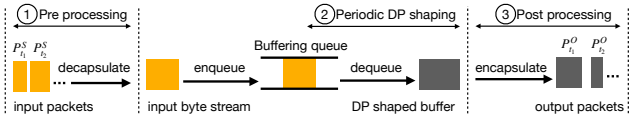

Figure 1: Overview of DP shaping

3 Differentially Private Traffic Shaping

The goal of differentially private shaping is to dynamically adjust packet sizes and timing based on the available data stream, while ensuring that the DP guarantees hold for any information that an adversary (§2.3) can observe.

We first formally model an application's input stream as a packet sequence $S = \{P_1^S, P_2^S, P_3^S, \dots\}$, where $P_i^S = (l_i^S, t_i^S)$ indicates that the i^{th} input packet in S has length l_i^S bytes and is transmitted at timestamp t_i^S. We call the total duration of a finite stream $\tau^S \triangleq \max t_i^S - t_1^S$. Without shaping, an adversary can precisely observe S and infer the content, which is correlated with the stream (§2.1).

Figure 1 provides a high-level overview of the differentially-private shaping mechanism. Shaping happens in periodic intervals of fixed length T, called the *DP shaping intervals*. (1) As the packets in an application's stream arrive, the payload bytes extracted from the packets are placed into a *buffering queue*, Q. (2) In each periodic interval, the DP shaping algorithm performs a *DP query*: it measures the length of Q with DP, to determine the number of bytes to transmit in the next interval. NetShaper then prepares a DP shaped buffer using the payload bytes from Q, and additional dummy bytes if required. This shaped buffer is enqueued to be sent over the network at the end of the DP shaping interval, right before the next interval starts. (3) Finally, data in the shaped buffer may be split into one or more packets, as part of a post-processing step, and transmitted to the network.

The size of each shaped buffer generated in an interval has $(\varepsilon_T, \delta_T)$-DP guarantees. The per-interval guarantees compose over a sequence of multiple intervals, thus providing DP guarantees for traffic streams of arbitrary lengths. The guarantees degrade as the stream length increases (Prop 2)

We now discuss the steps of building a DP mechanism for traffic streams in §3.1 and the privacy guarantees in §3.2.

3.1 DP for Traffic Streams

We now discuss the three steps for building a DP mechanism on traffic streams. Specifically, we present our neighboring definition for streams, define the DP query on streams that NetShaper runs and bounds its sensitivity, and show the DP mechanism that we use to make the query DP.

Step 1: Neighboring Definition. Building a DP mechanism requires a suitable definition of neighboring streams, which requires a notion of distance between streams. The neighboring definition has two implications. First, it determines the sensitivity for a "query" subject to the DP mechanism and, in turn, the amount of noise necessary for ensuring a given DP guarantee. Second, it defines the granularity of privacy guarantee: intuitively, neighboring streams are indistinguishable based on only the results of the DP mechanism applied to them. Hence, we aim for a neighboring definition for which "streams have many neighbors", and the sensitivity of the DP query we want to run is as low as possible.

Defining neighbors over streams has two challenges. First, the streams can be arbitrarily long and the distance between streams would typically increase with stream length. Secondly, if we consider streams with packet timestamps at the finest granularity, the distance between the streams may be as large as the sum of sizes of all packets in both streams. Both these factors imply that a stream would either have few neighbors (enabling weak privacy), or the neighboring definition would need to specify a large distance threshold, requiring a lot of noise for strong DP guarantees.

To keep the neighboring distance threshold small, we take two steps. First, we define the notion of a *neighboring window*, which is a time interval of configurable length W over input streams. For notational convenience, we set W as an integral multiple of the DP shaping interval T and write $W = kT$, although this is not a strict requirement.

Secondly, to measure the distance between streams over a neighboring window, we consider the total bytes in each stream (burst lengths) transmitted within coarse-grained time intervals and use the difference in the burst lengths in the intervals within the window. Intuitively, we need an interval granularity that is coarse enough to generate similar burst length sequences in more streams, but is also small enough to bound the accumulation of differences over time (to bound sensitivity, our next step). As will become clear with Prop 1, the DP shaping interval T is the coarsest granularity that we can use. Hence, considering a neighboring window starting at a timestamp t_w, i.e., $[t_w,\ t_w + W)$, we define the following representation of stream S over the window $[t_w,\ t_w + W)$ at granularity T: $S_{t_w,W} = \{L^S_{t_w}, L^S_{t_w+T}, L^S_{t_w+2T}, \ldots, L^S_{t_w+(k-1)T}\}$, where $L^S_t \triangleq \sum_{(l^S_i, t^S_i)\in S} \mathbb{1}\{t^S_i \in [t, t+T)\} l^S_i$ is the total application bytes accumulated in Q in the interval $[t, t+T)$.

We now present the following neighboring definition:

Definition 1. *Two streams S and S' are neighbors if, for any neighboring window $[t_w,\ t_w + W)$, the L1-norm distance between their representations $S_{t_w,W}$ and $S'_{t_w,W}$ is less than Δ_W. Formally, S and S' are neighbors if:*

$$\max_{t_w} \left\| S_{t_w,W} - S'_{t_w,W} \right\|_1 \leq \Delta_W. \tag{2}$$

We utilize the L1-norm (the sum of absolute values) to quantify the distance between two traffic streams, as it captures differences in both traffic size and temporal alignment, at the granularity of T. We will show (in Prop 1) that despite our restriction of defining neighboring streams at a granularity of T, and of computing distances over windows of length W, we can quantify NetShaper's DP guarantees for streams at any granularity and of any length.

The neighboring window length W and neighboring distance Δ_W are both configuration parameters, which are set before the start of an application's transmission. In practice, W would be in the order of milliseconds to seconds. Subsequently, one would determine Δ_W based on the typical difference of traffic between application streams over windows of length W. The practical upper bound for Δ_W is the NIC's line rate times window length W, but smaller values based on domain knowledge are often possible.

Step 2: DP query and sensitivity. In NetShaper, a DP query measures the buffering queue length L with DP at intervals T. This noisy measurement determines the number of bytes that must be transmitted in the interval. To make the measurement of L differentially private, we need to bound the sensitivity Δ_T of the queue length variable L. This sensitivity Δ_T is the maximum difference in L that can be caused by changing one application stream to neighboring one. Formally, consider two alternative neighboring streams S and S' passing through the queue. Suppose that when transmitting S (similarly S'), the queue length at time k is denoted by L_k (respectively L'_k). Then, assuming w.l.o.g. that $k \geq k'$:

$$\Delta_T = \max_{k=0}^{\tau} \max_{S,S'} |L_k - L'_k| \tag{3}$$

Bounding Δ_T is still challenging though, as our neighboring definition only bounds the difference in traffic between two streams over any window of length upto W. Because of this, when $\tau >> W$, differences between what S and S' would enqueue in Q can accumulate over time, and the difference betwen L_t and L'_t can grow unbounded over time.

To bound Δ_T, NetShaper relies on the key assumption that the tunnel can always transmit all incoming data from application streams within any W-sized time window. That is,

Assumption 1. *All bytes enqueued prior to or at time t are transmitted by time $t + W$.*

To enforce this assumption, NetShaper implements a time to live in the buffering queue, flushing all bytes older than W from Q (see §4 for more details). Intuitively, this assumption caps the accumulation of traffic differences in Q to the maximum difference over W, i.e., Δ_W. Since the size of Q

cannot differ by more than Δ_W when changing a stream by a neighboring one, the difference between DP query results of Q under two neighboring streams—which is the sensitivity of the DP query, Δ_T—is upper-bounded by Δ_W. Formally:

Proposition 1. *NetShaper enforces* $\Delta_T \leq \Delta_W$.

Proof sketch. Consider any two streams S and S', as in Equation 3, and any measurements time k. The proof proceeds in two steps. First, under Assumption 1, streams can accumulate queued traffic for at most W, so two different streams can create a difference $|L_k - L'_k|$ of at most Δ_W. Second, dequeuing can only make two different queues closer: Consider query time k, with queue lengths $L_k > L'_k$ (the opposite case is symmetric). For a DP noise draw z, we have $\tilde{L}_k > \tilde{L}'_k$. Since shaping sends at least as much data under $\tilde{L}_k$ as under $\tilde{L}'_k$, but no more than $\tilde{L}_k - \tilde{L}'_k$, after dequeuing we have $|L'_{k+1} - L_{k+1}| \leq |L'_k - L_k|$. In summary, the queue difference under two different streams Δ_T can grow to at most Δ_W due to data queuing, and dequeuing only decreases that difference, and hence $\Delta_T \leq \Delta_W$. The complete proof is in §C. □

Step 3: Adding Noise. With sensitivity bounded at Δ_W, we can now query L with DP using an additive noise mechanism, which entails sampling noise z from a DP distribution and computing the DP buffer queue length as $\tilde{L}_k \triangleq L_k + z$. Specifically, NetShaper uses the Gaussian mechanism, in which the noise z is sampled from a centered normal distribution $z \sim \mathcal{N}(\mu, \sigma^2)$, where the variance is parameterized by ε_T, δ_T, and Δ_W: $\sigma^2 = (2\Delta_W^2)/(\varepsilon_T^2)\ln(1.25/\delta_T)$. Parameters ε_T, δ_T determine the amount of noise added to each DP query result.

3.2 Privacy Analysis

The previous section defines $(\varepsilon_T, \delta_T)$-DP guarantees for the traffic transmitted in an individual shaping interval. We now discuss (i) the guarantees for longer application streams, (ii) the guarantees on a packet-level sequence derived from a shaped buffer sequence, and (iii) the privacy implications for streams that fall outside of the neighboring definition.

Guarantees for streams. Recall from the previous section that shaping happens at intervals T; in each interval we perform a DP query on the buffering queue length L and create a shaped buffer of length $\tilde{L}$, which is subsequently queued for transmitting over the network at the end of the interval. Enqueueing data into the shaped buffer at the end of each shaping interval creates a sequence of states for the shaped buffer $\{(\tilde{L}_1, T), (\tilde{L}_2, 2T), (\tilde{L}_3, 3T), \dots\}$. Although this sequence is not technically observable by an adversary, this is where we prove our DP guarantees using DP composition over queries performed during the stream transmission.

Proposition 2. *For any stream S of duration $\tau^S \leq \tau$, NetShaper enforces (ε, δ)-DP for the sequence $\{(\tilde{L}_1, T), (\tilde{L}_2, 2T), (\tilde{L}_3, 3T), \dots\}$, with $\varepsilon, \delta \triangleq$ DP_compose$(\varepsilon_T, \delta_T, \lceil \frac{\tau}{T} \rceil)$.*

Proof. Consider two neighboring streams S and S'. By design, the times at which shaped buffers are queued are independent of application data, so $\{(\tilde{L}'_1, T'), (\tilde{L}'_2, 2T'), (\tilde{L}'_3, 3T'), \dots\} = \{(\tilde{L}_1, T), (\tilde{L}_2, 2T), (\tilde{L}_3, 3T), \dots\}$, and we can restrict our considerations to the sequences $\{\tilde{L}_1, \tilde{L}_2, \tilde{L}_3, \dots\}$ and $\{\tilde{L}'_1, \tilde{L}'_2, \tilde{L}'_3, \dots\}$. By Prop. 1, the sensitivity of each measurement is at most Δ_W. By the Gaussian DP mechanism, the measured queue size $\tilde{L}$ in each interval is $(\varepsilon_T, \delta_T)$-DP. Using DP composition over the $\lceil \frac{\tau}{T} \rceil$ DP queries made during any duration τ yields the (ε, δ)-DP guarantee. □

We use Rényi-DP composition on the Gaussian mechanism for DP_compose(). NetShaper provides a DP guarantee for streams of any length t, with the guarantee degrading gracefully as DP composition (of order $\sqrt{\tau}$ as the length grows).

Guarantees for packet sequences. Data from the shaped buffer is sent over the network, and transmitted as a packet sequence denoted by $O = \{P_1^O, P_2^O, P_3^O \dots\}$. These packets are a post-processing of the DP-shaped buffer. As long as the packets are generated independently of any secret data, they preserve the DP guarantees of shaping due to the post-processing property of DP. This yields the following result, directly implied by Prop 2 and DP post-processing:

Corollary 1. *For any stream S of duration $\tau^S \leq \tau$, NetShaper enforces (ε, δ)-DP for its output packet sequence O, with $\varepsilon, \delta \triangleq$ DP_compose$(\varepsilon_T, \delta_T, \lceil \frac{\tau}{T} \rceil)$.*

Privacy for non-neighboring streams. Finally, if the distance between two streams is larger than Δ_W, e.g., say $k\Delta_W$ for some factor k, NetShaper still provides a (degraded) DP guarantee through group privacy [26, Theorem 2.2] applied to the Gaussian mechanism. Namely, a DP query in each shaping interval T for the non-neighboring stream provides $(k\varepsilon_T, \delta_T)$-DP, and the guarantees can be extended for the stream duration τ by applying DP composition to this new value.

Interpretation of the guarantees. NetShaper's shaping algorithm provides a $(\varepsilon_T, \delta_T)$-DP guarantee on the volume of application traffic enqueued (in the buffering queue) in a fixed-length interval (and, by post-processing, the volume of traffic observable on the network). Under perfect timing for the DP shaping interval T, the DP guarantee ensures that two neighboring streams, i.e., their contents, are indistinguishable with the probability as defined in Equation 1. Smaller ε_T and δ_T implies higher noise in shaping, which increases the uncertainty about the original stream in the shaped traffic.

Secondly, to enforce the DP guarantees, the DP noise of the Gaussian mechanism does not depend on the total number of flows. Intuitively, the DP guarantee is shared among all the streams multiplexed through the buffering queue simultaneously for a fixed amount of noise, and the overhead (i.e., noise added) gets amortized among the streams.

Privacy vs Performance. NetShaper's shaping mechanism introduces several parameters which impact privacy and performance, specifically latency and bandwidth overheads.

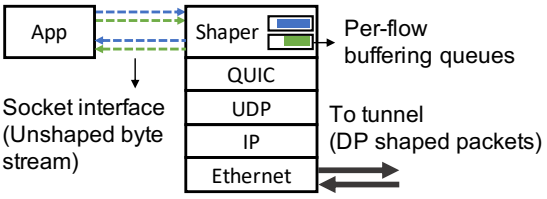

Figure 2: Overview of tunnel design (one endpoint)

These parameters include ε_T, δ_T, Δ_W, W, and T. Larger Δ_W requires lower ε_T for stronger privacy, which implies noisier measurements. Noisy measurements imply more overhead—when the noise is positive, dummy bytes need to be sent, incurring higher bandwidth overhead; when the noise is negative, fewer bytes are sent and the unsent bytes accumulated in the buffering queue incur a latency overhead. This is the privacy-overhead trade-off we expect from DP.

Additionally, the parameters T and W have a more subtle impact on the privacy-overhead trade-off. Traffic is shaped in intervals of T; thus, T impacts the latency and burstiness of the traffic. A smaller T provides lower transmission latency and smaller bursts per interval. However, it also requires more DP queries and, thus, incurs higher privacy loss when transmitting the complete stream of a given length τ. In practice, one would set T to the maximum value that can minimize privacy loss while providing tolerable latency.

A large W for a fixed Δ_W implies that neighboring streams can differ by at most Δ_W over a longer window size W, which weakens the neighboring definition and, hence, the privacy guarantees. While smaller W is desirable, the lower bound is T. Recall that, to bound Δ_T (Assumption 1), NetShaper must drop any bytes left in the buffering queue for longer than W. Since data leaves the buffering queue in each shaping interval after a DP query, setting $W = T$ would lead to immediate dropping of the bytes from the buffering queue that aren't transmitted in response to the DP query. This would happen in each interval where the DP query samples a negative noise value. These data drops would degrade NetShaper's performance in terms of both throughput and latency. Hence, we need $W >> T$ to ensure that data has time to leave the buffering queue before it is too old. Typically, one would set W based on application domain knowledge, such as the maximum size of a web request or the fact that videos often consist of a sequence of segments requested at 5s intervals.

We analyze the impact of different choices for these parameters on the privacy guarantees and overheads in §5.

4 Traffic Shaping Tunnel

A tunnel must address three requirements. First, it must satisfy DP guarantees. For this, the tunnel must complete DP queries and prepare shaped packets within each interval, and it must be able to transmit all payload bytes generated from an application within a finite window length (as defined in the DP strategy). Secondly, the payload and dummy bytes in the shaped packets must be indistinguishable to an adversary. For this, the payload and dummy bytes must be transmitted through a shared transport layer so that they are identically acknowledged by the receiver and subject to congestion control and loss recovery mechanisms. Finally, the tunnel must provide similar levels of reliability, congestion control, and loss recovery as expected by the application.

Figure 2 shows the design of one endpoint of NetShaper's traffic shaping tunnel. A similar endpoint is deployed on the other end of the tunnel. The shape of the traffic in the tunnel can be configured independently in each direction. The privacy loss in bidirectional streams is the DP composition of the privacy loss in each direction.

A tunnel endpoint consists of a shaping layer (Shaper) on top of QUIC, which in turn runs on top of a standard UDP stack. The tunnel endpoints establish a bidirectional QUIC connection and generate DP-sized transmit buffers in fixed intervals, which carry payload bytes from one or more application flows. In the absence of application payload, a tunnel endpoint transmits dummy bytes, which are discarded at the other endpoint. QUIC encrypts all outbound packets.

NetShaper adopts a transport-layer proxy architecture: each application terminates a connection with its local tunnel endpoint. The application byte stream is sent to the remote application over three piecewise connections: (i) between the application and its local tunnel endpoint, (ii) between the tunnel endpoints, and (iii) between the remote tunnel endpoint and the remote application. This ensures only one active congestion control and reliable delivery mechanism in the tunnel and that all bytes are subject to identical mechanisms[1].

The application and the tunnel endpoint shown in Figure 2 could either be colocated on the same host or located on separate hosts. In each case, the traffic between the application and the tunnel endpoint is assumed to be unobservable to an adversary. Our design (§4.1) does not distinguish between the two configurations. Our implementation (§4.2) assumes that the tunnel endpoint is located on a separate middlebox. We discuss security in §4.3 and alternate deployments in §4.4.

4.1 Tunnel Design and Operations

Tunnel setup and teardown. Before applications can communicate with each other, a NetShaper tunnel must be set up between their local tunnel endpoints. The initiator application sends a configuration message to its local tunnel endpoint with the source and destination IP addresses and ports, a reliability flag, and a privacy descriptor. The reliability flag indicates if the tunnel should provide reliable delivery semantics or not.

[1] We discard tunneling TCP through TCP as it causes TCP meltdown [4, 33], or TCP through UDP as it is unsafe. (TCP between the application hosts would retransmit lost payload bytes only, not any dummy bytes injected between the tunnel endpoints, making the dummy bytes observable.)

The privacy descriptor indicates the DP parameters to be used for shaping the tunnel traffic.

Upon receiving a configuration message, the Shaper establishes a QUIC connection with the remote tunnel endpoint and configures the reliability semantics and privacy parameters for each direction. It also initializes three types of bidirectional streams in the tunnel: control, dummy, and data streams. One *control stream* is used to transmit messages related to the establishment and termination of a connection between the application endpoints. A *dummy stream* transmits padding in QUIC packets in the form of STREAM frames[2]. The tunnel pre-configures a finite number of data streams, which carry payload bytes from one or more application flows.

When the tunnel is inactive for a period of time, one of the tunnel endpoints initiates a termination sequence and closes all open QUIC streams and the tunnel connection.

Connection establishment and termination. Once a tunnel is ready, applications can establish and terminate connections with each other, which is mediated by the tunnel. When the initiator application runs a connection establishment handshake with its local tunnel endpoint, the Shaper maps the application flow to a per-flow buffering queue and one of the inactive QUIC data streams in the tunnel, and notifies the remote tunnel endpoint. The remote tunnel endpoint establishes a connection with the receiver application and maps the receiver application's flow with the data stream. The connection termination handshake is handled similarly by the tunnel endpoints. The messages for connection establishment and termination are transmitted over the control stream in the tunnel and shaped according to the tunnel's parameters.

Outbound traffic shaping. The Shaper accumulates the outbound bytes of an application flow in a buffering queue before it transmits them in packets whose sizes and timing follow a distribution that guarantees DP. Within a tunnel, the Shaper transmits bytes from all active flows into a differentially-private packet sequence. At periodic intervals, called DP shaping intervals, it performs a DP query on the per-flow queues to determine the number of bytes $\tilde{L}$ to be transmitted according to the tunnel's DP parameters. It prepares a *shaped buffer* consisting of R payload bytes and D dummy bytes, where R is the minimum of $\tilde{L}$ and the application bytes available in the buffering queues, and $D = \tilde{L} - R$, which may lie between 0 and $\tilde{L}$. The Shaper then passes the buffer with the position and length of the padding to QUIC.

QUIC transforms the shaped buffer into one or more STREAM frames based on the congestion window, the flow window of the receiver endpoint, and the MTU (maximum transmission unit). It places the padding bytes into a dummy STREAM frame. QUIC packages the frames into packets, whose length is at most MTU minus the length of the headers and whose payload is encrypted. QUIC forwards the packets to the UDP layer, which subsequently transmits the prepared packets as quickly as it can, given the line rate of the NIC.

[2]We do not use QUIC's PADDING frames as they do not elicit acknowledgements and hence are distinguishable from STREAM frames [35].

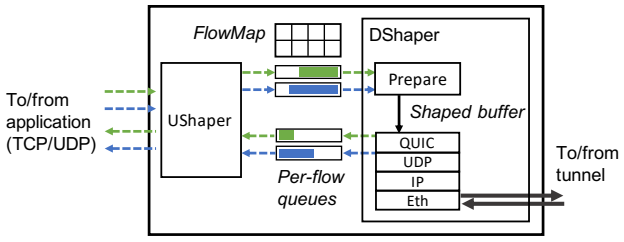

Figure 3: NetShaper middlebox design

To enforce Assumption 1, the Shaper tracks the expiry time of each byte enqueued in Q based on the arrival time and the neighboring window length W configuration. The Shaper drops the untransmitted bytes in the queue upon their expiry.

Inbound traffic processing. A tunnel endpoint receives shaped packets from the tunnel and applies inverse processing on each packet. QUIC receives the packet and sends an ACK to the sender. Subsequently, it decrypts the packet, discards the dummy frame, and forwards the payload bytes from the remaining STREAM frames to the application.

4.2 Middlebox Implementation

We present a middlebox-based NetShaper implementation. For ease of implementation, our prototype requires applications to explicitly connect to the middleboxes. In principle, NetShaper can transparently proxy application connections.

In our implementation (see Figure 3), a middlebox consists of two userspace processes. The `UShaper` mediates *unshaped* traffic between the applications and the middleboxes. The `DShaper` handles *DP shaped* traffic within the tunnel.

UShaper. The `UShaper` implements a transport server (or client) for interfacing with each local client (or server, respectively) application. For managing multiple flows, it shares a `FlowMap` table with the `DShaper`, which consists of an entry for each end-to-end flow. Each entry maps the piecewise connections with a pair of transmit and receive queues to carry the local application's byte stream, and shaping configurations (e.g., privacy descriptor) provided by an application at the time of flow registration.

The `UShaper` receives the outbound traffic from a sender application and enqueues the byte stream into a per-flow transmit queue shared with the `DShaper`. It also dequeues bytes from a per-flow receive queue, repackages them into transport packets and sends them to the receiver application.

DShaper. The `DShaper` consists of a `Prepare` thread and a QUIC worker thread. The `Prepare` thread instantiates a QUIC client/server to establish a tunnel with the remote middlebox and implements the DP shaping logic. On the transmit side, `Prepare` prepares shaped buffers based on DP queries on the transmit queues and then submits shaped buffers to the QUIC worker for transmission. On the receive size, the QUIC worker transmits ACK frames to the sender and then

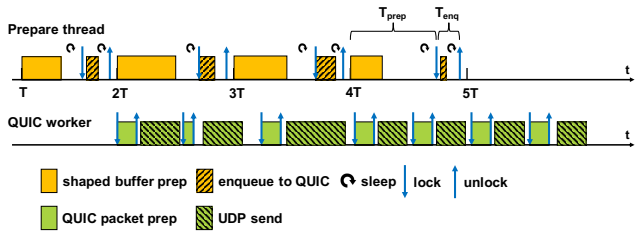

Figure 4: DShaper schedule

decrypts the QUIC packets, extracts the STREAM frames, and copies bytes (including dummy bytes) from each frame into the appropriate per-flow receive queue.

Ensuring secret-independent shaping. To enforce DP guarantees, DShaper should *transmit* exactly $\tilde{L}$ bytes in each DP shaping interval T. This would require ensuring: **P1.** Prepare computes $\tilde{L}$, allocates and prepares a buffer of length $\tilde{L}$, and passes the buffer to the QUIC worker within T, **P2.** the QUIC worker prepares encrypted packets from the buffer and sends them to UDP, such that the total payload size of the QUIC packets prepared in T is $\tilde{L}$, and **P3.** the UDP stack transmits packets totaling to $\tilde{L}$ payload bytes to the NIC in T. Enforcing all these properties would require a constant-time implementation for each step, which is non-trivial, or a strict time-triggered schedule for each step, which would significantly reduce link utilization and increase packet latencies.

Thanks to DP post processing, however, it suffices to ensure the property P1, and **P4.** that the QUIC worker transforms the shaped buffer into network packets independently of the application data. No other constraint on the sizes and timing of network packets is required to preserve DP.

Satisfying P1 involves one challenge. Although the application is physically isolated from the middlebox, its flow control behavior could be secret-dependent and could affect the middlebox's execution. For instance, the presence or absence of payload traffic from an application can affect the time DShaper requires to prepare the shaped buffers.

Thus, DShaper satisfies P1 as follows (see Figure 4 for reference). First, Prepare guarantees that $\tilde{L}$ is computed with a DP query in each interval. Secondly, Prepare guarantees that a shaped buffer of length $\tilde{L}$ is *prepared* within a fixed time T_{prep} within each interval. Thirdly, Prepare locks the shaped buffer for a fixed time, T_{enq}, during which it enqueues the buffer for a QUIC worker. This ensures that the buffer is completely enqueued before QUIC starts transmitting it and that QUIC receives the buffer only at fixed delays.

We empirically profile the time taken by Prepare for preparing and enqueueing shaped buffers for various DP lengths. We set T_{prep} and T_{enq} to maximum values determined from profiling, and T to the sum of these maximum values, i.e., T_{max}. If Prepare takes time less than T_{prep} (or T_{enq}, respectively) to prepare (or enqueue) a shaped buffer, it sleeps until the end of the interval before moving to the next phase.

To satisfy P4, Prepare and QUIC worker threads run on separate cores sharing only the shaped buffers. UShaper runs on yet a different core and shares the FlowMap and the per-flow transmit queues containing unshaped traffic only with Prepare. It shares the per-flow receive queues with the QUIC worker, but they contain only shaped frames from the QUIC worker. Finally, we assume that QUIC encrypts and decrypts shaped buffers in constant-time. With this, the execution of the QUIC worker becomes independent from Prepare and secret-independent overall. Consequently, the QUIC worker and the UDP stack can packetize the shaped buffers and transmit the packets at link speed, and any variance in packet transmit times constitute post-processing noise.

Limitations. Our prototype has two limitations in enforcing secret-independent timing. First, our QUIC implementation uses standard OpenSSL, which may not provide constant-time crypto. However, QUIC can be modified to adopt a constant-time crypto library [1, 2] to overcome this limitation. Secondly, it is difficult to find the true maximum values of T_{prep} and T_{enq} on general-purpose desktops. If Prepare's execution exceeds the profiled max values, it violates the theoretical DP guarantees. However, we note that it is difficult to practically exploit these violations for inferring traffic secrets.

4.3 Security Analysis

NetShaper provides the following security property: an adversary cannot infer application secrets from observing tunnel traffic. This property is ensured by a combination of a secure shaping strategy, the tunnel design, and implementation.

S1. Secure shaping strategy. The tunnel transmits traffic in differentially private-sized bursts in fixed intervals. Thus, the overall shape is DP. The proof of DP is in §C.

S2. Secure tunnel design. (i) The privacy guarantees of a tunnel are configured before the start of application transmission and do not change during the tunnel's lifetime. (ii) The tunnel mediates control between the end hosts, e.g., by transmitting custom connection establishment and termination messages. These messages are subject to the same DP shaping as the payload traffic (§4.1). (iii) The payload and dummy bytes in network packets are indistinguishable because all payload and dummy bytes are packaged into QUIC packets and encrypted uniformly. Moreover, QUIC handles acknowledgements, congestion control, and loss recovery for both payload and dummy bytes uniformly (§4.1).

S3. Secure middlebox implementation. (i) The unshaped traffic between an end host and its local middlebox is not visible to an adversary. (ii) DShaper follows the tunnel design in transmitting payload and dummy bytes. (iii) The time required for Prepare to prepare and enqueue shaped buffers is masked to secret-independent times. The packetization of buffers in QUIC is secret-independent (§4.2) and thus retains DP guarantees after post-processing. Any delays in transmitting the buffers can arise only due to congestion or packet losses in the tunnel network, which are secret-independent events.

4.4 Deployment and Maintenance

NetShaper's tunnel endpoint design and implementation are both very modular and portable. The middlebox components are compatible with all application layer protocols (e.g., HTTPS, QUIC-TLS) and network stacks (e.g., TCP, UDP, QUIC stacks). The `UShaper` could also be implemented as a standard SOCKS5 proxy [3].

A tunnel endpoint could be integrated with any node along an application's network path as long as the application traffic is unobservable until egress from the tunnel. By integrating with a trusted VPN gateway of an organization, network administrators could manage "long-term" tunnels between the organization's campuses and support multiple applications without modifying individual end hosts. For instance, separate tunnels may be configured per-application according to the organizational needs, or configurations may be adapted based on coarse-grained changes in the traffic patterns through the day.

Alternatively, by integrating with end user devices, e.g., with VPN clients, users could instantiate a new bidirectional tunnel with a service before each network activity, choose a different configuration for each tunnel instance, and close the tunnel after completion of the activity. A key requirement would be to secure the tunnel endpoint's execution from any internal side channels on the end host, which would be now more prevalent than in the middlebox setup.

5 Evaluation

Our evaluation answers the following questions. (i) How well does NetShaper mitigate state-of-the-art network side-channel attacks? (ii) What are the overheads associated with varying DP relevant configuration parameters? (iii) What are the packet latency overheads and the peak line rate and throughput sustained by our NetShaper middlebox? (iv) What are NetShaper's overall costs on privacy, bandwidth, client latency, and server throughput for different classes of applications? (v) How do NetShaper's privacy guarantees and performance overheads compare to prior techniques?

For our experiments, we use four AMD Ryzen 7 7700X desktops each with eight 4.5 GHz CPUs, 32 GB RAM, 1 TB storage, and one Marvell AQC113CS-B1-C 10Gbps NIC. We simulate client and server applications on two of the desktops and NetShaper's middleboxes on the other two desktops. The middleboxes are connected to each other via an additional Intel X550-T2 10Gbps NIC on each desktop. The client and server desktops are connected to one of the two middleboxes each via the Marvell NICs, overall forming a linear topology.

We implemented the `UShaper` and `DShaper` processes in 1100 and 1800 lines of C++ code, respectively, and deployed them on Ubuntu OS 22.04.02 (kernel version 5.19). NetShaper relies on the MSQUIC implementation of QUIC, libmsquic v2.1.8, which includes OpenSSL for traffic encryption, contributing an additional 180713 LoC to NetShaper's TCB.

For rapid evaluation, we built a simulator, which implements the `Prepare` thread's DP logic. The simulator transforms an application's original packet sequence (from tcpdump) into a sequence of burst sizes within fixed-length intervals, and outputs a sequence of transmit sizes corresponding to DP queries. We confirmed that the bandwidth overheads from the simulator closely match the overheads observed on the testbed. Thus, we report privacy and bandwidth overhead results from the simulator and latency and throughput results from the testbed, unless specified otherwise.

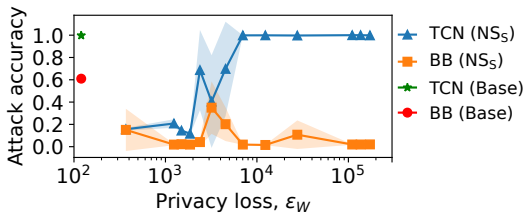
We use two applications for case studies, a video streaming service and a medical web service, which we describe below. Both applications are hosted on an Nginx 1.23.4 web server and the datasets are stored on the host file system.

Video service. The video streaming service is used to serve 100 YouTube videos in 720p resolution with 5 min to 130.3 min (median 12.6 min) durations and 2.7 MB to 1.4 GB (median 73.7 MB) sizes. We implement a custom video streaming client in Python, which uses one TCP connection for a single stream and requests individual 5s segments from the service synchronously. Unless specified otherwise, we stream the first 5 min of videos in our experiments. The configuration is in line with that used in prior work [55] and reasonable, given the popularity of short videos [60].

Web service. The web service is used to serve a corpus of 96 static HTML pages of a medical website, whose sizes range from 54 KB to 147 KB (median: 90 KB). As a client, we use modified wrk2 [5] that issues concurrent asynchronous HTTPS GET requests at a specified rate.

For all experiments, we use one baseline setup and one of three NetShaper configurations. In the baseline setup (**Base**), the client is directly connected to the server. In the simulator setup ($\mathbf{NS_S}$), we generated sequences of shaped burst sizes using DP shaping. With NetShaper, the traffic between the client and the server passes through two middleboxes, each implementing `UShaper` and `DShaper`. We consider two configurations of the middleboxes: (i) $\mathbf{NS_M}$: `DShaper` does not implement shaping (i.e., neither DP noise sampling nor the fixed length loop interval T_{max}), allowing us to measure the system overheads due to the middlebox implementation, and (ii) **NS**: `DShaper` implements the full shaping mechanism. By default, each middlebox is configured with 128 pairs of per-flow transmit and receive queues (unless specified otherwise). We configure the queue sizes for the max data that can be transmitted at line rate for a given DP shaping interval. We configure a max cutoff for the shaped buffer length based on the max burst length of the application and the number of active flows. This implies that the number of flows is public.

In addition, we compare with two other shaping strategies: constant-rate shaping (**CR**), which is the most secure shaping strategy, and Pacer (**Pacer**), a SOTA system that shapes traffic on a per-request basis. For **CR**, we configure the peak load corresponding to the largest object sizes in our applications, which involves transmitting 1.7MB in 5s for videos and 57KB



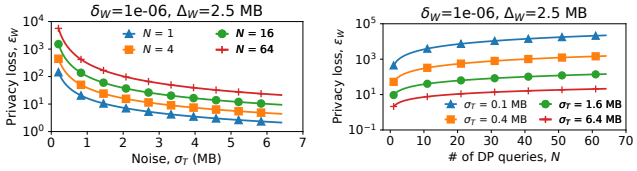


Figure 5: Classifier accuracy on shaped traces.

(a) (b)

Figure 6: Privacy loss vs (a) noise and (b) # of DP queries.

in 50ms for web. For Pacer, we pad all web pages to the largest page size, i.e., 147KB in our dataset. For videos, Pacer pads a segment at i^{th} index in a video stream to the largest segment size at that index across all videos in the dataset.

5.1 NetShaper Defeats Attack Classifiers

We start with an empirical evaluation of the privacy offered by NetShaper's traffic shaping. Recall that the traffic shaping depends on several DP parameters: the window length W, the sensitivity Δ_T, the length of the DP interval T, and the privacy loss ε. We evaluated the classifiers from §2.1 on shaped traffic generated using various values of these DP relevant parameters. We present the classifiers' performance based on only one set of values for W, Δ_T, and T, while varying ε between [200, 200000]. Our goal is to provide intuition about what values of ε are sufficient to thwart a side-channel attack.

We set (i) $W = 5s$ to align with the 5s video segments that comprise the videos, (ii) $\Delta_T = 2.5MB$, which covers 99th %ile of the distances in our dataset (§B), and (iii) $T = 1s$, which leads to composing the privacy loss over $N = 5$ DP queries on the buffering queues. The 1s interval provides a reasonable trade-off between privacy loss, and bandwidth and latency overheads, which we discuss in the subsequent sections.

We used 40 videos of 5 min duration each. We streamed each video 100 times through our testbed without shaping and collected the resulting tcpdump traces. For each value of ε, we transformed each unshaped trace into a shaped trace using our simulator to generate a total of 4000 shaped traces. We also shaped traces for **CR** and **Pacer**.

We train and test BB and TCN on shaped traces as in §2.1 and report the average and standard deviation of the accuracy of each classifier over three runs. Recall from §2.1, the BB and TCN accuracy on unshaped traffic (**Base**) is 0.61 and 0.99, respectively. For **CR** and **Pacer**, the accuracy of both BB and TCN classifiers is 0.025. This is expected since both strategies transform all unshaped traces into a single shape.

Figure 5 shows the classifiers' performance with NetShaper. While BB does not perform well for nearly all values of ε, TCN can be thwarted for ε upto 1000. *While even* $\varepsilon \approx 200$ *is too large to offer meaningful theoretical privacy guarantees, it is sufficient to defeat SOTA attacks.*

5.2 Impact of Privacy Parameters

We now evaluate how ε varies with Δ_T, σ_T, and N. Due to space constraints, we present plots for a fixed value of $\Delta_T = 2.5MB$ and defer other plots to §B. All analyses use $\delta = 10^{-6}$.

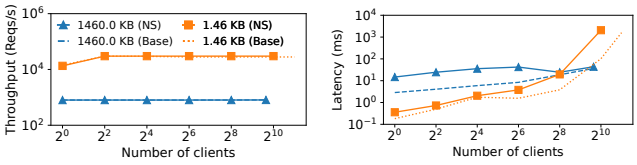

Figure 6a shows the tradeoff between ε and σ_T over four different values of N. Intuitively, a larger σ_T implies higher bandwidth overhead due to DP shaping. To retain a total privacy loss $\varepsilon = 1$ with at most 4 DP queries, we need to add noise with $\sigma_T = 18MB$ for each DP query. In contrast, $\varepsilon = 200$ with 4 DP queries (approx. configuration that defeats the classifiers in §5.1) only requires $\sigma_T < 0.3MB$. Figure 6b shows that the total privacy loss escalates with an increase in the number of DP queries. While fewer queries within a window (thus larger decision intervals) help to lower the total privacy loss, the tradeoff is the higher latency overhead. We discuss this tradeoff, as well as reduction in bandwidth overheads with concurrent flows in §5.4 and §5.5.

Using these plots, an application can choose suitable values of W and Δ_T to determine the tradeoff between ε and σ_T. For our web application serving static HTML, we recommend $W = 1s$, since web page downloads in our AWS setup (§2.1) finished within 1s, and $\Delta_T = 60KB$, which covers all distances. §5.1 explained the choices for our video application. Using ε and T, we can further determine the aggregate privacy loss over longer traffic streams using Rényi-DP composition. For instance, with $\varepsilon = 1$, $W = 5s$, and $T = 1s$, the total privacy loss for a 5 min video, which generates 300 DP queries at 1s intervals, is 8.92; the total loss for a 1 hr video is 38.8. We emphasize that Δ_T *and* ε *should be selected using plots like Figure 6, independently of the application's dataset.*

5.3 Performance Microbenchmarks

We now turn our attention to experiments to determine the overheads on per-packet latencies and the peak line rate and throughput sustainable by a NetShaper middlebox.

Middlebox throughput. We measure the peak throughput (requests/s) attained by a server application, the response latency experienced by the clients, and the impact on this throughput and latency due to the middleboxes. We restrict Nginx to one worker thread and one core on the server desktop. We evaluate using two object sizes: 1.4 KB (one MTU) and 1.4 MB. We identify the peak request rate that can be handled by a single wrk2 client, then increase the clients until we

(a) # clients vs throughput (b) # clients vs latency

Figure 7: Throughput and latency overhead due to middleboxes without shaping.

find the peak throughput the server can provide. We then vary the number of concurrent clients while generating the peak request load sustainable by the server to find the maximum number of concurrent clients that the server can handle and to measure the impact on the response latency.

We run experiments for 3 min and discard the measurements from the first minute to eliminate startup effects. Figure 7a shows the average of the peak throughput observed across 3 runs. The standard deviation is below 1% in all cases. For 1.4 KB and 1.4 MB objects, the **Base** server achieves a peak throughput of 30K req/s (64 clients) and 800 req/s (800 clients), respectively. $\mathbf{NS_M}$ matches the peak throughput and the max concurrent clients sustained by **Base**.

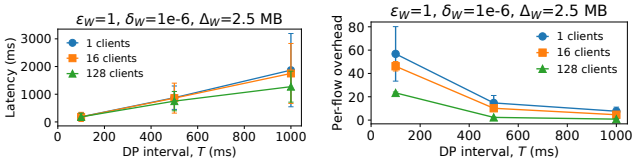
Latency. Figure 7b shows the average and standard deviation of the response latencies over a 2 min run. The ping latency between each pair of directly connected desktops is 0.56 ± 0.18 ms. This overhead comes from the fact that each packet traverses four additional network stacks (across two middleboxes) in each direction. This also involves data copy operations between the kernel and user space. The data copy overhead is proportional to the object size; thus $\mathbf{NS_M}$'s latency overhead increases with the larger response sizes.

The kernel data copy overheads are not fundamental to NetShaper's design. By using kernel bypass techniques or tools like DPDK [28], NetShaper can reduce the latency overhead.

Shaping interval, preparation, and enqueue times. We further profile the middlebox execution to measure the max latencies of the two components in the `Prepare` loop (§4.2): the preparation of the shaped buffer and queuing of the buffer to QUIC worker. These measures determine the maximum durations for preparing and enqueueing shaped buffers (T_{prep} and T_{enq}, respectively), and the minimum value for the shaping interval T. We profile the delays with the middlebox configured with 128 queues, thus supporting a maximum of 128 concurrent clients. One can profile the delays for a different number of queues and concurrent clients.

Based on our measurements, we set $T_{prep} = 6ms$ and $T_{enq} = 1ms$. The smallest value for T that we can configure is 10ms.

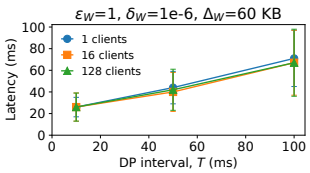
Throughput and latency with shaping enabled. We now re-run the microbenchmarks with **NS** configuration. We use three different configurations for T: 10ms, 50ms, and 100ms. We use 128 concurrent clients. The middlebox can sustain the peak throughput of 30K req/s with 1.4KB objects and 700 req/s with 1.4MB objects for each configuration of T. For 1.4KB objects, the average and standard deviation of the response latency with the three configurations are as follows: (i) $T = 10ms$: 30.47 ± 3.89 ms, (ii) $T = 50ms$: 51.39 ± 14.64 ms, (iii) $T = 100ms$: 77.49 ± 28.96 ms. For 1.4MB objects, the latencies are as follows: (i) $T = 10ms$: 41.31 ± 10.84 ms, (ii) $T = 50ms$: 76.96 ± 21.12 ms, (iii) $T = 100ms$: 127.48 ± 45.69 ms. The latency is dominated by the T configuration. The high variance in the latency is due to shaping. If a request arrives just after the decision loop has prepared a buffer in the current iteration, the request will be delayed by at least one iteration of the loop. Moreover, a negative sampling of DP noise may lead to a smaller shaped buffer than the available payload bytes in the buffering queues, thus delaying the requests by one or more intervals. This effect is particularly enhanced in a workload close to the line rate. Thus, NetShaper can perform well within about 12-15% of the line rate.



CPU utilization. The CPU utilization is 3-10% for the `Prepare` core and depends on the DP shaping interval; the utilization is 8-70% for the QUIC worker core, which depends on the network I/O. The `UShaper` core utilizes 100% of the CPU as it polls for packets from `Prepare`. As such, the `Prepare` and QUIC worker cores would be able to support additional tunnel instances by time-sharing their core. By using a polling interval, we could reduce the CPU utilization of `UShaper` to support additional requests at the cost of additional latency. In general, multiple tunnels can time-share the same physical cores, as long as each core runs the same type of thread, to suffice property P4 mentioned in §4.2.

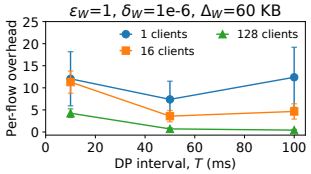
5.4 Case Study: Video Streaming

Next, we examine the effect of different privacy settings on bandwidth and latency overheads for video streaming clients.



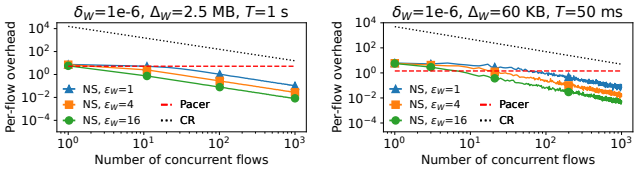
We run experiments with three values of T for the server: 100ms, 500ms, and 1s, and max per-flow DP length cutoff of 1.21 MB, 1.22MB, and 1.7 MB, respectively. We use $\Delta_T = 2.5MB$ and $\varepsilon = 1$. For all experiments, we set the DP parameters for client request traffic as follows: $\Delta_T = 200$ bytes, $W = 1s$, $T = 10ms$, $\varepsilon = 1$ and max per-flow DP length cutoff of 206 bytes. We run experiments with 1, 16, and 128 video clients; each client requests one video randomly selected from the dataset. For each set of configurations, we measure the average response latency for individual video segments with the testbed as well as the per-flow relative bandwidth overhead for the video streams in the simulator.

Latency and bandwidth overhead. Figures 8a and 8b respectively show the average segment download latency and the average per-flow relative bandwidth overhead as a function of different intervals and for varying number of clients. The **Base** segment download latency is 2.86 ± 1.41ms. The latency variance is due to variances in the segment sizes. The relative bandwidth overhead of a video is the number of dummy bytes transmitted normalized to the size of the unshaped video stream. The error bars show the standard



(a) Latency vs DP interval

(b) BW overhead vs DP interval



(c) Latency vs DP interval

(d) BW overhead vs DP interval

Figure 8: Latency and bandwidth overhead for different values of DP interval for video streaming (a, b) and for web (c, d).

(a) Video streaming.

(b) Web service.

Figure 9: Comparison of NetShaper, constant shaping, Pacer.

deviation in latency and bandwidth overhead.

First, Figure 8a shows that, for all values of T, the video segments can be downloaded well within 5s, which is the time to play each segment and request the next segment from the server. The high variance is due to negative DP noise, which delays payload transmission. Secondly, the results show the trade-off between latency and bandwidth. A larger DP interval implies higher download latency but fewer queries, thus yielding a lower bandwidth overhead. Thirdly, with multiple concurrent clients, the bandwidth overhead is amortized, while the average download latency only depends on T. Overall, NetShaper can secure video streams with low bandwidth overheads and no impact on the streaming experience.

5.5 Case Study: Web Service

We perform similar experiments as §5.4 with our web service. For the server responses, we use $\Delta_T = 60KB$, $W = 1s$, and $\varepsilon = 1$. We use T of 10ms, 50ms, and 100ms, and per-flow DP length cutoffs of 60.8KB, 60.8KB, and 110.9KB, respectively. For the client requests, we use the same configs as in §5.4. We run 3 min experiments with 1, 16, and 128 wrk2 clients with a total load of 1600 req/s; each client requests random web pages from the dataset. We discard the numbers of the first minute.

Latency and bandwidth overhead. Figures 8c and 8d respectively show the average response latency and the average per-web page relative bandwidth overhead, across all web page requests. The **Base** latency is 0.225 ± 0.3 ms. (The high variance is due to the time precision in wrk2 being restricted to 1ms.) The web workload is more sporadic than video streaming, thus web page download latencies have higher variance than video segment download latency. The absolute latency overhead for **NS** depends on the choice of T. The relative overhead depends on the underlying network latency, which unlike our testbed, is in the order of 10s to 100s of milliseconds in the Internet. Interestingly, the bandwidth overhead for web traffic first reduces with increasing DP shaping interval from 10ms to 50ms, but then increases again with an interval of 100ms. This is because, for small web pages, the DP interval of 100ms is larger than the total time required to download web pages. As a result, additional overhead is incurred due to the padding of traffic in the 100ms intervals.

5.6 Comparison with other techniques

Figures 9a and 9b show the per-flow relative bandwidth overhead of **NS**, **CR**, and **Pacer** for video and web applications, respectively, for varying number of concurrent flows.

For both video and web traffic, **NS** incurs three orders of magnitude lower overhead than **CR**, which requires continuously transmitting traffic at the peak server load (configured for 1000 clients). For video and web traffic, **NS** requires 11 flows and more than 40 flows, respectively to achieve lower overhead **Pacer**. Pacer shapes server traffic only upon receiving a client request and does not shape client traffic. Thus, it leaks the timing and shape of client requests, which could potentially reveal information about the server responses [19]. NetShaper shapes traffic in both directions, which incurs higher overhead at the cost of stronger privacy than Pacer.

Evaluation summary. Our evaluation provides four insights. (i) There is a huge gap between the theoretical DP guarantees and the privacy configurations required to defeat SOTA attacks. (ii) The latency overhead is dominated by the choice of DP shaping interval, (iii) NetShaper's middlebox can match about 88% of the 10Gbps NIC line rate; a single core of `UShaper` can match the peak throughput of a single core server, (iv) NetShaper's cost is in the two additional cores for `Prepare` and QUIC worker, which helps to avoid any secret-dependent interference in shaping and keep low DP shaping loop lengths. By optimising the implementation, we could use a single middlebox to support larger workloads.

6 Related Work

Traffic shaping for web. Prior work used traffic shaping for defending against website fingerprinting attacks. Walkie-Talkie [67], Supersequence [66], and Glove [50] use clustering techniques to group objects of a corpus and then shape the traffic of all objects within each cluster to conform to a similar pattern. Traffic morphing [71] makes the traffic of one page look like that of another. These techniques compute traffic

shapes that envelope or resemble the network traces of individual objects. Hence, they require a large number of traces to account for network variations. NetShaper dynamically adapts traffic shapes based on the prevailing network conditions.

Cs-BuFLO [16], Tamaraw [17], and DynaFlow [43], determine traffic shape directly at runtime. They pad object sizes to values that are correlated with the original object sizes, such as the next multiple or power of a configurable constant. These defenses provide privacy akin to k-anonymity, but have no control on the the size of the anonymous cluster. Tamaraw [17] formalizes the privacy guarantees. NetShaper's DP guarantees are strictly stronger than Tamaraw's (proof in §D).

Differential privacy over streams. Dwork et al. [24] study DP on streams, in which neighboring streams differ in at most one element and the query counts over the stream prefix (without forgetting old information) under a fixed DP budget for the entire stream. NetShaper requires a stronger neighboring definition to model application data streams (Def. 1), but is able to forget the past by dropping stale data from our queue (Assumption 1) and compose privacy loss over time.

NetShaper's neighboring definition is closer to that of user-level DP over streams in [25]. Instead of counting discrete change, however, we use the L1 distance which enables coarsening. Pan-privacy considers an adversary that can compromise the internals of the algorithms (e.g., our buffering queue). This makes the design of algorithms challenging and costly. Instead, we consider the buffering queue private and focus on practical algorithms to study the privacy/overheads trade-off.

Kellaris et al. [38] introduce a notion of DP, called w-event privacy, for streams of length w. Neighboring stream pairs are those whose individual events are pairwise neighbors within a window of upto w. NetShaper's neighboring definition accounts for the maximum stream distance over *any* window of length W, which is a better match for the streams we consider.

Zhang et al. [73] generate differentially private shapes for video streams using Fourier Perturbation Algorithm (FPA) [52]. FPA transforms a finite time series of bursts, into a series of DP shaped bursts of the same length. FPA requires the entire stream's profile upfront, and cannot guarantee complete transmission of an input stream within the shaped trace. NetShaper's DP guarantees simply compose over burst interval sequences, thus allowing shaping of streams of arbitrary lengths with quantifiable privacy and overheads.

Adversarial defenses. Adversarial defenses [6, 30, 34, 49, 51, 56] generate targeted and low-overhead noise to defeat specific classifiers. NetShaper provides provable and configurable privacy against both SOTA as well as future classifiers.

Network side-channel mitigation systems. NetShaper's shaping tunnel is conceptually similar to Pacer's [45] cloaked tunnel. However, Pacer mitigates leaks of a Cloud tenant's secrets to a colocated adversary through contention at shared network links. Pacer's cloaked tunnel controls the transmit time of TCP packets in accordance with the shaping schedule and congestion control signals. Thus, Pacer requires non-trivial changes to the network stack on the end hosts. NetShaper protects applications that are behind private networks but communicate using the public Internet. NetShaper's tunnel endpoints can be placed at the interface of the private-public networks, e.g., in a middlebox, thus supporting multiple applications without modifying end hosts. Moreover, by shaping above the transport layer, NetShaper needs to control only the precise timing for generation of bursts of DP length and not the subsequent transmission to the network.

Ditto [46] and NetShaper propose shaping traffic at network nodes separate from end hosts. NetShaper proposes a hardware-independent, modular and portable middlebox architecture that can be integrated with end hosts, routers, gateways, or even programmable switches as in Ditto.

Systems with other goals. Censorship circumvention systems [10, 11, 48, 53, 70] rely on traffic obfuscation, scrambling, and transformations of a sensitive application's shape to that of a non-sensitive application. These techniques prevent identification of original protocols by deep packet inspection, but do not prevent inference of secrets from traffic shapes.

Karaoke [40] and Vuvuzela [62] are anonymous messaging systems that use DP to hide participants in a conversation, but use constant-rate traffic among the participants. AnoA [8] is a framework to analyze anonymity properties of anonymous communication protocols. AnoA supports DP based quantification for various properties, such as sender anonymity and sender unlinkability. NetShaper's differentially-private traffic shaping hides the traffic content. In principle, NetShaper could be combined with an anonymous communication system to provide both content privacy and anonymity with DP.

7 Conclusion

NetShaper is a provably secure network side-channel mitigation system that provides quantifiable and tunable privacy guarantees in traffic shaping. We believe that NetShaper can eliminate the arms race in network side-channel attacks and defenses and can provide a portable and configurable framework for deploying mitigations for applications with diverse traffic characteristics and in different settings. NetShaper's DP based traffic shaping strategy as well as its modular and portable tunnel design can be extended to mitigate leaks in multi-node systems, but we leave the details to future work.

A Attack classifiers

Beauty and Burst. The Beauty and the Burst classifier (BB) [55] is a CNN (convolutional neural network) consisting of three convolution layers, a max pooling layer, and two dense layers. We use a dropout of 0.5, 0.7, and 0.5 between the hidden layers of the network. We train the classifier with an Adam optimizer, a categorical cross-entropy function, a learning rate of 0.01, with a batch size of 64, and for 1000 epochs.

Temporal Convolution Network. While CNNs are generally effective in sequence modelling, they look at future samples in a sequence and a very limited history of past samples to decide the output of the current sample. Consequently, they require a large number of traces and long traces for effective training and prediction.

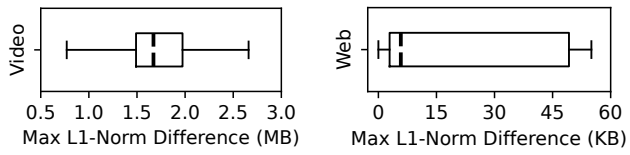
Temporal Convolutional Networks (TCNs) [9] overcome these problems of CNNs by utilizing a one-dimensional fully-convolutional network equipped with causal dilated convolutions, which allows them to examine deep into the past to produce an output for the sequence at any given moment.

Figure 10 shows the architecture of our TCN classifier, which follows the architecture proposed by Bai et al. [9]. It consists of two dilated causal convolutional layers, followed by weight normalization and dropout layers with a dropout probability of 0.05. We train the classifier for 1000 epochs.

B Extended evaluation of privacy vs overheads

Distribution of queue length differences. Figure 11 shows the distribution of the buffering queue length differences generated for each pair of an application's streams. We use W of 5s for video streams and 1s for web pages. The dashed lines show the median, which is 1.63 MB and 6 KB for videos and web pages, respectively.

Privacy loss vs overheads for other Δ_T. Figure 12 shows similar results as Figure 6 for Δ_T of 0.1 MB and 10 MB.



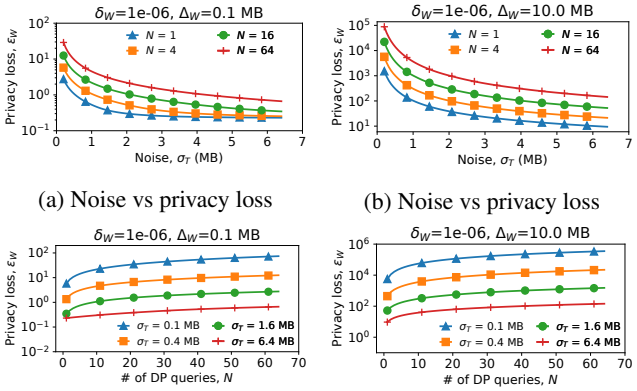


Figure 11: Distribution of the difference in buffering queue lengths for application stream pairs.

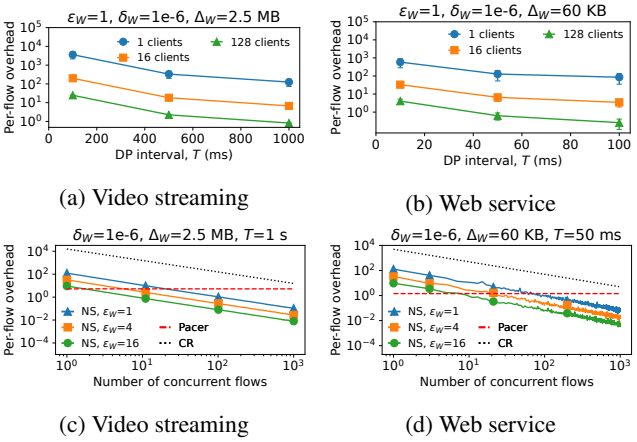
(a) Noise vs privacy loss (b) Noise vs privacy loss

(c) # DP queries vs privacy loss (d) # DP queries vs privacy loss

Figure 12: Privacy loss vs noise and # queries for different Δ_T.

Bandwidth overheads with a fixed cutoff. In §5, we explained that NetShaper applies a cutoff to the DP shaped buffer length (if the sampled noise is very large) that depends on the number of active flows. This reveals the number of active flows at any given time. To hide the number of flows, we can set the cutoff to a fixed value (e.g., based on the maximum flows that the system must support).

Figure 13a presents results similar to those of Figure 8b, but with the cutoff for the shaped buffer length set to a fixed value of 1.21 GB, 1.22 GB, and 1.7 GB. Figure 13b presents results similar to those of Figure 8d but with cutoffs of 60.8 MB, 60.8 MB, and 110.9 MB. Figures 13c and 13d show the results similar to those of Figures 9a and 9b. The fixed cutoffs correspond to 1000 flows, which lead to a significant increase in NetShaper's overheads. However, the overheads quickly amortize with several concurrent flows.



C Proof of NetShaper's DP based Shaping

Proposition 1. *NetShaper enforces* $\Delta_T \leq \Delta_W$.

To prove Prop 1, we show that at any DP query time k, any neighboring streams S, S' can only create a queue size difference such that $|L_k - L'_k| \leq \Delta_W$. This is formalized in the following Lemma:

Lemma 1. *Assume two neighboring traffic streams S and* S' ($\|S - S'\|_1 \leq \Delta_W$)*, are transmitted through NetShaper and get the same randomness draws* z_k *(they are parallel worlds with an identical NetShaper, but the streams differ). Then, at any DP query time k, the length of the buffering queue for S and* S' *are* Δ_W*-close. Formally:*

$$\forall k \geq 0 : |L_k - L'_k| \leq \Delta_W \tag{4}$$

(a) Video streaming (b) Web service

(c) Video streaming (d) Web service

Figure 13: Bandwidth overheads with a fixed cutoff.

Proof. NetShaper performs a DP query for the size of the buffering queue at intervals of length T. While transmitting S, the queue length at the end of the k^{th} interval T_k is a function of three variables: (i) The buffering queue length L_{k-1} at the end of T_{k-1}. (ii) The total number of payload bytes that have been dequeued from the buffering queue in the k^{th} interval, R_k. (iii) The number of new payload bytes from the application stream added to the buffering queue since the previous interval, which is the sum of sizes of all packets arriving between $(k-1)^{\text{th}}$ and k^{th} interval, i.e., $\sum_{T_{k-1} \leq t < T_k} P_t^S$. Therefore, the buffering queue length after dequeue in T_k is:

$$L_k = L_{k-1} + \sum_{T_{k-1} \leq t < T_k} P_t^S - R_k \tag{5}$$

The difference between the queue lengths of S, S' at T_k is:

$$L_k - L'_k = (L_{k-1} - L'_{k-1}) + \Big(\sum_{T_{k-1} \leq t < T_k} P_t^S - \sum_{T_{k-1} \leq t < T_k} P_t^{S'}\Big) - (R_k - R'_k) \tag{6}$$

We divide the proof into two steps. First, we show that the dequeue stage of the shaping mechanism does not increase the difference in queue lengths. Secondly, we show that under Assumption 1, the enqueue stage of incoming streams does not increase the difference in queue lengths beyond Δ_W.

To show that the dequeue stage never increases the difference between queue lengths, we show that in any period k, we always dequeue more (or equal) data from the larger queue at the time of the DP query. Formally:

$$(L_{k-1} - L'_{k-1}) \cdot (R_k - R'_k) \geq 0, \tag{7}$$

where the indexes are because removal amount in period k depends on the query result for the queue at $k-1$. Assume without loss of generality that $L_{k-1} \geq L'_{k-1}$. Since each DP query receives the same noise, we get $\tilde{L}_{k-1} \geq \tilde{L}'_{k-1}$, and thus:

$$R_k = \min\{0, \tilde{L}_{k-1}, L_{k-1}\} \geq \min\{0, \tilde{L}'_{k-1}, L'_{k-1}\} = R'_k.$$

The case for $L_{k-1} \leq L'_{k-1}$ is symmetric, and we have $\text{sign}(L_k - L'_k) = \text{sign}(R_k - R'_k)$, which implies Equation 7. Moreover, we show:

$$|R_k - R'_k| \leq |L_k - L'_k|, \tag{8}$$

using two cases and assuming that $L_k \geq L'_k$ (again the opposite case is symmetric). Either the DP noise is $\geq -L'_k$, and $L_k - L'_k = R_k - R'_k$.

Or the DP noise is $< -L'_k$, in which case $R'_k = 0$ but $R_k \leq L_k - L'_k$. Either way, Equation 8 holds. We can now study the queue length difference over time:

$$\begin{aligned}|L_k - L'_k| &= |(L_{k-1} - L'_{k-1}) + (\sum_{T_{k-1} \leq t < T_k} P_t^S - P_t^{S'}) - (R_k - R'_k)| \\ &\leq |(L_{k-1} - L'_{k-1}) - (R_k - R'_k)| + \sum_{T_{k-1} \leq t < T_k} |P_t^S - P_t^{S'}| \\ &\leq |L_{k-1} - L'_{k-1}| + \sum_{T_{k-1} \leq t < T_k} |P_t^S - P_t^{S'}|\end{aligned}$$

where the first equality uses Equation 6 and the last inequality uses Equation 7 and Equation 8. Intuitively, the dequeue stage never increases the difference between queue lengths.

Finally, we are ready to bound the difference in queue length due to enqueues. Let $d_k = |L_k - L'_k|$, and $d_0 = 0$:

$$\begin{aligned}d_k &\leq d_{k-1} + \sum_{T_{k-1} \leq t < T_k} |P_t^S - P_t^{S'}| = 0 + \sum_{i=0}^{k} (\sum_{T_{i-1} \leq t < T_i} |P_t^S - P_t^{S'}|) \\ &= \sum_{0 \leq t < T_k} |P_t^S - P_t^{S'}| = \sum_{0 \leq t < T_k - W} |P_t^S - P_t^{S'}| + \sum_{T_k - W \leq t < T_k} |P_t^S - P_t^{S'}| \\ &\leq \Delta_W\end{aligned}$$

since $\sum_{0 \leq t < T_k - W} |P_t^S - P_t^{S'}| = 0$ by Assumption 1, and $\sum_{T_k - W \leq t < T_k} |P_t^S - P_t^{S'}| \leq \Delta_W$ by Def 1. □

Lemma 1 $\implies$ Prop 1, since $\Delta_T = \max_k \max_{S,S'} |L_k - L'_k| \leq \Delta_W$.

D Comparison of NetShaper and Tamaraw

Tamaraw [17] provides a mathematical notion of privacy guarantee of a shaping strategy, called ε-security. To disambiguate with NetShaper's notion of (ε, δ)-DP, we rename Tamaraw's ε variable with γ. We show that NetShaper's (ε, δ)-DP definition is strictly stronger than Tamaraw's γ-security definition.

First, we explain Tamaraw's γ-security definition. In Tamaraw, W is a random variable representing the label of a traffic trace. For a trace w, the random variables T_w and T_w^D respectively represent the packet trace of w before and after shaping with a defense D. The distribution of T_w^D captures all variations in the observed shape of w resulting from both the defense mechanism and the network, while the distribution of T_w only contains variations due to the network. The attacker can measure the distribution of W and T_w^D independently. Upon observing a network trace t, an optimal attack A, selects the label of the trace with maximum likelihood of observation:

$$A(t) = \operatorname*{argmax}_w \Pr[W = w] \Pr[T_w^D = t]$$

The probability that an attack A outputs label w_i is $\Pr_A[w_i]$.

Definition (Tamaraw γ-privacy)**.** *A fingerprinting defense D is said to be uniformly γ-private if for the attack $\mathcal{A}$ if we have:*

$$\max_w \left[\Pr[A(T_w^D) = w]\right] \leq \gamma$$

Proposition 3. *Tamaraw γ-privacy is strictly weaker than the notion of ε-differential privacy.*

To prove Prop 3, we prove the following two lemmas.

Lemma 2. *There exists a Tamaraw γ-private defense mechanism that fails to satisfy ε-DP for any given value of ε.*

Proof. Consider a web service with a dataset of n web pages. We propose a defense D, which shapes pages to a constant-rate pattern O_c with probabilities α or β. D reshapes page w_j to O_c with probability β and all other pages $w_i \neq w_j$ with probability α. If a page is not shaped, it is revealed.

The probability that any attack can correctly identify the label for w_j is upper-bounded by: $\Pr[A(T^D_{w_{i=j}}) = w_j]$

$$\begin{aligned}&= \Pr[A(T^D_{w_{i=j}}) = w_j | T^D_{w_{i=j}} = T_{w_{i=j}}] \Pr[T^D_{w_{i=j}} = T_{w_{i=j}}] + \\ &\quad \Pr[A(T^D_{w_{i=j}}) = w_j | T^D_{w_{i=j}} = O_c] \Pr[T^D_{w_{i=j}} = O_c] \\ &\leq 1.(1-\beta) + \frac{1}{n}\beta = p_c^j\end{aligned}$$

For $(1 - \frac{n\gamma - 1}{n-1}) < \beta$ we have: $p_c^j \leq \gamma$. Similarly, the probability that any attack can correctly classify $w_{i \neq j}$ is upper-bounded by $p_c^i = 1 - \alpha + \frac{\alpha}{n}$, and for $(1 - \frac{n\gamma-1}{n-1}) < \alpha$ we have: $p_c^j \leq \gamma$. Therefore, for all values of α and β such that $(1 - \frac{n\gamma-1}{n-1}) < \beta < \alpha$, the probability that any attack can successfully guess a page is less than γ, and the defense is uniformly γ-private.

When the output of the algorithm is O_c, the probability of the page being w_j is β and any other page is α. Thus, $\log(\frac{\Pr[T^D_{w_{i \neq j}} = O_c]}{\Pr[T^D_{w_{i=j}} = O_c]}) = \log(\frac{\alpha}{\beta})$. By setting $\alpha > e^{\varepsilon}\beta$, we get a mechanism that is γ-private for Tamaraw but not ε-DP for NetShaper. □

Lemma 3. *A ε-DP shaping algorithm is Tamaraw γ-private for $\varepsilon \leq \log(n\gamma)$.*

Proof. For a trace w, the random variable T_w^{DP} represents the packet trace of w after a differentially private shaping mechanism is applied. The classification attack on shaped traffic can be considered a post-processing of the results of a differentially private shaping mechanism (i.e. defense) and, hence, is differentially private. Therefore, we have:

$$\frac{\Pr[A(T^{DP}_{w_i}) = w_i]}{\Pr[A(T^{DP}_{w_j}) = w_i]} \leq e^{\varepsilon} \Rightarrow \Pr[A(T^{DP}_{w_i}) = w_i] \leq e^{\varepsilon}.\Pr[A(T^{DP}_{w_j}) = w_i]$$

Intuitively, this implies that the likelihood of the attacker correctly classifying the trace with label i compared to incorrectly classifying it with label j is bounded by e^{ε}. The above inequality is correct for all $w_j : j \in \{1, 2, \ldots, n\}$, and we can extend the above equation to calculate the summation over j:

$$n \times \Pr[A(T^{DP}_{w_i}) = w_i] \leq e^{\varepsilon} \sum_{j=1}^{n} \Pr[A(T^{DP}_{w_j}) = w_i] = e^{\varepsilon} \Pr_A[w_i].$$

Thus, for any given trace w_i, the probability that any attack A, classifies it correctly is bounded by: $\Pr[A(T^{DP}_{w_i}) = w_i] \leq \frac{e^{\varepsilon} \Pr_A[w_i]}{n}$. The probability that an attacker can guess the victim's trace is bounded by: $\max_{w_i} \Pr[A(T^{DP}_{w_i}) = w_i] \leq \frac{e^{\varepsilon}}{n} \max_{w_i} \Pr_A[w_i] \leq \frac{e^{\varepsilon}}{n} \leq \gamma$. □

SoK: Neural Network Extraction Through Physical Side Channels

Péter Horváth* *Radboud University*
Dirk Lauret* *Radboud University*
Zhuoran Liu* *Radboud University*
Lejla Batina *Radboud University*

Abstract

Deep Neural Networks (DNNs) are widely used in various applications and are typically deployed on hardware accelerators. Physical Side-Channel Analysis (SCA) on DNN implementations is getting more attention from both industry and academia because of the potential to severely jeopardize the confidentiality of DNN Intellectual Property (IP) and the data privacy of end users. Current physical SCA attacks on DNNs are highly platform dependent and employ distinct threat models for different attack objectives and analysis tools, necessitating a general revision of attack methodology and assumptions. To this end, we provide a taxonomy of previous physical SCA attacks on DNNs and systematize findings toward *model extraction* and *input recovery*. Specifically, we discuss the dependencies of threat models on attack objectives and analysis methods, for which we present a novel systematic attack framework composed of fundamental stages derived from various attacks. Following the framework, we provide an in-depth analysis of common SCA attacks for each attack objective and reveal practical limitations, validated by experiments on a state-of-the-art commercial DNN accelerator. Based on our findings, we identify challenges and suggest future directions.

1 Introduction

Deep Neural Networks (DNNs) have been widely deployed in various applications, e.g., robot vision [138], conversational AI chatbots [96, 123], machine translations [111], and AI-assisted medical imaging [77]. The effectiveness of DNNs fuels their widespread deployment, rendering them prevalent in production. The data-driven nature of DNNs necessitates their dependency on the availability of extensive datasets and computational resources, which demands dedicated hardware accelerators, for which cloud and edge computing are typically being leveraged [3, 8]. However, various applications that are overly reliant on DNNs also increases the adversary's incentive to look at the vulnerabilities of DNN implementations.

Vulnerabilities of DNN implementations have been studied in Privacy-Preserving Machine Learning (PPML) research [7, 46, 88], where training and inference are implemented on hardware platforms from parties that do not trust each other. Current research on PPML is partly conducted at the software level. On the one hand, the data provider worries about data privacy, concerning leakage of private data to the party that conducts the computation. For example, the input to DNN models could be considered as privacy-sensitive, e.g., input to facial-recognition-enabled CCTV cameras [15], medical images locating diseases in a preliminary stadium [103], or a user's prompt to an online conversational AI [96]. Examples of attacks compromising the data privacy of end users are membership inference [108] and attribute inference [131] attacks. On the other hand, the service provider that owns DNN models has concerns that malicious users will steal the Intellectual Property (IP) of DNNs, i.e., the architecture and trained parameters, especially when deploying them to edge devices [11]. One representative attack is *model extraction*, where the adversary can rebuild the model by querying the DNN [66, 119]. Common ways to combat those threats for PPML include differentially-private machine learning [35, 62], secure multi-party computation [67], and homomorphic encryption [100].

Physical SCA attacks pose a substantial threat in the PPML scenario, where they have a different threat model than software-level attacks, hinting that guarantees provided by current defenses against software-based attacks may not hold. Dedicated hardware is being designed and optimized for DNN inference, and widely used in production environments [4, 8]. Physical SCA attacks on DNNs assume that the adversary is in the vicinity of the hardware device that runs DNN models and could collect traces that represent the device's physical properties, such as electromagnetic (EM) leakage or power consumption. Figure 1 provides an illustrative example showing the SCA setup when a DNN is running on hardware. Input data [12, 125], hyperparameters [81], and parameters [41] can

*Authors are listed in alphabetical order.

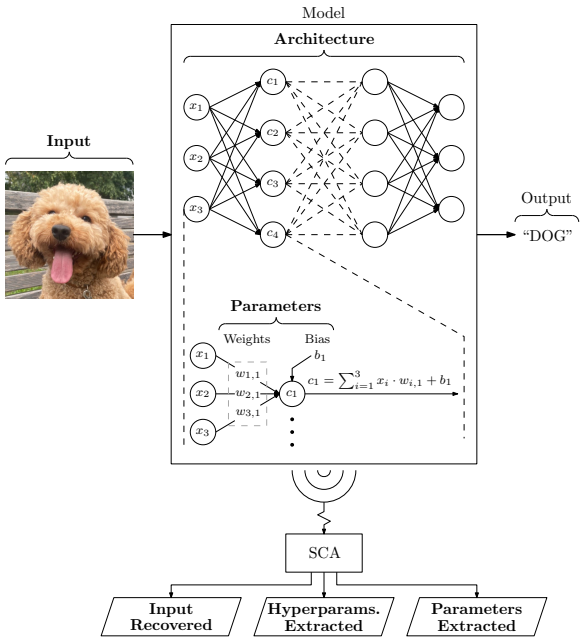


Figure 1: Illustration of physical SCA on a Multi-Layer Perception (MLP), where the model is running on hardware for image classification. In the first layer of the MLP, bias b_1 is added to the weighted sum of all input points (x_i) with weights ($w_{i,1}$) to get an intermediate value c_1. Under a specific threat model, intermediate values can be exploited in the trace analysis to mount an SCA attack to extract inputs or models.

be extracted by analyzing the collected traces, rendering a practical threat. Sometimes, the adversary does not even need to have any information about the model [11]. It indicates that anyone in the physical proximity of the hardware could be considered a threat, which is a valid hypothesis for adversaries being providers of cloud computing or end users of edge devices. For example, a hospital employee can install an EM probe on a portable ultrasound machine [122] and measure the leakage from the chip to steal the DNN models.

Extensive research has been conducted in the area of physical SCA on DNNs over the past few years. Current SCA attacks are highly platform dependent and employ distinct threat models for different attack objectives and analysis tools, demanding a general revision of attack methodology and assumptions. In addition, existing surveys do not consider the fundamental limitations introduced by model extraction through physical side channels [79], but rather focus on the wide scope of model extraction and discuss approaches only at a high level [94].

In this paper, we revisit previous SCA attacks on DNN implementations and provide a taxonomy where we systematize findings toward model extraction and input recovery. Specifically, we discuss the dependencies of threat models on attack objectives and analysis methods, motivated by which we also present a novel systematic attack framework composed of fundamental stages derived from various attacks. Furthermore, we provide an in-depth analysis of common SCA attacks for each attack objective and discuss uncovered potential practice limitations, validated by experiments on a state-of-the-art commercial Xilinx FPGA DNN accelerator.

Specifically, this SoK paper makes the following contributions:

- We taxonomize SCA attacks on DNNs that focus on extracting the architecture, parameters, and inputs exploiting physical side-channel leakages. By breaking down the attack into different stages, we provide a framework that can be used to analyze and categorize all attacks using side channels for model extraction and input recovery.
- Following our framework, we provide in-depth descriptions and comparisons of SCA attacks, summarize the common knowledge, and systematize the threat model.
- We demonstrate that strict assumptions that current approaches make for architecture extraction, can be relaxed in some cases. This results in a larger search space for architectural properties.
- We provide an analysis with simulations demonstrating that the current approaches for parameter extraction of DNNs are not efficient due to error propagation to different layers.
- We present a novel input recovery approach, in which attributes of the input can be recovered without any knowledge of the deployed DNN.
- We identify future challenges of physical SCA attacks based on our framework and edge-case analysis. We suggest future directions regarding hardware developments, physical-SCA-based attacks, and countermeasures.

The rest of the paper is structured as follows. We start the paper by providing background information on DNNs (Section 2) and SCA (Section 3). Then we present the motivation towards model and input recovery attacks, together with the generic threat model and our framework for current approaches (Section 4). We discuss existing approaches towards *architecture extraction* (Section 5), *parameter extraction* (Section 6), and *input recovery* (Section 7). Next, we provide an outlook on the development of SCA, identify new potential avenues for model and input recovery (Section 8). Finally, we discuss broader related works (Section 9) and provide concluding remarks (Section 10).

2 Deep Neural Networks and Hardware Accelerators

The flexibility and effectiveness of DNNs have made it the de facto solution for various applications, e.g., facial recognition [54]. Commonly used DNN architectures include, Multi-Layer Perception (MLP) [120], Convolution Neural

Networks (CNNs) [73], Generative Adversarial Networks (GANs) [42], diffusion models [47], and Transformers [123]. Lightweight models, for example, Binary Neural Networks (BNNs) [102] or compressed VGG-16 [109], can be deployed on edge devices without overly relying on cloud computation resources [43, 102].

For deployed DNNs, there are three main components of interest to adversaries: *the input*, *the architecture*, and *the trained parameters*. Depending on the application of the model, the input can take different forms, e.g., an image or a spoken sentence, for image and speech recognition, respectively. The architecture of DNNs defines the types and connections between the layers used in the network. Layers apply different transformations on their input data and forward their output to the subsequent layer(s). Each layer has a set of parameters, typically the *weights and biases*, that can be tuned so that the DNN can solve a certain task.

The architecture of a DNN consists of multiple layers, i.e., the building blocks that process and transform input data. The model part of Figure 1 provides an illustrative example of MLP and shows the calculation of one intermediate value in the first layer. While the various types of networks differ in architecture, the modules they use often overlap and share many similarities [45, 53, 58, 105]. Some common modules of these networks are used in different types of DNNs. By changing the variables in the configuration of these common modules, known as the *hyperparameters*, different DNN structures can be established.

Convolution layers and pooling layers are critical and fundamental building blocks in several types of Neural Networks, which are primarily employed for image recognition [72]. A convolution layer contains small *kernels* (also known as filters) that have trainable parameters and a predefined *shape*. During the forward pass, kernels convolve across the whole input with a certain step size, known as the *stride*. Pooling layers help control the number of parameters to control overfitting and reduce computational load.

Fully-connected layers (FC layers) have hidden nodes and each node applies a weighted sum over all inputs. The outputs of the layer are the weighted sums of each node, so the output size is determined by *the number of nodes* in the layer.

Activation functions introduce non-linearity into the DNN, enabling it to solve complex problems. Different types of activation functions are designed to increase efficiency [91] or reduce the vanishing gradient problem [44]. Typically used activation functions are *ReLU, Tanh, Softmax, and Sigmoid* [32].

Computational resource limit. Powerful DNNs require large computational resources, especially during training. Therefore, large DNNs are usually trained on GPUs, which by design greatly support parallel processing, to make this process more efficient. The inference latency of DNNs is critical for many applications, especially for resource-constrained environments such as embedded devices [74]. To this end, many accelerators have been developed, e.g., TPUs [65], and DPUs on FPGAs [8].

Implementations of DNNs on edge devices are further limited by available resources. To resolve this issue, resource-aware architectures have been designed, e.g., MobileNet [53] and EfficientNet [115]. Another solution is to quantize regular DNNs to reduce resource consumption during implementation, e.g., XILINX FPGA-based accelerators [8], and BNNs [102]. Hardware-wise, FPGAs are also used for edge applications where resources are limited. Due to their low computation overhead, low latency, and flexibility, FPGAs are popular choices for model inference [8, 112, 136].

3 Background on Side-Channel Analysis

Due to their physical implementation, electronic devices emit unintentional information about their state via *side channels*. Side-Channel Analysis (SCA) can be applied to obtain information about the executed operations and data processed by the device. Side channels can be either *physical* (e.g., timing, power, electromagnetic emanation) or *logical* (e.g., memory access patterns), based on the measured properties. In addition, SCA attacks are *non-invasive*, *passive* attacks where the adversary does not tamper with the normal execution of the device, just observes information, as opposed to fault attacks [13] which induce errors in the device's execution. In this work, we only consider passive physical SCA attacks that exploit timing, power or EM emanations as side channels.

Timing analysis exploits the variations in an algorithm's execution time where the amount of variation depends on the instruction executed or some other secret information. Variations in timing can occur for various reasons, e.g., non-constant time instruction, cache hit/miss, or branching [68]. In the context of neural networks, changing hyperparameters that alter the structure of a neural network can result in large variations in execution times [11].

Power analysis leverages the dependency of dynamic power consumption of an electronic device while processing and the data used in executed operations [69]. There are different flavors of power analysis of which we will focus on *Simple Power Analysis (SPA)* and *Differential Power Analysis (DPA)*. SPA analyses a few, or even just a single collected trace to extract information about the operations executed by the device or the used (secret) data. DPA and its variants, e.g., Correlation Power Analysis [16], recover secret data exploiting the data dependency of power consumption [83]. These dependencies can allow an adversary to perform statistical tests between the set of collected traces T and the hypothetical power consumption of secret data-dependent intermediate values of the algorithm, by using a leakage model, e.g., Hamming-weight (HW) or Hamming-distance (HD). In the context of neural networks, secret data are considered to be the parameters (i.e., the weights and biases) of the models in contrast to keys for crypto implementations.

Electromagnetic analysis takes advantage of electromagnetic (EM) emanations occurring due to moving charges that produce and change magnetic fields. Therefore, the EM emanations of a device executing an operation of interest can be measured by using an antenna to collect near- or far-field emanations from the target device. Since EM emanations depend on current flowing through components in a device, the concepts of SPA and DPA can also be used on EM emanations and they are called Simple EM Analysis (SEMA) and Correlation EM Analysis (CEMA), respectively. EM analysis has proven effective in eavesdropping on display units and breaking cryptographic implementations [36, 38, 50, 71, 80, 121].

Defenses against Side-Channel Analysis Thanks to the extensive research in the field, a broad range of different defenses can be used to protect devices against SCA. First of all, timing vulnerabilities can be mitigated by making implementations constant time with using, e.g., non-variable time instructions and only non-secret data-dependent branches. Defending against power analysis can be done both in hardware and software. In hardware, different logic styles than CMOS such as e.g. dual-rail [118] can be used for the hardware design (and production) of the device. In software, one can use masking, making the power dependent on other (masked) data, instead of actual data [24, 83, 101]. Finally, for EM analysis, specific hardware countermeasures, such as shielding, can prevent sensitive electromagnetic emanations leaking from the device [25].

4 Reverse Engineering Neural Networks

A trained DNN has multiple valuable facets that an adversary might try to acquire after the model is deployed:

1. the *inputs* during inference,
2. the *architecture* of the deployed model,
3. the *parameters* of the deployed model.

Inputs to DNNs can contain valuable or privacy-sensitive information, such as in medical applications [103]. The exact DNN architecture is IP and often kept secret because many cutting-edge models are closed-source and are usually modified versions of common architectures. For example, ChatGPT-4 [96] is a proprietary IP based on the Transformer architecture [123]. More importantly, the training of closed-source models can also include proprietary training data that an adversary may not be able to access. Furthermore, training a model requires a high level of expertise that the adversary may be lacking. Therefore, the parameters of the trained model are also of a paramount importance.

In this paper, we consider works whose objective is to recover one or more of these facets by exploiting *physical* side channels requiring proximity to the target device.

4.1 Threat Model

We decompose the threat model into *generic capabilities* and *objective-specific knowledge* to taxonomize previous SCA attacks. The generic capabilities are used across all investigated attacks, whereas the adversary may have additional knowledge, depending on the objective of the attack. These additional capabilities that an adversary may have are listed here as objective-specific knowledge.

Generic capabilities:

G1: Physical proximity to the hardware device, for which no countermeasures are implemented.
G2: Capability to collect and analyze power and EM traces.
G3: The attacker has access to a profiling device, identical to the device under attack.

Objective-specific knowledge:

Inputs:

I1: The input dimensions.
I2: The architecture of the DNN.
I3: The parameters used in the DNN.

Architecture:

A1: The input dimensions and values.

Parameters:

P1: The input dimensions and values.
P2: The architecture.
P3: The hardware design of the device under attack.

4.2 Taxonomy

We provide a taxonomy in Table 1 for all existing research works on reverse engineering DNNs via physical side channels to our best knowledge. Specifically, different SCA attacks are categorized by the objective and intermediate objectives of the attack, objective-specific knowledge of the adversary, the model type, the platform on which they are deployed, the SCA methods, and the attack path.

Objectives and dependencies. Objectives of adversaries are three-fold, namely input, architecture, and parameters, which are not always independent. The architecture of a DNN is the first secret that adversaries would like to extract, and hence the foundation to extract the parameters. As seen in Table 1, all parameter extraction methods need access to architectures either conducting architecture extraction or assuming that the architecture is known. Input recovery is less dependent on the other objectives, where only a two known approaches take parameters into account [82, 125].

Intermediate Objectives. The intermediate objective specifies the key intermediate results to achieve the final objective. For architecture extraction, the intermediate objective can be either component-level (layer and activation types, the number of layers (#layers) or number of neurons (#neurons), and kernel size) or model-level (candidate model ranking from known architectures). For parameter extraction and input recovery, the intermediate objective is often the ranking of the

Table 1: Taxonomy for reverse-engineering DL implementations with physical SCA.

target value, determined by e.g. applying DPA on the obtained power traces [16]. This ranking is distinguished by the precision of the parameters or pixels and the actual number of bits that were recovered are stated in brackets.

Platforms. Side-channel leakage is hardware-dependent: each platform processes DNNs differently, resulting in different leakage patterns. Microcontrollers, CPUs, FPGAs, and GPUs are the primary devices used to deploy DNNs for inference. Knowing the properties and specifications of the hardware platform, the adversary can decide on the side channel, i.e., EM- or power-based side channel, and collect the respective traces.

Analysis. When the adversary obtains the traces through the desired side channel, the SCA approach needs to be determined. For each of the different properties of a DNN, different analysis methods can be leveraged to analyze the obtained traces. Figure 2 shows the different flows of analysis methods that are currently used for extracting the architecture, parameters, and recovery of the input. From Figure 2 it can be seen that there is a finite number of combinations of attack paths that can be used to obtain a certain subset of objectives, of which the known combinations are shown in the attack path column of Table 1. For architecture extraction, we consider (1) SPA, (2a) Common Patterns (CP), (2b) Hyperparameter Optimization (HO), and (2c) hyperparameter derivation. Sec-

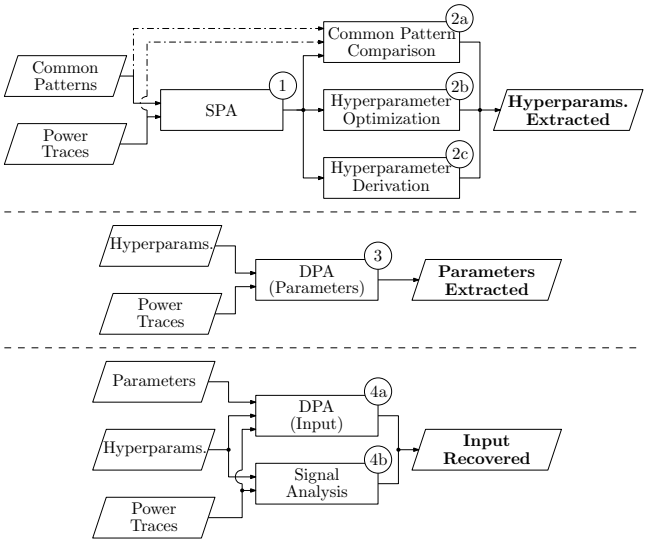

Figure 2: Physical SCA attack framework for model extraction and input recovery. Different attack stages are marked with different numbers, where a combination of different stages leads to an attack path. It should be noted that the three different targets require different inputs to the flow, where for both the parameters and input, the architecture should be provided.

ondly, for parameter extraction, we only consider (3) DPA. Lastly, for input recovery, we consider (4a) DPA and (4b) Signal Analysis (SA). The attack paths shown in Figure 2 can be combined to improve the threat model. For example, Gongye, et al. [41] use (2a) to extract the kernel size, similar to Xiang, et al. [127], which is then used to extract the parameters of the network. Detailed explanations for framework components can be found in corresponding sections.

5 Architecture Extraction

The first objective is to recover the architecture of the deployed model. The architecture of a model refers to the hyperparameters of a network, e.g., the number of layers in a network and their types. There are two main motivations for an adversary to extract the architecture of a network. First of all, the adversary may assume that the deployed model is a more general architecture and uses publicly available, pre-trained parameters. Therefore, knowing the architecture, the adversary could use pre-trained parameters to function as a substitute for the originally deployed model [5]. Secondly, the architecture itself could be a stepping stone towards the recovery of either the input or the trained parameters, as shown in Figure 2. For extraction of the architecture of a deployed DNN, a black-box scenario is being considered, i.e., the adversary has no knowledge of the deployed model, including the family of networks to which it belongs. The adversary only possesses the generic capabilities G1-G3 as described in Section 4.1 and may assume that the input is known (A1).

5.1 Current Approaches of Architecture Extraction

5.1.1 Simple Power Analysis

Some hyperparameters have shown to have very distinctive patterns for different values [11, 64]. These characteristics occur due to, e.g., the same operation having to be executed several times, or operations having varying execution times. The adversary can already extract information from the obtained traces by using SPA. Moreover, for most approaches towards architecture extraction, listed in Table 1, SPA is required as a first step, as shown in Figure 2. For example, Yu et al. first use SPA to recover the layer types, and then apply this knowledge to recover the remaining hyperparameters [135]. On the other hand, Xiang et al. [127] use a classifier trained on common configurations to extract information of the hyperparameters directly from the power trace, and hence do not use SPA. Due to the small resource footprint and proven effectiveness, SPA is in most cases preferred over more computationally-heavy approaches to extract hyperparameters. However, on more developed platforms, traces typically are less distinguishable, making SPA impractical.

Different types of layers in a DNN all consume power in a distinctive way, which is observed as variations in the power traces [41, 64, 76, 81, 135]. These patterns originate from the varying way in which the different types of layers access data [76]. Due to the differences in the power traces, the adversary is able to determine the type of layer that was executed, based solely on the observation of the recorded traces.
The number of layers can be determined from simply counting the different types of layers, in case of less powerful CPUs [81]. Due to the distinctive patterns, adjacent layers can be identified from the raw traces. These patterns can then be counted to determine the number of layers in the DNN. It should be noted that due to high parallelization in FPGAs and GPUs, simply counting the layers is often not possible.
Activation functions have a high variation in execution time, depending on their input. This varying execution time already makes it possible for an adversary to distinguish between the ReLU and Softmax activation function. However, for the Sigmoid and Tanh activation functions, the execution times are similar and not easily distinguished [11]. Nevertheless, the characteristic differences in power consumption of the Sigmoid and Tanh activation functions, allow them to be distinguished after all [114]. Therefore, the four most common activation functions, ReLU, Softmax, Sigmoid, and Tanh, can be often distinguished using SPA only.
The number of neurons in MLPs can also be determined from SPA, by observing the execution time. The execution time of each layer is dependent on the number of neurons in the layers of an MLP. From observing the execution time of MLPs, one can determine number of neurons in the network [11]. However, the measurement noise and re-alignment make it difficult to distinguish a single perceptron change [22].

5.1.2 Advanced Analysis

In practice, deployed models are part of a limited set of *common DNN models* [52, 76, 127, 135]. Therefore, the likelihood that a deployed model adopts a common architecture is higher than a custom-made architecture. Moreover, upon recovery of a limited number of hyperparameters, the remaining hyperparameters can be determined by applying the knowledge of the most common configurations for DNNs, depicted as the hyperparameter derivation step (2c) in Figure 2 [41, 56, 64, 81]. However, direct derivation of the remaining hyperparameters may not always be possible due to the lack of equations with unique solutions. To resolve this, an adversary can set fixed values for some of the unknown hyperparameters or use more advanced techniques to acquire these hyperparameters via physical SCA.
Common patterns are created to take into account the design philosophy of commonly used DNN models, from which assumptions can be made about the hyperparameter values. First of all, there is a common order in which layers can occur throughout a network, i.e., the type of layer $i+1$ can be de-

termined, provided the type of layer i by using knowledge of default layer combinations [56]. Secondly, hyperparameters such as the kernel size can be approximated when the layer type is known [76, 135]. For example, when considering a convolution layer, the used filter sizes in the most common models are either 1×1, 3×3, 5×5, or 7×7 [135]. For square kernels in BNNs, one could additionally observe the size of the kernel by executing a T-test on the input to distinguish between different filter sizes [104, 132]. Additionally, a classifier can be made, based on the common patterns, to determine directly from the power traces to which of the standard hyperparameter combinations the trace belongs [17, 52, 107, 126, 127]. Therefore, the correct hyperparameters can be extracted from the observed power traces, given common patterns.

Hyperparameter optimization can also help to fine-tune an estimate from commonly used hyperparameters. Typically, an initial estimation based on commonly used patterns of hyperparameters is not very accurate. It could be that, e.g., a wrong value for the stride has been chosen which causes the derived model to deviate from the original target model. Therefore, Maia et al., decided to jointly optimize all hyperparameters "*seeking values that best fit their initial estimates, subject to consistency constraints*" [81]. The technique of Maia et al., minimizes the convex quadratic form

$$\min_{x_i\in\mathbb{Z}^{0+}} \sum_{i\in\mathcal{X}} (x_i - x_i^*)^2, \tag{1}$$

where $\mathcal{X}$ is the set of all hyperparameters, and x_i^* and x_i are the initial and optimal value for the i^{th} hyperparameter [81]. Hence, optimization techniques could be used to extract a more accurate approximation of the target architecture [81].

5.1.3 Assumptions on Architecture Extraction

For all of the architecture recovery methods in Table 1, it is assumed that target models are common DNN configurations. Moreover, assumptions for single hyperparameters can also have consequences for other hyperparameters, e.g., restricting the output size of a layer inherently restricts the input size of the next layer [41]. Therefore, putting restrictions on architecture configurations reduces the search space for the hyperparameters, making it easier to recover the architecture of the target DNN.

Only four activation functions are assumed to be used in common DNNs, i.e., only ReLU, Sigmoid, Tanh, and Softmax are typically considered for activation functions [11, 22, 64, 114]. In theory, there exist more activation functions than only these four, e.g., ELU or the binary step function [23, 32]. In practice, because of the popularity, it is a valid assumption that the activation function used in a DNN is ReLU, Sigmoid, Tanh, or Softmax [32].

Only limited layer types are considered when extracting the hyperparameters of a DNN. For BNNs, the only two layer types that are used, are the pooling and convolution layers, which also reduces the search space of the hyperparameters [104, 132]. Additionally, the combination of layer types can be reduced based on common DNN implementations. For instance, it is unlikely that a convolution layer is followed by an FC layer, since it does not make sense to have two consecutive linear transformations in a DNN [56]. Additionally, the combination of layer types can be reduced based on common DNN implementations [56]. For instance, it is unlikely that a convolution layer is followed by an FC layer, since it does not make sense to have two consecutive linear transformations in a DNN. Hence, assumptions made about the layer types can also simplify the extraction of the entire network architecture.

The kernel is considered a square in all of the approaches listed in Table 1, that aim to extract the architecture. Since almost all publicly deployed models, in fact, use a square kernel, this assumption is valid. Nevertheless, there exist configurations in which the kernel is not a square [113], which are not considered in the discussed architecture extraction papers. Moreover, most papers listed in Table 1, limit the size of the filter to typically odd dimensions between 1 and 11. Due to the limited set of filter dimensions that is currently being deployed, it is reasonable to assume for an adversary that the filter dimension is also part of this limited set.

The stride is assumed to be 1 or 2 in most papers attempting to extract the architecture [41, 56, 76, 81]. Due to the limited size of the kernels that are being considered, a bigger stride could result in skipping input values during the convolutions, or the model not being feasible at all. Therefore, an increment of the stride on a DNN that has a small filter size could result in a lower accuracy of the overall model. Moreover, the most common DNN implementations also rarely use a stride that is bigger than 2 [76]. Hence, assuming the stride is limited to either 1 or 2 is a valid assumption that further reduces the search space for hyperparameters.

Aside from the most common assumptions listed above, there are additional assumptions that are still worth mentioning. One obvious assumption is that for image classification applications there are only three input channels used in the first layer [56]. With most input images being of color, all of them have red, green, and blue (RGB) channels representing the pixels. Aside from RGB images one could also consider only grayscale images, in which only one channel is considered. Secondly, in some scenarios it can be assumed that for the same layers in the network, the same configuration is being used, i.e., the first convolutional layer uses the same filter size as all other convolutional layers in the network [135].

5.2 Discussion on Architecture Extraction

Within the assumption spaces of each work, the full architectures of deployed DNNs can be extracted. Most of the works listed in Table 1 have a number of assumptions, hence considering only a subset of all the possible configurations for

the architecture. We argue that these assumptions are, in most cases, correct and can help simplify the attack process, but may fall short in less common but nevertheless, appropriate use cases. In particular, this section provides experimental analysis on the well-acknowledged assumption that the kernel shape in convolutional layers is always considered to be a square. Even though the square-shaped kernel is efficient to implement and is heavily used for image filtering in computer vision research, non-square convolution kernels are still being widely used [113].

If a deployed model has a non-square shaped kernel but the adversary classifies it as being a square, the recovery of the architecture will fail. Consequently, further extraction of the model may fail as well and result in a non-functioning model. In Figure 3, traces related to a 224×224 input convolved with a 1×4 and a 2×2 kernel are collected on a Xilinx Zynq UltraScale+ ZCU 104 board [9]. As can be seen from Figure 3, the traces for both square and non-square kernel are very similar; it is hard to distinguish them at first glance. If the adversary assumes that the kernel is of a square shape, and observes a trace for a non-square kernel, as shown in Figure 3, it may result in the adversary incorrectly classifying the kernel as a square. Therefore, if a limited set of configurations is considered, but the deployed model is in fact a corner-case it may result in an unsuccessful recovery of the architecture.

However, if one closely observes the traces in Figure 3 it can be seen that there is in fact a slight timing difference between the two traces. This timing difference between the traces can be used for distinguishing between the two different kernels. Therefore, if the adversary has the capacity obtain a pattern for multiple kernel configurations, it would be possible to distinguish between different kernel configurations.

Note that the traces in Figure 3 represent the execution time and the power consumption during the convolution. The power consumption and execution time of the observed traces are related to the number of operations that are being executed [127, 135]. For convolution layers, these operations are mainly the number of multiplications and loading of the values required for multiplication. The latter is dependent on the number of convolutions that are being executed. Therefore, the shape of the traces is not only dependent on the number of multiplications, but also on the number of convolutions. Given a kernel of height k_h and width k_w and an input of height i_h and width i_w, the number of convolutions C can be described by

$$C = \frac{i_w - k_w + 1}{s} \cdot \frac{i_h - k_h + 1}{s}, \tag{2}$$

where s is the stride. Consequently, the total number of multiplications M in a convolution layer can be described by

$$M = k_h \cdot k_w \cdot C. \tag{3}$$

It can be seen from eq. (2) and (3) that $\{C, M\}$ is not unique, i.e., there are different values for k_h, k_w, and s that will result in the same $\{C, M\}$. Therefore, theoretically different kernel configurations could result in similar power traces.

An example of different configurations for which the same number of convolutions and multiplications are used is when a kernel has a size of $k_1 = (k_{h1}, k_{w1})$ and the second kernel has a size of $k_2 = (k_{w1}, k_{h1})$. Figure 4 shows the power traces of a convolution layer with a 28×28 input convolved with both a 3×4 and 4×3 kernel. For both kernel configurations in Figure 4 it holds that both the number of convolutions and the number of multiplications are equal. However, Figure 4 shows that even with same number of multiplications and convolutions, the observed EM traces allow the adversary to distinguish between the two configurations.

Since equivalent configurations in terms of convolutions and multiplications can be distinguished through power traces, including additional configurations allows for the architecture extraction method to extract a bigger set of possible architectures. This expansion of the search space of an architecture extraction approach improves its applicability to different, possibly unknown, architectures. Therefore, relaxing assumptions about deployed architectures can help approaches introduced by, e.g., Hu, et al. [56] or Maia, et al. [81], to extract architectures that deviate from common configurations.

5.3 Conclusion on Architecture Extraction

Current approaches to architecture extraction extensively use hyperparameter-search-space limiting assumptions. Even though these assumptions are well grounded, it may be the case that the deployed model lies beyond the defined search space for hyperparameters. Due to high similarity between traces, it may be the case that the adversary incorrectly determines hyperparameters, resulting in an inaccurate architecture being extracted. However, we demonstrate that investing in expansion of the search space for hyperparameters could decrease this misclassification.

6 Parameter Extraction

With the trained parameters of the network, an adversary has all the information necessary to deploy an exact copy of the network. This could give the adversary both monetary and intellectual benefits. For instance, when an adversary possesses the trained parameters of ChatGPT-4 [96], he or she does not need to pay the subscription fee and can let others use the extracted model. Therefore, the trained parameters represent the most valuable part of a DNN, and hence an interesting target for an adversary.

In addition to the generic capabilities G1-G3 described in Section 4.1, the adversary has more knowledge about the deployed network when extracting the trained parameters. In particular, for parameter-recovery, the adversary knows the input to the model (P1), and knows the architecture of the deployed DNN (P2). For P1, it is a standard assumption in

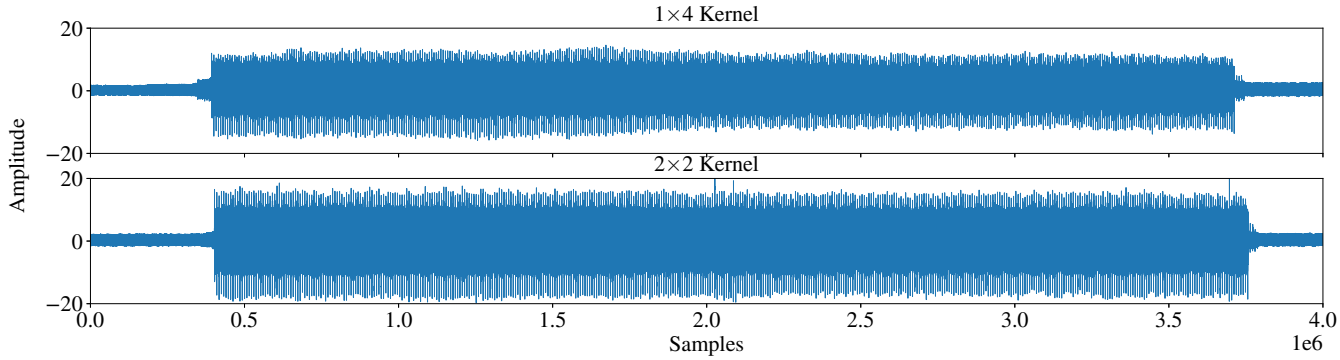

Figure 3: Averaged EM traces of convolutional layers with different 2D kernel sizes, taking 224×224 grayscale images as inputs. The top trace shows the execution of a convolutional layer with a 1×4 kernel, while the bottom trace uses a 2×2 kernel.

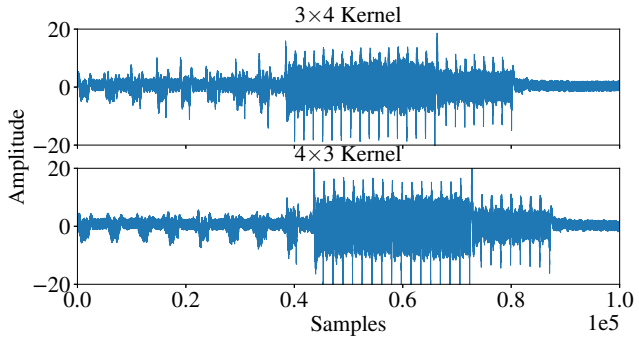

Figure 4: Averaged EM traces of convolutional layers with different 2D kernel sizes, taking 28×28 grayscale images as inputs. The top trace shows the execution of a convolutional layer with a 3×4 kernel, while the bottom trace uses a 4×3 kernel.

physical SCA attacks that the adversary knows the inputs [83]. For P2, we show that extraction of the architecture is possible with physical SCA approaches.

6.1 Current Approaches of Parameter Extraction

6.1.1 Differential Power Analysis

To extract the parameters of FC and convolutional layers, all current approaches towards parameter extraction in Table 1 use DPA to correlate measurements with the power consumption of hypothetical sensitive intermediate values, indicated by (3) in Figure 2. Since FC and convolutional layers are usually implemented as matrix multiplication operations [21], an adversary can target the multiplications and partial sums to extract the parameters.

In a 2D convolutional layer, with kernel size $k_h \times k_w$, the convolution result c_{res} between a kernel (w) and a piece of input x can be unrolled like

$$c_{res} = \mathbf{x} * \mathbf{w} = \sum_{i=1}^{k_h \cdot k_w} w_i \cdot x_i = w_1 \cdot x_1 + \cdots + w_{k_h \cdot k_w} \cdot x_{k_h \cdot k_w}. \quad (4)$$

The sensitive intermediate values in the unrolled convolution are the partial sums $c_j = \sum_{i=1}^{j} w_i \cdot x_i$ $(j = 1..k_h \cdot k_w)$ that are updated with the result of the multiplication of an input x_i and weight w_i.

Since the inputs are known, the attacker can compute the Pearson correlation between the traces (T), and the leakage model (L) of the i^{th} intermediate value $\rho(T, L(c_i))$ for every parameter candidate, where the candidate parameter for which $\rho(T, L(c_i))$ is the highest is considered to be the correct value for the targeted parameter [11, 29, 41, 51, 63, 75, 82, 133, 134]. Typically, due to the inter-dependency of the parameters, shown in eq. (4), the DPA approach recovers the weights one-by-one starting from w_1 until $w_{k_h \cdot k_w}$. However, convolution is a linear operation where multiple weight candidates can give the same hypothetical power consumption values which makes the DPA attack harder. Therefore, applying the HD leakage model, to model the behavior when a partial sum is updated can give better results [41, 51].

6.1.2 Developments of Parameter Extraction

All parameter extraction approaches in Table 1 leverage DPA, however the approaches can still be distinguished from each other based on the precision of the parameters and the performance of the approach. An example can be seen in Yoshida, et al. [133], Yoshida, et al. [134], and Li, et al. [75], where all of them leverage DPA to recover 8-bit integer parameters from MLPs deployed on FPGAs. Yoshida, et al., Yoshida, et al., and Li, et al. all face the same issues whilst extracting parameters through DPA: the parameters are inter-dependent, as shown in eq. (4). Each of these approaches cope with this inter-dependency in their own way, always improving on the latest research.

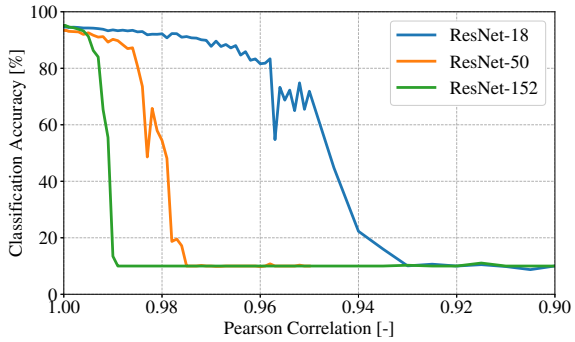

Figure 5: The classification accuracy of ResNet-18, ResNet-50, and ResNet-152 trained on CIFAR-10, plotted against the Pearson correlation between the original and transformed parameters. With the same architecture, models with more layers are more sensitive to measurement inaccuracy.

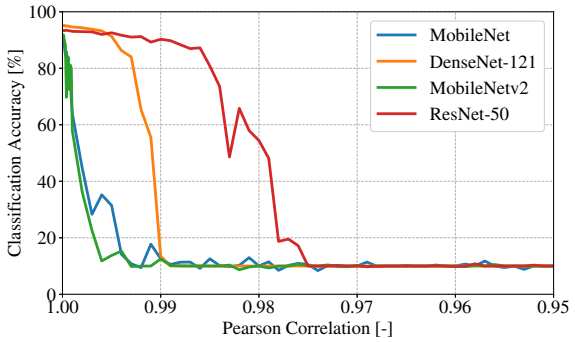

Figure 6: The classification accuracy of MobileNet, DenseNet-121, MobileNetv2, and ResNet-50, trained on CIFAR-10, plotted against the Pearson correlation between the original and transformed parameters. Here, sampled noises from Gaussian distribution are added to the kernels to simulate hardware-based environmental noise.

6.1.3 Assumptions on Parameter Extraction

In order to extract the parameters, current approaches need to access the exact inputs and the architecture of the deployed model [11, 29, 51, 63, 75, 82, 132–134]. Otherwise, accurate calculation of sensitive intermediate values is not possible, and the DPA attack will not be successful. In addition, the search space for the parameters is often limited to a range with certain precision [11, 51, 63, 82]. This allows an adversary to significantly reduce the number of candidates in DPA attack, especially if the parameters in the models use single-precision or double-precision data format. Furthermore, some attacks require that the inputs to the DNNs are carefully chosen but this assumes a stronger attacker that is able to control the inputs [41]. In addition, even if the victim's model parameters are updated after extraction, the adversary can still retrieve a functioning model that can be further trained with their data.

6.2 Discussion on Parameter Extraction

The DPA method described in Section 6.1 is a general solution that works across platforms and different data types to extract the parameters of a DNN. For BNNs, the accuracy of the extracted parameters through DPA even goes to 100% for the best method [132], and 99.99% for other methods [29]. However, as the data format of the parameters includes more bits, the more difficult it becomes to extract the correct parameters, and there can be errors in the recovered parameters [11].

There are two major limitations related to the state-of-the-art extraction of the parameters in DNNs: *parameter-extraction error propagation* and *complexity*. Firstly, it is yet unclear how the inaccurate extraction of parameters in one layer impacts the extraction of parameters in subsequent layers. Currently, none of the papers address this issue for large DNNs. Secondly, extracting all the parameters in DNNs is expensive. All papers note that the extraction of the parameters is an expensive operation, however the consequences for the extraction method are only slightly touched upon and notions of complexity are often missing. In this section, we will elaborate on the limitations present in the current extraction methods of DNN parameters.

6.2.1 Error Propagation of Parameter Extraction

Except for SCA attacks on BNNs [104, 132, 135], most previous works focus on extracting the parameters of the first layer in DNNs. Previous works hypothesize that it is feasible to reverse engineer entire DNNs by showing the successful extraction of the parameters of the first layer with a low error rate [11]. We seek to evaluate this hypothesis critically by detailed analysis and simulations in comparable scenarios.

Analysis on error propagation. We first provide an analysis showing that the error in parameter extraction can be propagated from shallow layers to deep layers in DNNs, and the error can accumulate layer by layer. In DPA, to estimate the parameters of a DNN, the adversary first needs to select an intermediate value and collect the corresponding traces. Given the search space of possible candidate values and the quality of collected traces, it could be that a large number of traces is required to predict the correct parameter. Even though a massive number of traces can be collected e.g., tens of millions, there is still a probability that predicted intermediate values deviate from the actual values due to noisy measurements, resulting in inaccurate parameter predictions. Since the intermediate values of the deeper layers of DNNs are calculated based on the estimated parameters of the previous layers, the error in deeper layers is amplified by inaccurate intermediate values in shallower layers. This inaccuracy of the measured traces is mainly due to noise induced in the measurements originating from environmental sources and is considered to be stationary, uncorrelated, and added to the power traces.

Therefore, this noise can be treated as a Gaussian distribution $\mathcal{N}(0,\sigma^2)$ [92]. Take, e.g., MobileNet [53] for which the average extraction error on the first-layer feature map (i.e., intermediate values) is 0 with a variance σ, and assume that the error follows a Gaussian distribution. Accordingly, the same error applies to predictions of the first-layer convolution kernels. Each value in the second-layer feature map depends on the 27 convolution kernels from the first layer if we know the activation and pooling functions. The accumulated error propagated from the previous layers then becomes approximately $\mathcal{N}(0,27\cdot\sigma^2)$. Hence, error propagation will be more influential in deeper DNNs, as shown in Figure 5 for ResNet-18, ResNet-50, and ResNet-152, with 18, 50, and 152 layers, respectively.

Simulation on error propagation. We provide a simulation to model the influence of the error propagation on the performance of the extracted model. We conduct experiments by simulating extracted parameters from MobileNet [53], MobileNetv2 [105], DenseNet-121 [58], and ResNet-50 [45] trained on CIFAR-10 [70], and we use classification accuracy on test data to represent the performance of the extracted model. In particular, we sample noises from Gaussian distributions which we add to the original parameters, to simulate errors in the extracted parameters. We then describe the introduced error by calculating the Pearson correlation between the original and extracted parameters. Figure 6 demonstrates that a high correlation may not guarantee the performance of an image classifier. From Figure 6 it can be seen that, e.g., MobileNet requires the correlation to be higher than 0.9994 to keep the classification accuracy above 77.80%. This required 99.94% extraction accuracy is above the 99.75% extraction accuracy that can currently be achieved, making it infeasible to accurately recover the parameters of MobileNet with the current approaches listed in Table 1.

Figure 6 shows that the architecture determines the sensitivity of the network against inaccurate measurements. If we compare, e.g., DenseNet-121 with 121 layers, and MobileNet with 27 layers, MobileNet requires an extraction accuracy of 99.95% to stay above a classification accuracy of 80% whereas DenseNet-121 only requires an extraction accuracy of only 99.7%. This is counter-intuitive, since we argued that more layers typically mean more error propagation and thus, typically, a lower performance of the extracted model, as demonstrated in Figure 5 for ResNet. Therefore, not only the number of layers, but also the overall architecture of the network determines the sensitivity against inaccurate measurements.

6.2.2 Complexity of Parameter Extraction

All methods for parameter extraction listed in Table 1, assume that the approaches can be used in deeper DNNs. Most of the parameter extraction approaches listed in Table 1 demonstrate the feasibility of their approach by only considering a single 3×3 kernel, i.e., recovering 9 weights. However, these approaches fail to mention how the solution can be applied to state-of-the-art DNN architectures, which can have millions of parameters. Therefore, the complexity of these approaches needs to be addressed.

We address the complexity of the DPA approach towards parameter extraction both from a measurement and an analysis point of view. First of all, during measurements, each collected trace contains d samples that should involve only the operations of interest, i.e., the operations where the parameters are involved. The larger the DNNs that are considered, the more samples it takes to fully capture their execution in a trace. Consider that in a convolution layer with a kernel size $k=k_h\cdot k_w$ there are C convolutions of k multiplications, then for a kernel of size $k+n$ there are $C\cdot n$ additional multiplications. These $C\cdot n$ additional multiplications then increase the number of samples that reside in a single trace with $n\cdot d/k$. Therefore, trace collection has a complexity of $O(n)$.

Secondly, for the analysis part of the DPA approach the obtained traces are correlated with all possible candidates for the parameters, of which the candidate with the highest correlation is being selected. The values for the candidate parameters of non-binary DNNs generally reside in a range $[-L/2,L/2]$, with $L\in\mathbb{N}$, and a precision p, so there are $N=L/p$ different candidates for each weight. Therefore, if we consider a kernel with n different weights, theoretically, there are N^n different combinations of candidates for the entire kernel. Nevertheless, extracting the parameters from the partial sums as described in Section 6.1 has a complexity of $O(N\cdot n)$. Moreover, with fixed kernel size, the complexity is linear w.r.t. the number of weights, i.e., $O(n)$. Therefore, the complexity of current approaches towards parameter extraction linear for both the trace collection and the analysis parts of the DPA approach.

6.3 Conclusion on Parameter Extraction

In conclusion, there are two fundamental issues with the current approach to use DPA as a method towards parameter extraction of DNNs. First of all, we showed that even the slightest errors in the recovered parameters can result in a non-functional model. Secondly, due to the linear complexity of recovering the parameters, the DPA approach can become computationally expensive for models with millions of parameters. Therefore, there exists a gap between the theoretical feasibility and practical implementation of current DPA approaches towards extracting the parameters in DNNs.

7 Input Recovery

In this section, we look at input recovery from a deployed DNN during inference. State-of-the-art CCTV cameras are equipped with a DNN chip that allows for facial recognition, which makes the input to the deployed DNN privacy-sensitive information [15]. Even with physical access to the target

device, the inputs might be encrypted in transit and only decrypted during inference. Therefore, methods such as monitoring I/O ports, network traffic, wireless communications, may not be able to recover the inputs. Instead, an adversary could launch an attack against DNN implementations to obtain the input, making it an interesting target for input recovery.

For recovery of the inputs, comparable to extraction of the parameters, the adversary has additional capabilities than the generic capabilities G1-G3. In both input recovery methods (4a) and (4b) shown in Figure 2 the adversary has different capabilities. For the DPA approach (4a), it is assumed that the adversary knows the architecture (I2) and the parameters of the deployed DNN (I3). For the signal analysis approach (4b), it is assumed that the adversary knows the architecture (I2) but not the parameters of the DNN.

7.1 Current Approaches of Input Recovery

7.1.1 Power Analysis

As can be seen from eq. (4) in Section 6.1, the intermediate values are not only dependent on the parameters, but also the input values. Then, for the first multiplication step ($i = 1$), the intermediate value in the multiplication is the partial sum which depends on both the input and weight. Therefore, recovery of the input can be already done in the first layer, in a similar manner as extraction of the parameters.

Similar to DPA for parameters, the possible input candidates are being correlated to the observed traces. In contrast to parameter extraction, the input is typically only used exactly once, e.g., an input frame of a CCTV camera will never be exactly the same as the previous one in a natural environment. Therefore, the adversary only has one shot to obtain the traces for the input recovery, for which correlating the entire trace to the candidates will not be sufficient to obtain a significant correlation difference between correct and incorrect candidates [12, 82, 125]. To cope with this limited number of available traces, knowledge about the architecture (I2) is leveraged to divide the traces in the corresponding multiplication operations. The known parameters are used to create hypotheses about possible intermediate values. These hypotheses are then correlated against the traces of singular multiplication operations to approximate the original values of the input [12, 82]. Additionally, when there is no knowledge about the parameters, but instead it is possible to provide input to the target model in a profiling stage (I1), a "*power template*" can be made [125]. This power template will be built by observing power trace from the target model with known inputs. In this way, the observed power traces from the target model, with the target input, can be matched to the generated power template to obtain a candidate for the input.

7.1.2 Signal Analysis

Even though it recovers exact values for the input, DPA is very expensive and it may not always be necessary to fully recover the input. The silhouette of an image may in some cases already disclose sufficient information for an adversary [125]. If the complete input image is not required, less computational-intensive methods can be used.

SA is an extension to SPA, where instead of directly interpreting patterns in the traces, additional computations have to be performed to extract information, e.g., interpreting bits from obtained traces [116]. As with DPA, SA approaches also exploit the data dependency in the power consumption of the deployed device, but without any knowledge of the parameters. Unlike DPA, the acquired traces can be processed individually rather than computing the correlation with other traces. Since the multiplications are dependent on the intermediate values, and hence the inputs, observing the magnitude and timing of the traces can already reveal information about the input, e.g., higher amplitudes or longer operations in the traces imply more computational intensity and hence it is most likely higher input values were used [27, 116, 125]. Similar to DPA, knowledge about the architecture (I2) can be used to split the observed traces in the different multiplication operations, making SA more accurate [125].

7.1.3 Assumptions on Input Recovery

Since inputs are recovered by observing similar leakages as for parameters, the assumptions made for input recovery are alike. Firstly, for recovering the inputs via DPA two assumptions are commonly used: the assumption that the architecture is known (I2) and the assumption that the parameters are known (I3). The architecture of the network reveals how the multiplications are executed and gives insight in how the traces are built up. To improve the recovery process, it is helpful to not only know when the multiplication operations are executed, but also what exact values are used. Therefore, knowing the parameters of the network could reveal more details about the inputs of the network, hence improving the recovery process [12, 125]. Secondly, for SA the only assumption made is knowledge about the architecture. This knowledge about the architecture is used, like for DPA, to split up the traces into single multiplication operations.

7.2 Discussion on Input Recovery

The state-of-the-art physical-SCA-based input recovery approaches have proven to be successful with single-shot traces [12, 116, 125]. For SA approaches, there is no strict requirement on the knowledge of the network, but here only attribute inversion can be performed, i.e., only partial information can be extracted about the inputs. On the other hand, for DPA approaches the adversary needs to know both the architecture and the parameters of the network to make ac-

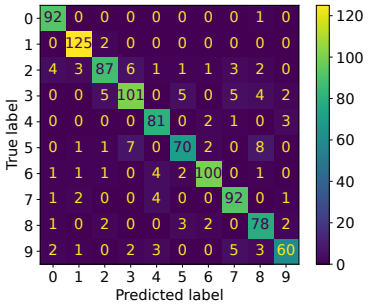

Figure 7: Prediction confusion matrix for inference-trace-based input prediction on 10 digits.

curate hypotheses. These strict requirements allow full input recovery to be possible.

However, as discussed in Section 6.2, if the adversary extracts inaccurate parameters, this inaccuracy may propagate through subsequent layers. Even though only one layer has to be considered, this error still propagates, through the DPA hypotheses, to recovered inputs. Therefore, if the adversary deals with a black-box scenario and wants to perform DPA, the adversary relies on the accuracy of extracted parameters.

To overcome the dependency on parameter extraction accuracy, we explore a new attack angle towards input recovery. In particular, we relax the purpose of the attack from reconstructing the raw input. Instead, we focus on attribute inversion, i.e. inferring sensitive attributes of the input such as the class it belongs to. This is similar to the "*passive adversary*" introduced by Wei et al. [125]. However, unlike Wei et al., we weaken the adversary and assume that, in addition to the exact parameters, also the architecture is unknown. We conduct a digit classification task on the MNIST [72] test split, for which the inference is implemented on a Xilinx Zynq UltraScale+ ZCU 104 board. EM traces are collected and then annotated during the digit inference, where 90% of the acquired traces are used to train and validate an X-vectors model [110]. Input digits can be predicted with an accuracy of 88.60% by EM traces during model inference, with details shown in the confusion matrix in Figure 7. Note that the number of different MNIST digits is not uniform, and our results are provided on the last 10% of the test split. Additionally, we attempt to distinguish the traces for different digits using SPA. However, the traces are indistinguishable from each other when using only SPA.

From the proof-of-concept discussed above, it can be seen that without any knowledge of the architecture, still attribute inversion can be performed on the input of the network. This opens up a new avenue of input recovery attacks, where attributes of the input can be recovered through physical side-channel attacks. Therefore, input recovery attacks may pose a larger threat than considered today.

Table 2: Physical SCA as an intermediate step for adversarial machine learning attacks. ●: Mounting existing adversarial machine learning attacks can directly exploit or primarily benefit from the extracted DNN information. ◐: Potential to benefit adversarial machine learning attacks. ○: Uncertain yet whether the extracted DNN information could benefit.

7.3 Conclusion on Input Recovery

The dependency on precise model parameters makes input recovery a less practical physical SCA. By adjusting the threat model and relaxing the dependency on model parameters and architecture, we demonstrate that input recovery could still be effective without deviating from the attack objective.

8 Outlook

SCA assumptions with substantial limitations. Current research makes strong assumptions about the knowledge and capabilities of the adversary. These assumptions are rarely subjected to comprehensive critical examination. We introduce a generic threat model and systematically classify all related existing research within this generalized framework. Furthermore, we encourage future studies to provide discussions on the constraints inherent to these assumptions.

SCA for novel neural network architectures. Regular SCA attack scenarios assume that all the components of DNNs are available for profiling, i.e., it is assumed that all layer types are publicly known. When a new type of module is introduced in the architecture and the component information is unavailable due to IP, profiling may fall short. As a consequence, the model extraction or input recovery attacks may fail. Moreover, current neural network extraction research is focused solely on MLPs, CNNs, and BNNs, while the interest for GANs, diffusion models, and transformers is increasing. Future research could look at the extraction of previously unexplored DNNs by either decomposing them into components [56] to extract or categorizing them in model type level [52, 127].

DNNs of FP8 formats The usage of the 8-bit floating point (FP8) binary interchange format in deep learning training and inference has been advanced by NVIDIA, Arm, and Intel [87]. FP8 in deep learning indicates a smaller parameter range and, accordingly, a smaller search space for SCA attacks. Such a smaller search space can substantially increase the SCA efficiency and reduce the error propagation (See Section 6). Future studies are encouraged to evaluate and provide simulation attacks against FP8 platforms.

Physical SCA as an intermediate step Physical SCA attacks not only pose a threat on their own but also have the

potential to provide information to assist algorithm-level adversarial machine learning attacks. From all works discussed Table 1, only Maia, et al. provided a discussion on the use of their approach as an intermediate step for evasion [81]. To facilitate future research, we, for the first time, systematically bridge physical SCA attacks and well-established adversarial machine attacks in Table 2.

Architecture extraction provides a solid initial step for various adversarial machine learning attacks that target DNNs. Extracted architectures can assist the adversary in building surrogate models that help query-based [98] and transfer-based [26, 81] evasion attacks. Furthermore, details of the architecture aid the model stealing attack to extract the decision boundaries [61], and there is a potential to aid poisoning.

Parameter extraction extracts a white-box DNN that benefits all attacks from Table 2. Membership inference [108] and model inversion [37] attacks can directly exploit extracted parameters to compromise data privacy. Even with errors in the extraction of parameters as discussed in Section 6.2.1, parameter extraction can still assist different attacks. For evasion, extracted parameters with an error or less precision may not substantially compromise the attack performance [130].

Input recovery directly undermines inference data privacy. When more input samples are extracted, data distributions of the inputs can be estimated, which could help evasion and poisoning attacks. Furthermore, input recovery has the potential to optimize the sampling process when querying a black-box learning model, improving the efficiency for both evasion and model stealing attacks [61, 97]. To better connect the physical SCA extraction and existing threats of machine learning systems, we refer security researchers to the general threat matrix of machine learning systems [1, 2, 6].

Countermeasures In parallel to evolving attacks, countermeasures are being developed to protect against DNN extraction attacks. These countermeasures are similar to those protecting cryptographic implementations. Software-based countermeasures include, e.g., shuffling [93] and desynchronization [14] to protect against parameter extraction. On the hardware side, masking countermeasure is proposed to protect dense layers and the ReLU activation functions in BNNs [29]. Subsequently, boolean masking is proposed to protect BNNs against parameter extraction [28, 30]. Although effective, these countermeasures come at a speed and silicon area cost.

9 Related Work

Non-physical SCA. This SoK only discusses physical SCA approaches towards model extraction and input recovery, that measure physical quantities without inferring data directly from it. Aside from this scope, there exist SCA attacks that do not rely on physical side-channel measurements. First, the power consumption can be measured through other channels, e.g., internal monitors [31, 39, 85, 86, 89, 90, 95, 99, 117, 137]. Second, DNN properties can be extracted by observing the memory access patterns, for which methods such as Prime+Probe and Flush+Reload can be leveraged [10, 18, 48, 49, 55, 57, 78, 95, 99, 124, 128, 129]. Third, the adversary could directly read information from the respective buses to obtain details about the DNN [55, 56, 139]. In addition, if in-memory computing architecture is used to implement DNNs then these are also susceptible to reverse engineering [106]. Last, timing analysis can be performed in software by observing the time it takes to execute a query to the target DNN [33, 34]. Therefore, if the adversary has more knowledge and access to the target system, other SCA approaches could be leveraged to extract the DNN as well. For instance, once the architecture is extracted using the methods mentioned in Section 5, software based memory access pattern attacks [39] can be used to extract the parameters. However, combined software and hardware approaches would assume a much stronger attacker, that can access the same device physically and locally. On the other hand, the results of the combined approaches are potentially superior.

Algorithm-based model stealing. Model extraction is not exclusively possible with SCA approaches, one could also leverage algorithm-based stealing to extract the network [19, 20, 94, 119]. We provided connections between algorithm-based model stealing and physical SCA attacks in Section 8.

Related surveys. No systematization paper provides a comprehensive overview of research on model extraction and input recovery techniques through physical SCA. Existing works discuss the general approach towards model extraction and related defenses against it [61, 79, 84, 94]. However, due to the more generic approach, these works fail to mention the specific attack scenario and limitations other than those noted. On the other hand, use-case-specific surveys exist that discuss model extraction, e.g., in reinforced learning [59], edge-deployed [60], and cloud-deployed neural networks [40]. This work extends the research field by discussing model extraction and input recovery attacks, specifically for the case in which physical SCA approaches are leveraged.

10 Conclusion

Our paper systematizes findings on physical SCA approaches towards model extraction and input recovery, and provides a framework that breaks down current SCA attacks into different stages. We provide a generic and specific threat model, and a taxonomy of relevant previous works on this topic. We offer a detailed analysis and perform experiments to illustrate potential shortcomings in common SCA practices towards model extraction and input recovery. Future works may benefit from the presented threat models, which increase the generalization and robustness of SCA approaches. Further directions could aim at making the SCA approaches more efficient, targeting DNNs with a larger architecture and more parameters.

ACAI: Protecting Accelerator Execution with Arm Confidential Computing Architecture

Supraja Sridhara Andrin Bertschi Benedict Schlüter Mark Kuhne Fabio Aliberti Shweta Shinde
ETH Zurich

Abstract

Trusted execution environments in several existing and upcoming CPUs demonstrate the success of confidential computing, with the caveat that tenants cannot securely use accelerators such as GPUs and FPGAs. In this paper, we reconsider the Arm Confidential Computing Architecture (CCA) design, an upcoming TEE feature in Armv9-A, to address this gap. We observe that CCA offers the right abstraction and mechanisms to allow confidential VMs to use accelerators as a first-class abstraction. We build ACAI, a CCA-based solution, with a principled approach of extending CCA security invariants to device-side access to address several critical security gaps. Our experimental results on GPU and FPGA demonstrate the feasibility of ACAI while maintaining security guarantees.

1 Introduction

Confidential computing allows cloud users to deploy security-sensitive applications on an untrusted cloud provider's platform. The trusted hardware provisioned in the cloud guarantees that the user's code and data are protected from malicious tenants as well as privileged administrators. While some hardware support for enabling trusted execution environments, such as enclaves in Intel SGX, is limited to process-level abstractions, there has been an increasing shift towards VM-level isolation of *confidential VMs* [1, 5, 30]. Another noticeable shift, especially in the cloud setting, is towards using accelerators (e.g., GPUs, FPGAs, TPUs) to meet the demands of large workloads [11, 48]. However, trusted execution on CPUs does not extend to accelerators. This leaves cloud users with a dilemma: render the workloads open to attacks by executing them outside the trusted execution boundary or take a performance hit by executing these workloads on CPUs.

Arm announced specification to enable confidential computing architecture, Arm CCA for short, in 2021 [5]. CCA isolates confidential VMs, referred to as realm VMs, from each other and the hypervisor with hardware-level access control via a newly introduced mechanism called granule protection checks. More importantly, these checks extend beyond the CPU cores to bus transactions as well as address translation for I/O operations, thus allowing CCA-enabled peripherals to securely access VMs. Further, CCA's VM abstraction is a good fit for the cloud setting that reasons about VMs and accelerators at a coarse granularity. For example, a P3 or F1 instance is provisioned as a bundle of a VM with a dedicated GPU or an FPGA respectively. Moreover, the accelerators are connected as PCIe devices. This is unlike mobile or desktops with integrated accelerators which are used intermittently by the applications (e.g., a browser renders a GUI with a GPU which is then used by a game app).

At the outset, accelerating confidential computing may seem trivial; especially in cases where accelerators, such as a GPU, have device-level TEEs. Accelerators require hardware modifications to enable TEE operations, which requires re-designing the device operations without loss of performance and increase in area size, as showcased with recent Nvidia GPUs [41]. Despite these hardware changes, we observe two main challenges remain. First, the accelerators cannot reason about the security of the host device, such as the authenticity of a realm VM, it connects to. Second, on the CPU side, the TEEs have to account for secure device access. The realm VMs have to be protected from rogue devices as well as devices controlled by co-tenant VMs. Achieving end-to-end secure accelerator execution requires addressing these gaps.

In this paper, we reconsider Arm CCA VMs with the goal of making access to accelerator devices a first-class primitive. Our choice of Arm CCA is inspired partly because it is an upcoming extension, unlike AMD SEV and Intel TDX which are already in production. The ability to experiment with CCA on Arm's Fixed Virtual Platform allows us to showcase the design choices and reason about its security transparently. CCA's native support for bus-level access control and memory protection allows us to re-purpose existing hardware protection mechanisms to our setting of PCIe peripherals. To this end we present ACAI, a CCA-based design that enables realm VMs to securely access accelerators.

Enabling ACAI requires careful consideration of security

and compatibility implications. In the existing CCA specification, external accelerators connected over PCIe can be allowed to access realm memory. If allowed to do so, such accelerators can break CCA protection that requires systematic enforcement of granule protection checks. Next, ACAI has to ensure that accesses from different accelerators are isolated to their designated share connected to the appropriate VM while thwarting accesses from malicious peripherals. Further, ACAI has to isolate all possible I/O and memory access paths, DMA and memory-mapped IO, from software and physical adversaries. Specifically, the hypervisor can manipulate the hardware I/O subsystem and a physical adversary can snoop and tamper the PCIe communication to bypass CPU and device TEE protections. Lastly, ACAI has to maintain compatibility i.e., incur minimal changes to the trusted RMM, monitor and guest Linux kernel as well as the untrusted hypervisor; especially while retrofitting software stacks written with a hierarchical trust model to trusted execution model.

Our main insight is to extend Arm CCA's security invariants for CPU-side protection to reason about devices. When a CPU core accesses a memory address, CCA checks if the CPU's execution mode is allowed to access the mode of the memory being accessed, thus protecting the realm from privileged software adversaries (OS and Hypervisor). ACAI enables a device to be securely marked as realm-mode, to leverage world-level isolation. CCA further isolates realm memory between VMs by using the MMU controlled by trusted software. ACAI uses a device-side MMU, called the SMMU, to similarly achieve VM-level isolation but from device accesses. While doing so, ACAI ensures that an untrusted hypervisor who can program the SMMU cannot tamper with the isolation guarantees. CCA employs bus-level memory encryption to protect VMs from physical adversaries, ACAI re-uses native hardware-level encryption support from PCIe and the device-side TEE to protect device-bound communication. CCA binds the VM's identity and encryption keys to the attestation report. ACAI includes the device attestation in the VM creation flow to additionally bind the device identity to the realm VM. In summary, ACAI invariants allow us to systematically reason about the confidentiality and integrity of the VM and device execution.

We prototype ACAI on Arm's public simulator that supports CCA. Arm provides a trusted firmware called TF-A and a trusted hypervisor called realm management monitor, along with an untrusted hypervisor in the form of a patched KVM. ACAI modifies these three components to enable secure accelerator execution. Arm provides a patched Linux Kernel that can execute both in the realm VM as well as the untrusted host VM. For compatibility, ACAI adapts the kernel and existing device drivers such that confidential user applications can continue to access the accelerators as they would in a legacy setting. We showcase ACAI with two existing accelerators, a GPU and an FPGA. Our experiments with existing benchmarks and applications show that ACAI supports accelerators out of the box, while maintaining compatibility with existing applications. When compared to execution without TEE protection on the CPU and the accelerator, ACAI incurs 43.5% and 12.1% overhead on average for GPUs and FPGAs respectively. We confirm that ACAI does not slow down the execution of the rest of the system, it incurs a minimal overhead of 3.8% and 1.9% when using the GPU and FPGA. Since CCA support is not available in CPUs, our performance estimates are based on a simulator and an Armv8 board port.

Contributions. The main contributions of this paper are:

- We present ACAI, the first system to demonstrate secure PCIe device access for Arm CCA-based confidential VMs.
- ACAI's novel security invariants identify security gaps in Arm CCA and achieve secure peripheral execution without any hardware changes to the Arm CCA-compliant hardware or TEE-enabled accelerators.
- Our evaluation shows that ACAI is feasible while achieving its security and compatibility goals. ACAI is open source.[1]

2 Confidential Acceleration

CCA considers all memory accesses from devices to be untrusted by default, thus preventing them from accessing realm memory of confidential VMs. Similarly, TEE architectures such as Intel SGX and AMD SEV do not allow devices to access protected enclave and confidential VM memory.

Encrypted Access to PCIe-based Accelerators. Most cloud deployments use PCIe to connect powerful CPU cores to dedicated accelerators. This offers the flexibility to plug in the best-suited devices after procurement as well as the scalability to connect 16-64 devices per node. The bus-level access control mechanisms, such as Arm TrustZone or RISC-V PMP, do not extend to such devices. Instead, existing proposals resort to a bounce-buffer design for encrypted communication. The VM encrypts the data buffer in software and sends it to the accelerator, which decrypts it using accelerator-specific logic (e.g., GPU kernel). Similarly, the accelerator generates results, encrypts them, and transfers them to the publicly accessible part of the CPU memory. Subsequently, the VM has to copy the encrypted data into its own protected memory and then decrypt it. As shown in Table 1, this approach leads to two extra copies and software-based encryption and integrity protection on both the processors and peripherals thus increasing the memory and compute overheads. This requires invasive API changes in the applications, drivers to perform encryption, and the device-side logic for encryption; thus breaking compatibility. Case in point, connecting Nvidia GPUs to AMD SEV VMs required cooperation from Nvidia, AMD, and Azure while still achieving 4Gbps bandwidth due to software encryption and memory copy bottlenecks [41].

The PCIe-5 specification introduces IDE (Integrity and Data encryption) which provides confidentiality and integrity

[1] https://sectrs-acai.github.io/acai/

Table 1: Number of data copies and encryption-decryption operations in hardware (Enc_{HW}) and software (Enc_{SW}) required per transaction between the CPU and the device.

Bounce Buffer			ACAI		
Copies	Enc_{SW}	Enc_{HW}	Copies	Enc_{SW}	Enc_{HW}
3	2	2	1	0	2

guarantees for PCIe packets [45]. IDE's hardware encryption feature can be leveraged to build a performant design without the need for software-based encryption. However, IDE is not designed for a threat model with an untrusted hypervisor.

3 Background: Isolation in Arm CCA

Arm Confidential Computing Architecture (CCA) enables the creation of VM-based isolated execution environments. CCA is enabled by a hardware extension to the Arm ISA, Realm Management Extensions (RME), that creates 2 new worlds (Realm and Root) along with the 2 existing worlds (Normal and Secure). Figure 1 shows how the schematic of exception levels and worlds works when CCA-based VMs are executing. On a CCA-enabled platform, a CPU core is allowed to access realm memory if it is in the right privilege and mode. Specifically, each core can program the access mode of physical address ranges to be root, realm, secure, or normal world. The architecture introduces a special data structure, called granule protection table (GPT) that tracks which physical address belongs to which of the four worlds. To perform the world isolation, CCA augments all processing elements (e.g., Arm cores, SMMU, caches, TLBs) with Granule Protection Checks (GPCs), where a Granule is the smallest block of memory that can be described. The GPTs are maintained in the main memory and belong to the root world such that only the monitor can access and update them. Whenever there is a change in the GPT, the GPCs are synchronized and may trigger the flushing of stale states. The GPCs, generated from the GPTs, effectively prevent accesses from the normal or secure world to the realm memory by performing access control on all memory accesses. Specifically, all bus transactions initiated from the core are guarded. The trusted firmware, executing in the monitor, sets the world bit for the core when it performs a context switch. Next, a trusted Realm Management Monitor (RMM) executes in the realm world at EL2. The RMM ensures that mutually distrusting realm VMs are isolated by managing stage-2 translations from guest physical address (IPA in Arm terminology) to host physical address (PA in Arm terminology). Lastly, a physical attacker cannot tamper with the data when it resides in the main memory because of the bus-level encryption and integrity protection mechanisms.

In summary, CCA enforces isolation for the realm world computation using a combination of stage-2 translations and GPCs. However, these isolation techniques do not apply to devices. Specifically, when a CPU core accesses memory, it

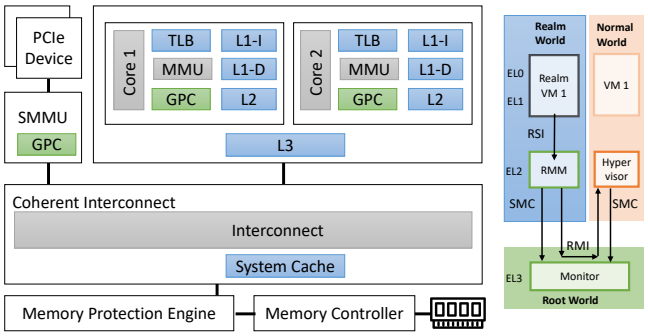

Figure 1: GPC in Arm CCA. Blue components are subject to GPC enforcement. The right figure shows interfaces between the realm VM, RMM, hypervisor, and monitor. Realm service interface (RSI) and realm management interface (RMI) are used by the Realm VM and hypervisor respectively.

is subject to access control checks by the MMU. But, when a PCIe device accesses the host memory, it bypasses the MMU. To remediate this, host systems place an SMMU between the device and the memory that can perform access control, such that all PCIe accesses (e.g., GPU requests to DMA data from the host to the device) are subject to checks. CCA augments the SMMU's legacy access control with GPC, such that all device accesses to memory are now isolated at a world granularity. For example, with TrustZone support, secure world devices are allowed to access secure and normal world memory, whereas normal world devices can only access normal world memory. CCA's RME Device Attach extends this notion to the realm world allowing devices to access realm memory.

4 Security Challenges

CCA's device-accessible realm memory along with hardware encryption on both CPU and accelerators, points to a performant design that removes the need for multiple data copies and software-based encryption-decryption (see Section 2). However, doing so requires carefully addressing security considerations to ensure that the end-to-end execution on device and host composes safely. We outline the security gaps and potential attacks when attaching PCIe devices to realm VMs.

Fine-grain Memory Isolation. Devices have to be securely allocated to a realm VM in a way that an attacker cannot launch man-in-the-middle attacks, tunnel the access through untrusted devices, or attach the same device to multiple mutually distrusting realm VMs. After device allocation, all its accesses (e.g., DMA) have to be isolated not only to the realm memory but specifically to the realm VM that owns the device. Otherwise, malicious devices attached to other realm VMs can compromise computation (Figure 2a). Protecting the shared memory between the device and the VM entails stopping other VMs (in the realm or otherwise), devices, and

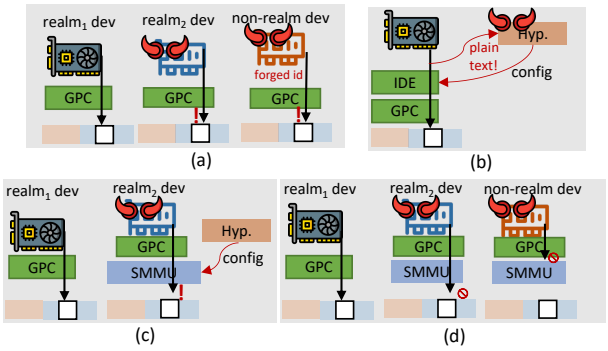

Figure 2: (a)-(c) Potential attacks when devices access realm memory. (d) ACAI protection

hypervisor from accessing it. CCA hardware ensures that the GPCs on the MMU and SMMU are in sync to reflect the latest state of access control rules at world granularity (e.g., that a specific page belongs to the realm or the normal world). For secure device access from a VM, this synchronization has to be extended to be at a VM granularity. Note that the isolation guarantees that GPCs provide depend on correctly deciding the world that the device belongs to. Therefore, device identities that tie them to worlds must be unforgeable to stop malicious devices from compromising security (Figure 2a).

Preserving Compatibility with Untrusted Code. Hypervisors, VMs, drivers, and user applications should not require invasive rewriting. Compatibility without compromising security requires ensuring that the untrusted hypervisor cannot maliciously reconfigure devices, the MMU, and the SMMU. Much like on Intel and AMD, the untrusted hypervisor on Arm controls and programs the SMMU. It can mount attacks on realm VMs by changing the SMMU's translation tables to allow an attacker-controlled device to access realm memory (Figure 2c). Further, the hypervisor can emulate devices or allocate compromised devices to break the realm VM's data confidentiality or execution integrity. Hypervisor optimization techniques that allow multiple VMs or devices to access the same physical page (e.g., memory sharing or copy-on-write) can pose a threat to the isolation of protected memory. Several device and SMMU features bypass all access control protections because they were designed for performance. These need to be reexamined under the CCA threat model as well.

Secure I/O Paths. Physical attackers can unplug devices, change their ports, probe the memory, and tamper with bus and PCIe transactions. Preventing such attacks requires bus- and PCIe-level encryption with key management that accounts for abrupt disconnections while ensuring that malicious devices, VMs, and the hypervisor cannot abuse it. For example, the untrusted hypervisor has access to the IDE keys in PCIe-5 and can compromise data protected by its encryption (Figure 2b).

5 Our Approach

ACAI adopts a principled approach to securely attach devices to realm VMs while preserving the existing CCA guarantees.

5.1 ACAI Isolation Principle

ACAI sets up a shared memory region between the realm VM and the corresponding device, that we refer to as *protected region*, in the realm world memory. ACAI aims to enforce isolation such that an attacker cannot access the protected region. Our approach is inspired by CCA's notion of isolation for CPU accesses. We use it to explain our design intuition and how it leads to ACAI's concrete invariants.

On the CPU, Arm CCA's secure boot and attestation mechanism ensures that the cores are in the right state to run confidential realm VMs. Similar to CCA, ACAI ensures that the device and the realm start in a clean state and that their identities are uniquely mapped to their dedicated protected memory region (INV_{id}). Once the identities are established, ACAI has to ensure that the device is uniquely assigned to a realm VM which can configure and manage it. Therefore, ACAI guarantees that a device and all the memory on the host used to configure the device is uniquely mapped to a realm VM (INV_{own}). Further, for physical attacker protection, ACAI leverages CCA's memory protection engine such that only the device and the owner VM have the key to encrypt and decrypt the data in the protected region.

With identity and ownership established, ACAI has to ensure the translations from guest PA to host PA used for the protected memory regions are secure and compatible with CCA. First, CCA dictates that for any host physical address P_h that is allocated to the realm VM, one and only one guest physical address P_g can map to it. The RMM, who is in charge of managing the realm world memory, enforces this invariant for the stage-2 translations between P_g and P_h. Since ACAI extends a realm VM to allow access to the protected memory region, our main intuition is to extend the existing CCA invariant to this protected memory (INV_{host}). Next, since the device also has access to the protected memory, ACAI ensures that a similar invariant (INV_{dev}) is applied to any device-side translations i.e., the SMMU. INV_{host} and INV_{dev} enforce correct translations for the host and device respectively. However, one problem still remains. If the host and device-side translations are not synchronized, an attacker can mount split-view type of attacks. Therefore, ACAI ensures that the realm VM and device always have the same view of memory by ensuring that the RMM and SMMU stage-2 translation tables are always synchronized (INV_{bind}).

ACAI **Invariants.** ACAI aims to achieve the same security guarantees for device-side accesses that Arm cores, monitor, and the RMM achieve for CPU-side accesses. More precisely, ACAI's design aims to enforce the following invariants:

INV_{id}: *Identity.* An accelerator attached to a realm VM is assigned a unique unforgeable identity after attestation.

INV_{own}: *Exclusive Ownership.* An accelerator is only accessible to one owner realm VM who is allowed to configure the device and setup protection keys and communicate with it.

INV_{bind}: *Owner binding.* Owner realm VM and the accelerators have the same guest PA to host PA mappings.

INV_{host}: *1:1 host and guest page mappings.* Only one VM-level guest PA resolves to the same host PA.

INV_{dev}: *No overlapping physical memory in the protected region.* For each host PA in the protected region, only one accelerator has a valid mapping from guest PA to host PA.

Threat Model. ACAI assumes a malicious cloud provider, cotenants, and privileged software such as the hypervisor and secure world software who want to compromise the confidentiality and integrity of a victim's realm VM and its device-bound operations. A physical attacker can plug in malicious devices, compromise the connectors between nodes, and launch probe attacks on DRAM chips that are not integrated into the devices and SoCs. ACAI trusts the manufacturer of Arm cores, devices, and PCIe port implementations. We include the firmware and the RMM in the TCB and rely on CCA attestation mechanisms to ensure that it is untampered. Further, each realm VM's TCB includes the guest OS, device drivers, runtimes necessary to access the devices, and the device-side programmable logic such as kernels and IPs. The TCB may be prone to Iago attacks when the VMs invoke untrusted hypervisor API. ACAI does not add any new API to the hypervisor and relies on existing CCA protection for sanitization and preventing Iago attacks [14].

Scope. ACAI does not protect against denial-of-service from the malicious hypervisor or cloud provider but ensures that realm VMs cannot cause denial of service to each other and to the cloud provider. Defending against speculation attacks and side-channel leakage due to micro-architectural implementation is orthogonal to our work and ACAI relies on existing techniques and CCA's native protection for such attacks.

5.2 Creating Protected Memory Regions

Background. In Arm CCA, the normal world Hypervisor creates the realm VM (source granules) and then transitions it to the realm world (destination granules). This invokes the trusted monitor who updates the GPT to change these pages from normal to realm world. The GPT changes trigger flushing of TLBs and caches of all GPCs. Then the RMM checks if the destination granule is valid and if so updates its stage-2 translation tables; thus allowing the realm VM's IPA to translate to the granule's host physical address (PA).

Shared Protected Region. ACAI requires a shared protected memory region between the realm VM and the accelerator. RME-DA enables devices to directly access realm world memory. Therefore, the ACAI protected memory region can reside in the realm world as shown in Figure 2(d). ACAI has to ensure that only the designated device and realm VM can access it in the presence of malicious devices and VMs (Figure 2d). ACAI uses the RMM page tables to ensure that only the realm VM that owns the protected region has the mappings in RMM's stage-2 translation tables (INV_{host}). Similar to RMM, ACAI programs the SMMU page tables to ensure that only the accelerator that was mapped to the protected region has the entries in the SMMU's stage-2 translation tables (INV_{dev}). Finally, on any changes to the RMM's page tables corresponding to the protected memory, ACAI explicitly synchronizes the SMMU to reflect these changes (INV_{bind}).

Protecting the SMMU. In CCA, the hypervisor has direct access to the SMMU by default and can tamper with ACAI enforced mappings (INV_{bind}, INV_{dev}) as shown in Figure 2c. To address this gap, ACAI uses the GPT to mark the SMMU data structures (stream tables, stage-2 translation tables per device, request-response buffers) to be only accessible in root mode. If the hypervisor attempts to program the SMMU, it will fault and trigger a handler in the monitor. Moving all the SMMU management code from the hypervisor to the monitor would result in a bloated monitor and cause loss of optimizations employed by different hypervisors. Instead, ACAI introduces an SMMU interface for the hypervisor to request SMMU updates. ACAI only allows selective hypervisor requests that satisfy its invariants on all SMMU operations.

5.3 Identity and Exclusive Ownership

Background. PCIe transaction packets contain a RequesterID that identifies the device that originated the packet. But devices can set this field to arbitrary values. Integrity and Data Encryption (IDE) in PCIe-5 ensures that each PCIe link per device has a unique key which is used for data protection.

IDE-based Identity & Enforcing Exclusive Ownership. To create a realm VM, the hypervisor sets up a new VM, prepares the accelerator, and then invokes the monitor. Here, ACAI amends the CCA's VM creation in the monitor to simultaneously initiate a secure accelerator attachment to enforce invariants INV_{id} and INV_{own}. The monitor probes the bus to locate the accelerator and check if the accelerator is not already mapped to any realm VM. If not, the monitor sends a reset signal and requests an attestation report. ACAI uses the RMM and monitor to ensure that only the owner realm VM has access to the accelerator's configurations ensuring INV_{own}. ACAI uses IDE to ensure that the accelerator has a unique ID that does not overlap with existing devices (INV_{id}). Specifically, ACAI relies on the IDE keys programmed in the root port of the host to ensure that accelerator IDs are unique. Packets with forged accelerator IDs (e.g., using a malicious device, plugging in a compromised device after attestation) do not decrypt successfully and are discarded at the PCIe root port. ACAI can use native device attestation support or the high-level building blocks of PCIe-5 compliance that can

attest the accelerator and sign it with root port keys [5, 31, 45]. ACAI requires that the attestation report from the device contains information about its firmware, configuration, and other state after secure boot. The monitor forwards the accelerator report to the RMM, who combines it with the realm VM's attestation for the remote verifier checks.

6 Accelerator Lifecycle

PCIe Devices & Memory. All PCIe devices, which are always connected to the PCIe root port, are behind the SMMU. To discover PCIe devices, the hypervisor invokes the firmware to probe the bus and read the configuration and Base Address Registers (BARs) size from the device. Each device can have up to 6 BARs in its PCIe configuration space. The device uses the address in the BAR to access regions that are memory-mapped by the kernel or hypervisor. Therefore, a device's memory comprises its PCIe configuration space, the memory-mapped BAR regions for MMIO communication, and dynamically allocated DMA regions. ACAI ensures that all these regions are protected according to its invariants.

Device Attach. ACAI augments the realm creation process to attach an accelerator while enforcing INV_{id} and INV_{own}. Note that attaching an accelerator to a realm VM is similar to adding data to the realm VM in the form of memory-mapped BAR regions and the PCIe configuration space. So, ACAI has to ensure that INV_{host} is enforced for these memory regions.

By default, the hypervisor resets the accelerator, disables all debug configurations, and sets up its PCIe configuration space. In CCA's realm creation process, the hypervisor moves all memory and data to the realm world before starting the realm VM. Similarly, before starting such an accelerator attach process, ACAI requires that the hypervisor has moved all BAR regions of the accelerator and the PCIe configuration space to the realm world and attached them to the realm VM.[2] This ensures that the accelerator is locked and not accessible to the hypervisor when it starts the device attach process. The RMM ensures that the hypervisor has performed these steps faithfully (INV_{host}) before starting the device attach process. Locking accelerator access from the hypervisor is important to correctly enforce INV_{id} and INV_{own}. Further, attaching the configuration space to the realm VM ensures INV_{own}.

To attach an accelerator to a realm VM in ACAI, the hypervisor adds two accelerator-specific details to the realm VM: the contents of the PCIe configuration space that it setup and the size of each BAR region. The RMM ensures INV_{host} for the PCIe configuration space. It checks that the IPA to PA mapping for the PCIe configuration space is valid and that the PA is in realm world. PCIe BARs represent contiguous regions of memory of sizes as indicated by the hypervisor. To ensure that the memory-mapped regions of the accelerators are correctly mapped to the realm VM (INV_{host}), for every BAR in the PCIe configuration space, the RMM checks that the whole memory region is already mapped to the realm VM.

Initialization & Device Attestation. In ACAI, the monitor initializes the device and sets it up to ensure INV_{id}. The RMM forwards the PCIe accelerator's bus address that it receives from the hypervisor and the PCIe configuration region's physical address to the monitor. The monitor uses the accelerator's bus address to re-scan the PCIe bus, proceeds to read the accelerator's configuration, and writes that to the physical address of the PCIe configuration space sent by the RMM.

ACAI monitor implements the attestation protocol according to the Security Protocols and Data Models (SPDM), a standard to enable authentication and attestation which can be used for devices [5, 21]. As part of the SPDM protocol, the monitor also invokes the IDE key management protocol according to the PCIe specifications [45]. The monitor blocks the return of this call until it receives the attestation report from the accelerator. When the protocol completes and the monitor receives the attestation report, it writes the attestation report to the RMM memory and returns from the call back to the RMM. Note that ACAI performs IDE key programming before reading the configuration and attestation reports from the accelerator. This prevents TOCTOU attacks—if the accelerator is replaced or reset after the key programming, all communications from the host will be encrypted with a key that is not accessible to the device. Therefore, this process securely resets the accelerator, creates an unforgeable identity using IDE, and collects the attestation report.

Realm Attestation. ACAI extends the attestation process of CCA to enable a remote verifier to check the attestation reports from the device. In CCA, the RMM extends the attestation measurement over the data that was copied into the realm VM. ACAI reuses this mechanism in the RMM for the memory-mapped regions and PCIe configuration space. Specifically, the BAR regions mapped to the device are added to the realm VM like any other realm VM memory. Further, the bus address of the accelerator, and the PCIe configuration space including the size of the BAR regions is part of the data added to the realm VM by the hypervisor. So the RMM's attestation report will indicate the accelerator attached to the realm VM, the PCIe configuration space, and the regions of memory that are used for the BARs and their sizes. Further, the RMM appends a new section to the attestation report with the accelerator attestation report that is returned by the monitor. A remote verifier can now use the attestation report to ensure that the accelerator is correctly initialized (e.g., correct firmware, debug disabled, non-PCIe ports disabled), attested, and all device-mapped memory is in the protected region.

Establishing Secure Accelerator Identities. In PCIe-5 with Integrity and Data Encryption (IDE), the data on the PCIe link is protected from a physical adversary. ACAI relies on PCIe features to establish unique accelerator identities (INV_{id}). The IDE keys are stored in the physical root ports of PCIe end-

[2] The data in the PCIe configuration space and BAR regions is deterministic on device reset

points, preventing a software adversary such as the hypervisor from tampering or replacing them. The manufacturer is expected to ensure this, either by keeping the keys in hardware-protected memory in the root port or in the protected SRAM of the host system [43]. ACAI requires these keys to be stored in memory that is only accessible to the monitor (e.g., root world SRAM). The PCIe root port is programmed by the monitor with a unique key during the device attach process. The monitor ensures that the RequesterID (RID) used for the key mapping is unique. If a malicious device originates PCIe transaction packets with forged RIDs, the packets will fail to decrypt in the root port and hence will be discarded.

Device Detach. ACAI only allows the hypervisor to detach devices from a realm VM in the realm VM destruction phase. When a realm is destroyed, the RMM invokes a call to the monitor to remove any devices attached to the realm with the realm's VMID. The monitor removes any device-to-VM mappings it has, and deletes the corresponding device state from the SMMU (see Section 7.1). All device memory is removed from the realm VM according to normal CCA mechanisms for realm destruction. Specifically, the hypervisor invokes the RMM to transition the granules back to the normal world. In Arm's RMM specification, in this phase, the monitor transitions all realm VM granules back to the normal world after the hardware scrubs the data in the pages.

Design Decisions. We opt for a conservative but secure design where devices have to be attached at realm VM creation and detached at realm VM destruction. This is in line with the cloud model, where the tenant has to pay for a VM and a device attached to it and is not allowed to dynamically allocate accelerators. For example, on AWS a VM with a GPU (P3) or an FPGA (F1) instance is provisioned together, as in ACAI. Some accelerators (e.g., GPUs) can operate in multi-tenant mode where a physical accelerator is shared among multiple VMs. Enabling such virtual shares in our threat model requires native device virtualization (e.g., MIGs on H100 [42]) to provide isolation and per-unit encryption keys. If available, ACAI is compatible to enable multi-tenancy because the IDE specification and CCA DA support device virtualization. However, we leave it to future work to closely examine the security challenges of device virtualization. For example, virtual shares have common state (e.g., address translation tables, cached translations) that an attacker can exploit.

7 Memory Isolation

Arm SMMU is an IOMMU that performs access control and address translation for devices using StreamID to identify the devices. The hypervisor sets up and manages the SMMU's configuration and stage-1 and stage-2 translations for the normal world. Specifically, the hypervisor configures the SMMU with the Stream Table's base address. The Stream Table contains entries called Stream Table Entries (STEs) that describe the configuration and translation tables for each device. For each incoming transaction, the SMMU uses StreamIDs to index into the Stream Table to look up the STE. Further, to perform stage-2 translation, the SMMU reads the translation table's base address from the STE. Before Arm CCA, the SMMU could differentiate incoming transactions as normal or secure based on a 1-bit long `world` bit. To support realm transactions, CCA extends the `world` bit to be 2-bits long (`world_ext`). The SMMU expects the `world_ext` bits to be set correctly, either by the device or the root port, for all transactions and does not perform any additional checks.

Applications use MMIO and DMA to communicate with the devices. They use memory-mapped IO (MMIO) regions to transfer small amounts of data to devices. Physical addresses that can be memory-mapped to devices are not backed by actual host memory (e.g., DRAM). Instead, the application directly accesses the device memory using address translation. The BARs indicate all the MMIO regions used by the device attached to a realm VM. In Section 7.1 and 7.2, we explain how ACAI protects the SMMU and MMIO/DMA operations.

7.1 SMMU Changes and Secure Setup

World-level Isolation. Arm CCA enables realm world transactions and a realm programming interface in the SMMU [5]. But it does not explain how one would identify a device to be associated with a realm VM. Further, CCA states that the protocol to set the `world_ext` bits is implementation defined [7]. In ACAI, identifying and binding transactions to realm VMs is critical for security. Therefore, ACAI defines how to set the `world_ext` securely to identify realm transactions and bind transactions to realm VMs, as summarized in Figure 3.

For each core, CCA has a core-specific register to track its execution world. The monitor sets this world for each core on context switch. The GPC reads this register to perform memory access checks. Similarly, the GPC on the SMMU needs to identify the world of each memory access from the device. ACAI leverages PCIe-5 IDE to infer the world of every device transaction to and set the `world_ext` bits. Specifically, it stipulates that all realm world transactions must be subject to IDE. ACAI expects the devices to explicitly tag all realm world transactions by setting a T bit. Note that, a transaction with T=0 cannot access realm world memory and will be rejected by the GPC as shown in Figure 3. Any transaction that accesses memory in the realm world (T=1 in Figure 3) has to be successfully decrypted in the PCIe root port. Therefore, this mechanism guarantees that the RID and the T bit are correct and can be safely used to infer the world of the transaction (`world_ext`=Rl in Figure 3). This approach ensures that the SMMU can correctly perform translation for all devices.

Intra-realm Isolation. With the above approach, GPC on the SMMU can isolate realm memory from non-realm devices. However, this is not sufficient to isolate mutually distrusting realm devices (Figure 2a). The RMM isolates mutually distrusting realm VMs using stage-2 translations. It stores these

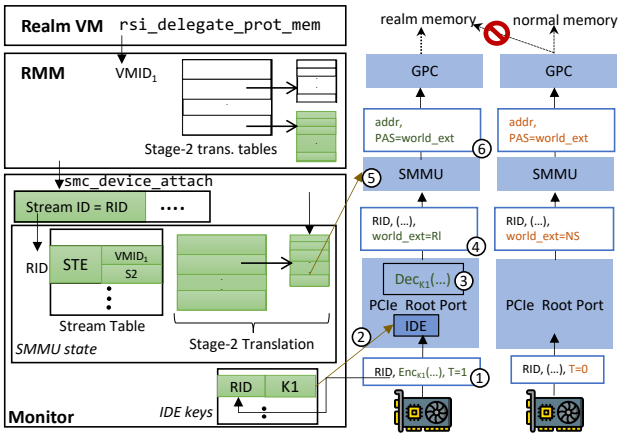

Figure 3: ACAI's interfaces and software. Green: new components; Brown arrows: accesses made with root world PAS. ① accelerator originates transaction with RID and T=1 for realm transactions. The data is encrypted with key K1 setup for IDE. ② Host Root Port (RP) reads K1 based on RID ③ to decrypt. ④ RP sends transaction to SMMU with `world_ext` bits set to realm world. ⑤ based on `world_ext`, SMMU indexes Realm Stream Table (as root world) with RID to perform stage-2 translation and gets a physical address. ⑥ SMMU tags the memory address with `world_ext` for GPC checks.

tables and other realm configurations in protected realm memory inaccessible to the hypervisor. Correspondingly, ACAI uses the SMMU's stage-2 translation to isolate mutually distrusting devices from accessing each other's protected realm memory. Updates to the SMMU's stage-2 translation tables must ensure INV_{bind} and INV_{dev}. Therefore, we need to protect both the Stream Table and the stage-2 translation tables as shown in Figure 3. Further, we need to protect the SMMU's memory-mapped configuration registers as they can be used to compromise the security of the system (e.g., turn off the SMMU, turn off stage-2 translations). In ACAI, the monitor checks all updates to the SMMU. It introduces ACAI interface, which the hypervisor has to use to perform its operations on the SMMU. Specifically, the monitor uses the list of realm devices that it maintains and only allows the hypervisor to change stage-2 translations of non-realm devices. For updates to the SMMU's configuration, the monitor maintains an allow-list of non-security critical fields and only allows the hypervisor to update them. To enforce INV_{dev}, for every update to the SMMU's stage-2 translation tables for realm devices, the RMM ensures that: (a) the PA is not mapped in any other device's stage-2 translation tables (INV_{dev}) by checking a reverse mapping;[3] (b) the IPA is not already mapped in the stage-2 table for this StreamID. Further, the RMM ensures INV_{bind} by checking that for every update to the stage-2 table of the SMMU, the corresponding IPA to PA mapping exists in the stage-2 tables of the owner realm VM.

To ensure INV_{own} during the device attach process discussed in Section 6, ACAI monitor also maintains a list of all realm device StreamIDs as shown in Figure 3. While attaching a device to a realm VM, the monitor locks the Stream Table before processing the request from the RMM (as explained in Section 6). It then checks that the StreamID for the device is not already assigned (INV_{own}) in its list and creates a new STE in the Stream Table. If the StreamID is already assigned, it aborts the realm creation process.

The SMMU performs root memory accesses for stage-2 translations (step 5 in Figure 3). Since the SMMU is trusted hardware, it can originate accesses in root mode to manage the stream and translation tables, irrespective of the world of the transaction itself. Independently, the device access is also subject to a GPC check, based on what world the device belongs to. Hence, the SMMU can perform stage-2 translations for all devices correctly while ensuring that the world isolation for memory accesses from devices is still enforced.

Security Decisions. The RME-DA allows the RMM to directly manage the realm streams. In ACAI, we make a conscious choice to move all the SMMU operations to the monitor, such that neither the untrusted hypervisor nor the trusted RMM can directly change it. Our choice is based on two main reasons: (a) the SMMU has several global configuration values, which if set incorrectly by the RMM or intentionally tampered by the hypervisor, can break the security guarantees; (b) If we allow the hypervisor and the RMM to simultaneously update the SMMU, it will open several attack vectors such as Iago attacks [14], race-conditions [15], and re-entrancy attacks. Defending against these attacks is challenging and requires careful handling of legacy hypervisor code as well as formal treatment of the resulting design [24, 39]. Instead, we choose to implement a centralized SMMU interface in the monitor which enforces our security invariants and serves as a single vantage point to enforce checks that disallow the hypervisor from enabling unsafe features such as debugging. Case in point, RME-DA allows the device to use a performance feature called Address Translation Services (ATS) wherein the device can bypass the SMMU translations and directly access host memory using real physical addresses. Our monitor explicitly disallows this and several other features. Specifically, ACAI maintains a limited allow-list of safe SMMU features, and rejects any requested settings that violate it.

7.2 MMIO and DMA

In ACAI, all memory-mapped regions for a device are transitioned to realm world and mapped to the realm VM as part of the device attach process as discussed in Section 6. The cores directly issue all the reads and writes to the memory-mapped regions without the involvement of the RMM or the monitor.

[3] For the reverse mapping, the RMM can maintain reverse page tables or an array indexed by PA. Currently, RMM does the latter.

Applications use DMA to transfer large amounts of data between host and device memory. In ACAI, this has to be mediated via protected region. The realm VM's OS builds a scatter-gather list of the memory to be marked as protected region memory before initiating the DMA operation. To enable secure DMA and enforce INV_{bind} and INV_{dev}, ACAI introduces a new RMM interface call for the realm VM's OS. Once this scatter-gather list is setup, the OS can invoke this interface to transition the DMA memory to the protected region. For this, the OS sends a list of IPA and the size of each region along with the device id to the RMM. The RMM services this request by first translating the IPA to PA using its stage-2 translation tables for the realm VM. This process ensures INV_{bind} and INV_{dev} because the same IPA to PA mapping is used to update the SMMU's stage-2 translation table. Note that, all memory transitioned to protected memory this way already belongs to the realm VM and abides by INV_{host}. But, allowing the device to access this memory requires explicit steps. To transition the memory to protected region, the RMM invokes the monitor which updates the SMMU's stage-2 tables as discussed in Section 7.1. After this, the device can access the protected region via DMA. This approach only changes the Linux Kernel. It requires no changes to the application (on both the processor and the device), the device driver, the runtimes, and accelerator logic.

Transparent Encryption & Decryption. In CCA, the main memory connection to the bus on the host includes a memory protection engine (MPE) that encrypts data before storing and decrypts it on the way to the bus. It relies on the Memory Encryption Contexts (MEC) extension which is a part of Arm CCA [4]. With MEC, CCA allows each realm VM to be associated with a unique key. Then the MPE ensures that all data from a realm VM, say with ID R_1, is encrypted with its own key (say K_{R1}). ACAI leverages the MPE and MEC to protect data stored in host DRAM. For PCIe communication, ACAI uses PCIe IDE support in the host and accelerator root ports to protect the data while it transits the PCIe links.

Concretely, the following steps are performed for DMA as summarized in Figure 4. When a realm VM writes plaintext data `pt` to memory, the MPE encrypts `pt` to form ciphertext `ct` (step a). Further, when the accelerator initiates a DMA read, the MPE decrypts `ct` and sends it to the RP_{host} (step b). Next, RP_{host} uses the RID_1 to encrypt `pt` to form `ct` (step 1). The `ct` is then transmitted over PCIe to the accelerator (step 2), to reach RP_{accl}. It uses the RID_1 to decrypt `ct` (step 3), and finally stores `pt` in the accelerator's DRAM (step 4). Similarly, for MMIO (step a'), when a realm VM writes (`pt`) to a memory-mapped region of the accelerator the write is forwarded to the RP_{host} by the MMU. Then, `pt` is transferred to the accelerator (steps $1-4$). Note that, `pt` in step 1 is safe from a physical attacker as it does not leave the Arm SoC before being encrypted by the RP_{host}. Similarly, step 4 writes `pt` to the accelerator's tightly integrated DRAM which is safe from a physical attacker [50].

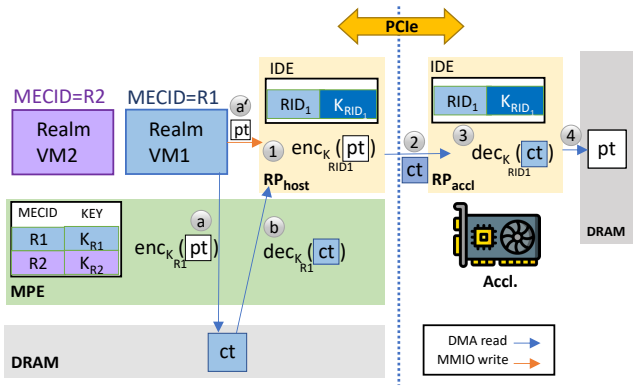

Figure 4: MMIO and DMA in ACAI. IDE keys in Root Ports (RPs) are setup by the monitor on device attach. Blue arrows show DMA read and Orange arrows show MMIO write.

8 Security Analysis

ACAI's invariants to setup device identities and memory protection achieve secure composition of CPU and device TEEs. Any attacks that remain would either break guarantees provided by the CPU TEE (i.e., CCA) or the device TEE itself.

Untrusted Hypervisor. It can compromise the MPE and IDE encryption keys. However, as explained in Section 6, these keys are protected in the root mode and inaccessible to the hypervisor. The hypervisor can emulate PCIe devices and trick ACAI into attaching them to realm VMs. Such attempts would be detected through attestation according to INV_{id}. Specifically, an emulated device cannot produce an authentic attestation report and would be detected by the remote verifier. Further, the hypervisor cannot emulate a device after attestation because the configuration space is locked by the monitor and the IDE keys are programmed before gathering the attestation report. During device attach, the hypervisor can allocate incorrect BAR region sizes, but it will be detected during attestation. Further, the hypervisor can allocate memory for the BAR regions in the normal world, instead of realm world. However, the RMM ensures that all memory-mapped regions are transitioned to realm world and assigned to the realm VM to ensure INV_{host}.

The hypervisor can change the PCIe configuration space of a realm device to setup memory-mapped regions in the normal world. Similarly, it can provision DMA memory for the realm devices in the normal world. Such memory mappings to the normal world memory would compromise security guarantees that ACAI accords to computation on the accelerator. These attacks are thwarted by ACAI by ensuring that all device memory and configurations are mapped solely to the realm VM that owns the device according to INV_{own} and INV_{dev}. The hypervisor can register a malicious realm device with the same identity (RequesterID) as a victim realm device. To enforce INV_{id} and INV_{own}, the monitor always checks that a

device is not already linked to a realm VM before assigning it. Therefore, such attacks from the hypervisor will be detected and stopped. The RMM exposes an interface to the hypervisor to allow it to transition realm memory back to normal world. While a device is performing DMA to a region of memory, the hypervisor can invoke the RMM to transfer this memory back to normal world. If this succeeds, the device would write sensitive data to unprotected normal world memory. However, CCA specification does not allow the hypervisor to transition realm memory that is still attached and in use by the realm VM thus stopping such attacks [6].

SMMU Configuration. The untrusted hypervisor can: (a) reconfigure the SMMU to bypass stage-2 translations, and (b) rewrite the stage-2 translation tables to allow attacker-controlled devices to access the protected region. The monitor prevents these attacks by storing all SMMU data structures (Figure 3) in root memory to enforce INV_{own}. Without direct access to the SMMU, the hypervisor can still setup overlapping mappings with a malicious realm device (e.g., map the same PA to the victim and malicious device during device attach). This attack is thwarted by the RMM which enforces INV_{dev}. Further, the hypervisor can set up SMMU mappings to allow a normal world device to access protected memory. When the normal world device originates such an access to realm memory, the GPC on the SMMU will deny it.

Malicious Co-tenants. A malicious realm VM can attempt to set up overlapping DMA memory regions with a victim's device to access its memory. As per INV_{host}, the RMM checks its stage-2 translation tables to find that the malicious realm VM is requesting DMA mappings for PAs it does not own, and denies such mapping requests.

Other Malicious Devices. They can originate PCIe packets with the identity (RequesterID) of a victim device attached to a realm VM. As per INV_{id}, the monitor ties the identity (RequesterID) of the realm device to the IDE key used for encryption. Therefore, any packet that the malicious device originates with the victim's identity will fail to decrypt successfully at the root port. Malicious co-tenant realm devices can originate PCIe traffic to access PAs that are mapped to victim devices. ACAI uses the SMMU's stage-2 translation tables to enforce INV_{dev} that ensures that these accesses are not possible. In particular, the stage-2 translation tables ensure that there is no valid mapping for the malicious device to access the victim device's protected realm region. Further, the PCIe network is not trusted and can have untrusted devices on path that can intercept the communication. However, all traffic between the host and the device is encrypted using IDE and cannot be compromised by such on-path devices.

Physical Attacker. It can read, inject, modify, record, and replay PCIe packets on the untrusted PCIe network (e.g., PCIe switches, interposers). ACAI uses PCIe IDE to ensure INV_{own} and encrypts all its PCIe traffic to thwart such attacks. Further, the attacker can read data from the host DRAM (e.g., cold boot attacks) which are stopped by CCA's MPE based encryption. A physical attacker can plug in compromised devices (e.g., debugging features enabled, old firmware). Such devices, if attached to a realm VM, can compromise its security. ACAI relies on attestation to ensure that the device attached to a realm VM is properly configured and expects the remote verifier to check for misconfigured devices. Further, a physical attacker can plug in or route the PCIe packets to a malicious device after the attestation checks pass. However, such a device will not have the IDE keys to encrypt/decrypt communications with the host realm VM.

Table 2: New interfaces and updates introduced by ACAI.

API	Status	Description
`rmi_data_create`	changed	add data from normal world to realm memory. ACAI adds `attach_dev` flag.
`rsi_delegate_prot_mem`	new	delegate realm memory to protected memory. calls `smc_delegate_prot_mem`.
`smc_device_attach`	new	attach and detach a device from realm.
`smc_delegate_prot_mem`	new	delegate realm memory to protected memory. add stage-2 translation for the SMMU.

9 Implementation

We prototype ACAI on ARM Fixed Virtual Platform (FVP) with RME-support and Cortex-A53 board with no RME.

9.1 Putting it together

Existing APIs. ACAI does not make any changes to CCA or Arm architecture. Instead, it extends the monitor and RMM software interface to realize its mechanisms (see summary in Table 2). We first explain the existing mechanism for creating realm VMs with CCA. As per Arm's specification, the hypervisor creates the realm VM and then transitions it to the realm world. When the RMM receives such a new realm creation request from the hypervisor, the RMM creates VMID, a unique ID per realm VM and uses it in all its internal data structures to track contexts that refer to this VM. Then the hypervisor transfers the VM to the realm world using two RMI calls: `rmi_granule_delegate` moves memory from normal to realm world; `rmi_data_create` populates data and assigns memory to the realm VM. For the data, the RMM copies contents from a source granule (`src`) to the destination granule (`dst`). Note that, `src` and `dst` are sent as arguments to the RMI call. Further, the RMM maps the destination granule to the `ipa` from the arguments of the call in its stage-2 translation tables, after checking that it is valid. A mapping is valid if (a) the PA, in this case the physical address of the `dst`, is not mapped to any other realm VM; and (b) the `ipa` is not already mapped in RMM's stage-2 translation tables.

FVP. Arm Fixed Virtual Platforms (FVP) are simulations of Arm systems, including processors, memory, and peripherals with annotations to run at speeds of real hardware. We

prototype ACAI on Arm FVP_Base_RevC-2xAEMvA with RME-support. We considered other open-source alternatives such as Samsung Islet [46], Huawei QEMU RME-support extension [27], Twinvisor [38], and virtCCA [51]. However, we decided to use the FVP with the Trusted Firmware-a (TF-A) and TF-RMM [8, 9] because they are officially supported by Arm and best represent Arm's hardware and software stack.

TF-A. It is an open-source software for the EL3 monitor [8]. We augment it to protect and manage stage-2 translation tables and configuration registers of the SMMU. We implement two new SMCs in the TF-A (See Table 2). The SMC `smc_device_attach` exposes an interface for the RMM to attach and detach a device to a realm VM. The FVP models PCIe devices connected to an SMMU. While we cannot use these modelled devices to generate traffic, we can use them in our implementation to measure the overheads of attaching a device. To this end, ACAI probes the PCIe bus and reads the configuration space of the device while attaching it. To detach a device, we probe the PCIe bus to emulate a device reset. With this approach, we cannot model device-side attestation, IDE key programming, and MPE. We add `smc_delegate_prot_mem` to enable the RMM to delegate device memory to the protected region and setup stage-2 translations (c.f. Section 7.1). Further, we implement an ACAI interface to securely allow the hypervisor to manage the SMMU configurations for the normal world.

RMM. We extend the open-source TF-RMM implementation with a new `rsi_delegate_prot_mem` for the realm VM to protect device memory during runtime, as discussed in Section 7.2. We also setup stage-2 translations for the SMMU as explained in Section 7.1. To attach the accelerator to the realm VM, we add a new flag called `attach_dev` to `rmi_data_create`. The hypervisor uses the `rmi_data_create` with the `attach_dev` flag to indicate that the data in this RMI call is used to attach a device to the realm VM. On receiving this call, the RMM performs the checks discussed in Section 6 and invokes `smc_device_attach` to attach a device to the realm VM. Further, we extend the realm VM destruction process to call `smc_device_attach` to detach a device, if present.

Linux. In the normal world, we boot Linux in EL2 with KVM patches that add support for RME and the creation of realm VMs. We change Linux's Arm SMMU driver to make SMC calls to configure the SMMU and its stage-2 translation tables by adding 636 LoC. We use `kvmtool`, a lightweight tool for hosting KVM guests, from Arm to build and deploy realm VMs from the normal world. We augment `kvmtool` to be able to invoke `rmi_data_create` with the `attach_dev` flag. For the realm VMs, we build Linux with patches to enable communication with the RMM. We extend the Linux kernel and add a kernel module to the realm VM to call `rsi_delegate_prot_mem` as explained in Section 7.2.

Device Communication. The Arm FVP does not provide functional interfaces to connect PCIe devices. Our host machine is an x86 workstation connected to PCIe devices. It runs the FVP user process, as shown in Figure 5. We have to allow the realm VM emulated in the FVP process to communicate with the real PCIe devices connected to our host machine. To enable this, we implement an FVP escape mechanism. We modify the Linux kernel on our x86 host machine to enable devices to directly access the FVP user process's memory. To allow applications running in the realm VM on the FVP to communicate with the devices, we implement stub drivers. On the x86 host, we register page-fault handlers to memory regions in the FVPs address space. When the stub drivers access these memory regions, the fault handler invokes the device drivers on the x86 host to perform the operations. To implement these stub drivers, we utilize an open-source device stack. For the GPU, we use Gdev [35] as a CUDA runtime and libdrm with Nouveau from the v5.10 Linux kernel as the driver on our host machine. We cross-compile Gdev for ARM using Arm GNU Toolchain. We run our experiments on a GeForce GTX 460 SE GPU that is compatible with Gdev and Nouveau. For the FPGA, we use a Xilinx Virtex Ultrascale+ VCU118 FPGA. We use Xilinx's XDMA driver, which we create stubs for and cross-compile for ARM.

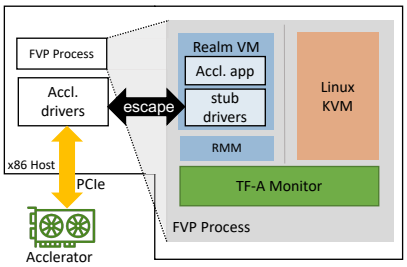

Figure 5: Experimental Setup. The full device drivers run on the x86 host. In the realm VM we run stub drivers that enable the FVP-escape mechanism. The x86 host setup is only used for evaluation and does not impact the security of ACAI.

GPU and FPGA. For the baseline encrypted mode, we augment the benchmark applications on the GPU with encryption/decryption kernels that use AES-CTR mode encryption with 256-bit block size [4]. Similarly, for the FPGA, we use standard implementations of AES-CTR mode from Vitis libraries to add encryption to the user logic executing on the FPGA. Because these Vitis Libraries are not natively supported for our FPGA, we port them using Vitis HLS and Vivado to run on our board. To measure the costs of encryption for GPU apps on the host, we cross-compile libopenssl 1.1.1*q* to Arm. The FPGA applications are written in Python so we cross-compile Python as well as libcrypto to run on the FVP.

Optimization. In ACAI, the realm VM requests stage-2 translation table mappings for DMA during runtime. ACAI_{OPT} optimises this by extending the realm creation explained for

[4] For simplicity, we use AES-CTR mode instead of AES-GCM.

ACAI in Section 6 to pre-setup SMMU stage-2 translation tables. Specifically, if a device is attached to the realm VM, ACAI_{OPT} adds SMMU stage-2 translation table entries for all realm VM memory before starting the realm VM. Further, during the runtime of the realm VM, ACAI_{OPT} ensures that any new memory added to the realm VM (via RMI calls) is also mapped in the SMMU's stage-2 translation tables. This approach ensures that the device has access to the entire realm VM memory eliminating the necessity of invoking `rsi_delegate_prot_mem` for each DMA. The trade-off is that this optimization increases the time for realm VM creation and extends realm VM memory as well as the size of the stage-2 translation tables stored in the root.

9.2 Performance Evaluation Prototype

We use the Zynq UltraScale+ MPSoC ZCU102 with an Arm Cortex-A53 64-bit quad-core processor to estimate ACAI performance. We run our modified TF-A with SMMU and GPT changes in EL3. Because the processors do not support GPC, we estimate the overhead of programming the GPT registers by using other idle EL3 registers (i.e., AFSR0_EL3 and AFSR1_EL3). The processor does not have RME support. Therefore, to emulate the realm world, we create a Realm context in the normal world. We run a modified RMM in the EL2 of the Realm context. To create this context, we use Xilinx PetaLinux tools that enable us to build a custom TF-A that also boots the modified RMM. We adapt the TF-A and RMM we run on the FVP to boot on the board. This requires us to replace RME specific instructions (e.g., to invalidate GPT TLBs) and adapt the translation tables to be compatible with Armv8-A. The RMM implementation requires that it is run in the realm world. In our Realm context, we ensure the right security state by setting the SCR_EL3 register. Xilinx Petalinux tools does not allow us to load custom stage-1 and stage-2 bootloaders. Therefore we move RME-specific initialization (e.g., GPT setup) to bl3. Since the processors do not have RME, our measurements do not reflect true GPC cost.

10 Evaluation

Compatibility. We build a VM with `kvmtool` that includes Arm's changes to support CCA. The VM uses a patched Linux kernel 6.2 that supports CCA both as host and guest OS. The only change that ACAI requires is adding an ACAI-helper kernel module comprising 320 LoC to the realm VM. We do not change the applications, accelerator drivers, or runtimes.
TCB. Our baseline setup is a confidential VM using an accelerator device with bounce buffer design [41]. Its TCB includes the monitor, the RMM, and the guest kernel (totals 25.9M LoC) as well as the device runtime, the driver, and the software implementation for memory encryption (totals 203KLoC and 6.5KLoC for GPU and FPGA respectively).[5] Our modifications to the monitor 1588 LoC, the RMM 382 LoC, and the guest kernel 1734 LoC are minimal. Overall, ACAI adds 3704 LoC to the TCB, totalling 26.1MLoC and 25.9KLoC for GPU and FPGA respectively.

Table 3: Overview of GPU Benchmarks. Task refers to the number of CUDA kernels launched on the GPU. T Size: Transfer size in MB. P Size: Problem Size in points

svd64	Singular Value Decomposition	128 KB	64×64

10.1 Experimental Setup

We run our experiments on an x86 host with a 32-core dual-socket Intel Xeon Gold 6346 CPUs and 378 GB RAM.
Benchmark Selection. We select a standard set of GPU benchmarks from the Rodinia testsuite [13]. Instead of the latest Rodinia release from gdev-bench [34], we use version 2.1 since it uses CUDA Driver APIs and is compatible with Gdev. Of the 11 available benchmarks, we successfully test 9. We exclude `lud` and `heartwall` because they crash even on the unmodified system, probably because they are incompatible with our GPU. Nevertheless, as shown in Table 3, the benchmarks cover a wide range of domains, data workloads, and sizes of applications. We fail to identify a standard benchmark that is used for FPGAs. We surveyed the hand-coded benchmarks from prior works [54]. Some of them are not supported on our FPGA (e.g., DNNWeaver runs on KCU1500). Our choice of FPGA was based on what is available on cloud FPGAs (e.g., Amazon F1). However, custom-coded apps for the cloud do not run on local FPGAs because they expect Amazon shell on AWS. Thus, we hand code Matrix Multiplication and Singular Value Decomposition (see Table 4) using existing algorithms from Vitis Libraries and Vitis HLS.
Benchmark Configurations. Our vanilla setup B_v which comprises an unmodified monitor, RMM, and hypervisor,

[5] For simplicity, we leave out the size of software encryption implementation (e.g., 835 KLoC) of OpenSSL, from the baseline TCB.

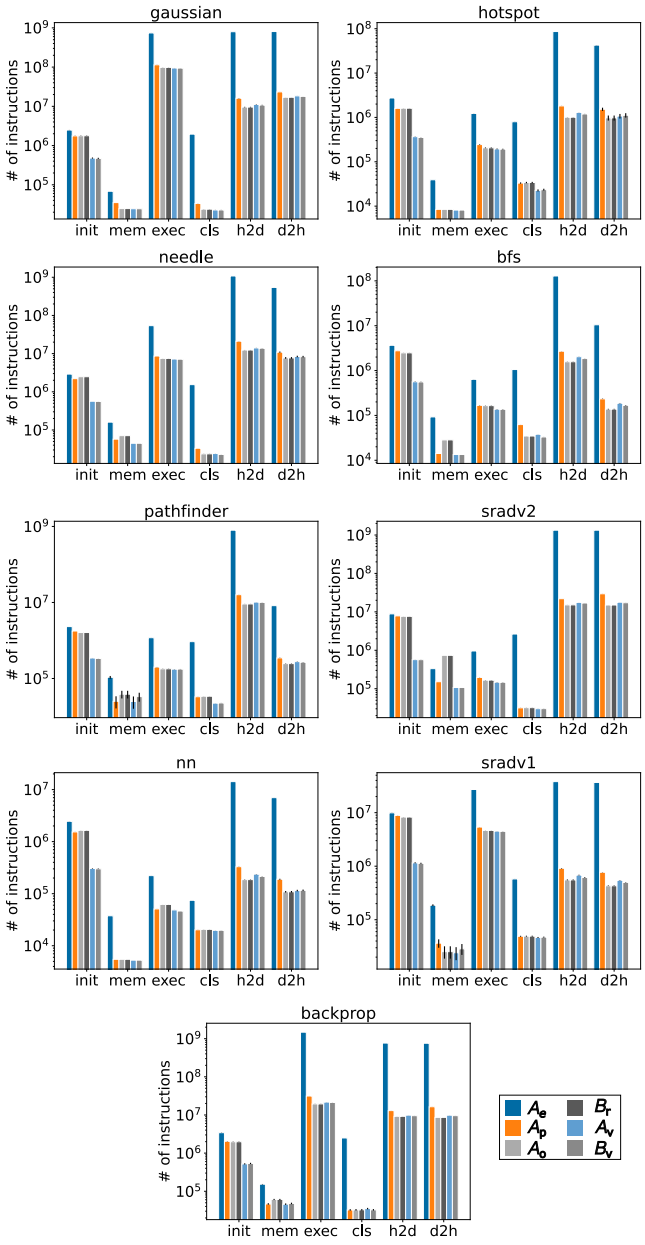

Figure 6: Overheads for GPU benchmarks.

measures the benchmark performance on a VM in the normal world. To measure the effect of ACAI changes on normal world operations (A_v), we execute the benchmarks in the normal world VM but with a modified monitor, RMM, and hypervisor. For measuring ACAI in encrypted mode (A_e) we launch the same setup as above but run the benchmarks in a realm VM equipped with software encryption. Then, we enable ACAI protected mode (A_p) and measure the benchmark performance with a modified monitor, RMM, hypervisor, guest Linux kernel hooks, and SMMU. Comparing A_e and A_p, we can quantify the improvements due to ACAI protection mode. Note that A_p and A_e include the pure cost of CCA's protection. To decouple the ACAI cost from baseline CCA cost, we setup a configuration where we launch the realm with unmodified software (B_r). Thus, we can compare the performance of ACAI (A_p and A_e) with normal world execution (B_v and A_v) by deducting the costs of CCA (B_r). Further, we do the optimization (A_o) (c.f. Section 9.1) and compare it to A_p.

Arm FVP. Our FVP base model, the proprietary version publicly offered by Arm, emulates 8 Arm cores with features from v8.2 to v9. We use the Model Trace Interface (MTI) in the FVP to count the number of instructions and events. This latest version of the FVP (FVP_Base_RevC-2xAEMvA) has support for RME. We thus use this model to emulate Arm CCA and realm VMs. The FVP simulates a limited implementation of the PCIe standard and does not support real device connections over PCIe. So the physical device (e.g., a real GPU) and FVP cannot access each other's memory to send and receive data. We address this in two steps: First, we run the FVP user process on a host machine that is connected to a PCIe device. We then add an escape mechanism on the host machine such that the device can access (parts of) the FVP process memory as shown in Figure 5. Specifically, when the VM inside the FVP allocates device memory, our escape mechanism presents this as a host memory to the PCIe device. This allows us to emulate direct device accesses from the FVP—when the VM makes DMA or MMIO operations, they are visible to the PCIe device and vice versa. Our SMMU GPT and stage-2 translations are setup to protect this memory. However, the FVP escape mechanism bypasses the SMMU in the FVP. Our second step addresses this issue. The FVP's CPU cores are connected to a SMMU engine that is driven by a stub. The stub can generate test traffic. So we record PCIe transactions on a real host-device setup and replay it to generate traffic plugged to the SMMU via the stub. This ensures that we trigger the SMMU for all device-related operations.

With this, one problem still remains. In the FVP, the SMMU is not RME-DA compliant. So, its GPC does not allow access to realm memory where ACAI creates the protected region. Because we cannot change the FVP, we remedy this issue by using two GPTs—one for the cores (GPC_c) and one for the SMMU (GPC_d)—to emulate the RME-DA functionality. The first GPC_c marks the protected memory as realm world for all cores. This way, only cores executing in realm mode (realm VMs and RMM) can access this region. We use this GPT for all CPU cores. On the other hand, the accelerator cannot access the shared memory if the GPT marks it as realm world. To address this, we create a second GPT (GPC_d) where the shared memory is marked as normal world. We then assign this GPT to the SMMU, thus enabling it to access the shared region. Whenever the monitor makes changes to the core GPT, we update the SMMU's GPT to ensure that the accelerator does not have access to any protected or realm memory that the core cannot access. We change the TF-A stage-2 and stage-3 boot loaders to create the additional GPC_d. Our accelerators and host are not PCIe-5 enabled, so we fall back to PCIe-4

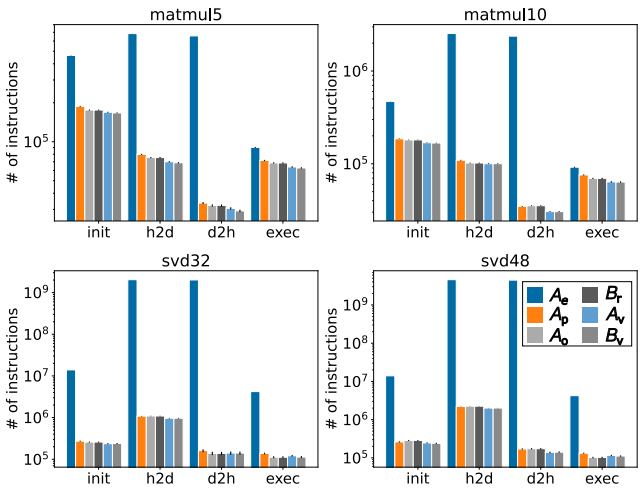

Figure 7: Overheads for FPGA benchmarks. We do not measure mem and cls stages for these benchmarks as they do not perform dynamic memory allocations.

and do not include one-time IDE setup cost.

Arm Board. The FVP is instruction-accurate, i.e., it reports the exact number of instructions that an Arm core will execute to perform operations. However, it is not cycle-accurate, i.e., we cannot use it to measure the wall-clock performance of an out-of-order core operating at a certain frequency. So while our instruction count measurements on the FVP are a proxy metric to estimate performance, they cannot be used to project real-time performance. Since there are no public performance reports for Armv9 cores with RME enabled for CCA, we cannot reliably predict the performance of any CCA workloads. As a best effort, we measure the costs of specific operations on a real Arm board with Cortex-A53 cores.We optimistically assume that Arm cores for CCA will perform close to traditional virtualization and calculate the projected performance of our workloads, while accounting for operational frequencies and average instructions executed per cycle. We do not claim that these performance numbers from the FVP and the board reflect real Arm CCA CPUs.

10.2 Lifecycle Costs & ACAI Breakdown

System Boot and Realm Creation. During system boot, ACAI adds a minimal overhead of 11.42% to delegate the SMMU's data structures to the root world as compared to B_v. Note that this overhead is a one-time cost. The realm creation operation is performed once per realm VM. The costs depend on the VM size and the reserved device memory size. Most init time is spent in transitioning pages from normal to realm world. Compared to just creating realm VMs (B_r), ACAI adds 5.34% overheads due to the additional RSI and SMC calls.

Deletion. ACAI does not add overhead for clean-up. The realm memory footprint of ACAI is the same as the baseline (B_r). For releasing the device, the only overhead is to delete the stream table entry for the SMMU (69 instructions). The subsequent TLB flush in the SMMU is necessary for any device deletion, even for the baseline. The cost of cleaning the device state such that it can be allocated to another VM is common across baselines, ACAI does not add any overheads.

Cost of Delegating SMMU Operations. Our monitor handles SMMU operations as described in Section 7.1. ACAI does not significantly change the memory footprint but simply moves it from normal world hypervisor to root world monitor. Most noticeable is the monitor state to store realm device IDs, which is 64 bits per realm device as shown in Figure 3. In Figure 6 and Figure 7, we see the effect of the SMC calls on hypervisor performance when comparing unmodified execution with the ACAI changes (B_v vs. A_v). The effect of adding and removing SMMU entries and stage-2 translation pages on TLB flushes is common for all configurations.

Interface Calls & Context Switches. ACAI incurs RSIs and SMCs necessary to setup and protect device memory with GPTs and the SMMU as shown in Table 5 and Table 6. They lead to expensive exception-level switches. On average, we incur 103.8% and 62.2% more context switches when compared to an unmodified execution in the realm world (B_r) for GPU and FPGA respectively. For GPU benchmarks we observe a higher number of switches for two reasons. First, the workloads perform several memory allocations. The execution is longer, which incurs more timer interrupts for scheduling the realm VM. Second, for large memory allocations, we observe a higher number of RSI calls. We report that this is due to fragmentation—the hypervisor allocates non-contiguous physical pages, which in the worst case, can result in an RSI call per page to update the SMMU's stage-2 translation table. While we do not observe such extreme cases, ACAI does not make any optimizations (e.g., contiguous memory allocation in the hypervisor). If enabled, such optimizations will reduce the number of RSIs. Consequently, the overhead for FPGA benchmarks is smaller because they allocate lesser memory. Table 5 and Table 6 summarize the interface calls and context switches for A_p. For GPU benchmarks with long-running task, a majority of RMI calls are attributed to timer interrupts. With ACAI enabled, we see an increase of 7.7% RMI calls compared to B_r.

Effect on Normal World Execution. We compare the performance of normal world execution that executes a (non-realm) VM connected to a GPU, with and without ACAI changes (B_v vs A_v). Figure 6 shows that ACAI's enforcement of SMMU protection and additional GPT operations do not impact the normal world performance. We report an average overhead of 3.8% and 1.9% for GPU and FPGA benchmarks. Among the GPU benchmarks, we see that `hotspot` incurs the highest slowdown (11.8%) even though it does not transfer the most amount of data as shown in Table 5. We note that this might be because of how its memory is allocated.

Optimization. ACAI_{OPT} (A_o) achieves an average speedup

Table 5: GPU Performance. Transfer size in MB. Interface calls, Context Switches & World Switches for A_p. *RSI prot* refers to *rsi_delegate_prot_mem* calls. Rl: Realm, Rt: Root, and N: Normal world. Setup & Runtime costs: E% percentage of the total execution for the stage, O% overheads of A_p to B_v. *H to D* and *D to H* refer to host to device transfers and vice-versa. A_p includes CCA protection overheads not present in B_v. Negative overheads imply A_p is faster than B_v.

Table 7: Measurements for GPT operations on Arm Board in cycles and % overhead. GPT Setup: creates two GPTs during boot. GPT Delegate: delegate one granule.

	CCA	ACAI	%
GPT Setup	84,672.0	102,247.0	20.8
GPT Delegate	8,516.0	8,574.5	0.7

of 26.05% and 3.1% compared to ACAI (A_p) for GPU and FPGA respectively as shown in Figure 6 and Figure 7.

Costs on Arm Board. Frequent operations during a realm VM's execution, i.e., transitions to EL2 and EL3, are not expensive. Transitioning from kernel to hypervisor takes 0.89 μs, and from hypervisor to monitor takes 0.77 μs. ACAI requires the hypervisor to use the ACAI interface to the monitor to update the SMMU data structures and update the SMMU's configuration registers. We see that performing an SMC call from the hypervisor and writing data to 1 page costs 2.33 μs as compared to 1.75 μs when directly performed in the hypervisor. Similarly, calls to the monitor to perform memory-mapped register writes require 0.60 μs instead of 0.13 μs to write to the register directly in the hypervisor.

Prototype with an Additional GPT. To verify the functional correctness of ACAI, we implement 2 GPTs in our prototype as explained in Section 9.1. With this, the realm VM allocates and frees device memory triggering changes to the device GPT. As a workload, we run a bare-metal application in the realm. We perform additional RMI and SMC calls for attaching a device which incurs 100 million extra instructions. This leads to 99.15% overhead for the realm VM boot. GPU workloads exhibit different numbers of device operations (between 11–9600) that cause one GPT change per operation. Additionally, each GPT change only incurs 10 extra instructions. Note that we report these measurements for completeness and the GPT changes do not affect ACAI's performance reported in Section 10. We also measure the cost of the GPT operations on our performance prototype as shown in Table 7.

10.3 Comparison to Encrypted Mode

FVP. We compare the impact of ACAI (A_p) with the encrypted mode (A_e) that uses a bounce-buffer design. On average, A_e requires 26.8× more instructions than A_p for GPU benchmarks. Backprop which transfers the most amount of data shows the highest slowdown of 47.8×. Similarly for FPGA, SVD requires 3271.7× more instructions for A_e because the FPGA apps poll for completion. These data transfers are small but frequent, incurring a high encryption overhead.

Estimates on Arm Board. Our FVP measurements use an expensive software-based cryptographic implementation in the realm VM for A_e. As a best-effort estimate we compare the impact of A_e on a real Arm board with support for hardware accelerated AES instruction set. We assume zero

Table 8: Encryption cost estimates for the A_e compared to A_p on the board. The values reflect speedup (x) of A_p compared to encryption measurements on the board and estimates from Graviton [50] for A_e. Arm cores' frequency is 1.2GHz.

	nn	gaussian	needle	pathfinder	bfs
board (x)	17.26	16.20	16.94	16.79	16.97

	srad_v1	srad_v2	backprop	hotspot	
board (x)	16.45	19.3	16.93	16.69	
graviton (x)	9.90	32.2	10.19	10.05	

costs for buffer management, SMMU setup in the A_e case, and only account for the cost of encryption, decryption, and data copies. We micro-benchmark a standard Arm encryption library and measure the performance for transferring a 4KB page with AES-GCM 256-bit block size. This allows us to project the approximate overheads of A_e, based on the total number of memory transfer operations required for each benchmark. Similarly, we estimate the performance of A_p by calculating the cost of RSI calls invoked per memory allocation and deallocation operation during the benchmark execution. Despite the fast hardware encryption, we still expect a slowdown of 2 orders of magnitude (c.f. Table 8).

Estimates on Graviton. How does the performance of ACAI compare to CPUs with native support for fast encryption? To answer this question, we consider the setup from Graviton [50], where the host CPU is Intel SGX with AES-NI support to perform AES-CTR mode encryption on 256-bit blocks and SHA-3 for integrity protection. Based on their evaluation, we calculate the cost of host-side encryption for a 4KB page and then apply that to our benchmarks. Table 8 summarizes these calculations. When compared to A_e on the Arm board, we see a reduction of 27.95% for Graviton. However, when compared to A_p, A_e is still ≈ 2 orders of magnitude slower. Note that, the performance of A_p depends on the number of RSI calls which is a function of how many memory transfers occur. Whereas the performance of A_e is impacted by the size of each memory transfer.

Note. Due to limited space, we defer implementation details and additional evaluation results to the extended version [49].

11 Related Work

CPU TEEs. Arm TrustZone provides secure world for sensitive computation [3], Intel SGX enclaves isolate user-level code [17], and AMD SEV protects confidential VMs [1]. Upcoming TEEs, such as Intel TDX [30] and Arm CCA [5] offer VM-level TEE abstractions. Similarly, Sanctum [18], Keystone [37], and Penglai [22] support TEEs on RISC-V platforms. These CPU-based TEEs do not support shared memory primitives between enclaves. Recent works offer memory sharing for RISC-V enclaves with PMP-based isolation [22, 52]. Further, several prior works create CPU-level TEEs using existing hardware mechanisms such as nested page tables and TrustZone address space controller [12,16,26]. ACAI re-purposes the hardware-enforced access-control and memory-sharing primitives to create a protected region accessible to the realm VM and the device.

PCIe Device TEEs. Graviton makes hardware modifications to support TEEs on GPUs [50] and Telekine makes them side-channel resistant [28]. The same goal can be achieved on other devices [20, 33, 54] and unmodified GPUs [32]. Nvidia Hopper H100 supports confidential computing, where the whole GPU can operate as a single isolated unit or can be viewed as multiple mutually untrusted isolated units called Multi-Instance GPUs (MIGs) [41]. The device TEE hardware can perform line-rate encryption [41]. ACAI requires such TEE-enabled devices to enforce it's invariants.

Protecting Integrated Devices with CPU TEEs. Recent works extend TEEs from CPUs to integrated devices connected directly to the system bus. Strongbox extends TrustZone-based isolation to integrated GPUs on Arm platforms while removing the driver from the TCB [19]. Composite enclaves leverages PMP on RISC-V to create shared memory between enclaves and devices [47]. Cure builds on RISC-V platforms and augments devices to expand the scope of CPU isolation to devices via bus-level enforcement [10]. Similarly, CCA compliant integrated devices can connect to realm VMs if the device-side GPCs enforce access control. ACAI's invariants are useful for these integrated devices, especially the SMMU protection and device binding. Addressing challenges in integrated mode may be easier—there is no dedicated device memory and the CPU protects the host DRAM. Future work can investigate the security and compatibility of such devices using ACAI's invariants.

TCB Reduction & Verification. ACAI does not aim to reduce TCB; it trusts the monitor, RMM, device driver, runtime, and guest kernel. Prior works remove the driver from the TCB for secure device communication with Arm TrustZone [19,25]. Shelter removes the RMM from the TCB by creating enclaves in the normal world instead of the realm world in Arm CCA [53]. Samsung Islet, a Rust-based RMM, reduces potential memory safety issues [46]. Further, the TrustZone firmware has been subject to formal verification [23, 40]. For Arm CCA, there are ongoing efforts to verify the RMM and the CCA firmware [24, 39]. Future works can use similar techniques to reduce ACAI's TCB and formally verify it.

ACAI Takeways for Upcoming Platforms. Upcoming IOPMP in RISC-V [36], PCIe-6 specification [44], its adoption as Intel TDX-Connect and AMD SEV-TIO are promising directions to expand ACAI to other devices and CPU-TEEs [2, 29, 41]. With these upcoming features, we hope that ACAI serves as a guiding principle for future cloud deployments. ACAI invariants amend CCA's security specification to ensure that the CPU-side isolation extends to accelera-

tors. Future works can use the same principle, but adapt it to specifics of the underlying isolation mechanisms: PMP and IOPMP in RISC-V, secure EPTs and IOMMU on Intel, or secure nested paging and IOMMU on AMD. Adapting ACAI to these systems will require revisiting challenges such as scalability and attestation, as well as compatibility with other hypervisor, kernel, and driver implementations.

12 Conclusion

ACAI is the first system that demonstrates CCA-based confidential VMs to directly use accelerators as a first-class abstraction. ACAI enforces strong isolation guarantees by extending existing CCA mechanisms to achieve security.

Abstract

Network functions virtualization enables tenants to outsource their service function chains (SFCs) to third-party clouds for better agility and cost-effectiveness. However, outsourcing may limit tenants' ability to directly inspect cloud-level deployments to detect attacks on SFC forwarding paths, such as network function bypass or traffic injection. Existing solutions requiring direct cloud access are unsuitable for outsourcing, and adding a cryptographic trailer to every packet may incur significant performance overhead over large flows. In this paper, we propose *ChainPatrol*, a lightweight solution for tenants to continuously detect and classify cloud-level attacks on SFCs. Our main idea is to "virtualize" cryptographic trailers by encoding them as side-channel watermarks, such that they can be transmitted without adding extra bits to packets. We tackle several key challenges like encoding virtual trailers within the limited side channel capacity, minimizing packet delay, and tolerating unexpected network jitters. We implement our solution on Amazon EC2, and our experiments with real-life data and applications demonstrate that *ChainPatrol* can achieve a better balance between security (e.g., 100% detection accuracy and 70% classification accuracy) and overhead (e.g., almost zero increased traffic and negligible end-to-end delay) than existing works (e.g., up to 45% overhead reduction compared to a state-of-the-art solution).

1 Introduction

By decoupling network functions from proprietary physical boxes, Network Functions Virtualization (NFV) [1] allows tenants to host their network services on top of existing clouds managed by third-party cloud providers [2–4]. For instance, Amazon AWS Cloud is reportedly used to deploy an entire cloud-native 5G network [2] and VMware Telco Cloud platform is also designed for similar purposes [4]. However, outsourcing network services to third-party clouds may also bring novel security challenges. Since tenants typically have limited visibility into the underlying cloud infrastructure, they cannot directly inspect the cloud-level deployment of Service Function Chains (SFCs) to ensure their deployment matches the specification. Therefore, cloud-level integrity breaches may silently arise and stay invisible to tenants [5]. For instance, an attacker can exploit a vulnerability or a misconfiguration in cloud-level resources (e.g., virtual switches) either to attack the SFC forwarding path (e.g., skipping a firewall inside the SFC [6]), or to attack the traffic (e.g., packet/flow injection, dropping, and reordering [7]).

Many existing solutions for verifying forwarding paths (e.g., ICING [8], OPT [9], and EPIC [10]) are not directly applicable to SFCs as they are incompatible with the inherent characteristics of SFCs (i.e., paths dynamicity and packets mutability) [6,11]). Later works [6,7,12] address this through adding a cryptographic trailer to every packet, which can guarantee the integrity and detect various attacks. However, such capabilities come at a cost, i.e., the added communication overhead is usually proportional to the flow size (e.g., three times increase of the packet size [9] and 1.69 times increase of the network traffic size [10]). Such an overhead may be prohibitive for applications with large flow sizes, e.g., music streaming, video conferencing, and virtual reality, which have become increasingly popular today.

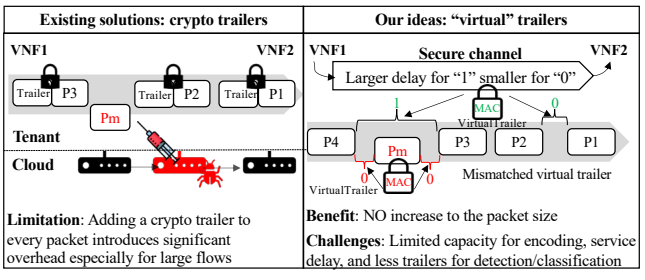

Figure 1: Example of crypto/virtual trailers

Example 1. Figure 1 shows an example to further illustrate the limitation of existing solutions (left), and our ideas (right). For simplicity, we consider a toy example of SFC con-

✉ Corresponding authors

sisting of two Virtual Network Functions (VNFs) connected through three cloud-level virtual switches, among which the middle one is compromised.

The Research Problem: The left side of Figure 1 illustrates a packet injection attack against the SFC. By exploiting either a vulnerability [13, 14] or misconfiguration [15] in the middle virtual switch, an attacker can inject a crafted packet (*Pm*) into the flow of normal packets (*P1*, *P2*, and *P3*) between *VNF1* and *VNF2*. Since the tenant has no direct access to cloud-level resources, it cannot easily uncover this attack. The protection provided by the cloud provider may also be limited since it is not necessarily aware of all tenants' SFCs and forwarding policies. Therefore, such attacks may fall into the gap and go undetected.

Existing solutions: The left side of Figure 1 also shows how existing cryptographic solutions (e.g., [6, 7, 12]) can detect the aforementioned attacks. Specifically, such solutions would modify *VNF1* to append a verifiable cryptographic trailer (including a Message Authentication Code (MAC) value computed over the packet and other trailer fields) to every packet before it leaves *VNF1*. *VNF2* is also modified to verify the trailer when the packet arrives. The malicious packet *Pm* can be reliably detected by *VNF2* since adversaries cannot forge such a trailer. However, as those solutions add a trailer to every single packet, they imply an overhead that is proportional to the flow size.

Our ideas: As shown on the right side of Figure 1, we "virtualize" the physical trailers as side channel watermarks, e.g., encoding a "virtual" trailer of '10' by slightly delaying packets *P1* and *P4* before they leave *VNF1*, such that the inter-packet delay between *P1* and *P2* becomes slightly smaller than usual, representing a '0' bit, while the delay between *P3* and *P4* becomes slightly larger than usual, representing a '1' bit. The injection of a malicious packet *Pm* can be detected as it will partially destroy our virtual trailer (there will now be two '0' bits after the injection, as shown in the figure). Moreover, as adversaries cannot forge the MAC (whose encoding is not shown in the figure and will be detailed in Section 3.2), they could not evade the detection with a fake trailer mimicking the expected inter-packet delays. Finally, the way the trailer is destroyed would also provide us additional information to not only detect the attack, but also to classify its type (detailed in Section 4).

Specifically, this paper presents *ChainPatrol*, a solution that applies the virtual trailer concept to SFCs for balancing security (i.e., attack detection and classification) with performance overhead (i.e., increased traffic and end-to-end delay). First, *ChainPatrol* offers a much lighter-weight solution than existing works based on physical trailers [6, 7, 12], since no extra bit needs to be added to packets (virtual trailers are encoded as side channel watermarks). Second, since virtual trailers contain similar information as in their physical counterparts, *ChainPatrol* can still guarantee the integrity of SFCs when the trailers are intact, and provide useful information for detecting and classifying attacks when the trailers are compromised (note these cannot be achieved by directly applying existing watermarking techniques [16–18], because the watermarks lack the semantics of a cryptographic trailer, e.g., sequence numbers of packets or flows and MAC values). Finally, unlike many existing works (which either require direct access to the underlying cloud infrastructure [19] or require modifications to the VNFs [20]), *ChainPatrol* provides a tenant-level solution that can be transparently integrated with existing SFCs, since IPDs are directly observable and mutable at tenant level and outside the VNFs. In summary, our main contributions are as follows.

- We propose the novel concept of *virtual trailer*, which inherits the advantages of both cryptographic trailer-based solutions (i.e., verifiable attack detection) and side-channel watermarking (i.e., lightweight). To realize this, we address several key challenges such as encoding virtual trailers within the limited capacity of a side channel, minimizing packet delay while computing virtual trailers, and handling unexpected network jitters. We believe this concept may potentially find other applications in a broader context.
- We apply the concept of the virtual trailer to design a tenant-based solution, *ChainPatrol*, for lightweight attack detection and classification in SFCs hosted on third-party clouds. First, *ChainPatrol* performs fast attack detection by identifying destroyed virtual trailers. Second, it performs in-depth attack classification through partial reconstruction of destroyed virtual trailers to match the expected ones. Finally, it verifies classification results through sharing a limited amount of information between the source and destination.
- We implement and deploy *ChainPatrol* based on Amazon EC2 and perform extensive experiments using both public datasets and an in-house 5G testbed. Our experimental results demonstrate the effectiveness (e.g., 100% detection accuracy and 70% classification accuracy) and efficiency (e.g., close to zero increased traffic and negligible end-to-end delay) of *ChainPatrol*. Our comparison of *ChainPatrol* to an existing physical trailer-based approach under real-world applications shows a significant reduction of communication overhead (up to 45%).

2 Background

This section provides background and our threat model.

2.1 SFC Forwarding Path Verification

Existing cryptographic solutions for forwarding path verification [6, 7] adapt traditional forwarding path verifica-

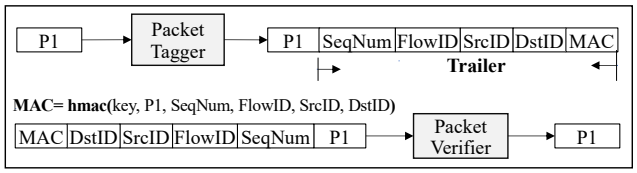

Figure 2: Example of a packet with cryptographic trailer [6]

tion protocols [8–10] to the NFV setting in order to meet its unique characteristics: (i) path dynamicity and unpredictability, (ii) packet modification by VNFs, and (iii) SFC migration and autoscaling. Specifically, those solutions intercept each egress packet at a source VNF to append a custom trailer to the packet, which consists of additional data fields along with a MAC computed over the entire packet content (including the trailer) using a secret key. A valid MAC extracted at the destination VNF (under the same key) would attest to the integrity of the packet content. This allows the traffic between VNFs to be verified for correctness.

Example 2. As shown in Figure 2, a packet tagger at the source VNF appends a packet trailer to each passing packet (top), and a packet verifier at the destination VNF verifies the packet and its trailer for integrity (bottom). First, `SeqNum` is a sequential number representing the ordering of packets between each pair of VNFs for a given flow. Together with `FlowID`, it is used to detect packet reordering and replay attacks within a given flow. Second, `FlowID` is uniquely mapped to the classic 5-tuple ⟨source IP address, destination IP address, source port, destination port, protocol⟩, and is used to detect flow-based attacks (e.g., flow injection and flow dropping). Third, `SrcID` and `DstID` refer to the source and destination VNFs, respectively, and are used to ensure compliance with the forwarding policy between the two VNFs. Finally, `MAC` is computed over both the packet content and above trailer fields and is used to authenticate the integrity of the packet and its trailer by the destination VNF.

2.2 Blind Watermarking

In this work, we adopt a *blind* watermarking approach (i.e., the packet verifier does not require knowledge about the original IPDs or watermarks). This choice was made for the following two reasons: (i) As we leverage watermarks to transmit virtual trailers without actually sending any bit, a non-blind approach, which must send information about the original IPDs and watermarks between the two VNFs, would defy our purpose. (ii) Although a non-blind watermarking approach is usually more resistant to network jitters (since the packet verifier knows the original IPDs), a blind approach is sufficient for our purpose, because the network connection between two VNFs in a data center is typically more stable (in contrast to the Internet for which most existing watermarking approaches are designed) [21].

Example 3. Figure 3 shows how a two-bit watermark message $\langle 1,0\rangle$ is encoded into the IPDs between four packets

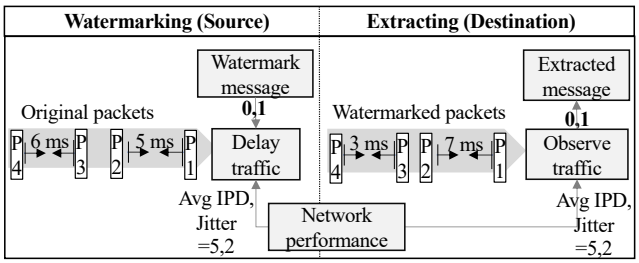

Figure 3: Example of watermarking and extracting two bits

at the source (left), and decoded at the destination (right). First, the average IPD (5 ms) and network jitter (2 ms) are continuously measured and used for reference on both sides. Second, the source encodes a bit 1 by increasing the original IPD between packets P_1 and P_2 corresponding to the summation of the average IPD and jitter (i.e., from 5 ms to 7 ms). Similarly, it encodes a bit 0 by decreasing the IPD between P_3 and P_4 corresponding to the difference between the average IPD and jitter (i.e., from 6 ms to 3 ms). Third, by comparing the observed IPD with the average IPD and jitter, the destination decodes a bit 1 between P_1 and P_2 as $7 \geqslant (5+2)$, and a bit 0 between P_3 and P_4 as $3 \leqslant (5-2)$. Note a jitter no greater than 2 would not change this result.

2.3 Threat Model

We consider a similar threat model as in recent works on crypto-based forwarding path verification [6, 7]. We also make assumptions related to our watermarking scheme.

In-Scope threats. Our in-scope threats include integrity breaches of the SFC forwarding paths or traffic caused by either (i) a malicious attacker compromising an underlying cloud-level forwarding device [14], or (ii) misconfigurations (intentionally or mistakenly) introduced by a cloud provider [15]. Specifically, we assume the network links between VNFs and the virtual switches used to steer traffic between such VNFs are both subject to the following attacks. First, a compromised cloud-level device may be used to skip VNFs or append malicious VNFs to the forwarding path, or to cause other unexpected forwarding decisions such as redirecting traffic intended for one VNF to another [7]. Second, a compromised cloud-level device may also be used to disrupt SFC traffic, such as injecting fake packets and dropping, modifying, reordering, or replaying packets. We assume the adversary may attempt to evade the detection through the so-called coward attack [9] (i.e., attacking selected flows not subject to detection) or attacks on the watermarking scheme used to encode virtual trailers (by deliberately altering the IPDs). A more detailed list of attacks covered in our work is given later in Table 2.

Out-of-Scope threats. By taking a tenant-based viewpoint, we assume no direct access to cloud-level resources or data, and therefore we must trust all the components to which the tenant has direct access. This includes the VNFs and

the gateway to access the SFC, and we also consider the cloud provider to be cheap-and-lazy but not malicious [15]. Attacks that can compromise those components or our solution itself (including the secret key used to compute the MAC) are out of scope of our work (which can be addressed through hardware-based solutions [6,12]). We focus on verifying the integrity of SFCs, and thus denial of service attacks (e.g., dropping all packets) and attacks on confidentiality or privacy of the traffic are out of scope. Moreover, since we leverage a fragile watermarking scheme, which relies on modified watermarks to detect attacks [22], watermark invisibility attacks [16]) are out of scope for our work. Finally, as demonstrated in Section 6, our solution is more beneficial for flows of relatively large sizes (for small flows, the overhead of physical trailers may be acceptable).

3 Virtual Trailer

This section defines the *virtual trailer* concept and details how to encode and decode virtual trailers based on IPDs.

3.1 Definitions

Our goal is to design virtual trailers to contain similar information as in their physical counterparts, such that they can support attack detection and classification (detailed in Section 4). However, there are several challenges. First, unlike a physical trailer which can be defined for (and added to) each packet, a virtual trailer can only be encoded in the IPDs of multiple packets. Therefore, we define a virtual trailer for each equal-sized group of consecutive packets within the same network flow, namely, a *block*. Second, due to the limited capacity of this side channel, we need to simplify the design of virtual trailers to only retain a minimal number of trailer fields, i.e., the identifiers of blocks and flows, while implicitly representing the source and destination VNFs inside the flow identifiers. Specifically, each flow identifier is now uniquely associated with a 7-tuple ⟨`source IP`, `destination IP`, `source port`, `destination port`, `protocol`, `source VNF`, `destination VNF` ⟩. Third, since a MAC value typically contains a much larger number of bits than what can be encoded inside a single block, we redefine the MAC to be computed over an equal-sized group of consecutive blocks inside the same flow, namely, a *SuperBlock*. Finally, to enable efficient attack classification and verification, the MAC is computed based on a Merkle hash tree [23] defined over the SuperBlock. The following first formally defines a virtual trailer for each block.

Definition 3.1 (Virtual Trailer) *Given block B_i ($1 \leqslant i \leqslant S_F$) inside a SuperBlock SB (with totally S_F blocks) in a flow F, the virtual trailer of B_i is a 3-tuple $VT_i = \langle BlockNum_i, FlowID, MAC_i \rangle$. First, $BlockNum_i \in \mathbf{N}$ is an integer value uniquely and sequentially assigned to each block in the given flow F. Second, $FlowID \in \mathbf{N}$ is an integer value uniquely and sequentially assigned to each flow. Third, $MAC_i \in \mathbf{N}$ is the $(\frac{i}{S_F})^{th}$ fraction of the Merkle tree [23] HMAC value computed over all the blocks in SB concatenated with their corresponding BlockNum and FlowID fields, i.e., $B_i||BlockNum_i||FlowID$ ($1 \leqslant i \leqslant S_F$).*

Table 1: Examples of Virtual Trailers (VT)

Flow	SB	B	VT		
			BlockNum	FlowID	MAC
<IP1,IP2,8,80,6,VNF1,VNF2>	1	1	0001	0001	0100
		2	0010	0001	1100
	2	3	0011	0001	1100
		4	0100	0001	1100
<IP1,IP2,4,80,6,VNF1,VNF2>	1	1	0001	0010	1010
		2	0010	0010	0101

Example 4. Table 1 shows an example with two flows, their SuperBlocks and blocks, and the corresponding virtual trailers (last three columns). The `BlockNum` is sequentially assigned to consecutive blocks inside the same flow, starting from a random number. Similarly, the `FlowID` is sequentially assigned to consecutive flows. For the first flow, the Merkle tree HMAC value of 01001100 is divided into two equal-sized bit strings (0100 and 1100) each of which forms the last field of the virtual trailer (similarly for the second flow). Figure 4 also depicts a virtual trailer (bottom right) and how the MAC value is computed (left) (the rest of the figure will be explained later in Example 5). Algorithm 1 in the appendix details the generation of virtual trailers.

3.2 Virtual Trailer Encoding

ChainPatrol intercepts packets at the egress of source VNF and determines their corresponding flows, SuperBlocks, and blocks (see Section 3.1). It then generates a virtual trailer for each block using Algorithm 1, and encodes the virtual trailer by modifying the IPDs (i.e., delaying one packet between every pair of packets, as explained in Section 2.2). Specifically, as each virtual trailer contains three fields (i.e., `BlockNum`, `FlowID`, and `MAC`), each block is divided into a series of three *frames*, and the IPDs in each frame are modified to encode a corresponding trailer field.

However, a key challenge lies in the encoding of the MAC trailer field. Specifically, since the MAC field of a virtual trailer is defined over a SuperBlock (as illustrated on the left side of Figure 4), it cannot be computed before the entire SuperBlock is received. Therefore, any received blocks of this SuperBlock must be delayed, since we do not yet know how to modify their IPDs. Such delays must be maintained until the last block arrives, after which we can then compute the virtual trailer, encode it by modifying the IPDs of all the buffered blocks, and finally forward all the blocks to the destination VNF. However, doing so would certainly cause prohibitive delay (proportional to the size of the SuperBlock). To address this, our key idea is to shift the encoding of each virtual trailer to the next SuperBlock. This allows us to compute the virtual trailer (which tells us how

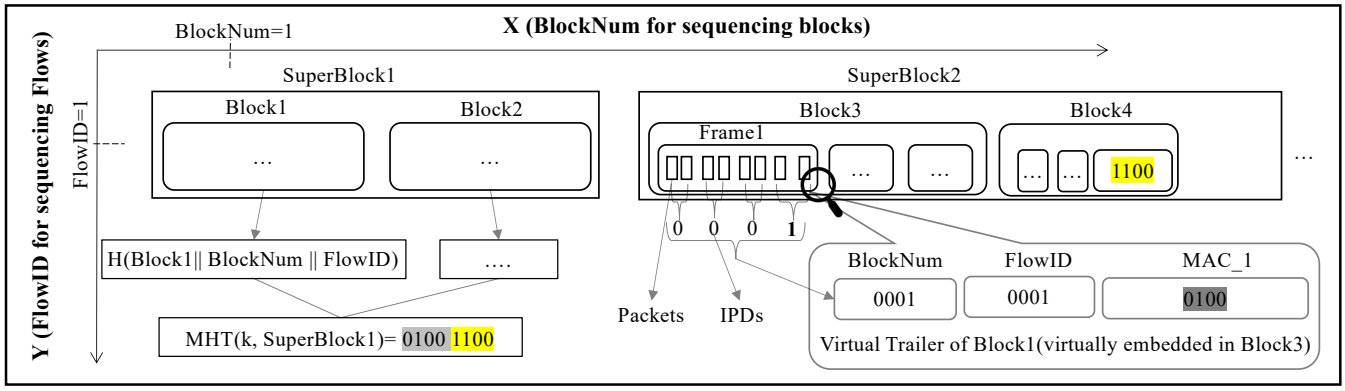

Figure 4: Example of a virtual trailer and its encoding

to modify the IPDs) ahead of the arrival of any block of the next SuperBlock, so we will know how to modify the IPD as soon as each such block arrives, and can forward the block with minimum delay (evaluated in Section 6).

Example 5. Figure 4 shows how the virtual trailer of a block (`Block1`) in the first SuperBlock (shown on the left) is encoded using a block (`Block3`) in the next SuperBlock (shown on the right). First, `Block3` is divided into three frames, each of which corresponds to a virtual trailer field. Second, the IPD between each pair of packets inside a frame is then modified (by delaying one of those packets) to encode each bit of the field. Similarly, the virtual trailer of `Block2` (i.e, the second block of `SuperBlock1`) is encoded in `Block4`. Note that, by the time `Block3` arrives, this virtual trailer of `Block1` would have already been computed. Therefore, we know how to modify the IPDs in `Block3` as soon as each pair of packets arrives, which can then be immediately forwarded.

Another challenge is to ensure the correct decoding of virtual trailers despite potential network jitters. For this purpose, *ChainPatrol* leverages an existing watermarking scheme [16] which is known to enable reliable extraction of watermarks at the destination side despite network jitters. The main idea is to introduce additional delay that is proportional to the expected level of jitters in order to cancel their impact on the encoded watermarks. Specifically, let $m_1 \cdots m_w$ be the w-bit representation of a virtual trailer field to be encoded. Denote the IPD between two packets arriving at time t_i and t_{i+1} as $IPD_i = (t_{i+1} - t_i)$. To encode bit m_i $(1 \leqslant i \leqslant w)$ using IPD_i, the new IPD, denoted by $nIPD_i$, is computed as: $nIPD_i = IPD_{AVG} + a \times M_i^e$, where IPD_{AVG} is the average IPD, a is the *watermarking amplitude* (computed using the Signal-to-Noise formula [16]), and $M_i^e = 1$ if $m_i = 1$, or $M_i^e = -1$ if $m_i = 0$ (whose effectiveness is further evaluated in Section 6). Algorithm 2 in the appendix details the encoding of the virtual trailers of a given SuperBlock.

3.3 Virtual Trailer Decoding

ChainPatrol passively monitors packets at the destination VNF and determines their corresponding flows, SuperBlocks, blocks, and frames. It then decodes the virtual trailers following a reversed process based on the observed IPDs. More specifically, let $rIPD_i$ $(1 \leqslant i \leqslant w)$ be the observed IPD between the i^{th} and $(i+1)^{th}$ packets, where w is the size of a virtual trailer field, and let IPD_{AVG} and a be the average IPD and the watermarking amplitude, respectively. Denote $M_i^d = (rIPD_i - IPD_{AVG})/a$. The w-bit binary representation of the virtual trailer field can be computed as: $m_i = 1$ if $M_i^d = 1$, or $m_i = 0$ if $M_i^d = -1$.

Attacks such as dropping, injection, or reordering of packets may shift the frames and blocks among the observed packets. Section 4 will detail how we address this issue and leverage it to classify attacks. Another challenge is related to the last SuperBlock. First, the virtual trailers of this last SuperBlock itself cannot be encoded using the IPDs of next SuperBlock (which does not exist). Second, when we divide a given flow into equal-sized blocks and SuperBlocks, the last SuperBlock may be incomplete, i.e., there are not enough packets remaining to compose a complete SuperBlock, which would prevent encoding the virtual trailers of the previous SuperBlock using IPDs. *ChainPatrol* addresses the first challenge by directly appending a physical version of the virtual trailers to the flow. Since *ChainPatrol* is designed for large flows (as stated in Section 2.3) with a significant number of SuperBlocks, the overhead of one trailer will be negligible in contrast to the flow size. To address the second challenge, *ChainPatrol* performs one of the following two options that introduce less overhead, i.e., (i) adding dummy packets to the last SuperBlock such that it can have enough IPDs for encoding the virtual trailers of the previous SuperBlock, or (ii) appending the physical trailers. Algorithm 3 in the appendix details virtual trailer decoding.

3.4 Handling Unexpected Network Jitters

ChainPatrol is designed for SFCs hosted inside cloud data centers, which is known to be more stable than the Internet [21], so network disturbance is expected to be rare. Nonetheless, since unexpected network jitters can still happen and disrupt the transmission of virtual trailers, we de-

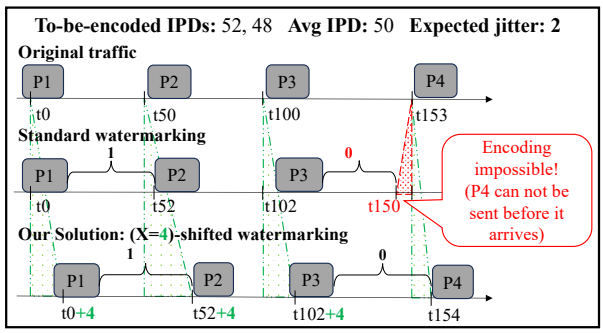

Figure 5: X-shift for encoding w/ unexpected IPD variation

sign *ChainPatrol* to provide three protection mechanisms against such jitters. First, as detailed in Section 3.2, our virtual trailer encoding scheme can already tolerate jitters through calculating and continuously updating the watermarking amplitude to be proportional to the average jitter. Second, we further design two mechanisms for the source and destination VNFs, respectively, to handle larger and unexpected jitters. Finally, we experimentally evaluate the effectiveness and overhead of those methods in Section 6.

The X-shift method. An unexpected amount of jitter exceeding the watermarking amplitude may render the encoding challenging for the source VNF. Specifically, if the second packet in a pair arrives so late, that it has not arrived when the VNF needs to send it to match the to-be-encoded IPD, then encoding becomes impossible since we cannot send a packet that has not yet arrived. For instance, Figure 5 shows two watermark bits 1,0 to be encoded with new IPDs 52,48 (assuming an average jitter of 2 ms) between two pairs of packets ($P1$ to $P4$). The top timeline depicts their actual arrival time, which shows an unexpected delay of 3 ms between $P3$ and $P4$. As the middle timeline shows, a standard encoding scheme will fail to encode the second bit, since $P4$ is supposed to depart at t=150 (to have an IPD of 48) but by that time it has not yet arrived. One naive solution here is for both VNFs to use two pre-defined high IPD values (which will never occur naturally) to encode 0 and 1, respectively, such that $P4$ can now be further delayed to encode 0. However, this could lead to significant delay considering that the watermarks in our application are generally large in size so this scenario may occur very often. To address this, we adopt a pragmatic X-shift approach as follows. As the lower axis in Figure 5 shows, the first packet in each pair will be proactively delayed by a small amount ($X = 44$ ms in this case) to minimize the likelihood of requiring the costly solution of using pre-defined large IPDs. The source-side VNF periodically updates X based on observed IPD variation (note, unlike watermarking amplitude, the destination VNF does not need to know X). Finally, the impact of delaying the first packet of each pair will not add up and hence remains negligible for the entire flow.

The α-amplitude method. An unexpected amount of jitter exceeding the watermarking amplitude may also prevent the correct decoding of virtual trailers at the destination VNF. Specifically, the jitter may cause the flipping of some bits in the virtual trailer during transmission, which can generate false positives for attack detection. To address this issue, we adopt the pragmatic approach of using a larger-than-necessary watermarking amplitude upon observing unexpected jitters. Specifically, the watermarking amplitude (as calculated in Section 3.2) will be multiplied with a parameter $\alpha(\alpha \geqslant 1)$, which is decided based on the observed level of jitter variation (i.e., observing a larger variation leads to a larger α being used). Using such a larger-than-necessary amplitude creates a bigger gap between the IPDs used to encode watermark bits 0 and 1, which ensures the destination VNF can still correctly distinguish between them and thus reduces the chance of a bit flipping caused by unexpected jitters. Finally, the watermarking amplitude, the X value, and the α parameter will all be constantly monitored and continuously updated to reflect changing network states (detailed in Section 5) and their effectiveness will be confirmed in Section 6.

4 Attack Detection and Classification

This section details how *ChainPatrol* detects and classifies various attacks using virtual trailers.

4.1 Attack Detection

Similar to existing works using physical trailers [6,7], *ChainPatrol* detects SFC attacks by matching decoded virtual trailers with corresponding blocks. However, the unique design of virtual trailers (detailed in Section 3) leads to two differences as follows. First, since the virtual trailers of one SuperBlocks are always encoded in the IPDs of next SuperBlock, *ChainPatrol* iteratively performs attack detection inside a moving window that slides over the next two consecutive SuperBlocks of the current flow in each iteration. Second, recall that the HMAC of a SuperBlock is computed based on a Merkle hash tree defined over all the blocks, and each virtual trailer only includes part of this HMAC value (as illustrated in Figure 4). Therefore, *ChainPatrol* first decodes the virtual trailers encoded in the second SuperBlock inside the moving window, and recomputes the Merkle tree HMAC based on the decoded `BlockNum` and `FlowID` values and all packets of the first SuperBlock. It then compares this re-computed HMAC with the decoded HMAC value (obtained by concatenating the `MAC` fields of all the virtual trailers decoded from the second SuperBlock).

One challenge is that, since an attack may cause the frames, blocks, or SuperBlocks to shift, *ChainPatrol* needs to identify the beginning of the next SuperBlock once an attack is detected. Specifically, if all the virtual trailer fields match the first SuperBlock in the window, *ChainPatrol* marks the

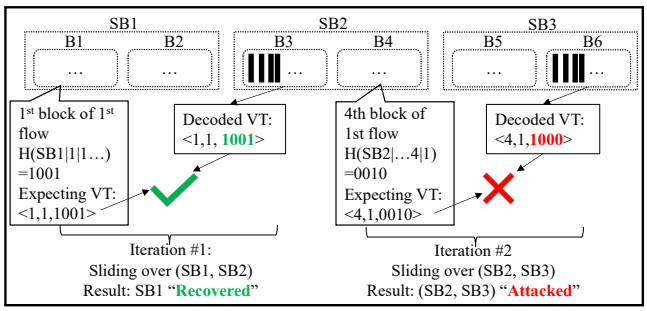

Figure 6: Example of attack detection

first SuperBlock as "recovered", and the window slides forward by one complete SuperBlock. When an attack is detected, *ChainPatrol* marks the current pair of SuperBlocks as "attacked" (which will be further inspected for attack classification), and the window slides forward by only a pair of packets in order to identify the beginning of the next SuperBlock. Once a new SuperBlock is identified, *ChainPatrol* resumes the normal attack detection as described above. Algorithm 4 in the appendix details the attack detection.

Example 6. Figure 6 (top) shows the first three SuperBlocks of the first flow, and (bottom) an example of attack detection.

- In the first iteration, the window slides over the first two SuperBlocks, `SB1` and `SB2`. For the first block of `SB1`, the expected `BlockNum` = 1) and `FlowID` = 1), as this is assumed to be the first block of the first flow. As the figure shows, the first virtual trailer decoded from `SB2` also contains the same `BlockNum` and `FlowID` values.
- The expected `MAC` needs to be computed over the content of *SB*1 concatenated with the decoded `BlockNum` and `FlowID` fields of both blocks inside `SB1`. As the figure shows, the first half of the MAC value decoded from `SB2` matches the expected value (1001). Assuming the second half also matches, `SB1` can be marked as "recovered" as no attack is detected.
- In second iteration, the window slides to `SB2` and `SB3`. Similarly, the expected `BlockNum` and `FlowID` match the ones decoded from `SB3`. However, assume the first half of the expected MAC value (0010) does not match the decoded one (1000), an attack is thus detected. At this point, it is unclear whether the attack happened to `SB2` or the virtual trailers (i.e., IPDs) in `SB3`, so both SuperBlocks are marked as "attacked" for classification.
- Since the attack may have caused packets to be injected, dropped, or reordered, we cannot take the beginning of the next SuperBlock for granted. Instead, the window can only slide forward by one pair of packets at a time, until we identify the next intact SuperBlock.

4.2 Attack Classification

Upon the detection of an attack, *ChainPatrol* classifies it with one of the known attack types listed in Table 2. In addition to the well-known packet-level attacks reported in the literature, *ChainPatrol* also considers block-level attacks that involve the manipulation of a whole packet block, flow-level attacks involving all packet blocks in a flow, and SFC-level attacks targeting the forwarding paths (instead of packets). To classify a SuperBlock marked as attacked during the detection stage (Section 4.1), *ChainPatrol* attempts to reconstruct the expected virtual trailers by applying each of the classification rules listed in the last column of Table 2, and it classifies with an attack type if the reconstruction is successful under the corresponding rule.

Table 2: Attack types covered by *ChainPatrol*

	Attack type	Classification rules based on virtual trailers
Packet	Injection	Unrecovered VT & larger block size
	Reordering	Partially recovered VT & expected block size
	Replay	Unrecovered VT & larger block size
	Modification	Unrecovered VT with mismatched MAC
	Dropping	Partially recovered VT & smaller block size
Block	Injection	Unrecovered VT & expected block size
	Reordering	Out of order `BlockNum`
	Replay	Recovered VT with repeated `BlockNum`
	Dropping	Missing VT with specific `BlockNum`
Flow	Injection	Unrecovered `FlowID`
	reordering	Out of order `FlowID`
	replay	Repeated VT for all blocks
	dropping	Missing `FlowID`
SFC	VNF Inj.	Unrecovered `FlowID`
	Reordering	Out-of-order `FlowID`
	VNF-Loop	Repeated `FlowID`
	Skipping	Missing `FlowID`

One challenge is that, depending on the level of the classification rule (first column of Table 2), this reconstruction may involve two SuperBlocks, the remainder of the flow, or even other flows (e.g., flow or SFC-level attacks). Therefore, the attack classification naturally requires more effort than attack detection. This explains why *ChainPatrol* adopts a layered approach to separate the (faster) detection from (slower) classification such that it can provide faster detection (as shown through experiments in Section 6).

Another challenge is that the missing information (e.g., in case of dropping or modification attacks) and lower granularity of virtual trailers (i.e., per block instead of per packet) together may prevent a full reconstruction of virtual trailers, and hence the attack classification result can no longer be guaranteed like with detection. To address this, we leverage our design choice of computing the MAC based on a Merkle hash tree [23] defined over a superblock (detailed in Section 3) to enable efficient source-assisted verification of the classification result in such cases. Specifically, the well-known property of a Merkle hash tree [23] allows us to verify the MAC (and hence the correctness of classification) by requesting selected tree nodes from the source, e.g., a single node (common ancestor) is sufficient for $log(N)$ consecutive blocks (in contrast, N nodes would be requested if the MAC were computed directly over the SuperBlock). Algorithm 5 in the appendix details the attack classification.

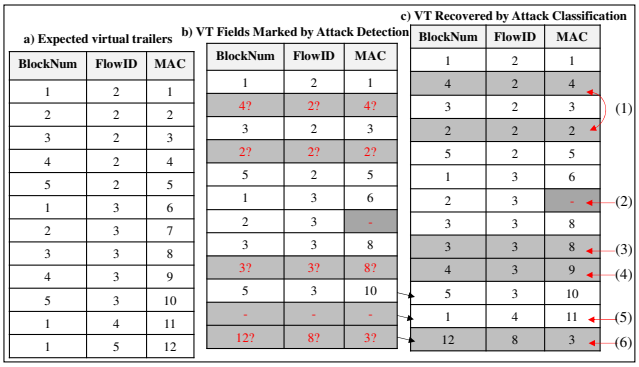

Figure 7: Examples of attack classification (a question mark (?) means mismatching with expected value; a dash (-) means no received packet; grey rows are involved in detection or classification; numbers (1-6) indicate attacks)

Example 7. Figure 7 depicts six examples of classification:

- Attack (#1) is classified as reordering of the two shaded blocks, since their `BlockNum` fields are out-of-order (Figure 7.c). Specifically, attack classification attempts to reconstruct the expected virtual trailers (i.e., first four rows in Figure 7.a) by applying each classification rule (last column of Table 2) to the attacked virtual trailers in Figure 7.b. The rule for block reordering leads to a successful reconstruction, and hence the attack is classified as such.
- Attack (#2) is classified as packet-dropping, since attack classification can partially reconstruct the virtual trailer for the seventh row (where the `BlockNum` and `FlowID` fields are intact) and beyond, while the block size is smaller than expected (the `MAC` field is missing), which matches the classification rule for packet dropping in Table 2. This result can be further verified by requesting the missing information (Merkle tree node).
- Attacks (#3) and (#4) are similarly classified as packet block replay and drop, respectively.
- Attack (#5) is a flow drop attack, as the expected `FlowID` is four (end of Figure 7.a) is missing in Figure 7.c, which matches the classification rule for flow dropping.
- Attack (#6) is a VNF skipping attack since a packet block received at the destination VNF (the last row in Figure 7.b) has a missing FlowID (which does not appear in Figure 7.a), which matches the classification rule for VNF skipping.

5 Implementation

ChainPatrol is composed of two *agents* per pair of communicating VNFs, plus a central *orchestrator*. The agents perform watermark encoding/decoding, attack detection, and local attack classification. The orchestrator is in charge of managing the agents and performing global attack classification. *ChainPatrol* is implemented in C++ programming language, with approximately 1300 lines of code at the agent, and 200 lines at the orchestrator. The following details the implementation and challenges.

***ChainPatrol* agent.** Each agent includes four components: 1. The *controller* performs the following functionalities. First, it receives *ChainPatrol* parameters from the orchestrator at initialization, and it then continuously monitors the network performance (*e.g.*, IPD and network jitter) to compute the watermark amplitude and X-shift values. Second, at the source VNF, it intercepts the egress traffic, generates virtual trailers (the Merkle hash trees are stored inside shared storage in case the destination-side agent may need selected nodes, as discussed in Section 4.2), triggers the watermarker, and forwards the traffic. Third, at the destination VNF, it passively monitors the ingress traffic to measure the IPDs, triggers the watermarker, attack detector, and attack classifier, and finally reports the detection and classification results to the orchestrator. 2. The source-side *watermarker* encodes the virtual trailers generated by the controller using Algorithm 2, and the destination-side watermarker decodes the virtual trailers from the ingress traffic using Algorithm 3. 3. Once triggered by the controller, the *attack detector* applies Algorithm 4 to mark SuperBlocks as either recovered or attacked. 4. Finally, once triggered, the *attack classifier* applies Algorithm 5 to classify the detected attacks using classification rules that only involve local traffic.

***ChainPatrol* orchestrator.** The orchestrator includes three components: (1) The *agents manager* is responsible for instantiating the agents and communicating with them. (2) The *attack classifier* is responsible for global attack classification that cannot be performed locally at each agent (e.g., flow or SFC-level attacks). (3) The *Audit Table* is used to store the detection and classification results both from the agents and from the orchestrator. At the initialization of *ChainPatrol*, the orchestrator shares with the agents the following *ChainPatrol* parameters: 1. SuperBlock size and block size per flow type (as different numbers of packets can be exchanged per flow type, for example, HTTP vs. SSH). 2. Initial seed values per pair of agents (used with a pseudo-random generator for virtual trailer generation). 3. A cryptographic key per pair of agents (for computing the MAC).

Avoiding VNF instrumentation. To simplify deployment, *ChainPatrol* intercepts egress traffic from the source VNF for encoding and monitors ingress packets at the destination VNF for decoding, without requiring instrumentation of the VNFs. This is achieved using raw sockets to attach agents as proxies to VNF interfaces, allowing traffic monitoring and forwarding. Additionally, iptables are used at the source to ensure only watermarked traffic forwarded by ChainPatrol reaches the destination VNF.

Minimizing communications. *ChainPatrol* minimizes

communication overhead by: (1) The agents at source and destination VNFs independently generate virtual trailer fields using common seed values obtained at initiation, avoiding ongoing communication. (2) Agents and orchestrator communicate via shared storage, leveraging Amazon ElastiCache for Memcached [24]. (3) AWS Lambda [25] facilitates access to Memcached, enhancing efficiency.

Root privileges and control packet filtering. While working with raw sockets, we faced two challenges. First, the agent couldn't attach to VNFs due to lacking root privileges, causing silent failures. To solve this, we split the code into privileged and non-privileged chunks, applying setuid for the former. Second, the destination-side agent struggled to decode virtual trailers due to confusion from control packets mixed with data traffic. We address this issue by filtering out control packets through inspecting the `PSH (Push) flag` field in the TCP header of packets (control packets have this flag set to `zero`, while data packets set to `one` for the packets to be delivered without buffering).

Multithreading. *ChainPatrol*'s layered design separates faster watermark encoding/decoding from slower attack detection. Implementing agents with a single thread would cause unacceptable delays, as the controller must wait for tasks to finish before forwarding packets. Thus, we use multiple threads: one for capturing packets, generating virtual trailers, and encoding them; and two more for independent attack detection and classification. The controller component ensures necessary thread execution serialization.

6 Performance Evaluation

This section presents the evaluation of *ChainPatrol*.

6.1 Evaluation Environment

Testbed setup. We deploy *ChainPatrol* in Amazon EC2 using EC2 instances of the `t3a.small` type (*i.e.*, 2 vCPUs of 2.50 GHz AMD EPYC 757, 2 GB RAM, up to 5Gbps of network bandwidth). Each instance runs Amazon Linux 2 (based on Ubuntu 22.04). We leverage the *Memcached database cluster*[1] (a high-performance, distributed memory object caching system) running on a `t3.micro` instance (2 vCPUs of 3.10 GHz Intel Xeon Scalable processor, Skylake 8175M or Cascade Lake 8259CL, 1 GB RAM, up to 5Gbps of network bandwidth) as shared storage between the *ChainPatrol* orchestrator and agents. We additionally use *Lambda Functions*[2], written in Python 3, as the interface between *ChainPatrol* and the Memcached cluster. Our evaluation focuses on data plane TCP flows between VNFs inside a SFC, although *ChainPatrol* can work for other types of traffic.

[1] Amazon ElastiCache: https://aws.amazon.com/elasticache/memcached/

[2] AWS Lambda: https://aws.amazon.com/lambda/

Datasets. We evaluate *ChainPatrol* based on: (i) a public dataset [26], (ii) our Free5GC/Kubernetes-based 5G testbed deployed on Amazon EC2, and (iii) the packet sizes of real-world applications in [27, 28] (for comparing to a state-of-the-art solution [6]). First, since IPD has the most significant impact on performance, we use the realistic IPD values from a public cyber defense dataset [26] for our first dataset (Dataset1). Second, to obtain live data from a real cloud, we deploy our own 5G core testbed on Amazon EC2 to generate a large live-streaming dataset with up to 600-750 packets per second for our second dataset (Dataset2). As shown in Table 3, those two datasets demonstrate distinct ranges of IPDs (80 ms vs. 7 ms) and jitters, which are representative of traditional networks (based on physical infrastructures) and virtual networks (based on containers and virtual machines), respectively. Finally, we use the packet sizes of several real-world applications in [27, 28] to compare with AuditBox [6].

Table 3: Datasets description

Dataset	IPD range	Source	Application	Rate
Dataset1	70-90ms	Public	Cyber defense	600K/s
Dataset2	5-10ms	Amazon EC2	5G core	500K/s

6.2 Experimental Results

We first evaluate the impact of various *ChainPatrol* parameters on its effectiveness and overhead. Then, we measure the accuracy and efficiency of its attack detection and classification. Finally, we compare *ChainPatrol* with a state-of-the-art physical trailer-based solution, namely, AuditBox [6].

6.2.1 Parameters Evaluation

We study how watermarking parameters may affect its effectiveness, and how *ChainPatrol* parameters may impact the service delay and its overhead.

Watermarking effectiveness. Figure 8.A and Figure 8.B show the impact of the two watermarking parameters, i.e., the watermarking amplitude (Section 3.2) and the X-shift value (Section 3.4), on the watermark extraction rate (the standard metric for watermarking effectiveness [29]). First, Figure 8.A shows that a watermark amplitude value of 1.2 (for Dataset1) and 1.6 (for Dataset2) can already achieve 100% extraction rate. The results also show that Dataset2 generally requires a slightly larger amplitude value than Dataset1 (this can be explained by the relatively higher percentage of jitter in Dataset2, as shown in Table 3). Second, Figure 8.B shows that a larger X-shift value is required for Dataset1 to achieve 100% extraction rate (which implies this parameter is more closely related to the average IPD). Specifically, Datatset1, whose average IPD is 80 ms, requires $X \approx 3$; Dataset2, whose average IPD is 8 ms, requires $X \approx 0.5$. The results also show that, without our X-shift solution (i.e., $X = 0$), the extraction rate would be significantly

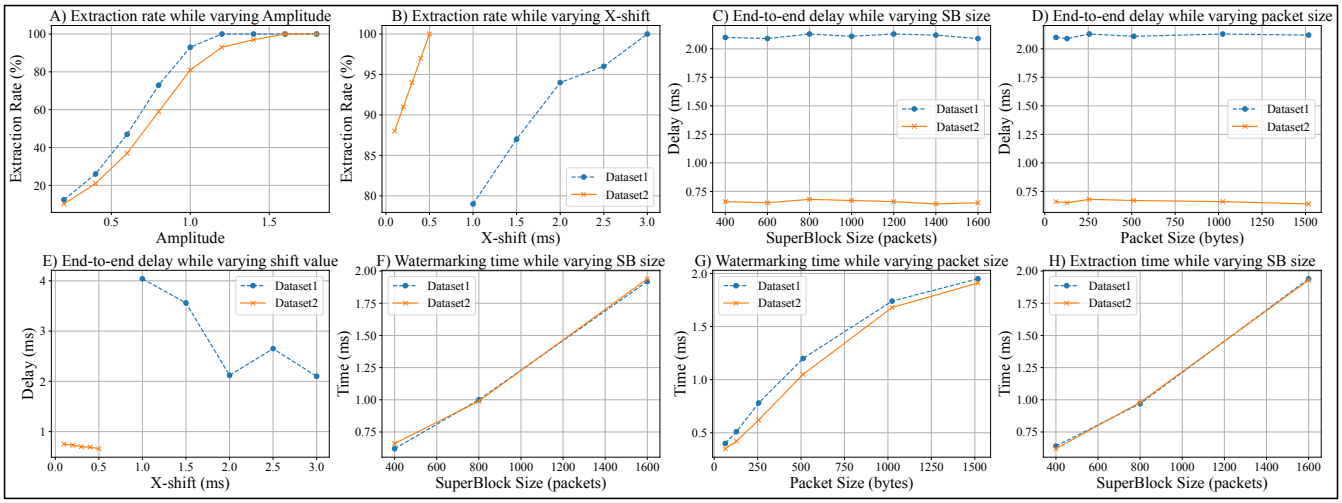

Figure 8: Parameters evaluation results

lower (less than 80% for Dataset1 and 90% for Dataset2). Note in both experiments, we fix the other parameter (at a value achieving 100% extraction rate).

Service delay. In this set of experiments, we study how the end-to-end service delay may be affected by different *ChainPatrol* parameters. Figure 8.C and Figure 8.D show the end-to-end service delay for different SuperBlock sizes (a parameter of *ChainPatrol*) and packet sizes (a characteristic of the traffic), respectively. Both results show that *ChainPatrol* introduces negligible end-to-end service delay on both datasets (around 2.1 ms for Dataset1 and 0.68 ms for Dataset2), and varying the SuperBlock and packet size has almost no impact on the end-to-end delay. This is mainly due to the facts that *ChainPatrol* agents mainly examine the headers (hence packet sizes have little impact), and the virtual trailers are always encoded in the next SuperBlock (see Section 3.2) so the time for generating virtual trailers (which depends on the SuperBlock size) does not affect packet processing (as the trailers are already ready when the packets arrive). Figure 8.E shows how the X-shift value affects the end-to-end delay. As we can see, a larger X value generally leads to a lower delay before it reaches the value that produces 100% extraction rate.

Overhead. In this set of experiments, we evaluate the overhead of *ChainPatrol* with respect to time. First, Figure 8.F and G show the average watermarking time (i.e., the time taken for a source-side agent to generate and encode virtual trailers) for different SuperBlock and packet sizes. The results show that the watermarking time increases almost linearly in SuperBlock size (as more packets need to be processed) and increases more slowly in packet size (as only the MAC field is affected), while the maximum watermarking time is less than $2ms$ for both datasets. Second, Figure 8.H shows the extraction time (i.e., the time taken for a destination-side agent to decode and verify virtual trailers) for different SuperBlock sizes. The results are very similar to Figure 8.F since the two agents perform similar but reversed operations (the results on extraction time vs. packet size are also very similar to Figure 8.G and omitted).

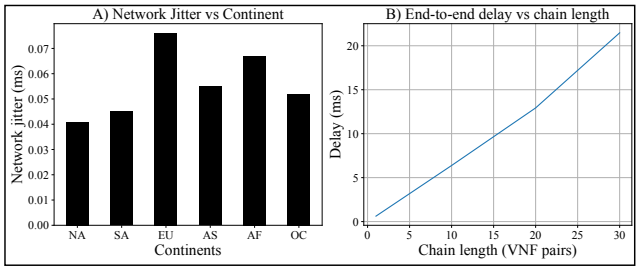

Figure 9: Parameters evaluation results (continued)

Jitter vs. AWS regions. In order to understand the potential impact of VNF locations on *ChainPatrol*, we measure the network jitter between our location (North America) and one region in each continent. We repeat the experiment over a period of several weeks and observe a relatively stable jitter over time. As shown in Figure 9.A, the jitter value within the same continent (North America) is the lowest. The highest value of jitter is observed between North America and Europe, which is roughly double the value of jitter within the same continent (in contrast, our experiments reported in Section 6.2.4 will use up to six times larger jitters). Finally, we also experiment with the Elastic Network Adapter (ENA) feature of AWS (which provides Enhanced Networking for EC2 instances), and our results show that jitters within the same continent drop from 0.175ms without ENA to 0.041ms with ENA. For the remaining experiments, we have used EC2 instances with ENA enabled.

End-to-End delay vs chain length. In this experiment, we evaluate the end-to-end delay introduced by *ChainPatrol* by varying the number of VNFs in the chain up to 30 VNF pairs (according to the literature [30], 25 VNF pairs represent a reasonably large NFV setup). As shown in Figure 9.B, the processing delay of *ChainPatrol* agents is roughly con-

stant for each pair (i.e., 0.63ms), and accumulative along the chain (which also holds for physical trailers). The maximum cumulative delay observed for a chain with 30 pairs of VNFs is about 22ms (which is barely noticeable for interactive music and not noticeable for games [31]). In practice, the length of a VNF chain is usually much smaller, and hence the end-to-end delay of *ChainPatrol* should be negligible.

Summary. It is relatively easy (i.e., with small amplitude and X values) for *ChainPatrol* to ensure the correctness of its decoding of virtual trailers due to the more stable nature of traffic between VNFs (as explained in Section 5, *ChainPatrol* also continuously adjusts those parameters based observed traffic). Moreover, our results show that *ChainPatrol* causes negligible end-to-end delay to services on both datasets, e.g., the entire flow will be delayed by only about 2.1 ms and 0.68 ms (2.6% and 9.8% of the normal delay between two packets), respectively. Finally, the overhead of *ChainPatrol* in terms of delay is negligible.

6.2.2 Attacks detection and classification

We evaluate the accuracy and efficiency of attack detection and classification.

Accuracy evaluation. First, Figure 10.A shows that *ChainPatrol* achieves 100% detection accuracy with up to 50 attacks of different types (as listed in Table 2) performed on both datasets. This is expected as the experiment is performed with the *ChainPatrol* parameters that can ensure 100% watermark extraction rate (detailed in Section 6.2.1), and the extracted virtual trailers possess similar cryptographic properties as physical trailers to guarantee accurate detection (detailed in Section 4.1). Second, Figure 10.B shows the attack classification accuracy. To evaluate the true capability of virtual trailers for attack classification, this experiment deliberately skips the source-assisted verification step (described in Section 4.2), such that all inaccurate classification results will be counted. The results show that the attack classification accuracy stays almost fixed at around 70% under different amounts of attacks for both datasets. In contrast to detection, classification shows a lower accuracy. This is expected due to missing information caused by attacks and potential collision between attack types (e.g., a packet reordering attack may impact virtual trailers same as a combination of packet dropping and injection attacks).

Efficiency evaluation. First, we evaluate the attack detection time while varying the block size and the number of compromised blocks, respectively. In Figure 10.C, the total number of compromised blocks is fixed at 30, and we measure the time required to detect those compromised blocks. As the results show, the detection time increases almost linearly in the block size, with less than 2.4 seconds required for all block sizes for both datasets (no significant difference between the datasets). Note the detection time has no impact on the service delay (due to our multithreading implementation, as detailed in Section 5), and the second-level detection time is reasonable since the detection results are meant to be inspected by human experts. Second, we evaluate the time required to detect different amounts of block-level attacks while fixing the total number of SuperBlocks at 50. In Figure 10.D, the detection time increases almost linearly in the number of attacks, with up to 5.5 seconds required for detecting all 50 attacks.

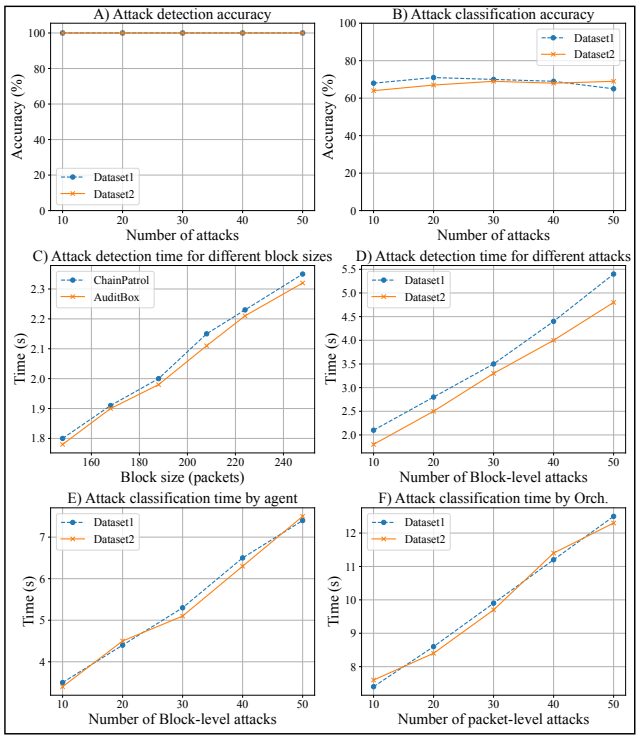

Figure 10: Attacks detection and classification results

Next, we evaluate the attack classification time by both the agents and the orchestrator, for block-level attacks and packet-level attacks, respectively, while varying the number of attacks. First, in Figure 10.E, the total number of SuperBlocks is fixed at 50, and we measure the time required to classify different amounts of block-level attacks locally by the destination-side agent. As the results show, the local classification time increases almost linearly in the number of block-level attacks, with around 7.5 seconds required for classifying all the 50 block-level attacks, which is slightly higher than the time for detection (i.e., 5.5 seconds). Second, Figure 10.F shows the global classification time taken by the orchestrator for classifying different amounts of packet-level attacks. The results show a similar linear trend, with around 12.5 seconds required for classifying all the 50 attacks. The orchestrator is taking more time since the global classification it performs involves more input information, and the packet-level attack classification rules may require the orchestrator to slide forward more slowly (by two packets, instead of a block, as detailed in Section 4.2).

Summary. Virtual trailers can guarantee 100% detection accuracy like their physical counterparts do. Virtual trailers provide a lower (70%) but still acceptable classification accuracy, since the result will be further verified in the source-assisted verification step described in Section 4.2. Our results also show attack detection and classification to be efficient (both take a few seconds for 50 attacks), scalable (both show a linear trend), and lightweight (both consume negligible resources).

6.2.3 Comparison with existing work

We compare *ChainPatrol* to a state-of-the-art physical trailer-based solution, namely, AuditBox [6] (which is re-implemented to ensure the two solutions can be compared under the same environments and settings). We compare them using Dataset2 (which is more representative of SFC applications) with packet sizes varied based on different real-world applications in two public datasets [27, 28]. Table 4 shows a general comparison in terms of end-to-end delay and communication overhead. Overall, AuditBox [6] has less delay and higher communication overhead than *ChainPatrol* on both datasets. Between the two datasets, the end-to-end delay of *ChainPatrol* stays the same while AuditBox incurs slightly more end-to-end delay for [27]. The communication overhead of *ChainPatrol* stays almost zero for both datasets while AuditBox incurs slightly more communication overhead for [28]. The different results of AuditBox between the two datasets can be explained by the different packet sizes (572 bytes on average for [27] and 85 bytes for [28]) due to different applications (e.g., audio/video in [27] v.s. Chat and VOIP in [28]).

More specifically, Figure 11.A shows the top four applications for which *ChainPatrol* achieves the most reduction in communication overhead (between 45% for DNS and 22% for Chat) compared to AuditBox. To further study the impact of packet sizes on overhead, we compare the overhead added by *ChainPatrol* and AuditBox while varying the packet size (with fixed flow size). Figure 11.B shows that *ChainPatrol* has almost zero overhead across all packet sizes (as *ChainPatrol* only adds a negligible amount of bits at the end of each flow, as discussed in Section 3.2), while the overhead of AuditBox's physical trailers ranges from around 10% (for large packet sizes up to 512 bytes) to 200% (for small packet size of 20 bytes). Next, Figure 11.C shows an average end-to-end delay between 0.35 and 0.55 ms for AuditBox, and 0.65 to 0.68 ms for *ChainPatrol*. The relatively higher delay of ChainPatrol is expected due to its more complex design of virtual trailers (e.g., a virtual trailer is computed over a group of packets, whereas a physical trailer is over a single packet). Nonetheless, the delay has a negligible impact on application performance (see Section 6.2.1).

Next, we compare *ChainPatrol* to an extension of Auditbox, namely, *density reduction trailer*, in which each physical trailer is computed over, and added to a group of packets

Table 4: General comparison in terms of delay and overhead

	Delay		Overhead	
	Dataset [27]	Dataset [28]	Dataset [27]	Dataset [28]
ChainPatrol	0.67 ms	0.67 ms	1.0 X	1.0 X
AuditBox [6]	0.48 ms	0.38 ms	1.12 X	1.38 X

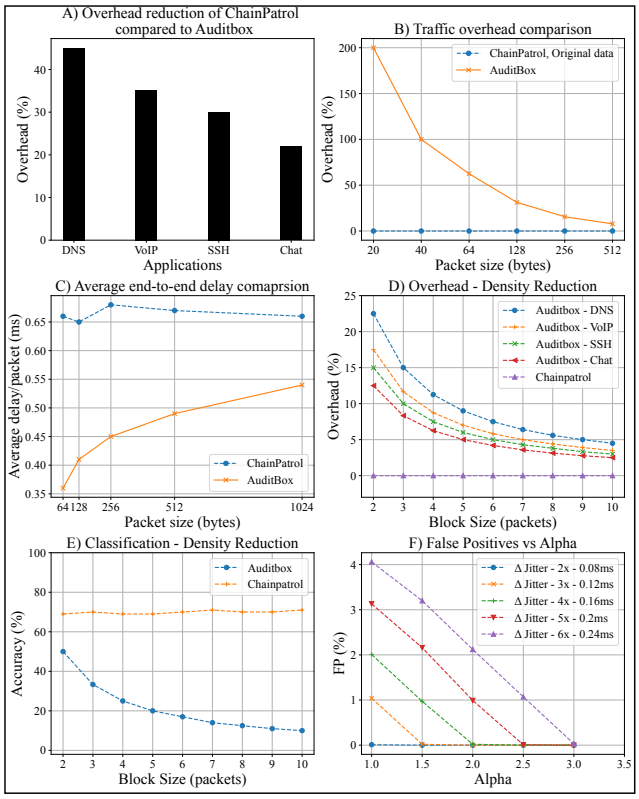

Figure 11: Detailed comparative evaluation results

(i.e., block) to reduce the overhead. As Figure 11.D shows, *ChainPatrol* overhead stays around zero regardless of the block size, while Auditbox constantly shows higher overhead even though density reduction trailers can reduce it. Specifically, as the block size increases from 2 to 10 (packets), the Auditbox overhead decreases from around 23% to 4.5% (45% without density reduction). On the other hand, as Figure 11.E shows, while *ChainPatrol* can maintain a stable classification accuracy when block size increases, the accuracy of Auditbox drops quickly. This can be explained by the fact that a MAC value stored physically can only indicate a "match"or "no match" (to the packet and trailer content), which helps attack detection but not classification. In contrast, a MAC value virtually stored (encoded) inside (the IPDs of) multiple packets can additionally provide useful information to help attack classification. For instance, if a packet is dropped, the mismatched MAC in a (density reduction) physical trailer cannot provide any information about which packet inside the block is dropped. In contrast, since this dropped packet is also used to encode part of the MAC value for the previous SuperBlock (detailed in Section 3.2),

comparing the expected MAC value (recomputed from the previous SuperBlock) to the current SuperBlock can easily pinpoint which packet is missing (similar for other attacks).

Summary. The comparison between AuditBox [6] and *ChainPatrol* shows that *ChainPatrol* introduces almost no extra communication overhead regardless of the packet or flow sizes, whereas the overhead of physical trailers can be significant, especially for applications with large flows and smaller packets. *ChainPatrol* is shown to provide a significant reduction in communication overhead (up to 45% of the original traffic) for common applications. Although the more complex virtual trailer design of *ChainPatrol* inevitably incurs slightly more end-to-end delay, such delay is still negligible for most applications (e.g., 20-30 ms is shown to be noticeable for interactive music, and 100 ms for games [31]). Finally, density reduction (physical) trailers can reduce the overhead, but it also causes the classification accuracy to deteriorate. Therefore, we conclude that virtual trailers enable *ChainPatrol* to provide a lightweight solution with both negligible communication overhead and negligible service delay, whereas physical trailers are better for applications with small flows with large packet sizes.

6.2.4 Handling unexpected jitters

In this experiment, we evaluate the two methods proposed in Section 3.4 for handling unexpected network jitters. As shown in Table 5, we evaluate our methods using artificial jitters up to six times the real-life jitter (i.e., the EC2 jitter in DS2[3]). The second and third columns show that both the X-shift method (for source VNF) and the α-amplitude method (for destination VNF) cause low false positive rates (up to 3% and 2%, respectively). The X-shift method shows a marginally higher rate, since it needs to update the X value upon every observation of unexpected jitters, and a delay in such updating may cause false positives. As to the α-amplitude method, it is "proactive" in the sense that using a larger-than-necessary amplitude may prevent false positives for multiple subsequent changes in jitters. The fourth and fifth columns of Table 5 show the end-to-end delay under only the X-shift method, and under both the X-shift and α-amplitude methods, respectively. We can see that both methods cause negligible increase in end-to-end delays, since they only introduce extra delays to one packet inside each pair, which affects the IPDs but does not significantly impact the end-to-end delay. Finally, Figure 11.F shows how the false positive rates is affected by the value of α under different jitters. Based on those results, *ChainPatrol* chooses the minimum α that can reduce the false positive rate to nearly zero (e.g., $\alpha = 1.5$ for $3x$ jitters).

[3] Note this experiment is performed several months later than those in Section 6.2.1, which explains the difference in delay (0.63 ms vs. 0.68 ms).

Table 5: The X-shift and α-amplitude methods

Δ jitter	X-shift FP(%)	α-amplitude FP(%)	X-shift delay(ms)	α-amplitude delay(ms)
0.04	2	1	0.63	0.65
0.08	3	1	0.64	0.66
0.12	3	2	0.64	0.66
0.16	2	1	0.65	0.67
0.20	3	2	0.65	0.67
0.24	2	2	0.66	0.68

7 Discussions

Security of *ChainPatrol*. The security of *ChainPatrol*, i.e., its capability of detecting and classifying attacks, depends on both the security guarantee provided by virtual trailers, and their successful decoding from IPD-based watermarks.

First, as virtual trailers are designed with similar fields as in their physical counterparts [6, 7] (detailed in Section 3.1), they can also provide similar cryptographic guarantees. First, as `FlowID` is uniquely and sequentially assigned to each flow, any injection, reordering, dropping, and replay of flows or VNFs can be easily detected using this trailer field. Second, `BlockNum` works similarly against those attacks at block level. Third, as it is computationally infeasible to forge a `MAC` (which is computed over both blocks and the previous two trailer fields) without knowing the secret key, packet-level attacks and tampering with virtual trailers themselves can both be detected using this trailer field. Finally, the continuous detection on all packets defeats the coward attack [9] (i.e., attacking only unprotected flows).

Second, virtual trailers encoded in IPD-based watermarks are much like physical trailers stored inside packets, which are both visible to adversaries (as confidentiality is not the goal), and can be easily modified or removed by them. Therefore, the issue of watermark invisibility (i.e., using smaller delays [17] or delays similar to normal network jitters [16] to hide watermarks against attacks that aim to locate the watermarks [18, 32]) is not applicable in our case, as we do not intend to hide the watermarks. Although adversaries can freely modify or remove watermarks in any way they like (by tampering with IPDs), the corresponding changes to virtual trailers can always be detected.

Specifically, adversaries can prevent the decoding of virtual trailers by changing all IPDs to equal values, randomly perturbing them, or replacing them with fake values. Although all those attacks will be detected by *ChainPatrol* (as failed decoding of virtual trailers indicates an attack), attack classification may become difficult or infeasible due to lack of virtual trailers. However, this essentially amounts to a denial of service attack (the same may happen to physical trailers, e.g., an adversary can simply delete them), which is out of the scope of this paper (a large amount of missing or destroyed trailers will likely trigger an investigation by the administrator). Finally, a smart adversary may disturb the IPDs in a way that mimics normal, but larger jitters to make the decoding harder. This will be handled by *ChainPatrol*,

as its agents continuously monitor the traffic and compensate observed jitters through both the encoding/decoding scheme (Section 3.2) and our X-shift approach (Section 3.4) (an unexplained increase in jitters will eventually raise suspicion from the administrator).

False negatives and positives. As mentioned above, virtual trailers share similar cryptographic guarantees with their physical counterparts, including no false negative and impossible-to-bypass [6, 7]. Note that, although virtual trailers and physical trailers can both be removed or modified by attackers, doing so will not cause false negatives as long as attackers cannot forge the MAC. On the other hand, a network disturbance such as out-of-order packets and packet loss can cause false positives under both virtual and physical trailers. What is unique to *ChainPatrol* is that jitters may also cause false positives (no effect on physical trailers), which has been addressed in our methodology (Section 3.4) and evaluation (Section 6.2.4), Also, as *ChainPatrol* agents are attached to two VNFs that directly communicate with each other, they are only affected by out-of-order or lost packets happening between them (which would be rare).

Limitations and future directions. The main limitations of *ChainPatrol* are as follows. First, *ChainPatrol* will report out-of-order packets or packet losses between two VNFs even if these are not caused by attacks. An interesting future work is to identify such cases (e.g, by learning different patterns of virtual trailers). Second, the limited capacity of side channel dictates less virtual trailers per packet, which causes slower attack detection (1.8s-2.4s detection time) and less accurate classification (around 70% accuracy). Whether such delays and accuracy are acceptable depends on use cases, e.g., reasonable for a regular IDS reporting attacks to humans (who can tolerate seconds-level delays and inaccuracies), but not ideal for real-time prevention (where physical trailer is better by working on each packet independently). A future direction is to improve those aspects through more compact design of virtual trailers. Finally, as a tenant-level solution, *ChainPatrol* cannot ensure the integrity of VNFs and cloud infrastructure like hardware-based solutions (e.g., [6, 12]).

8 Related work

SFC integrity. Traditional forwarding path verification protocols [8, 9, 33] cannot be directly applied to SFCs hosted in an NFV environment, since some of their underlying assumptions become unrealistic in the NFV context, e.g., forwarding paths are no longer fixed or known in advance in NFC, and network nodes (VNFs) are no longer transparent to packets as they might legitimately modify packets. More recent works tackle such issues to enable forwarding path verification in NFV. In [34], the authors study the issue of stateful and dynamic actions performed by VNFs, and propose a solution for VNFs to add tags to outgoing packets in order to bind packets with their origin. However, this scheme becomes ineffective when one or more switches are compromised. Therefore, FlowCloak [19] proposes an advanced packet tagging approach to randomize the tag generation such that the tags are probabilistically unknown by compromised switches. In contrast to *ChainPatrol*, FlowCloak requires modification to the internal logic of VNFs which may complicate its deployment. In [35], the authors propose a verification layer that is decoupled from the processing of VNFs, and is embedded in VMs supporting those VNFs. Nonetheless, vSFC requires modification at the cloud level, whereas *ChainPatrol* is a tenant-level solution that regards the cloud as a blackbox.

SFC-Checker [36] proposes a static analysis-based framework to ensure the correct behavior of dynamic and stateful forwarding paths. EasyOrch [37] performs verification based on a formal model that provides the flexibility of specifying both a forwarding policy and the set of anomalies to verify. In contrast to *ChainPatrol*, those solutions are static in nature and cannot detect run-time integrity breaches, as they either take snapshot of the network state to perform verification offline [36] or work before SFC deployment [37]. In [12], the authors propose a hardware-based solution to enclose both VNF processing and verification inside enclaves to preserve data confidentiality and VNF integrity against powerful adversaries, which are different from the focus of *ChainPatrol* (i.e., network links between VNFs). Closest to our work, AuditBox [6] provides runtime guarantees on the compliance with forwarding path policies using a hop-by-hop cryptographic trailer-based protocol, and by running each VNF inside enclaves. While *ChainPatrol* borrows similar design of trailers as AuditBox, our virtual trailer concept can significantly reduce its communication overhead (as demonstrated through experiments in Section 6).

Digital watermarking. There is a rich literature on digital watermarking in different contexts (e.g., image, audio, video, and network packets) and for different applications (e.g., copyright protection, traffic analysis, and tampering identification). The literature may be categorized along different dimensions. For instance, *blind* (e.g., [38]) or *non-blind* (e.g., [16, 17]) watermarking indicate whether the embedding and extraction of the watermarks require sharing knowledge about the original data. *ChainPatrol* leverages a blind watermarking scheme to avoid the overhead of sharing additional information about the original data. Second, for applications such as copyright protection and traffic analysis, the watermarks will be subject to either natural network noises on the Internet, or malicious tempering. Therefore, the watermarks should be *robust* [39] and/or *invisible* [16, 17] (i.e., hide watermarks against adversaries who aim to locate the watermarks [18, 32]). On the other hand, a *fragile* watermarking scheme (e.g., [40]) is mainly used for tampering identification as well as localisation of tampered data, and hence the watermarks should be sensitive to modifications and are not necessarily invisible. *ChainPa-*

trol belongs to the fragile (and non-invisible) category, since its watermarks are used to detect and classify tampering. The key innovation of *ChainPatrol* is it introduces an additional abstraction layer, i.e., virtual trailers, over watermarks, in order to leverage the latter's cryptographic properties.

Timing-based side channels are shown to have a larger capacity to share more information compared to other side channels [29]. In particular, packet timing-based flow watermarking modulates the IPDs of target network flow to embed watermarks and achieve the goal of linking flows for different applications, such as detection of stepping stone attacks, and compromising anonymity systems. For instance, the authors in [38] propose an IPD-based probabilistically robust watermarking scheme, which embeds watermark bits through slightly adjusting the independently and randomly selected IPDs. In [41], the authors propose an enhanced scheme where the watermarker can adaptively choose values of watermark parameters according to packet timing and packet size features of target flows. In [42], the authors propose a scheme that resists timing perturbations through grouping-based flow watermarking. In [43], the authors propose a flow watermarking technology based on packet matching and IPDs. In [44], the authors propose a blind flow watermarking system, which modulates fingerprints into the timing patterns of network flows through slightly delaying packets into secret time intervals only known to the fingerprinting parties. More recent works explore the intersection between machine learning and watermarking schemes. For instance, Fang et al. [45] apply deep learning techniques to obtain more robust flow-based watermarking schemes to ensure high consistency between the encoder and the decoder, and Xu et al. [46] design a watermarking scheme for graph data in order to verify the ownership of Graph Neural Networks (GNN) models.

9 Conclusion
