Abstract

A severe vulnerability in the DNS resolver's cache is exposed here, introducing a new type of attack, termed DNS CacheFlush. This attack poses a significant threat as it can easily disrupt a resolver's ability to provide service to its clients.

DNS resolver software incorporates various mechanisms to safeguard its cache. However, we have identified a tricky path to bypass these safeguards, allowing a high-rate flood of malicious but seemingly existent domain name resolutions to thrash the benign DNS cache. The resulting attack has a high amplification factor, where with a low rate attack it produces a continuous high rate resource records insertions into the resolver cache. This prevents benign request resolutions from surviving in the DNS LRU cache long enough for subsequent requests to be resolved directly from the cache. Thus leading to repeated cache misses for most benign domains, resulting in a substantial delay in the DNS service. The attack rate amplification factor is high enough to even flush out popular benign domains that are requested at a high frequency ($\sim 100/1sec$). Moreover, the attack packets introduce additional processing overhead and all together the attack easily denies service from the resolver's legitimate clients.

In our experiments we observed 95.7% cache miss rate for a domain queried once per second under 8,000 qps attack on a resolver with 100MB cache. Even on a resolver with 2GB cache size we observed a drop of 88.3% in the resolver benign traffic throughput.

A result of this study is a recommendation to deny and drop any authoritative replies that contain many server names, e.g., a long referral response, or a long CNAME chain, before the resolver starts any processing of such a response.

1 Introduction

Several DDoS attacks on the DNS system have been discovered by attackers and researchers in the past decade [10, 11, 14, 42]. These attacks have targeted the communication or/and computation load of either resolver or authoritative DNS servers, by generating high packets or CPU load amplification factors, or simply using a large botnet. None of these attacks have succeeded in effectively thrashing the DNS resolvers' benign cache (as oppose to the negative cache, NCache), making the resolver ineffective.

In this paper we present a low rate, e.g., $\sim 8Kqps$ (queries per sec.), carefully crafted attack requests that generate a high rate (cors. $\sim 12M$ per sec.) of record insertions into the benign cache of the resolver, that is, a high amplification factor attack on the benign cache, which we call *cache amplification factor (CAF)*. Such a continuous high rate stream of records insertion into the benign cache ($12Mrecords\ ps$) evicts from a cache of size $10MB$ any domain name that is not queried at least 800 times per second, thus effectively leaving the resolver without a cache. This requires the resolver to re-query the authoritative servers on each client query, except perhaps the absolutely most popular one, thus deteriorating the resolver operation until it denies service to its clients.

Mounting such an attack on the benign cache of a resolver is not trivial. Simply using a huge botnet to request hundreds of thousands of different domain names at a rate of millions or even thousands per second is expensive and hard. It would choke the communication lines before reaching the resolver itself, in addition to being easily detected and blocked by behavioral analysis systems, such as IPS's and/or firewalls. Furthermore, using randomly generated fake domain names, as in the water torture attack [42], would go into the NCache (Negative Cache, or NX - NonExistent) limited size portion of the cache, thus leaving the benign cache unaffected.

Here we discovered a vulnerability by which an attacker can cause the insertion of a large number of records into the benign cache with just one query to the resolver, that is over a million records per second by an attack of 1K malicious

queries per second to the resolver. More precisely, in a maximum size TCP message ($\sim 65KB$) response by a malicious NS, about 2000 NS names that can fit (the exact number depends on the number of characters in each NS name) which results in the insertion of 2000 resource records into the cache. As each benign query to a resolver adds at least one resource record into the resolver's cache, the cache amplification factor is 2000. In bytes each malicious request may result in the insertion of at least $100KB$ into the cache since a minimum resource record of a NS name in the cache is about $50B$. The query our attacker employs generates a response from an authoritative server hosting an attacker zone file, that instructs the resolver to delegate and recursively resolve a large number (up to 2000) name server (NS) names. Such a technique was used by [10, 11] to create a large communication and computation amplification factor attacks. As a result of these attacks the vendors have issued a number of CVE's limiting the number of recursive resolutions (to 5 and 20) each client query may result in [36, 37]. However, these mitigations do not limit the number of NS names stored in the cache while resolving the limited number of NS names. Thus leaving the door open to the current DNS CacheFlush attack.

In this paper we point out two types of such large responses by authoritative servers that require recursive resolution of many additional names; the CNAME and the referral types.

In addition to the high cache miss rate, these large referral responses from the authoritative server come with another complexity price tag due to the extra processing each such referral response (and as we show in this paper also long CNAME chains) requires. These processing include, opening a TCP session (the response does not fit in a UDP packet), checking the consistency and whether an IP address is already available for each name in the response, inserting the list into a memory buffer (in addition to inserting them into the benign cache), and issuing the corresponding extra (20 rather than 1800) resolution requests to resolve the IP address of each of the first 20 names in the list. This overhead together with the extra cache misses easily takes the resolver down and denies service to legitimate clients.

In this paper we conclude and suggest that the DNS system should be changed to eliminate large referral responses (> 13 NS names) and long (> 8 NS names) long CNAME chains. Resolvers should discard such responses before performing any processing on them, and authoritative servers should prohibit zone files that generate such responses. A few more modest mitigation suggestions are provided here, such as, trimming the long responses upon their reception.

In this paper we built a test bed and measured the effect of DNS CacheFlush on the latest versions of BIND9 [24] and UNBOUND [26] with default cache sizes ranging from 10MB to 100MB, as well as with a 2GB cache size that simulates our university environment, using two methods: CNAME chains containing 17 domains and a referral response with 1,500 NS names. To determine whether a benign domain is likely to experience a high rate of cache misses, we developed a model that predicts whether the cache entry of a domain is going to be flushed between two queries of the same benign domain, and the likelihood of a high cache miss rate as a function of the attacker and benign rates, and the cache size. It is also possible to apply the model to the distribution of benign domains, which means that, given a resolver's benign domain distribution and cache size, we can determine for each attack rate the benign domain rate starting from which all benign domains with a lower rate are highly likely to have a cache miss. Furthermore, we carried experiments to estimate the effect of some mitigation suggestions, to separate the contribution of the cache amplification factor from that of the long response processing cost, to the attack strength.

A review of the benign and negative cache importance, as well as cache management techniques is presented in Section 2 followed by a discussion of the threat model in Section 3. The CacheFlush Attack versions and the attack model are discussed in Section 4. The experimental set-up and comparison between our model prediction and the experimental results are presented in 5. Alternative mechanisms to mitigate the CacheFlush attack are suggested in Section 6. Additional vulnerabilities we found during our research are shortly mentioned in Section 7 and related work is shared in Section 8. We review the responsible disclosure procedure in Section 9, and draw conclusions in Section 10.

2 Preliminaries

2.1 DNS Resolution Process

DNS Resolver Server (sometimes called recursive resolver server, or just recursive server). To obtain the IP address of hello.world.com a client (e.g., a browser) queries a DNS resolver with the name hello.world.com. If the answer is not in the resolver cache, the resolver then issues several queries to the authoritative hierarchy to obtain the desired IP address, which it then stores in its cache and returns to the querying client.

Authoritative Name Servers. An authoritative name server maintains and provides official up-to-date DNS records (containing the IP addresses) for domain names.

Resource Records. Data from DNS is organized and stored in resource records (RRs). Each RR consists of an owner name, which is the fully qualified domain name of the tree node where the RR is located, a type, a time-to-live field (TTL), and a value. Value fields are structured differently according to the type of record. It is noteworthy that multiple records with the same owner name and type can coexist, provided they contain distinct data, together forming an RRset. The various record types, including TXT, SOA, NS, A, CNAME, serving different purposes.

2.2 Delegation Response

In response to a resolver query an authoritative server may delegate (refer) the resolver to obtain the answer from a different authoritative server (the delegation can also be to a different name in the same authoritative server). For example, ".com" can delegate the resolution of hello.world.com to world.com.

In a referral response with a list of NS names, the resolver is delegated to obtain its answer from any one of the name servers in the list. The number of NS names may be large, and their IP addresses (known as glue record) may not always be included. The referral-list response does not include glue records because authoritative servers cannot provide IP addresses for domains whose origins reside outside their zone. This policy protects the servers from DNS poisoning attacks by identifying them as Out-of-Bailiwick name servers [23]. For example, in Figure 1, attack.com delegates the resolution of e1.attack.com to the name servers (NS) cacheflush1.delegation.attack in a referral response. Hence, the resolver would send a new query to resolve the NS name cacheflush1.delegation.attack.

2.3 CNAME Record

A Canonical Name (CNAME) record in the Domain Name System (DNS) is a pivotal element that enables aliasing or redirection of one domain to another. Essentially, a CNAME record serves as a pointer, allowing a domain to function as an alias or nickname for another domain's canonical or primary name. This redirection is not limited to a single level; it can create a CNAME chain, where one CNAME points to another, forming a sequential chain of aliases. When a DNS query encounters a CNAME record, it redirects to the domain specified in the record, inheriting its associated DNS information. This functionality is commonly employed for various purposes, such as creating subdomains, facilitating domain migration, CDNs, providing alternate names for existing domains etc. For example, in Figure 2 the CNAME record e1.attack.com points to e2.attack.com

2.4 DNS Resolver Cache: Benign vs. Negative Cache

DNS resolver cache plays a critical role in making the Domain Name System (DNS) resolution process more efficient. The cache serves as a temporary storage repository within the resolver, storing previously resolved DNS queries. It retains a variety of DNS resource records (RRs) types, including domain names and their IP addresses, NS records, and CNAME records, which alias one domain to another. The resource records may be classified into two classes: benign cache records, which store successful resolutions, and negative cache [21] , which store information about non-existent domains or names for which a NXDOMAIN or NODATA is received in the resolution attempt.

Resolvers provide a special limited size section of the cache for the negative replies, called Ncache. It is crucial in preventing unnecessary repetition of failed queries, which could be an attack such as Water torture [42]. While negative caching was previously optional, it is now part of the DNS specification [21]. A large proportion of DNS traffic on the Internet is eliminated by the negative cache [21]. Chen et al. [16] analyze real-life DNS traces and show that the Non-Existent Domain (NXDomain) traffic constitutes almost 40% of the traffic from the authoritative structure to the recursive resolvers.

There is a dynamic distribution of memory allocation between the positive and negative caches in the resolvers we examined, with the positive cache having a priority advantage [27]. When the cache reaches its size limit and a positive record arrives, a record from the negative cache will be evicted from the cache, in the event that the cache is full and a non-existent record arrives, a record will be evicted from the negative cache, or from the positive cache if its TTL value is zero.

2.5 BIND Queue Management

BIND resolvers systematically push DNS queries into their management queue based on their arrival. By default, the queue size is determined based on the resources allocated to the resolver, but this configuration can also be customized as necessary on specific requirements. The queue is governed by a recursive client deletion mechanism, which imposes both a soft limit and a hard limit on its size. Upon reaching the soft limit, the resolver selectively drops pending requests, allowing it to manage and prioritize ongoing queries. However, when the hard limit is reached, the resolver takes a more stringent approach by dropping all requests [13].

3 Threat Model

To mount a DNS CacheFlush attack an attacker has to:

1. Control one or more clients from which it issues the malicious queries.

2. Control an authoritative name server configured to respond with a CNAME chain or with referral responses with the crafted list of NS names.

It is easy and affordable to acquire authoritative name servers by first buying and registering new domain names. In our experiment, we bought 2 domain names for just under 1 USD each in less than five minutes and dynamically connected them to our authoritative server in our cloud setup.

The attacker associates 1500 NS names with each malicious domain name in the authoritative zone file, leading to a large zone file. Each record of NS name looks for example like this: "e1 8600 IN NS cacheflush1.delegation.attack", that is,

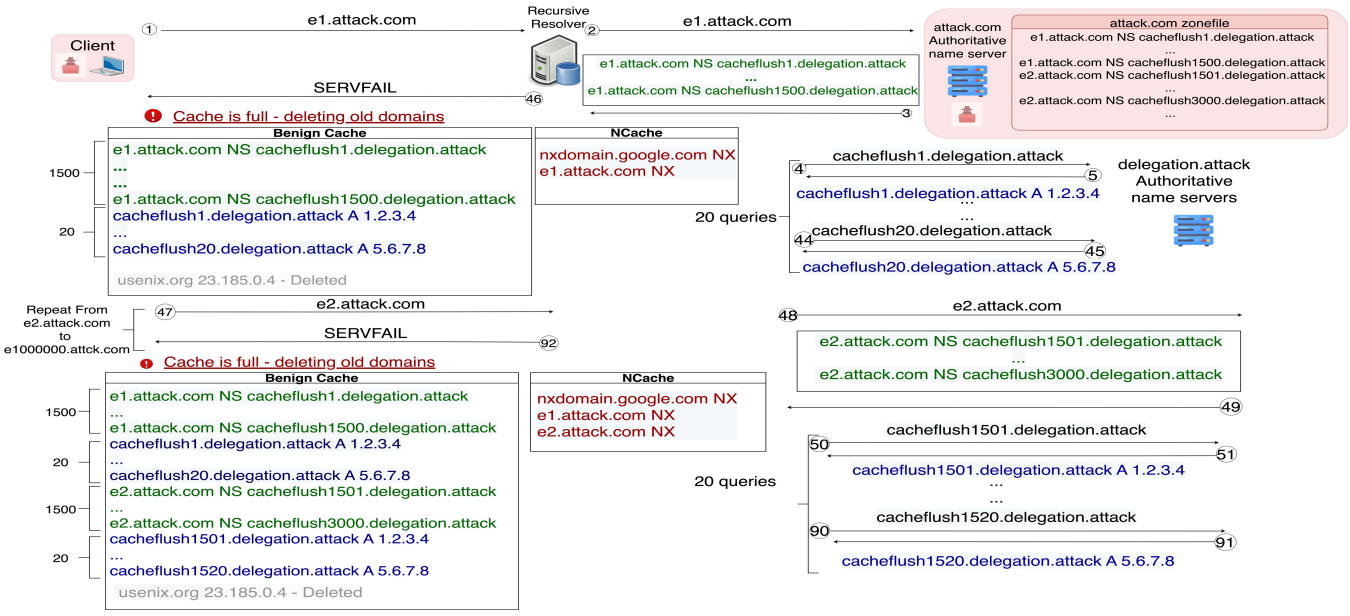

Figure 1: NS records type of CacheFlush Attack; An attacker requests e1.attack.com following by e2.attack.com and gets referral responses with 1500 names from the authoritative name server. The resolver queries the first 20 names in each list and evicts from the benign cache the RR corresponding to the referral list and the 20 responses. This evicts usenix.org from the cache.

contains 42 bytes. Therefore, a referral list of length 1500, has $42 * 1500 = 63KB$ in the zone file. Clearly, the larger the cache of the target resolver the more malicious domains the attacker needs to maintain in the zone file. For a 100MB target cache the required zone file is $1,000 * 63KB = 63MB$ since each line of the zone file results in flushing $1KB$ in the cache.

The cost of operating the malicious authoritative DNS server is relatively low. There are two options (1) self-managing either in the cloud or on-premises or, (2) outsourcing to a managed DNS service provided by companies such as Cloudns, Cloudflare, GoDaddy and Namecheap [18, 19, 22, 35]. The main expense of self-managed authoritative DNS in the cloud is the cost of outgoing traffic. It typically amounts to around $0.6 per minute for an attack that flushes a 2GB resolver cache so benign domains that are requested once per second or less have to be re-fetched on each query. See Appendix A for more details.

The four managed DNS services, Cloudns, Cloudflare, GoDaddy and Namecheap, allow the configuration of long referral lists (with 1000 NS or more) or long CNAME chains for each domain. Each service was tested by configuring a long referral list or long CNAME chain for one domain, and making sure it returned a large response that contained the entire referral list or CNAME chain, all while adhering to ethical guidelines. However, there is a limit on the free-of-charge authoritative services, including the total number of supported domains and resource records (RR) in the Zone. Performing an attack as in our experiments requires a zone file size larger than the free version allowances. For example, to flush a 1GB cache, 10,000 domains each containing 1,500 RRsets are required. Nevertheless, the cost to upgrade and support an unlimited number of requests in Cloudns [19], is $14.95 per month. For the others, customized plans are available, with costs varying according to usage.

An alternative common practice for example, is for attackers to compromise DNS operators' credentials and manipulate zone files, sometimes even getting access to their registrar records, as demonstrated by recent DNS hijacking attacks [30, 32]. Thus getting all the required services for free.

Adaptive attacker: An adaptive attacker can measure the target cache size and determine the required zone file size. To measure it the attacker requests a seemingly benign test domain name at rate r at which it wants to flush the target cache. So that any domain name that is queried at a rate lower than r would then be evicted. The attacker authoritative is the authoritative for the test domain. During the attack, the attacker expects to receive queries for the test domain in its authoritative at rate r, or otherwise, if it receives fewer queries, the cache is not flushed fast enough. In which case the attacker should increase the number of distinct malicious domains in the zone file and increase the attack rate.

Multi-threading: All our tests and measurements use BIND and Unbound multi-threading packages. Clearly if we used a single thread version, then the attack would be more harmful.

The default cache size of most resolvers is between 8MB to 200MB [3–7, 9], in practice, medium size resolvers (e.g.,

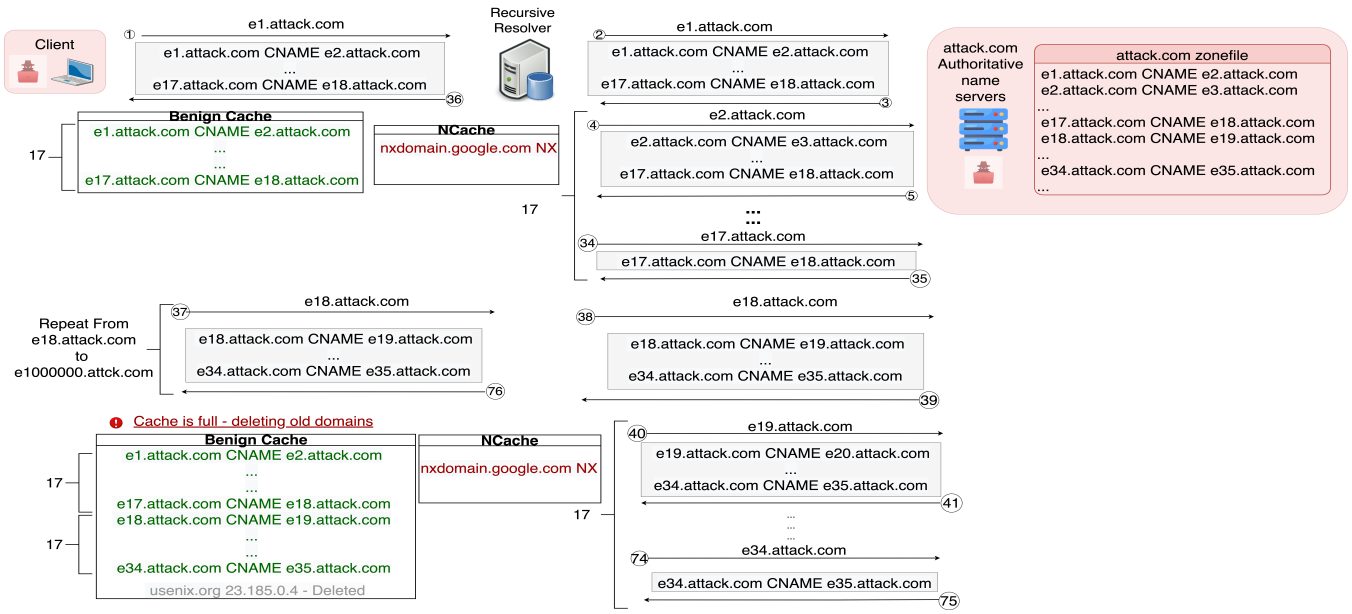

Figure 2: CacheFlush Attack using CNAME records example; An attacker requests the e1.attack.com domain and fills the benign cache with 17 RR sets from his authoritative name server

University resolver) use a 2*GB* to 4*GB* cache. We therefore use in our experiments, a cache size of 10*MB*, 100*MB*, and 2*GB*.

4 CacheFlushAttack

Two variations of the CacheFlush attack are presented here: the Name-servers based, NSCacheFlush, where the attackers' authoritative response includes a large referral response of NS delegations, and the CNAME based, CNAMECacheFlush, where the response includes a long chain of CNAMEs.

Notice that in either attack variant the malicious RR records (NS or CNAME) are inserted into the benign cache (and not to the ncache) regardless of whether the DNS resolution of the original query from the attacker results in an IP address, failure, or NS response.

4.1 NSCacheFlush Attack

Upon receiving a response with a referral response with many NS names from the authoritative name server, the resolver caches the entire list, even though it is not going to resolve the names in the list except the first 5.

Figure 1 illustrates the attack: the attacker sends malicious requests from the client to the targeted resolver, such as e1.attack.com, e2.attack.com, etc. For each query, the resolver queries the relevant authoritative (controlled by the attacker) and receives a referral response containing 1,500 names (step 3). As a result, all 1,500 names are stored in the resolver's benign cache.

Subsequently, in order to resolve the original query, the resolver queries the first k NS and caches them as well in the benign cache (steps 4-45). In BIND and UNBOUND implementations, the resolver queries the first k=5 names [11]. These NS names can be domains of DNS servers, or domains that correspond to DNS non-responsive servers, which are not controlled by the attacker.

Finally, the resolver queries the NS (e.g., e1.attack.com) to resolve the original query. If the resolution succeeds, it stores it in the benign cache; otherwise, it stores it in the Ncache (if it received SERVFAIL, as in step 92 our example).

In the attack, the attacker controlled authoritative server repeatedly responds with a referral response with n new NS names from the zone file, until all the names in the zone file have been used at which point it starts all over. For each such referral response, 1520 RR are evicted from the benign cache, for a total of $n \times 1520$ RRs, regardless of whether the resolution was successful or failed. The attacker can use the adaptive attack zone file (see Section 3 to adjust the zone file size until flushing the entire cache).

In our example, the benign domain usenix.org is queried less frequently than the cache flushing rate, causing it to be evicted from the cache by the LRU algorithm before it is queried again.

4.2 CNAMECacheFlush Attack

This attack version relies on the fact that a resolver resolves a CNAME chain sent from an authoritative name server until it reaches the limit of p CNAMES set by its vendor and store only the p first CNAMEs in its benign cache. BIND9

sets a resolution limit for a CNAME chain up to 17 times (UNBOUND allows 9, Google 15, and Cloudflare 20) [15], aiming to prevent infinite loops.

Figure 2 illustrates the attack on BIND implementation by an attacker who sends a malicious query to the attacked resolver, the authoritative name server controlled by the attacker responds with a chain of 17 CNAME records (the maximum number of records that will be stored also in the benign cache). The resolver saves the first CNAME record in its benign cache and queries the same authoritative name server for the next name in the chain even though it received the entire chain in the first answer [28], so it continues until BIND's limit is reached, saving a total of 17 records in its benign cache (steps 4-35). This version differs from NSCacheFlush in that only the limit 17 names are stored in the cache, regardless of the length of the CNAME chain. Therefore, this attack is not as effective at filling the cache as NSCacheFlush. In 7.1, we describe the effect of a CNAME chain with a length of 1,500 on the resolver. This version works the same when an IP address is returned at the end of the chain or not, and in either case the chain is not inserted into the negative cache but into the benign cache, as depicted in the figure, the negative cache does not change during an attack.

4.3 Effective Flush Rate

What rate of attack causes a high cache miss rate ($> 80\%$) for a benign domain d that is queried at a rate r_d? A cache of size s is flushed at a rate of $\frac{attack\_rate * CAF}{s}$, where CAF is the attack cache amplification factor, the amount of cache memory evicted by each attacker request. For simplicity, we assume the benign and the attacker querying rates are at a constant uniform rate. Thus a cache miss would occur iff, the benign rate is lower than the flushing rate:

$$\frac{\text{Attacker Request Rate} \times \text{CAF}}{\text{Cache Size}} > \text{Benign Rate} \qquad (1)$$

CAF is a function of the number of RRs sent in a response to the resolver, times the size of each corresponding RR. In the conducted NSCacheFlush experiments, every response results in the insertion of $1,520$ RRs, of size (~ 67 bytes), i.e., CAF = $100KB$.

4.4 Resolver Cache Miss

Next we calculate the average cache miss on a resolver. The distribution of domain queries can be characterized by a power law distribution [44] (see details in Section 5.3): $y = ax^{-b} + c$, where y is the domain rate in qps, x is the domain rank (1 is the most frequent domain), b is the exponent and it determines the slope of the power-law line on a log-log scale plot (the steeper the slope, the greater the variation in the rate between the top ranked domains). a and c are both related to the popularity of the resolver, the number of clients and the frequency with which it is used. a scales the function vertically and c is a constant that shift the function vertically.

Similar to Equation (1) above, we find the *border rate* of an attack, which is the rate such that all benign domains with lower rate than this border rate with high probability experience a cache miss under this attack rate, using the response size (rsize) and cache size (csize):

$$\text{Border rate}_{\text{csize, rsize}}(\text{attacker rate}) = \frac{\text{Attacker rate} \times \text{rsize}}{\text{csize}} \qquad (2)$$

We will then place the *border rate* as y in the power-law function $y = ax^{-b} + c$ and find the domain rank x. We denote it as m and name it the *border rank*.

The sum of the rates (y) over the domains with rate up to the *border rate* (n denotes the total number of domains the resolver was queried), represents the number of cache misses predicted by the model:

$$\sum_{x=m}^{n} ax^{-b} + c$$

Thus the average cache miss percentage for the resolver, is:

$$\frac{\sum_{x=m}^{n}(ax^{-b}+c)}{\sum_{x=1}^{n}(ax^{-b}+c)} \qquad (3)$$

[1] In the next section 5.4, we present experiments that show the accuracy of our simple modeling.

5 Experimental Results

5.1 Experiment Setup

Our experiment setup resides in Azure cloud and included DNS recursive resolvers, Authoritative name servers, an attacker, and two benign machines that issue requests in parallel to demonstrate multiple users simultaneously. This allowed us to evaluate the impact of the attack on benign users. The following machines, each Intel(R) Xeon(R) CPU E5-2673 v4 @ 2.30GHz x64 with 2 vCPUs 8 GiB RAM and Linux (Ubuntu 20.04) operating system, were used:

1. Resolver machine with most recent versions, BIND9 (9.18.21) or UNBOUND (1.19.0) resolvers

[1] It is possible to approximate the function using generalized harmonic numbers $H_n^{(r)}$:

$$\frac{\sum_{x=m}^{n}(ax^{-b}+c)}{\sum_{x=1}^{n}(ax^{-b}+c)} = 1 - \frac{\sum_{x=1}^{m}(ax^{-b}+c)}{\sum_{x=1}^{n}(ax^{-b}+c)} = 1 - \frac{aH_m^{(b)}+cm}{aH_n^{(b)}+cn} \qquad (4)$$

which can be expressed alternatively with Riemann [8] and Hurwitz [2] zeta functions:

$$1 - \frac{aH_m^{(b)}+cm}{aH_n^{(b)}+cn} = 1 - \frac{a(-\zeta(b,m+1))+a\zeta(b)+cm}{a(-\zeta(b,n+1))+a\zeta(b)+cn} \qquad (5)$$

2. Client machines, benign clients and an attacker client, each equipped with a Resperf tool.

3. Authoritative server that is used to craft the malicious CNAME and referral response.

4. Authoritative server that owns the domain referred to by the NS names in the referral response.

5. Authoritative server to which benign users are referred.

We placed the client, resolver, and authoritative servers in the same Azure region so our measurements would not be impacted by any significant Internet delays. In order to simulate as closely as possible to real world situation, the machines communicated through their internet interfaces rather than through a local area network.

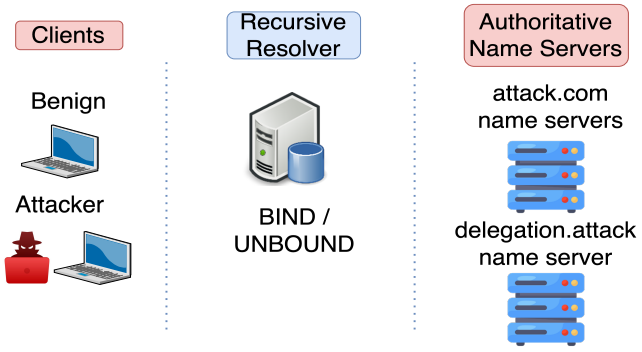

Figure 3: Test environment

5.2 Isolated Lab Setup

In addition to the cloud environment, we have created an isolated lab environment for conducting research and reproducing experiments. This setup includes a BIND resolver with the latest version (9.18.21), and four authoritative servers: a local root authoritative server and three others to simulate the "attack.com" and "delegation.attack" authoritative servers depicted in Figures 1 and 3. The authoritative name servers are implemented with Name Server Daemon (NSD) version 4.3.3. To ensure the setup poses no external risk, it operates locally within a closed Docker container environment. The clients are deployed on the same machine, configured to send DNS queries directly to the local recursive resolver. The setup configuration and environment are available on GitHub [43].

5.3 Domain Rate Distribution

To test the effectiveness of our attack in a realistic environment, we collected statistics on the DNS environment of our university over a period of 39 days and used it to model typical clients' behavior. We also examine two data sets that

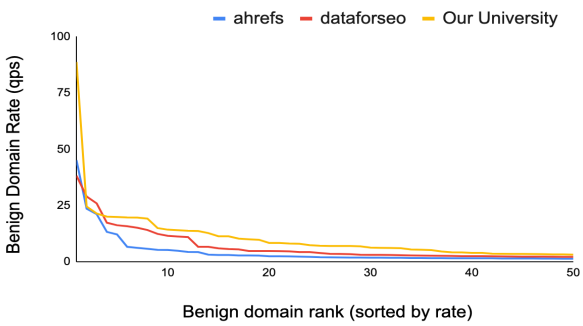

Figure 4: Domain Rate Distribution for three datasets, our university, AHREFS, DATAFORSEO (on 50 highest-ranked domains).

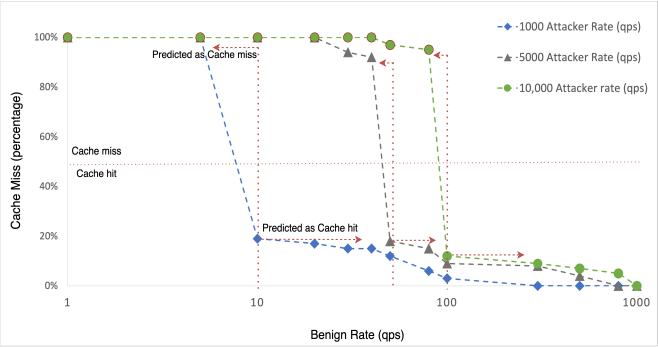

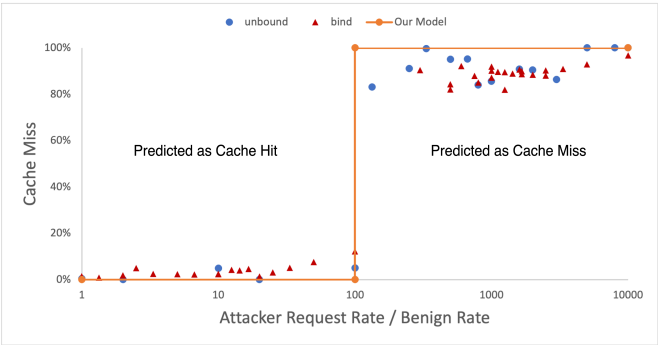

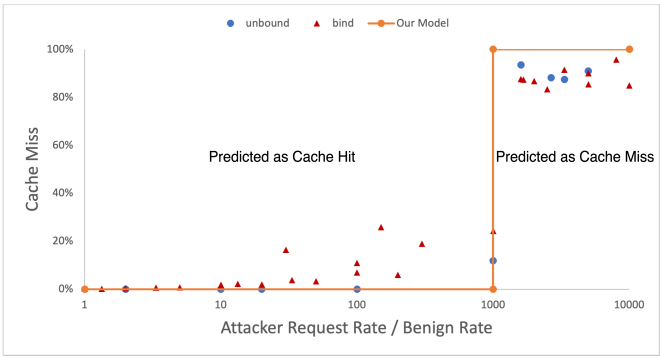

Figure 5: Cache miss percentage measured on different benign domain request rates with different NSCacheFlush attacker request rates on BIND resolver with 10MB cache size.

indicate how frequently the most common domains are visited [12,20]. The distribution of domains from all the data sets was characterized by a power law distribution [44]: $ax^{-b}+c$ where $b = 0.79$ for our university data, b = 0.93 for [12] and $b = 0.7$ for [20] (a and c relate to the number of clients which is reflected in the variety of Attacker rates in our experiments). Figure 4 illustrates the similarity between our university and the other data set we checked. Due to its similarity to real-world distributions, our university's distribution was used to test the domain distribution model. We use these distributions on our own domains in order not to overload public domains on the internet. The attack file was constructed in which each domain is evenly distributed in the file according to its distribution (e.g., a common domain that accounts for 20% of all domains appears 20% times at equal intervals in the attack file). By running the attack file at a higher rate in different experiments, we were able to control the rate at which each domain was queried.

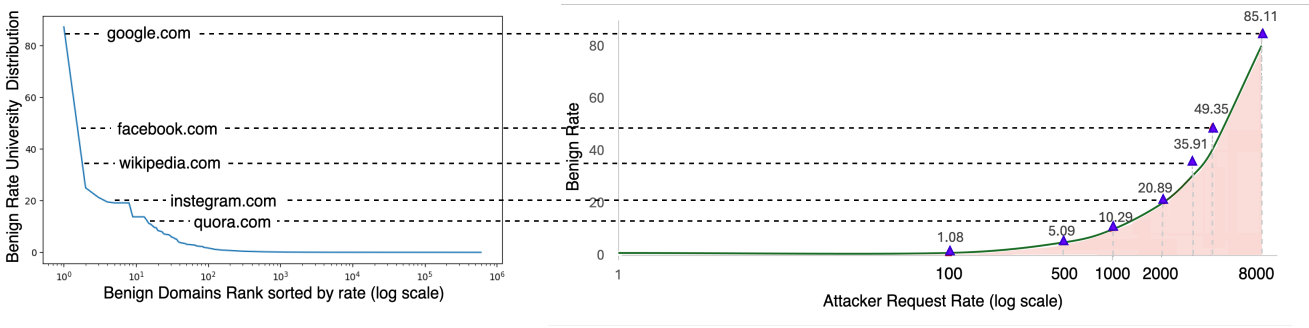
(a) Results for 10MB cache size; According to our model, there is a high probability of cache misses when the $\frac{\text{attacker request rate}}{\text{benign rate}} > 100$, similar to the results obtained in the experiments.

(b) Results for 100MB cache size; According to our model, there is a high probability of cache misses when the $\frac{\text{attacker request rate}}{\text{benign rate}} > 1,000$, similar to the results obtained in the experiments.

Figure 6: The results of the experiments on BIND9 and UNBOUND implementations compared to our model predictions on NSCacheFlush attack; The percentage of cache miss as a function of attacker request rate divided by benign rate for a different cache sizes.

5.4 Attack model vs Experimental results

Here we show the experiments that were conducted to test the model's results. First, we measured (Figure 5) the cache miss percentages for one benign domain under various benign rates between 1 to 1000 qps and attacker request rates of 1000, 5000 and 10,000 qps using a BIND9 resolver with a cache size of 10 MB. According to our model, a cache miss is expected with high probability for benign domain with a rate less than 10qps and attack rate of 1000qps. An attack rate of 5000qps should result in a cache miss for any domain with a rate below 50qps and an attack rate of 10,000 should result in a cache miss for any domain with a rate below 100qps. Figure 5 shows that the model predicts well the cache misses under different attack rates.



The second experiment (Figure 6) expands upon the first experiment and validated the predictions made by the model for BIND and UNBOUND implementations using two cache sizes of 10mb and 100mb for different attacker request rates between 100 and 10,000 qps and benign domain queries between 1 and 1000 qps. The analysis of Figure 6 shows that the model correctly predicts the cache miss rates for all the different experiments; For example, according to equation (1), for cache size of 10MB (10,000 KB): $\frac{\text{attacker request rate}x100}{\text{benign rate}} > 10,000$ so $\frac{\text{attacker request rate}}{\text{benign rate}} > 100$; and as shown in Figure 6a, 100 is indeed the value after which all cache misses occur.

As can be seen in both experiments, the cache miss rate is high or very low based on our model, but mostly it was not 0% or 100%, this is because the resolver manages a multi-threaded queue that holds queries since they arrive at the resolver until the client receives a response. When the queue reaches its quota (hard limit) , see Section 2.5 for details, it is reset and all malicious queries waiting for an answer in the queue are deleted. At this point, if the cache has not yet filled up and a benign domain is queried, a cache hit occurs.

The third experiment (Figure 7) included testing the validity of equation (2) on our university domains' distribution, when different domains were queried at different rates in an attempt to illustrate a real-world scenario. Each attacker request rate in the model is matched with a *border rate*, which all benign domains with a lower rate have a high probability of missing the cache. In Figure 7, we present the results of our comparison between the graph model and the experiment results on BIND9 implementation with a cache size of 10MB.

Figure 7a shows the distribution of domains in our university; for example, we observe that the most popular domain, google.com, is requested an average of 85 qps. For each domain rate in Figure 7a, we draw a parallel line to Figure 7b, where the green graph within it represents the prediction of the distribution model (2) we described earlier. In Figure 7b, for each benign domain rate (y) the x-axis indicates the attack rate, from which the domain will most likely be deleted from the cache. For example, for Instagram.com from Figure 7a which has a rate of 20 qps, a line is drawn to Figure 7b, and where it meets the model graph point [2000,20], so the rate of attack most likely needed to remove Instagram.com and all domains with lower rates from the cache is 2000. The purple triangles indicate the results of the experiment so that it is easy to see that our model's prediction (the green graph) matches the experiment's results.

Furthermore, the predictions of Equation (3) was also tested (Table 1) at five different attack rates, using the university distribution presented in Section 4. As an example, in the case of Instagram.com again, which is the 5th most frequently queried domain (rank 5), with a query rate of 20 qps, an attack of 2000 qps is required to remove this domain, and all domains with lower query rates, from the cache (according to Equation (2)). Using Equation (3), we predicted an average

(a) The distribution of the domains measured on the resolver of our university, sorted by the rate at which they were requested.

(b) The green line estimates for an attacker request rate what is the border rate from which all domains with a lower rate will be evicted with a high probability from the cache. The purple triangle points represent the results of our experiments on this distribution of domains, i.e, in what attack rate the specific domain was evicted from the cache.

Figure 7: The attacker request rate necessary to remove each benign domain with a high probability from the cache along with all benign domains with a lower rate; As an example, for the benign domain Instagram.com, which received 20 requests per second, a rate of 2000 attacker requests per second removed in high probability the domain and all domains with a lower rate (the area created under the graph) from the cache.

cache miss rate of 46.2%, and observed a cache miss rate of 48.6% during our experiment.

Attack Rate	Domain Rank with 100% cache miss	Overall experiment cache miss	Overall predicted cache miss (by Equation (3))
8000	1-n	100.0%	96.4%
2000	5-n	48.6%	46.2%
1500	10-n	41.4%	40.1%
800	20-n	22.2%	21.7%
600	30-n	12.5%	11.3%

Table 1: The overall average cache miss predicted by equation (3) compared to five experiments overall average cache miss results, with five different attack rates, on a BIND9 resolver with a 10MB cache size, using the domain distribution of our university.

5.5 Resolver Cache Miss and Throughput under CacheFlush attack

This section examines the impact of both CacheFlushAttack versions (CNAME and NS) on benign domains in a resolver under attack. Using different attack rates and cache sizes, we tested the latest version of BIND9 (9.18.21) and UNBOUND (1.19.0). We utilized two Resperf [40] tools in our cloud set-up environment: the first modeled the attacker and generated malicious domains at a fixed rate for each experiment, and the second ramped up the university benign domain requests rate until failure was encountered. For each combination of attacker request rate and cache size, we tested the impact of the following attacks:

1. NSCacheFlush
2. CNAMECacheFlush
3. Water-torture [42] - floods the resolver with pseudo-randomly generated nonexistent sub-domains.
4. NRDelegationAttack - floods with 50 different packets with the same 1500 names length referral response. (This is a complexity attack, to which the two resolver versions are patched, it generates a high CPU load but does not overload the cache. In total $50 \times 1520 = 76,000$ records are inserted into the cache in this attack.)
5. Existing domains - floods the resolver with queries for existing domains that return A records as an answer, similar to Water-torture [42] (point 3 above) except that the domains are stored in the benign cache.

Both Bind and Unbound suffer from a significant degradation in the benign domain request throughput measurements and increase in the average cache miss rate under CacheFlush, as shown in Figures (8,9).

NRDelegation has little impact on the throughput and on the cache miss rate on these patched versions of the resolver, because in the patch (that CacheFlush circumvents) it inserts

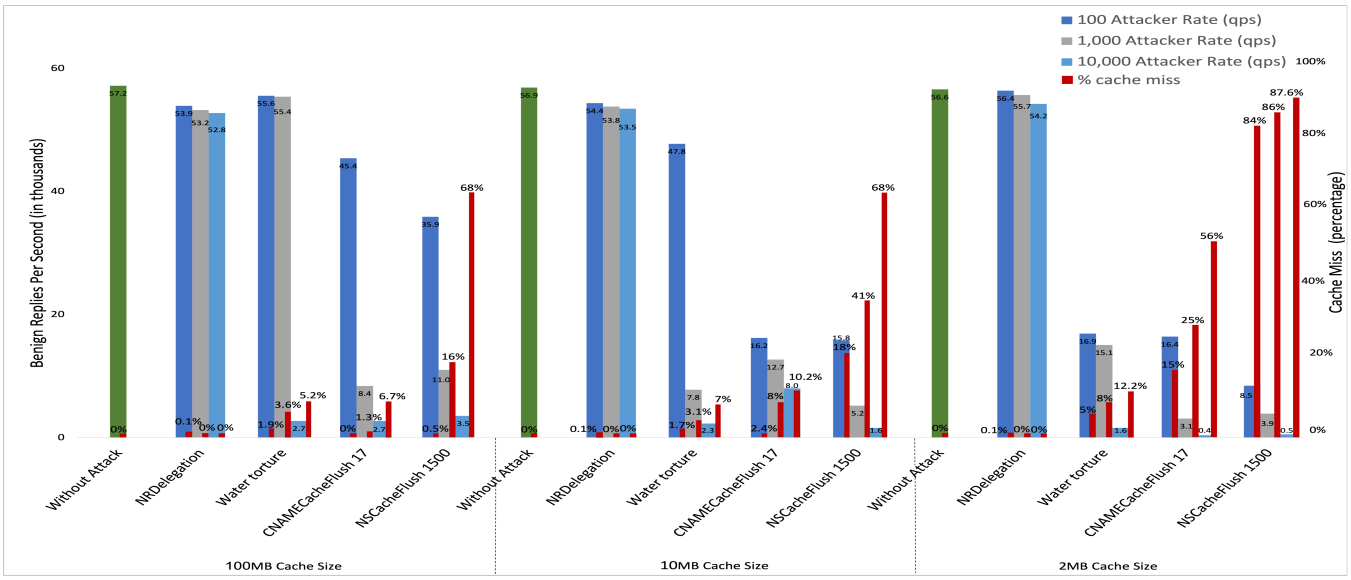


Figure 8: Cache miss and throughput for BIND9 resolver using two CacheFlush attack variants with a variety of attacker request rates and cache sizes, in comparison to NRDelegation on the fixed version of the resolver and water-torture attacks.

only a limited number of records into the benign cache. Water torture negatively impacts resolver throughput at high attack rates and has a low impact on the benign domain cache miss rate since the records are inserted into the negative cache. The Existing domains attack did not affect the resolvers because it cached only a single A record for each "malicious" query. Thus taking approximately 30 Bytes in the cache, whereas in the CacheFlushNS attack, each query consumes 100KB (3,333 times more), which means that in order to achieve the same cache depletion as in our attack, the attacker would have to issue 33.3M ($3,333 * 10,000$) queries, which is well beyond the capacity of the resolver. As a result, using the Exisiting Domains attack in the rate of our cacheFlush attack, there are no cache misses, and the throughput remained unchanged since both benign queries and existing domains were successfully resolved, hence we did not add this attack to our figures.

The attack does not affect High Rate Domains (HRD) since the attack does not fill up the cache before the HRD domain is queried again. At the same time the attack has a little impact on benign domains that are queried at a very low rate, even without our attack, since these domains are removed from the cache once it is full or their TTL has expired. Furthermore, we investigated the latency variation between our attacks and the average latency observed for all benign domains. On average, the latency during an attack is 15.6 times higher than the average latency of the benign domains without the attack, which was increased from 8.53 milliseconds to 133.1 milliseconds.

Testing a 2GB Cache Size: Since, as noted in Section 3, in practice medium size resolvers (e.g., University resolver) use a 2*GB* to 4*GB* cache we experimented with a 2*GB* cache as well. However, as predicted by equation (1), the larger the cache, the larger the attack rate required in order to flush it with in a given time interval. Therefore, the attack rate in this test is increased and had to be performed from two clients instead of one, as is done in the smaller cache sizes. Furthermore, the maximum benign rate tested was reduced from 1000 qps to 1 qps for this test. In testing BIND with the higher attack rate we encountered farther difficulties since as mentioned in Section 5.4, in high attack rates Bind's queries-queue purges many queries from the queue before being processed. This caused many benign domain queries to be removed from the queue and not queried by the resolver. In the 2*GB* experiment on Bind, most of the benign queries are deleted from the queue, and no response is received by the client, nor a query to the authoritative is observed. Therefore, we are unable to determine whether there is a cache miss or not. Hence, we performed the 2*GB* experiment only on Unbound.

Figure 9 illustrates the effect of our attack on the throughput and cache miss rate in Unbound with a cache size of 2GB based on the distribution of our university domains.

Figure 10 presents a similar experiment to Figure 5, but on 2*GB* cache and the attack rate is higher, while the benign domain rate is lower.

Equation (1) correctly predicted the cache miss rate for larger and smaller cache sizes once we filtered out malicious domains for which we did not receive a response to the clients, thus implying that these domains were not saved in the cache. Additionally, Figure 11 shows a similar experiment to Figure 6, for 2*GB* cache size equation (1) correctly predicted the results of cache misses for all attack and benign rates. By

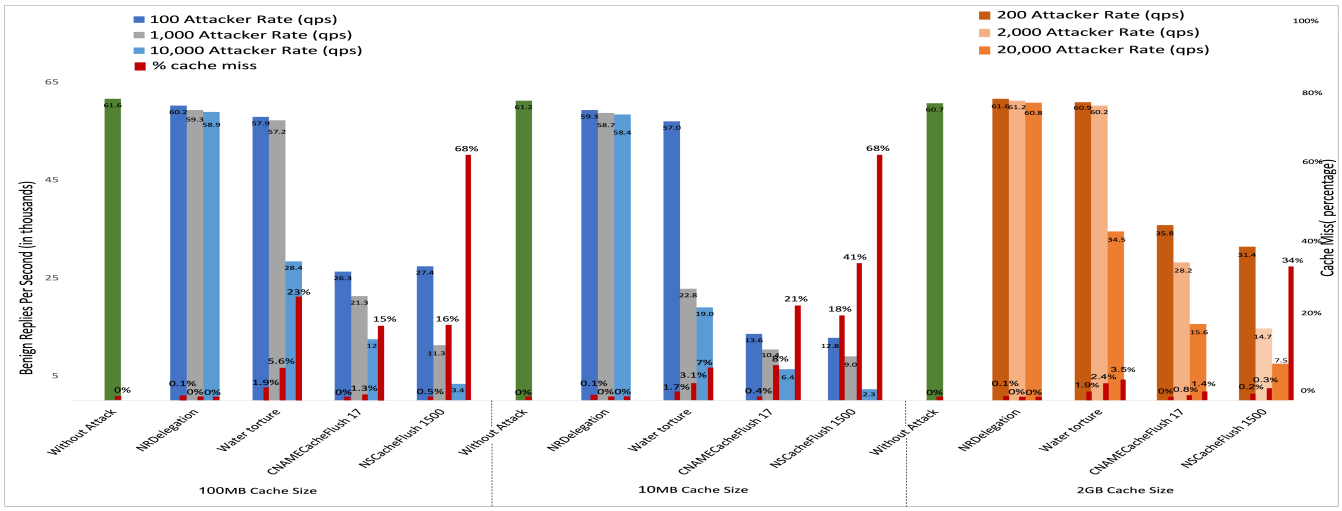

Figure 9: Cache miss and throughput for UNBOUND resolver using two CacheFlush attack variants with a variety of attacker request rates and cache sizes, in comparison to NRDelegation on the fixed version of the resolver and water-torture attacks.

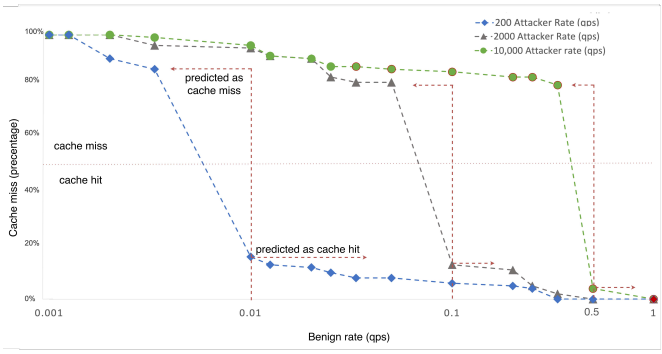

Figure 10: Cache miss percentage measured on different benign domain request rates (0.1 indicates one query every 10 seconds) with different NSCacheFlush attacker request rates on Unbound resolver with 2GB cache size.

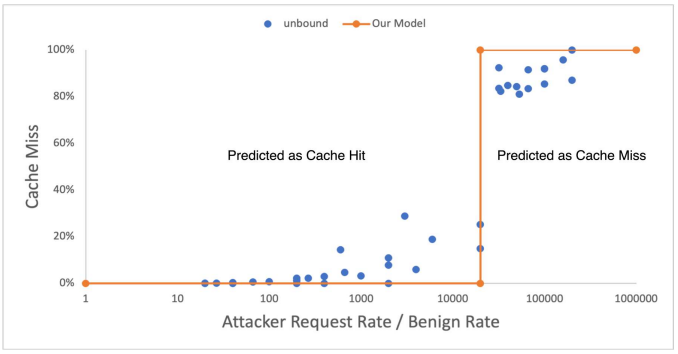

Figure 11: 2GB cache size UNBOUND resolver cache miss percentage measured on different benign domain request rates with different NSCacheFlush attacker request rates; According to our model, there is a high probability of cache misses when the $\frac{\text{attacker request rate}}{\text{benign rate}} > 20,000$, similar to the results obtained in the experiments. E.g., to flush the 2GB cache once per second, $20,000$ requests per second are required.

equation (1), for $2GB$ cache size, when $\frac{\text{attacker request rate}x100}{\text{benign rate}} > 2,000,000 \geq \frac{\text{attacker request rate}}{\text{benign rate}} > 20,000$ cache misses are almost surely to occur.

6 CacheFlush Mitigation

6.1 Bounding NS referral list

Although the resolver considers only the first p (e.g., 20) NS names from the referral response, the entire list is cached. It is noted in [10] that the top million domains have an average of 2.52 NS names in their corresponding RRs, with 99.5% fewer than 7. Since many root servers return 13 NS names in the RR, $p = 20$ was selected [36, 37] as a safe number that does not affect benign domain resolution.

As such, it is reasonable to limit the number of names stored in the cache to 20, even though this will not entirely eliminate the attack, it will result in a significant reduction in the impact of the attack, as shown in Figures (14,15). For a more complete mitigation/patch the processing complexity of the referral list (even if only 20) should be resolved. Here we only examine the impact of the limited mitigation of trimming the referral list to store at most 20 NS names.

6.2 Bounding the length of CNAME chains

One obvious solution is to bound the CNAME chain length, in order to eliminate entering multiple records to the cache. To determine what CNAME restriction is needed, we ran an experiment on the 5,000 most common domains (based on Cloudflare Radar [17]), using 8,000 resolvers in 230 countries and territories. During the period of 2022-07-10 to 2022-07-19, with 160 million queries were sent each day, using BGProtect monitoring [1]. As shown in Figure 12, 75.26% of the 5000 domains did not use CNAME at all. The maximum CNAME chain length is six with only one domain (0.02%), and only 3.64% of the domains had a CNAME chain longer than one. A recent querying of the single domain with a chain of length 6 discovered the chain is now five CNAME long.

Moreover, we also conducted a test using one machine in our Azure cloud environment located in the west-us region, on the million most popular domains in the world [17], and we checked how long their CNAME chains were. Figure 13 shows 98.7% of the domains do not have CNAME records, and only 0.0001% have a chain of length 7, while only 0.4% have a chain that exceeds one.

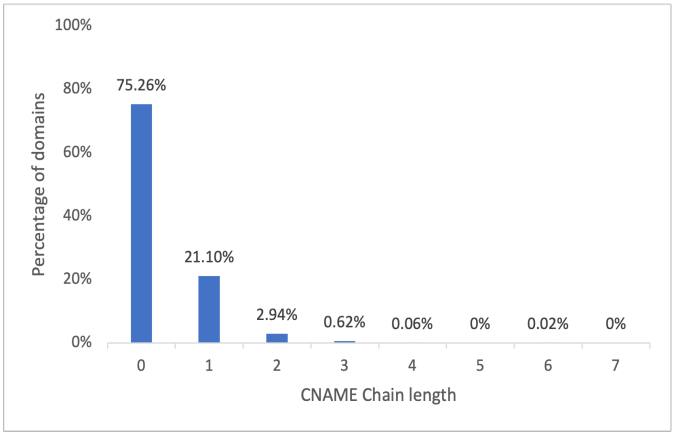

Figure 12: Percentage of domains with varying CNAME chain lengths among the 5,000 most popular domains, queried from 8,000 different resolvers spread over the world.

In Figures (14,15) we show the impact of limiting to 8 the CNAME chain as well of the CNAMECahceFlush with a length of 1,500 names to compare the effect of filling the cache to the complexity effect of our attack that we describe later in Section 7.1.

7 Additional Large DNS Messages Vulnerabilities

During the investigation of our CacheFlush attacks on the resolvers, we discovered additional implementation problems in the cache which we reported to the vendors under a responsible disclosure procedure. Some of these problems have been patched while others require further work.

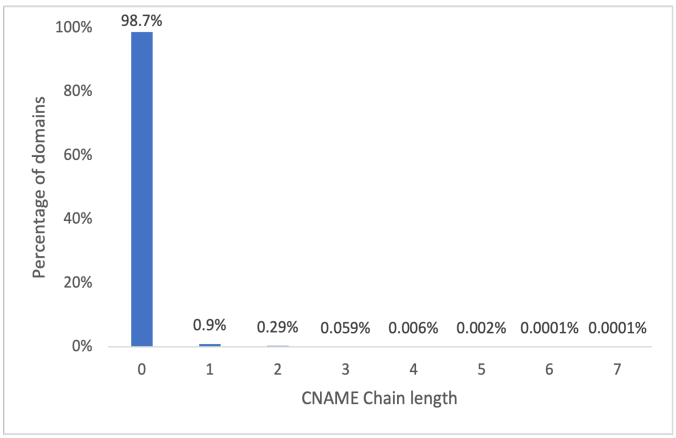

Figure 13: Percentage of domains with varying CNAME chain lengths among the million most popular domains, queried from one location.

7.1 CPU quadratic complexity when parsing large DNS messages

The CNAMECacheFlush Attack allows you to send a CNAME chain with 1,500 names, similar to NSCacheFlush, but unlike NSCacheFlush, only 17 records are saved in the benign cache and the cache miss percentage remains similar. Despite this, we detected differences in the throughput of the resolver when we sent these large messages and identified a vulnerability (CVE-2023-4408 [39]) in the validation check for large responses. In the event that a message arrives at the resolver, it performs validation checks to ensure that there are no conflicting information between the records (for example, the same domain should not point to two different names in the CNAME chain). Each domain in the response is checked to determine if it has already appeared in the answer so as to unify all of its answers into one data structure and eliminate duplicates. In this check, each domain is compared to all previous domains that have appeared in the CNAME chain before, causing a quadratic search for each message sent by the attacker, which results in approximately $\frac{17\times1500^2}{2} = 19million$ tests for each message sent by the attacker, which causes the machine to execute more than 1 billion clock instructions for each message sent by the attacker, Figure 16 present a test from the CVE disclosure discussion. As can be seen in Figures (14, 15) the resolver throughput dropped by average of 22.1% when CNAME chains of length 17 were compared to chains of length 1500, while it increased by average of 333.7% when chains of length 8, indicating that cache misses are the primary determinant of throughput.

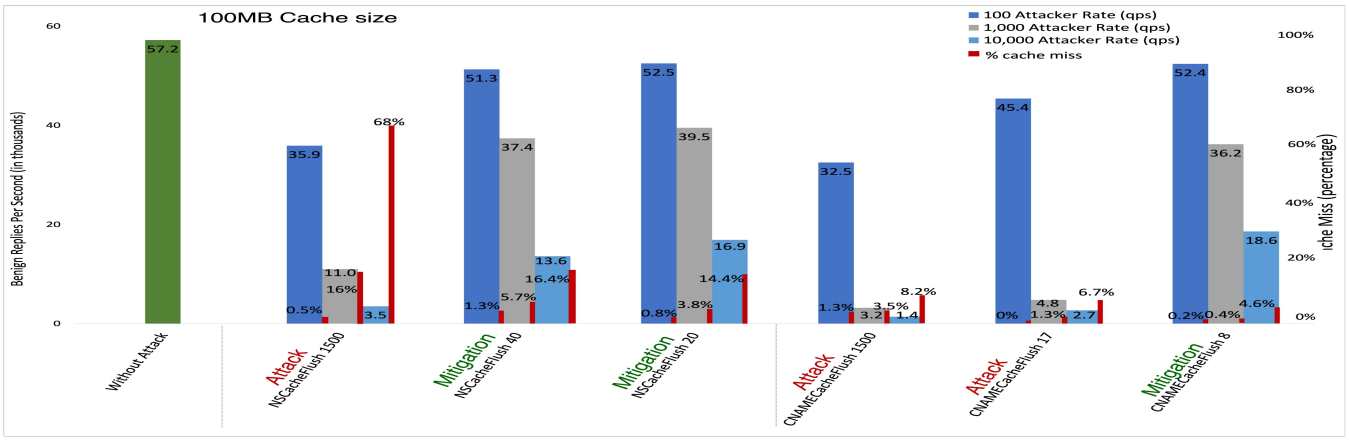

Figure 14: Cache miss and throughput mitigations compared to the CacheFlush attacks on BIND resolver with 100MB cache size; CNAMECacheFlush attacks with 8, 17 and 1500 chain length and NSCacheFlush using 1500, 20 and 40 RRs

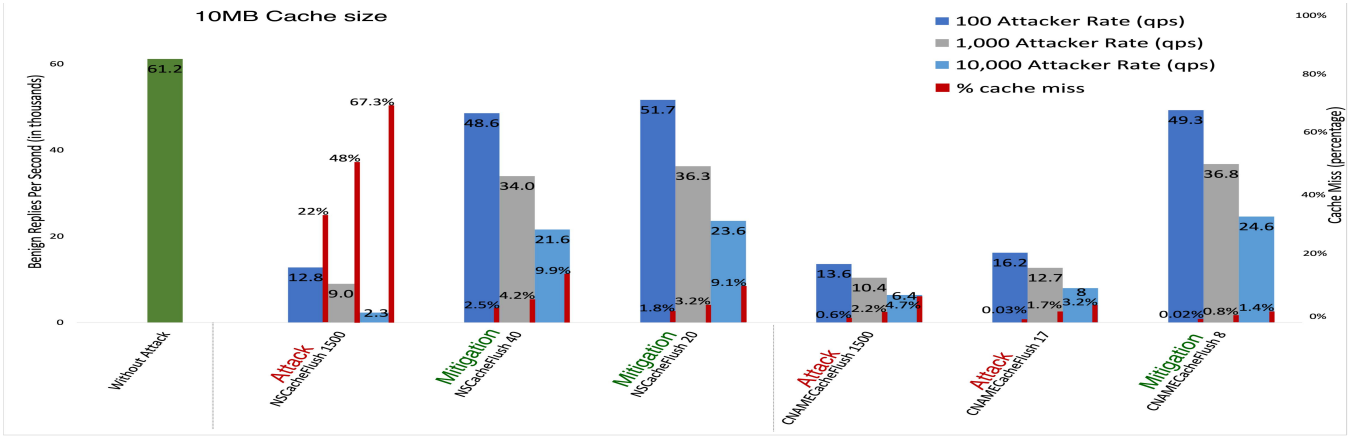

Figure 15: Cache miss and throughput mitigations compared to the CacheFlush attacks on UNBOUND resolver with 10MB cache size; CNAMECacheFlush attacks with 8, 17 and 1500 chain length and NSCacheFlush using 1500, 20 and 40 RRs

7.2 Overallocating cache memory until the resolver crashes

Another issue was discovered in the cache in that large DNS messages were not taken into account when the replacement of an old domain with a new one when the cache is full. While there is a limit to the size of the cache, it is possible to replace some small messages with larger ones in order to increase the cache until it exceeds the amount of RAM the machine has and the resolver crashes. This bug was fixed under a responsible disclosure procedure, and a CVE-2023-2828 [38] has been issued.

8 Related Work

In recent years, DNS amplification attacks have received a lot of attention. Moura et al. introduced an attack called TsuName [34], which created a loop of queries between two malicious authoritative servers, based on NS records. An adversary can register two or more domains, later reconfigure them to create a cyclic dependency, and then inject client traffic from a botnet.

Bushart et al. [15] demonstrated the amplification of packets by chaining CNAME records, causing a resolver to overload a target authoritative name server with valid requests.

Maury [31] presented another packet amplification attack that exploits the delegations of name servers in a referral response. In the attack named iDNS, the attacker's name server sends self-delegations back and forth to the attacker's name server, potentially reaching an infinite depth.

In contrast to all the above work, our research focuses on flushing the benign cache using a small number of packets, and none of the above works address benign cache flushing.

Luo, et al. [29] analyzed the prevalence and characteristics of NXDomain and water torture attacks. Our attack is not an NXDomain attack but involves flooding the benign cache

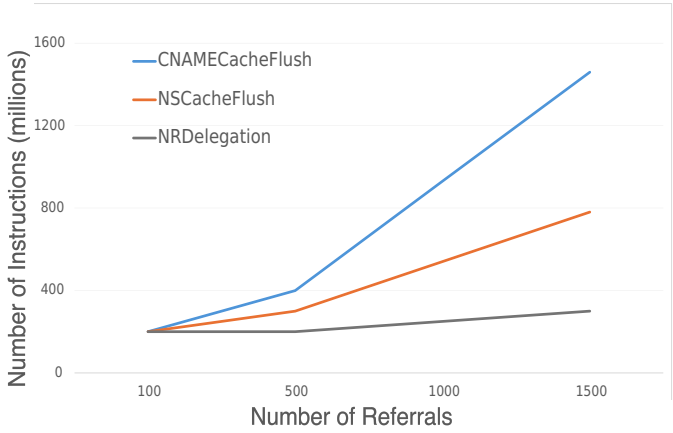

Figure 16: Instructions executed on the resolver processor per one malicious CNAMECacheFlush attack request (in millions), tested on BIND9 fixed NRDelegation attack version (9.19.13) compared to NRDelegation attack instructions.

with seemingly existent domains. NXDomain attacks flood the Ncache, and as we demonstrate, our attack results in a higher cache miss at the resolver and a greater reduction in throughput compared to water-torture [42].

NXNSAttack [10] is a packet amplification attack that exposed a vulnerability, causing a flood of queries between the recursive resolver and authoritative server, resulting in an overload on both and producing an amplified DDoS effect. However, the CacheFlush attack is not a packet amplification attack. While the NXNSAttack uses NXDomains that may be saved in the Ncache (and might flush it), our work floods the benign cache with seemingly existent domains.

NRDelegation [11] is a DNS complexity attack that uses a small number of different domains with a lengthy referral list to overload the CPU of a resolver and reduce its performance. The NRDelegation attack does not aim to attack the resolver's cache and only fills it with a few domains. In contrast, our attack emphasizes flooding the cache with different domains consistently to induce high cache miss rates and reduce the resolver's throughput. While a new complexity issue is also present in our paper, as a side problem we found, it does not play a significant role in harming the throughput as the CacheFlush, however new CVEs were issued.

In the discussion of DNS defenses during a DDoS attack, Moura et al. [33] demonstrate the impact of caching and long TTL. Since our attack removes domains from the cache before they reach the TTL by flooding the cache, the TTL does not play a significant role in our attack.

Liu et al. [28] build a DNS environment and modify the configurations of the resolver, authoritative, and zone files to discover vulnerabilities. This paper also raises the issue of the resolver continuing to query the authoritative for the CNAME chain that was already received in its entirety in the first message. However, they did not show that it can be exploited to flush the benign cache.

Kakarla et al. [25] create a verifier named GRoot that performs static analysis of DNS authoritative configuration files, enabling proactive and exhaustive checking for common DNS bugs. They develop a formal semantic model of DNS resolution and apply it to the configuration files from a campus network with over a hundred thousand records to reveal bugs. Our CacheFlush attacks do not contradict the RFC, and this paper cannot find it with their approach. The primary issue CacheFlush exploits is that the DNS RFC leaves many bounds open on the work after a DNS query, including the number of entries that can be entered into the benign cache.

9 Responsible Disclosure Procedure

We initiated a responsible disclosure procedure with several vendors after discovering the CacheFlush attack. In addition to collaborating with several parties one-on-one via encrypted email and GitLab channels, we also share our attack in a Mattermost channel with DNS-related vendors and third parties. Our cloud setup has been shared along with instructions on how to test the CacheFlush attack using the setup. Two CVEs [38, 39] have been already issued and additional ones are pending publication. The following are two quotations from one of the large parties involved in the disclosure: "It has been discovered that the effectiveness of the cache-cleaning algorithm used can be severely diminished by querying the resolver for specific RRsets" and "The rationale for this issue having a CVSS score of 7.5 (A:H) rather than 5.3 (A:L) is that the attacker can literally cause all legitimate traffic to time out when the attack is ongoing".

10 Conclusions

The vulnerability of DNS to DDoS attacks is well known and disturbing, as it is a key component of the welfare of the Internet. The Mirai attacks in 2016, which rendered services like Netflix unavailable for hours, demonstrated how vulnerable DNS can be and how much we rely on it. Since then, the research literature has made a lot of effort to make DNS more resilient and to identify and close vulnerabilities that still exist.

This paper sheds light on a key component of DNS and its resilience to attacks, which was overlooked until now: the cache. A key vulnerability stems from the fact that there is still no tight bound on the number of cache entries that can be added due to one DNS query. We show that surprisingly this can be up to 1520 records in NS and 20 in CNAME cacheFlush attacks, and it seems that much tighter bounds can be applied (8 and 20 respectively) as hinted in the mitigations suggested here.

While analyzing the Cache amplification factor of current DNS, we also discovered two additional complexity attacks.

This clearly demonstrates, once again, how important it is to systematically address the resource consumption in DNS servers.

A Appendix: The cost of attacking from the Cloud

The main expense of self-managed authoritative DNS in the cloud is the cost of outgoing traffic. As of June 2024, OCI [41], charges \$0.0085 for the transmission of 1 GB of outbound data from the VM. To flush a 2GB cache once per second, the largest cache tested in our experiments (rightmost column in Fig. 9), an attacker authoritative needs to send 20,000 query responses per second, which equals 1.3GB of data transfer ($20,000x65KB = 1.3GB$), which would cost \$0.01105 with OCI ($= 1.3GBx\$0.0085$). Thus it costs \$0.663 per minute for an attack that flushes a 2GB resolver cache so domains that are requested once per second or less have to be re-fetched on each query. In AWS, it costs \$0.09 to send 1GB to the Internet and \$0.01 for transfer within the same zone. Therefore, if the targeted resolver is maintained in AWS, the attacker can determine the zone based on the IP address and create the authoritative server in that zone area. In Azure, the price for internet-bound traffic is \$0.087, and \$0.02 for 1GB traffic within the same zone. In Google Cloud Platform (GCP), there is no cost for sending data within the same zone, \$0.01 for inter-zone transfers, \$0.085 for the first 10TB to the Internet, \$0.065 for 10-150TB, and \$0.045 for over 150TB. Consequently, if the target resolver is located in GCP, an attacker can exploit the attack without incurring costs. The secondary cost involves operating the machines for both the authoritative server and the client. For example running each machine in OCI costs \$0.00126 per minute. In comparison, the cost per minute for running a machine is \$0.00166 on AWS, \$0.0016 on Azure, and \$0.00158 on GCP. The most negligible cost is sending a DNS request from the attacker client. Each DNS query is approximately 100 Bytes. Therefore, sending 10,000 packets equates to 1MB of outgoing traffic. This cost is 1/1000th of the cost for the authoritative server, amounting to \$0.0000085. In total, the cost per minute to flush a 2GB cache every second for the authoritative server is $0.663 + 0.00126 = \$0.66426$. The cost for the client is $0.00126 + 0.0000085 = \$0.0012685$. Therefore, the total cost is \$0.6655285 per minute.

SnailLoad: Exploiting Remote Network Latency Measurements without JavaScript

Stefan Gast, Roland Czerny, Jonas Juffinger, Fabian Rauscher, Simone Franza, Daniel Gruss
Graz University of Technology

Abstract

Inferring user activities on a computer from network traffic is a well-studied attack vector. Previous work has shown that they can infer websites visited, videos watched, and even user actions within specific applications. However, all of these attacks require a scenario where the attacker can observe the (possibly encrypted) network traffic, e.g., through a person-in-the-middle (PITM) attack or sitting in physical proximity to monitor WiFi packets.

In this paper, we present SnailLoad, a new side-channel attack where the victim loads an asset, e.g., a file or an image, from an attacker-controlled server, exploiting the victim's network latency as a side channel tied to activities on the victim system, e.g., watching videos or websites. SnailLoad requires no JavaScript, no form of code execution on the victim system, and no user interaction but only a constant exchange of network packets, e.g., a network connection in the background. SnailLoad measures the latency to the victim system and infers the network activity on the victim system from the latency variations. We demonstrate SnailLoad in a non-PITM video-fingerprinting attack, where we use a single SnailLoad trace to infer what video a victim user is watching momentarily. For our evaluation, we focused on a set of 10 YouTube videos the victim watches, and show that SnailLoad reaches classification F_1 scores of up to 98 %. We also evaluated SnailLoad in an open-world top 100 website fingerprinting attack, resulting in an F_1 score of 62.8 %. This shows that numerous prior works, based on network traffic observations in PITM attack scenarios, could potentially be lifted to non-PITM remote attack scenarios.

1 Introduction

Side channels can leak information from implementations that are functionally correct and free of implementation errors [40]. Software-based side channels have gained an increasing amount of attention in the system security community, in particular cache attacks, which exploit timing differences induced by the caching infrastructure of a system [52, 79]. Software-based timing attacks, in particular on the cache, have been demonstrated on cryptographic algorithms [8], on ASLR (address-space layout randomization) [23, 31], secure enclaves [61], from websites [51], and to build covert channels [45, 59]. Most of these works study local scenarios where an attacker can execute native code [31], sandboxed code [77], or code run in an interpreter [62].

Other works study remote scenarios, typically with implementation-specific operations, such as encryption interfaces [10] or special hardware interfaces [42]. A more extensive set of works focuses on fingerprinting [65] using remote side channels, e.g., via passive traffic analysis from within the same network [7, 47, 70, 71]. Alexander and Crandall [4] focused on a more active attack scenario with spoofed SYN packets, triggering interaction between victim and server that the attacker can passively observe. Most works in this space, however, focus on person-in-the-middle scenarios to fingerprint, e.g., applications [69, 74] or websites [9, 58]. That is, they assume that the attacker controls at least one gateway or router in the path between server and victim. Naturally, this allows to monitor precise transmission times of packets, as well as their types and sizes [2, 16, 17, 26, 29, 38, 39, 41, 54, 66, 67, 72]. Passive remote attacks have so far only been demonstrated in the context of the Tor anonymity network [46, 48]. Murdoch and Danezis [48] showed that they can reconstruct the activity of a Tor relay node using passive latency measurements.

Given this prior work we ask the following question: *Can a passive remote attacker use latency measurements as a side channel for browsing activity on a victim system? Can such a side-channel attack be mounted over the Internet?*

In this paper, we answer both questions in the affirmative: We show that neither specific code on the victim machine nor direct observation of the possibly encrypted network traffic is required to infer browsing activity on the victim system. We show that these attacks are possible from arbitrary Internet servers, with distances of more than 8 hops to the victim, and with only minimal network activity. SnailLoad exploits the subtle variations in the round-trip times (RTTs) of net-

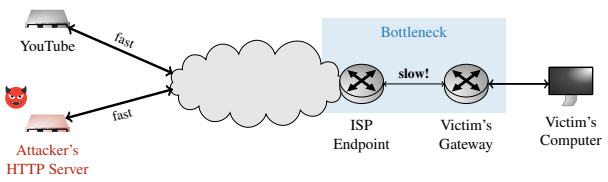

Figure 1: The attack setup for SnailLoad. A victim downloads data from an attacker's HTTP server while it watches a video on a video-sharing platform, e.g., YouTube. Due to the network bottleneck on the victim's side, the attacker can infer the transmitted amount of data by measuring the packet round trip time. The round trip time traces are unique per video and can be used to classify the video watched by the victim.

work packets that carry a side-channel signal influenced by activity of the victim. This enables an attacker to perform network side-channel attacks, that so far required a person-in-the-middle (PITM) scenario, from a fully passive and fully remote scenario off the transport path between victim and server.

We investigate the latency variations by analyzing the RTTs for different internet connections. Our analysis shows that the root cause of SnailLoad are bandwidth differences in the transport path between victim and server. As the server cannot know how fast the victim can receive the packets, it sends a certain amount (*i.e.*, a burst) of data in a short time frame. If there is a node on the transport path that hands over data from a higher bandwidth channel to a lower bandwidth channel, it has to buffer packets to transmit them sequentially over the lower bandwidth channel. Extreme cases where buffering leads to unusually high latencies are known as the *bufferbloat* phenomenon. While bufferbloat has only been considered a quality-of-service issue so far, SnailLoad shows that the timing differences induced by this buffering are exploitable by any attacker that can send packets through the same network node to the victim. Importantly, this node is typically the last node connecting the victim exclusively to the internet, *i.e.*, all packets to and from a victim pass through this node.

We evaluate SnailLoad in the first fully remote, non-person-in-the-middle web activity fingerprinting attack. To remain stealthy and to evade widely-used firewall restrictions (e.g., ICMP ping messages being dropped), we masquerade our SnailLoad latency measurements as a slow HTTP transfer from an attacker-controlled web server. This HTTP transfer can be a background connection, e.g., for a messenger app, or a slow website component embedded (e.g., an advertisement, image, font, or style sheet) in an otherwise benign and responsive website. Importantly, SnailLoad runs no code, e.g., no JavaScript, on the victim system. We show that a single SnailLoad trace from this scenario suffices to infer what video a victim user is watching momentarily. For our evaluation, we focused on a set of 10 YouTube videos the victim watches, and reach classification F_1 scores of up to 98 %. We also evaluated SnailLoad in an open-world website fingerprinting attack, resulting in a macro-averaged F_1 score of 62.8 %. When using SnailLoad across connections, with training data from one connection applied to another, we still achieve an F_1 score of 40 % in a top-10 closed-world fingerprinting scenario.

We evaluate the general applicability of SnailLoad on 10 home internet connections using ADSL, FTTH, FTTB, LTE, and cable access technologies. With training data from the victim's internet connection over the top 10 YouTube videos, played for 90 s with Firefox, we achieve F_1 scores between 37 % on an FTTB connection and 98 % on an FTTH connection. Our evaluation shows variations in the accuracy between internet access technologies, depending on whether the last-mile transport medium is shared among multiple subscribers or not. We evaluate the attack performance for probing frequencies between 20 Hz to 5 000 Hz, resulting in 0.4 kB/s to 320 kB/s of network traffic, in relation to differently-sized network activity of the victim ranging from 512 B to 8 MB. Our results show that with a higher probing frequency, we can observe also smaller-sized network activity of the victim. However, below a size of 512 kB, we find no probing frequency that leaks the network activity reliably. This is most likely due to not causing sufficient traffic for a visible amount of contention on the packet queue before the last mile, resulting in no visible delay for the attacker's packets.

We conclude that numerous prior works on network side channels in PITM attack scenarios could potentially be lifted to a remote non-PITM attack scenario based on SnailLoad.

Contributions. We summarize our contributions as follows:

1. We present SnailLoad, a new side-channel attack exploiting latency variations of the victim's network connection measured by loading an asset from an attacker-controlled server; allowing to infer web activity of a victim.
2. We show that the root cause of the side channel is buffering in a transport path node, typically the last node before the user's modem or router, related to a quality-of-service issue called bufferbloat.
3. We show that SnailLoad works despite the blocking of ICMP echo packets, through a low-bandwidth background connection such as a slow download, slow loading image in a website, or a connection for a chat client.
4. We evaluate SnailLoad in a user study with 10 different internet connections and 6 different connection technologies, achieving video-fingerprinting F_1 scores of 37 % to 98 %. We also evaluate SnailLoad in a top-100 open-world website-fingerprinting attack, achieving an F_1 score of 62.8 %.

Outline. Section 2 provides background on internet technologies and remote fingerprinting side-channel attacks. Section 3 presents the basic latency measurements that are the foundation of SnailLoad. Section 4 examines the root cause

of SnailLoad. Section 5 presents the threat model and attack setup of SnailLoad. Section 6 evaluates SnailLoad in a video-fingerprinting scenario. We performed a user study comprising 10 different internet connections and 6 different internet connection technologies. Section 7 presents a top-100 open-world website-fingerprinting attack. We discuss the impact of SnailLoad and the relevant scenarios in Section 8. We conclude in Section 9.

2 Background

We provide background on internet access technologies typically used by end users to connect to the internet. Furthermore, we briefly introduce TCP/IP networking and dynamic adaptive streaming over HTTP. Finally, we describe video fingerprinting attacks and remote timing side channels.

2.1 Internet Access Technologies

While fast backbone internet routers deliver 100 Gbit/s per trunk line [24], with a recently ongoing shift to 400 Gbit/s technology [15], the last mile of an internet connection still forms a bandwidth bottleneck. For Q3 2023, a recent study [37] of an internet speed test provider shows a worldwide median download speed of 83.95 Mbit/s for wired connections and a worldwide median download speed of 203.04 Mbit/s for 5G connections, with high variations between different countries.

The prevalent connection types for end-users are DSL, cable, fiber optic, and mobile. In this section, we briefly describe their characteristics.

Digital Subscriber Line (DSL) DSL is an internet connection technology utilizing existing copper telephone lines. Multiple subscribers are connected to a DSL access multiplexer (DSLAM) before forwarding the connection to the internet service provider (ISP). The location of the DSLAM is an essential factor in the achievable bandwidth due to signal attenuation increasing with the length of the copper lines [21].

DSL has a low bandwidth and high latency compared to other technologies like cable and fiber optics. Download bandwidths typically range from 5 Mbit/s to 120 Mbit/s, with upload bandwidths from 1 Mbit/s to 20 Mbit/s. Since the last mile of DSL is shared between multiple participants, the bandwidth can be limited when many participants use the shared line. This also influences the latency.

Cable Similarly to DSL, cable internet also takes advantage of existing infrastructure: the coaxial cables for cable television. The Data Over Cable Service Interface Specification (DOCSIS) is a set of specifications standardizing data transmission over television cable systems [32]. In contrast to DSL, the length of the data cable, due to being a coaxial cable, is not that influential on the bandwidth.

However, the number of end users sharing the same connection strongly influences the bandwidth. The download bandwidth of cable internet is up to 10 Gbit/s with DOCSIS 4.0, and the upload bandwidth is up to 6 Gbit/s [32].

Fiber optic Fiber optic internet connections use light impulses transmitted via a fiber optic cable. They provide the highest bandwidth and lowest latency for data transmission, reaching up to 50 Gbit/s symmetric [19]. The fiber optic cable itself does not constrain this bandwidth but instead by the capabilities of the terminal equipment [56].

Fiber optic internet connections vary based on the composition of the last mile's connectivity. In a fiber-to-the-home (FTTH) setup, the entire last mile exclusively uses fiber optic cables, resulting in a non-shared, highly efficient connection.

In different, less costly configurations, such as Fiber-to-the-Curb (FTTC) or Fiber-to-the-Building (FTTB), existing infrastructure like coaxial cables links homes to the optical fiber network. In many instances, this leads to sharing lines with other users, similar to cable and DSL connections.

Mobile In contrast to the previously described wired technologies, the router is wirelessly connected to a cellular tower for a mobile internet connection. Because they generally serve multiple clients, the last mile of the connection is inherently shared, making the bandwidth and quality of the connection highly dependent on the number of clients.

The 5G standard uses higher frequency bands to increase bandwidth and reduce latency compared to 4G. Due to the higher frequency, 5G towers can only serve a smaller area than 4G towers. This leads to fewer users sharing the last mile, improving signal quality due to reduced congestion.

The bandwidth of 4G is up to 150 Mbit/s for download and up to 50 Mbit/s for upload. 4G+ increased it to 300 Mbit/s and 150 Mbit/s respectively [55]. 5G can reach significantly higher bandwidths, with up to 20 Gbit/s for download and 10 Gbit/s for upload [33].

2.2 TCP/IP Networking

The Transmission Control Protocol (TCP) is a protocol ensuring the correct and ordered transmission of data over a network. It works closely with the Internet Protocol (IP) that enables the transmission of packets across network boundaries from a specific source to a receiver. TCP/IP, the combined suite, forms the foundation of most modern internet communications, supporting a wide array of applications like web browsing (HTTP), E-Mail, and file transfers.

Packet Acknowledgment TCP is a connection-oriented protocol, using a handshake mechanism to establish a connection between sender and receiver. Upon the arrival of a packet,

the receiver sends an acknowledgment packet (ACK) back to the sender, enabling the retransmission of lost packets.

TCP is implemented using send and receive buffers. Packets reside in the send buffer until an ACK is received. The size of the send buffer determines how many not-yet-acknowledged packets can be in transit. A receive buffer holds all received packets the application still needs to read.

Congestion Control Another vital feature of TCP is congestion control, which is crucial for maintaining a stable network, especially when it becomes heavily loaded. TCP employs several mechanisms to avoid or remove network congestion.

A congestion window determines the amount of data the sender may send before receiving an ACK packet. The size of the congestion window is controlled by the sender and is based on its perception of network congestion using information like lost or delayed ACK packets. The value adapts dynamically to the current load of the network.

To determine the congestion window size, typically, an algorithm known as *slow start* is employed. The initially small congestion window size is doubled upon each successful round trip until it reaches a threshold where packet loss is detected. Once the threshold is reached, TCP transitions from *slow start* to *congestion avoidance*. In this mode, the window size is changed more slowly to avoid congestion.

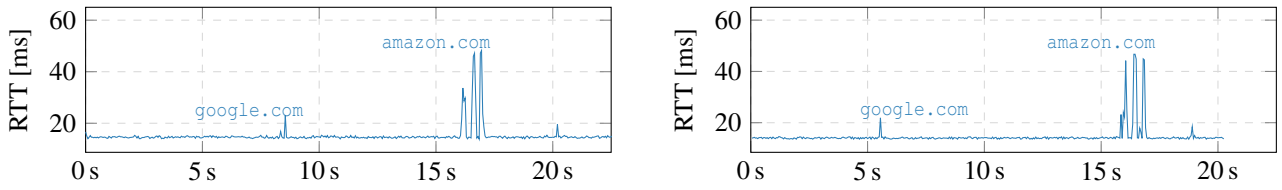
2.3 Dynamic Adaptive Streaming over HTTP

Dynamic Adaptive Streaming over HTTP (DASH) is a standard for video streaming [35], used by multiple video streaming services, including YouTube [26, 39]. DASH servers split videos into small chunks of typically 2–6 seconds, each with multiple quality levels, allowing the client to request each chunk on demand, dynamically choosing a suitable bitrate, based on the available bandwidth. Video codecs and streaming services typically use variable-bitrate (VBR) encoding [6], enabling them to save bandwidth for scenes with only minor picture changes and to increase the bitrate for scenes containing more motion. Consequently, timing and sizes of transferred chunks differ for each video, based on the content.

2.4 Video Fingerprinting Attacks

As the timings and sizes of the transferred chunks form an individual fingerprint of each video, an attacker can infer the video played from the victim's network traffic by matching the observed traffic metadata against prerecorded traces. Multiple prior video fingerprinting attacks monitored network traffic directly from a PITM position [16, 26, 27, 38, 39] or from a WiFi signal [16]. More recent work [57] demonstrated a video fingerprinting attack based on the detection of network interrupts on the victim machine, indirectly observing network traffic. Inferring videos from traces is a typical classification task. Prior attacks used different classification methods, such as Dynamic Time Warping [26], Minimum Variance Matching [26], Nearest Neighbor Classification [16], Support Vector Machines [16], Sequential Minimal Optimization [39] or, more recently, convolutional neural networks [38, 39, 57].

2.5 Remote Timing Side Channels



In the context of side-channel attacks, the term *remote* has been used for a variety of scenarios. Some works described JavaScript-based attacks as *remote* [18, 25, 51, 76], other attacks focus on specific interfaces, e.g., encryption interfaces or encrypted web traffic [8, 10, 13, 14, 63], and a third category of attacks works by only sending network packets to a machine without targeting specific interfaces [42, 44, 73]. All of these attacks rely on implementation-specific operations that the victim system performs that are unrelated to the actual victim activity targeted. Contention of buffers within the local (wireless) network [75] same system [20] can also contribute to performance anomalies that SnailLoad exploits.

In the context of IoT devices, passive traffic analysis from within the same network has been demonstrated to allow derivation of privacy-related information [7, 47, 71]. This is related to a line of research fingerprinting encrypted web traffic [65]. Previous works have demonstrated application fingerprinting [69, 74], video fingerprinting [16, 68], and website fingerprinting [9, 58]. The two attack scenarios for these works are either a *local network attacker*, controlling a gateway in the local network far enough to spy on the traffic of a specific machine [7, 47, 70, 71], or a *remote network attacker*, controlling a router somewhere in the path between server and victim. More active attacks can also trigger interaction between victim and server that the attacker then measures [4]. Different features that are available to such person-in-the-middle attackers have been exploited [2, 16, 17, 26, 29, 38, 39, 72], e.g., message type [41, 67], packet length [54, 66]. Rather passive remote attacks have so far only been demonstrated in the context of the Tor network [46, 48]. Murdoch and Danezis [48] showed that they can reconstruct the activity of a Tor relay node using passive latency measurements. Finally, many network side-channel works focus on the information recovery rather than the information collection aspect [9, 16, 58, 68].

3 The Latency Side Channel

In this section, we **do not** yet mount an SnailLoad but only study the latency side channel. We examine latency variations on internet connections depending on different activities and show that the ISP's endpoint and the last mile have a significant influence. Our initial experiments also show that the effect can be observed by any unauthorized and unprivileged third party with a network connection to the system.

For now, we measure latencies using ICMP pings. For our SnailLoad attack later on, we have to resort to other packets as networks today commonly filter "ping packets" by default.

(a) Same machine pinging `8.8.8.8`.

(b) Different machine in the same network pinging `8.8.8.8`

Figure 2: Effect of internet connection activity on the round trip times. A machine is constantly pinging `8.8.8.8` while the two websites `google.com` and `amazon.com` are opened. The internet is provided by a 50 Mbit/s ADSL connection.

The `ping` command sends an *ICMP Echo Request* to the target machine, which in turn responds with an *ICMP Echo Reply*. The latency between sending the ICMP Echo Request and receiving the ICMP Echo Reply is recorded as the *round trip time (RTT)*. Typical use cases of the `ping` command focus on the round trip time, e.g., to monitor the network status.

For our first experiment, we use a 50 Mbit/s ADSL connection, with a client machine directly connnected to the internet gateway (*i.e.*, home router) via an Ethernet cable. On the client machine, we `ping` the Google DNS server (IP: 8.8.8.8) with an interval of 50 ms and record the RTTs over time. Accessing `google.com` and `amazon.com` on the same machine shows RTT spikes while loading (cf. Figure 2a). We can see that this effect is quite subtle for a comparably plain website like the Google start page, while it is more noticeable for more complex websites like the Amazon start page. This is a surprising observation as either of the websites only triggers a few hundred kilobytes of traffic, nothing that should affect the network response times in a significant way.

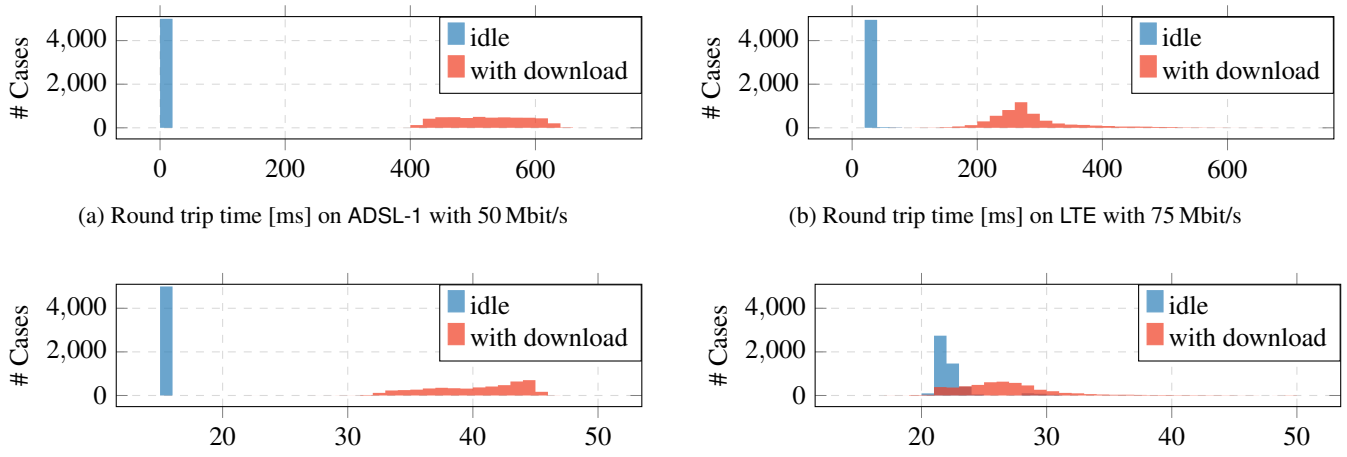
> The latency is influenced by small degrees of victim internet activity already.

In a second experiment, we show that the latency spikes are not caused by an effect on the client computer, e.g., kernel- or user-level packet handling, or system activity due to rendering. We repeat the experiment on the same internet connection but on a second machine directly connected to the gateway. We still `ping` the server from the first machine but load the websites on the second machine. This experiment results in the same latency spikes as shown in Figure 2b. This observation shows that the effect is not caused by any hardware or software component of either of the two client computers.

> The latency is influenced by internet activity on other systems in the same network.

We also verify that the effect is not caused by the network connection between the two client machines. For this, the first client machine `ping`s the second machine, with the second machine loading the websites. In this scenario, we do not observe any latency spikes corresponding to website loads. We repeat the same experiment with a `ping` interval of 10 ms, again without observing latency spikes. The average RTT in this setting is 0.91 ms ($n = 2\,223$), with a maximum of only 1.5 ms at the start of the measurement, unrelated to the website loads. These results indicate that the observed latency spikes are caused by either the ISP's endpoint, the home internet gateway, or the last mile in between.

> The latency is influenced by the ISP's endpoint and the last mile.



4 Latency Side Channel Root Cause Analysis

In this section, we analyze the root cause for the latency spikes observed in Section 3. We show that these can be explained by packet buffering at the ISP's endpoint, to which the customer's internet gateway is connected on the last mile.

As the last mile of the user's internet connection has a significantly lower bandwidth than backbone internet infrastructure (see Section 2.1), there is a bandwidth bottleneck at the ISP's endpoint (*i.e.*, DSLAM, CMTS, ONT, or cell tower). Network components, such as switches and routers, connect a high-bandwidth to a low-bandwidth network segment and buffer packets to be forwarded to the low-bandwidth segment. This prevents packet loss when the low bandwidth segment is congested. However, as packets have to be forwarded sequentially, a busy low-bandwidth connection delays the delivery of packets coming from the high-bandwidth segments.

> The root cause of the latency side channel is the buffering of packets in nodes between high-bandwidth and low-bandwidth network segments, often located directly before the last mile. Typically, all internet packets for a specific user have to pass through this node.

We investigate the extent of this delay for 11 internet connections by comparing their baseline and congested `ping` round-trip times (RTTs). We directly connect a client computer to the home internet gateway (*i.e.*, router) via a standard 1000BASE-T (ethernet) cable and `ping` the Google DNS server (IP address: `8.8.8.8`). To measure the baseline RTT, we perform the measurement while the connection is other-

wise idle. For the congested RTT, we perform the measurement while downloading a large file from a web server. We verify that the chosen download server has a transfer rate higher than the maximum download rate of the tested home internet connections by measuring its transfer rate at the university, where we measure a transfer rate of approximately 800 Mbit/s.

Our results, summarized in Table 1, show a substantial increase in the average RTTs for all the internet connections we tested. The histograms in Figure 3 show the distributions of the RTTs with and without a download running in parallel for an ADSL, an LTE, an FTTH, and a cable connection. Each of the internet connections we tested has characteristic distributions, showing that we are observing an effect specific to the internet connection itself.

Some of the tested connections show average RTTs of more than 150 ms when they are congested, such as the ADSL connections (ADSL-1 and ADSL-2 in Table 1) and the mobile connections (LTE and LTE+). These more extreme latency increases are caused by excessive buffering in network components, a networking problem known as bufferbloat [5, 20, 36]. While bufferbloat can be mitigated by Active Queue Management (AQM) schemes, such as CoDel [50, 64] or PIE [53], we want to emphasize that these only prevent excessive buffering and reduce the delay caused by it. Even with AQM schemes, the low-bandwidth bottleneck still exists, and some (reduced) form of buffering is required to prevent excessive packet loss. Thus, AQM reduces the difference in RTTs between an idle and a congested last mile. However, it cannot entirely eliminate the difference. Hence, all the tested connections carry a side-channel signal leaking usage information. Only for some of these connections, the side-channel signal is amplified by a heavy bufferbloat. Figure 4 illustrates the latency differences for idle, busy, and bufferbloat-affected connections.

(a) Connection idle: packet forwarded immediately.

(b) Connection busy: packet buffered for a short delay.

(c) Bufferbloat: Excessive packets lead to long delays.

Figure 4: The effect of congestion on network latencies. The forwarding delay of the measurement packet correlates with the occupancy of the buffer in the router.

In extreme cases, the latency is amplified by the bufferbloat phenomenon.

While our analysis provides a good understanding of the latency side channel and the root cause of the latency variations and spikes, we now move on to the SnailLoad attack.

5 SnailLoad: Video-Fingerprinting Attack

In this section, we describe the SnailLoad attack in detail, starting with the threat model and attack overview. Because we cannot use `ping` to measure RTTs, we show a new accurate method to measure RTTs using TCP ACK packets. This method uses only 400 B/s of network traffic. Using it, we record network latency traces of streamed videos and classify them using a convolutional neural network. The average classification accuracy of 10 videos over all 10 tested internet connections is 66.8 %.

5.1 Threat Model

The attacker wants to know which video the victim user is watching. The attacker runs a native code TCP server and causes the victim to initiate a TCP connection with a download from the server while watching the video. As any background TCP transfer is enough to conduct SnailLoad, there are numerous ways to deploy it, e.g., download mirrors for legitimate benign software, (third-party) website assets like images, and several other scenarios (see Section 8). Importantly, the attacker cannot run any code on the victim machine, *i.e.*, the client application accessing the web server does not execute JavaScript or WebAssembly originating from the attacker's web server. We furthermore do not assume ICMP Echo Requests and ICMP Echo Responses to be forwarded between the victim and the attacker, *i.e.*, `ping` is blocked, a standard router configuration today [60].

Algorithm 1: Measuring round trip times using TCP Acknowledgment messages from a Linux process

Input: A socket descriptor `sock` with the **TCP_NODELAY** option set
Input: A single byte `b` to be sent to the client
Result: The measured round trip time `rtt`

```
1  begin
2      acked ← false;
3      start ← get_current_time();
4      send(sock, b, 1, 0);
5      repeat
6          if ioctl(sock, SIOCOUTQ) = 0 then
7              acked ← true;
8          end
9      until acked;
10     end ← get_current_time();
11     return end − start;
12 end
```

5.2 Attack Overview

Our video-stream fingerprinting attack consists of an online recording phase and an offline post-processing phase. During the recording phase, the attacking server records the network latency trace of the victim watching the first 90 seconds of a video, measuring the round trip times of single-byte TCP packets and their corresponding acknowledgment messages. In the post-processing phase, we infer which video was played from the recorded trace using a convolutional neural network trained with traces from an identical network setup.

5.3 Network Latency from TCP ACKs

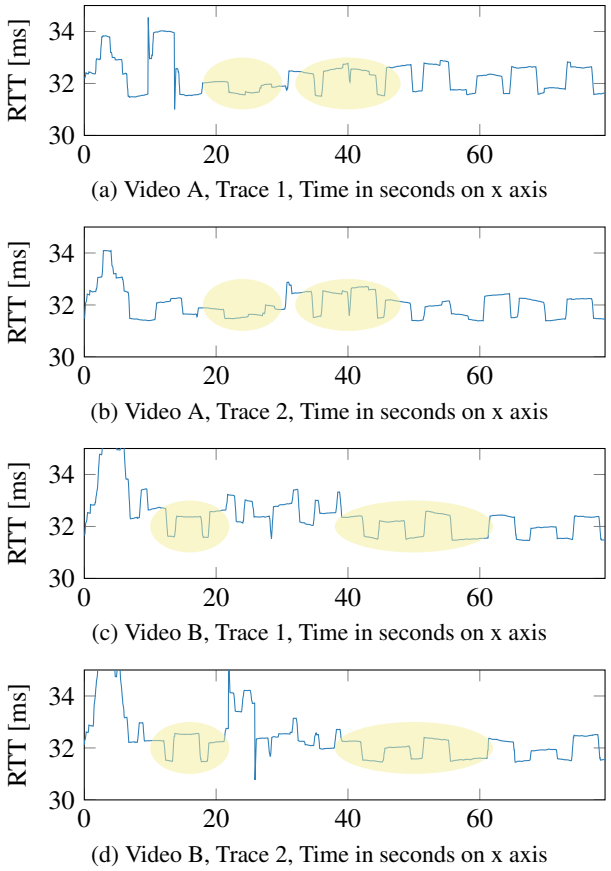
In the previous experiments, we measured network round trip times using the `ping` command that was running on the victim machine. However, in our threat model, the attacker does not have control over the victim machine. We implement a similar measurement with code only running on the attacker-controlled server. While, in principle, it is possible to ping the public IP address of the victim machine, the attacker might not know the victim's public IP address in advance, and the internet gateway of the victim might be configured to drop ICMP echo requests for security reasons [60]. In this section, therefore, we exploit the TCP acknowledgment mechanism to measure round trip times, *i.e.*, any open TCP connection between victim and server is sufficient to record round trip times periodically.

5.3.1 TCP Packet Acknowledgments

To ensure reliable transmission, TCP requires the recipient to acknowledge each segment back to the server. For this, the receiver sends back a TCP message to the sender with the `ACK`

flag and the acknowledgment number set in the TCP header (see Section 2.2). Measuring the time between sending some data and receiving the corresponding TCP acknowledgment again results in the round trip time, similar to using ICMP Echo Requests and Replies as before. However, unlike ICMP Echo Requests and Echo Responses, TCP acknowledgments are required for every TCP connection, and, therefore, they cannot be blocked globally.

A single, low-traffic TCP connection is sufficient to mount SnailLoad. Blocking ICMP Echo messages does not prevent SnailLoad.



5.3.2 TCP Packet Acknowledgment Detection

Linux does not provide a standardized way to inform a user space application of packet acknowledgments. However, by probing the number of packets in the send buffer, we can see when a packet was acknowledged because it is removed from the send buffer. The equivalent information can also be obtained using *libpcap*, as we show in Section 7.

Algorithm 1 shows how such a measurement is implemented in a Linux server process. After obtaining the start time (Line 3), we invoke the `send` system call to enqueue a single byte to be transmitted to the victim machine (Line 4). As `send` returns immediately after placing the data to be sent in the send buffer, only timing the `send` system call is not sufficient. However, as described in Section 2.2, sent data is removed from the send buffer as soon as the server receives an acknowledgment for it. Consequently, in Line 5 until Line 9, we wait until the send buffer becomes empty again, using the `SIOCOUTQ` socket `ioctl` call to retrieve the number of bytes currently in the send buffer (Line 6). As soon as that number is 0 again, we leave the loop and obtain the end time in Line 10, yielding the round trip time as the difference between the end time and the start time (Line 11). Alternatively, an equivalent approach with *libpcap* can be used to match outgoing packets and incoming ACKs (cf. Section 7). For probing frequencies that may exceed the round-trip time of the connection, we resort to *libpcap*, and use the send buffer for lower frequency attacks (e.g., Section 6).

By setting the `TCP_NODELAY` socket option, we disable Nagle's Algorithm [34,49] to ensure that each of the single bytes is sent out immediately in separate TCP packets without merging multiple bytes into a single TCP packet. Consequently, each single byte is acknowledged separately by the victim machine. Therefore, each single-byte transmission enables the server to measure the round trip time to the victim. Furthermore, sending each byte in a separate TCP packet prevents measurement influence from changing TCP transmission window sizes.

It is possible to detect TCP packet acknowledgments with user privileges by polling the TCP send buffer.

(d) Video B, Trace 2, Time in seconds on x axis

Figure 5: Averaged RTT traces from a client watching two different videos twice. There are features to distinguish the two videos and match the two traces of the identical videos.

5.3.3 Web Server Implementation

While SnailLoad works with any TCP connection, we implement a web server offering a file via HTTP to record network latency traces due to the large compatibility with existing client applications, *i.e.*, web browsers. The victim connects to the web server and requests the file. After sending back the HTTP header, the server performs latency measurements while transferring the file content. Every 50 ms, the server sends a single byte to the client and measures the round trip time by polling the send buffer, as previously described. We choose 50 ms as the time slice, since we want to have a high temporal resolution, yet we do not want to exceed the regular round trip time of an idle connection. This results in a low transfer rate of only $\frac{1\,\mathrm{B}}{50\,\mathrm{ms}} = 20\,\mathrm{B/s}$ visible to the user, which gives SnailLoad its name. Effectively, due to the overhead of TCP/IP, this results in 400 B/s of network traffic, which is still very unsuspicious given that internet connections today can commonly handle multiple megabytes per second. Figure 5 shows the traces of one client watching two different videos two times. We can recognize the clear similarity between the

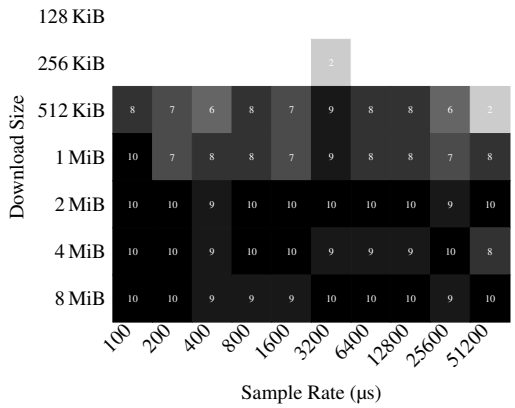

Figure 6: Identified downloads for different download sizes and sampling rates ($n = 10$). Evaluation with ADSL-1 (50 Mbit/s) connection.

same videos (traces 1 and 2) and see distinctive features for the other video (traces 3 and 4).

5.4 Attack Parameter Sweep

To determine the conditions under which the side channel works, we perform a parameter sweep, shown in Figure 6, with different download sizes and sample rates. The evaluation was done on the ADSL-1 (50 Mbit/s) connection. We evaluated sampling rates specified as window sizes between 100 µs, corresponding to 100 kHz, to 51 200 µs, corresponding to 19.5 Hz. Translating the connection capacity to these window sizes we obtain 336 kB per 51 200 µs and 655 B per 100 µs. Thus, in theory, transmitting as much data within this time frame should lead to contention in the buffer before the last mile and thus to a visible latency difference. However, as we see in Figure 6, even for higher sampling rates, we cannot reliably detect downloads of less than 512 kB. The reason for this may be that slow-start or congestion-avoidance mechanisms successfully prevent the negative impact of the download's packets on other packets. Furthermore, at higher sampling rates the TCP stack also starts grouping packets, effectively keeping the sampling rate higher than attempted. This observation can also be the reason for lower accuracies for some websites in our website-fingerprinting attack in Section 7.1, *i.e.*, due to their relatively low size.

5.5 Classifying Network Latency Traces with a Convolutional Neural Network

In order to efficiently classify the network latency traces, we employ a method typically used in signal classification [12, 30, 57, 78]. To classify a network latency trace, we first apply a Short-Time Fourier Transform (STFT) to it. An STFT performs multiple Fourier Transforms on short time windows of the network trace. The output of the STFT consists of two dimensions, with one dimension being the time and a second dimension being individual Fourier Transforms on the time slices, corresponding to the change in frequency over time. These two dimensions provide us with frequency information from the network trace while partially preserving the time domain. The 2D STFT allows us to perform convolutions on the data, which would not be directly possible with the initial one-dimensional network latency traces. We feed the output of the STFT into a convolutional neural network (CNN) for classification. We use KERAS (Tensorflow) on an Intel(R) Core(TM) i5-10210U CPU, with a runtime of 5 min to 10 min. The layout of the CNN is shown in Table 2. The CNN consists of three convolutional layers followed by three dense layers. The final layer outputs the likelihood that the input corresponds to a specific label for each possible label.

Table 2: CNN Parameters

6 SnailLoad: Video-Fingerprinting Evaluation

In this section, we show that SnailLoad leaks privacy-relevant information about which video a victim is playing. We evaluate SnailLoad on 10 different home internet connections. For a set of 10 YouTube videos, played for 90 s in Full HD resolution, our evaluation shows an accuracy of up to 98 %.

We select the videos in two steps: From the videos trending in the USA between October 2022 and September 2023, we first select the videos with at least 70 million views, yielding 23 videos. In the second step, we randomly select 10 videos out of this subset.

For each internet connection, we repeat the following three steps: First, we record 50 traces of the first 90 s of each of the 10 videos (Section 6.1). In the second step, we reserve a randomly selected subset of 10 traces per video as a test set and use the remaining 40 traces to train our CNN-based classifier (Section 6.2). Finally, we evaluate the trained model on the test set (Section 6.3).

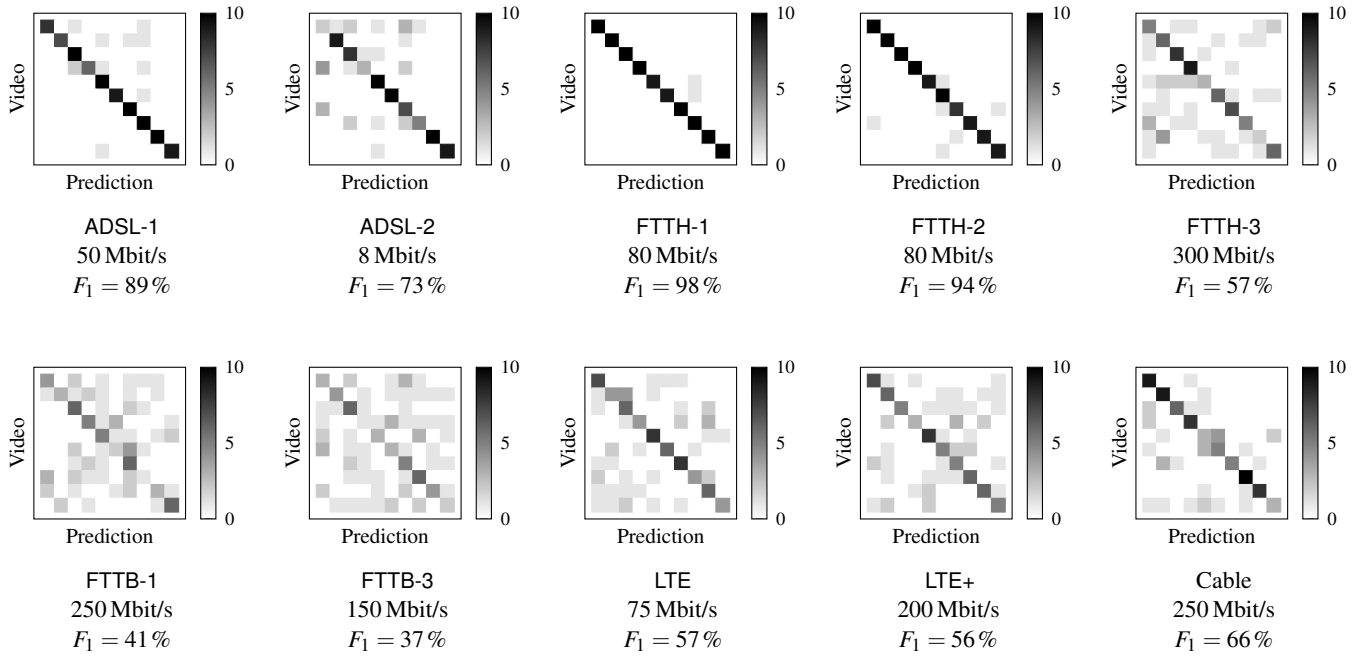

Figure 7: Confusion matrices for YouTube video fingerprinting on 10 internet connections.

6.1 Recording the Network Latency Traces

For each connection, we successively record traces for the 10 videos and repeat the recording in 2 batches with 25 iterations. Recording the videos successively during each iteration prevents correlations between daytime-dependent noise and the played video. For each trace, the client starts the SnailLoad HTTP file transfer and, after waiting for 3 s, also starts watching the video. After 90 s, the client aborts the file transfer and closes the video. After a pause of 3 s, the client continues with the next video. In total, recording all 500 traces for a single connection takes approximately 13.5 h.

Each recording is performed on one of two hosted servers, both of them connected to the Internet via a 1 Gbit/s downlink. Both servers are more than 8 hops away from the client machine, as tested with the `traceroute` command.

On the client machine, we use Firefox for both the HTTP file transfer and for watching the video. However, as the network-latency side channel is independent of the browser and operating system being used, we can expect similar results using another client configuration. We also tested this in smaller experiments but focused on this specific setup for the large-scale evaluation. As our traces shall only contain data from videos requested by the user, without any advertisements, we use uBlock Origin [28] as an ad blocker. Using an ad blocker is not strictly required for the attack because advertisements are effectively separate videos, and prior work [6] has shown that each video starts with a characteristic burst of network traffic, allowing the attacker to separate the advertisements from the video. However, it would increase the time until the video starts, prolonging the time the participants of our user study need to run the measurement. Hence, we opted for ad blocking to reduce the time for the participants.

6.2 Training the Classifier

After recording, we split the 50 traces of the 10 videos into training, validation and test sets. Following best practices [1], we use a training set of 36 traces per video to fit the model, a validation set of 4 traces per video to evaluate the model during training and a test set of 10 traces for the final evaluation of the trained model. For each internet connection, the individual hyperparameters for the CNN were empirically chosen to achieve good generalization against the validation set.

6.3 Results

After training the classifier for the internet connection, we evaluate the model on the test set. Figure 7 shows the results for all the 10 internet connections we tested. Each cell shows the probability that the classifier assigns the label indicated by the column to the videos indicated by the row. White or light gray cells indicate a low probability, whereas black or dark gray cells indicate a high probability. We also provide the F_1 scores we obtained for each connection.

For all the internet connections we tested, we obtain F_1 scores significantly better than random guessing (which would be $F_1 = 10\,\%$). The high probabilities along the diagonals in the confusion matrices also support that our attack works

on all the tested connections. Overall, our F_1 scores range from 98 % for the FTTH-1 connection to 37 % for the FTTB-3 connection.

When comparing the FTTH connections, we notice a difference in accuracy between the 80 Mbit/s (FTTH-1, FTTH-2) and the 300 Mbit/s connection (FTTH-3). A lower bandwidth increases the transfer duration of the video segments, resulting in signal features that are easier to detect for our classifier. Thus, on the lower bandwidth FTTH-1 and FTTH-2 connections, we achieved accuracies of 98 % and 94 %, respectively, whereas on the higher bandwidth FTTH-3 connection, the accuracy was 57 %.

When comparing the results from the fiber-based connections, we notice a difference in accuracy between the FTTH connections and the FTTB connections. The accuracy with the FTTB-1 and FTTB-3 connections was significantly lower, with F_1 scores of only 41 % and 37 %, respectively. This might be caused by noise from other customers using the same shared fiber cable of the FTTB connection simultaneously. Especially for the FTTB-3 connection, when measuring the RTTs for the congested case in Section 4, we observed significant fluctuations in the measured latencies, which have a standard deviation of $\sigma = 12.595$ ms ($n = 5000$). This is relatively high when compared to the average RTT difference between the idle and congested case of only 13.014 ms, and thus makes detecting relevant features more challenging for the classifier.

Compared to the FTTB connections, we achieved higher accuracies on the cable and mobile connections. With the Cable connection, the accuracy was $F_1 = 66$ %. For the mobile LTE and LTE+ connection, we achieved similar F_1 scores of 57 % and 56 %, respectively. These comparatively high accuracies are surprising, as for both cable and mobile connections, the last mile is shared among multiple customers, similar to FTTB. However, both cable [32] and LTE [55] divide the frequency band used for transmissions into separate channels, possibly reducing the sharing between customers.

On both ADSL connections, we also achieved high accuracies of $F_1 = 89$ % (ADSL-1) and $F_1 = 73$ % (ADSL-2). The relatively low bandwidth contributes to prominent signal features (as shown in Figure 5) that improve the accuracy.

Overall, as with other fingerprinting attacks, the accuracy can be improved with more training data, *i.e.*, more or longer traces per video. However, we aimed to cover a wide variety of internet connections and recruited volunteers for recording the traces. While our recording time was limited for practical reasons, we assume that a dedicated attacker has the resources available to record more training data and thus to improve the accuracy of the attack even further.

We repeated the attack on the ADSL-1 connection, with the video quality reduced to 720p. On that connection, we have not observed any significant degradation in accuracy, even with the lower playback quality.

7 SnailLoad: Website-Fingerprinting

In this section, we present an open-world website-fingerprinting attack on the top 100 websites from the Alexa top 1 million list [3]. We use an *other* class for randomly sampled websites not in the top 100.

Threat Model and Attack Setup Our website-fingerprinting attack works in the same threat model as the video-fingerprinting attack in Section 6. The attacker wants to know which website the victim user opens while a background transfer is running a SnailLoad attack, *i.e.*, the online recording phase of the attack. The attacker still cannot run any code on the victim machine, *i.e.*, also no JavaScript. We again assume a standard router configuration [60], with ICMP Echo messages blocked. As most websites load within just a few seconds, we have to increase the attack sample rate to obtain a sufficient number of samples per trace. On the attacking download server, we therefore capture outgoing TCP packets and ingoing TCP ACKs using *libpcap* and compute the timings from the recorded packets, instead of using Algorithm 1. This allows us to increase the sample rate to 5 000 Hz, as we can now have multiple unacknowledged TCP packets in flight, without having to wait for each single packet to be acknowledged before sending the next packet. In an offline post-processing phase, we again use an STFT and a CNN-based classifier to identify the website visited by the victim. As we collect substantially more data, with a higher sample rate and more traces in total, we now use KERAS (Tensorflow) on an NVIDIA RTX 4080 GPU, with a runtime of 3 min to 7 min per training run. We also evaluate a cross-connection scenario, trained on one connection (ADSL-1) and applied to another (FTTH-1).

7.1 Evaluation

We evaluate our SnailLoad on in an open-world scenario. We collect 30 traces per classified website (3 000 in total). Since we evaluate an open-world scenario, we collect an additional 750 traces from randomly sampled from the Alexa top 1 million list [3], which are not in the top 100. With 10 seconds per trace and about 6.5 seconds to switch between websites, this yields a data collection runtime of about 17 hours. We randomly split the data for each class into 5 equally large parts and perform a 5-fold cross-validation, while making sure that the test set never overlaps with the training set in the same run. Consequently, in the open-world scenario, test set traces of the *other* class belong to websites that the model has never seen during training. We train our CNN with a validation split of 10 % of the training set.

Our classifier achieved a macro-averaged F_1 score of 62.8 %. The confusion matrix is shown in Figure 8 and Table 3 in the appendix shows the results for all websites in detail. The color of each cell indicates the prediction probability

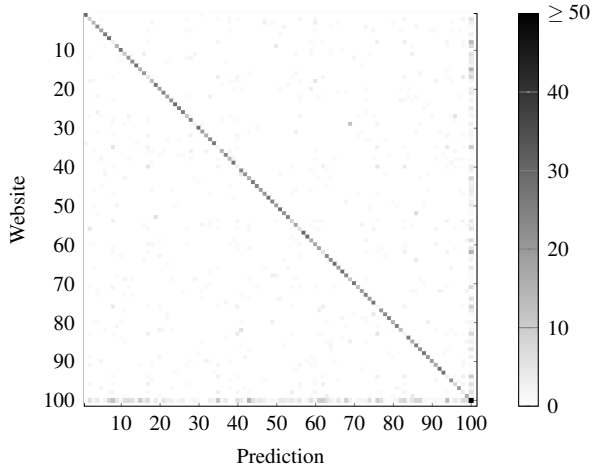

Figure 8: The confusion matrix for our top-100 open-world fingerprinting attack. The macro-averaged F_1 score is 62.8 %.

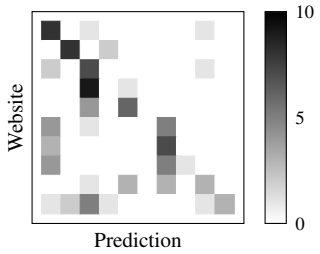

Figure 9: Training our neural network on connection ADSL-1 and applying the model to a trace from connection FTTH-1 yields a substantially higher accuracy than random-guessing, as visible with on the diagonal.

for each website, with a diagonal showing the high accuracy of our classifier across the vast majority of websites. The classification did not work well for 10 websites, resulting in F_1 scores below 20 %. These 10 websites include `wikipedia.org`, `t.co`, `yahoo.co.jp`, `jianshu.com`, which transfer less than 120 kB and thus are harder to detect for SnailLoad (see Figure 6). For `alipay.com` and `amazonaws.com`, we observe relatively slow loading times which may have moved the relevant features outside of our trace, which was restricted to only 10 seconds. All of the above websites had an F_1 score below 10 %. Four further websites had an F_1 score below 20 %, where `taobao.com`, `tmall.com`, and `cnki.net` were likely loading too slowly and `google.com.hk` was mostly misclassified as other Google domains. Excluding these websites, the macro-averaged F_1 score increases to 68.5 %. For 76 classes, including the *other* class, the F_1 score is above 50 %. The low performance for some websites is not surprising as different domains lead to the same actual page, e.g., Google domains are often misclassified as other Google domains.

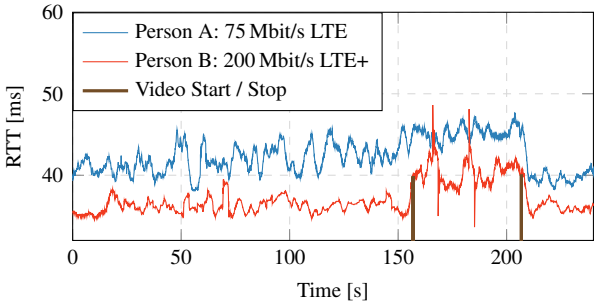

Figure 10: Detecting that two persons had a video call on Discord with each other. At around 155 s, the video call was started, resulting in an increase of RTTs on both connections. When the call ended at 205 s, the RTTs on both connections returned back to the lower baseline level.

In the cross-connection scenario, we apply a model trained on one connection (ADSL-1) to another connection (FTTH-1). We only performed a test on the top-10 websites in a closed-world scenario to minimize the time involvement for the participants of our study. In this scenario, we still achieve an F_1 score of 40 % (see Figure 9), which is significantly higher than random guessing.

8 Limitations and Discussion

While SnailLoad shows that obtaining a network latency trace of a victim system from only a TCP connection is feasible, inferring the specific web activity of the victim can be more challenging in practice. For our fingerprinting attacks, we used data from the same network connection for training set and test set. While we demonstrated in Section 7.1 that applying a model trained on one connection to a trace from another connection can yield a significantly higher accuracy than random-guessing, other scenarios may offer the possibility to obtain training and test data through the same network connection. This might be realistic if an attacker has access to the same network connection but in this situation the attacker likely already has other means than SnailLoad to observe the network latency, or even packet transmissions, of the victim. The attacker could also run the fingerprinting through a website, where one `iframe` shows the website of video to fingerprint, whereas another resource in the website is used to record a latency trace using SnailLoad. Consequently, the attacker has different means to obtain traces and mount an attack that can be adapted to the concrete setup and attacker capabilities. More generally, once SnailLoad leaked traces from a victim, an attacker can take arbitrary time to analyze or store the data until enough information is available to infer videos, websites, or other information contained in the trace.

In contrast to the remote timing side channels discussed in Section 2.5, which focus on JavaScript-based attacks or

special network interfaces, SnailLoad is a *remote* attack in the sense that we do not rely on the victim system's own hardware or software implementation but contention of buffers that are in the transport path to the victim (close to the victim). SnailLoad is more similar to passive traffic analysis [7,47,71] but, in contrast to these works, does not require a person-in-the-middle attack scenario. SnailLoad instead can target any machine it can reach with a network connection. Gong et al. [22] already observed that ICMP ping times correlate with network activity on a DSL connection in 2010. However, ICMP ping packets are commonly blocked by default today [60]. In contrast to ICMP ping packets, the TCP ACKs used by SnailLoad are fundamental for reliable data transmission and cannot be blocked. Murdoch and Danezis [48] used passive latency measurements to estimate traffic on a Tor relay node. We go significantly beyond their attack and show that SnailLoad can infer specific videos a user watches on arbitrary network connections. In contrast to prior work focusing on information recovery, e.g., with deep-learning techniques [9, 16, 58, 68], SnailLoad focuses on the information channel itself. Hence, SnailLoad could be combined with any of these works for generic non-person-in-the-middle information recovery, significantly amplifying the impact of these attacks.

To provide an example of such a use case of SnailLoad, we show that a scenario similar to the one explored by Li et al. [43] is also possible with SnailLoad. Instead of an instant messenger, we evaluate a video call scenario, where the attacker obtains latency traces of multiple victim systems and tries to infer which of these systems are interacting with each other, *i.e.*, which ones are having a joint video call. Figure 10 shows this for two persons having a short video call with each other on Discord, while the attacker records latency traces of both of them, as described in Section 5.3. The video call runs from $t = 155\,\text{s}$ to $t = 205\,\text{s}$. The attacker observes a clear increase in RTTs for both victims in this specific time frame. Consequently, the attacker can deduce that they had a video call with each other in this time frame, again without requiring a PITM setting or the installation of stalkerware [11].

Mitigation of SnailLoad. Mitigating SnailLoad is not trivial as the root cause, the different bandwidths of channels in the transport path, cannot be eliminated. To provide adequate performance to multiple users simultaneously, the backbone network infrastructure has to have a higher bandwidth than the user's connection. Thus, the critical bottleneck is typically close to the user (*i.e.*, the last mile), and thus, the buffering occurs in a node that also handles the attacker's packets, even if packets have different priorities, e.g., due to quality-of-service measures. Dropping packets to avoid the bottleneck would not close the side channel, as the attacker could instead measure the share of dropped packets.

Similar as other side channels, SnailLoad is affected by noise and adding additional noise can hinder attacks. Noise is added to contention side channels by adding spurious random contention. In our case, the contention comes from the last-mile bottleneck. Thus, we have to establish random traffic with an external server. We implemented a simple proof-of-concept that for every 5-second interval occupies the network connection randomly between 0 % to 100 %. To evaluate the effect of this noise on SnailLoad, we run a top-10 website-fingerprinting attack. Without noise, we achieve an F_1 score of 77 %, with a very clear diagonal visible in the confusion matrix in Figure 11. With noise, the F_1 score drops to 15 %, when using noisy traces for training and tests. This is just barely above the random-guessing probability and the diagonal does not stand out anymore. When using clean traces for the training, and noisy traces for the tests, the F_1 score drops even lower, to 10 %, which is the apriori probability of random guessing. This shows that noise can effectively mitigate SnailLoad. However, the noise also introduces an inconvenience for the user as it occupies part of the network connection.

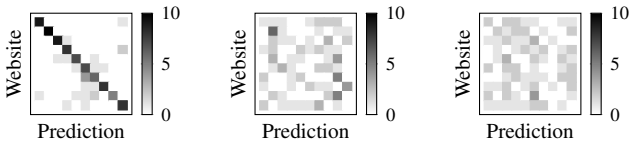

Figure 11: Adding noise on the FTTH-1 connection lets the fingerprinting accuracy deteriorate from an F_1 score of 77 % (left), to an F_1 score of 15 % when using noisy training and test sets (middle), and to an F_1 score of 10 % when using clean training and noisy test traces (right), which is the random-guessing probability.

Ethical Considerations. For our user study, we approached local undergraduate and graduate students who volunteered to run our measurement script. We asked the students not to perform any operations on the network that could expose personal information while running our script. Furthermore, it is essential to note that we only search for correlations between our measurements and the YouTube videos our measurements script opened. Thus, no personal information of the students was exposed to information leakage at any point. For the remaining possibility that students still used their network during the measurement time frame in a sensitive way, we are planning to destroy the traces after the publication of the paper and provide students with the option to ask us for the deletion of their traces and exclusion of their results from the paper at any point.

Responsible Disclosure. We demonstrated our video-fingerprinting attack on YouTube and, therefore, reported our attack to Google on March 9. Google acknowledged the sever-

ity and that it is a generic, unaddressed problem. For YouTube, they are investigating server-side mitigations.

9 Conclusion

While a substantial amount of research has studied person-in-the-middle side-channel attacks on encrypted web traffic, the possibility of such attacks in non-person-in-the-middle scenarios remained unclear. In this paper, we presented a novel attack, SnailLoad, that exploits the network packet latency as a side channel for activities on a victim system. Our root cause analysis indicates that buffering in a transport path node close to the victim is the root of the latency variations, as well as their connection to the bufferbloat quality-of-service phenomenon. We demonstrated SnailLoad in a scenario where the attacker hides the latency measurement in a network connection of the victim to retrieve an asset, e.g., a file or an image, from a seemingly benign attacker-controlled server. SnailLoad requires no JavaScript, no form of code execution on the victim system, no user interaction but only a constant exchange of network packets, e.g., a network connection in the background. We evaluated SnailLoad with a video-fingerprinting attack, inferring what video a user is watching from a single SnailLoad trace. Our user study comprised 10 internet connections with 6 different internet connection technologies. Over a set of the top 10 YouTube videos, we obtain classification F_1 scores between 37 % and 98 %. In a top-100 open-world website-fingerprinting attack, we achieve an F_1 score of 62.8 %. SnailLoad highlights that numerous prior works on network side channels could potentially be lifted to an non-PITM remote attack scenario.

Acknowledgments

We would like to thank our anonymous reviewers and our shepherd for their valuable and timely feedback. We furthermore thank David Bom, Lukas Maar, Sebastian Felix, Andreas Kogler, Lorenz Schumm, and Martin Glasner. This research was supported in part by the European Research Council (ERC project FSSec 101076409) and the Austrian Science Fund (FWF SFB project SPyCoDe 10.55776/F85 and FWF project NeRAM I6054). Additional funding was provided by generous gifts from Red Hat, Google, and Intel. Any opinions, findings, and conclusions or recommendations expressed in this paper are those of the authors and do not necessarily reflect the views of the funding parties.

An Interview Study on Third-Party Cyber Threat Hunting Processes in the U.S. Department of Homeland Security

William P. Maxam III
*United States Coast Guard Academy**

James C. Davis
Purdue University

Abstract

Cybersecurity is a major challenge for large organizations. Traditional cybersecurity defense is reactive. Cybersecurity operations centers keep out adversaries and incident response teams clean up after break-ins. Recently a proactive stage has been introduced: Cyber Threat Hunting (TH) looks for potential compromises missed by other cyber defenses. TH is mandated for federal executive agencies and government contractors. As threat hunting is a new cybersecurity discipline, most TH teams operate without a defined process. The practices and challenges of TH have not yet been documented.

To address this gap, this paper describes the first interview study of threat hunt practitioners. We obtained access and interviewed 11 threat hunters associated with the U.S. government's Department of Homeland Security. Hour-long interviews were conducted. We analyzed the transcripts with process and thematic coding. We describe the diversity among their processes, show that their processes differ from the TH processes reported in the literature, and unify our subjects' descriptions into a single TH process. We enumerate common TH challenges and solutions according to the subjects. The two most common challenges were difficulty in assessing a Threat Hunter's expertise, and developing and maintaining automation. We conclude with recommendations for TH teams (improve planning, focus on automation, and apprentice new members) and highlight directions for future work (finding a TH process that balances flexibility and formalism, and identifying assessments for TH team performance).

1 Introduction

Computer network security is a challenge in the modern world. Cyber intrusions are a concern for both governments and private corporations. Unauthorized network infiltrations cost individual organizations an average of $13 million a year [8] and may compromise their operations or intellectual property. Governments have additional non-monetary concerns, such as protecting election systems and maintaining national security [7]. The longer an adversary dwells undetected on a network, the more damage the adversary can cause. One analysis found that a 50% reduction in dwell time would reduce the cost of an attack by ∼30% [36]. IBM found that data breaches cost on average $1.12 million more if not contained within the first 200 days, with costs including lost revenue, regulatory and legal fees, and forensics activities [9]. They estimate the average adversary-dwell-time at 230 days, not including additional time to respond to the breach [9].

The primary method of finding undetected network intruders is a Cyber Threat Hunt (TH). Threat Hunting is "*a focused and iterative approach to searching out, identifying, and understanding adversaries internal to the defender's networks*" [60]. The government routinely performs **third-party hunting**, *i.e.,* TH on contractors' networks [7]. The private sector conducts threat hunting as well [24], more commonly within their own organizations. According to a 2017 SANS Institute survey, across sectors including telecommunications, technology, government, healthcare, and finance, most organizations engage in threat hunting but in an immature way [59]. Under half of the organizations had a defined TH process [59].

The processes currently used by TH teams are not well documented [94]. Prior research on TH teams does not describe TH processes in detail [25,37,92,95] or is focused on internal hunt teams [94]. This knowledge gap limits a team's ability to adopt best practices and improve their processes over time, and it also limits how well researchers can assist TH teams.

To address the lack of TH process understanding, we interviewed professional threat hunters. We used a semi-structured interview methodology, selected as a result of the data available from previous work done in the TH domain and an anticipated small sample size (§3.3). We interviewed 11 TH practitioners from two organizations within the US Department of Homeland Security (DHS). Each subject was interviewed for ∼1 hour. We combined subjects' TH process sketches and dialogue to create a unified process model of the US DHS threat hunt process. We also thematically coded the transcripts to elicit subjects' problems and solutions.

*Work performed while at Purdue University.

Our results provide researchers with a better understanding of TH processes. We provide the first academic description of the cybersecurity landscape to include TH teams (§2) and the first published process model describing DHS TH teams (Figure 2). Unlike prior literature that recommends a hypothesis-driven process, we report that the studied TH teams incorporate a *data-driven* process. We also document the challenges that practitioners report with this process, and describe the best practices they recommend (Table 3). Their open questions are captured as future work (§5).

Our contributions are:

- We provide an updated description of the cybersecurity landscape that includes Threat Hunting teams (§2).
- We characterize US DHS Threat Hunt processes, both in comparison to prior work and via a novel process induction (§4.1 and Figure 2).
- We describe problems, possible solutions, and open questions discussed by TH practitioners (§4.2 and Table 3).

2 Background and Related Work

In §2.1 we describe the landscape of current cybersecurity defenses and the role of Threat Hunting (TH). §2.2 summarizes what is known about public and private TH teams. §2.3 describes common TH frameworks and processes. As there is little academic literature on Threat Hunt, this section is expository. We rely in part on reputable "grey literature".

2.1 Layers of cybersecurity defense

Figure 1 illustrates typical layers of cybersecurity defense as they interact with an adversary. We discuss each layer in turn.

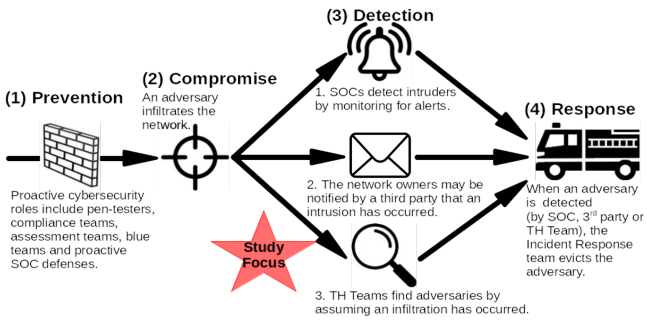

Figure 1: Threat hunt is one of three common ways to discover an adversary once they have circumvented cyber defenses. Once an adversary is discovered, an IR team responds.

2.1.1 Prevention (Diagram Step 1)

As Figure 1 shows, *preventative* cybersecurity teams are the first line of defense against adversaries. These teams include traditional defensive teams such as Blue Teams, Compliance Teams, and Security Operations Centers (SOCs). Blue teams seek to protect the network from intruders by improving the network's security [98]. Compliance Teams enforce cybersecurity best practices across a network [43]. SOCs are primarily responsible for detecting adversaries as they attempt to gain access to a network [26]. SOCs in particular have received much attention from researchers. Researchers have interviewed SOC members [39] and embedded in SOCs [88]. Classification systems exist for SOCs to measure their maturity and capability [54], best practices have been enumerated [62] and SOC processes are being studied [78].

There are also offensive preventative security teams. They include Red Teams and Penetration Testing Teams [44]. These teams take offensive actions in order to simulate adversaries. Penetration Testing Teams typically look only for vulnerabilities at the network edge, while red teams seek to infiltrate past the network edge and further into the network.

2.1.2 Compromises (Diagram Step 2)

In Step 2 of Figure 1, the adversary evades these countermeasures and *compromises* the network. If an adversary compromises a network without detection, they can cause significant damage [36]. The longer adversaries remain undetected, the more costly the intrusion becomes [9, 36]. Attackers constantly innovate their capabilities, and many works have described compromises such as SolarWinds [27], Stuxnet [63], and the 2015 Ukrainian power grid attack [99].

2.1.3 Detection (Diagram Step 3)

Step 3 of Figure 1 shows three ways in which such an adversary may subsequently be *detected*. The upper route depicts the SOC detecting the adversary, *e.g.,* via one of the SOC's internal network or host-based sensors. The middle route shows a notification by an agency such as the US FBI. The third path is *proactive discovery*, *i.e.,* Threat Hunt, our study's focus.

TH teams perform a unique function, hunting for adversaries internal to the network boundary. To identify undetected adversaries on the network, TH teams search for adversaries that have evaded detection by usual methods [60]. This is analogous to a military unit relying both on gate guards (the SOC) and also patrols inside the camp to "hunt" for adversaries that breach the gate. TH teams do not configure network defences (as blue teams and compliance teams do), nor do they take offensive action (as red teams and penetration testers do) [66]. Threat Hunt teams only search the network for adversaries that existing defenses may have missed [6]. They hunt on the assumption that an adversary has infiltrated the network, when there is no sign of a compromise [37]. ***Unlike the other steps in Figure 1, there is little empirical data about TH team processes, practices, and challenges.***

2.1.4 Response (Diagram Step 4)

The last step in Figure 1 is *response*. Once an adversary is detected, an Incident Response (IR) team is called to respond. Incident Response teams are responsible for evicting adversaries that have been found on the network [72]. IR teams

react to adversaries regardless of how they are detected. IR teams have also been studied by academia and government agencies [40]. Researchers have interviewed IR team members [69, 97] and embedded in IR teams [72, 90].

2.2 Threat Hunting Teams and Organizations

In this section we describe how TH is implemented in the private and public sectors. Although TH is a new discipline [76, 94], it is considered an important cybersecurity capability for security practitioners and academia [47, 68]. TH is mandated for Federal Civilian Executive Branch Agencies [15] like the National Aeronautics and Space Administration (NASA) and the Department of the Treasury [21].

Since TH is an emerging discipline of cybersecurity, it is little researched. The government TH process is particularly important to understand and improve because recent US presidential executive orders [15] and the US National Cybersecurity Strategy of 2018 [7] *mandate* the use of (third-party) government hunters on government contractors' networks.

2.2.1 TH in the Private Sector

TH can either be done using personnel internal to the organization or using a third party's TH team. For an internal TH team, organizations either designate SOC personnel to perform hunting or maintain teams dedicated to TH [60]. Some companies offer threat hunting as a service, including Booz Allen Hamilton [20], Crowdstrike [17] and Cisco [19]. Most organizations in the private sector opt for internal TH teams [59], *e.g.,* for privacy or intellectual property protection.

2.2.2 TH in the Public Sector

The US Government uses both civilian and military teams. For example, the Cybersecurity and Infrastructure Security Agency's (CISA) Hunt and Incident Response Team (HIRT) [12] is a team of civilians that performs TH. On the military side, all branches of the US military [91] and some state National Guards [64] have Cyber Protection Teams (CPTs) — some CPTs conduct TH work along with other cybersecurity functions [16]. Government teams are deployed to federal civilian [15], military [2], and even private sector networks [7, 12]. The Department of Homeland Security includes both CISA and the Coast Guard and thus operates both civilian (CISA) and military (Coast Guard) Hunt Teams.

2.2.3 Common Problems Affecting TH Teams

Both government and private sector TH teams have substantial personnel turnover [11, 65, 74]. In cybersecurity organizations, public and private, cybersecurity analysts commonly change jobs every two years [14]. Military organizations often rotate personnel every 2–3 years [34, 70, 82], placing this concern beyond the control of the individual TH teams to address. Good processes have been shown to mitigate the adverse effects of fewer expert personnel [71], helping mitigate the adverse effects of personnel turnover. Our study describes existing processes as a step toward this goal.

2.3 TH Frameworks and Processes

This section presents TH frameworks and processes. A *TH Framework* is a way of organizing information to assist with the task of hunting. A *TH Process* is a way of organizing the tasks associated with Threat Hunting across time. Beyond this material, the technical report (Appendix A) gives illustrations of the frameworks and processes described here.

2.3.1 TH Frameworks

Both academia [37] and private sector [94] documents suggest three popular frameworks: Lockheed Martin's Kill Chain [3], the Mitre ATT&CK framework [28], and the Pyramid of Pain [32]. All three of these frameworks describe adversary activity in a way that assists the defender in categorizing events and focusing their search. The Kill Chain and ATT&CK frameworks outline the steps an attacker takes to carry out a successful attack; ATT&CK goes into greater detail. The Pyramid of Pain instead assesses what information is most valuable for disrupting adversary activity.

Researchers often suppose a framework called the hypothesis method [25, 29, 37, 52, 95]. The hypothesis method is when the TH team outlines a possible intrusion that could have occurred on the network and then tests that hypothesis using the data available. An example hypothesis is: *"Advanced Persistent Threat #0 exploited CVE-2021-44228 to compromise a VPN Server then moved laterally to the domain controller."*

An alternative to hypothesis hunting is *data-driven unstructured hunting* [83, 84, 94]. Here, threat hunters search for adversaries without a hypothesis, guided by statistical or behavioral analysis to identify adversary activity. Some authors consider this as hunting without a process [84]. Others say it is less efficient than the hypothesis method [13, 83].

These frameworks and methods are complementary [94]. For example, a TH team could build a hypothesis using the steps in the Kill Chain framework. The team could then look up the associated techniques using the ATT&CK framework and prioritize the search based on the Pyramid of Pain.

2.3.2 TH Processes

Currently, the most common way to hunt for an adversary is *ad hoc*, *i.e.,* without a formal process [59]. Some TH teams may have privately documented processes, but public descriptions are rare. We describe what is known.

Private sector processes: To address the lack of standardized processes and definitions, four organizations from the Dutch financial sector shared a process known as the Targeted Hunting integrating Threat Intelligence (TaHiTI) process [94].

TaHiTI describes the behavior of internal threat hunters rather than third-party/external hunters, and thus makes assumptions about the network information that the threat hunters have.

The private sector has made other attempts to explain TH processes but none as detailed as TaHiTI. Endgame published *The Endgame Guide to Threat Hunting* [45, 81]. They proposed a 4-phase process with 6 hunting steps. Other TH guides did not provide a TH process [10].

These TH process models — TaHiTI and Endgame — are prescriptive, not descriptive. TaHiTI was derived from a private sector round table, describing what should occur, not necessarily what does occur. Endgame is similar.

US government processes: There is no public documentation of the TH process used by Government TH teams. The closest work is by Trent *et al.* [92]. They created a *cognitive* model of activities performed by US Army CPTs. Their goal was not specifically to outline a Threat Hunting *process*, but as CPTs perform TH their findings are somewhat relevant.

Academic perspectives: Previous academic works on TH methodologies do not describe current TH practices. They propose novel approaches to assist TH teams [25, 95].

Comparing private sector and govt. TH processes: Comparison between the TH processes proposed by TaHiTI [94] and Trent *et al.* [92] is imperfect for two reasons: (1) TaHiTI was focused on TH while Trent *et al.* covered TH as well as other cybersecurity roles; and and (2) TaHiTI is a process while Trent *et al.* is a cognitive model. Nevertheless, our analysis of these works suggests differences between private sector and government TH teams. TaHiTI is for internal TH teams, while Trent focuses on third-party CPTs. This means that TaHiTI assumes more shared context across missions, *e.g.,* keeping "investigation abstracts" in a backlog for future hunts. In contrast, the external hunts from Trent are more self-contained, with tasks devoted to "Planning and Logistics" and "Closure". Perhaps related, we also observe that TaHiTI is more abstract while the Trent model is more detailed, including tasks such as Forensic analysis as distinct from Host, Malware, and Network analysis. Finally, the TaHiTI TH process uses the hypothesis method, while Trent *et al.* does not indicate a hypothesis (even though generating a hypothesis would be a unique cognitive task).

2.4 Summary and Unknowns

Although threat hunting is a mandated government function, little is known about TH team processes. The most detailed TH process is TaHiTI, a process described by threat hunters from four private sector institutions [94]. However, government TH processes likely differ from private sector ones because government teams often hunt on third-party networks rather than within their own networks [7]. The TH process used by government teams is unknown.

Since most organizations that perform TH do so without a formal process, understanding TH processes outside of the "internal private sector team" context (TaHiTI) will help organizations developing their own TH processes. Typical TH team practices and challenges are also undocumented — learning these would benefit all TH organizations, whether or not they that have a TH process. One specific area of interest is the effect of turnover and integration of newcomers, a concern shared by private and public-sector TH teams.

3 Research Questions and Methodology

Historically, the US government have driven the creation of cybersecurity standards [86]. For example, after the 2015 Office of Personnel Management (OPM) data breach [55], many private organizations sought to improve their processes from shortcomings observed in the OPM process [4, 5, 57, 61]. Describing the government TH process may be beneficial for the same reasons, both as an example and to assist in identifying shortcomings. The government is among the sectors most often targeted by cyberattackers [22]. The US government's cybersecurity defenses, including its TH processes, are thus of great interest. We provide a first view.

3.1 Research Questions

Describing all US government TH processes is beyond the scope of a single study. As a step toward this goal, in this work we examine TH processes from one branch of the government, the US Department of Homeland Security (DHS). In this context, we address two research questions:

- **RQ1:** What processes are used by DHS TH teams?
- **RQ2:** What shortcomings exist with current DHS TH processes and what might be done to alleviate them?

3.2 Statement of Positionality

One of the authors is a former DHS Threat Hunter. This author's background shaped, both directly and indirectly, our study design, recruiting, analysis, and findings [42]. For example, their professional experiences informed our interview protocol, and we recruited their former colleagues as subjects. The researcher's relationship with some of the subjects may have had positive and negative effects: responses could be biased by the relationship, but they may also be enriched because interviewer-subject trust had already been developed. Despite the potential biases, we emphasize that access to TH personnel has been a barrier to research. Capturing aspects of DHS TH experiences is valuable, even if incomplete.

3.3 Study Design

An Interview methodology was chosen for this study as a result of the data available and the population being studied. We felt the prior work of Trent *et al.* [92] and van Os *et al.* [94] provided enough initial structure to frame the collection instrument and initial analysis. Long-form ($\sim$1hr) interviews allowed us to make the most of a relatively small sample size.

Little information exists on the processes used by government Threat Hunting teams, so our study will direct future research.

We considered and decided against other methodologies. It would be difficult to capture the complexity of the TH process through a survey, which would not allow for iteration on the collection instrument to pick up unexpected intricacies [100]. Additionally, since the population of government threat hunters is small and difficult to access, a meaningful sample size for a survey would be difficult to achieve [30]. We also considered a grounded theory methodology, which is suitable when no prior theory or framework exists [58]. In our case, however, we had access to prior work done by private TH teams (TaHiTI) and studies on TH-adjacent cybersecurity teams (Trent et al.) which we used to guide our study.

The TH teams we studied have three roles: *Leadership*, *e.g.,* officers, deal with TH strategic concerns but do not deploy with the team. Team Leads deploy with a hunt team and act as the on-site manager. Analysts deploy and perform the analytic tasks associated with hunting. Each role may have different perspectives on the TH process, challenges, and solutions, so we recruited subjects in each role.

3.4 Recruitment and Subject Demographics

Government Threat Hunting teams are a difficult group of practitioners to study due to the small size of the teams and the sensitive information they often deal with. One author's US government security clearance and previous TH duties allowed us access to these TH team members and helped ensure no sensitive information was disclosed.

Participants were recruited for interviews through the authors' professional network. Emails were sent to TH members with varying experience and roles. At both organizations, subjects were representative of multiple internal teams and analyst populations, including primary organizational divisions. The response rate from direct contacts was 59% (10/17). One additional subject offered to be interviewed after hearing about the study. 6 out of the 11 participants had previously worked with one author as a peer (1), subordinates (3), or managers (2). Participants were uncompensated volunteers to avoid conflict of interest with their colleague (the interviewer).

We tried to go beyond our professional network, but recruitment was challenging. We contacted TH analysts from other agencies (DOE and DOD) and received one response. We ultimately excluded the other organizations from the study and focused on the one to which we had access.

Subject Demographics: The distribution of subjects by organization and by position is in Table 1.[1] Some subjects had operated on teams in multiple organizations within the last three years so the count in Table 1 exceeds 11. As precise titles could de-anonymize subjects, subjects are mapped to three general job roles: Leadership, Team Lead, and Analyst.

[1] Technical report has subjects' experience in years and # of missions.

Table 1: Subject breakdown by organization and position.

Organizations	# Subjs.
DHS Organization # 1	10
DHS Organization # 2	3

Position	# Subjs.
Leadership	4
Team leads	4
Analysts	3

Table 2: Summary of interview protocol. The first column is the topic and the number of questions for that topic.

Topic (#)	Example questions
Demographics (2)	• How many missions have you been on? • How many found an adversary?
TH process (11)	• Draw your team's TH process. • What parts are problematic? • In what ways do you incorporate hypotheses into the process? • (Critical incidents) Tell us about 1-2 missions where the process failed?
New members (6)	• How long does it take a new team member to become productive? • What is a good measure of a member's expertise?

3.5 Interview Procedure

Interview protocol creation: The main body of our instrument focused on the knowledge gaps identified in §2.4: eliciting the TH process and understanding its challenges. Guided by previous TH literature, we asked about analysis frameworks and process automation [25, 37, 94]. Based on the frequency of personnel turnover, we also had a line of questions about incorporating new members.

Interview protocol refinement: Following best practices [38], we conducted two mock interviews. The primary researcher (who has TH experience) was interviewed by the other researchers. The protocol was tuned for clarity. Transcripts from these mock interviews were not used in analysis.

After the mock interviews, we divided the real interviews into two stages. In the first stage, we held two interviews to pilot our protocol, one with a CGCYBER team lead and one with a CISA team lead. After these interviews we reviewed the transcripts, assessed validity, and made changes as needed. Following this pilot, we added 2 questions and 3 follow-up questions, and re-worded one follow-up question. Over the course of the entire study, 92% of the main questions (22/24) were held constant. As there was little change in the instrument, our results include the 2 pilot interviews.

The final semi-structured interview protocol is summarized in Table 2 and detailed in the technical report (Appendix A). Interviews were conducted by one author, who had security clearance (for national security, §3.6) and prior TH experience (so that they could ask domain-appropriate follow-up questions). Interviews lasted 1 hour and used Microsoft Teams.

3.6 Ethics and National Security

This study was approved by our institution's Internal Review Board (IRB). A signed consent form was collected from participants before their interviews.

The studied organizations have small TH communities so care was taken to anonymize subjects. Specifically, we removed identifying information from quotes, and we describe and quote subjects in terms of generic job roles (Table 1).

Due to the sensitive information being discussed, we took measures to ensure that no classified information nor data from customer sites was collected. The interviewer reminded each subject of the unclassified nature of the research. All audio was reviewed for sensitive information before being sent to the transcription service. The transcript was then reviewed again by the research team before being used for analysis.

3.7 Data Analysis

We used three types of analysis on the resulting transcripts. Process coding and inductive process discovery were used for RQ1. Thematic coding was used for RQ1 and RQ2. All codebooks are in the technical report (Appendix A).

3.7.1 RQ1: Process Identification

First, process coding was done as described in Saldaña [80]. In this method, a pre-existing process is represented in a codebook used to analyze (code) a transcript. We created a codebook from TaHiTI using their descriptions of hunt triggers. We likewise created a codebook for the Trent model. The subjects' descriptions of their TH process were then coded against these process codebooks to assess fit. [2]

In our results (§4.1), neither TaHiTI nor Trent was a good fit, so we induced a TH process model from the interview data. First, all nodes from all subject diagrams were placed into one interconnected diagram. Similar nodes were combined. When possible, more precise nodes took precedence over general nodes. If a node was only on one diagram and not mentioned in multiple subjects' interviews, that node was removed.

As this process was relatively objective, a single analyst combined nodes and made the diagram. Another analyst iteratively reviewed the resulting process model.

3.7.2 RQ2: Shortcoming Identification

Following process coding and diagram discovery, further analysis was conducted on the transcripts. Since the interview protocol contained primarily focused questions, the interviews proceeded in a readable linear fashion. This allowed one analyst to re-code the transcripts using thematic coding as described in Guest *et al.* [50]. Memos were written by the primary analyst. This researcher arranged the 636 memos into themes. Codes were iteratively refined, ultimately yielding 57 codes under 10 topics.A second analyst assessed reliability, using the codebook and excerpts from 6 of the 11 transcripts. For completeness, excerpts were selected from each set of Question-Answer in the interview protocol. The measured agreement was fairly high (Cohen's $\kappa = 0.82$).

Completeness of results: Saturation was measured after all 11 interviews were complete. We measured saturation following Guest *et al.* [49], by measuring the number of (cumulative) new codes appearing in each interview. We found saturation after seven subjects, with no new codes being observed in the last five interviews. All organizations and all position categories had been represented at that point, indicating substantial homogeneity. Codes on a per-interview basis were also charted. We found that each interview covered many topics ($\geq$30 codes per interview).

After analysis was complete we performed member checking [33] by circulating our results to two experienced subjects (one team lead and one member of leadership). They felt properly anonymized and that their TH data was represented.

3.8 Limitations and Threats to Validity

Like many qualitative studies, our primary limitations are the sample size (11 subjects) and the reliance on self-report.

- *N=11*: Guest *et al.* argue as few as six interviews can suffice if the population is homogeneous and the data collected is specific [49]. We believe this is the case here. Samples of $\sim$10 are common in interview studies [41, 53, 75, 79]. Also note our sample is relatively large compared to the population, which is $\sim$5,000 at the studied organizations.
- *Self-report:* For validity, we followed best practices in interview instrument creation [38] including conducting 2 internal mock interviews and slightly modifying the instrument after the first 2 subject interviews. We performed member checking [33] by circulating our results to two experienced subjects (one team lead and one member of leadership). They both felt properly represented. Unfortunately, triangulating against public documents was not possible, as those from TH teams lack process information [18] and internal documents are confidential.

We note two additional threats. First, the analysis was done primarily by one researcher. Bias is mitigated by measurements of inter-rater agreement on a subset of the data. Second, our study may not generalize, *e.g.,* to the rest of the government or to private sector teams. Government teams and agencies differ by mission, training, etc. The differences between the TaHiTI process and the Trent model suggest differences between public and private sector teams.

[2] The TH process description was the first part of the interview. The TaHiTI and Trent codebooks were only used on this part of the interview. It was rare for a subject to mention a new component of their process unprompted after their process description.

4 Results

4.1 RQ1: TH Processes of DHS Teams?

> The process described by Government practitioners differed from the TaHiTI and Trent processes. We induce a unified process model capturing the participants' TH processes, comprising 7 stages and 25 distinct activities (Figure 2).

Each subject provided two types of data to indicate the process they used. First, at the beginning of their interview, 10 out of 11 subjects provided a process diagram. (The remaining subject did not feel sufficiently familiar with the process.) Second, in the remainder of the interview they described their team's process. We used process coding to compare our subjects' TH processes to the TaHiTI [94] and Trent [92] models. Our observed TH processes did not match (§4.1.1), and we describe the induced model in §4.1.2.

4.1.1 TH Process Comparison to Related Work

We coded processes against the TaHiTI and Trent models.

TaHiTI: We found TaHiTI a poor match to our subjects' processes. 88% of the TaHiTI codes matched to activities described by the subjects. However, every subject described at least one activity that occurred in addition to the TaHiTI process, including Baselining (8 subjects), Sensor Placement (8 subjects), Team Arrival (5 subjects), and Customer Meetings (5 subjects). We suggest two reasons for this poor fit:

(1) Internal Team Assumed: Some tasks that are only required for external organizations were omitted by TaHiTI. For example, when describing their process 8 subjects were mentioned placing sensors on site prior to the team's arrival. TaHiTI discusses data sources and ensuring data availability, but its concerns are different than our subjects' concerns about sensor placement. Sensor placement is not discussed by TaHiTI but was important to our subjects because their organizations operate on external third-party networks.

(2) Only Hypothesis Hunting Described: Some tasks described by subjects are more important for data-driven hunting than hypothesis-driven hunting. For example, baselining was described by subjects as a 1-3 day process in which the TH team, deployed on an unfamiliar network, takes time to document typical network behaviors. Subjects indicated that baselining was especially important for filtering out false positives and for behavior analysis. However, since TaHiTI describes hypothesis-based hunting, it does not cover data-driven hunting techniques like behavior analysis.

Trent: We found Trent a poor match to our subjects' processes because of the unit of analysis. The Trent model was designed to distinguish between cognitive tasks. Our subjects more often drew administrative or temporal distinctions between tasks. For example, the Trent model describes four types of analysis: Network, Host, Malware, and Forensic. Our subjects instead described their analysis work in terms of two processes, a manual behavior-driven loop and an automatic alert-driven loop. Both loops involved host and network analysis — although these are distinct cognitive tasks, most subjects did not perceive them as distinct process components. We observed the same dynamic with baselining — Trent groups baselining activities with similar activities in other phases of a hunt, while our subjects emphasized the importance of a separate task for baselining distinct from the analysis step of the process. Numerically, 21% of the process components mentioned by our subjects did not match any of Trent code.

Incorporation of Different Frameworks: Each subject was specifically asked about their use of the hypothesis method and three other models observed in TH descriptions across academia and the private sector (see §2.3). In both organizations, Mitre's ATT&CK framework was the most used, although its role differed across subjects.

4.1.2 Description of the Induced TH Process

We concluded that our subjects' TH processes differed from the available literature. We induced a unified process model following the method given in §3.7.1. Figure 2 shows the high-level result, with activities grouped into seven stages based on our judgment. A detailed version is in the technical report (Appendix A). This section walks through Figure 2.

(1) Begin Hunt: Subjects described two ways to begin a TH mission.[3] (1) In a *proactive* mission, the customer has no suspicion of adversarial activity but still wants a TH team to check. One subject said: "*Some of our [missions]...people just say: 'Well, we're interested in having you come see if anyone's here'.*" (2) In a *triggered* mission, there is no specific indication of compromise but the customer believes an adversary may be undetected on their network and requests a TH team. In one subject's words: "*Maybe you get...intelligence that says, '...a system that belongs to you may be communicating to a malicious command and control infrastructure'.*"

(2) Mission Planning: In the mission planning task, the TH team coordinates with the customer. A leader subject said: "*I think [planning is] the most critical piece...This is really what I think creates a useful engagement.*" This process typically starts with a customer's request, then a survey of their system and network admins, and then TH-customer meetings (*e.g.,* "*multiple technical phone calls...to discuss any details*"). Subjects described three components of mission planning: scoping, hypothesis creation, and mission plan creation.

Scoping is when the TH team decides on what parts of the network will be included in the hunt mission. Organizations may constrain the hunt in ways such as parts of their network,

[3] Subjects used different names for an individual hunting operation. We use the term *mission*. Third-party TH teams consider a mission as one engagement with a specific customer over a few weeks. In contrast, internal TH teams hunt continuously, with few-day missions by hypothesis.

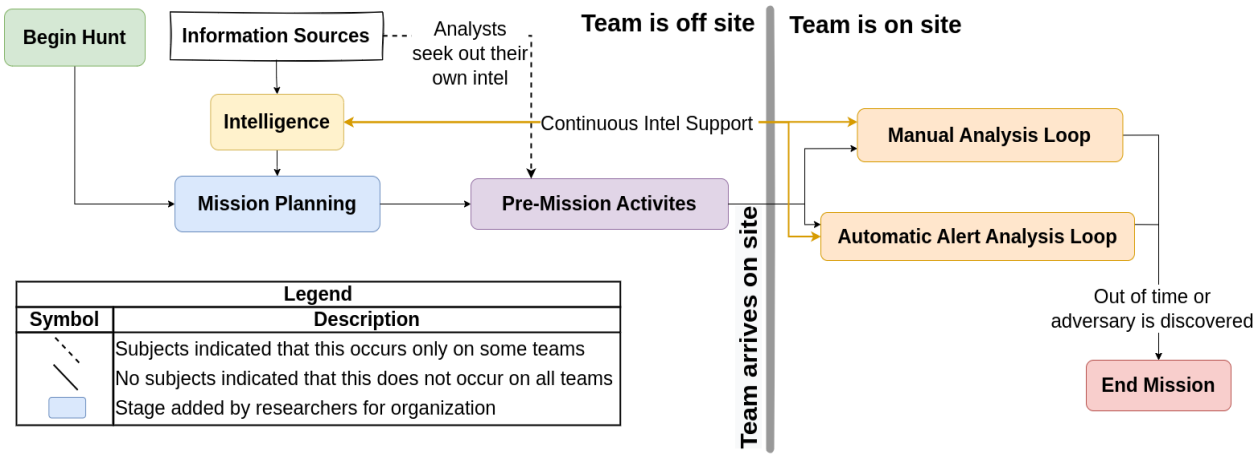

Figure 2: Unified TH process induced from interview data. A detailed version appears in the technical report.

types of threats considered, and time limit. In one subject's words: "*We got to figure out what kind of environment we're going to be working in, how many endpoints, how many users, inventory, ...how much data... stuff like that. We have a scoping questionnaire we send to the partner.*" Internal hunt teams often have a fixed scope of operation.

During *hypothesis creation*, a TH team generates a hypothesis to test in the hunt. Some teams do this during planning; others create hypotheses after deployment; others do not use hypotheses. Of the three studied organizations, two formally document hypotheses in the mission plan or elsewhere.

The *mission plan* documents the structure of the mission. It could include a timeline with associated deliverables, specific TH objectives, and 1-3 hypotheses if any. Not every team created a mission plan document. It may be unnecessary for internal teams as their hunt missions tend to be shorter.

Subjects in leadership positions often mentioned the importance of objectives in the mission plan, *e.g.,* "*The really important thing for TH is you go in with specific objectives. You're not just trying to find all bad activity.*"

Plans and objectives are not always communicated to the whole team. When asked if their team used a mission plan, one experienced analyst said: "*Yes, but I didn't have access — I was just a lowly [low rank] at the time. It was the team lead who ... would come up with it.*"

(3) Collect Intelligence: Subjects described 3 intelligence collection tasks. (1) When a specific trigger exists, intelligence is tailored around that trigger. (2) On proactive missions, current attacker trends are used: "*If there's a current prevalent exploit that's being used, like that you're seeing in the news... we're gonna go ahead and look for those.*" (3) Regardless if the hunt is proactive or triggered, teams will often collect and upload additional Indicators of Compromise (IOCs) to achieve increased coverage: "*we'll...load IOCs from all the threat intelligence providers.*"

Subjects provided many example intelligence sources but 4 sources were recurring: (1) A distinct intelligence team supporting the TH team; (2) Publicly Available Information (PAI) like social media or news feeds; (3) Open-Source Repositories like InQuest's Indicators of Compromise (IOC) database [23]; and (4) Classified or Subscription Feeds.

(4) Pre-Mission Activities: Before a TH team begins a mission, they fine-tune their tools using the Intelligence and the mission scope, hypothesis, and plan. One subject described typical pre-mission activities and how these can vary between internal and external hunts:

> "*So you plan the mission...dates [and] goals... And then you'll push that into developing your specific tools and analytics. If you're hunting yourself [i.e., internally], you probably already have most of your sensors and tools in place ... If you don't have tools or specific analytics to cover what you're going after, then you need to develop or buy or get those plugged in.*"

(5/6) Manual and Automatic Analysis Loops: At this point, the TH team deploys to the customer's site and spends 1–4 weeks hunting. Most of the TH time is spent here.

Subjects described two different modes of analysis. Both modes included cyclical tasks so we term them "loops". In the Manual Analysis Loop, TH team members enrich their baseline and perform manual analysis of the collected data, looking for potentially malicious behaviors. In the Automatic Alert Analysis Loop, members triage sensor notifications of possible IOCs. These loops continue concurrently and members are assigned to them at the team lead's discretion. A team lead summarized: "*Those two processes...are our constant back and forth over a couple weeks that we're doing on-site until we can either find something or not.*"

One subject described these loops ("paths"): "*So the first path is your alerting path [Note: the automated loop]. Those are your indicators and signature based detections ... And then the second path [Note: the manual loop] I see kind of starts with understanding the environment which is some baseline analysis...that path then feeds into your two like core detections, which are ... your behavioral analysis ... and then you*

also have anomaly based analysis."

(7) End Mission: The goal of a hunt mission is to detect adversaries, if they exist on the network. If adversary activity is observed, the hunt is over and a response is necessary. One subject said: "*If we find commodity malware on the computer, it may not require a lot of resources...If it's something bigger...we're probably going to shift into IR mode.*"

At the end of the mission, TH teams report their findings and provide recommendations: "*We come back to those hypothesis in our final report, too....[the report] goes to the entity and back to our leadership saying, 'We tried to see if your exchange server was compromised by doing X, Y, and Z. Here's some things we investigated as a part of that. Here's our conclusion or what that led us to believe.*"'

4.1.3 Process management

Process Creation: Process creation differed across organizations. One organization's process was devised by a group of team leads. At another organization, the TH process was created by 1-2 people in leadership positions and was deliberately imitative of other government TH teams. This imitation lets their TH teams interoperate with other organizations, enabling personnel sharing in the event of a national cyberattack.

Process Changes: At both organizations, the TH process changes frequently, and changes can be proposed by any experienced personnel: "*everyone who had prior experiences or is now part of the [team] and been on a mission...can submit edits.*" Subjects describe the process changes positively, in terms of continuous improvement — "*We're constantly looking for how we can improve... So basically after every mission... we do a hot wash and we say: 'Okay, what could have gone better?'*". One team lead did warn that process change in the middle of a mission can be problematic: "*If you change the tactics too often, you are going to tire out your analysts ... You're gonna tire out yourself and you're gonna get confused when you go to write the final report.*" They implement changes between missions instead.

4.2 RQ2: Process shortcomings and solutions?

Table 3 shows process issues, proposed solutions, and open questions. Common process challenges are (1) determining expertise of team members (to assign appropriate tasks); and (2) Improving automation.

This section describes TH process challenges noted by ≥ 3 subjects across both organizations, and possible solutions where available. Shortcomings are ordered by frequency. To avoid biasing to a single subject's "pet peeves", in this section all subjects are quoted at least twice and no more than 5 times.

4.2.1 Identifying expertise

Problems: TH team leaders want to assign members different tasks depending on the members' expertise. Many indicators of expertise exist — three common indicators are external certifications, internal certifications, and training. Subjects seemed to dislike these. Instead, they used *ad hoc* indicators such as experience and time spent working off-hours.

(1) Certifications: Six subjects did not believe certifications were a good measure of expertise. One subject was skeptical that certifications measured even baseline knowledge: "*It's really hard to define what a baseline of cybersecurity understanding is ... You can't really say it's having a certain certification because there's plenty of people that have certifications that don't know what they're talking about.*"

(2) Internal Certification: One organization maintains an internal certification as mentioned by five subjects. One subject stated that it helped the team be interoperable with other government TH teams. Three subjects voiced dissatisfaction with the certification stating it was irrelevant or poorly implemented: "*I have some mixed feelings on [the certification]...It doesn't ...apply to us all that well and the proficiency needed to complete it isn't ...much either.*"

(3) Training: Two subjects, both inexperienced, spoke favorably of training as an indicator of expertise: "*I think it's just training experience, time with the tools, time with the knowledge base — I think training has a big part of it though. And I think just hands-on is pretty key as well, which the training could help with.* " Two experienced subjects were more cautious. For example, one said: "*There is a mild or weak correlation between number of training courses and analyst success*". Four subjects spoke unfavorably of training as an indicator of expertise. A team lead said "*having a [certain] course under your belt or any other course, usually doesn't give me immediate confidence.*". One analyst strongly critiqued their required training courses: "*We have [an agency] requirement... just a massive waste of time. <laugh>*" However, this analyst recognized that some trainings can help: "*I've given the team several trainings [about tools]...little exercises to help people get up to speed.*"

Solutions: Developing indicators of expertise remains an open question. Subjects had some suggestions, which we list next, though each idea was opposed by $\geq$1 subject.

(1) Time with tools: The importance of time with the tools was a theme that often accompanied discussions about training, as an indicator of expertise or a tactic to integrate newer members. When subjects discussed the value of training, they often spoke in terms of whether it let them improve their skills with their tools. For example, one subject said: "*looking at the [training]... it's a good experience but... they don't use the tools we currently use...It doesn't provide the training that we need per se, for the tools that we use.*"

(2) Working on personal time: Working off-hours was viewed more positively than training or certifications. Five

Table 3: Process challenges and proposed solutions noted by subjects. Open problems have no consensus solution or occur when subjects verbalized difficulty or uncertainty. Only challenges noted by ≥ 3 subjects and observed in both orgs. are included.

Observed process challenge	# subjects (# orgs)	Proposed Solutions	Open Problems
Poor measures of expertise (§4.2.1)	6 (2)	Make training more tool oriented	Determining TH expertise?
Insufficient automation (§4.2.2)	6 (2)	Automate baselining & set-up tasks	Will automation hinder the analysts?
Teams lack needed data (§4.2.3)	5 (2)	Deploy sensors ahead of time	What data to collect?
Inappropriate process detail (§4.2.4)	4 (2)	Give team leads flexibility	*None mentioned by subjects*
High turnover (§4.2.5)	3 (2)	Pair new and experienced members; Enhance process documentation	*None mentioned by subjects*

subjects said doing cybersecurity activities on personal time was a good metric for potential or expertise. Subjects made comments like: "*I can't really put my finger on a single thing that...explains our expertise. I would say, a big part of it is just being willing to kind of play around with the tools and even in their own time. I mean, we have a lot of downtime between missions where we do trainings, but I'm thinking more, even within that time-frame, they have a lot of free time where they can kind of play around with the tools or do you know, capture the flags ...that almost has been a bigger indicator.*" We note that not all analysts will be able to devote free time and that making this an indicator of expertise could have undesired effects such as marginalizing certain otherwise high performing analysts as has happened in similar cyber security fields [46].

(3) Experience: Ten subjects mentioned experience (*e.g.,* the number of missions) in the context of expertise. Five subjects were generally positive about experience as an indicator of expertise, while four demurred. One subject said: "*I think experience is a key metric. ...most of the guys that we got that had already done threat hunting [before joining our organization] are our best analysts*". A common counter-argument was: "*Experience does not equal quality...just because someone has experience doesn't mean they're good at their job.*"

Subjects who affirmed experience as an indicator of expertise often did so hesitantly, recognizing it as a heuristic. For example, the positive subject quoted earlier also said "*You...have people who've been on a hundred missions and they just don't have the aptitude or the thought ability. You...have people who have never been on a mission who have the aptitude and who are gonna outperform people who have been on 20 missions. ... I think it's a little hard to answer that question directly, but I would say the biggest <hesitates> there is a correlation between number of missions and analyst success.*"

4.2.2 Improving Automation

Problems: Automation is often emphasized as a way to reduce costs or to discover adversaries more quickly. The subjects indicated their automation was insufficient or ineffective.

(1) Insufficient Automation: One issue was that both organizations had little automation. When subjects were asked how much of their process was automated, answers ranged from "*None of it's automated*" to "*25 – 35%*".

Six subjects indicated dis-satisfaction with the current level of automation. They made statements like "*that's a big point that could be improved*". Two additional subjects indicated that the process was all or mostly manual, making statements like: "*It's still pretty manual.*"

Seven subjects described hindrances to more automation. Two subjects mentioned that analysts had insufficient time to generate automation. Subjects made comments like "*Mainly just lack of time development time. We've just been very busy.*" Two subjects described a lack of personnel. For example one subject responded: "*Probably just personnel gaps.*" Two subjects mentioned that the team did not have the necessary knowledge to automate tasks that should be automated. When asked why more had not been automated one of these two subjects said: "*because nobody understands [tool]*".

Two subjects hesitated about further automation. One team lead did not want the automation to become a crutch. Another subject (in a leadership role) had a philosophical concern:

> "*Hunting...should start where automation stops. That's...the whole premise of hunting...the sophisticated actor already bypassed all that [automation] and now you have to apply manual techniques to...find them... It's good to automate [repetitive] things, maybe like deploying kit. But I think most of the analytical work should...rely on human factor.*"

(2) Ineffective Automation: A second issue with automation is its effectiveness. Figure 2 includes two analysis loops: manual and automated. Out of the subjects that had detected adversaries on hunt missions (7/11), none of their examples described activity found by the automated alert loop. One team lead said: " *[The adversary] was almost exclusively found by analysts observing the data for living off the land techniques or new zero days.*[4] *I would say that we found at least three or four zero days, which, couldn't have been detected by [automation or intelligence reports].*" A member of leadership said: " *[What] we find are mostly analytical kind of behavioral activity. Like an analyst spots.*"

Solutions: Five subjects suggested opportunities for greater automation. Two subjects said baselining took too long and should be automated. One said: "*Have the baseline step be an*

[4] "Living off the land": using the victim's own tools instead of downloading external tools. "Zero day" vulnerabilities: unknown to network defenders.

automatic step. ... where baseline is also is almost automatic. ... then you can kind of shift the window baseline out from two to three days...to a five minute thing." Two other subjects discussed equipment preparation tasks. One suggested: "*It would be cool to automate the indicator portion, other than us having to manually feed in that stuff.*" Subjects also suggested automating endpoint log collection and automating the reporting of important artifacts and their contexts to the team.

4.2.3 Improving Data Collection

Problems: A successful threat hunt needs timely and sufficient data. Subjects noted challenges in both dimensions.

(1) Delayed data collection: Many teams would only begin collecting data when the team arrived on site. This created an issue because the team was forced to start hunting before much baseline data had been collected. Without data, threat hunting is virtually impossible or as one experienced team lead said: "*you can't find anything without data*". Seven subjects either mention this issue or said that they have learned to deploy sensors ahead of time to combat it. One team lead said: "*We did a threat hunting engagement...for about two weeks, but we plugged sensors in on Day One of those two weeks. When you do that, you don't have a baseline of what even one work week looks like much less a couple...we ... didn't have the baseline to actually do real analysis on the network.*"

(2) Un-prioritized Data Collection: Some TH teams collected too much data or the wrong type of data. This extraneous data obscures potentially relevant data. One experienced member of leadership said: "*I know with [former TH organization]...we would ask for a ton of stuff. Give us this, and that...and for no reason, right? ... Just because you have all the data does not necessarily mean that you're going to be more effective doing your hunt. I think it's the opposite and that's kind of the mindset that needs to change.*"

Another subject, a team lead, gave an example of a mission where so much data was collected that the servers containing the data stopped behaving properly. The subject reported that in this environment: "*if you tried to follow the checklist you ended up getting really confusing results because the logs that were coming in were non-deterministic ... trying to stick to [the checklist] was counterproductive because if you tried to stick to it, the data made less sense.*"

Solutions: Five subjects had been on teams that had experienced the issue of lacking data when the team began analysis. These subjects described a solution that worked for their teams: Weeks before the TH teams' arrival, a predeployment team would install sensors on the network. One subject said: "*I'll bring up a problem that we had. <laugh>our first one that we've worked through, which was a huge improvement, was the prep work in advance, right? [Before] we just set sensors the day that we arrived and that was terrible.*"

The issue of unhelpful data being collected seemed to be difficult. No subjects mentioned having solved this issue. One experienced member of leadership suggested more precise scoping as a possible solution. They said: "*We go into these environments, you see a lot of guest networks, or IOT devices, like cameras and security badges and stuff. It's stuff that we don't necessarily need to monitor ...and then it just fills up our sensors ...[queries] take forever to get results. Let's concentrate on one thing, but do more in depth work. Concentrate on quality, I guess, versus quantity.*"

4.2.4 Improving Process Documentation

Subjects expressed opposing views on their team's process documentation, as well as what would constitute good process documentation. We therefore do not present this theme in terms of problem-solution, but rather in terms of these opposing views. Conflicts in these views are reminiscent of the "contradictions" observed in SOCs by Sundaramurthy *et al.* [89]. These views may be influenced by the level of detail in process documentation on each team. One organization had a detailed checklist. Another had a similarly detailed process but allowed team leads to adapt it per deployment.

View–More detailed process documentation: Four subjects requested or supported more detailed process documentation. "*I think having the [detailed process documentation] will help [new members] be more effective, faster, because it will give them a guideline of what to do. So instead of sitting there not knowing what the first step to take, at least they know a general network to look in. So instead of sitting there: 'I don't even know where to start.' It's: 'I'm looking for connections on odd ports. That's my first thing. And that's how I'm gonna learn to build my first queries.'* " More documentation and process rigidity was considered helpful for newer members. One analyst described the creation of a spreadsheet documenting the task that had to be completed on a TH mission: "*We didn't really know what we were looking for before spreadsheet. ... I took the idea of the spreadsheet by looking at Mitre ATT&CK and seeing what we could look for. ... so it helped [new members] focus on each task at a time.*"

View–Less detailed process documentation: In contrast, four subjects spoke in favor of less detailed process documentation. One subject said their team's process was too detailed: "*For the current experience level of [my team], I would like it to see it a bit more vague... [subject gave an example of a VPN checklist item for a network without VPN] ...It's too specific, you know? ...[We should] make that more abstract and say like, 'Hey, why don't [you] just look for any remote access software?'*". One organization addresses this conflict by giving team leads autonomy: "*[Team leads] are responsible for their mission...They are given leeway to adjust as things happen.*" When asked how often team leads adjust the process, this subject said: "*I'd say 25 to 50% of the time*".

In support of this view, one team lead gave an example of a mission where the process felt over-specified and switching to a more abstract process improved their performance. Another

subject in leadership spoke to the importance of flexibility: "*I dislike making rigid guidelines ...I think the goals of each engagement may be different based on the partner, the threat actor, the geopolitics ...I think making it too strict makes it so that we lose some of the flexibility to do the missions that have the most impact or that we can't meet the goals we want based on a checklist that wasn't developed for them.*"

4.2.5 Turnover

Problem: Three subjects mentioned the negative effects of turnover. One subject said: "*our biggest problem right now is turnover ... [at] any given time, you maybe have a quarter to a third of your team, [that] has been on more than one mission*". They mentioned a case where their entire team was replaced with new members.

Solutions: Two possible solutions were offered by subjects: pairing members and improving process documentation.

(1) Pairing Members: Six subjects recommended pairing new members with expert members to improve the integration of newer members. One less experienced subject found it quite helpful, saying "*[Observing more experienced members] was nice because I was basically able to look over the shoulder over all the missions that have happened so far and see where I fit in the puzzle piece of Threat Hunting.*".

Two more experienced subjects agreed that pairing members can help, but voiced warnings. One spoke about short- vs. long-term payoffs: "*It's a balance between, do we need to succeed in this mission or do we need train our junior analysts to succeed in the next mission?*" The other emphasized that pairing requires learner engagement: "*If the new member isn't particularly motivated then they're just gonna be staring at a screen and not learning anything ...it would be nice to ...have ...a side saddle process...[where] let's both do it at the same time separately [and] you show me how to do it.*"

(2) Process Documentation: Five subjects described good process documentation as important for assisting new members. Some subjects felt that process documentation helps a team meet a minimum standard, *e.g.,* "*I think defining...baselines...really well so you have the minimum standards and a clear task list... What [are] the 10 steps that you absolutely will do before going deeper? And if you have that well defined and built into your tools with automations when possible, that makes it...easier for people to come on board and get up to speed.*" Another subject said: "*Usually the less experienced ones are better at following the process, mostly because they don't know any better to do anything else.*"

5 Discussion & Future Work

Our work has two audiences: operations teams and researchers. We discuss TH among other cybersecurity operations (§5.1), then share implications of our study for TH teams (§5.2) and opportunities for future research (§5.3).

5.1 Threat Hunt and Other CyberOps

As discussed in §2, TH work is adjacent to Incident Response (IR) and Security Operation Centers (SOCs). The experiences of our DHS TH team member subjects thus echo, yet are distinct, from the experiences of IR and SOC teams.

The DHS TH teams described many challenges shared by IR teams. Our subjects said that measuring TH team effectiveness is difficult due to lack of feedback; IR teams have a similar issue [93]. IR analysts express similar concerns about automation hindering analysis capability [73]. Data access is an issue for both TH and IR teams [48]. However, IR teams differ from our TH subjects in the data they have about the adversary. One reason why models such as ATT&CK and Kill Chain are popular is that they show IR teams the "next step" when investigating an incident. For TH teams (and SOCs), there is no confirmed incident, so a TH team must investigate everything, hoping a clue was dropped along the kill chain.

With respect to SOCs, the studied TH teams operate as a third-party "check" on the SOCs' networks. Our subjects thus undertake similar activities, but with different information. The DHS TH teams get intelligence from other government entities, much of which cannot be shared with private sector SOCs. The DHS TH teams also set up their own sensors to check for blind spots in the SOCs' surveillance. Beyond these informational strengths lie weaknesses: DHS TH teams struggle to baseline because they are not on the network for long. This may be why some subjects and other TH researchers that believe that TH can never be fully automated [31, 66] — automation requires a baseline that third-party hunters lack.

5.2 Recommendations for Threat Hunt Teams

In §4.2 we presented challenges and potential solutions. Now we synthesize our observations into three recommendations.

(1) Improve Planning. Although many subjects focused on the TH activities *after* deploying to a customer site, about half of our unified TH process (Figure 2) occurs before deployment. We were surprised by the range of planning activities and formality reported by subjects. We recommend that all TH teams create mission planning documents **and** share the objectives with everyone on the team. Following the advice of one subject: "*plan the mission...your high-level goals...and push that into...specific tools and analytics.*"

(2) Revisit the Automated Alert Loop. In §4.1.2 we described the two analysis loops applied by the TH teams we studied (see Figure 2). However, in §4.2.2 our subjects reported that their automated alert loops rarely find adversary activity. There are many possible causes, including redundant automation (*e.g.,* already applied by SOC teams), human error (*e.g.,* important alert is forgotten and not uploaded to tool) and absent automation (*e.g.,* zero-day exploits). We recommend either making the automated alert loop more effective or reducing the resources devoted to it.

The ineffectiveness of automated alerts might be a flaw in threat intelligence. One analyst, describing adversary detection on a previous mission, was surprised that there was no alert for the activity. They said: "*I don't think there was an alert on it. Which is odd thinking about it now...you definitely would think that [tool] would contain some...but I don't think there was.*" Eight subjects claimed that their intelligence component supplies the team with at least some of the alerting rules used during a hunt. Perhaps TH teams should revisit the trust they place in these turnkey automated rules.

If TH teams do not revisit their automated alert strategy, then they might re-evaluate how many resources they invest in it. For example, one subject estimated that intelligence/alerting only accounts for "*maybe a tenth*" of adversary detections. If the amount of resources put into this analytic loop exceeds 10%, this could indicate an inefficiency.

(3) Formalize apprenticeship. Many subjects voiced concern about the quality of existing TH training and certifications §4.2.1. Some teams addressed this by pairing new and experienced members (§4.2.5). These teams appear to be reinventing the concept of *apprenticeship*, which is an educational strategy for disciplines that are more art than science [1]. There is much literature on the virtues and shortcomings of apprenticeship [35, 77] and apprenticeship is currently being used with success in cybersecurity [85, 87]. Since subjects seem to agree that pairing is a good way to integrate new members, teams may benefit from a more robust apprenticeship program. According to subjects, this should include providing time while on mission, since hunting with trainees takes longer. We recommend ensuring trainees not just watch others hunt, but rather interact with data and tools under supervision (the "side saddle" process suggested by one subject).

5.3 Future Work

Threat Hunt is a young cybersecurity discipline. Our exploratory study suggests many beneficial directions of study.

Tailor automation to needs: We reported subjects' suggestions for automation in §4.2.2. The most popular suggestions were automating baselining and recurring equipment set-up tasks. In contrast, most of the automation in the academic literature focuses on automating the entire TH process [52, 56, 67, 96]. This class of automation may address the current shortcomings of the automated analysis loop. However, it does not address the needs verbalized by our subjects.

Does automation hinder analysts? In §4.2.2, one team lead and one subject in a leadership role expressed concerns that automation would lead analysts to not think for themselves. Measuring whether, and under what conditions, automation reduces team effectiveness would provide useful data for TH decision-makers.

Process formalism or flexibility? In §4.2.4, subjects request more detailed TH process documentation. However, in that section, an example is given of a process that was too precise, becoming a hindrance to the team. A second subject indicates that they wish the process were more vague. Some teams deal with this tension by allowing team leads to make process changes. Not all organizations require their team leads to have TH experience so not all team leads will be capable of making these decisions. It is possible that this tension is inherent to a creative and open-ended activity, but tracking and measuring it may be helpful.

Process evaluation: Subjects did not agree on metrics for measuring TH team effectiveness. The goal of TH is to reduce adversary dwell time [94]. However, this metric may not be applicable to the TH teams we studied because they act in a third-party capacity and do not necessarily revisit organizations. Additionally, organizations may be compromised so infrequently that measuring dwell times does not provide a TH team with actionable feedback.

Other metric recommendations include security improvement [45], and risk reduction [51]. These metrics measure whether a TH team added value by identifying vulnerabilities or security blind spots. An objective measure of this kind of effectiveness may help evaluate the quality of a TH process. A final proposal is Bianco's Hunt Maturity Model [31], which measures a team's capabilities rather than its products. None of these metrics has been systematically evaluated in practice.

6 Conclusion

Many organizations have recently adopted Threat Hunting as a way to detect adversaries who have infiltrated their networks undetected. There is little academic literature on Threat Hunting processes, and no description of the Threat Hunting process as performed by US government hunt teams working on third-party networks. In this work, we provide the first description of the US government Threat Hunting process model as practiced by teams in the US Department of Homeland Security. We found that these teams have different processes than those reported in prior literature, differing from both private-sector internal hunt teams and other government teams. We provide a novel model of the Threat Hunt process, complemented with a set of open problems and possible solutions suggested by Threat Hunt practitioners. Much work remains: in the short term, these process recommendations can be implemented and tested; in the long term, experiments in this sensitive context remain an open challenge.

7 Acknowledgments

We acknowledge support from the US Coast Guard. We thank our research subjects for their participation. We thank G. Cramer for assistance in coding, and A. Kazerouni for feedback on the manuscript. We thank the CCS and USENIX reviewers for constructive criticism.

A Summary of the Technical Report

An extended version of this paper is available as a technical report at arXiv:2402.12252. It includes:

- The full interview protocol.
- Saturation charts showing that our $N = 11$ interviews saturated the coding space under consideration.
- Discussion of the possible effects of subjects' organizational ranks.
- The codebooks used in our analysis.
- Details about cybersecurity frameworks and related TH processes.
- Additional details of our methodology and results, notably a detailed TH process diagram refining the high-level version presented in Figure 2.

A Linear Reconstruction Approach for Attribute Inference Attacks against Synthetic Data*

Meenatchi Sundaram Muthu Selva Annamalai

Luc Rocher
University of Oxford

Abstract

Recent advances in synthetic data generation (SDG) have been hailed as a solution to the difficult problem of sharing sensitive data while protecting privacy. SDG aims to learn statistical properties of real data in order to generate "artificial" data that are structurally and statistically similar to sensitive data. However, prior research suggests that inference attacks on synthetic data can undermine privacy, but only for specific outlier records.

In this work, we introduce a new attribute inference attack against synthetic data. The attack is based on linear reconstruction methods for aggregate statistics, which target all records in the dataset, not only outliers. We evaluate our attack on state-of-the-art SDG algorithms, including Probabilistic Graphical Models, Generative Adversarial Networks, and recent differentially private SDG mechanisms. By defining a formal privacy game, we show that our attack can be highly accurate even on arbitrary records, and that this is the result of individual information leakage (as opposed to population-level inference).

We then systematically evaluate the tradeoff between protecting privacy and preserving statistical utility. Our findings suggest that current SDG methods cannot consistently provide sufficient privacy protection against inference attacks while retaining reasonable utility. The best method evaluated, a differentially private SDG mechanism, can provide both protection against inference attacks and reasonable utility, but only in very specific settings. Lastly, we show that releasing a larger number of synthetic records can improve utility but at the cost of making attacks far more effective.

1 Introduction

Modern scientific research benefits from large datasets of personal data, facilitated by data sharing between organizations. In the past decade, data breaches, privacy threats, and lost public trust have challenged access to data, putting reproducibility and open data efforts at risk. Data anonymization—the process of sanitizing data so that individuals are no longer identifiable—is one of the main ways to share data while minimizing privacy risks for data subjects. However, a large body of research has shown that traditional anonymization techniques are generally inadequate and do not provide a good tradeoff between privacy and statistical utility for modern data [50, 57].

Synthetic data generation (SDG) has emerged as a potential solution to provide both high utility and privacy protection. This approach relies on algorithms that learn the underlying distribution of the data, to then generate structurally and statistically similar data. The resulting synthetic data may not contain any original record, yet can be seamlessly integrated into analysis pipelines at little to no cost. One of the main use cases of synthetic data is in tabular data publishing, with the US National Institute of Standards and Technology (NIST) suggesting that synthetic data can "serve as a practical replacement of the original sensitive data" [47]. The UK Royal Society further argued that it "retain(s) the statistical properties of the original dataset" such that "the anonymity of the original dataset is not compromised" [61].

Despite these positive early evaluations, the fact that synthetic records are "artificial" does not, per se, guarantee that the privacy of all individuals in the original dataset are protected. In the past few years, the privacy guarantees provided by generative models and synthetic data have come under heightened scrutiny [10, 11, 28–31, 51, 62, 70]. For instance, having full access to the internal parameters of the trained generative model allows adversaries to run powerful attacks against high-dimensional synthetic data [10, 11, 29, 30]. However, this adversarial model, referred to as the *white-box* setting, is often unrealistic as the trained model is typically not shared in the context of synthetic data [61, 74].

In the *black-box*[1] setting, where the adversary has exact

*An extended version of this paper can be found here.

[1] We note that black-box is used also with a slightly different meaning in the context of attacks against machine learning models [45]. However, in the context of synthetic data, this taxonomy [31] is more suited as it reflects the way synthetic data is generated and released in practice.

knowledge on the specifications of the SDG algorithm along with some auxiliary knowledge, Stadler et al. [62] propose a membership inference attack (with an adversary attempting to predict presence in the training dataset), adapting the shadow modelling technique from Shokri et al. [60]. They show that information leakage can in fact be exploited without directly relying on overt memorization by the generative model, but only for specific outlier records.

In the most restrictive scenario where the adversary has no knowledge of the SDG algorithm (*no-box* setting), while prior work has proposed attacks, they have limited effectiveness in practice. Against generative models that memorize and output training data, Chen et al. suggested a simple heuristic attack—searching for the closest synthetic record to a victim's record [11]. However, their attack has limited effectiveness in the context of synthetic tabular data [31]. Stadler et al. proposed a second attack that uses machine learning to infer the secret attribute of a target record (attribute inference attack). However, in their experiments, the adversary can precisely infer the target record's sensitive attribute even when the target record is *not present in the original dataset*. This means that the attack may, in principle, be exploiting population-level associations, making it difficult to assess whether synthetic data actually "remembers" information about the original records (nor, arguably, on whether the SDG mechanism protects privacy [7]). This issue has been referred to as the base rate problem by Houssiau et al. [31].

Contributions. Here, we study the privacy leakage from synthetic tabular data in the *no-box* setting. To that end, we introduce a new attribute inference game with a *partially informed* adversary who has access to two datasets: the synthetic dataset and the 'quasi-identifiers' of the records from the original dataset (i.e. all the attributes except the one that is to be inferred). Under our privacy game, the adversary tries to infer the *randomized* secret attribute of a given record. This solves the base rate problem mentioned above and enables us to evaluate information leakage about individual users. Our main contributions are as follows:

1. We propose a new attribute inference attack on synthetic data that leverages overly-accurate aggregate statistics computed on the synthetic data. Specifically, our attack does not directly rely on overfitting or overt memorization by the generative model. Instead, the attack is based on linear reconstruction attacks [13, 36], which aims to reconstruct the whole dataset (or column) without targeting specific users or outliers.

2. We show that many users can in fact be vulnerable to attribute inference attacks against synthetic data, not just outliers. Specifically, our attack can infer a target record's secret attribute with up to 94.8% probability, compared to a random baseline of 50%. Our attack can increase accuracy by up to 9.6 percentage points compared to prior attacks, when evaluated on our privacy game. This shows that simple heuristics, such as the distance to closest synthetic record, can underestimate the privacy risks of synthetic data.

3. We provide a quantitative framework to evaluate privacy-utility tradeoffs of synthetic data. In particular, we show that, *for the same trained SDG model*, releasing a larger number of synthetic records can result in better utility but worse privacy. To the best of our knowledge, the impact of synthetic data size has not been studied for privacy, and has been mentioned only marginally for utility [3]. This has important practical implications, suggesting that empirical evaluations on small benchmark datasets can strongly underestimate privacy risk if larger synthetic datasets are then released.

4. We find that synthetic data, on its own, can hardly provide both good utility and good privacy protections—not only for outliers but even for arbitrary records. As an example, in our empirical evaluations, none of the state-of-the-art SDG algorithms could provide both accurate observations with a mean relative error below 0.20 and attack accuracy below 60%.

5. Lastly, we investigate the effect of formal differentially private (DP) defenses on synthetic data generation. We show that, in specific cases, recent DP mechanisms can offer good privacy-utility tradeoffs in practice, at the cost of weak formal guarantees.

2 Related Work

Since the first membership inference attack (MIA) against machine learning models was proposed by Shokri et al. [60], a long line of work has investigated MIAs against generative models. The models under study include large language models [10], generative adversarial networks [11, 29, 30], diffusion models [75], and variational autoencoders [30]. These prior work have focused both on the *white-box* setting (where an adversary has full access to the trained model) and on the *black-box* setting (where an adversary has exact knowledge of the specifications of the generative model). However, in the context of synthetic data, the underlying generative model is typically not shared and the adversary only has access to the generated synthetic dataset [61, 74]. Therefore, these prior attacks propose strong adversarial models that may be unrealistic in practice. Here, we instead focus on the *no-box* setting: the adversary has access to the anonymised synthetic dataset but no information about the underlying generative model or even the specifications of the synthetic data generation algorithm [31].

Early work on attacks against synthetic data have proposed simple heuristics, with the intuition that synthetic

datasets might violate privacy if they overtly memorize and output the training data. In such cases, records in the original dataset would appear as-is or with small differences in the synthetic dataset. To quantify privacy leakages, researchers have suggested to compute the distance to closest synthetic record [30, 41], which we refer to as the DCR heuristic. By introducing artificial privacy leakage, Giomi et al. suggest that the DCR heuristic works best when the generative model overtly memorizes training data by generating synthetic records that are very close to or almost the same as records in the training data [28]. However, information can leak in many more complex ways than direct memorization as has been previously shown for other types of analyses such as aggregate statistics [18, 53, 54] and machine learning [9, 29, 71].

In the context of synthetic data, Stadler et al. [62] were the first to show that individual-level information can in fact be leaked from synthetic data beyond simple heuristics. In their membership inference attack, Stadler et al. follow the shadow modelling approach of Shokri et al. and show that 4 out of 5 outlier records tested were vulnerable to membership inference attacks. However, even amongst the outlier records, 1 out of 5 achieved close to perfect privacy protections. Additionally, under their framework, all 5 randomly chosen records achieve close to perfect privacy protections which suggests that there is little to no privacy leakage for the average user from synthetic data. While attacks against a small minority of users can be useful to measure theoretical risks, they may not be necessarily relevant in practice especially if the adversary does not have a precise way to recognize vulnerable users [12, 25].

On the other hand, attribute inference attacks are an understudied area of research in the context of synthetic data. Stadler et al. additionally propose an attribute inference attack where the adversary trains a machine learning classifier on the synthetic data to predict the secret attribute. The adversary then uses this classifier to infer the secret attribute for the target record. However under their privacy game, the adversary could infer the target record's sensitive attribute *even if the target record was not in the original dataset* thus making it hard to determine if enough information pertaining to a specific target record was present in the synthetic data. Therefore, whether synthetic data are vulnerable to attribute inference attacks remains an open question.

3 Preliminaries

Datasets. A *dataset*, $\mathcal{D}$, is a multiset of n records from a domain with d discrete attributes $\mathcal{X} = \mathcal{X}_1 \times ... \times \mathcal{X}_d$. For simplicity, we assume that the domain of each attribute, $\mathcal{X}_i$, is finite so that each attribute is discrete[2]. $\mathcal{D}$ can be seen as a matrix of n records and d attributes, and we write $\mathcal{D}$ as $\mathcal{D} = \{X|\mathbf{y}\}$, where X is the first $d-1$ columns and $\mathbf{y}$ is the last column. In the next section, we will consider, without loss of generality, the d-th attribute as the secret that the adversary tries to infer.

Following prior work in the area of linear reconstruction attacks [13, 20, 22], we assume for simplicity that the secret attribute is binary i.e. $\mathcal{X}_d = \{0,1\}$ and $\mathbf{y} \in \{0,1\}^n$.

Synthetic data generation. A *synthetic data generation (SDG) algorithm* is any algorithm (deterministic or randomized) that takes as input an *original dataset* $\mathcal{D}$ and outputs a *synthetic dataset* $\mathcal{S} \sim \text{SDG}(\mathcal{D}, m)$. We denote by m the number of generated records, called *synthetic data size*. We consider only SDG algorithms where original ($\mathcal{D}$) and synthetic ($\mathcal{S}$) records are from the same domain $\mathcal{X}$.

In practice, most SDG algorithms work by training a generative model $\mathcal{G}$ on the original dataset $\mathcal{D}$. The trained model $\mathcal{G}(\mathcal{D})$ can be modelled as a stochastic function that generates synthetic data records. As we are not concerned with attacking the underlying generative model in this work, we abstract out these details and consider any SDG algorithm as a function that outputs records from the domain $\mathcal{X}$.

Marginal queries. Marginal queries, also called cross tabulations, are one of the most important and useful statistics computed on tabular datasets [47]. Informally, they take the form "what fraction of people in the dataset are *married*, *employed* and *have a college degree*?" and encode associations in the dataset. Formally, a k-way marginal query is defined as follows:

Definition 3.1 (**k-way marginal query**). Given a dataset $\mathcal{D}$ over a data domain with d attributes, $\mathcal{X} = \mathcal{X}_1 \times ... \mathcal{X}_d$, a k-way marginal query is defined by a subset of attributes $A \subseteq \{1, 2, ..., d\}$, $|A| = k$ and corresponding values for each of the attributes $v \in \prod_{i \in A} \mathcal{X}_i$. Given the pair (A, v), define $\mathcal{X}(A, v) = \{x \in \mathcal{X} : x_i = v_i \; \forall i \in A\}$. The corresponding k-way marginal query is then defined as follows where $\mathbb{1}$ is the indicator function that maps elements of the set to 1 and the rest to 0:

$$Q_{A,v}(\mathcal{D}) = \frac{1}{|\mathcal{D}|} \sum_{x \in \mathcal{D}} \mathbb{1}(x \in \mathcal{X}(A, v))$$

4 Attribute Inference Attacks

Successful attribute inference attacks have been considered as an important privacy risk in machine learning [24] and data publishing [38]. However, in recent years, the validity of some attribute inference attacks in the literature has come into question [7, 31, 34]. In order to mitigate these concerns, we first formalize attribute inference in a new privacy *game*. Thereafter, we introduce a new attribute inference *attack* against synthetic data under our privacy game.

[2] In the context of synthetic data, this assumption is often true in practice, as continuous attributes are often discretized before the generative model is trained [3, 43, 73].

4.1 Attribute Inference Privacy Game

Threat model. Before formalizing the attribute inference attack model as a game, we provide an intuitive description. We consider an original dataset $\mathcal{D} = \{X|\mathbf{y}\}$ and a target user u that is known to belong to the original dataset. We assume that the adversary has access to the target's partial record $\mathbf{x}_u \in X$, and aims to infer the value of the target's secret attribute $\mathbf{y}_u$. Our threat model follows the *no-box* setting [31]: the adversary has access only to the synthetic dataset $\mathcal{S}$ and no other information on the synthetic data generation procedure.

While previous work [11, 29, 62] often assumes that the adversary has access to a reference dataset (typically sampled from the same distribution as the target dataset), we do not make such assumption. Instead, we assume that the adversary is *partially informed*: the adversary has access to X (the adversary's auxiliary information), but not to the secret attribute values $\mathbf{y}$. We call X the matrix of *quasi-identifiers*, representing information that may be publicly available through additional data releases. Table 1 provides a summary of the notation and the adversary's knowledge. We motivate the use of this threat model in Section 7.4.

In this setting, an SDG algorithm protects against attribute inference if the synthetic dataset $\mathcal{S}$ does not leak any information about the secret attribute values $\mathbf{y}$.

We now provide the formal description of the game:

Attribute Inference Privacy Game.

- *Step 1.* Challenger samples original dataset $\mathcal{D} = \{X|\mathbf{y}\}$ with n records.
- *Step 2.* Challenger selects a random target record u such that its quasi-identifiers $\mathbf{x}_u$ are unique in X.
- *Step 3.* The Challenger then randomizes its secret attribute to create the target dataset. That is, $\mathcal{D}' = \{X|\mathbf{y}'\}$ such that $\mathbf{y}'_i = \mathbf{y}_i \; \forall i \in [n], i \neq u$ and $\mathbf{y}'_u \leftarrow \{0,1\}$ uniformly at random.
- *Step 4.* Challenger generates synthetic dataset $\mathcal{S}$ with m records based on the target dataset $\mathcal{D}'$. That is, $\mathcal{S} \sim \text{SDG}(\mathcal{D}', m)$.
- *Step 5.* Challenger sends the synthetic dataset $\mathcal{S}$, the quasi-identifiers of the target record $\mathbf{x}_u$, and the quasi-identifiers of all records X to Adversary.
- *Step 6.* Adversary runs an attack $\mathcal{A}$ to guess the secret bit of the user $\widehat{\mathbf{y}'_u} = \mathcal{A}(\mathcal{S}, \mathbf{x}_u; X)$

Adversary wins game if $\widehat{\mathbf{y}'_u} = \mathbf{y}'_u$

In Step 2, we ensure that the target's quasi-identifiers are unique. This is a common assumption in the literature [14] and simplifies the evaluation of the attack. When two or more records share the same quasi-identifiers, it might not be possible to infer their correct secret attribute even with access to the target dataset $\mathcal{D}'$, unless they also share the same secret attribute. Furthermore, this reflects the typical re-identification scenario where a user can be uniquely identified from their quasi-identifiers [26,41,63] and has been shown to be realistic in high dimensional settings [57].

In Step 3, we randomize the secret attribute of the target record u in order to measure individual-level leakage as opposed to population-level inferences. In Section 7.2, we discuss this aspect and compare our Attribute Inference Privacy Game with prior games from the literature.

Symbol	Description	Known to Adv
$\mathcal{D} = \{X\|\mathbf{y}\}$	Original dataset	✗
$\mathcal{S}$	Synthetic dataset	✓
SDG	Synthetic data generation function	✗
n	Number of records in original dataset	✓
m	Number of records in synthetic dataset	✓
X	Quasi-identifiers in original & target dataset	✓
$\mathcal{X}$	Combined domain of attributes in target dataset	✓
$\mathcal{X}_i$	Domain of i^{th} attribute in target dataset	✓
$\mathbf{y}$	Secret attributes of records in original dataset	✗
Adv	Adversary	
$\mathcal{D}' = \{X\|\mathbf{y}'\}$	Dataset targeted by adversary in game	✗
$\mathbf{y}'$	Secret attributes of records in target dataset	✗
$\mathbf{x}_u$	Quasi-identifiers of target record	✓
$\mathbf{y}'_u$	Secret attribute of target record in target dataset	✗
$\widehat{\mathbf{y}'_u}$	Adversary's guess for the target's secret attribute	✓

Table 1: Main notations for datasets, adversary, and game.

4.2 Linear reconstruction attacks against synthetic data

In this work, we introduce a new attribute inference attack under the Attribute Inference Privacy Game presented above. Our attack is based on linear reconstruction attacks, that we extended and adapt to specifically perform attribute inference on synthetic data. To the best of our knowledge, linear reconstruction attacks have not been previously studied in the context of synthetic data.

Synthetic data aims to serve as a safe replacement for original data while retaining the statistical properties of the original dataset. Therefore, we should expect that statistical queries on the synthetic data are reasonably accurate, with low error compared to original data. Intuitively, this is what our attack exploits. Given the synthetic dataset and the quasi-identifiers of the records in the target dataset, the adversary generates a set of statistical queries that should be preserved by the synthetic data. The adversary then estimates the most likely vector of secret attributes by minimising the error between these statistical queries on synthetic and reconstructed data. Hence, we adapt the linear reconstruction attack approach originally presented by Dwork et al. [22] in this work.

Limitations of prior linear reconstruction approaches. Linear reconstruction attacks were first presented against data query systems that return noisy answers to queries made over a private dataset [20][3]. These attacks require random subsets of users to be selected, as it can typically be done using a unique user identifier present in data query systems. To our knowledge, the only linear reconstruction attack in a non-interactive setting was proposed by Kasiviswanathan et al. [36], who show that linear reconstruction attacks can theoretically be mounted using k-way marginals as well. By recognizing that one of the primary use cases of synthetic data is to preserve k-way marginals, we adapt and extend Kasiviswanathan et al.'s attack specifically for synthetic data.

Linear reconstruction attack ($\mathbf{Adv}_{recon}$). We refer the reader to Table 1 which contains a summary of the notation used in the attack. Formally, given the synthetic dataset $\mathcal{S}$, quasi-identifiers of the target record $\mathbf{x}_u$, and quasi-identifiers of all records X, the adversary generates a set of k-way marginal queries $\mathbf{Q} = \{Q_{A_1,v_1}, \ldots, Q_{A_q,v_q}\}$, each involving the secret attribute. The adversary then evaluates the noisy answers to these queries from the synthetic dataset $\widehat{\mathbf{r}}$. Then, the adversary solves the following linear program given below which minimizes the total error in all queries ($\sum_{j\in[q]} |\mathbf{e}_j|$). The linear program outputs a vector of reconstructed secret attributes ($\mathbf{t}$) for each record in the target dataset. We set the adversary's guess for the target record's secret attribute as outputs $\widehat{\mathbf{y}'_u} = \lfloor \mathbf{t}_u \rceil$ (nearest integer). In the extended version of the paper [2], we show empirically that 3-way queries provide the best tradeoff between number of queries available to the attack and total noise in the queries.

Linear Program.

$$\begin{aligned}
&\textbf{variables: } \mathbf{t} = (\mathbf{t}_i)_{i\in[n]} \in \mathbb{R}^n \text{ and } \mathbf{e} = (\mathbf{e}_j)_{j\in[q]} \in \mathbb{R}^q \\
&\textbf{minimize: } \sum_{j\in[q]} |\mathbf{e}_j| \\
&\textbf{subject to: } \forall j \in [q],\ \mathbf{e}_j = \widehat{\mathbf{r}}_j - Q_{A_j,v_j}(\{X|\mathbf{t}\}) \\
&\qquad\qquad \forall i \in [n],\ 0 \le \mathbf{t}_i \le 1
\end{aligned}$$

Our attack follows the same general structure of Kasiviswanathan et al.'s attack, but we extend it in the following way to improve our attack's success in the SDG setting (see Section 6.6). Since the adversary is *partially informed*, they can calculate more accurate answers to the 3-way marginal queries by using 3-way *conditional* queries on the synthetic data instead. While marginal queries take the form "what fraction of people in the dataset are married, employed, and have a college degree?", conditional queries on the other hand are of the form "of the people in the dataset that are married and employed, what fraction of them have a college degree?".

In order to compute the conditional queries, the adversary first generates a set of queries corresponding to the 3-way marginals not involving the secret attribute ("what fraction of people in the dataset are married and employed?") i.e. $\mathbf{Q}^- = \{Q_{A_1^-,v_1^-}, \ldots, Q_{A_q^-,v_q^-}\}$ where $|A_i^-| = k-1$. We then expect $\forall i$, that the fraction:

$$\frac{Q_{A_i,v_i}(\mathcal{D}')}{Q_{A_i^-,v_i^-}(\mathcal{D}')} \approx \frac{Q_{A_i,v_i}(\mathcal{S})}{Q_{A_i^-,v_i^-}(\mathcal{S})}$$

Note that $Q_{A_i^-,v_i^-}(\mathcal{D}') = Q_{A_i^-,v_i^-}(X)$ since the secret attribute is not involved. Furthermore, the adversary can readily calculate this since they have access to the quasi-identifiers of the original dataset, X. Therefore $\forall i$:

$$\widehat{\mathbf{r}}_i = \frac{Q_{A_i,v_i}(\mathcal{S})}{Q_{A_i^-,v_i^-}(\mathcal{S})} \cdot Q_{A_i^-,v_i^-}(X)$$

In Section 6.6, we show empirically that conditional queries allow the adversary to increase the attack accuracy by up to 10 percentage points compared to marginal queries.

4.3 Prior attacks on synthetic data

In this article, we analyze the performance of Adv_{recon} and compare it with two prior attacks on synthetic data: distance-based attacks and machine learning inference attacks, respectively introduced by Chen et al. [11] and Stadler et al. [62].

Distance-based attack ($\mathbf{Adv}_{dcr}$). Chen et al. have proposed a memorization-based heuristic [11], by measuring the distance between the target record and the closest synthetic record. Intuitively, if the SDG algorithm has in fact memorized parts of the target dataset, then it might tend to output synthetic data samples close to the target dataset.

Formally, given $\mathcal{S}$ and $\mathbf{x}_u$, the adversary outputs

$$\widehat{\mathbf{y}'_u} = \arg\min_{t\in\mathcal{X}_d} \left(\min_{\mathbf{z}\in\mathcal{S}} ||(\mathbf{x}_u|t) - \mathbf{z}||_2 \right)$$

We note that, in practice, for a given partial record $\mathbf{x}_u$, both records $(\mathbf{x}_u|0)$, $(\mathbf{x}_u|1)$ can be present in the synthetic dataset $\mathcal{S}$. This trivially weakens the adversary, since such a record cannot be attacked (the minimum distance is zero no matter the value t). In order to mitigate this scenario, we extend the attack proposed by Chen et al. [11], using a preprocessing step that collapses records by mode. Before calculating the minimum distances, the adversary groups the records in $\mathcal{S}$ according to the quasi-identifiers and sets the corresponding secret attribute to the most common value (mode) amongst all records with the same quasi-identifiers. If both records appear an equal number of times, the secret attribute is chosen uniformly at random by the adversary.

[3] Dinur and Nissim did not explicitly restrict the attention to interactive data query systems. However, their attack as originally proposed assumes that the adversary is able to run queries over known sets of users (the *row-naming* problem). While this assumption is realistic in the context of interactive systems (e.g. those supporting SQL), they do not show how the assumption can be met in context such as pre-defined statistics or synthetic data.

ML inference attack ($\mathbf{Adv}_{infer}$). Stadler et al. proposed an attribute inference attack on synthetic data [62] utilizing a classifier $C_\theta : \prod_{i=1}^{d-1} \mathcal{X}_i \to \mathcal{X}_d$ that maps the quasi-identifiers of records to the secret attribute. This classifier is trained on the synthetic data and later applied on the partial target record to retrieve the adversary's guess for the secret bit $\widehat{\mathbf{y}}'_u = C_\theta(\mathbf{x}_u)$.

Intuitively, if the underlying generative model in the SDG algorithm overfits on the training dataset, patterns of association between quasi-identifiers and secret attributes in the training dataset will be reflected in the synthetic data, including for the training record. These patterns of association can then be learned by a classifier to infer the secret attribute of the target record from its quasi-identifiers.

5 Evaluation Framework

5.1 Datasets

We use two datasets commonly used for synthetic data generation research [8, 39] and in the NIST competition on synthetic data [47]: the American Community Survey (ACS) and the San Francisco Fire Department Calls for Service (FIRE).

The ACS dataset, derived from US Census data, is increasingly used in the machine learning community to benchmark new methods [19] as a modern alternative to the UCI Adult dataset. Specifically, we use the 2018 ACS Employment task for California dataset, used for instance by Liu et al. to evaluate synthetic data [39]. This dataset has 16 discrete attributes; we arbitrarily set the secret attribute to be `SEX`.

The FIRE dataset records fire units' responses to calls [16]. An earlier version was used for the NIST synthetic data competition [47, 56]. The dataset has a large number of attributes (34). To reduce computational cost, we reduce the dataset to 10 attributes (`ALS Unit`, `Call Type Group`, `Priority`, `Call Type`, `Zipcode of Incident`, `Number of Alarms`, `Battalion`, `Call Final Disposition`, `City` and `Station Area`) and arbitrarily set the secret attribute to be `ALS Unit`.

5.2 Synthetic data generation algorithms

A large range of computational techniques have been proposed to generate synthetic data from original data, dating back to Rubin's research on synthetic microdata in 1993 [59]. Synthetic data generation techniques fall into three categories. Firstly, the traditional statistical paradigm relies on low-dimensional statistical models, including Bayesian networks [73], Gaussian and vine copulas [35], Markov models [8], and decision trees [55]. Secondly, the modern machine learning paradigm relies on high-dimensional deep learning models such as generative adversarial networks (CTGAN) and variational autoencoders (TVAE) [69]. Finally, the 'select–measure–generate' paradigm relies on resampling techniques such as Iterative Proportional Fitting (IPF, also called raking) [17], Relaxed Adaptive Projection (RAP) [3], and Adaptive and Iterative Mechanism (AIM) [43].

Algorithms considered. To evaluate the success of our attack, we select three widely-used generative models for tabular data, one for each category: BayNet from the traditional statistical paradigm, CTGAN from the machine learning paradigm and RAP from the 'select–measure–generate' paradigm.

Baseline algorithms. We also include two baseline algorithms, NonPrivate (high utility, low privacy) and IndHist[4] [52] (low utility, high privacy).

We introduce the NonPrivate algorithm here, while descriptions for the other algorithms included in this study can be found in Appendix A.

The NonPrivate algorithm is a baseline synthetic data generation algorithm, simply sampling from the private dataset with replacement. This can be seen as the setting where the algorithm has completely overfitted to the private dataset and treats the private dataset as an empirical distribution to sample "synthetic" records from. In this setting, the only privacy guarantees for users come from the sampling error inherent to synthetic data generation algorithms.

5.3 Measuring utility with error metrics

To evaluate the loss in utility between original and synthetic data, we follow standard practices using statistical metrics from the privacy and statistical disclosure control community, used notably by the US Census Bureau, NIST, and EU JRC [6, 32, 42]. We use two metrics reporting observational error (or measurement error) between marginal distributions of the synthetic data $\mathcal{S}$ and the original data $\mathcal{D}$: the Mean Relative Error (MRE) and the Total Variation Distance (TVD).

Evaluations of utility in privacy-preserving technologies, from de-identification to synthetic data, include a wide range of error metrics [67]. Some SDG evaluation studies include metrics reporting the accuracy of machine learning (ML) classification tasks [65]. Due to the complexity of defining a proper classification task (including defining a useful classification target, holdout dataset, hyperparameter search, ML model), we do not include ML metrics in our evaluation. Similar choices were made for the NIST Differentially Private Synthetic Data Competition [47] and in various works in the area of synthetic tabular data [3, 39, 42, 43].

[4] The IndHist algorithm samples each attribute independently from its respective histogram (see Appendix A). Pairwise associations between attributes are therefore absent from the synthetic dataset, resulting in low utility and high privacy with respect to attribute inference attacks.

5.3.1 Mean Relative Error ($MRE_{>10}$)

To measure the Mean Relative Error (MRE) between marginal queries on original and synthetic data, we follow the practice set forth in the NIST Differentially Private Synthetic Data Challenge [47] by reporting relative error of random 3-way marginal queries. The MRE is equivalent to the Mean Absolute Percentage Error (MAPE = MRE $\times$ 100), used notably by the US Census and EU JRC to evaluate the utility of data releases [1, 32].

Since 3-way marginal queries might be often be null or have very small values—which might be suppressed in the synthetic data—we report only the mean relative error on queries that evaluate to more than 10 on the original data ($MRE_{>10}$).

5.3.2 Total Variation Distance (3-TVD)

The Total Variation Distance, also called statistical distance or variational distance, is often used to evaluate the utility of synthetic data [8, 43, 73] and differential private releases of the US Census [46]. Informally, it reports the absolute error in histograms calculated from the synthetic data and is bounded between 0 and 1, making it easier to compare errors across different datasets.

Definition 5.1 (Total Variation Distance)**.** Given a fixed subset of attributes $A \subseteq [d]$, $|A| = k$

$$\text{TVD}_A(\mathcal{D},\mathcal{S}) = \frac{1}{2}\sum_{v\in\prod_{i\in A}\mathcal{X}_i} |Q_{A,v}(\mathcal{D}) - Q_{A,v}(\mathcal{S})|$$

We report the Total Variation Distance averaged across random subsets of k attributes:

Definition 5.2 (Average k-Total Variation Distance)**.** Given a set of random subsets of attributes $\Omega = \{A_1, A_2, ..., A_p\}$ s.t. $\forall i\ |A_i| = k$

$$k\text{-TVD}(\mathcal{D},\mathcal{S}) = \frac{1}{p}\sum_{i=1}^{p} \text{TVD}_{A_i}(\mathcal{D},\mathcal{S})$$

Previous work used both subsets of size $k = 3$ and $k = 5$ [8, 43, 73]; we here select $k = 3$ to align with MRE evaluations.

6 Results

We evaluate attacks on synthetic data by running the attribute inference privacy game (see Section 4.1) on datasets ACS and FIRE. From each complete dataset, we first sample a dataset $\mathcal{D}$ of size $n = 1000$ records. We then run the attack game, generating synthetic datasets using each of the SDG algorithms, and compute the privacy and utility metrics. We average all results (attack accuracy and error metrics) across 500 repetitions of the game. We run our experiments on a single server with a AMD EPYC CPU parallelizing across all 500 games using 32 cores and 500GB of RAM. A detailed analysis of the computational cost of the attack is given in Section 6.7. The code to reproduce the results is available at https://github.com/synthetic-society/recon-synth.

6.1 Evaluation of Adv_{recon}

We first evaluate the effectiveness of our adversary Adv_{recon} when sufficient synthetic data is available. We execute the attribute inference game for a fixed synthetic data size $m = 10^6$, testing Adv_{recon} against the six SDG algorithms considered. To compare the estimated score from our attack $\mathbf{t}_u$ with the true secret bit $\mathbf{y}'_u$, we report on Figure 1 the receiver operating characteristic (ROC) curve between $\mathbf{t}_u$ and $\mathbf{y}'_u$.

Our attack achieves a consistently high AUC (> 0.75) for RAP and BayNet algorithms, as well as the NonPrivate baseline, across both datasets. The attack is not effective on CTGAN and IndHist, achieving an AUC close to a random prediction (AUC ≈ 0.5). This is expected for IndHist, which should be protected against most attribute inferences since any association between attributes is lost. While the low AUC on CTGAN and IndHist suggests resistance to such attribute inference attacks, this comes at a significant cost to utility as will be shown in Section 6.3.

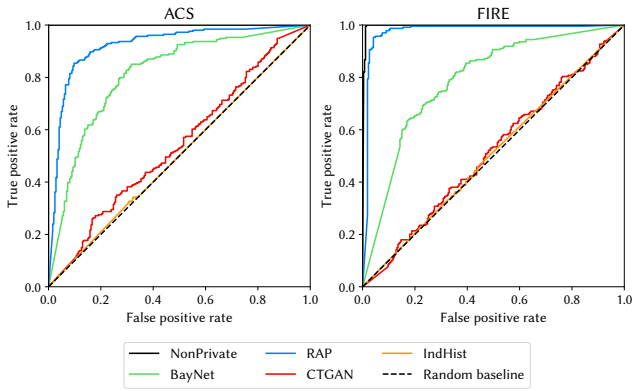

Figure 1: Receiver operating characteristic (ROC) curves of Adv_{recon} for a synthetic data size $m = 10^6$.

6.2 Comparison to prior attacks

We then compare our attack with two prior attacks (Adv_{dcr} and Adv_{infer}) from the literature. Figure 2 reports the accuracy between $\mathbf{y}'_u$ and $\widehat{\mathbf{y}'}_u$ for each attack, for a synthetic data size $m = 10^6$ (see extended version of the paper [2] for $m = 10$ to 10^6).

Our adversary outperforms or performs statistically close (within 2 standard deviations) to Adv_{dcr} and Adv_{infer} for all SDG algorithms. In particular, our attack achieves a much higher accuracy on RAP than previous attacks, with a 9.60 and 4.80 percentage point (p.p.) increase in attack accuracy over

the memorization-based and inference attacks for the ACS and FIRE datasets respectively. This suggests that state-of-the-art attacks can potentially underestimate the privacy risks of synthetic data specifically in the 'select-measure-generate' paradigm. Lastly, for the CTGAN and IndHist algorithms, we notice that even when a synthetic dataset with a large number of records ($m = 10^6$) is released, none of the adversaries are able to perform significantly better than the random baseline.

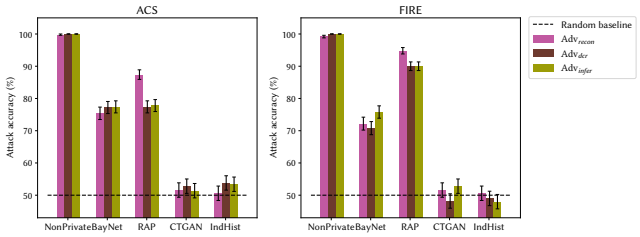

Figure 2: Comparison of attack accuracy (mean ± s.d.) between Adv_{recon} and prior attacks Adv_{dcr} and Adv_{infer} for a synthetic data size $m = 10^6$.

6.3 Impact of synthetic data size

We have so far evaluated attack accuracy when sufficient synthetic data is released ($m = 10^6$). However, data releases can in practice be restricted to small samples. To evaluate if attacks still succeed when fewer synthetic records are released, we test our attack on synthetic datasets from $m = 10$ to $m = 10^6$.

Figure 3 shows that the accuracy of our attack is low for $m = 10^2$ and increases with m against NonPrivate, BayNet and RAP. The accuracy is close to 50% for CTGAN and IndHist for all values of m. The attack accuracy is 87.4% and 94.8% against RAP on resp. ACS and FIRE datasets, at $m = 10^6$. In contrast, this accuracy is reduced by resp. 15.2 and 21.8 p.p. when evaluating the attack on a small synthetic dataset of size $m = 10^3$. When even fewer records are released, the attack accuracy is further reduced, resulting in low accuracy of resp. 55.4% and 54.8% against RAP at $m = 10^2$. We observe that similar trends exist for the BayNet algorithm as well: a decrease of 14.6 and 11.0 p.p. in accuracy from $m = 10^6$ to $m = 10^3$, for the ACS and FIRE datasets respectively.

This suggests that benchmark evaluations on small synthetic datasets can understate the practical risks of attribute inference. As a result, we argue that while it may be common currently to only evaluate the privacy risks for the specific synthetic data size that is to be released, privacy evaluations of SDGs should potentially include evaluations on larger synthetic data sizes as well in order to achieve a more comprehensive and robust understanding of the privacy leakage from SDGs. We note, however, that the association between synthetic data size and attack accuracy is not trivial: too large synthetic data sizes could, for instance, result in overflow errors or reach a limit in computational power that may, in turn,

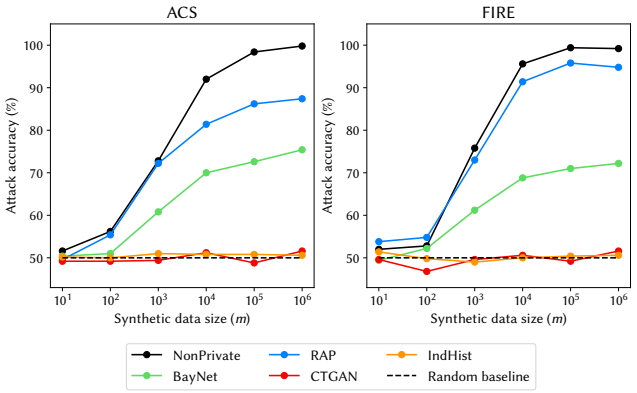

Figure 3: Attack accuracy of Adv_{recon} for a synthetic data size from $m = 10$ to 10^6.

lower attack accuracy.

While releasing smaller synthetic data can limit the likelihood of inference attack, this comes at a high cost in terms of utility. Figure 4 reports the utility error decreases fast as the synthetic data size increases (see extended version of the paper [2] for exact error values). This is a natural consequence of the sampling error (the more records, the more accurate statistics—as demonstrated by NonPrivate). The error metric appears to asymptotically reach zero for NonPrivate and RAP only. This suggests that RAP is, in our experiment, the only SDG algorithm that provides low bias. The error metrics on IndHist, BayNet, and CTGAN plateau often or always, suggesting evidence of model bias. This is expected for the IndHist baseline: after $m = 10^3$, all univariate marginals are correctly estimated, yet the error remains high due to the absence of higher-order associations.

6.4 Privacy-utility tradeoff

Our findings show that protection against inference attacks and utility of synthetic data are both conditioned on multiple factors such as the SDG algorithm, the synthetic data size, and the type of attack. To understand if SDG algorithms can provide sufficient utility while protecting against attribute inference, we systematically evaluate the tradeoffs between attack accuracy and measurement error.

Figure 5 shows the tradeoff between privacy and utility achieved by all models for synthetic data sizes from $m = 10$ to 10^6. For each data point, we report the maximum attack accuracy across the three attacks (Adv_{recon}, Adv_{infer}, and Adv_{dcr}):

$$\text{Acc}_{max} = \max_{\text{Adv} \in \{\text{Adv}_{recon}, \text{Adv}_{dcr}, \text{Adv}_{infer}\}} \text{Accuracy}^{\text{Adv}}$$

The maximum accuracy represents an upper-bound empirical estimate, and may not be reached by an adversary in practice. However, it can be a useful worst-case metric when evaluating privacy-utility tradeoffs empirically (tradeoffs for

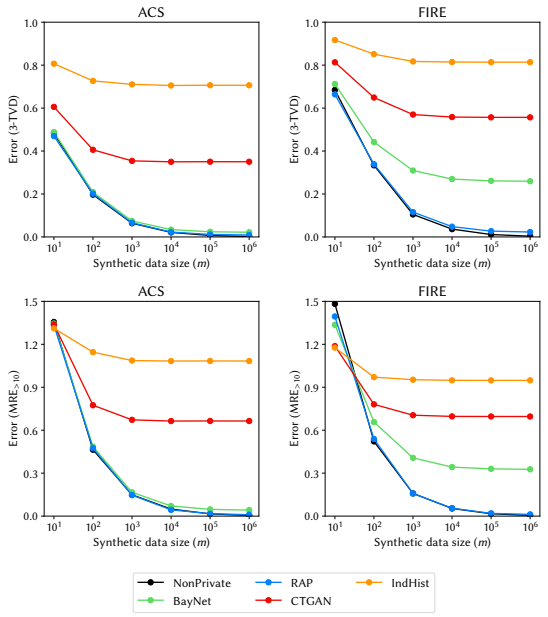

Figure 4: Measurement errors for synthetic data sizes $m = 10$ to 10^6.

each attack separately are reported in the extended version of the paper [2]).

To help visualise these tradeoffs, we set baseline rates at $\text{Acc}_{max} > 60\%$ (high attack accuracy, y-axis) as well as $\text{MRE}_{>10} < 0.20$ and 3-TVD < 0.20 (low error rate, x-axis). We stress, however, that there is no consensus on which attack accuracy above 50% in a game would be sufficient to significantly breach privacy in practice. Even at $\text{Acc}_{max} = 50\%$, some outlier records may still be at risk [62]. Similarly, an average relative error rate of 0.20 might, for instance, be too high for statistical analyses in low-powered study and result in incorrect estimates of effect, especially at small synthetic data sizes [40].

Firstly, we observe that whenever the synthetic data has high utility (low error), it also offers little to no privacy protection. On the ACS dataset, when $\text{MRE}_{>10} < 0.20$ and 3-TVD < 0.20, the lowest Acc_{max} is 60.8% for BayNet (at $m = 10^3$), and 65.4% for RAP (at $m = 10^3$). Similarly, on the FIRE dataset, when $\text{MRE}_{>10} < 0.20$ and 3-TVD < 0.20, the lowest Acc_{max} is 68.6% for RAP (at $m = 10^3$). On both datasets, at all synthetic data sizes m considered, CTGAN never yields an error metric $\text{MRE}_{>10}$ or 3-TVD below 0.20.

On the other hand, whenever synthetic data offers strong privacy protection, this results in low utility with large errors. On the ACS dataset, when $\text{Acc}_{max} < 60\%$, the lowest error $\text{MRE}_{>10}$ is 0.664 for CTGAN (at $m = 10^4$), 0.485 for BayNet (at $m = 10^2$), and 0.474 for RAP (at $m = 10^2$). Similarly, on the FIRE dataset, when $\text{Acc}_{max} < 60\%$, the lowest error $\text{MRE}_{>10}$ is 0.696 for CTGAN (at $m = 10^6$), 0.657 for BayNet (at $m = 10^2$), and 0.539 for RAP (at $m = 10^2$). These high error rates would prevent most research tasks on these two datasets.

In all our experiments, we could not find a setting where any of the considered SDG algorithms both provide sufficient privacy protection ($\text{Acc}_{max} < 60\%$) as well as utility that would enable some research tasks ($\text{MRE}_{>10} < 0.20$ and 3-TVD < 0.20).

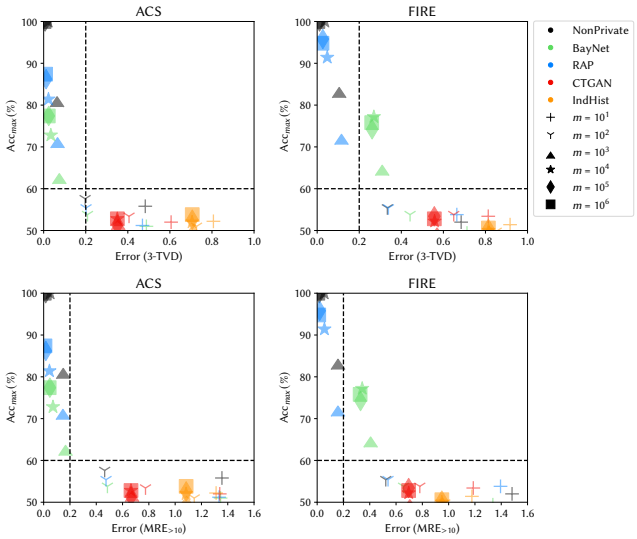

Figure 5: Tradeoff plot between privacy (attack accuracy) and utility (measurement error).

6.5 Impact of differential privacy

Differential privacy [21] is a popular approach to preventing privacy leakages that provides strong theoretical privacy guarantees by design. Differentially private mechanisms are defined using a parameter ε which controls the privacy-utility tradeoff. This parameter, also referred to as the privacy budget, ranges from 0 (perfect protection) to ∞ (no added protection).

Intuitively, differential privacy guarantees that adding, removing, or changing the content of an individual record will not affect much the (distribution of) synthetic datasets that are generated. In our attribute inference privacy game, the challenger randomizes the target record's secret attribute (see Section 7). Differential privacy should therefore significantly reduce the attack accuracy of any potential adversary. At the same time, research shows that differentially private mechanisms can also strongly limit utility and affect model performance in disparate and unpredictable ways [4, 27, 62, 66]. Below, we investigate the privacy-utility tradeoffs of differential privacy in the context of synthetic data and attribute inference.

To understand if implementing DP can help provide a better privacy-utility tradeoff, we replicate our experiments of the SDG algorithms with their DP equivalents. Out of the SDG algorithms considered, three have differentially private equivalents—$\text{RAP}^{\text{softmax}}$ [39] for RAP, PrivBayes [73] for

BayNet, and DPCTGAN [58] for CTGAN (see to Appendix A for details about each algorithm). Since CTGAN does not provide sufficient utility in our experiments, we restrict ourselves to evaluating only RAP$^{\text{softmax}}$ and PrivBayes.

We note that RAP$^{\text{softmax}}$ and PrivBayes satisfy two different variants of differential privacy. RAP$^{\text{softmax}}$ satisfies a relaxation known as approximate or (ε, δ)-DP [39]. PrivBayes satisfies the original ε-DP [73]. In our evaluation, we set $\delta = \frac{1}{n^2} = 10^{-6}$ for RAP$^{\text{softmax}}$, using the same value set by Liu et al. [39].

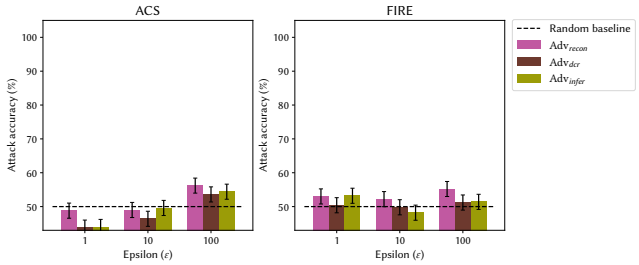

Figure 6: Attack accuracy of Adv$_{recon}$, Adv$_{dcr}$ and Adv$_{infer}$ as a function of privacy parameter ε for RAP$^{\text{softmax}}$ synthetic data of size $m = 10^6$

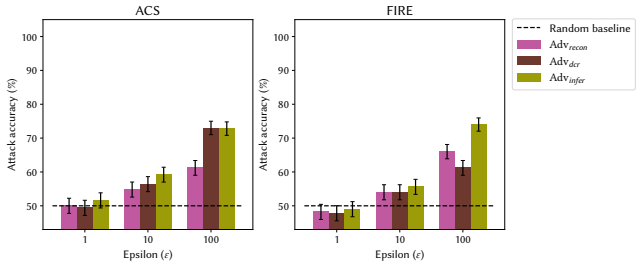

Figure 7: Attack accuracy of Adv$_{recon}$, Adv$_{dcr}$ and Adv$_{infer}$ as a function of privacy parameter ε for PrivBayes synthetic data of size $m = 10^6$

Impact of privacy budget. We first evaluate the impact of the privacy budget ε on attack accuracy. Figure 6 and Figure 7 show the accuracy of all three attacks (Adv$_{recon}$, Adv$_{infer}$ and Adv$_{dcr}$) increases with ε for both RAP$^{\text{softmax}}$ and PrivBayes. We observe that differential privacy has a large impact on attack accuracy, even for a moderately large privacy budget $\varepsilon = 10$. DP mechanisms severely reduce the attack accuracy for all three adversaries compared to their non-differentially private counterparts, across both datasets. For example, for the RAP algorithm on the ACS dataset, the accuracy of Adv$_{recon}$, Adv$_{dcr}$ and Adv$_{infer}$ are reduced by resp. 38.4, 31.0, and 28.2 percentage points (p.p.) by using RAP$^{\text{softmax}}$ at $\varepsilon = 10$. This suggests that mechanisms with moderately large privacy parameters could significantly reduce the risk of attribute inference attacks against realistic adversaries.

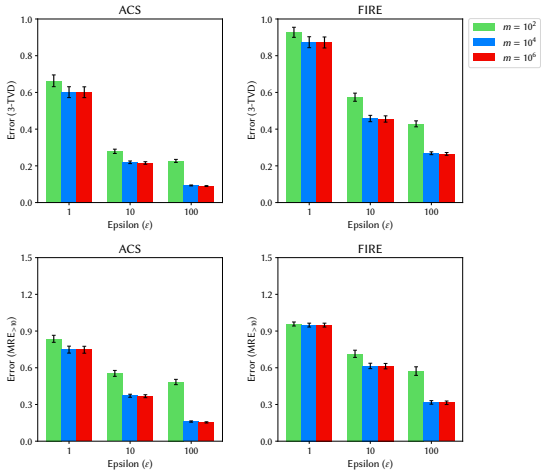

Figure 8: Error as a function of privacy parameter ε for RAP$^{\text{softmax}}$

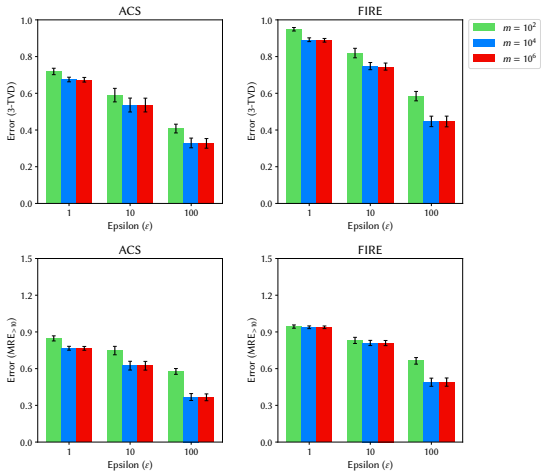

Figure 9: Error as a function of privacy parameter ε for PrivBayes

At the same time, DP mechanisms are known to significantly impact utility [15, 37]. We therefore evaluate the effect of the privacy budget ε on the two error metrics in Figure 8 and Figure 9 (see extended version of the paper [2] for exact values) for the RAP$^{\text{softmax}}$ and PrivBayes algorithms respectively. We find that at each ε level, RAP$^{\text{softmax}}$ provides better utility (lower error) than PrivBayes, on both metrics and for both datasets ACS and FIRE.

We observe that, unlike the non-DP synthetic data generation algorithms, the utility of RAP$^{\text{softmax}}$ and PrivBayes is not as strongly dependent on the size of the synthetic data released. For example, the relative error on the RAP and BayNet algorithms decreases by resp. 0.46 and 0.44, when releasing ACS synthetic data of size 10^6 compared to 10^2. However, the drop in relative error for the RAP$^{\text{softmax}}$ and PrivBayes algorithms is at most 0.33 and 0.21 resp. (achieved at $\varepsilon = 100$).

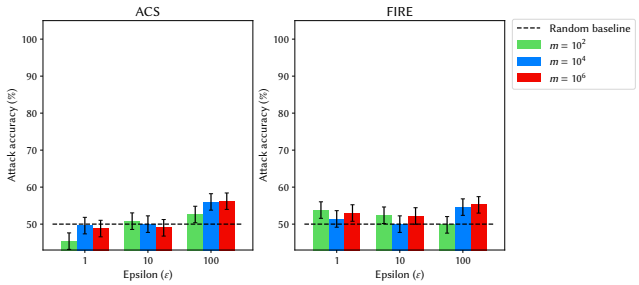

Figure 10: Attack accuracy of Adv_{recon} as a function of privacy parameter ε for $\text{RAP}^{\text{softmax}}$

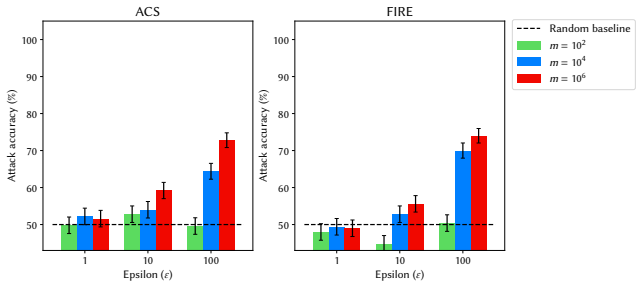

Figure 11: Attack accuracy of Adv_{infer} as a function of privacy parameter ε for PrivBayes

Impact of synthetic data size. Adv_{recon} achieves higher accuracy than all other adversaries for $\text{RAP}^{\text{softmax}}$. Similarly, Adv_{infer} achieves higher accuracy for PrivBayes. We therefore show the accuracy of Adv_{recon} and Adv_{infer} respectively for three synthetic data sizes ($m = 10^2$, 10^4 and 10^6) in Figure 10 and Figure 11. We note that for moderate to large privacy parameters ($\varepsilon \geq 10$), the synthetic data size heavily impacts the accuracy of Adv_{infer} whereas the accuracy of Adv_{recon} is no longer impacted by the synthetic data size even at $\varepsilon = 100$. Similar to our earlier finding, we see here that, at moderate to large privacy parameters, there can be up to a 23.2 p.p. drop in attack accuracy when sampling a small synthetic dataset of size 10^2 (achieved for Adv_{infer} on PrivBayes at $\varepsilon = 100$). This confirms that, for certain SDG algorithms, the synthetic data size is ultimately an important factor when evaluating practical privacy risks of synthetic data, even when differentially private noise is added.

Privacy-utility tradeoffs. Figure 12 and Figure 13 show the attack accuracy and measurement errors of the two DP SDG algorithms, across datasets and synthetic data sizes. For PrivBayes, we note that the privacy gains achieved by differential privacy guaranteed are subject to similar drops in utility as for BayNet. Across all datasets and error metrics, the PrivBayes algorithm is not significantly closer to the bottom left-hand corner than the BayNet algorithm.

On the other hand, $\text{RAP}^{\text{softmax}}$ at $\varepsilon = 100$ can in fact produce synthetic data that has better combination of utility and

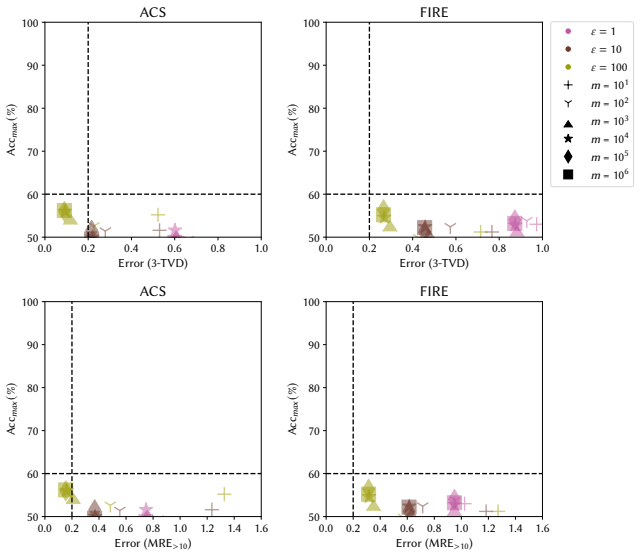

Figure 12: Tradeoff between privacy and utility for $\text{RAP}^{\text{softmax}}$ at ε = 1, 10 and 100

privacy compared with non-DP methods we previously evaluated (see Fig 5), but only on the ACS dataset. Synthetic data generated by $\text{RAP}^{\text{softmax}}$ at $\varepsilon = 100$ is closer to the bottom left-hand corner than that generated by the RAP algorithm. This suggests that, although moderate to large values of ε may not provide strong theoretical protections, the way these guarantees are implemented can help provide slightly better privacy-utility tradeoffs against practical attacks.

6.6 Impact of choice and number of queries

In previous sections, we have analyzed the impact of *external* factors such as the SDG algorithm, synthetic data size, and differential privacy defenses on the success of our attack. Here, we further analyze the impact of the *internal* parameters used to define the attack and provide an explanation for why our attack works. Specifically, we focus on the two main parameters that enable our attack to achieve good accuracy—the choice and number of queries. In this section, we consider synthetic data of size $m = 10^6$ and the FIRE dataset (see extended version of the paper [2] for a more in-depth analysis). We do not include CTGAN and IndHist as these factors do not affect the attack accuracy since even in the best case, the attack accuracy for CTGAN and IndHist is close to the random baseline.

Choice of queries. In our work, we use conditional queries to maximize accuracy, compared to simple marginal queries used for instance by Kasiviswanathan et al. [36]. Figure 14 show that using conditional queries improve the attack accuracy systematically compared to simple marginal queries. For instance, using conditional queries improves the attack accuracy by up to 11.2 p.p. against RAP, at $m = 10^3$ on the FIRE dataset. This suggests that our attack is particularly suc-

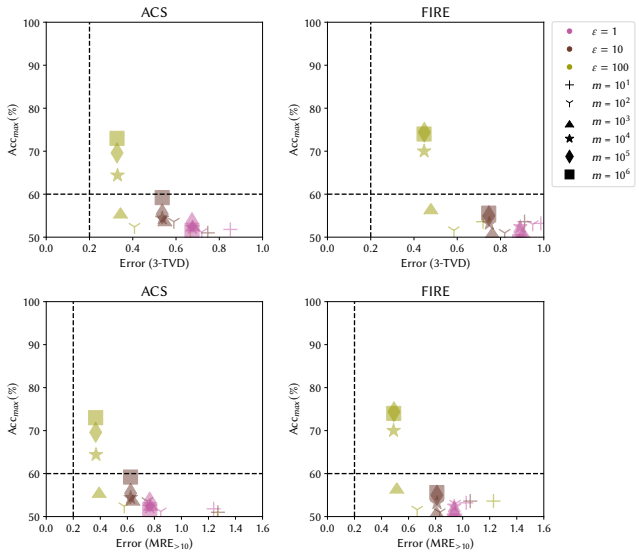

Figure 13: Tradeoff between privacy and utility for PrivBayes at various ε = 1, 10 and 100

cessful because the conditional queries leverage additional knowledge from quasi-ids available to the *partially informed adversary*.

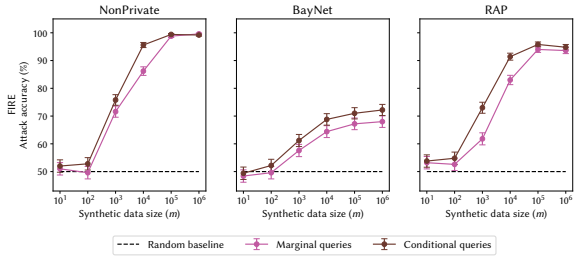

Figure 14: Comparison of attack accuracy of Adv_{recon} when using conditional queries compared to marginal queries.

Number of queries. Increased data dimensionality and higher computational budget could help an attacker run our attack with more queries. Figure 15 shows that the accuracy of Adv_{recon} increases with the number of 3-way conditional queries used. For instance, for the FIRE dataset and the RAP algorithm, increasing the number of queries from 10^3 to 10^4 results in a more than 20 p.p. increase in attack accuracy. This suggests that for higher dimensional datasets, our attack could potentially leverage a larger number of available queries to achieve even higher accuracy. Since our attack is no-box, and does not rely on shadow modelling, an adversary in practice will not be computationally constrained by increased data dimensionality. However, as increased data dimensionality heavily increases the computational cost of generating a large number of synthetic datasets necessary for the evaluation of privacy risk, in our work, we restrict ourselves to more tractable datasets such as ACS and FIRE.

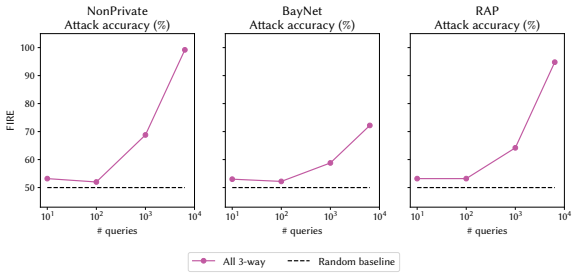

Figure 15: Comparison of attack accuracy of Adv_{recon} when uses varying number of queries for synthetic data size, $m = 10^6$

6.7 Computational cost

m	No. of queries $\lvert Q \rvert$				
	10^1	10^2	10^3	10^4	10^5
10^1	2.10	2.20	2.39	4.43	25.2
10^2	2.10	2.22	2.39	4.47	25.6
10^3	2.11	2.21	2.42	4.74	28.6
10^4	2.11	2.22	2.50	5.80	39.0
10^5	2.19	2.41	3.75	15.4	134
10^6	2.82	4.12	16.5	113	1130

Table 2: Time taken (s) for single attack for various number of queries and synthetic data sizes, m

Lastly, in order to show that our attack is in fact practical, we evaluate the computational cost of running our attack with respect to the two main factors—number of queries and synthetic data size. While linear reconstruction attacks have already been known to be practical, most prior work [13, 22] have only implemented such attacks with a couple of thousand queries. In our work, we make use of parallelization and efficient commercial solvers such as Gurobi to run our attack efficiently even when tens and hundreds of thousands of queries are used.

To that end, we record the time taken for our attack to run against the NonPrivate algorithm (without loss of generality) on the FIRE dataset for 1 repetition. We vary the number of synthetic data sizes and numbers of queries and report the cost of running a single attack in Table 2. We find that our attack runs very efficiently, taking less than 5 mins to run in almost all settings and finishing in under half an hour even in the most computationally intensive setting (No. of queries = 10^5, $m = 10^6$). In this setting, the amount of memory required to run a single attack is also small (3.26 GB). Therefore, we can see that our attack runs very efficiently and increasing the number of queries when available is still possible.

7 Discussion

7.1 Linear reconstruction attacks

There has been a rich literature on linear reconstruction attacks (which led to the formulation of *The Fundamental Law of Information Recovery* [23]), which has thus far not been considered in the context of synthetic data. Informally, the law states that answering too many queries with too much accuracy destroys privacy "in a spectacular way" and is formally defined in relation to linear reconstruction attacks [20, 22, 36]. Linear reconstruction attacks provide theoretical asymptotic results on the amount of secret information that can be reconstructed when a large fraction of linear queries are answered with insufficient noise by any mechanism.

Linear reconstruction attacks are typically studied in the context of systems (e.g. interactive data query systems) that compute some aggregate statistics and add some noise before releasing them (e.g. Gaussian noise subject to clipping and memoization [13]). In this work, we see synthetic data as a noise-addition mechanism as well—with the noise being the difference between the aggregate statistic computed on the original data and the same statistic computed on the synthetic data. However, unlike systems that add noise in a coherent way, the noise added by most SDG algorithms does not follow a coherent structure. This work therefore shows that it is in fact possible to extend linear reconstruction attacks to synthetic data in practical settings.

7.2 Attribute Inference Privacy Game

Yeom et al. formalized the risk of attribute inference as an *attribute inference privacy game* [72]. However, Jayaraman et al. noted that, under this formulation, some of the state of the art attacks can be trivially outperformed by a naive baseline [34]. They showed that a naive baseline—outputting the most common value as the secret attribute—outperforms three of the previous state of the art attacks. Furthermore, Houssiau et al. noted that this formulation suffers from the base-rate problem [31]. If the secret attribute, say income, is strongly correlated with non-secret attributes such as age, education, and country, then the secret attribute can be predicted with very high confidence by simply having access to population-level knowledge, even without access to the released model.

In our game, the challenger randomizes the target record's secret attribute in Step 2. This achieves two goals. Firstly, correlations between the secret and non-secret attributes are broken specifically for the target record. This means that any adversary without access to the synthetic data cannot possibly predict the secret attribute more accurately than the random baseline which solves the base-rate problem that was discussed by Houssiau et al [31]. Secondly, the naive baseline presented by Jayaraman et al. [34]—predicting the most common secret attribute—cannot possibly perform better than the random baseline.

7.3 Broader impacts of Attribute Inference Attacks

Attribute inference attacks are widely considered a significant privacy breach in privacy-preserving data publishing. Indeed, inferring an individual's attribute may pose concrete risks to that person [48, 49]. The risks posed by attribute inference attacks became well recognized in 1997, when Sweeney demonstrated how to infer medical records relating to Massachusetts governor by linking his quasi-identifiers (sex, date of birth, ZIP code) to his records in a pseudonymized public health dataset [64]. However, when the target dataset consists of aggregate or synthetic data, it is not always easy to establish whether a successful attribute inference attack reveals a breach of individual privacy [7, 44]. In fact, simply revealing population-level information, such as correlations, can be sufficient to accurately infer an attribute from quasi-identifiers [44].

In our work, we build our attribute inference privacy game to separate out the individual-level information leakage from the population-level inferences discussed by Jayaraman et al. [34]. Our findings show that Adv_{recon} is in fact able to exploit access to the synthetic data beyond what is theoretically possible from population-level knowledge and precisely determine the secret attribute of a single individual. This leakage comes directly from the individual participation in the data, individuals whose secret attribute would not have been otherwise leaked from "distributional inference". We believe that our work makes a strong case for attribute inference attacks being considered a significant risk for synthetic data in practice.

7.4 Partially informed adversary

In this work, we consider a partially informed adversary: an adversary with access to all the quasi-identifiers X (i.e. the non-secret attributes) of the original dataset. This adversary was previously discussed by Kasiviswanathan et al. [36] for medical and retail data. While this is a strong assumption, it is still a much weaker and more practical assumption than the exact knowledge setup used to verify differential privacy guarantees [33]. Moreover, the partially informed setting can be realistic in the context of multiple data releases. For example, national statistics, public health, and medical institution often publish multiple releases from the same original dataset(s) [5, 68]. Some releases will require a particular disclosure method, e.g. de-identification or pseudonymised microdata for low-risk data, while others will rely on synthetic data generation. This is for instance the case for the Survey of Income and Program Participation (SIPP), released both as microdata and as synthetic data (combined with more sensitive

IRS tax data) [5].

7.5 Higher order marginal queries

In this work, our adversary uses 3-way marginal queries to carry out attribute inference attacks. While higher order marginal queries could also be used to mount our attack, this does not naturally lead to stronger attacks. Including higher order marginal queries (such as 4 and 5-way marginal queries) increases the overall number of queries available to the attack thus increasing the amount of knowledge that can potentially be exploited by our reconstruction attack. At the same time, higher order marginal queries have larger amounts of error, even in the NonPrivate setting, thus reducing the overall power of the attack. In the extended version of the paper [2], we empirically show that 3-way queries provide the highest accuracy. There are too few 2-way queries involving the secret attribute that could be used to mount a successful attack. On the other hand, including a high number of 4-way queries does not improve the overall performance of our attack.

Recent work by Creţu et al. [14] suggests that machine learning techniques could in fact be adapted to identify informative higher order queries. In the context of query-based systems, they show that evolutionary algorithms can be used to identify a small set of queries that reveal the sensitive attribute of a target record. By viewing SDG algorithms as noisy query-based systems, their attack can potentially be adapted to similarly select a small set of k-way marginal queries that are highly informative and can be used by our attack to boost the attack accuracy. As this may require significant research to adapt their technique on synthetic data generation algorithms, we leave this for future work.

7.6 Binary secret attributes

Attribute inference attacks are often evaluated on binary attributes. Successfully attacking a binary attribute is sufficient to show that a mechanism is vulnerable to privacy leakage [14, 34].

In theory, it is possible to relax this assumption and modify our attack to target categorical secret attributes. For instance, we can employ one-hot encoding in order to attack a categorical attribute. The attribute $y \in \{0,1,...,Y\}$ is encoded into a Y-dimensional vector $\mathbf{v} \in \{0,1\}^Y$ where $\mathbf{v}_i = 0 \; \forall i \neq Y$ and $\mathbf{v}_y = 1$. Our attack can then be run repeatedly Y times, for each binary attribute $\mathbf{v}_i$. The $\mathbf{v}_i$ with highest score can be returned as the reconstructed secret attribute y, where the score is computed according to an appropriate function on $\mathbf{v} \in \{0,1\}^Y$.

However, successfully mounting this attack against any attribute and testing its accuracy in our evaluation framework remains challenging. Firstly, the modified attack requires Y times more computational power than for a single binary attribute, increasing linearly with the domain of the secret attribute. Furthermore, the error resulting from the Y iterations would accumulate, resulting in a lower attack accuracy. Although this effect could be possibly mitigated by choosing a better score function, addressing these and other challenges is outside the scope of this paper.

8 Conclusion

In this work, we studied the privacy-utility tradeoffs of synthetic data generation algorithms for tabular data. We showed how to extend and adapt linear reconstruction attacks for synthetic data in order to successfully perform attribute inference even when the adversary has no access to the underlying generative model. We showed that prior attacks can underestimate the privacy risk of synthetic data by up to 10 percentage points compared to our linear reconstruction attack, suggesting that empirical resistance to attacks requires evaluations on multiple attack methods. Furthermore, our work showed that information leakage on arbitrary records is in fact possible from synthetic data. This suggests that when the synthetic data provides good utility, data subjects can in fact be at risk of privacy leakage.

Our analysis further revealed that generating and releasing a large amount of synthetic records can marginally increase utility while simultaneously enabling much more powerful attacks, a finding that has not been widely studied in prior work. This has important implications when releasing synthetic data: evaluations on small synthetic benchmarks may underestimate the actual risks if larger synthetic datasets are released.

We finally evaluated differentially private synthetic mechanisms. We showed that, while some mechanisms provide worse privacy-utility tradeoffs in practice, recent mechanisms such as RAP$^{\text{softmax}}$ can in fact provide better empirical privacy-utility tradeoffs than non-DP mechanisms in specific settings and synthetic data sizes.

In conclusion, our results suggest that current synthetic data generation mechanisms may not simultaneously preserve high utility and high privacy at the same time. Privacy-utility tradeoff analyses are highly context dependent and require careful calibration of privacy and utility thresholds to make definitive conclusions. Therefore, synthetic data on its own should not be seen as an all encompassing solution to privacy-preserving data publishing. We hope that our work will support practitioners to evaluate the robustness of synthetic data against violations of privacy and anonymity.

A Descriptions of synthetic data generation algorithms

BayNet [73]. Bayesian networks are trained by building a probabilistic graphical model that represents the conditional dependence between attributes in the original dataset. This graphical model factorizes the joint distribution between the attributes into a product of low dimensional conditional distributions. The algorithm is defined by the degree of the network which is a parameter that defines the number of attributes in the conditional distributions. We use Ping et al.'s implementation in the DataSynthesizer [52] library and additionally, set the degree of the network to be 3 in order for 3-way marginal queries to be well preserved in our utility

analysis.

PrivBayes [73] is the differentially private version of the BayNet algorithm. Differentially private laplace noise is added to the conditional distributions such that the overall algorithm satisfies ε-DP. We use Ping et al.'s implementation in the DataSynthesizer [52] library and set the degree of the network to 3 similar to the BayNet algorithm.

RAP [3]. The relaxed Adaptive Projection algorithm follows the 'select-measure-generate' approach. Firstly, a set of summary statistics of interest are selected. Secondly, these statistics are measured on the original dataset. Finally, an optimisation model is used to generate a synthetic dataset with consistent summary statistics. Specifically, the RAP algorithm takes as input a set of differentiable functions $\mathbf{Q}$ and outputs a synthetic dataset using a iterative optimization algorithm (such as the stochastic gradient descent):

$$\arg\min_{\mathcal{S}} ||\mathbf{Q}(\mathcal{S}) - \mathbf{Q}(\mathcal{D})||_2$$

We set the number of optimization iterations to 2000 and set $\mathbf{Q}$ to be the continuous relaxation of all 3-way marginal queries as 3-way marginal queries are important statistics that the original authors intended to be preserved by the algorithm. As such, this makes RAP particularly vulnerable to linear reconstruction attacks on marginal queries.

RAP^{softmax} [39] is the differentially private version of the RAP algorithm. Differentially private gaussian noise is added to the query measurements made by RAP ($\mathbf{Q}(\mathcal{D})$). Additionally, the exponential mechanism is used to select queries with the largest query errors in each iteration to be optimized. Lastly, the softmax function is used to normalize the output of the algorithm before being projected back to the data domain. Similar to RAP, we set the number of iterations to 2000 and set $\mathbf{Q}$ to be the continuous relaxation of all 3-way marginal queries. δ is set to $\frac{1}{n^2} = 10^{-6}$.

CTGAN [69] is an extension of the Generative Adversarial Network model that trains two deep neural networks, a generative network and a discriminative network, in tandem to generate synthetic data. The generative network takes as input random values from a gaussian distribution and outputs samples in the domain, $\mathcal{X}$. The generative network is then trained to eventually output samples that are indistinguishable from samples from the original dataset by the discriminative network. Random noise is then provided as input to the generative network that generates synthetic samples that form the synthetic dataset. CTGAN is a variant of this architecture and uses a conditional generative network (a generative network that receives the class label as input) and mode-specific normalization to generate synthetic datasets in the context of tabular data.

IndHist, for 'independent histogram', is a baseline algorithm for synthetic data generation [52], independently sampling from the individual distribution of each attribute. Any association between attributes are removed in the synthetic dataset. In particular, this means the best attribute inference attack simply outputs the most common value of the secret attribute, resulting in an attack accuracy of 0.5. In this setting, the synthetic dataset is expected to have very low utility but have good privacy with respect to attribute inference. We use Ping et al.'s [52] implementation in the DataSynthesizer library to evaluate this algorithm.

Document-level Membership Inference for Large Language Models

Matthieu Meeus

Abstract

With large language models (LLMs) poised to become embedded in our daily lives, questions are starting to be raised about the data they learned from. These questions range from potential bias or misinformation LLMs could retain from their training data to questions of copyright and fair use of human-generated text. However, while these questions emerge, developers of the recent state-of-the-art LLMs become increasingly reluctant to disclose details on their training corpus. We here introduce the task of document-level membership inference for real-world LLMs, i.e. inferring whether the LLM has seen a given document during training or not. First, we propose a procedure for the development and evaluation of document-level membership inference for LLMs by leveraging commonly used data sources for training and the model release date. We then propose a practical, black-box method to predict document-level membership and instantiate it on OpenLLaMA-7B with both books and academic papers. We show our methodology to perform very well, reaching an AUC of 0.856 for books and 0.678 for papers (Fig. 1). We then show our approach to outperform the sentence-level membership inference attacks used in the privacy literature for the document-level membership task. We further evaluate whether smaller models might be less sensitive to document-level inference and show OpenLLaMA-3B to be approximately as sensitive as OpenLLaMA-7B to our approach. Finally, we consider two mitigation strategies and find the AUC to slowly decrease when only partial documents are considered but to remain fairly high when the model precision is reduced. Taken together, our results show that accurate document-level membership can be inferred for LLMs, increasing the transparency of technology poised to change our lives.

1 Introduction

Over the last year, Large Language Models (LLMs) have become ubiquitous. By understanding and producing coherent natural language, models such as GPT-2/3/4 [10, 47, 51], BLOOM [59] and LLaMA 1/2 [67, 68], promise to revolutionise society. ChatGPT, a fine-tuned version of GPT-3, was the fastest consumer-focused application in history to reach 100 million users [24]. Since this breakthrough, investment in Artificial Intelligence (AI) is estimated to reach $200 billion globally by 2025 [57].

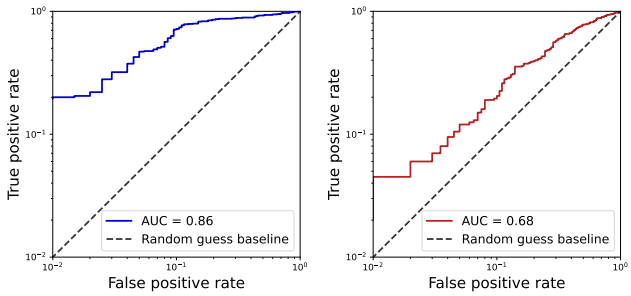

Figure 1: ROC curve for the best performing membership classifier (see Tables 1 and 3 for details). Results for books from Project Gutenberg (left) and ArXiv papers (right).

While these models undoubtedly represent a major technical achievement, their capabilities stem from having been trained on enormous amounts of human-generated text. For instance, Meta's first generation model, LLaMA, had reportedly been trained on as many as 1.4 trillion tokens [67]. The capabilities of these models furthermore seem, at least at the moment, to keep improving with the size of the model (up to 100+ billion parameters) [7, 34]. This–in turn–fuels the need for increasingly more data, even leaving some wondering whether they might soon have consumed all the available data on the internet [71].

As LLMs become increasingly embedded into our daily life, simplifying tasks, generating value, but also making decisions, questions are being raised regarding the data from which their capabilities emerge. This includes questions about what they will learn, e.g. whether modern models will learn the societal biases present in the data or amplify them [1, 43, 62] or whether they might learn and propagate disinformation [5,

44,66,75]. Additionally, it also raises questions on ownership of the knowledge extracted by LLMs and whether copyright or *fair use* apply [58]. Indeed, content creators have raised concerns and filed lawsuits claiming copyright infringement by models trained on the books from the Books3 dataset, which would contain pirated copies of their content [25,32], but also on songs [20] or news articles [45].

Unfortunately, as those questions are being asked, model developers are becoming increasingly reluctant to disclose and discuss their training data sources. One of the currently most widely used models, GPT-4, releases no information on its training dataset [47], while Meta initially released details on the training dataset of LLaMA [67], but now resists to do so in their release of LLaMA-2 [68].

Contribution. We here introduce the concept of document-level membership inference and propose what is -to the best of our knowledge- the first setup and methodology to infer whether an LLM has seen a document during training or not. Our method can help organizations, regulators, content creators and model users to evaluate whether a piece of content has been included in the training dataset of an LLM.

First, we formalize the task of document-level membership inference and propose a procedure and dataset for the development and the evaluation of document-level membership inference methodologies. The development of a meta-classifier, requires a dataset with *members*, documents that were likely seen by the model during training, and *non-members*, documents that are unlikely to have been seen by the model. Finding members is typically easy as most LLMs today have seen sources such as Common Crawl [16] or Project Gutenberg [26]. Given the large amount of data seen by LLMs today, finding *non-members* is more challenging. We thus propose to use documents similar to the one available in public sources but now made available after the LLM was released. We then construct a dataset to train and validate our inference methodology for books (Project Gutenberg [26]) and academic papers (ArXiv) and for OpenLLaMA [22], whose training dataset is known, RedPajama-Data [17].

Next, we introduce our methodology to infer, based on black-box access to the language model, whether a given document has been seen by a model or not. The methodology consist of the following steps: querying the model for token-level predictions, normalizing the predictions for how common the token is, aggregating the predictions to the document level, and lastly building a meta-classifier.

Our approach achieves an AUC of 0.856 and 0.678 for books and ArXiv papers respectively, on average. We also find that for this setup we retrieve a 64.4% and 19.5% true positive rate at a 10% false positive rate, for books and papers respectively, implying that our classifier can accurately identify members. Given the immense corpus used to train a state-of-the-art LLM such as OpenLLaMA [22], we find it remarkable that our auditor can distinguish the contribution of an individual document. Our results also show that normalizing by both how common a token is and by the maximum probability returned by the model, is essential and that the signal for document-level membership lies in the detailed distribution of the token-level information within a document.

We then implement a sequence-level membership inference approach, such as previously considered in the privacy literature [14,41,73]. We show that state-of-the-art sequence-level baselines, scaled to document-level in three distinct ways, to perform poorly on our setup, reaching a maximum AUC of 0.56 and 0.57 for books and papers respectively.

Further, we investigate whether smaller models would impact the ability of an auditor to infer document membership. We find that even the smallest OpenLLaMA model, with 3 billion parameters, memorizes enough information about specific documents for the inference to be successful. In fact, our results show that the AUC remains at 0.86 and 0.68 for books and ArXiv papers respectively when switching from the 7B parameters to the 3B parameters models, indicating that even "smaller" models are at risk.

Finally, we consider potential membership inference mitigation strategies. We find that the AUC slowly decreases for partial documents, reaching an AUC of 0.62 for books when only 100 tokens are considered. For quantized versions of the language model, we still recover an AUC of 0.84 for books when the model is queried with *int4* precision.

2 Background

2.1 Language modeling

Recently, large language models (LLMs) have dominated the research in natural language processing [10,51,70]. Being trained in a self-supervised way on a large set of human generated text, LLMs are increasingly able to understand and generate natural language.

LLMs require a tokenizer T that discretizes a sequence of text to a sequence of n tokens $\{t_1,\ldots,t_n\}$. A token can be any sequence of characters that appear in language (e.g. a single word, part of a word or a combination of words). There is a finite number of tokens, and the collection of the tokens is referred to as the vocabulary $\mathcal{V}$ of size $V = |\mathcal{V}|$.

Given a sequence of n tokens, "foundation" language models are trained to optimize the probability for the model to generate a sequence of tokens $\{t_1,\ldots,t_n\}$, i.e. $p(t_1,\ldots,t_n)$. More specifically, auto-regressive language models like GPT-2 and GPT-3 [10,51] are trained for "next-token prediction", i.e. to predict the likelihood of the next-token given the preceding tokens. These models have shown to improve understanding and particularly generation of natural language. They compute the probability of a sequence of tokens from a series of conditional probabilities as $p(t_1,\ldots,t_n) = \prod_{i=1}^{n} p(t_i|t_1,\ldots,t_{i-1})$.

The preceding sequence of tokens used to predict the probability of the next token is commonly referred to as the *context*, consisting of length $C = |\text{context}|$. Typically, language mod-

els have a maximum context length that can be taken into account, which we denote as C_{max}.

LLMs use neural networks to estimate this probability distribution, with a significant amount of parameters θ to be fit during training (up to 100+ billion). The predicted probability of LM with parameters θ for token t_i and context of length C can be formalized as $LM_\theta(t_i|t_{i-C},\ldots,t_{i-1})$.

The values for θ are optimized to maximize the likelihood of the sequence of tokens in a large dataset $\mathcal{D}_{\text{train}}$. $\mathcal{D}_{\text{train}}$ can for instance include a book or a Wikipedia page and in practice contains up to trillions of tokens. Here, we denote the total number of tokens in the training data as N_{train}. More formally, the model parameters θ are determined to minimize the following loss function: $\mathcal{L}(\theta) = -\log\prod_{i=1}^{N_{\text{train}}} LM_\theta(t_i|t_{i-C},\ldots,t_{i-1})$.

In the past, recurrent neural networks were the standard choice for the architecture of language models, but, over recent years, they have been replaced by attention-based models [70], in particular the transformer-based models, which now dominate the scene.

Since the release of ChatGPT, a fine-tuned version of GPT-3 optimized for chat-like behaviour, the development of ever better language models has further accelerated. Examples include Palm 1/2 [2, 15], BLOOM [59], LLaMA 1/2 [67, 68] and Mistral 7B [31]. At the same time, newly developed models are increasingly made publicly available on the open platform hosted by Hugging Face, which also deploys a LLM leaderboard to track and compare performances [1].

2.2 Datasets used for training

State-of-the-art LLMs consist of billions of parameters, which are trained on large-scale datasets [7, 34] containing trillions of tokens. Web-scraped data from the internet has long been the primary source for these large-scale datasets. Data retrieved from the frequently updated Common Crawl [16] has for instance been the majority of the training data for GPT-3 [10], LLaMA [67] and BLOOM [59].

Controlling the quality of the language included from these sources is however crucial. This led to the creation of curated datasets, such as WebText (which only contains text scraped from links sufficiently recognized on the social media platform Reddit, used for GPT-2) [51] and C4 [53] and the inclusion of more moderated content such as from Wikipedia.

Technology companies and researchers are in competition to develop ever better performing LLMs. The search for textual data, ideally of high quality, to be used to train the models is thus crucial. Exactly for this purpose, the training datasets have often been extended by other sources of high quality text, such as academic papers from ArXiv [37] or books from Project Gutenberg [26]. The latter contains thousands of English books in the public domain.

With the same objective of releasing high quality textual data, Goa et al [65] released the Pile, a 800GB dataset consisting of a diverse set of English text. This includes Books3, a dataset consisting of around 200,000 books obtained from pirate sources, most of which were published in the last 20 years and are thus not free of copyright [36, 55]. It is known that for instance BloombergGPT [72] and LLaMA [67] have been trained on Books3.

2.3 Copyright and generative AI

Content creators, such as authors or artists, have raised concerns about the inclusion of their work in the training data of generative AI, including LLMs but also multi-modal models such as DALLE-2 [54] and Stable Diffusion [56]. These concerns have led to multiple lawsuits against technology companies who have acknowledged the use of copyrighted material for training, without the consent of the creators.

For instance, Stability AI is currently defending against two lawsuits, one filed by Getty Images [23] and one filed as a class action lawsuit by multiple creators [3], both of which argue the use of copyright-protected content to train Stable Diffusion. Further, US comedian Sarah Silverman and other authors have filed lawsuits against Meta [32], claiming Meta has infringed their copyrights by training LLaMA on pirated copies of their content. The US Authors Guild also published an open letter, signed by more than 15,000 authors, calling upon AI industry leaders to protect their content [25]. Since then, other content creators have filed lawsuits against LLM developers claiming copyright infringement, including the New York Times [45] and Universal Music [20].

Notably, since these lawsuits and public concerns have emerged, the original data source for the Books3 dataset has been removed [2] and technology companies tend to not disclose details on the dataset used to train the latest language models any longer [31, 47, 68].

Recognizing these ongoing court cases, Samuelson [58] articulates the challenges between copyright laws and generative AI. In particular, they mention that the court will need to decide whether the inclusion of in-copyright works in the training data of AI models falls under *fair use*, in which case it would not be copyright-protected. While it is still uncertain how copyright applies to generative AI, it is clear that content creators are concerned [25] while the technology will continue to evolve rapidly without necessarily taking these concerns into account [8, 9].

2.4 Membership inference attacks

Homer et al. [28] introduced Membership Inference Attacks (MIAs) to study whether the presence of a certain target individual can be inferred from a genomic DNA mixture. They

[1] Hugging Face leaderboard

[2] https://huggingface.co/datasets/the_pile_books3

used statistical tests to distinguish between mixtures including the target and mixtures including individuals randomly drawn from a reference population. Since then, MIAs have been widely used to evaluate the privacy risk of aggregate data releases, such as location data [50] or survey data [6].

Since then, in the privacy literature, MIAs have also been developed against Machine Learning (ML) models [11, 19, 29, 64, 69]. Given a certain record D, a ML model trained on dataset $\mathcal{D}_{\text{train}}$, the attacker aims to infer whether the particular record was part of $\mathcal{D}_{\text{train}}$ or not. In many cases, the MIA setup makes additional assumptions on the access to the training data distribution and the ML model available to the attacker.

Shokri et al. [64] is seen as a foundational contribution in the field of MIAs against ML models. They assume the attacker to have black-box access to the model, i.e. they can query the model for predictions for a given input, and consider various assumptions on access to the training data. In their approach, the attacker uses the shadow modeling technique enabling them to learn a decision boundary for membership through a meta-classifier. Our proposed method also leverages a similar meta-classifier, inspired by the shadow modeling technique, while adapting it to our auditing setup.

MIAs against ML models have since been extensively studied in subsequent works and have become a common tool to assess what a ML model memorizes and whether its release poses any privacy risk [11, 18, 19, 29, 42, 65]. Importantly for this paper, MIAs have also been developed against (large) language models, which we discuss in the related work (Sec. 8).

3 Auditing setup

We consider an auditor $\mathcal{A}$ that has access to a document D, e.g. a book or a research article, and wants to check if D was used to train a language model *LM*. Thus, if we assume *LM* is trained using dataset $\mathcal{D}_{\text{train}}$, then the auditor wants to infer whether $D \in \mathcal{D}_{\text{train}}$ or not.

We define document D consisting of tokens t_i such that $i \in \{1,...,N\}$, or

$$D = \{SOS, \text{t}_1, .., t_i, .., \text{t}_N, EOS\} \tag{1}$$

where *SOS* is start-of-sequence token, and *EOS* is end-of-sequence token. Any such document D is highly likely to consist of significantly more tokens than the maximum context length of existing language models. Thus, we further assume that D consists of N tokens, and $N > C_{max}$.

We further assume that the auditor $\mathcal{A}$ has:

1. Query-only access to the language model *LM* and full access to its tokenizer T. This means that the auditor can query the model with a sequence of tokens S, and receive the probability output for all tokens v in vocabulary $\mathcal{V}$. This is a realistic assumption as trained models (along with their tokenizers) like LLaMA-2 [68] and Mistral 7B [31] are fully and freely released on platforms such as the one hosted by Hugging Face. We assume that the auditor is able to query *LM* an arbitrary number of times.

2. Access to two sets of documents, that stem from the same distribution as the document D e.g. if D is a book then D_{M} and D_{NM} also contain books. D_{M} and D_{NM} are defined as follows:

   (a) D_{M}: A subset of documents used in training of *LM*, also referred to as members, $\forall D \in D_{\text{M}}, D \in \mathcal{D}_{\text{train}}$.

   (b) D_{NM}: A subset of documents not used in training of *LM*, also referred to as non-members, i.e. $\forall D \in D_{\text{NM}}, D \notin \mathcal{D}_{\text{train}}$.

Note that access to D_{M} and D_{NM} is realistic in practice. First, most models use very similar datasets from sources such as Common Crawl [16] and Project Gutenberg [26], that are publicly available and easily accessible to include in D_{M}. Second, these sources are regularly updated and timestamped, which allows the auditor to construct D_{NM} by collecting the data that has been added after the training data has been collected (for which reasonable assumptions can be made as the model release is typically known). We leverage exactly this intuition to build the dataset for our experiments (Sec. 5.2). While not strictly required for the setup, we here consider a model for which each member document has been seen exactly once, and in its entirety, during training (Sec. 5.1).

Further, we assume that *LM* is a foundation model trained for next-token prediction on $\mathcal{D}_{\text{train}}$ which has not been subject to any measure that could shift the predicted probability distributions such as instruction tuning [74], reinforcement learning from human feedback [4] or watermarking [35].

Under these assumptions, the auditor aims to infer whether document D has been used to train the language model *LM*.

4 Methodology

The auditor $\mathcal{A}$ wants to build a meta-classifier $\mathcal{M}$ able to detect whether document D was used to train the language model *LM*. To achieve this, we extract document-level features for document D that could carry meaningful information on the membership of documents for the training of *LM*.

Intuition. From the privacy literature on MIAs against ML models [19, 64, 73], we learn that models tend to make more confident predictions on data samples that were seen during training than on data samples that were not. It is exactly this information that an auditor can leverage to infer membership. For LLMs, this confidence is reflected in the predicted probability for the true next token in the dataset given the preceding tokens. We use this intuition to construct the document-level features, which are then used as input for our meta-classifier $\mathcal{M}$. Specifically, our method considers the following four steps:

1. We first query LM to retrieve the predicted probability $LM(t_i|t_{i-C},\ldots,t_{i-1})$ of a token given the context of length C, and we do this for all tokens in document D, i.e. $\forall t_i \in D$. We try different values of C in our approach.

2. We then normalize the predicted probability of a token using a normalization algorithm NORMALIZE, for which we consider different options (Sec. 4.2).

3. We then consider multiple strategies FEATAGG to aggregate all the token level information for a document D to construct document level features.

4. Finally, the meta-classifier $\mathcal{M}$ takes as input the document-level features of D to make a binary prediction on membership of D.

We further formalize these four steps in the sections below.

4.1 Querying the model

The auditor queries LM to retrieve a value per token t_i in document D. As the maximum context length of the model C_{max} is likely to be smaller than the length of the document N, the auditor runs the model through the document with a certain fixed context length C and stride s.

The document is split in N_s sequences $S_j, j = 1,...,N_s$ with $S_j = (t_{j,1},\ldots,t_{j,C})$ consisting of C consecutive tokens. The last sequence has C' tokens, which can be $\leq C$ depending on the total number of tokens N in D and stride s. We apply the same operations for this last sequence using C' instead of C.

Each sequence is passed to the model as input and results in a sequence of predicted probabilities for the corresponding true tokens:

$$LM_\theta(S_j) = \left\{LM_\theta(t_{j,2}|t_{j,1}),\ldots LM_\theta(t_{j,C}|t_{j,1}\ldots t_{j,C-1})\right\} \quad (2)$$

Note that $|LM_\theta(S_j)| = |S_j| - 1 = C - 1$, as the model does not return a prediction for the first token $t_{j,1}$ in the absence of a meaningful context to do so. Thus, when using context length C, we move through the document with stride $s = C-1$. We then get sequences S_j for $j = 1\ldots N_s$ where $N_s = \lceil \frac{N}{C-1} \rceil$, so the resulting set of all $LM_\theta(S_j)$ contains predictions for all tokens t_i in D, except for the very first token t_1. We further refer to this probability of token t_i in document D for language model LM_θ simply as $LM(t_i)$.

The value for C is a fundamental hyperparameter of the setup and can be chosen to be any integer value smaller than C_{max}. Note that the predictions of a language model typically become more accurate for a longer context length C. However, as the goal is to retrieve information that should be meaningful for membership, it is not clear if this information is more likely to be at predictions with smaller or larger context.

4.2 Normalization (NORMALIZE)

In the section above, we query LM to extract $LM(t_i)$, i.e. the probability with which the LM would predict the next token in question given a certain context. However, in natural language, some tokens are more rare than others. Intuitively, the probability with which a model predicts a certain token would depend on how rare such a token is. For instance, for a frequently occurring token such as *the* or *and* the model might predict a high probability, while for a more infrequent token the model naturally predicts a lower probability. We hypothesize that this occurs regardless of whether the model has seen the sequence of interest at training time or not.

Thus, to optimally retrieve the information meaningful for membership we *normalize* the model output with a value that takes into account the rarity of a token. Prior work on sequence-level membership inference has approached this in various ways. For instance, Carlini et al. [14] consider the zlib entropy of a sequence or use the predicted probability of a reference model. While zlib considers the entropy of a sequence and does not provide token-specific information, the use of a reference model requires using another model which also uses the exact same tokenizer T as LM, which is often not available. Instead, we propose different token-specific NORMALIZE approaches based on the data and the model the auditor $\mathcal{A}$ already has access to.

4.2.1 Computing a normalization dictionary

We consider the token $t_i = v$ in document D with v the token value part of the vocabulary $\mathcal{V}$. We then normalize the predicted probability of t_i, $LM(t_i)$, using reference value $R(v)$. $R(v)$ is calculated for each token v in vocabulary $\mathcal{V}$ to capture the rarity of v. We propose two ways of computing $R(v)$.

Token frequency (TF). Recall that the auditor is assumed to have access to both D_{M} and D_{NM}. With the concatenated dataset as reference $D_{\text{ref}} = D_{\text{M}} \cup D_{\text{NM}}$, the token frequency $R^{TF}(v)$ for token v in vocabulary $\mathcal{V}$ is then computed as follows:

$$R^{TF}(v) = \frac{\text{count}(v, D_{\text{ref}})}{\sum_{j=1}^{V} \text{count}(v_j, D_{\text{ref}})} \quad (3)$$

where $\text{count}(v, D_{\text{ref}})$ corresponds to the number of times token v appears in the set of documents D_{ref}. For tokens that do not appear even once in our dataset D_{ref} we use the smallest frequency in the normalization dictionary divided by 2 as a reference value.

General probability (GP). While the token frequency quantifies how rare a certain token is in the dataset, its computation does not take into account the specific context with which the token appears. Also, when a token v does not appear even once in D_{ref}, no valid value for the frequency $R^{TF}(v)$ can be computed.

In order to address both concerns, we propose to compute the *general probability* $R^{GP}(v)$ of the token v in vocabulary $\mathcal{V}$. Here, we run through D_{ref} as described in Sec. 4.1 and compute the average of all the predicted probabilities for v.

Note that we consider all predictions, also when the true token $t_k \in D_{\text{ref}}$ is not equal to v, as the model predicts the probability distribution over the entire vocabulary every time. $R^{GP}(v)$ is computed as follows:

$$R^{GP}(v) = \frac{1}{|D_{\text{ref}}|} \sum_{k=1}^{|D_{\text{ref}}|} LM_\theta(v \mid t_{k-C}, \ldots, t_{k-1}) \tag{4}$$

4.2.2 Normalization strategies

We here propose different normalization strategies NORMALIZE for $LM(t_i = v)$ using $R(v)$.

No normalization (*NoNorm*). In this case we use the predicted probabilities as they are and do not apply any normalization, or:

$$NoNorm(t_i = v) = LM(t_i) \tag{5}$$

Ratio normalization using the token frequency (*RatioNormTF*). We here compute the ratio of the predicted probability of the token of interest and the corresponding token frequency $R^{TF}(v)$ in D_{ref} as discussed in Sec. 4.2.1.

$$RatioNormTF(t_i = v) = \frac{LM(t_i)}{R^{TF}(v)} \tag{6}$$

Ratio normalization using the general probability (*RatioNormGP*). We here compute the ratio of the predicted probability of the token of interest and the corresponding general probability $R^{GP}(v)$ in D_{ref} as discussed in Sec. 4.2.1.

$$RatioNormGP(t_i = v) = \frac{LM(t_i)}{R^{GP}(v)} \tag{7}$$

Maximum probability normalization (*MaxNorm*). For a given token t_i, the model predicts the probability distribution over all tokens in the vocabulary $\mathcal{V}$. For now we have only considered the probability that the model returns for the true token t_i, regardless of how this probability compares to the predicted probability for the other token values with the same context. Intuitively, we could expect that the difference between the maximum predicted probability over all tokens $t \in \mathcal{V}$, with corresponding token $v_{\max}$, and the predicted probability for the true token t_i carries information about how likely the model is to predict the token of interest. Fig. 2 illustrates how the predicted probability for the true token and the maximum probability differ on a real example. We hypothesize that exactly the difference between both values could be meaningful to infer membership.

Formally, we denote the maximum probability being predicted for t_i for context C_i as

$$LM_{\max}(t_i|C_i) = \max_{t \in \mathcal{V}} LM(t|C_i) \tag{8}$$

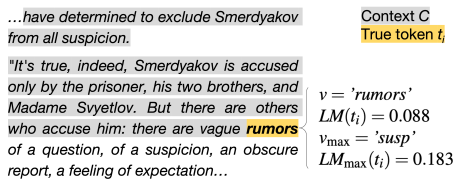

Figure 2: Querying OpenLLaMA-7B on an example from the book *The Brothers Karamazov by Dostoyevsky* (member, Sec. 5.2).

regardless of whether the probability corresponds to the true token t_i or not. For rest of the paper, $LM_{\max}(t_i)$ implies $LM_{\max}(t_i|C_i)$. We then combine this with the ratio normalization strategies to get *MaxNormTF* and *MaxNormGP*.

$$MaxNormTF(t_i = v) = \frac{1 - (LM_{\max}(t_i) - LM(t_i))}{R^{TF}(v)} \tag{9}$$

$$MaxNormGP(t_i = v) = \frac{1 - (LM_{\max}(t_i) - LM(t_i))}{R^{GP}(v)} \tag{10}$$

Note that we ensure that the numerator never equals zero, even when the model predicts the highest probability for the true token t_i, or when $LM_{\max}(t_i) = LM(t_i)$.

4.3 Feature extraction (FEATAGG)

For all the tokens t_i in document D, we have so far normalized the predicted probabilities using normalization strategy NORMALIZE. We now use these normalized values to set $F(t_i)$ as the negative log of the output after normalizing token-level probabilities, or $F(t_i) = -\log(\text{NORMALIZE}(LM(t_i)))$.

Note that when we do not apply any normalization, or *NoNorm*, the value for $F(t_i)$ corresponds to the cross-entropy loss for the predicted probability, as used to optimize the model parameters during training.

While we now have computed a final value on the token level, our ultimate goal remains to predict binary membership for a document. Hence, from all token-level information $F(t_i), \forall t_i \in D$, we need to extract document-level features that could capture meaningful information for membership. We consider two feature extractors *AggFE* and *HistFE*.

Aggregate feature extractor (*AggFE*). For each document D, *AggFE* computes aggregate statistics from the token-level information. Specifically, it uses $F(t_i), \forall t_i \in D$ to compute the minimum, maximum, mean and standard deviation and the values at x-percentiles for $x \in X_{\text{perc}}$.

Histogram feature extractor (*HistFE*). *HistFE* uses N_b equal-sized histogram bins and for each document it computes the fraction of total values $F(t_i)$ in each bin. These N_b features are then used as document-level features. The N_b equal-sized bins are determined using all token-level values in the training dataset, across all documents.

4.4 Meta-classifier

As a final step, the document-level features extracted using FEATAGG are used as input to the meta-classifier $\mathcal{M}$, which returns a prediction for binary membership of input document D. As $\mathcal{M}$ we only consider a random forest classifier, allowing to fit non-linear dependencies across input features. We train $\mathcal{M}$ on a training subset of D_{M} and D_{NM} and evaluate its performance for binary classification on a disjoint subset.

5 Experimental setup

5.1 Model

As language model *LM* we use OpenLLaMA [22], a fully open-source reproduction of LLaMA [67], an auto-regressive LLM developed by Meta. While LLaMA is made publicly available for research and details on their training data have been provided [67], the exact training dataset has not been released. Instead, OpenLLaMA is trained on RedPajama-Data [17], which is a best-guess, open replication of the original dataset used to train LLaMA. We here opt for OpenLLaMA in order to be in full control of the training dataset. The models are publicly available hosted by Hugging Face in three sizes: 3, 7 and 13 billion parameters. The tokenizer T has a vocabulary of size $V = 32,000$ and the maximum input length equals $C_{max} = 2048$.

5.2 Dataset for membership

We use two distinct types of documents, books and academic papers in LaTeX, to evaluate the effectiveness of our methods in inferring the document-level membership. For each type, we collect a fixed number of member (D_{M}) and non-member (D_{NM}) documents and train a separate meta-classifier.

As indicated in Sec. 3, we use realistic assumptions for the auditor to collect both D_{M} and D_{NM} for each document type. Specifically, for the members, we use data sources that are typically used for language modeling and are readily available. For non-members, we leverage the fact that these sources are regularly updated to retrieve the documents that have been added after the time the training data has been collected. While we believe these assumptions are reasonable in practice, we additionally ensure there is no overlap by using our exact knowledge of RedPajama-Data [17]. Below we describe in detail how we approach this for each document type.

5.2.1 Books (Project Gutenberg)

Project Gutenberg [26] is a volunteering project aiming to digitize and freely distribute books. The resulting online library contains thousands of books from a wide range of languages and publication dates. The vast majority of the releases are in the public domain in the United States, meaning that copyright laws do not apply.

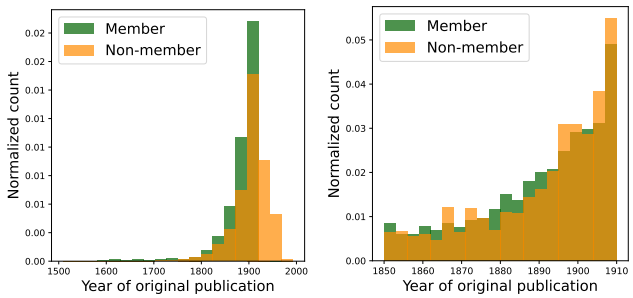

Figure 3: Density distribution of the original year of publication for books included in Project Gutenberg, for members and non-members. Both the raw distribution (left) and the filtered distribution for years 1850-1910 (right) are displayed.

Members D_{M}. We note that the RedPajama-Data includes both books from Project Gutenberg and the Books3 dataset made available by the Pile [21]. We exclusively consider the set of books PG-19 made available by Rae et al. [52]. This dataset contains 28,752 English books that were published before 1919 and made available on Project Gutenberg.

Non-members D_{DM}. Project Gutenberg is an ongoing project with new books added regularly. We create a comparable book dataset that has not been used for training by downloading books added to Project Gutenberg after the PG-19 dataset was created. Of all books included in PG-19, the latest release date on the Gutenberg project was February 10, 2019. We then use an open source library [49] to download all English books that were added to Project Gutenberg after this date. In our setup, this led to a total of 9,542 books that we could use as non-members. In line with how PG-19 has been constructed, we only consider the text between the explicit start and end of the uniformly formatted text files.

Two books published in different eras could be easily distinguished from the writing style. In that regard, Fig. 3 shows that there is a meaningful shift in year of original publication between books considered as member and non-members. Thus, there is a possibility that language written in books from for instance the 1700s can lead to data drift compared to books written in the 1900s. To ensure the meta-classifier $\mathcal{M}$ focuses on the memorization of the model, and does not focus on a potential drift in language, we only consider books with a year of original publication between 1850 and 1910. Fig. 3 shows that the distributions of members and non-members for these now filtered books are highly similar. This makes us confident that the model would focus on the membership rather than on the language drift.

5.2.2 Academic papers (ArXiv)

We use academic papers as posted on the online research-sharing platform ArXiv. In line with prior work training LLMs on academic papers [37], RedPajama-Data includes the raw

LaTeX text after removing the bibliography, the comments and everything before the occurrence of the first section.

Members $D_{\mathbf{M}}$. As RedPajama-Data includes the preprocessed LaTeX text from ArXiv papers, we download documents that were part of the training dataset using their instructions [3]. This leads to approximately 1.5 million ArXiv papers to be considered as members of the training dataset.

Non-members $D_{\mathbf{NM}}$. The Github repository of RedPajama-Data [17] also provides instructions on how to download academic papers from ArXiv directly. ArXiv maintainers host an Amazon S3 bucket containing all source LaTeX files, which gets updated on a monthly basis and can be retrieved at a moderate charge [4]. The data is grouped by the month on which the first version of the document has been added to ArXiv. From RedPajama-Data, we found that the last month that had been included in the training dataset was February 2023, which allows us to download all academic papers uploaded on ArXiv from March 2023 and use them as non-members. After applying the same preprocessing recipe as for the members, our non-member dataset of ArXiv paper eventually consists of around 155 thousand documents.

5.2.3 Training and evaluation setup

We use the documents considered as members and non-members to train and validate our method to predict membership of document D in the training data. To ensure our model focuses on documents of a reasonable length, and sufficiently longer than the maximum context length, C_{max}, we remove all documents, from both the books and academic papers, that have fewer than 5,000 tokens. We then randomly sample 1,000 member and 1,000 non-member documents. Next, we construct $k = 5$ different chunks of 400 documents, each chunk consisting of 200 member documents and 200 non-member documents. This allows us to train our set-up using $k-1$ chunks, i.e. 1600 documents, and validate the performance on the held-out chunk, i.e. on 400 documents. By executing this k times, the classification performance is robustly estimated with a mean and standard deviation across k runs. For both document types, books and academic papers, we construct this setup to train and evaluate a distinct meta-classifier $\mathcal{M}$ k times.

5.2.4 Methodology parameters

We here describe the methodology parameters (Sec. 4.4) used in our experiments.

As context length C to query the model, we consider three different values$\{128, 1024, 2048\}$, the last of which is same as the maximum context length C_{max}. As D_{ref} to compute the normalization dictionaries in NORMALIZE, we use the same sets of documents used to train the meta-classifier. This means that $k-1=4$ chunks, with a total 800 members and 800 non-members are used, leading to $|D_{\text{ref}}| = 1,600$ for every run. For feature extractor *AggFE* we use a set of percentiles $X_{\text{perc}} = \{1,5,10,25,50,75,90,95,99\}$ and for *HistFE* number of bins $N_b = 1,000$. For the meta-classifier $\mathcal{M}$ we use a random forest classifier from scikit-learn [48] with 500 trees of a maximum depth of 5 and a minimum of samples per leaf of 3. We ran all language model queries on a set of A100 NVIDIA GPUs with a floating point precision of 16 bits.

6 Results

6.1 Evaluation across setups and datasets

Tables 1 and 3 summarize the performance of our binary membership classifier for books from Project Gutenberg and ArXiv papers respectively. We measure the performance of $\mathcal{M}$ using the Area Under the Receiver Operating Characteristic Curve (AUC-ROC) and report the mean and standard deviation over $k = 5$ runs (Sec. 5.2.3).

The highest mean AUC achieved across setups for books and papers is 0.856 and 0.678 respectively, which is significantly higher than the random baseline of 0.5. This effectively shows that our model queries, normalization strategies and feature extraction enables the meta-classifier to learn the decision boundary for membership of a document D in the training data of an LLM. Around 250,000 books and 1.5 million ArXiv papers contribute to around 4.5% and 2.5% of the entire training dataset [67]. This makes the contribution of one document to the entire dataset negligible, and highlights the difficulty of membership inference. In this context, our meta-classifier's performance demonstrates the ability of our simple NORMALIZE and FEATAGG strategies to separate signal from the noise.

Further, the results allow us to compare the combinations of different setups, i.e. combination of context length C, normalization strategy NORMALIZE, and feature aggregation strategy FEATAGG as discussed in Sec. 4.4. First, we notice fairly little difference in performance across different values of context length C. This would imply that memorization is equally exposed for lower and larger values of context length. Second, we find that normalization is required to reach reasonable classification performances. Compared to the raw predicted probabilities *NoNorm*, all normalization strategies lead to an improved performance. Notably for *MaxNormTF*, we find that, for $C = 128$ and *HistFE*, the mean AUC increases by 0.29 and 0.10 for books and papers respectively when compared with *NoNorm* performance. Additionally, we find fairly little difference between normalizing with the *token frequency* $R^{TF}(v)$ or *general probability* $R^{GP}(v)$ across setups. This would imply that both normalization dictionaries provide similar information on the rarity of a token value. Third, we find that the histogram feature extraction *HistFE* is significantly more effective than the more simple aggregate statistics extraction

Table 1: Books from Project Gutenberg - mean and standard deviation AUC for binary membership across k folds.

FEATAGG	NORMALIZE	Context length C 128	1024	2048
AggFE	*NoNorm*	0.550 ± 0.011	0.551 ± 0.009	0.554 ± 0.012
	RatioNormTF	0.605 ± 0.025	0.552 ± 0.017	0.556 ± 0.012
	RatioNormGP	0.621 ± 0.031	0.539 ± 0.022	0.553 ± 0.021
	MaxNormTF	0.620 ± 0.029	0.546 ± 0.021	0.543 ± 0.016
	MaxNormGP	0.626 ± 0.025	0.542 ± 0.025	0.553 ± 0.021
HistFE	*NoNorm*	0.566 ± 0.022	0.528 ± 0.024	0.541 ± 0.017
	RatioNormTF	0.766 ± 0.030	0.786 ± 0.028	0.799 ± 0.020
	RatioNormGP	0.779 ± 0.010	0.790 ± 0.013	0.804 ± 0.011
	MaxNormTF	$\mathbf{0.856 \pm 0.021}$	0.854 ± 0.026	0.855 ± 0.027
	MaxNormGP	0.849 ± 0.019	0.853 ± 0.0218	0.852 ± 0.026

AggFE. For *MaxNormTF* and $C = 128$, *HistFE* leads to an increase in AUC of 0.24 and 0.05 for books and papers respectively compared with *AggFE* in an equivalent setup. This makes us confident that the information for membership truly lies in the detailed distribution of token-level values per document, rather than in high-level aggregates. Overall, $C = 128$, normalization using *MaxNormTF*, and feature aggregation using *HistFE* results in the best performing meta-classifier $\mathcal{M}$ for both books and academic papers.

Dataset	TPR@FPR 10%	1%
Project Gutenberg	$64.44 \pm 9.32\%$	$18.75 \pm 3.82\%$
ArXiv	$19.50 \pm 0.94\%$	$5.92 \pm 2.13\%$

Table 2: True positive rates at low false positive rates for the best setup in Tables 1 and 3.

Fig. 1 shows the ROC curve for one trained meta-classifier $\mathcal{M}$, randomly selected out of the k, for the best performing setup. In line with Carlini et al. [11], we also provide the true positive rate at low false positive rates for this setup in Table 2. Especially for the books, a true positive rate of 18.75% at a false positive rate of 1% implies a meta-classifier $\mathcal{M}$ that can confidently identify members in a given set of documents.

6.2 Comparison to sequence-level baseline

In the privacy literature, prior work on Membership Inference Attacks (MIAs) against language models has exclusively focused on inferring membership at the sequence-level [11,14,41,73]. In contrast, our setup concerns an auditor who aims to infer document-level membership.

We here compute how state-of-the-art sequence-level MIAs perform in our setup when scaled to the document-level. We consider as MIA methodologies to compute a sequence-level membership score α:

1. The *Loss* attack [73], which uses the language model cross-entropy loss computed for the given sequence.

2. Both the *Zlib* attack and *Lower* attack [14], which divides the target language model loss by the sentence zlib compression entropy and the target language model loss computed with all lower-case characters.

3. The *Ratio* attack [14], which divides the target language model loss for a given sample by the loss computed using a reference model. As a reference model, we here use both GPT-2 [51] (*Ratio-GPT-2*) and the OpenLLaMA-3B [22] (*Ratio-3B*).

4. The *Neighborhood* attack [41]. For each sample, we use a RoBERTa-based masked language model [39] to sample 50 neighboring samples with 1 token replacement. We use the difference between the target language model loss computed on the sample and the mean loss of the neighboring samples.

We now consider whether the sequence-level MIA can be scaled to the document-level. First, we split each document D in sequences $S_j = (t_{j,1}, \ldots, t_{j,C})$ of the same length $C = 128$. We found 1000 tokens to approximately map to 750 words, and hence using $C = 128$ tokens is a good proxy for selecting a sentence. For each document D, we randomly sample 40 sequences S_j, ensuring each document has the same number of sequences and then use the same membership label for sequences as for the corresponding document. We consider three ways of scaling the sequence-level membership inference to the level of the document:

1. *Sequence*. We compute the AUC on the sequence-level membership scores directly.

2. *Document (average)*. We use the average sequence-level

Table 3: ArXiv papers - mean and standard deviation AUC for binary membership across k folds.

FEATAGG	NORMALIZE	Context length C 128	1024	2048
AggFE	*NoNorm*	0.617 ± 0.015	0.605 ± 0.031	0.602 ± 0.022
	RatioNormTF	0.609 ± 0.027	0.614 ± 0.027	0.613 ± 0.017
	RatioNormGP	0.605 ± 0.028	0.609 ± 0.019	0.616 ± 0.014
	MaxNormTF	0.630 ± 0.021	0.622 ± 0.026	0.623 ± 0.026
	MaxNormGP	0.635 ± 0.016	0.632 ± 0.022	0.626 ± 0.023
HistFE	*NoNorm*	0.579 ± 0.029	0.580 ± 0.026	0.580 ± 0.028
	RatioNormTF	0.644 ± 0.028	0.647 ± 0.026	0.654 ± 0.033
	RatioNormGP	0.643 ± 0.031	0.638 ± 0.026	0.645 ± 0.030
	MaxNormTF	$\mathbf{0.678 \pm 0.024}$	0.668 ± 0.031	0.668 ± 0.031
	MaxNormGP	0.675 ± 0.019	0.665 ± 0.021	0.668 ± 0.029

membership score per document to compute the document-level AUC, in line with the group-level attack from [30].

3. *Document (threshold)*. We consider a threshold T for the membership score, below which a sequence is classified as member and non-member otherwise. We determine T so that a maximum classification accuracy is reached on the sequence-level on the training dataset. We then take the ratio of sequences within a document, i.e. $\forall(S_j) \in D$, that are predicted as member, to compute the document-level AUC.

Similarly to Sec. 6.1, we compute the AUC for membership on the sequence-level for k chunks. Table 4 summarizes the results, with the mean and standard deviation AUC for all MIA methodologies and strategies to scale to the document-level.

Overall, we find most baselines to barely perform better than a random guess, with the maximum AUC of 0.56 and 0.57 reached using *Ratio-3B* and *Lower* for books and papers respectively. This suggests that sequence-level MIAs from the privacy literature might not work out-of-the-box for LLMs trained on a significantly larger corpus than previously considered [11, 14, 41]. Further, this implies that using sequence-level information to predict document-level membership is possibly sub-optimal. Indeed, the signal for document membership might lie within the distribution of the token-level predictions rather than in the sequence-level predictions.

Comparison with concurrent work. Concurrently with this work, *Min-K% Prob* has been proposed as a new technique for sequence-level membership inference, which can also be scaled to detect document-level contributions to language model pretraining data [63]. Table 4 also summarizes the results for $K = 20$. For both datasets, we find *Min-K% Prob* to perform barely above a random guess baseline.

6.3 Evaluation across model sizes

Note that all results in the section above were achieved with the OpenLLaMA model with 7 billion parameters (7B) [22]. We here evaluate whether our membership inference methodology would work equally well for models with less parameters. We thus use $C = 2048$ and *HistFE* feature-aggregation strategy, against the model with 3B parameters. We consider the two best performing normalization strategies *MaxNormTF* and *MaxNormGP*, along with *NoNorm* for comparison.

Fig. 4 shows that the AUC for membership classification remains highly consistent for even the smallest model. This implies that the memorization, as measured by our meta-classifier, for a "smaller" model of 3 billion parameters remains fairly similar. While these findings contrast with prior work [12, 14], which show that memorization increases with model size, we note that our setup is significantly different. First, we only compare across larger models (3B+ parameters) and second, we measure memorization by evaluating document-level inference, which is very different than the extraction of specific sensitive information. Lastly, we also evaluate our setup using the model with 13 billion parameters and find that, again, the membership inference performance remains highly consistent.

6.4 Membership inference mitigations

Partial documents. All results above consider the documents in their entirety, leveraging all token-level probabilities. In some cases, the entire document might not be known to the auditor, or there could be limitations in how many times the LLM can be queried. Hence, we here evaluate how the membership inference performance changes when only partial documents are considered.

Table 4: Baselines - mean and standard deviation AUC for binary membership across k folds.

Attack	Project Gutenberg Sequence	Project Gutenberg Document (average)	Project Gutenberg Document (threshold)	ArXiv Sequence	ArXiv Document (average)	ArXiv Document (threshold)
Loss	0.485 ± 0.012	0.478 ± 0.025	0.533 ± 0.016	0.530 ± 0.012	0.556 ± 0.027	0.563 ± 0.028

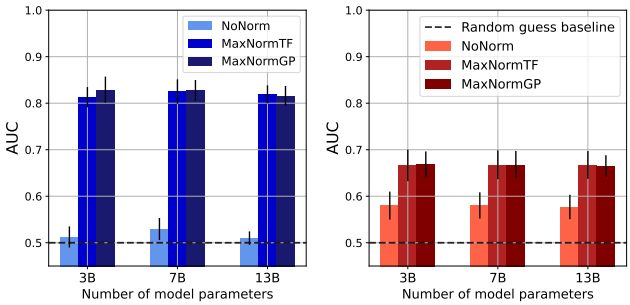

Figure 4: Mean AUC for $C = 2048$ across model sizes, for books from Project Gutenberg (left) and ArXiv papers (right).

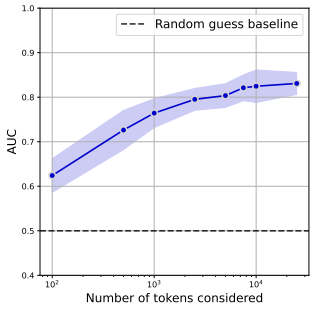

Figure 5: Mean and standard deviation AUC for books from Project Gutenberg for an increasing number of tokens in a random excerpt sampled from the document.

Fig. 5 shows how the AUC varies for an increasing number of tokens taken into account for books from Project Gutenberg using the best setup from Table 1. In order to cleanly measure the impact of the number of tokens, we take a maximum number of tokens of $25,000$ and only consider books that have at least this number of tokens, eliminating 13.2% of the books. For a given number of tokens, a random excerpt of this length is sampled from the book and then considered as the full document to run the membership inference.

We find that even for 100 tokens a mean AUC of 0.62 is achieved, showing that even for smaller paragraphs sampled from documents our proposed method performs better than a random guess baseline. The AUC however steadily increases for an increasing number of tokens up until 0.83 for $25,000$ tokens, effectively showcasing how considering a larger part of the document can significantly increase the membership inference performance.

Quantized models. All results above consider the OpenLLaMA-7B in floating point precision of 16 bits. We here consider querying the language model with varying precision and evaluate the membership inference performance for books using the best setup from Table 1. From the results in Table 5, we observe similarly good membership inference performance when querying the language model with lower precision. We hypothesize that the signal for membership picked up by our method likely does not change drastically with model precision when aggregating predicted probabilities over often more than $100,000$ tokens.

Precision	AUC
int4	0.841 ± 0.025
int8	0.835 ± 0.023
float16	0.856 ± 0.021
float32	0.843 ± 0.028

Table 5: Mean and standard deviation AUC for the best setup (Tab 1), querying OpenLLaMA-7B with varying precision.

6.5 Performance difference between datasets

The results in Tables 1 and 3 show a significant difference between the document-level membership inference performance on the books versus papers, with the highest mean AUC across setups of 0.856 and 0.678, respectively. We here discuss multiple hypotheses for this difference.

First, the data itself is inherently different. The papers from ArXiv consist of data from raw LaTeX files. This contains a highly specific set of characters (e.g. LaTeX formatting, table content) while the natural language included in books from the literature is expected to contain a wider diversity of tokens. Fig. 6 (a) compares how the token frequency R^{TF} is distributed across the top 20,000 tokens between papers and books. This confirms our hypothesis that LaTeX papers contain more of a limited set of tokens, while the tokens used in books are more widely spread over the entire vocabulary $\mathcal{V}$, possibly affecting the distribution of predicted probabilities that our method requires as input.

Second, academic papers and books have a different length, i.e. total number of tokens per document. Fig. 6 (b) confirms that the books considered in our experiments consist of significantly more tokens than the ArXiv papers, with an average of approximately 112,000 and 19,000 tokens respectively. This means that the language model has seen more tokens from member-books than from member-papers. Moreover, books typically contain repeated occurrences of characters, e.g. *Harry Potter*, across the document. These characters would likely be rare tokens, occurring more often for the longer books than for papers, likely impacting the model memorization more for books than for papers and thus also the classification performance. Further, the document length could also play a role at inference time of the meta-classifier. Indeed, during feature extraction, more rare tokens contribute to our final feature set in the case of books than for papers, which again would impact the classification performance.

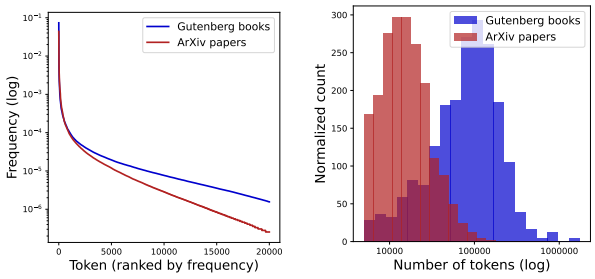

Figure 6: (a) Distribution of token frequency R^{TF} for the top 20,000 tokens. (b) Density distribution of number of tokens per document. Both contain results for 2,000 documents.

Third, we anticipate that books in Project Gutenberg often represent the pieces of literature that are wide-spread across the internet. This means that there might exist an overlap between the books as included in the PG-19 dataset for training and the data scraped from the internet such as Common Crawl [16] and C4 [53] which are also included in the training of OpenLLaMA [22]. This leads to a potential level of duplication, which is reasonably more likely for books that have been added to Project Gutenberg earlier than later (i.e. members). This will likely impact the memorization of these books in *LM* while, in contrast, academic papers, especially in LaTeX, are rarely distributed widely.

7 Discussion

We here construct a novel setup for document-level membership inference for real-world LLMs.

First, we introduce a general paradigm to construct a labeled dataset for document-level membership that we believe to be realistic in practice. Indeed, LLMs typically use similar data sources to construct a training dataset, such as Common Crawl [16], C4 [53] and Project Gutenberg [26]. This makes the identification of member documents fairly feasible in practice. Moreover, these sources are typically continuously updated and timestamped, which enables an auditor to retrieve similar documents that were added after the LLM training dataset was created, i.e. a comparable set of non-members.

This, however, depends on how recently a model was released and how frequently the data source of interest is updated. For ArXiv, more than 10,000 new papers are added monthly [5]. Hence, the retrieval of a sufficient amount of non-members (we here consider 1,000) should be feasible shortly after the model release, especially as training data is typically collected some time prior to the model release. For Project Gutenberg, we find that a handful of new books are added daily [6]. While less frequent, a reasonable amount of non-members could still be collected not too long after the model release.

Using this paradigm, we created a dataset of members and non-members for OpenLLaMA [22] that we could verify using the publicly available RedPajama-Data [17]. We leave for future work how the meta-classifier performance changes when the full knowledge of training data is not available. In particular, our setup could be applied to the original LLaMA [67] model and potentially even on LLaMA-2 [67].

In Sec. 6.3 we demonstrate the effectiveness of our method to language models of different model sizes (3B, 7B and 13B parameters) separately. In practice, it is however common that the entire model 'family' is trained on exactly the same dataset. We hypothesize that the auditor could construct a meta-classifier that takes as input document-level features queried from models of different sizes to make a potentially more accurate prediction for membership in practice.

In Sec. 6.4, we find that when the target language model is

[5] https://arxiv.org/stats/monthly_submissions
[6] Project Gutenberg release date

queried with less precision, the membership inference remains accurate. We note, however, that we here exclusively consider pre-trained models, and leave for future work how alignment methods [4, 74] or watermarking [35], when applied to the language model, could alter these results.

Further, we constrained ourselves to use a dataset of members D_{M} and non-members D_{NM} of size 1000 each. With our computational resources, it takes us approximately a day to generate the predicted probabilities for each token in the books dataset by querying language model *LM*. We expect that researchers with a large resource pool could explore the impact of having larger datasets of members and non-members on the performance of the meta-classifier $\mathcal{M}$.

Lastly, with this proof-of-concept, we hope to provide a way to retrieve a reasonable estimate of whether a document has been included in the training dataset of an LLM. Not only does this improve our understanding of memorization in ever larger models in practice, it also encourages increased transparency in what LLMs are trained on.

8 Related work

There exists a significant literature focusing on privacy attacks against (large) language models, which are relevant to our setup for document-level membership inference.

Carlini et al. [13] proposes a framework to quantitatively asses unintended memorization in generative sequence models, such as language models trained for next token prediction. They effectively showcase how log-perplexity from a LSTM recurrent neural network trained for next token prediction can be used to extract potentially sensitive sequences from the training data (such as emails or credit card information). Further, Song et al. [65] proposes a method to audit text generation models. Specifically, they use the shadow modeling technique to train a binary classifier for membership of the training data. For text generation, they implement this on the user level, aggregating predictions from individual pieces of text associated with the same user. While conceptually similar to the document-level membership inference in this paper, Song et al. apply their approach on recurrent neural networks trained on small datasets. Due to the computational cost to train a state-of-the-art, real-world large language model [10,31,51,67,68], the use of the shadow modeling technique is no longer feasible. Further, the size of the dataset used to train these models [7] has drastically increased, making the contribution of an individual document distinctly harder to distinguish. For both reasons, new methods such as we here propose, are required to infer document-level membership against the most recent models.

Subsequently to their prior work, Carlini et al. [14] introduces a novel method for training data extraction from the transformer-based GPT-2, with up to 1.5 billion parameters trained on a vast training dataset of 40GB of text [51]. Importantly for this paper, they show that a combination of perplexity queried from the model and zlib entropy (which gives a certain reference notion of surprise for a certain sequence of characters) allows for effective extraction of training data. Additionally, they show that larger models, i.e. neural networks with more parameters, tend to memorize more from their training data. Mattern et al. [41] proposes a neighborhood attack for MIAs against language models. They also attack GPT-2, although now fine-tuned on specific data for which membership is then inferred. They use the difference between the target model loss computed on a given sequence and the loss computed on neighboring samples, obtained by replacing tokens using masked language models.

In contrast with the prior contributions mentioned above, this paper focuses specifically on document-level membership inference and applies it to real-world, large language models (7B+ parameters). This is, to the best of our knowledge, the first work of its kind.

Further, researchers have proposed defenses against these privacy attacks, such as de-duplication of the training data [33] or differentially private training [38]. However, Lukas et al. [40] challenges this, stating that these defenses do not reduce the risk posed to personal identifiable information. Lastly, various other works have developed membership inference attacks on more domain as well as task-specific language models, such as clinical language models [30] or language models in non-English languages [46], or fine-tuned models for machine translation [27] or classification [60, 61].

9 Conclusion

This paper proposes the first setup and methodology for document-level membership inference for real-world LLMs.

First, we formalize the task and introduce a procedure to realistically construct a labeled training dataset. For non-members, we rely on original documents that are similar to documents seen by the model but made available after the release date of the model. We then construct a dataset for the OpenLLaMA [22] model for both books from Project Gutenberg [26] and academic papers from ArXiv.

We then propose a methodology to infer document-level membership. We find that the distribution of predicted probabilities for all the tokens within a document, normalized by a value reflecting the rarity of the token, contains meaningful information for membership. Indeed, in the best performing setup, the meta-classifier infers binary membership with an AUC of 0.86 and 0.68 for books and papers respectively. This suggests our classifier's ability to accurately infer whether a document has been seen by the LLM during training.

Availability

The code used to generate the results in this paper has been made publicly available on Github[7].

MIST: Defending Against Membership Inference Attacks Through Membership-Invariant Subspace Training

Abstract

In Member Inference (MI) attacks, the adversary tries to determine whether an instance is used to train a machine learning (ML) model. MI attacks are a major privacy concern when using private data to train ML models. Most MI attacks in the literature take advantage of the fact that ML models are trained to fit the training data well, and thus have very low loss on training instances. Most defenses against MI attacks therefore try to prevent the model from heavily overfitting the training data. Doing so, however, generally results in lower accuracy.

We observe that training instances have different degrees of vulnerability to MI attacks. Most instances will have low loss even when not included in training. For these instances, they are less vulnerable to MI attacks and the model can fit them well without concerns. An effective defense only needs to (possibly implicitly) identify instances that are vulnerable to MI attacks and avoids overfitting them. A major challenge is how to achieve such an effect in an efficient training process.

Leveraging two distinct recent advancements in representation learning: counterfactually-invariant representations and subspace learning methods, we introduce a novel Membership-Invariant Subspace Training (MIST) method to defend against MI attacks. MIST avoids overfitting the vulnerable instances without significant impact on other instances. We have conducted extensive experimental studies, comparing MIST with various other state-of-the-art (SOTA) MI defenses against several SOTA MI attacks. We find that MIST outperforms other defenses while resulting in minimal reduction in testing accuracy.

1 Introduction

Neural network-based machine learning models are now prevalent in our daily lives, from voice assistants [27], to image generation [35] and chatbots (e.g., ChatGPT-4 [32]). These large neural networks are powerful but also raise serious privacy concerns, such as whether personal data used to train these models are leaked by these models. One way to understand and address this privacy concern is to study membership inference (MI) attacks and defenses [31, 39]. In MI attacks, an adversary seeks to infer if a given instance was part of the training data. If the optimal MI attack is merely as good as random guessing, then there is no privacy leakage in the sense of information theory [24].

Most MI attacks in the literature are loss-based blackbox attacks, which exploit the fact that ML models tend to overfit the training data and have higher confidence on training instances. Several defenses were proposed to alleviate this effect by making the label of training instance "softer" so that the trained model would behave less confidently on training instances. Shokri et al. [39] propose to use temperature in softmax function to increase the entropy of the predictions. Li et al. [22] suggest to train with mix-up instances (linear combinations of two original training instances). Chen and Pattabiraman [7] propose two methods to reduce confidence on training instances: (1) change labels of training instances to soft labels, and (2) use a regularizer to penalize low entropy predictions in training. Forcing labels of training instances to be "softer", however, will inevitably incur some penalty of lower testing accuracy.

We observe that these defenses fail to take advantage of the differences among training instances. Some instances have low loss whether they are included in the training set or not, while other instances will incur high loss when they are not included in training [43]. Hereafter, we will refer to these specific cases as "distinctive". Distinctive instances are naturally more vulnerable to MI attacks. While this phenomenon has been exploited in MI attacks that set different loss thresholds for different instances [3, 43, 44], existing defenses fail to take advantage of this effect. By forcing all training instances to be "softer", these defenses incur accuracy loss that can be avoided.

In this paper, we propose a novel training approach that naturally differentiates among instances with different degree of distinctiveness. It can be viewed as making the label "softer" **only** for the distinctive instances, avoiding unnec-

essary penalty in testing accuracy. Our approach uses ideas similar to subspace learning [18], and uses a novel regularizer to train models to be counterfactually invariant to the membership of each instance in the training data D. We thus call our approach Membership-Invariant Subspace Training (MIST).

The algorithm behind MIST is detailed in Section 3.2 and here we give a brief description. MIST divides the training dataset into multiple subsets. While one epoch of standard SGD can be viewed as sequentially updating the model on these subsets one by one, each epoch in MIST has three steps. In the first step, we train on all subsets simultaneously, resulting in a subspace of multiple submodels (one for each subset). In the second step, for each such submodel M_i, we perform gradient updates to reduce the differences on instances used in computing M_i between predictions given by M_i and the average predictions given by other submodels. In the third and last step, we average the resulting submodels. The effect is that, if an instance used to train M_i is not distinctive, M_i's output on the instance would be similar to the average, resulting in little impact to the model. On the other hand, if an instance is distinctive, the gradient update step would pull the model towards the average of other submodels, which approximates the counterfactual scenario where this instance is not used in training.

Contributions.

1. We propose the **Membership-Invariant Subspace Training** (MIST) defense designed to specifically defend against blackbox membership inference attacks on the most vulnerable instances in the training data (which also helps defending against overall blackbox MI attacks). MIST uses a novel two-phase subspace learning procedure that trains models regularized to be counterfactually invariant to the membership of each instance in the training data D.

2. We compare our defenses against baselines and provide extensive experiments showing that our defense can significantly reduce the effectiveness of existing membership inference attacks. To the best of our knowledge, MIST is the first effective defense against LIRA and CANARY-style blackbox MI attacks that focuses on defending the most vulnerable instances in the training data, while improving the overall MI attack robustness.

Roadmap. The rest of this paper is organized as follows. In section 2, we introduce some machine learning background and summarize existing membership inference attacks and defenses in centralized setting. In section 3, we propose our new defense, the **Membership-Invariant Subspace Training** (MIST) defense. In section 4, we present our extensive experimental evaluations and compare our proposed defense with existing defenses. In section 5, we summarize the findings presented in this paper. In section 6, we discuss limitations of the proposed MIST defense and potential future directions.

2 Preliminary

In this section, we describe the MI attacks that we use in our experimental evaluation and defense mechanisms that we compare against. We focus on blackbox attacks, where the adversary queries the target model and uses the model prediction to infer membership. Other works in this area are discussed in Section A in the Appendix.

2.1 MI attacks in blackbox setting

We classify these attacks based on what they use to query the target model F^T.

2.1.1 Using the Target Instance

In these attacks, one uses the target instance x to query the model.

LOSS (Using loss with a global threshold). Yeom et al. [47] introduced an attack that predicts x is a member when the target model's loss on x is below the average training loss.

Class-NN (Training class-specific Neural Networks for MI). Shokri's attack [39] trains multiple neural network-based membership classifiers, one for each class. Training data are obtained using the shadow-mode technique, which is widely used in later attacks.

Using the **shadow-model** technique, one assumes that the adversary knows a dataset D^A, which contains the target instance and is from the same distribution as the dataset used to train F^T. The adversary creates k subsets $D_1, D_2, \ldots, D_k$ from D^A, and uses the same process used for training F^T to train k models, one from each D_i. These are called shadow models. For each instance x, some shadow models were trained using x, and others were trained without. The predictions of these models on instances in D^A provide training data for membership classifiers.

Modified Entropy. Song et al. [40] proposed to use a class-specific threshold on a modified entropy measure based on the model prediction to determine membership. This can be viewed as a simplified version of the attack in [39], and is very similar to using a class-specific loss threshold to determine membership.

LIRA. Carlini et al. [3] proposed an instance-specific threshold attack. For each instance, from the shadow models, one obtains a distribution for losses from models trained with x, and another distribution from models trained without x. A threshold can be chosen using likelihood ratio. Carlini et al. suggest to choose the threshold that optimizes for attack effectiveness at a very low false positive rate. We refer this attack as LIRA attack in later sections.

2.1.2 Using Perturbations of the Target Instance

Random perturbations. Jayaraman et al. [19] proposes an attack that generates multiple perturbed instances by adding Gaussian noise to x, and then query F^T using these perturbed instances and count how many times the prediction loss of them is higher than that of x. The instance x is predicted to be a member if the count is beyond a threshold. We refer this attack as the random-perturbation attack in later sections.

CANARY. The attack proposed in Wen et al. [44] also uses shadow models. For each target instance x, the shadow models are partitioned into two sets: those trained with x, and those trained without. One then computes a set of canaries, each generated via gradient descent starting from a slightly perturbed version of x, searching for an x' such that the difference between the average losses of x' from models in the two sets are as large as possible. One then use these canaries to query the target model and use the loss to predict membership. We call this attack the CANARY attack in later sections.

Adversarial perturbation label only. Choquette-Choo et al. [8] proposed two attacks for the situations where only the predicted label is provided and identified the adversarial perturbation attack as more effective. In this attack, one applies the adversarial example generation technique from [6] to generate x' that is close to x while have a different predicted label by F^T. The attack predicts membership if $||x'-x||_2$ is high.

2.2 Defenses against MI Attacks

Adversarial Regularization (Adv-reg). Nasr et al. [30] proposed a defense that uses similar ideas as GAN. The classifier is trained in conjunction with an MI attacker model. The optimization objective of the target classifier is to reduce the prediction loss while minimizing the MI attack accuracy.

Mixup+MMD. Li et al. [22] proposed a defense that combines mixup data augmentation and MMD (Maximum Mean Discrepancy [12,14]) based regularization. Instead of training with original instances, mixup data augmentation uses linear combinations of two original instances to train the model. It was shown in [48] that this can improve target model's generalization. Li et al. [22] found that they also help to defend against MI attacks. Li et al. [22] also proposes to add a regularizer that is the MMD between the loss distribution of members and the loss distribution of a validation set not used in training. This helps make the loss distribution of members to be more similar to the loss distribution on non-members.

Distillation for membership privacy (DMP). Distillation uses labels generated by a teacher model to train a student model. It was proposed in [17] for the purpose of model compression. Shejwalkar et al. [38] proposed to use distillation to defend against MI attacks. One first trains a teacher model using the private training set, and then trains a student model using another unlabeled dataset from the same distribution as the private set. The intuition is that since the student model is not directly optimized over the private set, their membership may be protected. the authors also suggested to train a GAN using the private training set and draw samples from the trained GAN to train the student model, when no auxiliary unlabeled data is available.

SELENA. Tang et al. [41] proposed a framework named SELENA. One first generates multiple (overlapping) subsets from the training data, then trains one model from each subset. One then generates a new label for each training instance, using the average of predictions generated by models trained without using that instance. Finally, one trains a model using the training dataset using these new labels.

HAMP. Chen et al. [7] proposed a defense combining several ideas. First, labels for training instances are made smoother, by changing 1 to λ and each 0 to $\frac{1-\lambda}{k-1}$, where λ is a hyperparameter and k is the number of classes. Second, an entropy based regularizer is added in the optimization objective. Third, the model does not directly return its output on a queried instance x. Instead, one randomly generates another instance, reshuffle the prediction vector of the randomly generated instance based on the order of the probabilities of x and returns the reshuffled prediction vector. In essence, this last defense means returning only the order the classes in the prediction vector but not the actual values.

Mem-guard. Jia et al. [20] proposed the **Mem-guard** defense. In this defense, one trains an MI attack model in addition to the target classifier. When the target classifier is queried with an instance, the resulting prediction vector is not directly returned. Instead, one tries to find a perturbed version of the vector such that the perturbation is minimal and does not change the predicted label, and the MI attack model output (0.5,0.5) as its prediction vector.

Differential Privacy. Differential privacy (DP) [9–11] is a widely used privacy-preserving technique. DP based defense techniques, such as DP-SGD [1], add noise to the training process. This provides a theoretical upper-bound on the effectiveness of any MI attack against any instance. Unfortunately, achieving a meaningful theoretical guarantee (e.g., with a resulting $\varepsilon < 5$) requires the usage of very large noises. However, model trainer could use much smaller noises in DP-SGD. While doing this fails to provide a meaningful theoretical guarantee (the ε value would be too large), this can nonetheless provide empirical defense against MI attacks. In [7,22,41], extensive experiments have shown that several other defenses can provide better empirical privacy-utility tradeoff than DP-SGD.

3 Proposed Defense: Membership-Invariant Subspace Training

Almost all MI attacks take advantage of the fact that training aims to reduce the loss on member instances to zero. Many defenses thus try to deviate from this optimization objective. Unfortunately, this usually results in significant testing accuracy drop. Our key insight is that we can take advantage of the fact that relatively few number of instances are truly vulnerable to MI attacks. For example, under the LIRA attack at 0.001 False Positive Rate, less than 5% of members are identified. That is, for most instances, whether it is included in the training set or not will not drastically affect their loss. Intuitively, we only need to change the optimization objective for the vulnerable instances to avoid overfitting them. This avoids suffering from unnecessary testing accuracy reduction. The challenge is how to achieve this effect in the training process without incurring a very high runtime overhead.

3.1 Threat Model

We consider a blackbox attacker, who can query the target model and get its prediction, but does not use the internal state of the target model, such as model parameters. We also assume that the adversary knows the model architecture, the training recipe, and the distribution of training data, and is capable of training shadow models. This type of adversary is able to get the member prediction distribution and nonmember prediction distribution for a particular instance of interest by training multiple shadow models and then perform the LIRA attack or the CANARY attack, which are the strongest blackbox MI attacks in the literature.

3.2 Our Proposal

To effectively protect the membership of vulnerable instances without incurring accuracy reduction for less vulnerable instances, our proposed defense capitalizes on the combined strengths of two distinct recent advancements in representation learning: Counterfactually-invariant representations [21, 29, 34, 42] and subspace learning methods [18, 45].

A *counterfactual dataset* is a set of data samples whose distribution has been changed by an intervention. Inspired by differential privacy, given a training dataset D, we define $n = |D|$ environments $D_1, D_2, \cdots, D_n$ such that $D_M = D \setminus \{(x_M, y_M)\}$ for $1 \leq M \leq n$. That is, each D_M has the same distribution as the training data $p(x,y)$, except for the intervention that the M-th training example (x_M, y_M) has probability zero.

Let $F(\cdot;\theta)$ denote a classifier with parameters θ such that $F(x;\theta)$ gives a vector of predicted probabilities for the classes. Let $T_F(\cdot)$ denote the training algorithm such that $\theta_D = T_F(D)$ is the parameters trained using dataset D. Ideally, we want T_F to be counterfactually-invariant to the interventions, i.e., $\forall M \in \{1,\ldots,n\}$, $F(x;T_F(D))$ and $F(x;T_F(D_M)$ have the same classification behavior. Note that this objective is related to yet different from the objective of ε-differential privacy (DP) [9–11]. This objective is less strict than ε-DP when $\varepsilon = 0$, which requires $T_F(D)$ and $T_F(D_M)$ to have exactly the same distribution. Here we expect that $\theta_D = T_F(D)$ and $\theta_{D_M} = T_F(D_M)$ to have the same classification behavior, even though the parameters may be different.

We will denote our type of counterfactual invariance as *membership-invariance*. Employing membership-invariant classifiers as a defense against MI attacks appears both promising and "straightforward" at first glance. Closer inspection, however, reveals that the task of training a membership-invariant classifier (that generalizes well in test) to be immensely challenging, especially over large training datasets. Standard invariant representation training methods include invariant risk minimization [2], adversarial training, such as Ganin et al. [13], that uses a minimax game to ensure representations cannot predict the environments, and the Hilbert-Schmidt conditional independence criterion [33] used by Quinzan et al. [34] for counterfactually-invariant predictors). Using these methods for training membership-invariant classifiers would require constructing n leave-one-out datasets from D, each a new environment. This is infeasible for large datasets commonly used in state-of-the-art models.

The main technical challenge we need to overcome is thus: *How can we efficiently learn membership-invariant classifiers to defend against MI for all vulnerable instances?*

3.2.1 Cross-difference loss

We start by defining a regularization that we call *cross-difference loss* as follows:

$$\begin{aligned}&\mathrm{xdiff}(\theta_D, \theta_{D\setminus\{(x_M,y_M)\}}) \\ &\quad = \sup_{(x,y)\in\Omega} \|F(x;\theta_D)_y - F(x;\theta_{D\setminus\{(x_M,y_M)\}})_y\|_1,\end{aligned} \tag{1}$$

where Ω is the support of $p(x,y)$ and $\|\cdot\|_1$ is the L_1 norm. Equation (1) pushes the classifier $F(\cdot;\theta_D)$ trained with (x_M, y_M) to have the same output as the classifier $F(\cdot;\theta_{D\setminus\{(x_M,y_M)\}})$ trained without (x_M, y_M). Then, any classifier F that satisfies

$$\sum_{M\in\{1,\ldots,n\}} \mathrm{xdiff}(\theta_D, \theta_{D\setminus\{(x_M,y_M)\}}) = 0, \tag{2}$$

is membership-invariant. This is easy to verify since the condition in Equation (2) implies $F(x;\theta_{D\setminus\{(x_M,y_M)\}}) = F(x;\theta_D) = F(x;\theta_{D\setminus\{(x_{M'},y_{M'})\}})$, for all $M, M' \in \{1,\ldots,n\}$, that is, the classifier output is invariant to the environment in which it was trained.

3.2.2 Membership-invariance via Two-Phase Subspace Learning

The challenge of training a classifier that satisfies Equation (2) is the computational cost. To support the fast optimization

of F using the cross-difference loss in Equation (2), we will make use of the concept of subspace learning [45]. Subspace learning optimizes neuron weights in a subspace that contains diverse solutions that can be ensembled, approaching the ensemble performance of *independently* trained neural networks without the associated training cost. Originally designed by Wortsman et al. [45] to boost accuracy, calibration, and robustness to label noise, we will repurpose subspace learning for learning membership-invariant classifiers. In particular, our approach (MIST) leverages a version of subspace learning based on (virtual) federated learning: DART (Diversify-Aggregate-Repeat Training) [18].

Our core idea adapts DART and simultaneously trains multiple diverse models that are regularized with a computationally efficient approximation of the regularization implied by Equation (2). These diverse models within the subspace, in effect, regularize each other. They impose penalties on each other if discrepancies arise in their outputs when trained on their respective subsets of the training data. We denote the resulting method MIST and detail it in Algorithm 1; we also summarize the method below.

MIST. Training in MIST consists of E global epochs. We use $\overline{\theta}_e$ to denote (parameters of) the aggregated (i.e., global) model at epoch $e = 0,\ldots,E$. $\overline{\theta}_0$ is initialized with random parameters. The e-th epoch (where $1 \leq e \leq E$) consists of the following steps.

Initialization: Data Partitioning. The training data D is split into C disjoint subsets D^c, $c = 1,\ldots,C$. We use $\overline{\theta}_{e-1}$ to initialize C (local) models.

Phase 1: Exploring diverse models (local training). For each $c \in \{1,\ldots,C\}$, we use D^c to update the c-th local model, by performing gradient updates $T_1 \geq 1$ times, where T_1 is a hyperparamenter. We use θ_e^c to denote (parameters of) the c-th local model after the gradient updates.

Phase 2: Finding models with small cross difference loss. In Phase 2, we aim to find models near the diverse models found in Phase 1 that have low cross-difference loss. For $c = 1,\ldots,C$, let $w_0^c = \theta_e^c$, we perform T_2 gradient update steps, using the following approximation of the cross-difference loss (described in Equation (1)) to regularize w_t^c in Algorithm 1:

$$\text{xdiff}_c(w_t^c) = \sum_{(x,y)\in D^c} \left\| F(x;w_t^c)_y - \frac{\sum_{i\neq c} F(x;\theta_e^i)_y}{C-1} \right\|_1 . \quad (3)$$

Minimizing Equation (3) will push our models towards satisfying Equation (2). Note that if an instance $(x,y) \in D^c$ is not vulnerable to MI attacks, the confidence from the c-th local model (trained using (x,y)) $F(x;w_t^c)_y$ will be similar to the average confidence from other local models, and the L_1 norm in Equation (2) is close to 0, resulting in little change to the model parameter. If, however, $(x,y) \in D^c$ is vulnerable to MI attacks, then the L_1 norm in Equation (2) will be large, resulting the c-th local model to be updated to fit less well on (x,y).

In Equation (3) we are not computing the L_1 loss over the entire support Ω of the training distribution $p(x,y)$ as in Equation (1) but, rather, restricting the cross-difference loss to the examples in D^c. This is a reasonable approximation since these examples are the ones used to directly optimize the c-th local model, and we thus focus on protecting their membership.

In Equation (3), we use L_1 norm. In Section 4.8, we compare the effect of using L_1, L_2 norms, and KL divergence in an ablation study.

Model aggregation. The (global) training epoch $e \geq 1$ ends by averaging the parameters of all C local models into a new parameter $\overline{\theta}_e$. In general, as in subspace learning, the averaging can be a convex combination of the model parameters. In our experiments we just use the arithmetic mean $\overline{\theta}_e = (1/C)\sum_{c=1}^{C} \theta_e^c$.

Returning. At the end of our MIST algorithm, we return $\overline{\theta_E}$ as the final trained model parameters.

Algorithm 1 (MIST) Membership-Invariant Subspace Training

Input: C: the number of local models; D: the training dataset; E: the number of epochs. Hyperparameters T_1, T_2, and λ (weight for cross difference loss).

Initialize $\overline{\theta}_0$ ▷ Model initialization
for $e = 1$ **to** E **do**
  Partition D into D^c, where $1 \leq c \leq C$
  for $c = 1$ **to** C **do** ▷ can be performed in parallel
    $\theta_e^c = \text{local\_training}(\overline{\theta}_{e-1}, D^c, T_1)$
  for $c = 1$ **to** C **do** ▷ can be performed in parallel
    $\theta_e^c = \text{xdifference\_update}(c, \theta^1, \ldots, \theta^C, D^c, \lambda, T_2)$
  $\overline{\theta}_e = \frac{\sum_{c=1}^{C} \theta_e^c}{C}$ ▷ Aggregate and average model weights
Output: $\overline{\theta_E}$

Function local_training($\overline{\theta}, D^c, T_1$): ▷ Phase 1
  $w_0^c = \overline{\theta}$
  for $t = 1$ **to** T_1 **do**
    gradient updates to w_t^c to minimize $\frac{1}{|D^c|}\mathcal{L}(w_{t-1}^c, D^c)$
Output: $w_{T_1}^c$

Function xdifference_update(c, $\theta^1,\ldots,\theta^C, D^c, \lambda, T_2$): ▷ Phase 2
  $w_0^c = \theta^c$
  for $t = 1$ **to** T_2 **do**
    gradient updates to w_t^c to minimize $\frac{\lambda}{|D^c|}\text{xdiff}_c(w_{t-1}^c)$
Output: $w_{T_2}^c$

3.2.3 Further improvements

MIST can be augmented with some existing MI defense approaches. For instance, the Mix-up data augmentation MI defense proposed by Li et al. [22] can be easily integrated

into MIST (Algorithm 1). Li et al. [22] shows that Mix-up data augmentation can reduce the generalization gap between train and test data, consequently making black-box MI attacks more difficult. Mix-up training uses linear interpolation of two different training instances to generate a mixed instance and train the classifier with the mixed instance. The generation of mixed instances can be described as follows:

$$\tilde{x} = \beta x_i + (1-\beta)x_j,$$
$$\tilde{y} = \beta y_i + (1-\beta)y_j, \quad (4)$$

where $\beta \sim \text{Beta}(\alpha,\alpha), \alpha \in (0,\infty)$. Here x_i and x_j in Equation (4) are instance feature vectors randomly drawn from the training set; y_i and y_j are one-hot label encodings corresponding to x_i and x_j. The new tuple $(\tilde{x},\tilde{y})$ is used in training.

4 Evaluation

In this section we present our extensive experimental results. We start by describing the details of our experimental setup. Next we discuss the computational cost of considered defenses. Then we dive into the detailed comparison between MIST and other defenses. After this, we present the evaluation of MIST against label-only attacks. In the following subsection, we show how to choose hyperparameters for our MIST defense. Lastly, we present ablation studies.

4.1 Experimental Setup

4.1.1 Datasets

Our evaluation uses the datasets most commonly used in MI attack literature [7, 20, 30, 31, 37, 39, 47].

CIFAR-10 and CIFAR-100. They contain 60,000 color images of size 32 × 32, divided into 50,000 for training and 10,000 for testing. In CIFAR-100, these images are divided into 100 classes, with 600 images for each class. In CIFAR-10, these 100 classes are grouped into 10 more coarse-grained classes; there are thus 6000 images for each class. We use AlexNet, ResNet-18 and DenseNet-BC(100,12) (abbreviated as DenseNet), which are the standard neural networks used in prior work [22, 31]. The model architectures and hyperparameters for training are described in Table 7 in the Appendix.

TEXAS-100. The records in the dataset contain information about inpatient stays in several health care facilities published by the TEXAS Department of State Health Services. We obtained the dataset from the authors of [39]. The dataset contains 67,330 records and 6,170 binary features. The records are clustered into 100 classes, each representing a different type of patient. We use the fully connected neural network from [31] as the target model.

PURCHASE-100. This dataset is based on the "acquire valued shopper" challenge from Kaggle. This dataset includes shopping records for several thousand individuals. We obtained the processed and simplified version of this dataset from the authors of [39]. Each data instance has 600 binary features. This dataset is clustered into 100 classes and the task is to predict the class for each customer. The dataset contains 197,324 data instances. We use the fully connected neural network from [31] as the target model.

LOCATION. This dataset contains the location "check-in" records of different people. It has 5,010 data records with 446 binary features, each of which corresponds to a certain location type and indicates whether the individual has visited that particular location. The goal is to predict the user's geo-social type. There are 30 classes in this dataset. We use the fully connected neural network from [31] as the target model.

4.1.2 Evaluated Attacks and defenses

Attacks. We consider the six attacks described in Section 2.1: LOSS [47], Modified Entropy [40], Class-NN [39], random perturbation attack from [19], the online version of the LIRA attack from [3] and the CANARY attack from [44]. Readers may want to review Section 2.1 on how these attacks work. The latter two are the state-of-the-art blackbox membership inference attack. We set the number of shadow models to be 100, which is common in the literature. We assume that the attackers are adaptive attackers, which means that the attackers already know MIST defense mechanism (including hyperparameters) and can train similar models in exactly the same setting.

Defenses. We compare with the following existing defenses: adversarial regularization (adv-reg) [30], Mem-guard [20], DMP [38], Mixup+MMD [22], SELENA [41], HAMP [7] and DP-SGD [1]. Readers may want to review Section 2.2 on how these defense methods work. As for our MIST defense, we use the following setting: for T_1, we set it to be the number so that each data instance in subset D^c can be visited just once and we set $T_2 = T_1$. The chosen λ for each model and dataset is also listed in Table 7. We first tune the C to achieve the highest validation accuracy possible then we tune the λ so that the test accuracy drop is less than 1%.

4.1.3 Evaluation Metrics

Following existing literature [3, 31], we use a balanced evaluation set. For CIFAR-10 and CIFAR-100 datasets, we assume that the model trainer has 20,000 data instances to perform the model training. For PURCHASE dataset and TEXAS dataset, we assume the model trainer has 40,000 training data instances. For LOCATION dataset, we assume the model trainer has 4,000 training data. We mainly use PLR (positive likelihood ratio, which is the ratio between TPR and FPR where lower means a more effective defense) at a fixed low FPR as suggested in Carlini et al. [3] to evaluate different

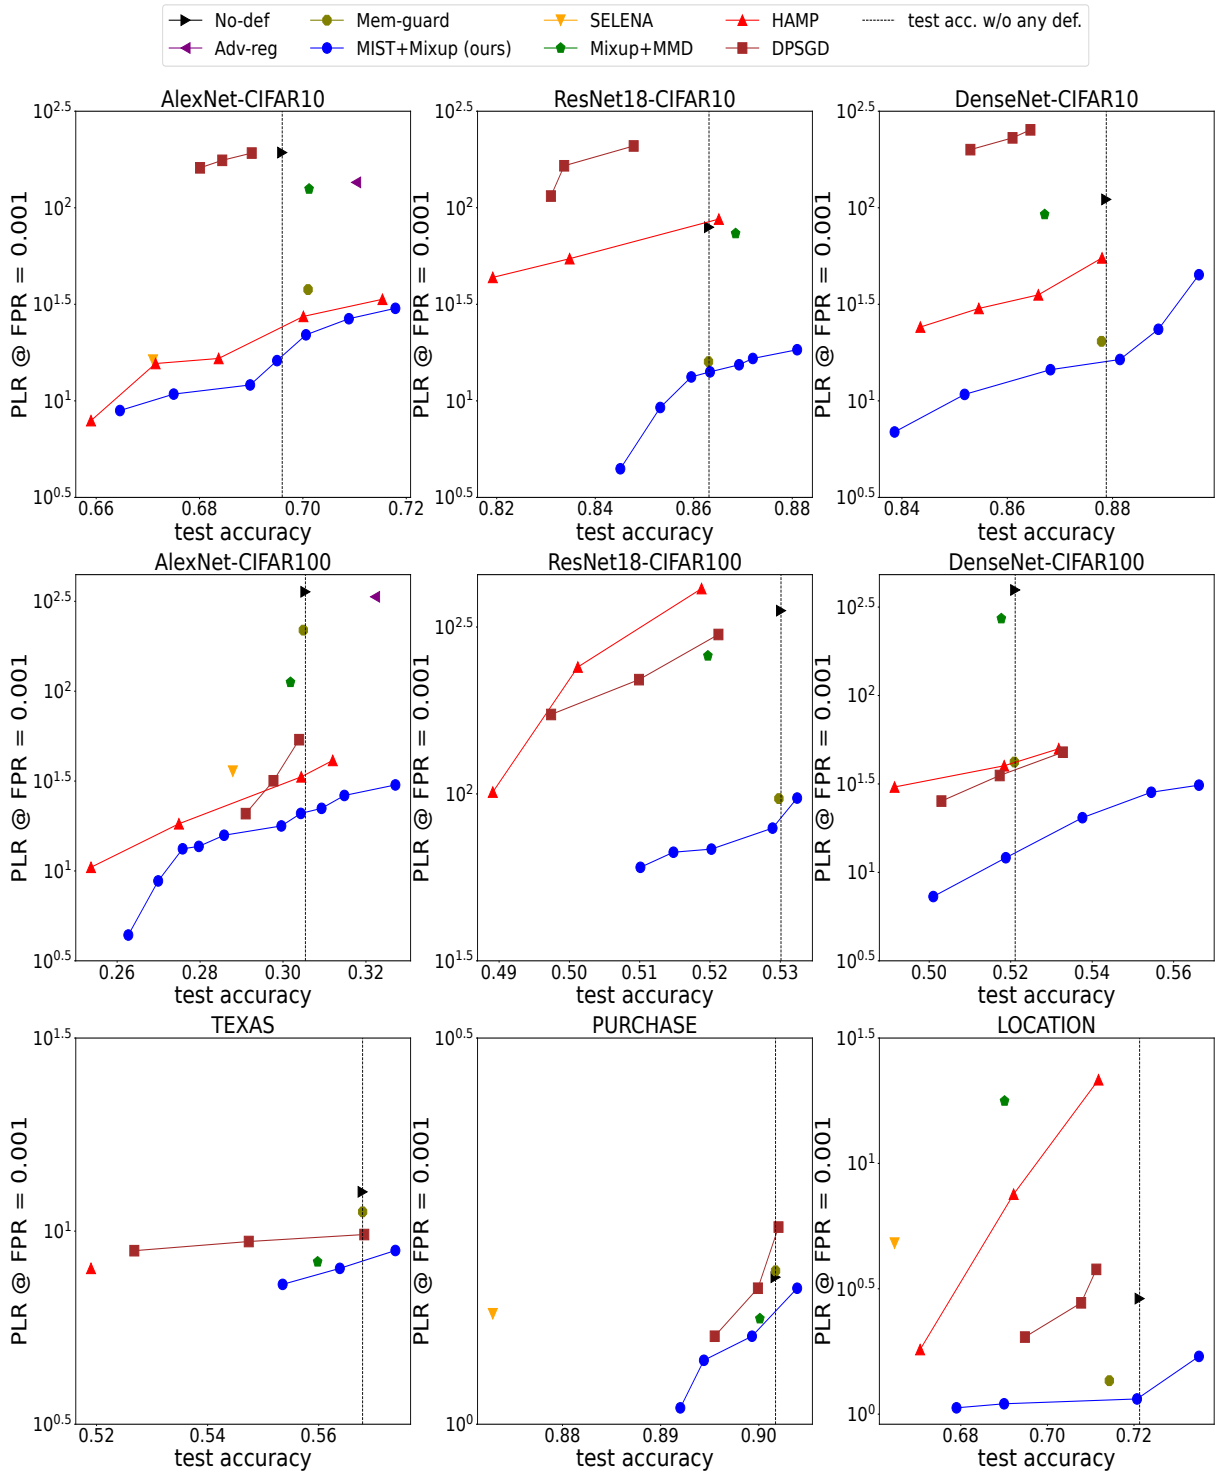

Figure 1: Comparing all defenses using the highest MI attack PLR @ 0.001 FPR among all evaluated attacks. **Defenses placed at the lower right corner are better** (high test accuracy and low PLR). Notice that for PURCHASE, TEXAS and LOCATION datasets the mixup data augmentation is not applied. We exclude some results when the test accuracy drop is larger than 5% for clearer comparison.

Defense name	Running time (s)	memory cost factor
SGD baseline	1195	1
Adv-reg	7008	1
DMP	2543	2
Mem-guard	36373	1
SELENA	20320	26
Mixup+MMD	3154	1
HAMP	1280	1
MIST+Mixup	2139	4

Table 1: Computational cost comparison for different defenses. For memory cost, we only count the number of models C to be trained.

attacks. For completeness, we also include AUC (area under curve) scores in the Appendix.

4.2 The computational cost (time and memory) of defenses

Here we assume that all the hyperparameters are already chosen, and compare the time that that model optimization needs to produce a final usable model and predictions for the test set. We run this comparison experiments on a server with one GTX-1080Ti GPU and we use CIFAR-100 on AlexNet as an example to compare. Table 1 shows our results, where we can see that MIST achieves the second fastest running time among all defenses (only slower than HAMP defense). Note that the SELENA defense requires significantly more time and space comparing to the other defenses, since it needs to train many extra models (25 with the code's default parameters) and store them. Moreover, the Mem-guard defense also requires significant time, because the noise for each prediction needs to be optimized separately. As for memory cost of our MIST defense, it depends on the number of models C (usually 2 to 4). The training time of MIST is about twice that of the baseline because at each epoch MIST performs two backprop steps instead of one to perform the regularization step. In conclusion, MIST requires moderate extra time and memory for model training where the best privacy-utility tradeoff is provided.

4.3 Defense effectiveness evaluation

Figure 1 presents the experimental results comparing MIST with other defenses on 5 datasets (with three model architectures for each of CIFAR-10 and CIFAR-100). We include only data points where the test accuracy drop is no more than than 5% for clearer comparison. In Figure 1, the x-axis gives test accuracy and the y-axis gives $\text{PLR}_{0.001}$ (PLR when FPR$=0.001$) in log-scale. We prefer methods to be in the lower-right region, as they can provide higher test accuracy under the same $\text{PLR}_{0.001}$. Note that our proposed defense method MIST+Mixup performs the best in all experiments.

When $\text{PLR}_{0.001} = 100$, it means that when we ensure that no more than 0.1% of non-members are falsely identified as members, if we identify 101 instances as members, we can expect that 100 are indeed members, and 1 of them is a false positive. When $\text{PLR}_{0.001} = 2$, it means that when we ensure that no more than 0.1% of non-members are falsely identified as members, if we identify 3 as members, we can expect 2 of them are indeed members. Due to page limit, we exclude the detailed numbers of experiments in this section and please refer to the appendix of the arxiv version of this paper if interested.

Effect of MIST+Mixup. We first look at how well our proposed defense (MIST+Mixup) prevents MI attacks. For CIFAR-10, our defense can reduce the highest PLR among all attacks from 127.63 to 17.48 (averaged over all models); for CIFAR-100 dataset, our defense can reduce the highest PLR from 368.94 to 29.97 (averaged over all models). For PURCHASE dataset, TEXAS dataset and LOCATION dataset, the highest PLR is reduced from 6.51 to 4.10, 1.55 to 1.08, 2.89 to 1.15 respectively. As for the average case attack effectiveness, our defense can also provide noticeable AUC drop comparing to the case without any defense. In summary, our new defense can provide significant attack effectiveness (including PLR and AUC) reduction for highly vulnerable cases (CIFAR-10 and CIFAR-100) and provide further attack effectiveness reduction on less vulnerable cases (PURCHASE, TEXAS and LOCATION), while incurring less than 1% test accuracy drop.

Comparison with adv-reg. We note that the adversarial regularization defense incurs significant test accuracy drop for all cases except when AlexNet is used (for CIFAR-10 or CIFAR-100). However, for these two cases, MIST+Mixup (blue curve) provides much lower PLR than adversarial regularization (purple dot) when similar test accuracy is achieved, as shown in Figure 1. In the adv-reg defense, the model is trained to defend against one attack model that evolves with it in adversarial training, and the resulting model can still be vulnerable to other attacks. Furthermore, the nature of adversarial training is such that one has to be very careful on tuning the hyperparameters because it is highly likely that the target model will have very low test accuracy.

Comparison with Mem-guard. The Mem-guard defense is a post-processing defense, which means the model utility (test accuracy in our case) is maintained. From Figure 1, we can conclude that MIST+Mixup (blue curve) provides lower PLR than Mem-guard (olive dot) when similar test accuracy is achieved. We note that due to computational resources and time constraint, we are not able to evaluate Mem-guard against the CANARY attack, since the CANARY attack involves instance optimization through multiple iterations and for each iteration the Mem-guard defense needs to calculate a new noise regarding each newly perturbed instance. If we

only compare the PLR of the LIRA attack, we can see that MIST+Mixup outperforms Mem-guard for all cases. Moreover, the PLR of the CANARY attack against MIST+Mixup is still lower than the PLR of the LIRA attack against Mem-guard for all CIFAR experiments. The Mem-guard defense uses one attack model to generate the noise to be added to each prediction, however this particular noise may not be effective against other attacks.

Comparison with DMP. In this comparison, we consider the case where no auxiliary unlabeled data is available because in practice collecting extra data is intractable for most privacy-concerning cases, for example medical images. More specifically, we train a GAN using the private training set and draw samples using the trained GAN to train the student model. However in our experiments, we see that the DMP defense also incurs significant test accuracy drop comparing to the no-defence case.

Comparison with Mixup+MMD. From Figure 1, we can conclude that MIST+Mixup (blue curve) provides lower PLR than Mixup+MMD (green dot) when similar test accuracy is achieved. We note that our proposed cross-difference loss is similar to the MMD (mean maximum discrepancy) loss proposed in Li et al. [22]. There are two key differences. One is the granularity, i.e., our proposed cross-difference loss is calculated on instance level, but the MMD loss is calculated on class level, where the loss is defined as the difference between averages of two classes. The other is that in [22], MMD loss is relative to a validation dataset. Here, we divide the dataset into multiple subsets and the cross-difference loss is relative to results from update from other subsets. As demonstrated in 4.8, training using divided subset can help the model generalize better (and less vulnerable to MI attacks) even without using the cross-difference loss.

Comparison with SELENA. We first note that the SELENA defense and its evaluation against shadow-model based attacks require extraordinarily large amount of computational resources. This is because the SELENA defense needs to train 25 (the default value) models and then train one distilled model from these 25 models. Moreover, if we want to evaluate the LIRA attack against the SELENA defense and the number of shadow models is 100, then we need to perform the SELENA training procedure for 100 times to generate 100 distilled models and in total we need to train 2600 models for all our models and datasets, which is unattainable in our experimental scenario where each model is not small. Thus, for our experiments we restrict SELENA defense evaluation to the following scenarios: CIFAR-10 with AlexNet, CIFAR-100 with AlexNet, PURCHASE, TEXAS and LOCATION. From Figure 1, we can conclude that MIST+Mixup defense (blue curve) provides lower PLR and higher test accuracy than SELENA defense (yellow dot). Particularly for the TEXAS dataset, the SELENA defense results in more than 25% test accuracy drop, thus we exclude this data point from Figure 1 for clearer comparison. One reason that our defense can outperform SELENA is that, during the training process, there is communication (regularizing each other and averaging parameters) between each submodels, however SELENA does not have communication between submodels. Moreover, this communication takes advantage of the proposed cross-difference loss, which helps to mitigate the overfitting and generalize better, thus is more favorable.

Comparison with HAMP. For the HAMP defense, we only evaluate the effectiveness of their training-time defense, since the test time defense can be integrated with any training time defenses and the test time defense is approximately equivalent to providing the predicted label only. In Figure 1, if we compare MIST+Mixup (blue curve) with HAMP (red curve), we can conclude that MIST+Mixup gives better privacy-utility tradeoff than HAMP. For the HAMP defense, our defense considers the MI difficulty of different individual instances and regularize more on vulnerable instances, however the HAMP defense treats all instances in the same fashion by applying an entropy-based regularizer and smoothed label. Moreover, by leveraging subspace learning, we can achieve better model generalization.

Comparison with DP-SGD. Note that for the DP-SGD defense we tune the hyperparameter so that the model trained with DP-SGD can achieve similar test accuracy and in this case, the privacy budget is huge. In Figure 1, if we compare MIST+Mixup (blue curve) with DP-SGD (brown curve), we can conclude that MIST gives better privacy-utility tradeoff than DP-SGD. The DP-SGD defense add random noise drawn from a given gaussian distribution, thus adding (expected) the same amount of noise for each instance, which implicitly treats each instance in the same way. However, our proposed MIST defense is able to treat each instance with different level of protection via the proposed cross-difference loss, thus can outperform the DP-SGD defense.

To summarize, our MIST defense can outperform all existing defenses for all evaluated cases. In addition, our defense also provides a "knob" (the parameters λ and T_2 of Phase 2) to further fine-tune the model, so practitioners can obtain different tradeoffs between test accuracy and MI attack robustness. This tradeoff flexibility is absent from some of the baseline defenses, unfortunately.

4.4 Evaluating against label only MIAs

Now we evaluate the effectiveness of MIST against label-only MIAs from Choquette-Choo et al. [8]. Particularly, we evaluate the more effective adversarial perturbation label-only MIA. The intuition of this label-only MIA is that the training samples need more perturbations to get their predicted class to be flipped. We use both the PLR at FPR$=0.1\%$ and the AUC score to evaluate the effectiveness of the distance attack. The results are shown in Table 2. It is easy to see that the label-

Defense	Attack PLR (FPR@0.1%) on CIFAR-10	Attack PLR (FPR@0.1%) on CIFAR-100	Attack AUC on CIFAR-10	Attack AUC on CIFAR-100
No Defense	1.10	0.90	0.641	0.826
Adv-reg	1.39	1.13	0.631	0.815
Mem-guard	1.10	0.90	0.641	0.826
Mixup+MMD	1.30	1.50	0.605	0.742
SELENA	1.21	1.11	0.542	0.545
HAMP	1.73	1.94	0.577	0.633
DP-SGD	1.40	1.03	0.645	0.661
MIST+Mixup (ours)	**1.05**	**0.70**	**0.536**	**0.540**

Table 2: Evaluation against label only MIA. CIFAR dataset, AlexNet. The DMP defense would result in training failure (model not converging), thus excluded from this table.

only MI attack is not effective in detecting most vulnerable instances (PLR close to 1 means that TPR is close to FPR). Moreover, we can conclude that our proposed defense can significantly reduce the AUC score of the distance attack and outperform all existing attacks in defending against this label only membership inference attack.

4.5 Evaluating against white-box MIAs

Carlini et al. [4] proposed a model extraction method that can accurately extract parameters for a 5-layer fully connected neural network with 1110 parameters. If an effective model extraction attack against deep DNNs is discovered, then black-box access to a target model becomes equivalent to whitebox access, and we need to evaluate defenses against whitebox attacks as well. In this subsection, we evaluate all defenses against the white-box MIA from Nasr et al. [31] to understand the effect of our proposed defense against white-box attacks. The results are shown in Tables 3 and 4. One can also see that our proposed defense can provide significantly lower PLR and AUC score comparing to other existing defenses, which shows that our proposed defense can provide benefits against both black-box attacks and white-box attacks. From the results we can also see that this whitebox attack is no more effective than state-of-the-art blackbox attacks such as LiRA. This fact may not be as counter-intuitive as it first seems. Exact model parameters are affected by many factors beyond the training dataset, including initial randomness in initialization, hyper-parameters, and randomness during training (e.g., due to dropout). A member instance affects the model parameters because the parameters are trained to minimize loss on the instance, thus the loss on the instance (which is used in black-box attacks) is the main "footprint" left the instance being a member.

4.6 Comparing against other baselines on the most vulnerable instances

In this subsection, we want to understand the impact of all defenses over the most vulnerable instances in the training set. For this experiment we consider AlexNet, CIFAR-100 and CIFAR-10 datasets. Our first step is finding the set of most vulnerable instances, which we will denote X_{vul}. The size of X_{vul} is set to be 1000 in this experiment. We train 100 models using AlexNet on CIFAR-100 (and CIFAR-10 datasets) without any defense and perform LIRA attack. Recall that the LIRA attack would produce two normal distributions of the loss (one for member case and one for non-member case) for each instance. For each instance, we calculate the non-overlapping area of these two normal distributions and choose the top 1000 instances with the largest non-overlapping area to construct the X_{vul}. Intuitively, the larger the non-overlapping area is, the more vulnerable the instance is against membership inference attacks.

Using the X_{vul} above we can evaluate two metrics: the test accuracy on X_{vul} and the highest attack PLR on X_{vul}. Moreover, we add the highest attack PLR on the whole training set for comparison and further illustration in Table 5. Note that for a fair comparison between different defenses (defenses evaluated in this subsection should result in less than 1% test accuracy drop) and clearer results presentation, we remove the SELENA defense and the DMP defense from this experiment, since these two defenses would result in significant test accuracy drop. In conclusion, the results in Table 5 show that our MIST defense can outperform all existing membership inference defenses in terms of attack effectiveness reduction on both the vulnerable instances X_{vul} and on the whole MI evaluation dataset X_{whole}.

In particular, a natural defense is the removal from training of the most vulnerable instances against membership inference attacks. The intuition is that, once the most vulnerable instances are removed, the remaining training instances should

Defense	No-def	MIST+Mix-up	Adv-reg	Memg-guard	Mix-up+MMD	SELENA	HAMP	DP-SGD
PLR(FPR@0.1%)	1.01	**0.00**	0.00	1.01	0.00	0.97	0.40	0.33
AUC score	0.734	**0.503**	0.706	0.741	0.512	0.541	0.579	0.584

Table 3: Evaluation against white-box MIA. CIFAR-10 dataset, AlexNet. The DMP defense would result in training failure (model not converging), thus excluded from this table.

Defense	No-def	MIST+Mix-up	Adv-reg	Memg-guard	Mix-up+MMD	SELENA	HAMP	DP-SGD
PLR(FPR@0.1%)	1.61	**0.00**	1.68	1.61	0.00	2.08	3.12	0.32
AUC score	0.871	**0.505**	0.866	0.871	0.542	0.541	0.663	0.667

Table 4: Evaluation against white-box MIA. CIFAR-100 dataset, AlexNet. The DMP defense would result in training failure (model not converging), thus excluded from this table.

Dataset-Model	Defense	Acc. on X_{vul}	Test Acc. on X_{test}	PLR (FPR@1%) on X_{vul}	PLR (FPR@1%) on X_{whole}
CIFAR-100, AlexNet	No Defense	1.00	0.30	73.89	25.65
CIFAR-100, AlexNet	Adv-reg	0.77	0.32	83.31	8.18
CIFAR-100, AlexNet	Mem-guard	0.95	0.30	81.98	32.19
CIFAR-100, AlexNet	Mixup+MMD	0.37	0.30	52.61	23.13
CIFAR-100, AlexNet	HAMP	0.30	0.31	41.45	17.00
CIFAR-100, AlexNet	DP-SGD	0.21	0.30	18.76	7.23
CIFAR-100, AlexNet	Data Removal	0.08	0.28	N/A	26.53

CIFAR-10, AlexNet	Data Removal	0.30	0.68	N/A	19.11
CIFAR-10, AlexNet	MIST+Mixup (ours)	0.41	0.70	**13.15**	**5.26**

Table 5: Evaluation against label only MIA. CIFAR dataset, AlexNet. The DMP defense would result in training failure (model not converging), thus excluded from this table. The SELENA defense is also removed for a fair comparison. X_{vul} stands for the vulnerable instance set (of size 1000). X_{test} stands for the whole test set. X_{whole} stands for the whole evaluation set that we use in previous experiments, which includes $20,000$ training instances. For No Defense case, the X_{vul} is included in training, thus the test accuracy on X_{vul} is not applicable. For the PLR metric on X_{vul}, since this is not part of the training set for the data removal defense, this metric is not applicable.

be more robust against MI attacks. Unfortunately, our experiments show that this defense is surprisingly ineffective, with re-identification metrics close to the "No Defense" scenario, which is also detailed in Table 5.

The difference between MIST and the data removal defense is worth a closer look. For the test accuracy on X_{vul}, the performance of the data removal defense is significantly worse than MIST defense. For the PLR at 1% FPR on X_{vul}, since the whole X_{vul} is removed for the data removal defense, this PLR metric is not applicable to the data removal defense and there is no privacy threat against X_{vul}. However, for the PLR at 1% FPR on X_{whole}, the data removal defense performs much worse than MIST defense and close to the "No Defense" scenario, which makes the data removal defense similar to having no defense.

Let's take CIFAR-100, AlexNet as one example. Intuitively, when FPR=1%, the PLR is 25.65 for no-defense case, which means that $0.01 \times 25.65 \times 20000 = 5130$ instances have been detected as members. If we remove the X_{vul} from training, then the expected PLR at FPR=1% should be $\frac{4130}{5130} * 25.65 = 20.65$, however, the resulted PLR is now 26.53. This result implies that even though the vulnerable instances X_{vul} are removed from the training set, now other instances became vulnerable against MI attacks. One intuitive explanation is that, since X_{vul} is mostly constructed by outliers (since outliers are harder to fit and thus easier to be attacked by membership inference attacks), removing them from training would make some other instances to become outliers, just like peeling an onion. This finding is aligned with the recent findings of Carnili et al. [5], which show that removing vulnerable instances from the training set allows other instances to become outliers and thus vulnerable.

To summarize, the data removal defense seems to be ineffective. Moreover, we show that MIST, our proposed defense, can provide the most reduction in attack effectiveness on the most vulnerable set, while achieving the best average case test accuracy and (both average case and extreme case) privacy tradeoff of all baselines.

4.7 Choosing hyperparameters

Now we discuss how to determine the two most crucial hyperparameters of our proposed defense: the number of models C and the weight of the cross-difference loss. In this paper, we use the following method to determine these two hyperparameters: we choose the number of models C to achieve the highest validation accuracy possible and then choose the weight of the cross-difference loss to provide the strongest defense while making sure the test accuracy drop is less than 1% comparing to the base case without any defense. In Figure 5 in the Appendix , we show that the customized subspace learning (without the cross-difference loss) can help the model generalize better, thus we would like to use the model with the highest validation accuracy. Moreover, the mixup data augmentation can also help to further improve the validation accuracy. Hence, subspace learning and mixup combined get higher test accuracy boost compared to standard SGD, which then gives us room to increase the regularization of the cross difference loss without lower test accuracy when compared against standard SGD.

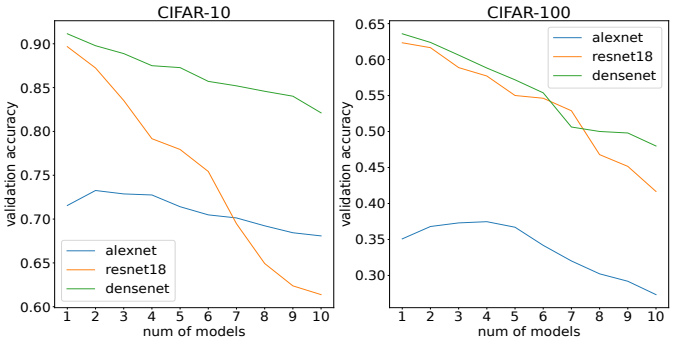

Figure 2: Validation accuracy v.s. number of models C. Mixup data augmentation is applied.

In Figure 2, we show the validation accuracy curve v.s. the number of models C for all models and datasets where mixup data augmentation is applicable. Recall that we need to choose the number of models C that achieves the highest validation accuracy. However, we also need to have at least two models, so that our cross-difference loss is applicable. Thus, where mixup data augmentation is applicable, for all models and datasets except CIFAR-100 and AlexNet, the number of models C should be 2. For the CIFAR-100 and AlexNet, the number of models C should be four. For the case where the mixup data augmentation is not applicable (TEXAS dataset and PURCHASE dataset), we choose to use 4 models for TEXAS dataset and 4 models for PURCHASE dataset based on Figure 5 in the Appendix. In practice, we recommend developers to generate this validation accuracy curve for their own datasets to determine the number of models C. If the computational resources are limited, our ad-hoc advice is to use 2 to 4 models since this range was suitable for all our datasets.

As for the choice of the hyperparameter λ of Phase 2 (the cross-difference loss minimization), we choose λ as to provide the strongest defense while making sure the test accuracy drop is less than 1%. In practice, the training does not need to follow this procedure, as λ may be utilized as a knob to tune a privacy-utility tradeoff, which allow practitioners to determine this tradeoff based on their needs.

4.8 Ablation Study

The positive impact of subspace learning and cross-difference loss. In this ablation study, we use AlexNet on CIFAR-10 and CIFAR-100 dataset. For CIFAR-10 dataset,

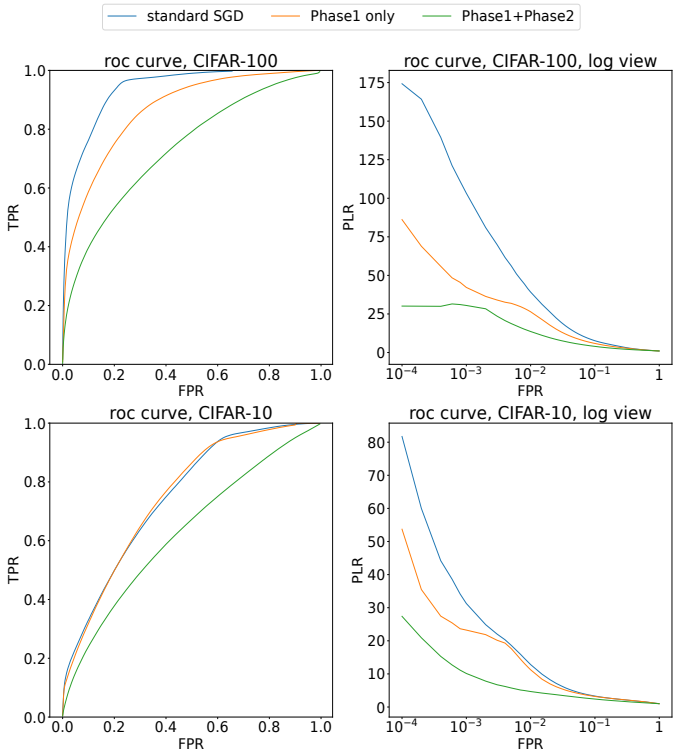

Figure 3: The clear positive impact of Phase 1 and Phase 2. Impact measured on ROC curve and PLR at low FPR region. LIRA attack is evaluated to produce the ROC curve and PLR curve. CIFAR-100 and CIFAR-10 using AlexNet.

we use 3 models and for CIFAR-100 dataset we use 7 models. These two values are chosen because the highest test accuracy (higher than the standard SGD case with one model) can be achieve with this choice when no cross-difference loss and mix-up data augmentation is applied . For the λ of the cross difference loss, we choose the λ so that the maximum defense can be provided while the test accuracy drop is less than 1% in this experiment. We compare the attack effectiveness against model trained without defense, trained with Phase 1 only and trained with both Phases 1 and 2. The results are shown in Figure 3. We can conclude that the only performing Phase 1 of our MIST algorithm (ignoring Phase 2) can still be used as a defense which can preserve utility and decrease attack effectiveness at the same time with appropriate number of models C. We also repeat this experiment on other models and datasets and we observe similar phenomenon. Moreover, adding Phase 2 (cross-difference loss minimization) can provide further robustness against the LIRA attack.

Different cross-difference loss implementations. In this ablation study, we experiment on different implementations for the cross-difference loss. More specifically, we use three different implementations: KL-divergence, Equation (3) and L_2 version of Equation (3). We run experiments using AlexNet

Loss function	Test accuracy	PLR at 0.1% FPR
L1	0.3049	17.43
L2	0.2997	17.54
KL-divergence	0.3003	19.72

Table 6: Comparing different implementations of the MIST loss. CIFAR-100 dataset on AlexNet.

on CIFAR-100 dataset and we choose the optimal weights that we can find for each loss function so that the test accuracy drop is less than 1% comparing to the case without any defense. The results are shown in Table 6, where we can conclude that the L_1 variant slightly outperforms the other two variants and the KL-divergence variant performs the worst. One possible reason for the KL-divergence variant being worse than L_1 is because the KL-divergence considers the distance between two prediction vectors, while the state-of-the-art attacks only focus on the probability of the correct label. Moreover, we also observe that this KL-divergence variant makes the model training unstable, meaning that sometimes the model fails to converge, thus we recommend the use of L_1.

5 Conclusion

In this work we introduce Membership-Invariant Subspace Training (MIST), a method for training classifiers that acts as a defense designed to specifically defend against black-box membership inference attacks on the most vulnerable instances in the training data (which also helps defending against overall blackbox MI attacks). MIST uses a novel two-phase subspace learning procedure that trains models regularized to be *membership invariant* (counterfactually invariant to the membership of each instance in the training data D). Through our proposed two-phase subspace learning method, and a new proposed loss (*cross-difference loss*), we can efficiently regularize neural network training towards membership-invariant classifiers. Our experiments empirically show that our trained classifiers are significantly less vulnerable against blackbox membership inference attacks than baselines, especially on those most vulnerable training examples.

6 Limitation and Future Works

The main limitation of the proposed MIST defense is the computational overhead of maintaining multiple models. This is because at each epoch, the MIST defense requires maintaining multiple copies of the central model, performing local model updates, update local models based on predictions from other models, and averaging the model weights. More specifically, if the training set is divided into C subsets, this results

in a memory overhead by a factor C. One possible mitigation strategy is to perform the training for each submodel in a sequential way and only load one model into memory. However, this solution would result in a time overhead of a factor C. Another interesting future direction is adapting the MIST to regression and other non-classification tasks. Finally, there may be other, yet unknown, ways to apply the cross-difference loss that may reduce overhead and improve performance (better privacy-utility tradeoff).

A Further Related Work

Other MI attacks that are similar to LIRA but weaker. Several MI attacks are similar to LIRA and are shown in [3] to be less effective in LIRA; we thus do not consider them in the experiments. We list these attacks below.

Long et al. [26] proposed to train instance-specific MI classifiers. For each instance x, there will be two sets of models: trained with x and trained without x. Then, the average prediction of x from the member set and the average prediction of x from the non-member set is calculated. x is predicted to be a member if the target model's prediction of x is more similar to the average prediction of the member set (in the sense of KL divergence).

Ye et al. [46] followed the same shadow model procedure as [43] to produce a collection of loss for one instance when this instance is not used in the training. Next, a one-sided hypothesis testing is proposed to predict membership. The advantage of this hypothesis testing is that the attacker could select a false positive rate. However, the possible false positive rate range is limited by the number of shadow models.

Watson et al. [43] propose to use the shadow models to set a per-instance loss threshold by the average of loss of the instance on shadow models that are not trained using this example.

Other membership inference defenses. In [39], it was proposed to reduce the information given by the prediction vectors, such as providing only the top-k probabilities and using high temperature in softmax. This has limited effectiveness as the top-k probabilities give enough information needed by the best attacks, and high temperatures change only the absolute values of confidences, but not the fact that confidences for members tend to be higher than that for non-members. Moreover, this defense is not effective against LIRA, thus we do not consider this defense in our experiments.

Membership inference attacks in other settings. Melis et al. [28] identified membership leakage when using FL for training a word embedding function, which is a deterministic function that maps each word to a high-dimensional vector. Given a training batch (composed of sentences), the gradients are all 0's for the words that do not appear in this batch, and thus the set of words used in the training sentences can be inferred. The attack assumes that the participants update the central server after each mini-batch, as opposed to updating after each training epoch.

Nasr et al. [31] use gradient updates as feature vectors and train an auto-encoder to generate a single-number embedding to predict membership. This attack was also applied in the white-box setting, for which it performs worse than attacks that directly use gradient norm to predict membership, which show only small improvement over blackbox attacks. Another interesting idea in [31] is that a malicious server can actively improve MI attacks, by applying a gradient ascent with respect

to the target instance. If the instance is a member, then the gradients tend to be larger in order to compensate for the malicious gradient ascent.

Li et al. [23] proposed a new membership inference attack against the federated learning setting. They observed that the cosine similarity between gradients of each data instance and the parameter updates sent by each client has very different distribution for members and non-members. Thus, the cosine similarity is used as the metric to predict members. They also proposed to use the gradient difference between the gradients of each data instance and the parameter updates to predict membership. Their results show that the new proposed attacks can achieve higher TPR at low FPR than the attack proposed in [31].

Song et al. [40] evaluated how adversarial training would affect the privacy leakage. Experiments showed that adversarial training would boost the performance of instance loss membership inference attack and the testing accuracy of the target model will be decreased.

Liu et al. [25] evaluated the privacy leakage of pre-trained models which are trained using unsupervised contrastive learning strategy. The authors proposed a specific membership inference attack against pre-trained models. Given one instance, this new attack generates many perturbed versions of this instance and gather all the embeddings of these perturbed versions using the pre-trained model. The intuition is if one instance is used in the training of this pre-trained model, then the embeddings of its perturbed versions are generally closer to each other. He et al. [15] utilized the same contrastive learning idea and proposed to fine-tune the pre-trained model to get the final target model. Experiments showed that using pre-trained model as feature extractor would reduce privacy leakage, comparing to training models from scratch.

Hidano et al. [16] evaluated MI attack under the setting where the attacker can know the parameters of some shallow layers. In the experiment, the author assumed that the attacker can get all but the last layer and the parameters of these layers are used to initialize shadow models to facilitate the class-vector attack. With these known parameters, the class-vector attack can outperform its black-box version.

Other privacy-threatening attacks. Salem et al. [36] studied the possible information leakage of an update set when the machine learning model is updated using the update set. To detect the information leakage, the authors proposed two different attacks: label inference attack and instance reconstruction attack. These two attacks can be applied to both single instance update set case and multi-instances update set case, with only black-box access to the machine learning model.

Zhu et al. [49] presented a gradient-based instance reconstruction attack. If the gradients of one specific instance are revealed to one adversary who can access the trained model, then the adversary is able to reconstruct the specific instance with high fidelity. One random instance is gradually optimized

LOCATION	LOCATION	0.10	100	None	100	4	14.0

Table 7: Training recipe for different models. Learning rate is adjusted to 0.1x when current epoch is in schedule.

dataset on AlexNet. We perform experiments while varying the number of models K from 1 to 8 for CIFAR-10 (10 for CIFAR-100). D, which contains 20,000 training instances, is divided into K equal-size, disjoint partitions, and each model will be trained using one partition for one epoch, before we average the model. For each number of models choice, we experiment with two cases: with mixup and without mixup. The results are shown in Figure 4. From Figure 4, for CIFAR-100 dataset, the first thing we can observe is that the training accuracy is decreased and the testing accuracy is increased when mixup is applied for the same number of models. Furthermore, by adding the mixup data augmentation, the LIRA attack AUC and LIRA attack PLR at low FPR are both reduced when the same number of models are created. This validates the effectiveness of the mixup data augmentation. However, we also noticed that the testing accuracy is always decreasing while creating more than one models and when the number of models is seven, the testing accuracy is very similar to the testing accuracy when there is no defense. Thus, there is a privacy-utility tradeoff that should be considered by the model trainer and the model trainer should choose the number of models based on their own needs. In addition, in order to regularize the trained model with the cross-difference loss, there should be at least two models. For CIFAR-10 dataset, we also notice that the training accuracy is decreased and the testing accuracy is increased when mixup is applied for the same number of models, which again verifies the effectiveness of the mixup data augmentation. The only difference is that, the testing accuracy increases and then decreases while having more models. Therefore, we suggest the model trainers to generate similar figures like Figure 4 and choose the number of models based on their needs.

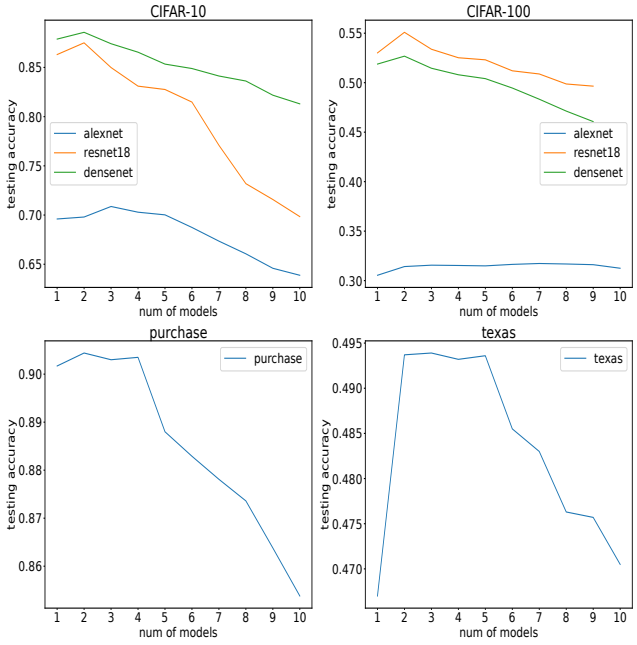

Figure 5: Testing accuracy v.s. number of models for all datasets and models considered in this paper. No mixup data augmentation. The main observation is that testing accuracy can be improved by adding a few models. However, adding too many models would cost testing accuracy.

C Additional Experimental Details and Results

Hyperparameters. In Table 7, we present all the hyperparameters used in our evaluation. Due to page limit, we exclude the detailed numbers for all defenses evaluation and extra additional experiments. Please refer to the arxiv version of this paper if interested.

Inf^{2}Guard: An Information-Theoretic Framework for Learning Privacy-Preserving Representations against Inference Attacks

[1]*Illinois Institute of Technology,* [2]*University of Connecticut,* [*]*Equal contribution*

Abstract

Machine learning (ML) is vulnerable to inference (e.g., membership inference, property inference, and data reconstruction) attacks that aim to infer the private information of training data or dataset. Existing defenses are only designed for one specific type of attack and sacrifice significant utility or are soon broken by adaptive attacks. We address these limitations by proposing an information-theoretic defense framework, called Inf^{2}Guard, against the three major types of inference attacks. Our framework, inspired by the success of representation learning, posits that learning shared representations not only saves time/costs but also benefits numerous downstream tasks. Generally, Inf^{2}Guard involves two mutual information objectives, for privacy protection and utility preservation, respectively. Inf^{2}Guard exhibits many merits: it facilitates the design of customized objectives against the specific inference attack; it provides a general defense framework which can treat certain existing defenses as special cases; and importantly, it aids in deriving theoretical results, e.g., inherent utility-privacy tradeoff and guaranteed privacy leakage. Extensive evaluations validate the effectiveness of Inf^{2}Guard for learning privacy-preserving representations against inference attacks and demonstrate the superiority over the baselines.[1]

1 Introduction

Machine learning (ML) models (particularly deep neural networks) are vulnerable to inference attacks, which aim to infer sensitive information about the training data/dataset that are used to train the models. There are three well-known types of inference attacks on training data/dataset: membership inference attacks (MIAs) [12, 58, 73], property inference attacks (PIAs) (also called distribution inference attacks) [6, 20, 63], and data reconstruction attacks (DRAs) (also called model inversion attacks) [7, 28]. Given an ML model, in MIAs, an adversary aims to infer whether a particular data sample was in the training set, while in PIAs, an adversary aims to infer statistical properties of the training dataset used to train the targeted ML model. Furthermore, an adversary aims to directly reconstruct the training data in DRAs. Leaking the data sample or information about the dataset raises serious privacy issues. For instance, by performing MIAs, an adversary is able to identify users included in sensitive medical datasets, which itself is a privacy violation [30]. By performing PIAs, an adversary can determine whether or not machines that generated the bitcoin logs were patched for Meltdown and Spectre attacks [20]. More seriously, DRAs performed by an adversary leak all the information about the training data.

To mitigate the privacy risks, various defenses have been proposed against MIAs [35, 45, 54, 56, 58, 59, 61, 71] and DRAs [21, 25, 38, 48, 55, 62, 69, 81][2]. However, there are two fundamental limitations in existing defenses: 1) They are designed against only one specific type of attack; 2) Provable defenses (based on differential privacy [3, 18]) incur significant utility losses to achieve reasonable defense performance against inference attacks [33, 56] since the design of such randomization-based defenses did not consider specific inference attacks (also see Section 5); and empirical defenses are soon broken by stronger/adaptive attacks [9, 16, 59].

We aim to address these limitations and consider the question: *1) Can we design a unified privacy protection framework against these inference attacks, that also maintain utility? 2) Under the framework, can we further theoretically understand the utility-privacy tradeoff and the privacy leakage against the inference attacks?* To this end, we propose an information-theoretic defense framework, termed Inf^{2}Guard, against inference attacks through the lens of *representation learning* [11]. Representation learning has been one of the biggest successes in modern ML/AI so far (e.g., it plays an important role in today's large language models such as ChatGPT [1] and PaLM2 [2]). Particularly, rather than training large models from scratch, which requires huge computational

[1]Source code and the full version at: https://github.com/leilynourbakhsh/Inf2Guard.

[2]To our best knowledge, there exist no effective defenses against PIAs. [26] analyzes sources of information leakage to cause PIAs, but their solutions are difficult to be tested on real-world datasets due to lack of generality.

costs and time (e.g., GPT-3 has 175 billion parameters), learning shared representations (or pretrained encoder)[3] presents an economical alternative. For instance, the shared representations can be directly used or further fine-tuned with different purposes, achieving considerable savings in time and cost.

More specifically, we formulate Inf^{2}Guard via two mutual information (MI)[4] objectives in general, for privacy protection and utility preservation, respectively. Under this framework, we can design customized MI objectives to defend against each inference attack. For instance, to defend against MIAs, we design one MI objective to learn representations that contain as less information as possible about the membership of the training data—thus protecting membership privacy, while the other one to ensure the learnt representations include as much information as possible about the training data labels—thus maintaining utility. However, directly solving the MI objectives for each inference attack is challenging, since calculating an MI between arbitrary variables is often infeasible [49]. To address it, we are inspired by the MI neural estimation [4,10,15,29,47,50], which transfers the intractable MI calculations to the tractable variational MI bounds. Then, we are capable of parameterizing each bound with a (deep) neural network, and train neural networks to approximate the true MI and learn representations against the inference attacks. Finally, we can derive theoretical results based on our MI objectives: we obtain an inherent utility-privacy tradeoff, and guaranteed privacy leakage against each inference attack.

We extensively evaluate Inf^{2}Guard and compare it with the existing defenses against the inference attacks on multiple benchmark datasets. Our experimental results validate that Inf^{2}Guard obtains a promising utility-privacy tradeoff and significantly outperforms the existing defenses. For instance, under the same defense performance against MIAs, Inf^{2}Guard has a 30% higher testing accuracy than the DP-SGD [3]. Our results also validate the privacy-utility tradeoffs obtained by Inf^{2}Guard[5].

Our main contributions are summarized as below:

- **Algorithm:** We design the first unified framework Inf^{2}Guard to defend against the three well-known types of inference attacks via information theory. Our framework can instantiate many existing defenses as special cases, e.g., AdvReg [45] against MIAs (See Section 3.1) and Soteria [62] against DRAs (See Section 3.3).
- **Theory:** Based on our formulation, we can derive novel theoretical results, e.g., the inherent tradeoff between utility and privacy, and guaranteed privacy leakage against all the considered inference attacks.
- **Evaluation:** Extensive evaluations verify the effectiveness of Inf^{2}Guard for learning privacy-preserving representations against inference attacks.

[3] *Pretrained encoder as a service* has been widely deployed by industry, e.g., OpenAI's GPT-4 API [1] and Clarifai's Embedding API [17]. We will interchangeably use the pretrained encoder and learnt representations.

[4] In information theory, MI is a measure of shared information between random variables, and offers a metric to quantify the "amount of information" obtained about one random variable by observing the other random variable.

[5] A recent work [53] formulates defenses against inference attacks under a privacy game framework, but it does not propose concrete defense solutions.

2 Background and Problem Definition

Notations: We use s, $\mathbf{s}$, $\mathbf{S}$, and $\mathcal{S}$ to denote (random) scalar, vector, matrix, and space, respectively. Accordingly, $\Pr(s)$, $\Pr(\mathbf{s})$, and $\Pr(\mathbf{S})$ are the probability distribution over s, $\mathbf{s}$, and $\mathbf{S}$. $I(\mathbf{x};\mathbf{r})$ and $H(\mathbf{x},\mathbf{r})$ are the mutual information and cross entropy between a pair of random variables $(\mathbf{x},\mathbf{r})$, respectively, and $H(\mathbf{x}) = I(\mathbf{x};\mathbf{x})$ as the entropy of $\mathbf{x}$. $KL(p||q)$ is the KL-divergence between two distributions p and q. We denote $\mathcal{D}$ as the underlying distribution that data are sampled from. A data sample is denoted as $(\mathbf{x},y) \sim \mathcal{D}$, where $\mathbf{x} \in \mathcal{X}$ is data features, $y \in \mathcal{Y}$ is the label, and $\mathcal{X}$ and $\mathcal{Y}$ are the data space and label space, respectively. We further denote a dataset as $D = \{\mathbf{X},\mathbf{y}\} = \{(\mathbf{x}_i, y_i)\}$, that consists of a set of data samples $(\mathbf{x}_i, y_i) \sim \mathcal{D}$, and will interchangeably use D and $\{\mathbf{X},\mathbf{y}\}$. We let $u \in \mathcal{U}$ be the private attribute within the attribute space $\mathcal{U}$. For instance, in MIAs, $u \in \mathcal{U} = \{0,1\}$ means a binary-valued private membership; in PIAs, $u \in \mathcal{U} = \{1,2,\cdots,K\}$ indicates a K-valued private dataset property; and $u \in \mathcal{U} = \mathcal{X}$ indicates the private data itself in DRAs. The composition function of two functions f and g is denoted as $(g \circ f)(\cdot) = g(f(\cdot))$.

2.1 Formalizing Privacy Attacks

We denote a classification model[6] $F_\theta : \mathcal{X} \to \mathcal{Y}$ as a function, parameterized by θ, that maps a data sample $\mathbf{x} \in \mathcal{X}$ to a label $y \in \mathcal{Y}$. Given a training set $D \sim \mathcal{D}$, we denote $F \leftarrow \mathcal{T}(D)$ as learned by running a training algorithm $\mathcal{T}$ on the dataset D.

Formalizing MIAs: Assume a data sample $(\mathbf{x},y) \sim \mathcal{D}$ with a private membership u that is chosen uniformly at random from $\{0,1\}$, where $u = 1$ means $(\mathbf{x},y)$ is a member of D, and 0 otherwise. An MIA A_{MIA} has access to $\mathcal{D}$ and F, takes $(\mathbf{x},y)$ as input, and outputs a binary $A_{MIA}^{\mathcal{D},F}(\mathbf{x},y)$. We omit $\mathcal{D},F$ for notation simplicity. Then, the attack performance of an MIA A_{MIA} is defined as $\Pr_{(\mathbf{x},y,u)}(A_{MIA}(\mathbf{x},y) = u)$.

Formalizing PIAs: PIAs define a private property on a dataset. Given a dataset $D_u \sim \mathcal{D}$ with a private property u chosen uniformly at random from $\{1,2,\cdots,K\}$. A PIA A_{PIA} has access to $\mathcal{D}$ and F, and outputs a K-valued $A_{PIA}(D_u)$. Then, the attack performance of a PIA A_{PIA} is defined as $\Pr_{(D_u,u)}(A_{PIA}(D_u) = u)$.

Formalizing DRAs: Given a random data $(\mathbf{x},y) \in D$, DRAs aim to reconstruct the private $\mathbf{x}$. A DRA A_{DRA} has access to $\mathcal{D}$ and F, and outputs a reconstructed $\hat{\mathbf{x}} = A_{DRA}(\mathbf{x},y)$. The DRA performance is measured by the similarity/difference between $\hat{\mathbf{x}}$ and $\mathbf{x}$. For instance, [7] introduces the (η,γ)-reconstruction metric defined as $\Pr_{(\mathbf{x},y)}(\|\hat{\mathbf{x}} - \mathbf{x}\|_2 \le \eta) \ge \gamma$, where a smaller η and a larger γ imply a more severe DRA.

[6] In this paper, we focus on classification models for simplicity.

2.2 Threat Model and Problem Formulation

We have three roles: *task learner*, *defender*, and *attacker*. The task learner (i.e., data owner) aims to learn an accurate classification model on its training data. The defender (e.g., data owner or a trusted service provider) aims to protect the training data privacy—it designs a defense framework by learning *shared data representations* that are robust against inference attacks. The attacker can *arbitrarily* use data representations to perform the inference attack. The attacker is also assumed to know the underlying data distribution, but cannot access the internal encoder (e.g., deployed as an API [1, 17]).

Formally, we denote $f_\Theta : \mathcal{X} \to \mathcal{Z}$ as the *encoder*, parameterized by Θ, that maps a data sample $\mathbf{x} \in \mathcal{X}$ (or a dataset $\mathbf{X} \in \mathcal{X}$) to its representation vector $\mathbf{r} = f(\mathbf{x}) \in \mathcal{Z}$ (or representation matrix $\mathbf{R} = f(\mathbf{X}) \in \mathcal{Z}$), where $\mathcal{Z}$ is the representation space. Moreover, we let $C : \mathcal{Z} \to \mathcal{Y}$ be the *classification model* on top of the representation $\mathbf{r}$ or encoder f, which predicts the data label y (or dataset labels $\mathbf{y}$). We further let $A : \mathcal{Z} \to \mathcal{U}$ be the *inference model*, which infers the private attribute u using the learnt representations $\mathbf{r}$ or $\mathbf{R}$. Then, our defense goals are:

- **Defend against MIAs:** Given a random sample $(\mathbf{x}, y, u) \in \mathcal{D}$, we expect to learn f such that the MIA performance $\Pr(A_{MIA}(f(\mathbf{x}), y) = u)$ is low, and the utility loss/risk, i.e., $\text{Risk}_{MIA}(C \circ f) = \Pr(C \circ f(\mathbf{x}) \neq y)$, is also small.
- **Defend against PIAs:** Given a random dataset $(\mathbf{X}, \mathbf{y}, u) \in \mathcal{D}$, we expect to learn f with low PIA performance $\Pr(A_{PIA}(f(\mathbf{X}), \mathbf{y}) = u)$, and also a small utility loss/risk, i.e., $\text{Risk}_{PIA}(C \circ f) = \frac{1}{|\mathbf{y}|} \sum_{(\mathbf{x},y) \in \{\mathbf{X},\mathbf{y}\}} \Pr(C \circ f(\mathbf{x}) \neq y)$.
- **Defend against DRAs:** Given a random sample $(\mathbf{x}, y) \in \mathcal{D}$, we expect to learn f with low DRA performance, i.e., $\Pr_{(\mathbf{x},y)}(\|\hat{\mathbf{x}} - \mathbf{x}\|_2 \geq \eta) \geq \gamma$ with a large η and γ (flipping the inequality direction on η for DRAs), and also a small utility risk $\text{Risk}_{DRA}(C \circ f) = \Pr(C \circ f(\mathbf{x}) \neq y)$.

3 Design of Inf^{2}Guard

3.1 Inf^{2}Guard against MIAs

3.1.1 MI objectives

Given a data sample $\mathbf{x} \sim \mathcal{D}$, from the training set D (i.e., $u = 1$) or not (i.e., $u = 0$), the defender learns the representation $\mathbf{r} = f(\mathbf{x})$ that satisfies the following two goals:

- **Goal 1: Membership protection.** $\mathbf{r}$ contains as less information as possible about the private membership u. Ideally, when $\mathbf{r}$ does not include information about u (i.e., $\mathbf{r} \perp u$), it is impossible to infer u from $\mathbf{r}$. Formally, we quantify the membership protection using the MI objective as follows:
$$\min_f I(\mathbf{r}; u), \tag{1}$$
where we minimize such MI to maximally reduce the correlation between $\mathbf{r}$ and u.
- **Goal 2: Utility preservation.** $\mathbf{r}$ should be effective for predicting the label y of the *training* data (i.e., $u = 1$), thus preserving utility. Formally, we quantify the utility preservation using the below MI objective:
$$\max_f I(y; \mathbf{r} | u = 1), \tag{2}$$
where we maximize such MI to make $\mathbf{r}$ accurately predict the training data label y during training.

3.1.2 Estimating MI via tractable bounds

The key challenge of solving the above two MI objectives is that calculating an MI between two arbitrary random variables is likely to be infeasible [49]. Inspired by the existing MI neural estimation methods [4, 10, 15, 29, 47, 50], we convert the intractable exact MI calculations to the tractable variational MI bounds. Specifically, we first obtain an MI upper bound for membership protection and an MI lower bound for utility preserving via introducing two auxiliary posterior distributions, respectively. Then, we parameterize each auxiliary distribution with a neural network, and approximate the true MI by minimizing the upper bound and maximizing the lower bound through training the involved neural networks. *We emphasize we do not design novel MI neural estimators, but adopt existing ones to assist our MI objectives for learning privacy-preserving representations. Note that, though the estimated MI bounds may not be tight (due to the MI estimators or auxiliary distributions learnt by neural networks) [15, 29], they have shown promising performance in practice. It is still an active research topic to design better MI estimators that lead to tighter MI bounds (which is orthogonal to this work).*

Minimizing the upper bound MI in Equation (1). We adapt the variational upper bound proposed in [15]. Specifically,

$$I(\mathbf{r}; u) \leq I_{vCLUB}(\mathbf{r}; u) = \mathop{\mathbb{E}}_{p(\mathbf{r},u)}[\log q_\Psi(u|\mathbf{r})] - \mathop{\mathbb{E}}_{p(\mathbf{r})p(u)}[\log q_\Psi(u|\mathbf{r})],$$

where $q_\Psi(u|\mathbf{r})$ is an auxiliary posterior distribution of $p(u|\mathbf{r})$ needing to satisfy the below condition on KL divergence: $KL(p(\mathbf{r},u)||q_\Psi(\mathbf{r},u)) \leq KL(p(\mathbf{r})p(u)||q_\Psi(\mathbf{r},u))$. To achieve this, we thus minimize:

$$\begin{aligned}
&\min_\Psi KL(p(\mathbf{r},u)||q_\Psi(\mathbf{r},u)) = \min_\Psi KL(p(u|\mathbf{r})||q_\Psi(u|\mathbf{r})) \\
&= \min_\Psi \mathop{\mathbb{E}}_{p(\mathbf{r},u)}[\log p(u|\mathbf{r})] - \mathop{\mathbb{E}}_{p(\mathbf{r},u)}[\log q_\Psi(u|\mathbf{r}))] \\
&\Longleftrightarrow \max_\Psi \mathop{\mathbb{E}}_{p(\mathbf{r},u)}[\log q_\Psi(u|\mathbf{r})],
\end{aligned} \tag{3}$$

where we note that $\mathbb{E}_{p(\mathbf{r},u)}[\log p(u|\mathbf{r})]$ is irrelevant to Ψ. [15] proved when $q_\Psi(u|r)$ is parameterized by a neural network with high expressiveness (e.g., deep neural network), the condition is satisfied almost surely by maximizing Equation (3). Finally, our **Goal 1** for privacy protection is reformulated as solving the below *min-max* objective function:

$$\min_f \min_\Psi I_{vCLUB}(\mathbf{r}; u) \Longleftrightarrow \min_f \max_\Psi \mathop{\mathbb{E}}_{p(\mathbf{r},u)}[\log q_\Psi(u|\mathbf{r})] \tag{4}$$

Remark. Equation (4) can be interpreted as an *adversarial game* between an adversary q_Ψ (i.e., a membership inference classifier) who aims to infer the membership u from $\mathbf{r}$; and the encoder f who aims to protect u from being inferred.

Maximizing the lower bound MI in Equation (2). We adopt the MI estimator proposed in [46] to estimate the lower bound of Equation (2). Specifically, we have

$$\begin{aligned} I(y;\mathbf{r}|u=1) &= H(y|u=1) - H(y|\mathbf{r},u=1) \\ &= H(y|u=1) + \mathop{\mathbb{E}}_{p(y,\mathbf{r},u)}[\log p(y|\mathbf{r},u=1))] \\ &= H(y|u=1) + \mathop{\mathbb{E}}_{p(y,\mathbf{r},u)}[\log q_\Omega(y|\mathbf{r},u=1))] \\ &\quad + \mathop{\mathbb{E}}_{p(y,\mathbf{r},u)}[KL(p(\cdot|\mathbf{r},u=1)||q_\Omega(\cdot|\mathbf{r},u=1))] \\ &\geq H(y|u=1) + \mathop{\mathbb{E}}_{p(y,\mathbf{r},u)}[\log q_\Omega(y|\mathbf{r},u=1))], \end{aligned}$$

where q_Ω is an *arbitrary* auxiliary posterior distribution that aims to accurately predict the training data label y from the representation $\mathbf{r}$. Hence, our **Goal 2** for utility preservation can be rewritten as the following *max-max* objective function:

$$\max_f I(y;\mathbf{r}|u=1) \Longleftrightarrow \max_f \max_\Omega \mathop{\mathbb{E}}_{p(y,\mathbf{r},u)}[\log q_\Omega[(y|\mathbf{r},u=1)] \quad (5)$$

Remark. Equation (5) can be interpreted as a *cooperative game* between the encoder f and q_Ω (e.g., a label predictor) that aims to preserve the utility collaboratively.

Objective function of `Inf`^{2}`Guard` against MIAs. By combining Equations (4) and (5), our objective function of learning privacy-preserving representations against MIAs is:

$$\begin{aligned} \max_f \Big(\lambda \min_\Psi &- \mathop{\mathbb{E}}_{p(\mathbf{x},u)}[\log q_\Psi(u|f(\mathbf{x}))] \\ &+ (1-\lambda)\max_\Omega \mathop{\mathbb{E}}_{p(\mathbf{x},y,u)}[\log q_\Omega(y|f(\mathbf{x}),u=1)]\Big), \end{aligned} \quad (6)$$

where $\lambda \in [0,1]$ tradeoffs privacy and utility. That is, a larger λ indicates a stronger membership privacy protection, while a smaller λ indicates a better utility preservation.

3.1.3 Implementation in practice

In practice, we solve Equation (6) via training three parameterized neural networks (i.e., encoder f, membership protection network g_Ψ associated with the posterior distribution q_Ψ, and utility preservation network h_Ω associated with the posterior distribution q_Ω) using data samples from the underlying data distribution. Specifically, we first collect two datasets D_1 and D_0 from a (larger) dataset, and they include the members and non-members, respectively. Then, D_1 is used for training the utility network h_Ω (i.e., predicting labels for training data D_1) and the encoder f; and both D_1 and D_0 are used for training the membership protection network g_Ψ (i.e., inferring whether a data sample from D_1/D_0 is a member or not) and the encoder f. With it, we can approximate the expectation terms in Equation (6) and use them to train the neural networks.

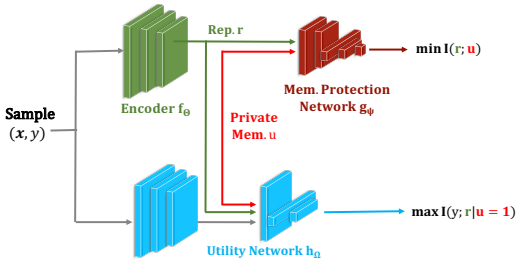

Figure 1: `Inf`^{2}`Guard` against MIAs.

Training the membership protection network g_Ψ: We approximate the first expectation w.r.t. q_Ψ as[7]

$$\mathop{\mathbb{E}}_{p(\mathbf{x},u)} \log q_\Psi(u|f(\mathbf{x})) \approx -\sum_{(\mathbf{x}_j,u_j)\in D_1\cup D_0} H(u_j, g_\Psi(f(\mathbf{x}_j))),$$

where $H(a,b)$ is the cross-entropy loss between a and b. Take a single data $\mathbf{x}$ with private u for example. The above equation is obtained by: $-H(u, g_\Psi(f(\mathbf{x}))) = \log g_\Psi(f(\mathbf{x}))_u = \log q_\Psi(u|f(\mathbf{x}))$, where $g_\Psi(f(\mathbf{x}))_i$ indicates i-th entry probability, and $q_\Psi(u|f(\mathbf{x}))$ means the probability of inferring $\mathbf{x}$'s member u. The adversary maximizes this expectation aiming to enhance the membership inference performance.

Training the utility preservation network h_Ω: We approximate the second expectation w.r.t. q_Ω as:

$$\mathop{\mathbb{E}}_{p(\mathbf{x},y,u)} \log q_\Omega(y|f(\mathbf{x}),u=1) \approx -\sum_{(\mathbf{x}_j,y_j)\in D_1} H(y_j, h_\Omega(f(\mathbf{x}_j))).$$

We maximize this expectation to enhance the utility.

Training the encoder f: With the updated g_Ψ and h_Ω, the defender performs gradient ascent on Equation (6) to update f, which can learn representations that protect membership privacy and further enhance the utility.

We iteratively train the three networks until reaching predefined maximum rounds. Figure 1 illustrates our `Inf`^{2}`Guard` against MIAs. Algorithm 1 in Appendix details the training.

Connection with AdvReg [45]. We observe that AdvReg is a special case of `Inf`^{2}`Guard`. Specifically, the objective function of AdvReg can be rewritten as:

$$\max_f \Big(\lambda \min_\Psi \sum_{(\mathbf{x}_j,u_j)\in D_1\cup D_0} H(u_j, g_\Psi(f(\mathbf{x}_j))) - (1-\lambda) \sum_{(\mathbf{x}_j,y_j)\in D_1} H(y_j, f(\mathbf{x}_j))\Big),$$

where $f: \mathcal{X} \to [0,1]^{|\mathcal{Y}|}$ now outputs a sample's probabilistic confidence score and g_Ψ is a membership inference model aiming to distinguish between members and non-members.

3.2 `Inf`^{2}`Guard` against PIAs

Different from MIAs, PIAs leak the training data properties at the *dataset-level*. To align this, instead of using a random sample $(\mathbf{x},y)$, we consider a random dataset $(\mathbf{X},\mathbf{y})$ in PIAs. Specifically, let $\mathbf{X} = \{\mathbf{x}_i\}$ consist of a set of independent data samples and $\mathbf{y} = \{y_i\}$ the corresponding data labels that are sampled from the underlying data distribution $\mathcal{D}$; and $\mathbf{X}$ is associated with a private (dataset) property u.

[7] We omit the sample size $|D_1|$, $|D_0|$ for description brevity.

3.2.1 MI objectives

Given a dataset $\mathbf{X} \sim \mathcal{D}$ with a property u, the defender learns a dataset representation $\mathbf{R} = f(\mathbf{X})$ that satisfies two goals[8]:

- **Goal 1: Property protection.** $\mathbf{R}$ contains as less information as possible about the private dataset property u. Ideally, when $\mathbf{R}$ does not include information about u (i.e., $\mathbf{R} \perp u$), it is impossible to infer u from $\mathbf{R}$. Formally, we quantify the property protection using the below MI objective:

$$\min_{f} I(\mathbf{R}; u). \tag{7}$$

- **Goal 2: Utility preservation.** $\mathbf{R}$ includes as much information as possible about predicting $\mathbf{y}$. Formally, we quantify the utility preservation using the MI objective as below:

$$\max_{f} I(\mathbf{y}; \mathbf{R}). \tag{8}$$

3.2.2 Estimating MI via tractable bounds

We estimate the bounds of Equations 7 and 8 as below.

Minimizing the upper bound MI in Equation (7). Following membership protection, **Goal 1** is reformulated as solving the below min-max objective function:

$$\min_{f} I(\mathbf{R}; u) \Longleftrightarrow \min_{f} \max_{\Psi} \mathop{\mathbb{E}}_{p(\mathbf{R},u)} [\log q_\Psi(u|\mathbf{R})], \tag{9}$$

where $q_\Psi(u|\mathbf{R})$ is an arbitrary posterior distribution.

Remark. Similarly, Equation (9) can be interpreted as an *adversarial game* between a property inference adversary q_Ψ who aims to infer u from the dataset representations $\mathbf{R}$ and the encoder f who aims to protect u from being inferred.

Maximizing the lower bound MI in Equations (8). Similarly, we adopt the MI estimator [46] to estimate the lower bound MI in our **Goal 2**, which can be rewritten as the following max-max objective function:

$$\max_{f} I(\mathbf{y}; \mathbf{R}) \Longleftrightarrow \max_{f} \max_{\Omega} \mathop{\mathbb{E}}_{p(\mathbf{y},\mathbf{R})} [\log q_\Omega(\mathbf{y}|\mathbf{R})], \tag{10}$$

where q_Ω is an *arbitrary* posterior distribution that aims to predict each label $y \in \mathbf{y}$ from the data representation $\mathbf{r} \in \mathbf{R}$.

Remark. Equation (10) can be interpreted as a *cooperative game* between f and q_Ω to preserve the utility collaboratively.

Objective function of `Inf`^{2}`Guard` against PIAs. By combining Equations (9) and (10), our objective function of learning privacy-preserving representations against PIAs is:

$$\max_{f} \Big(\lambda \min_{\Psi} - \mathop{\mathbb{E}}_{p(\mathbf{X},u)} [\log q_\Psi(u|f(\mathbf{X}))] + (1-\lambda) \max_{\Omega} \mathop{\mathbb{E}}_{p(\mathbf{X},\mathbf{y})} [\log q_\Omega(\mathbf{y}|f(\mathbf{X}))] \Big), \tag{11}$$

where $\lambda \in [0,1]$ tradeoffs between privacy and utility. That is, a larger/smaller λ indicates less/more dataset property can be inferred through the learnt dataset representation.

[8] For notation simplicity, we use the same f to indicate the encoder. Similar for subsequent notations such as g_Ψ, h_Ψ, q_Ω, h_Ω, etc.

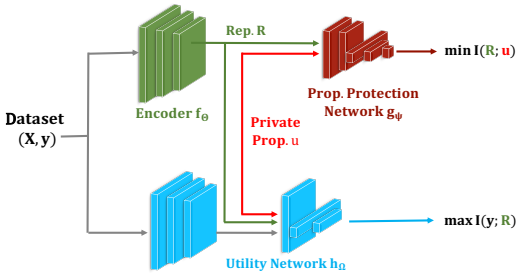

Figure 2: `Inf`^{2}`Guard` against PIAs.

3.2.3 Implementation in practice

Equation (11) is solved via three parameterized neural networks (i.e., the encoder f_Θ, the property protection network g_Ψ associated with q_Ψ, and the utility preservation network h_Ω associated with q_Ω) using a set of *datasets* sampled from a data distribution. Specifically, we first collect a large reference dataset D_r. Then, we randomly generate a set of small datasets $\{D_j = (\mathbf{X}_j, \mathbf{y}_j)\}_j$ from D_r. We denote the dataset property value for each D_j as u_j. With it, we can approximate the expectation terms in Equation (11).

Training the property inference network g_Ψ: We approximate the first expectation w.r.t. q_Ψ as

$$\mathop{\mathbb{E}}_{p(\mathbf{X},u)} \log q_\Psi(u|f(\mathbf{X})) \approx - \sum_{\{\mathbf{X}_j \in D_j\}} H(u_j, g_\Psi(f(\mathbf{X}_j))), \tag{12}$$

where $f(\mathbf{X}_j)$ is the aggregated representation of a dataset $\mathbf{X}_j$, i.e., $f(\mathbf{X}_j) = \mathrm{Agg}(\{f(\mathbf{x})\}_{\mathbf{x} \in \mathbf{X}_j})$. We will discuss the aggregator $\mathrm{Agg}(\cdot)$ in Section 5.2.2. The adversary maximizes this expectation to enhance the property inference performance.

Training the utility preservation network h_Ω: Similarly, we approximate the second expectation w.r.t. q_Ω as:

$$\mathop{\mathbb{E}}_{p(\mathbf{X},\mathbf{y})} \log q_\Omega(\mathbf{y}|f(\mathbf{X})) \approx - \sum_{\{D_j\}} \sum_{(\mathbf{x}_i, y_i) \in D_j} H(y_i, h_\Omega(f(\mathbf{x}_i))), \tag{13}$$

where we maximize this expectation to enhance the utility.

Training the encoder f: The defender then performs gradient ascent on Equation (11) to update f, which mitigates the PIA and further enhances the utility.

We iteratively train the three networks until reaching maximum rounds. Figure 2 illustrates our `Inf`^{2}`Guard` against PIAs. Algorithm 2 in Appendix details the training process.

3.3 `Inf`^{2}`Guard` against DRAs

Different from MIAs and PIAs, DRAs aim to *directly* recover the training data from the learnt representations. A recent defense [62] shows perturbing the latent representations can somewhat protect the data from being reconstructed. However, this defense is broken by an advanced attack [9]. One key reason is the defense perturbs representations in a *deterministic* fashion for already *trained* models. We address the issues and propose an information-theoretic defense to learn

randomized representations against the DRAs in an end-to-end *learning* fashion. Our core idea is to learn a *deterministic* encoder and a *randomized* perturbator that ensures learning the perturbed representation in a controllable manner.

3.3.1 MI objectives

Given a data sample $\mathbf{x} \sim \mathcal{D}$ with a label y, the defender learns a representation $\mathbf{r} = f(\mathbf{x})$ such that when $\mathbf{r}$ is perturbed by certain perturbation (denoted as $\boldsymbol{\delta}$), the shared perturbed representation $\mathbf{r}+\boldsymbol{\delta}$ cannot be used to well recover $\mathbf{x}$, but is effective for predicting y, from the information-theoretic perspective. Then we aim to achieve the following two goals:

- **Goal 1: Data reconstruction protection.** $\mathbf{r}+\boldsymbol{\delta}$ contains as less information as possible about $\mathbf{x}$. Moreover, the perturbation $\boldsymbol{\delta}$ should be effective enough. Hence, we require $\boldsymbol{\delta}$ can cover all directions of $\mathbf{x}$, and force the entropy of $\boldsymbol{\delta}$ to be as large as possible. Formally, we quantify the data reconstruction protection using the below MI objective:

$$\min_{f, p(\boldsymbol{\delta})\sim\mathcal{P}} I(\mathbf{r}+\boldsymbol{\delta};\mathbf{x}) - H(\boldsymbol{\delta}), \tag{14}$$

- **Goal 2: Utility preservation.** To ensure $\mathbf{r}$ be useful, it should be effective for predicting the label y. Further, as we will share the perturbed representation $\mathbf{r}+\boldsymbol{\delta}$, it should be also effective for predicting y. Formally, we quantify the utility preservation using the MI objective as follows:

$$\max_{f, p(\boldsymbol{\delta})\sim\mathcal{P}} I(\mathbf{r}+\boldsymbol{\delta};y) + I(\mathbf{r};y), \tag{15}$$

3.3.2 Estimating MI via tractable bounds

Minimizing the upper bound MI in Equation (14). Similarly, we adapt the variational upper bound in [15]. Our **Goal 1** for data reconstruction protection can be reformulated as the below *min-max* objective function:

$$\begin{aligned} &\min_{f, p(\boldsymbol{\delta})\sim\mathcal{P}} I(\mathbf{r}+\boldsymbol{\delta};\mathbf{x}) - \alpha H(\boldsymbol{\delta}) \\ \Longleftrightarrow &\min_{f, p(\boldsymbol{\delta})\sim\mathcal{P}} \big(\max_{\Psi} \mathop{\mathbb{E}}_{p(\mathbf{r},\boldsymbol{\delta},\mathbf{x})} [\log q_\Psi(\mathbf{x}|\mathbf{r}+\boldsymbol{\delta})] - \alpha H(\boldsymbol{\delta})\big). \end{aligned} \tag{16}$$

Remark. Equation (16) can be interpreted as an *adversarial game* between an adversary q_Ψ (i.e., data reconstructor) who aims to infer $\mathbf{x}$ from $\mathbf{r}+\boldsymbol{\delta}$; and the encoder f who aims to protect $\mathbf{x}$ from being inferred via carefully perturbing $\mathbf{r}$.

Maximizing the lower bound MI in Equation (15). Based on [50], we can produce a lower bound on the MI $I(\mathbf{r};y)$ due to the non-negativity of the KL-divergence:

$$\begin{aligned} I(\mathbf{r};y) &= \mathop{\mathbb{E}}_{p(y,\mathbf{r})} [\log q_\Omega(y|\mathbf{r})/p(y)] + \mathop{\mathbb{E}}_{p(\mathbf{r})} [KL(p(y|\mathbf{r})||q_\Omega(y||\mathbf{r}))] \\ &\geq \mathop{\mathbb{E}}_{p(y,\mathbf{r})} [\log q_\Omega(y|\mathbf{r})] + H(y), \end{aligned} \tag{17}$$

where q_Ω is an *arbitrary* posterior distribution that predicts the label y from $\mathbf{r}$ and the entropy $H(y)$ is a constant.

We have a similar form for the MI $I(\mathbf{r}+\boldsymbol{\delta};y)$ as below

$$I(\mathbf{r}+\boldsymbol{\delta};y) \geq \max_{p(\boldsymbol{\delta})\sim\mathcal{P}} \mathop{\mathbb{E}}_{p(y,\mathbf{r},\boldsymbol{\delta})} [\log q_\Omega(y|\mathbf{r}+\boldsymbol{\delta})] + H(y), \tag{18}$$

where we use the same q_Ω to predict the label y from the perturbed representation $\mathbf{r}+\boldsymbol{\delta}$.

Then, our **Goal 2** for utility preservation can be rewritten as the following max-max objective function:

$$\begin{aligned} &\max_{f, p(\boldsymbol{\delta})\sim\mathcal{P}} I(\mathbf{r}+\boldsymbol{\delta};y) + I(\mathbf{r};y) \\ \Longleftrightarrow &\max_{f,\Omega} \Big(\max_{p(\boldsymbol{\delta})\sim\mathcal{P}} \mathop{\mathbb{E}}_{p(y,\mathbf{r},\boldsymbol{\delta})} [\log q_\Omega(y|\mathbf{r}+\boldsymbol{\delta})] + \mathop{\mathbb{E}}_{p(y,\mathbf{r})} [\log q_\Omega(y|\mathbf{r})] \Big). \end{aligned} \tag{19}$$

Remark. Equation (19) can be interpreted as a *cooperative game* between the encoder f and the label prediction network q_Ω, who aim to preserve the utility collaboratively.

Objective function of `Inf`^{2}`Guard` against DRAs. By combining Equations (16)-(19), our objective function of learning privacy-preserving representations against DRAs is:

$$\begin{aligned} &\max_{f, p(\boldsymbol{\delta})\sim\mathcal{P}} \Big(\lambda \big(\min_{\Psi} - \mathop{\mathbb{E}}_{p(\mathbf{x},\boldsymbol{\delta})} [\log q_\Psi(\mathbf{x}|f(\mathbf{x})+\boldsymbol{\delta})] + \alpha H(\boldsymbol{\delta}) \big) \\ &+ (1-\lambda) \big(\max_{\Omega} \mathop{\mathbb{E}}_{p(\mathbf{x},\boldsymbol{\delta},y)} [\log q_\Omega(y|f(\mathbf{x})+\boldsymbol{\delta})] + \mathop{\mathbb{E}}_{p(\mathbf{x},y)} [\log q_\Omega(y|f(\mathbf{x}))] \big) \Big), \end{aligned} \tag{20}$$

where $\lambda \in [0,1]$ tradeoffs privacy and utility. A larger λ implies less data features can be inferred through the perturbed representation, while a smaller λ implies the shared perturbed representation is easier for predicting the label.

3.3.3 Parameterizing perturbation distributions

The key of our defense lies in defining the perturbation distribution $p(\boldsymbol{\delta})$ in Equation (20). Directly specifying the optimal perturbation distribution is challenging. Motivated by variational inference [36], we propose to parameterize $p(\boldsymbol{\delta})$ with trainable parameters, e.g., Φ. Then the optimization problem w.r.t. the perturbation $\boldsymbol{\delta}$ can be converted to be w.r.t. the parameters Φ, which can be solved via back-propagation.

A natural way to model the perturbation around a representation is using a distribution with an explicit density function. Here we adopt the method in [36] by transforming $\boldsymbol{\delta}$ such that the reparameterization trick can be used in training. For instance, when considering $p_\Phi(\boldsymbol{\delta})$ as a Gaussian distribution $\mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\sigma}^2)$, we can reparameterize $\boldsymbol{\delta}$ (with a scale ε) as:

$$\boldsymbol{\delta} = \varepsilon \cdot \tanh(\mathbf{u}), \quad \mathbf{u} \sim \mathcal{N}(\boldsymbol{\mu}, \mathrm{diag}(\boldsymbol{\sigma}^2)), \tag{21}$$

That is, it first samples $\mathbf{u}$ from a diagonal Gaussian with a mean vector $\boldsymbol{\mu}$ and standard deviation vector $\boldsymbol{\sigma}$, and $\boldsymbol{\delta}$ is obtained by compressing $\mathbf{u}$ to be $[-1,1]$ via the $\tanh(\cdot)$ function and multiplying ε. $\Phi = (\boldsymbol{\mu}, \boldsymbol{\sigma})$ are the parameters to be learnt.

3.3.4 Implementation in practice

We train three neural networks (i.e., the encoder f, reconstruction protection network g_Ψ, and utility preservation network h_Ω) using data samples from certain data distribution. Suppose we are given a set of data samples $D = \{\mathbf{x}_j, y_j\}$.

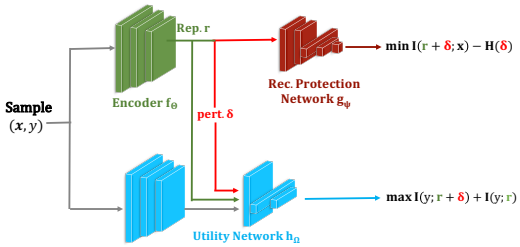

Figure 3: Inf^{2}Guard against DRAs.

Learning the data reconstruction network g_Ψ: As $\mathbf{x}$ and its representation $\mathbf{r}$ are often high-dimensional, the previous MI estimators are inappropriate in this setting. To address it, we use the *Jensen-Shannon* divergence (JSD) [29] specially for high-dimensional MI estimation. Assume we have updated Φ. We can approximate the expectation w.r.t. g_Ψ as

$$\begin{aligned}&\mathop{\mathbb{E}}_{p(\mathbf{x}),p_\Phi(\boldsymbol{\delta})} \log q_\Psi(\mathbf{x}|f(\mathbf{x})+\boldsymbol{\delta}) = I^{(JSD)}_{\Theta,\Psi}(\mathbf{x}; f_\Theta(\mathbf{x})+\boldsymbol{\delta})\\ &\approx \sum_{\mathbf{x}_j\in D,\boldsymbol{\delta}_j\sim p_\Phi(\boldsymbol{\delta})} [-\mathrm{sp}(-h_\Psi(\mathbf{x}_j, f_\Theta(\mathbf{x}_j)+\boldsymbol{\delta}_j))]\\ &\quad - \sum_{(\mathbf{x}_j,\mathbf{x}'_j)\in D,\boldsymbol{\delta}_j\sim p_\Phi(\boldsymbol{\delta})} [\mathrm{sp}(h_\Psi(\mathbf{x}'_j, f_\Theta(\mathbf{x}_j)+\boldsymbol{\delta}_j)],\end{aligned} \tag{22}$$

where $\mathbf{x}'_j$ is an independent and random sample from the same distribution as $\mathbf{x}_j$, and $\mathrm{sp}(z) = \log(1+\exp(z))$ is the softplus function. We maximize $I^{(JSD)}_{\Theta,\Psi}$ to update g_Ψ.

Learning the utility preservation network h_Ω: We first estimate the below expectation:

$$\mathop{\mathbb{E}}_{p(\mathbf{x},y)p_\Phi(\boldsymbol{\delta})} \log q_\Omega(y|f(\mathbf{x})+\boldsymbol{\delta}) \approx - \sum_{(\mathbf{x}_j,y_j)\in D,\boldsymbol{\delta}_j\sim p_\Phi(\boldsymbol{\delta})} H(y_j, h_\Omega(f(\mathbf{x}_j)+\boldsymbol{\delta}_j)). \tag{23}$$

Similarly, we can approximate the third expectation as:

$$\mathop{\mathbb{E}}_{p(\mathbf{x},y)} \log q_\Omega(y|f(\mathbf{x})) \approx - \sum_{(\mathbf{x}_j,y_j)\in D} H(y_j, h_\Omega(f(\mathbf{x}_j))). \tag{24}$$

We minimize the two cross entropy losses to update h_Ω.

Updating the distribution parameter Φ: Due to the reparameterization trick, the gradient can be back-propagated from each $\boldsymbol{\delta}_j$ to the parameters Φ. For simplicity, we do not consider the JSD term in Equation (22) due to its complexity. Then we have the terms relevant to Φ as below:

$$\mathop{\mathbb{E}}_{\mathbf{z}\sim\mathcal{N}(0,1)} \sum_{(\mathbf{x}_j,y_j)} H(y_j, h_\Omega(f(\mathbf{x}_j)+\varepsilon\cdot\tanh(\boldsymbol{\mu}+\boldsymbol{\sigma}\mathbf{z}))) - \beta\cdot H(\varepsilon\cdot\tanh(\boldsymbol{\mu}+\boldsymbol{\sigma}\mathbf{z})), \tag{25}$$

where $\beta = \lambda\alpha/(1-\lambda)$. The first term is the cross entropy loss, while the second term is the entropy. The gradient w.r.t. Φ in each term can be calculated. In practice, we approximate the expectation on $\mathbf{z}$ with (e.g., 5) Monte Carlo samples, and perform the *stochastic gradient descent* to update Φ. Details on updating Φ are in Algorithm 3. With Φ, we use it to generate $\boldsymbol{\delta}$ and add it to $\mathbf{r}$ to produce the perturbed representation.

Learning the encoder f. Finally, after updating g_Ψ, h_Ω, and Φ, we can perform gradient ascent to update f.

We iteratively train the networks until reaching a predefined maximum round. Figure 3 illustrates Inf^{2}Guard against DRAs. Algorithm 4 in Appendix details the training process.

4 Theoretical Results

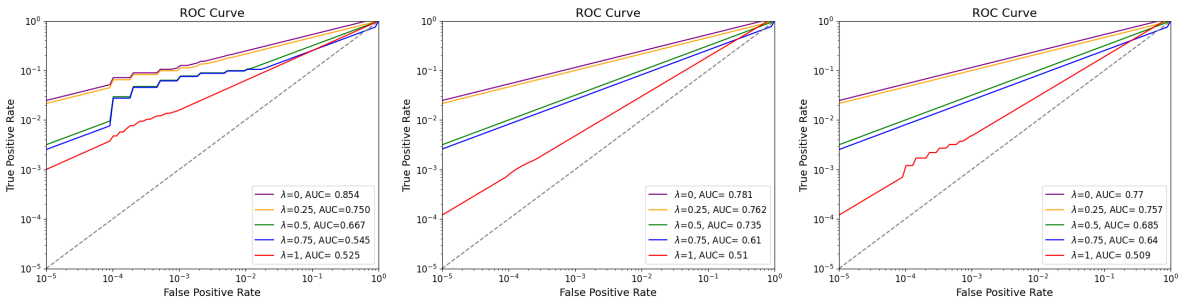
Due to limited space, we mainly show the guaranteed privacy leakage under Inf^{2}Guard. We also derive an inherent utility-privacy tradeoff of Inf^{2}Guard, which requires a binary classification task, and binary-valued dataset property in PIAs. Details and proofs are deferred to the full version.

Guaranteed privacy leakage of MIAs: Let $\mathcal{A}_{MIA}$ be the set of all MIAs $\mathcal{A}_{MIA} = \{A_{MIA} : \mathcal{Z} \to u \in \{0,1\}\}$ that have access to the representations $\mathbf{r}$ by querying f with data $\mathbf{x}$ from the distribution $\mathcal{D}$. The MIA accuracy is bounded as below:

Theorem 1. *Let f be the learnt encoder by Equation (6) over a data distribution $\mathcal{D}\subset\mathcal{X}$. For a random data sample $\mathbf{x}\sim\mathcal{D}$ with the learnt representation $\mathbf{r} = f(\mathbf{x})$ and membership u, we have $Pr(A_{MIA}(\mathbf{r}) = u) \le 1 - \frac{H(u|\mathbf{r})}{2\log_2(6/H(u|\mathbf{r}))}, \forall A_{MIA}\in\mathcal{A}_{MIA}$.*

Remark. Theorem 1 shows if $H(u|\mathbf{r})$ is larger, the bounded MIA accuracy is smaller. Note $H(u|\mathbf{r}) = H(u) - I(u;\mathbf{r})$ and $H(u)$ is a constant. Achieving a large $H(u|\mathbf{r})$ implies obtaining a small $I(u;\mathbf{r})$, which is our **Goal 1** in Equation (1) does. In practice, once the encoder f is learnt on a dataset from $\mathcal{D}$, $I(u;\mathbf{r})$ can be estimated, then the bounded MIA accuracy can be calculated. A better encoder f or/and better MI estimator of $I(u;\mathbf{r})$ can yield a smaller MIA performance.

Guaranteed privacy leakage of PIAs: Let $\mathcal{A}_{PIA}$ be the set of all PIAs that have access to the representations $\mathbf{R}$ of a dataset $\mathbf{X} = \{\mathbf{x}_i\}$ sampled from the data distribution $\mathcal{D}$, i.e., $\mathcal{A}_{PIA} = \{A_{PIA} : \mathcal{Z} \to u = \{0,1\}\}$. The PIA accuracy is bounded as:



Theorem 2. *Let f be the learnt encoder by Equation (11) over a data distribution $\mathcal{D}$. For a random dataset $\mathbf{X}\sim\mathcal{D}$ with the learnt representation $\mathbf{R} = f(\mathbf{X})$ and dataset property u, we have $Pr(A_{PIA}(\mathbf{R}) = u) \le 1 - \frac{H(u|\mathbf{R})}{2\log_2(6/H(u|\mathbf{R}))}, \forall A_{PIA}\in\mathcal{A}_{PIA}$.*

Remark. Theorem 2 shows when $H(u|\mathbf{R})$ is larger, the PIA accuracy is smaller, i.e., less dataset property is leaked. Also, a large $H(u|\mathbf{R})$ indicates a small $I(u;\mathbf{R})$—This is exactly our **Goal 1** in Equation (7) aims to achieve.

Guaranteed privacy leakage of DRAs: Let $\mathcal{A}_{DRA}$ be the set of all DRAs that have access to the perturbed data representations, i.e., $\mathcal{A}_{DRA} = \{A_{DRA} : \mathbf{r}+\boldsymbol{\delta}\in\mathcal{Z}\times\mathcal{P}\to\mathbf{x}\in\mathcal{X}\}$. An ℓ_p-norm ball centered at a point $\mathbf{v}$ with a radius ρ is denoted as $\mathcal{B}_p(\mathbf{v},\rho)$, i.e., $\mathcal{B}_p(\mathbf{v},\rho) = \{\mathbf{v}' : \|\mathbf{v}'-\mathbf{v}\|_p \le \rho\}$. For a space $\mathcal{S}$, we denote its boundary as $\partial\mathcal{S}$, whose volume is denoted as $\mathrm{Vol}(\partial\mathcal{S})$. Then the reconstruction error (in terms of ℓ_p norm difference) incurred by any DRA is bounded as below:

Theorem 3. *Let f be the encoder learnt by Equation (20) over a data distribution $\mathcal{D}\subset\mathcal{X}$ and $\boldsymbol{\delta}$ be the perturbation for a random sample $\mathbf{x}\sim\mathcal{X}$. Then, $Pr(\|A_{DRA}(\mathbf{r}+\boldsymbol{\delta}) - \mathbf{x}\|_p \ge \eta) \ge 1 - \frac{I(\mathbf{x};\mathbf{r}+\boldsymbol{\delta})+\log 2}{\log Vol(\partial\mathcal{X}) - \log Vol(\partial\mathcal{X}(\eta))}, \forall A_{DRA}\in\mathcal{A}_{DRA}$, where $Vol(\partial\mathcal{X}(\eta)) = \max_{\mathbf{x}\in\mathcal{X}} Vol(\partial\mathcal{B}_p(\mathbf{x},\eta)\cap\mathcal{X})$.*

Remark. Theorem 3 shows a lower bound error achieved by the strongest DRA. Given an η, when $I(\mathbf{x};\mathbf{r}+\boldsymbol{\delta})$ is smaller, the lower bound data reconstruction error is larger, meaning the privacy of the data itself is better protected. Moreover, minimizing $I(\mathbf{x};\mathbf{r}+\boldsymbol{\delta})$ is exactly our **Goal 1** in Equation (14).

Figure 4: TPR vs FPR of Inf^{2}Guard against LiRA on different λ's.

5 Evaluations

In this section, we will evaluate Inf^{2}Guard against the MIAs, PIAs, and DRAs on benchmark datasets. Inf^{2}Guard involves training the encoder, the privacy protection network, and the utility preservation network. The detailed dataset description and architectures of the networks are given in the full version.

5.1 Defense Results on MIAs

5.1.1 Experimental setup

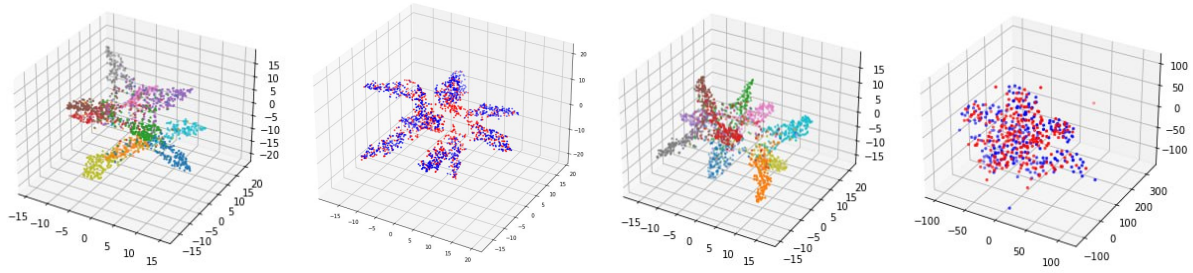
Datasets: Following existing works [35, 45], we use the CIFAR10 [37], Purchase100 [45], and Texas100 [58] datasets, to evaluate Inf^{2}Guard against MIAs.

Defense/attack training and testing: The training sets and test sets are listed in Table 9 in Appendix A. For instance, in CIFAR10, we use 50K samples in total and split it into two halves, where 25K samples are used as the *utility training set* ("members") and the other 25K samples as the *utility test set* ("non-members"). We select 80% of the members and non-members as the *attack training set* and the remaining members and non-members as the *attack test set*.

- **Defense training:** We use the utility training set and attack training set to train the encoder, utility preservation network, and membership protection network simultaneously. Then, the learnt encoder is frozen and published as an API.
- **Attack training:** To mimic the strongest possible MIA, we let the attacker know the exact membership protection network and attack training set used in defense training. Specifically, s/he feeds the attack training set to the learnt encoder to get the data representations and trains the MIA classifier (same as the membership protection network) on these representations to maximally infer the membership.
- **Defense and attack testing:** We use the utility test set to obtain the utility (i.e., test accuracy) via querying the trained encoder and utility network. Moreover, we use the attack test set to obtain the MIA performance.

Privacy metric: We measure the MIA performance via both the MIA accuracy and the true positive rate (TPR) vs. false positive rate (FPR), suggested by the SOTA LiRA MIA [12].

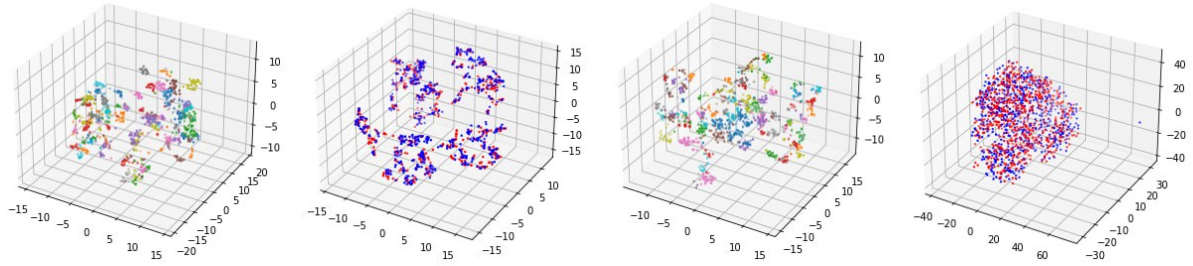
Table 1: Inf^{2}Guard results against MIAs on the three dataset. $\lambda = 0$ means no privacy protection, while $\lambda = 1$ means no utility preservation. Random guessing MIA accuracy is 50%.



CIFAR10			Purchase100			Texas100		
λ	Utility	MIA Acc	λ	Utility	MIA Acc	λ	Utility	MIA Acc
0	78.9%	70.1%	0	81.7%	68.4%	0	49.9%	70.2%
0.25	78.2%	55.9%	0.25	80.9%	60%	0.25	49.1%	61%
0.5	78%	53.5%	0.5	80%	51%	0.5	47%	53%
0.75	77.2%	51.1%	0.75	78%	50%	0.75	46%	50%
1	20%	50%	1	20%	50%	1	2%	50%

Specifically, the MIA accuracy is obtained by querying the trained encoder and trained MIA classifier with the attack test set. Moreover, we treat the representations and membership network learnt by Inf^{2}Guard as the input data and target model for LiRA. We then train 16 *white-box* shadow models (i.e., assume LiRA uses the exact membership network in Inf^{2}Guard) on the data representations of the utility training set, and report the TPR vs. FPR on the attack test set.

5.1.2 Experimental results



Utility-privacy results: According to Equation (6), $\lambda = 0$ indicates no privacy protection. Increasing λ's value enhances Inf^{2}Guard's resilience against MIAs. $\lambda = 1$ means the maximum privacy protection without preserving utility. Table 1 shows the utility-MIA Accuracy results of Inf^{2}Guard. We have the following observations: 1) The MIA accuracy is the largest when $\lambda = 0$, implying leaking the most membership privacy by MIAs. 2) When only protecting privacy ($\lambda = 1$), the MIA accuracy reaches to the optimal random guessing, but the utility is the lowest. 3) When $0 < \lambda < 1$, Inf^{2}Guard obtains reasonable utility and MIA accuracy. Especially, when $\lambda = 0.75$, the utility loss is marginal (i.e., $< 4\%$), while the MIA accuracy is (close to) random guessing. The results show the learnt privacy-preserving encoder/representations are effective against MIAs, and maintain utility as well.

Further, Figure 4 shows the TPR vs FPR of Inf^{2}Guard against LiRA. Similarly, we observe that the TPR at low FPRs is relatively large (strong membership inference) in case of no privacy protection, but it can be largely reduced by increasing λ. This implies that Inf^{2}Guard indeed learns the representations that can defend against LiRA to some extent.

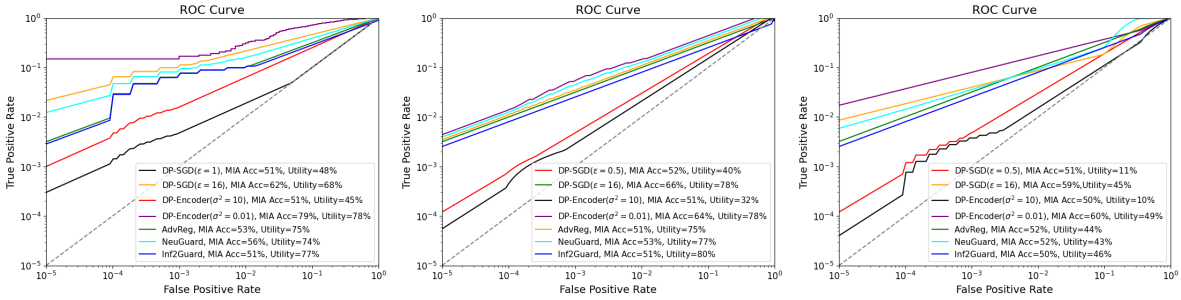

Figure 7: Inf^{2}Guard against MIAs: 3D t-SNE embeddings results on the learnt representation on Texas100.

Visualizing the learnt representations: To better understand the learnt representations by Inf^{2}Guard, we adopt the t-SNE algorithm [64] to visualize the low-dimensional embeddings of them. λ is chosen in Table 1 that achieves the best utility-privacy tradeoff. We also compare with the case without privacy protection. Figures 5-7 show the 3D t-SNE embeddings, where each color corresponds to a label in the learning task or (non)member in the privacy task, and each point is a data sample. We can observe the t-SNE embeddings of the learnt representations without privacy protection for members and non-members are separated to some extent, meaning the membership can be inferred via the learnt MIA classifier. On the contrary, the t-SNE embeddings of the learnt representations by our Inf^{2}Guard for members and non-members are mixed—hence making it difficult for the (best) MIA classifier to infer the membership from these learnt representations.

Comparing with the existing defenses against MIAs: All empirical defenses are broken by stronger attacks [16, 59], except adversarial training-based AdvReg [45] (a special case of Inf^{2}Guard). NeuGuard [71] is a recent empirical defense and shows better performance than, e.g., [35, 57]. Differential privacy is the only defense with privacy guarantees. We propose to use two DP variants, i.e., DP-SGD [3] and DP-encoder (details in Appendix A). The comparison results of these defenses are shown in Table 2 (more DP results in Table 12 in Appendix B) and Figure 8. From Table 2, we observe DP methods have bad utility when ensuring the same level defense performance (w.r.t. MIA accuracy) as Inf^{2}Guard. AdvReg and NeuGuard also perform worse than Inf^{2}Guard.

Table 2: Comparing Inf^{2}Guard with existing defenses against MIAs on the three datasets. DP methods are under the same/close defense performance as Inf^{2}Guard.

Defense	CIFAR10		Purchase100		Texas100	
	Utility	MIA Acc	Utility	MIA Acc	Utility	MIA Acc
DP-SGD	48%	51%	40%	52%	11%	51%
DP-enc	45%	51%	32%	51%	10%	50%
AdvReg	75%	53%	75%	51%	44%	52%
NeuGuard	74%	56%	77%	53%	43%	52%
Inf^{2}Guard	77%	51%	80%	51%	46%	50%

(a) CIFAR10 (b) Purchase100 (c) Texas100

Figure 8: Comparing $\texttt{Inf}^2\texttt{Guard}$ ($\lambda = 0.75$) with the existing defenses against LiRA.

Figure 8 shows the TPR vs. FPR of these defenses against LiRA under the results in Table 2. For DP methods, we also plot the TPR vs FPR when their utility is close to $\texttt{Inf}^2\texttt{Guard}$. With an MIA accuracy close to random guessing (but low utility), we see DP methods have the smallest TPR at a given low FPR. This means DP methods can most reduce the attack effectiveness of LiRA, which is also verified in [12]. However, if DP methods have a close utility as $\texttt{Inf}^2\texttt{Guard}$, their TPRs are much higher than $\texttt{Inf}^2\texttt{Guard}$'s at a low FPR. Besides, $\texttt{Inf}^2\texttt{Guard}$ has smaller TPRs than AdvReg and NeuGuard.

Overhead comparison: All MIA defenses train a task classifier. AdvReg trains a task classifier and membership inference network. NeuGuard trains a task classifier with two regularizations. DP-SGD trains the task classifier on noisy models, while DP-encoder normally trains the encoder first and then trains the utility network on (Gaussian) noisy representations. In the experiments, we define the task classifier of the compared defenses as the concatenation of our encoder and utility network. In our platform (NVIDIA GeForce RTX 3070 Ti), it took $\texttt{Inf}^2\texttt{Guard}$ (72,7,6), AdvReg (66,6,6), NeuGuard (62,5,5), DP-SGD (60,4,3) and DP-encoder (59,4,3) seconds to run each iteration on the three datasets, respectively[9].

5.2 Defense Results on PIAs

5.2.1 Experimental setup

Datasets: Following recent works [13, 63], we use three datasets (Census [63], RSNA [63], and CelebA [40]) and treat the female ratio as the private dataset property.

Defense/attack training and testing: We first predefine a (different) female ratio set in each dataset. For each female ratio, we generate a number of subsets from the training set and test set with different subset sizes. The generated training/test subsets and all data samples in these subsets are treated as the attack training/test set and the utility training/test set, respectively. More details are in Table 10 in Appendix A.

- **Defense training:** We use the utility training set and attack training set to train the encoder, utility preservation network, and property protection network simultaneously. Then, the learnt encoder is frozen and published as an API.

[9] We have similar conclusions on defending against the other two attacks.

Table 3: $\texttt{Inf}^2\texttt{Guard}$ results against PIAs with a **mean**-aggregation. $\lambda = 0$ means no privacy protection, while $\lambda = 1$ means no utility preservation. Random guessing PIA accuracy on the three datasets are 25%, 14.3%, and 9.1%, respectively.

Census			RSNA			CelebA		
λ	Utility	PIA Acc	λ	Utility	PIA Acc	λ	Utility	PIA Acc
0	85%	68%	0	83%	52%	0	91%	50%
0.25	80%	61%	0.25	82%	25%	0.25	91%	28%
0.5	78%	52%	0.5	82%	24%	0.5	91%	17%
0.75	76%	34%	0.75	80%	19%	0.75	89%	11%
1	45%	26%	1	50%	15%	1	53%	10%

- **Attack training:** We mimic the strongest possible PIA, where the attacker knows the exact property protection network, the aggregator, and attack training set used in defense training. Specifically, s/he feeds each subset in the attack training set to the learn encoder to get the subset representation, applies the aggregator to obtained the aggregated representation, and trains the PIA classifier (same as the property protection network) on these aggregated representations to maximally infer the private female ratio.
- **Defense/attack testing:** We utilize the utility test set to obtain the utility via querying the trained encoder and utility network, and the attack test set to obtain the PIA accuracy via querying the trained encoder and trained PIA classifier.

5.2.2 Experimental results

Utility-privacy results: Table 3 shows the utility-privacy results of $\texttt{Inf}^2\texttt{Guard}$, where the encoder uses a mean-aggregator (i.e., average the representations of a subset of data. Note different subsets have different sizes). We have similar observations as in defending against MIAs: 1) The PIA accuracy can be as large as 68% without privacy protection ($\lambda = 0$ in Equation (11)), implying the PIA is effective; 2) When focusing on protecting privacy ($\lambda = 1$), the PIA performance can be largely reduced. However, the utility is also significantly decreased, e.g., from 85% to 45%. 3) Utility and privacy show a tradeoff w.r.t. $0 < \lambda < 1$. In most of the cases, the best tradeoff is obtained when $\lambda = 0.75$. Again, the results show the learnt privacy-preserving encoder/representations are effective against PIAs, and also maintain utility.

Table 4: Inf^{2}Guard results against PIAs with a **max**-aggregation. Random guessing PIA accuracy on the three datasets are 25%, 14.3%, and 9.1%, respectively.

Census			RSNA			CelebA		
λ	Utility	PIA Acc	λ	Utility	PIA Acc	λ	Utility	PIA Acc
0	85%	65%	0	83%	52%	0	91%	50%
0.25	83%	51%	0.25	82%	24%	0.25	91%	25%
0.5	79%	49%	0.5	82%	24%	0.5	91%	15%
0.75	77%	37%	0.75	81%	21%	0.75	88%	15%
1	47%	30%	1	50%	16%	1	53%	9%

Table 5: Comparing Inf^{2}Guard with DP against PIAs.

Defense	Census		RSNA		CelebA	
	Utility	PIA Acc	Utility	PIA Acc	Utility	PIA Acc
DP-encoder	52%	34%	57%	19%	66%	11%
Inf^{2}Guard	76%	34%	80%	19%	89%	11%

Visualizing the learnt representations: Figures 12-14 in Appendix B show the 3D t-SNE embeddings of the learnt representations with $\lambda = 0, 0.75$. Similarly, we observe the t-SNE embeddings of the aggregated representations without privacy protection can be separated to a large extent, while those with privacy protection by Inf^{2}Guard are mixed. This again verifies it is difficult for the (best) PIA to infer the private female ratio from the representations learnt by Inf^{2}Guard.

Impact of the aggregator used by the encoder: In this experiment, we test the impact of the aggregator and choose a max-aggregator for evaluation, where we select the element-wise maximum value of the representations of each subset of data. Table 4 shows the results. We have similar conclusions as those with the mean-aggregator. In addition, Inf^{2}Guard with the max-aggregator has slightly worse utility-privacy tradeoff, compared with the mean-aggregator. A possible reason could be the mean-aggregator uses more information of the subset representations than the max-aggregator.

Comparing with the DP-based defense: There exists no effective defense against PIAs, and [63] shows DP-SGD [3] does not work well. Here, we propose to use a DP variant called DP-encoder, similar to that against MIAs. More details about DP-encoder are in Appendix A. The compared results are shown in Table 5. We can see that, with the same level privacy protection as Inf^{2}Guard, DP has much worse utility.

5.3 Defense Results on DRAs

5.3.1 Experimental setup

Datasets: We select two image datasets: CIFAR10 [37] and CIFAR100 [37], and one human activity recognition dataset Activity [51] to evaluate Inf^{2}Guard against DRAs.

Defense/attack training and testing: Table 11 in Appendix shows the statistics of the utility/attack training and test sets.

- **Defense training:** We use the training set to train the encoder, utility preservation network, reconstruction protection network, and update the perturbation distribution parameters, simultaneously. Then, the learnt encoder and perturbation distribution are published.

Table 6: Inf^{2}Guard results against DRAs. A smaller SSIM or PSNR indicates better defense performance (λ =0.4).

CIFAR10			CIFAR100			Activity		
Scale ε	Utility	SSIM/PSNR	ε	Utility	SSIM/PSNR	ε	Utility	MSE
0	89.5%	0.78 / 15.97	0	52.7%	0.92 / 22.79	0	95.1%	0.81
0.75	85.2%	0.42 / 12.09	0.75	49.1%	0.36 / 13.36	0.5	90.1%	1.06
1.25	**78.0%**	**0.21 / 11.87**	1.00	**46.5%**	**0.19 / 12.70**	1.0	**85.6%**	**1.32**
1.75	68.9%	0.17 / 11.21	1.25	43.3%	0.14 / 12.29	1.5	81.0%	1.64

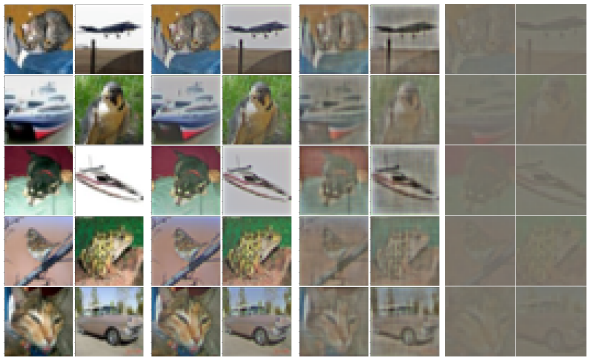
Table 7: Impact of λ on Inf^{2}Guard against DRAs ($\varepsilon = 1.25$).

CIFAR10			CIFAR100			Activity		
λ	Utility	SSIM/PSNR	λ	Utility	SSIM/PSNR	λ	Utility	MSE
0.1	83.2%	0.52 / 12.79	0.1	46.8%	0.46 / 14.75	0.1	90.0%	1.25
0.4	78.0%	0.21 / 11.87	0.4	46.5%	0.21 / 12.70	0.4	85.6%	1.32
0.7	67.9%	0.15 / 11.43	0.7	46.5%	0.20 / 12.42	0.7	85.0%	1.62

- **Attack training:** We mimic the strongest DRA, where the attacker knows the reconstruction protection network, training set, and perturbation distribution. S/he feeds each training data to the learnt encoder + perturbation distribution to get the perturbed representation. Then the attacker trains the reconstruction network (using the pair of input data and its perturbed representation) to infer the training data.
- **Defense/attack testing:** We use the utility test set to obtain the utility via querying the encoder and utility network; and use the attack test set to obtain the DRA performance by querying the trained encoder and reconstruction network.

Privacy metric: For image datasets, we use the common Structural Similarity Index Measure (SSIM) and PSNR metrics [27]. A larger SSIM (or PSNR) between two images indicate they look more similar. An effective attack aims to achieve a large SSIM (or PSNR), while the defender does the opposite. For human activity dataset, we use the mean-square error (MSE) between two samples to measure similarity. A smaller/larger MSE indicates a more effective attack/defense.

5.3.2 Experimental results



Utility-privacy results: Table 6 shows the defense results of Inf^{2}Guard with the Gaussian perturbation distribution, where $\lambda = 0.4$ in Equation (20). We can observe ε acts a utility-privacy tradeoff. A larger ε implies adding more perturbation to the representation during defense training. This makes the DRA more challenging, but also sacrifice the utility more.

We also test the impact of λ and the results are shown in Table 7. We can see λ also acts as a tradeoff—a larger λ can protect data privacy more, while having larger utility loss.

Comparing with the DP-based defense: All empirical defenses against DRAs are broken are by an advanced attack [9]. A few papers [7, 53] show if a randomized algorithm satisfies DP, it can defend against DRAs with provable guarantees. We compare Inf^{2}Guard with DP and Table 8 shows the DP results. Viewing with results in Table 6, we see Inf^{2}Guard obtains better utility-privacy tradeoffs than DP-SGD.

Table 8: DP-SGD defense results against DRAs. A smaller SSIM or PSNR indicates better defense performance.

CIFAR10			CIFAR100			Activity		
Scale ε	Utility	SSIM/PSNR	ε	Utility	SSIM/PSNR	ε	Utility	MSE
0	89.5%	0.78 / 15.97	0	52.7%	0.92 / 22.79	0	95.1%	0.81
0.75	85.6%	0.50 / 13.21	0.75	49.5%	0.43 / 13.77	0.5	91.8%	0.88
1.25	**77.4%**	**0.37 / 12.45**	1.00	**46.7%**	**0.24 / 12.87**	1.0	90.1%	0.90
1.75	65.3%	0.36 / 12.35	1.25	43.3%	0.18 / 12.54	1.5	**84.1%**	**1.01**

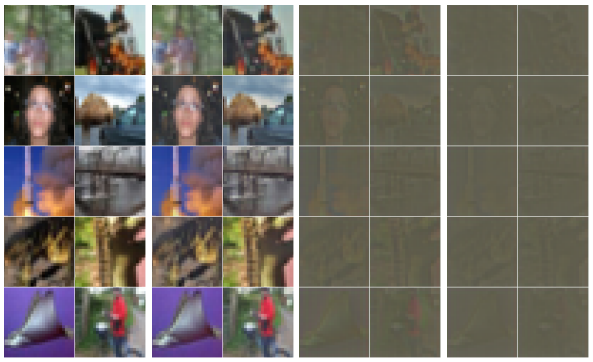

Figure 9: Raw images vs. reconstructions on CIFAR10. DP Utility: 77%, Inf^{2}Guard Utility: 78%.

Visualizing data reconstruction results: Figure 9 and Figure 10 show the reconstruction results on some CIFAR10 and CIFAR100 images, respectively. We see that, without defense, the attacker can accurately reconstruct the raw images. With a similar utility, visually, Inf^{2}Guard can better defend against image reconstruction than DP. Figure 11 summarizes the reconstruction results on 50 samples in Activity, where we report the difference between each reconstructed feature by Inf^{2}Guard and that by DP to the true feature. A (larger) positive value implies Inf^{2}Guard is (more) dissimilar than DP to the true feature. We can see Inf^{2}Guard has better defense results than DP in most (413 out of 516) of the features.

6 Discussion and Future Work

Inf^{2}Guard and DP: Essentially, Inf^{2}Guard and DP are two different provable privacy mechanisms, and they complement each other. First, DP mainly measures the user or sample-level privacy risks in the worst case while Inf^{2}Guard can accurately measure the average privacy risks at the dataset level with the derived bounds. Second, DP has been shown to provide some resilience transferability across some inference attacks [53] (but not all of them). It is also interesting to study the resilience transferability for the proposed Inf^{2}Guard, which we will explore in the future. More importantly, our Inf^{2}Guard can complement DP. For instance, we can use the learnt (deterministic) data representations by Inf^{2}Guard as input to DP-SGD or add (Gaussian) noise to the representations to ensure DP guarantees against MIAs.

Task-agnostic representation learning: Our current MI formulation for utility preservation knows the labels of the learning task (e.g., see Equation (2)). A more promising solution would be task-agnostic, i.e., learning task-agnostic representations that can benefit many (unknown) downstream tasks. We note that our framework can be easily extended to this scenario. For instance, in MIAs, we now require the learnt representation $\mathbf{r}$ includes as much information about the *training* sample $\mathbf{x}$ as possible (i.e., $u = 1$). Intuitively, when $\mathbf{r}$ retains all information about $\mathbf{x}$, the model trained on $\mathbf{r}$ will have the same performance as trained on the raw $\mathbf{x}$, despite the learning task. Formally, the MI objective becomes $\max_f I(\mathbf{x};\mathbf{r}|u=1)$.

(a) Raw images (b) No defense (c) DP (d) Inf^{2}Guard

Figure 10: Raw images vs. reconstructions on CIFAR100. DP Utility: 47%, Inf^{2}Guard Utility: 47%. Better zoom in.

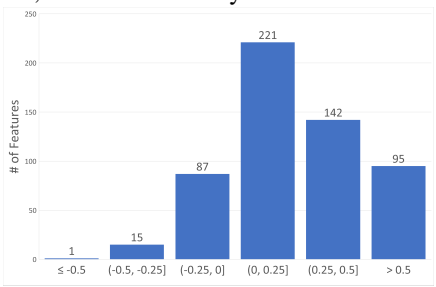

Figure 11: Inf^{2}Guard vs. DP on 50 samples in Activity (both utility=86%). We count #features located in each bin. The value range in each bin means the difference between the reconstructed feature by Inf^{2}Guard and that by DP to the true feature. A positive value implies Inf^{2}Guard produces more dissimilar reconstruction than DP.

Defending against multiple inference attacks simultaneously: We design the customized MI objectives to defend against each inference attack in the paper. A natural solution to defend against multiple inference attacks is unifying their training objectives (by summarizing them with tradeoff hyperparameters). While this is possible, we emphasize that the learnt encoder is weak against all attacks. This is because the encoder should balance the defense effectiveness among these attacks, and cannot be optimal against all of them.

Generalizing our theoretical results: Our theoretical results assume the learning task is binary classification and dataset property is binary-valued. We will generalize our theoretical results to multiclass classification and other types of learning such as regression and multi-valued dataset property.

Generalizing our framework against security attacks: In our current framework, each privacy protection task is formalized via an MI objective. An important future work would be generalizing our framework to design customized MI objectives to learn robust representations against security attacks such as evasion, poisoning, and backdoor attacks.

7 Related Work

7.1 MIAs and Defenses

MIAs [12, 14, 16, 31, 39, 54, 58–60, 70, 73, 76]. Existing MIAs can be classified as *training based* [12, 14, 16, 39, 52, 54, 58, 60, 72, 73] and *non-training based* [16, 59]. Given a (non)training sample and its output by a target ML model, training based MIAs use the (sample, output) pair to train a binary classifier, which is then used to determine whether a testing sample belongs to the training set or not. For instance, [58] introduces multiple shadow models to perform training. In contrast, non-training based MIAs directly use the samples' predicted score/label to make decisions. For instance, [59] designs a metric *prediction correctness*, which infers the membership based on whether a given sample is correctly classified by the target model or not. Overall, an MIA that has more information is often more effective than that has less information.

Defenses [35, 45, 54, 56, 58, 59, 61, 71]. They can be categorized as *training time* based defense (e.g., dropout [54], L_2 norm regularization [58], model stacking [54], adversary regularization [45], loss variance deduction [71], DP [3, 32, 75], early stopping [59], knowledge distillation [56]) and *inference time* based defense (e.g., MemGuard [35]). Almost all of them are empirical and broken by stronger attacks [16, 59]. DP is only defense offering privacy guarantees. Its main idea is to add noise to the gradient [3, 75] or objective function [32] during training. The main drawback of current DP methods is that they have significant utility losses [33, 56].

7.2 PIAs and Defenses

PIAs [5, 6, 13, 20, 24, 41, 42, 63, 66, 77, 79]. Ateniese et al. [6] are the first to describe the problem of the PIA (against support vector machines and hidden Markov models), where the attack is performed in the the white-box setting and consists of training a meta-classifier on top of many shadow models. Ganju et al. [20] extend PIAs to neural networks, particularly fully connected neural networks (FCNNs). Zhang et al. [77] propose PIAs in the black-box setting and train a meta-classifier based on shadow models. Mahloujifar et al. [41] observe that data poisoning attacks can be incorporated into training the shadow model and increase the effectiveness of PIAs. Suri and Evans [63] are the first to formally formalize PIAs as a cryptographic game, inspired by the way to formalize MIAs [73]. They also extend the white-box attack on FCNNs [20] to convolutional neural networks (CNNs). Zhou et al. [79] develop the first PIA against generative models, i.e., generative adversarial networks (GANs) [23], under the black-box setting. Chaudhari et al. [13] propose a data poisoning strategy to perform the efficient private property inference.

Defenses. To our best knowledge, there exist no known effective defenses against PIAs. DP cannot mitigate PIAs since it obfuscates individual samples, while PIAs care about the entire datasets [63]. [63] also shows that DP does not work as a potential defense (also verified in Section 5).

7.3 DRAs and Defenses

DRAs [7–9, 19, 22, 27, 28, 34, 67, 68, 74, 78, 81]. Existing DRAs mainly reconstruct the training data from the model parameters or representations. They are formulated as an optimization problem that minimizes the difference between gradient from the raw training data and that from the reconstructed data. For instance, Zhu et al. [81] proposed a DLG attack method which relies entirely on minimization of the difference of gradients. Furthermore, several methods [22, 28, 34, 67, 74] propose to incorporate prior knowledge (e.g., total variation regularization [22, 74], batch normalization statistics [74]) into the training data, or introduce an auxiliary dataset to simulate the training data distribution [28, 34, 67] (e.g., via GANs [23]). A few works [22, 80] derive close-formed solutions to reconstruct the data, by constraining the neural networks to be fully connected [22] or convolutional [80].

Defenses [21, 25, 38, 48, 55, 62, 69, 81]. Most of these defenses have none/little privacy guarantees. For instance, Zhu et al. [81] propose to prune model parameters with smaller magnitudes. Sun et al. [62] propose to obfuscate the gradient for a single layer (called defender layer) such that the reconstructed data and the original data are dissimilar. Gao et al. [21] propose to generate augmented images that, when they are used to train the network, produce non-invertible gradients. These defenses are broken by an advanced attack based on Bayesian learning [9]. Only defenses based on DP-SGD [3], a version of SGD with clipping and adding Gaussian noise, provide formal privacy guarantees.

8 Conclusion

We propose a unified information-theoretic framework, dubbed `Inf`^{2}`Guard`, to learn privacy-preserving representations against the three major types of inferences attacks (i.e., membership inference, property inference, and data reconstruction attacks). The framework formalizes the utility preservation and privacy protection against each attack via customized mutual information objectives. The framework also enables deriving theoretical results, e.g., inherent utility-privacy tradeoff, and guaranteed privacy leakage against each attack. Extensive evaluations verify the effectiveness of `Inf`^{2}`Guard` for learning privacy-preserving representations and show the superiority over the compared baselines.

Algorithm 1 `Inf`^{2}`Guard` against MIAs

Input: Dataset D_1 of members and dataset D_0 of non-members, tradeoff hyperparameter $\lambda \in [0,1]$, learning rates lr_1, lr_2, lr_3; #local gradients I, #global rounds T.
Output: Network parameters: Θ, Ψ, Ω.

Initialize Θ, Ψ, Ω for the encoder f, membership protection network g_Ψ, and utility preservation network h_ϕ;
for $t = 1$ to T **do**
  $L_1 = \sum_{(\mathbf{x}_j, u_j) \in D_1 \cup D_0} H(u_j, g_\Psi(f(\mathbf{x}_j)))$;
  $L_2 = \sum_{(\mathbf{x}_j, y_j) \in D_1} H(y_j, h_\Omega(f(\mathbf{x}_j)))$;
  for $i = 1$ to I **do**
    $\Psi \leftarrow \Psi - lr_1 \cdot \frac{\partial L_1}{\partial \Psi}$;
    $\Omega \leftarrow \Omega - lr_2 \cdot \frac{\partial L_2}{\partial \Omega}$;
    $\Theta \leftarrow \Theta + lr_3 \cdot \frac{\partial(\lambda L_1 - (1-\lambda) L_2)}{\partial \Theta}$;

Algorithm 2 `Inf`^{2}`Guard` against PIAs

Input: N datasets $\{D_j\}_{j=1}^N$ sampled from a reference dataset D_r with each D_j having a property value u_j, tradeoff hyperparameter $\lambda \in [0,1]$, learning rates lr_1, lr_2, lr_3; #local gradients I, #global rounds T.
Output: Network parameters: Θ, Ω, Ψ.

Initialize Θ, Ψ, Ω for the encoder f, property protection network g_Ψ, and utility preservation network h_ϕ;
for round $t = 1$ to T **do**
  $L_1 = \sum_{\{(\mathbf{x}_j, \mathbf{y}_j) = D_j\}_j} H(u_j, g_\Psi(f(\mathbf{X}_j)))$;
  $L_2 = \sum_{(\mathbf{x}_i, y_i) \in \bigcup_j D_j} H(y_i, h_\Omega(f(\mathbf{x}_i)))$;
  for $i = 1$ to I **do**
    $\Psi \leftarrow \Psi - lr_1 \cdot \frac{\partial L_1}{\partial \Psi}$;
    $\Omega \leftarrow \Omega - lr_2 \cdot \frac{\partial L_2}{\partial \Omega}$;
    $\Theta \leftarrow \Theta + lr_3 \cdot \frac{\partial(\lambda L_1 - (1-\lambda) L_2}{\partial \Theta}$.

Algorithm 3 Update perturbation distribution parameter Φ

Input: K Monte Carlo samples, the encoder f_Θ in the previous round, objective function Eqn (20). learning rate lr, #epochs I_l
Output: Perturbation distribution parameters Φ

Initialize $\Phi = (\boldsymbol{\mu}, \boldsymbol{\sigma})$.
for $i = 1$ to I_l **do**
  for $j = 1$ to K **do**
    Sample $\mathbf{z}_j$ from $\mathcal{N}(0,1)$ and compute $\boldsymbol{\delta}_j = \boldsymbol{\mu} + \boldsymbol{\sigma} \boldsymbol{z}_j$;
    Calculate the gradient $\mathbf{g}_\Phi$ of Eqn (25) w.r.t. Φ;
    Update Φ by: $\Phi \leftarrow \Phi - lr \cdot \mathbf{g}_\Phi$.

Algorithm 4 `Inf`^{2}`Guard` against DRAs

Input: A dataset $D = \{\mathbf{x}_n, y_n\}$, hyperparameters $\lambda \in [0,1]$, learning rates lr_1, lr_2, lr_3, #local gradients I, #global rounds T.
Output: Network parameters: Ω, Ψ, Θ.

Initialize $\Theta, \Psi, \Omega, \Phi$ for the encoder f, data reconstruction network g_Ψ, utility preservation network h_Ω, and perturbation distribution parameter.
for round $t = 1$ to T **do**
  for each batch $bs \subset D$ **do**
    Update Φ via Algorithm 3;
    Update g_Ψ (given Θ and $\{\boldsymbol{\delta}_i\}$): Calculate $I^{(JSD)}_{\Theta,\Psi}$ on bs with $\{\boldsymbol{\delta}_i\}$ via Eqn (22); $\Psi \leftarrow \Psi + lr_1 \cdot \partial I^{(JSD)}_{\Theta,\Psi} / \partial \Psi$;
    Update h_Ω (given Θ and $\{\boldsymbol{\delta}_i\}$): Calculate CE loss L_1 on bs with $\{\boldsymbol{\delta}_i\}$ via Eqn (23); Calculate CE loss L_2 on bs with clean data via Eqn (24); $\Omega \leftarrow \Omega - lr_2 \cdot \partial(L_1 + L_2)/\partial \Omega$;
    Update f_Θ (given Ψ, Ω, and $\{\boldsymbol{\delta}_i\}$): $\Theta \leftarrow \Theta - lr_3 \cdot \frac{\partial}{\partial \Theta}(\lambda I^{(JSD)}_{\Theta,\Psi} + (1-\lambda)(L_1 + L_2))$;

A More Experimental Setup

Training and testing: Table 9-Table 11 show the utility training/test and attack training/test sets on the three datasets.

Differential Privacy (DP) against MIAs: DP provides an upper bound on the success of any MIA. We can add noise in several ways (e.g., to input data, model parameters, gradients, latent features, output scores) to ensure DP. Note that there exists an inherent trade-off between utility and privacy: a larger added noise often leads to a higher level of privacy protection, but incurs a larger utility loss. Here, we propose to use the below two ways.

- **DP-SGD [3]:** *1) DP-SGD training:* It clips gradients (with a gradient norm bound) and adds Gaussian noise to the gradient in each SGD round when training the ML model (i.e., encoder + utility network). More details can be seen in Algorithm 1 in [3]. After training, the model ensures DP guarantees and the encoder is published. *2) Attack training:* The attacker obtains the representations of the attack training data via querying the trained encoder and uses these representations to train the MIA classifier. *3) Defense/attack testing:* The utility test set is used to obtain the utility via querying the trained ML model; and the attack test set to obtain the MIA accuracy via querying the trained encoder and trained MIA classifier.

  We used the Opacus library (https://opacus.ai/), a PyTorch extension that enables training models with DP-SGD and dynamically tracks privacy budget and utility. In the experiments, we tried ε in DP-SGD from 0.5 to 16.

- **DP-encoder:** *1) Normal training:* It first trains the encoder + utility network using the (utility) training set. The encoder is then frozen and can be used to produce data representations when queried by data samples. *2) Defense via adding noise to the representations:* We add Gaussian noise to the representations by querying the encoder with the attack training data to produce the noisy representations. *Notice that, since the Gaussian noises are injected to the matrix-outputs (data representations), if needed, the actual DP guarantee (i.e., privacy bounds) can be derived via Rényi Differential Privacy [43], similar to the theoretical studies in [44, 65]. We skip the details here since this work does not focus on the derivation for the privacy bounds of DP-encoder. 3) Attack training:* The attacker uses the noisy representations of attack training data to train the MIA classifier. *4) Defense/attack testing:* We use the utility test set to obtain the utility via querying the trained encoder and utility network; and use the attack test set to obtain the MIA accuracy on the trained encoder and trained MIA classifier. We call this *DP-encoder* as we add noise to the representations outputted by the well-trained encoder.

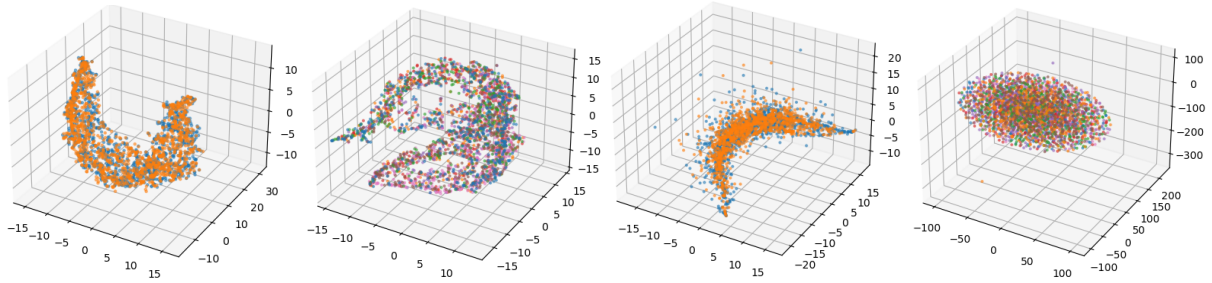
0.5	82%	44%	0.5	82%	21%	0.5	91%	15%
0.75	81%	28%	0.75	81%	15%	0.75	88%	9%
1	60%	25%	1	60%	14%	1	63%	9%



DP-encoder against PIAs: We follow the strategy in DP against MIAs and choose the DP-encoder, as DP-SGD is ineffective in this setting [63]. The only difference is that we now add Gaussian noise to the mean-*aggregated* representation of a subset, instead of the individual representation.

Data reconstruction attack/defense on shallow encoder: As shown in [27], when the encoder is deep, it is difficult for the attacker to reconstruct the input data from the representation. To ensure DRAs be effective, we use a shallow 2-layer encoder. As a result, this makes the defense more challenging.

B More Experimental Results

More results on defending against MIAs: Table 12 shows more DP results (vs varying ε's) against MIAs. We can see Inf^{2}Guard obtains higher utility than DP methods under the same privacy protection performance.

More results on defending against PIAs: Figure 12-Figure 14 shows the t-SNE embeddings of Inf^{2}Guard against PIAs. Table 13 shows Inf^{2}Guard results against PIAs, where the attacker does not the true (mean) aggregator and use a substitute one (i.e., max-aggregator). We can see the attack performance is less effective and Inf^{2}Guard can yield (close to) random guessing attack performance (when $\gamma = 0.75$), with a slight utility loss. This implies the aggregator plays a critical role in designing effective PIAs against Inf^{2}Guard.

Table 14: Inf^{2}Guard results against DRAs with uniform perturbation distribution. A smaller SSIM or PSNR indicates better defense performance (λ =0.4).

CIFAR10		
Scale ε	Utility	SSIM/PSNR
0	89.5%	0.78 / 15.97
1.25	85.7%	0.28 / 13.23
2.25	77.7%	0.24 / 12.34
3.25	64.9%	0.20 / 12.93

More results on defending against DRAs: Table 14 shows the Inf^{2}Guard results against DRAs, where the perturbation distribution is uniform distribution. We observe similar utility-privacy tradeoff in terms of the noise scale ε.

Property Existence Inference against Generative Models

Abstract

Generative models have served as the backbone of versatile tools with a wide range of applications across various fields in recent years. However, it has been demonstrated that privacy concerns, such as membership information leakage of the training dataset, exist for generative models. In this paper, we perform *property existence inference* against generative models as a new type of information leakage, which aims to infer whether any samples with a given property are contained in the training set. For example, to infer if any images (i.e., samples) of a specific brand of cars (i.e., property) are used to train the target model. We focus on the leakage of existence information of properties with very low proportions in the training set, which has been overlooked in previous works. We leverage the feature-level consistency of the generated data with the training data to launch inferences and validate the property existence information leakage across diverse architectures of generative models. We have examined various factors influencing the property existence inference and investigated how generated samples leak property existence information. In our conclusion, most generative models are vulnerable to property existence inferences. Additionally, we have validated our attack in Stable Diffusion which is a large-scale open-source generative model in real-world scenarios, and demonstrated its risk of property existence information leakage. The source code is available at https://github.com/wljLlla/PEI_Code.

1 Introduction

Remarkable progress has been made in generative models with numerous new models outperforming previous models in terms of fidelity and scalability. The development of generative models has driven their use in commercial applications. Generative models like Stable Diffusion [36] and Imagen [37] provide interfaces for receiving user-input captions (descriptions of the desired generated data), allowing users to generate data with a payment. Many previous studies [3,5,17,41,44,58] have indicated that generative models can leak sensitive private information of their training sets. Existing information leakages of the training sets include the membership information leakage in GANs [5, 14, 17] and Diffusion Models [58], the property information leakage in GANs [57], and the duplication phenomena between the generated images and the training images of Diffusion Models and GANs [3,44]. These leakages can be classified into two types based on the object of the information: leakage of the global information of the training set and the leakage of the information of specific samples in the training set.

Many inference attacks emerge to obtain sensitive information from the training set. Among these, the most popular inference attacks against generative models are the property inference and the membership inference. For the leakage of global information, the property inference is proposed to infer the proportion of global properties of the training set, such as the proportion of a gender in a facial generative model. For the leakage of the information of specific samples, the membership inference is proposed to infer whether a specific sample exists in the training set, such as the existence of a specific facial image in a facial generative model.

In this paper, we focus on an inference attack against generative models called property existence inference, which aims to infer whether any samples with the target property are used to train the target model. Compared to property inference, property existence inference focuses on the leakage of more personal and personalized privacy. For example, while property inference will choose property such as gender in the inference of facial generative models, property existence inference focuses on more personally sensitive properties, such as individual identities. Compared to membership inference, property existence inference is evaluated under a more practical setting where no samples in the training set can be obtained by the adversary. The property existence inference carries potential privacy risks. With the property existence

* Corresponding author

inference, personal and personalized information can be inferred from the generative model that trainers may not want to share, such as whether specific individuals' images have been used to train the target model. Property existence inference can also be used to determine the presence of unauthorized data in the training set. For instance, if a vehicle manufacturer does not want images of their cars to be used for generating similar-model images, they can perform property existence inference to safeguard copyright.

We perform the property existence inference under the most practical black-box setting and design the method with the motivation that generative models will generate data with features related to the properties existing in the training set. For example, an image generated by a facial generative model may not depict the face of a specific person from the training set, but it may be similar in features like eyes to individuals in the training set. Therefore, we perform property existence inference through similarity comparisons between the generated images and the images with the target property. Specifically, we do the similarity comparison in the embedding space based on a well-trained property extractor which learns to distinguish features from different properties. During this stage, we mitigate data-induced uncertainties in similarity scores. We finally train shadow models to simulate the behavior of the target model and obtain the similarity score distributions of properties existing and not existing in the training set, to select a threshold for making the final decision.

We conduct comprehensive evaluations and find that generative models used in the evaluations including Stable Diffusion [36], the largest open-source diffusion model, exhibit the potential risk of property existence information leakage. Our method effectively determines whether the target properties exist in the training set. For example, we obtain AUCs for determining the existence of the target properties above 0.81 and 0.95 in generative models trained on ImageNet and CompCars respectively. Based on our evaluations of state-of-the-art generative models, it can be concluded that most of the generative models we evaluated suffer from property existence information leakage. To gain a deeper understanding of property existence inference, we further investigate the elements that impact the effectiveness of the property existence inference such as the size of the training sets, the adversary knowledge and the granularity of properties. Our evaluations further reveal that there is an increased risk of property existence information leakage for a generated image that closely resembles a larger number of samples that share the same properties as those in the training set.

Contributions. We summarize our contributions in the following.

- To the best of our knowledge, we are the first to perform the property existence inference against generative models and emphasize that property existence inference should focus on properties with very low proportions.
- We propose a method to perform the property existence inference by exploiting the differences in similarities between the generated samples and samples with the target property, based on whether or not the target property is present in the training set.
- We have conducted comprehensive evaluations on the state-of-the-art generative models including large-scale models like Stable Diffusion to study the effectiveness of our method and explored which generated samples are most likely to be utilized to extract information.

Roadmap. In Section 2, we introduce the generative models and the property inferences. In Section 3, we formally define the property existence inference and clarify the threat model. In Section 4, we detail the method to perform the property existence inferences. In Section 5, we analyze the effectiveness of property existence inference under different generative models and the factors that affect the attack effectiveness. In Section 6, we discuss the related work. In Section 7, we discuss the cost and effectiveness of our method. In Section 8, we conclude our work.

2 Background

2.1 Generative Models

We focus on three types of generative models: generative adversarial networks (GANs) [12], Variational Auto-Encoder (VAEs) [24] and Diffusion Models [8, 18, 34–37, 47].

GANs. GAN [12] consists of a generator G and a discriminator D. The generator is trained to learn the underlying distribution of the real data p_{data} by minimizing the divergence between the distribution p_{data} and the distribution of the generated data p_g, while the discriminator is trained to distinguish the two distributions p_{data} and p_g. The generator and the discriminator are trained simultaneously in an adversarial manner using the objective function below:

$$\min_G \max_D V(D,G) = \mathbb{E}_{x\sim p_{\text{data}}(x)}[\log D(x)] + \mathbb{E}_{z\sim p_z(z)}[\log(1-D(G(z)))]$$

where z is the input of the generator sampled from $p_z(z)$.

VAEs. As another broadly used generative model, VAE [24] maximizes the lower bound of the log-likelihood $\log p(x)$ of all observed real data x. The lower bound is quantified as the evidence lower bound (ELBO) and can be derived as the left term of the following equation:

$$\mathbb{E}_{q_\phi(z|x)}\left[\log \frac{p(x,z)}{q_\phi(z\mid x)}\right] = \mathbb{E}_{q_\phi(z|x)}\left[\log p_\theta(x\mid z)\right] - D_{\text{KL}}\left(q_\phi(z\mid x)\|p(z)\right) \quad (1)$$

where $q_\phi(z\mid x)$ is the approximated posterior parameterized by ϕ, and $\log p_\theta(x\mid z)$ denotes the deterministic func-

tion parameterized by θ that converts a given latent variables z into an observation x. As Equation 1 shows, ELBO can be derived as the difference between the reconstruction term $\mathbb{E}_{q_\phi(z|x)}[\log p_\theta(x \mid z)]$ and the prior KL divergence term $D_{\mathrm{KL}}\left(q_\phi(z \mid x) \| p(z)\right)$.

VAE uses an encoder parameterized by ϕ to approximate the posterior distribution and a decoder parameterized by θ to generate the data from latent variables z. Therefore, VAE maximizes ELBO by optimizing parameters ϕ and θ.

Diffusion Models. The training of diffusion models involves two Markovian procedures: the forward diffusion process and the backward denoising process. In the forward diffusion process, Gaussian noise is added to the input data x_0 in T steps until x_0 is transformed into a standard Gaussian noise x_T. Transitions $q(x_t|x_{t-1})$ of each step $t \in [1,T]$ can be seen as: $x_t = \sqrt{\alpha_t}x_{t-1} + \sqrt{1-\alpha_t}\varepsilon$. where α_t is used to control the diffusion velocity and $\varepsilon \sim \mathcal{N}(0,I)$. In the backward denoising process, the original data x_0 is obtained by sequentially removing the added noise from x_T. Transitions of removing steps is denoted as $p(x_{t-1} \mid x_t), t \in [1,T]$. $p_\theta(x_{t-1} \mid x_t)$ parameterized by θ is learned to approximate $p(x_{t-1} \mid x_t)$.

Based on these two Markovian procedures, diffusion models maximize the lower bound of the log-likelihood $\log p(x)$ which can be derived from the following inequality:

$$\begin{aligned}\log p(x) \geq & \mathbb{E}_{q(x_1|x_0)}[\log p_\theta(x_0 \mid x_1)] - D_{\mathrm{KL}}(q(x_T \mid x_0) \| p(x_T)) \\ & - \sum_{t=2}^{T} \mathbb{E}_{q(x_t|x_0)}[D_{\mathrm{KL}}(q(x_{t-1} \mid x_t, x_0) \| p_\theta(x_{t-1} \mid x_t))]\end{aligned} \tag{2}$$

The first term in the right equation $\mathbb{E}_{q(x_1|x_0)}[\log p_\theta(x_0 \mid x_1)]$ can be regarded as a reconstruction term. The second term $D_{\mathrm{KL}}(q(x_T \mid x_0) \| p(x_T))$ which equals to zero in assumption. The third term can be considered as the mean difference between the cumulative equivalent of noise at each step and the predicted noise [18]. During the generation phase, the diffusion model generates data by gradually removing the predicted noise from x_T.

2.2 Property Inference Attacks

Property inference attacks aim to extract the overall (global) information about the training set from the target model. Property inference attacks against machine learning models are first introduced by [1] and formally defined by [48]: given two hypotheses $(\mathcal{H}_0, \mathcal{H}_1)$ about the distribution of the training set, the adversary is asked to determine which hypothesis is more consistent with the distribution of the training set of the target model. The hypotheses are widely adopted in previous studies as the description of the proportion of the samples with target property $\mathbb{P}$ as follows:

- $\mathcal{H}_0$: The proportion of samples with target property $\mathbb{P}$ in the training set of the target model is t_0.
- $\mathcal{H}_1$: The proportion of samples with target property $\mathbb{P}$ in the training set of the target model is t_1.

Previous studies commonly use a binary meta-classifier trained under numerous shadow models of $\mathcal{H}_0$ and $\mathcal{H}_1$ to make the final decision [1, 11, 31, 56]. [4, 31] assume the adversary could poison the training set to perform property inference attacks. [57] first introduces the property inference attack into the GANs. Different from typical property inference attacks, it aims to directly infer the proportion of the samples with target property. In this paper, we focus on the property existence inference which can be regarded as an extension of the property inference to determine whether any samples with target property are used to train the target model.

3 Problem Statement and Threat Model

In this section, we present the formulation of property existence inference, the significance of investigating this problem, and the clarity of our threat model.

3.1 Property Existence Inference

We follow the points of [4] and formally define the property existence inference as follows:

Definition 1 (Property Existence Inference)**.** *given a target model and two hypotheses $(\mathcal{H}_0, \mathcal{H}_1)$ about the distribution of the training set, the adversary is asked to determine which hypothesis is true. Each pair of hypotheses is defined as:*

- *$\mathcal{H}_0$: The proportion of samples with target property $\mathbb{P}$ in the training set of the target model is 0.*
- *$\mathcal{H}_1$: The proportion of samples with target property $\mathbb{P}$ is larger than 0.*

According to the definition of the property inference in Section 2.2, if we set t_0 in $\mathcal{H}_0$ as 0 and change the condition of $\mathcal{H}_1$ to $t_1 > 0$, the property inference is turned into our property existence inference.

3.2 Significance of Property Existence Inference

The property existence inference considers more personal and personalized privacy such as personal unauthorized training data while proposing a more practical setting where the adversary cannot obtain any samples in the training set.

As an extension of the property inference, property existence inference is very similar to the property inference in their forms of definitions. However, the proportion of target properties differs depending on the target of the adversary. Previous studies of the property inference usually focus on properties (e.g., gender) that account for more than 10% of

the samples in the training set [1, 11, 56, 57]. Therefore, the property inference usually serves as a fairness auditor of the training set to assess the sensitive global properties by predicting the absolute proportion of the properties [57]. By setting one of the proportion of samples with target property in hypotheses to 0, the property existence inference does not focus on the absolute proportion of the target property. Whatever the proportion, it only infers the existence of the target property. It might be meaningless to infer the existence of certain properties that account for a large proportion of the training set, such as inferring whether there are women in the world. However, for those properties that account for only a small proportion (e.g. person's identities and styles of painting), the existence of that property can leak personal and personalized privacy, which has not ever been considered by the previous works of the property inference.

Another well-known attack to infer the existence of samples in the training set is the membership inference [2, 20, 21, 26, 29, 33, 46, 52, 54, 55]. Though sharing a similar purpose of existential judgment, the property existence inference differs from the membership inference. Membership inference focuses on samples identical to (e.g., same objects in the same environment) those in the training set and ignores samples that share the same property (e.g., the same type of objects in different environments) with the training set which is considered in our property existence inference. The adversary who performs property existence inference can hardly obtain the exact data used to train the target model. Therefore, in our evaluations, the property existence inference considers a more practical setting where samples exactly the same as the training set cannot be obtained, which has never been considered in the membership inference.

3.3 Threat Model

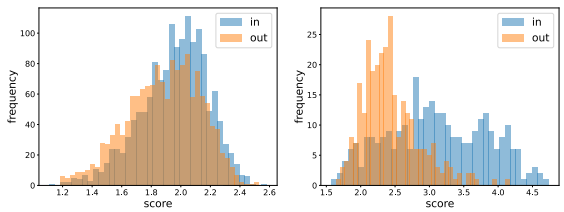
We consider an adversary $\mathcal{A}$ interacting with a generative model based on the neural network f_θ. The goal of the adversary $\mathcal{A}$ is to infer whether any samples of the given property $\mathbb{P}$ are used to train the target generative model. For the sake of expediency in exposition, if there are samples with this property present in the training set of the target model, we refer to this property as in-property; otherwise, we call it out-property.

Adversary's Knowledge. In this paper, we focus on the practically and commonly utilized black-box setting where the adversary can only query the target model with a certain input prompt and get its corresponding output images. For generative models, the adversary is limited to passively getting a generated dataset D_{gen} of the target model without any knowledge of its parameters and structures. In particular, the adversary can specify the additional information such as captions for conditional generative models which generate corresponding outputs by accepting specific inputs from the user. However, the adversary has no way of specifying them for unconditional generative models which only use random noise as input.

We follow the assumption widely adopted in the research of privacy-preserving machine learning that the adversary can access the overall dataset that is used to collect the training set of the target model. Therefore, the adversary can sample data from the overall dataset to assist in conducting the inference. It is further assumed that the overall dataset is sufficiently large, thereby rendering it impossible for the adversary to access the samples with the same properties as those in the training set. Under this assumption, the adversary is always able to collect a dataset D_{out} with completely different properties from the training set. For each target property $\mathbb{P}$, we allow the adversary to collect a dataset D_A, where each sample in this dataset contains the target property.

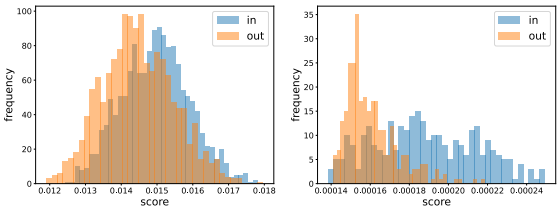
4 Attack Methodology

In this section, we start by providing the overall attack procedure and then detail how to conduct the property existence inference against generative models.



4.1 Overall Attack Procedure

The procedure of our property existence inference consists of three stages: property extractor training, similarity computation, and threshold selection. Firstly, we train a property extractor to map the data of D_A and D_{gen} into the embedding space based on different properties. Secondly, we assign the target property a score by computing the similarities between the embedding obtained from the data of D_A and D_{gen}. Finally, we train the shadow models to select a threshold to make the final decision.



4.2 Property Extractor Training

Since we aim to utilize the influence of target properties on the generated images, we need to train a property extractor to distinguish features from different properties. We design the property extractor as a network trained with the triplet loss function [40]. It utilizes a triplet dataset containing three images for each data point: a base image with a specific property, a positive image with the same property, and a negative image with a different property. Samples used to train the target property extractor are labeled according to the same classification criteria as the target property. For instance, if we consider "identity = Alice" as the target property, then the properties we use to train the network are the identities of different people.

During the training stage, the siamese network architecture is employed with shared weights to embed these images into an embedding space. We train the network to minimize the cosine distance between the base and the positive embedding while maximizing the cosine distance between the base and the negative embedding. Evidently, the utilization of data with target property for training the network would yield

(a) CelebA-HQ wo. (b) Imagenet wo.

(c) CelebA-HQ w. (d) Imagenet w.

Figure 1: The frequency distribution of the similarity score on CelebA-HQ and Imagenet among all data generated by DDPMs. Scores computed with similarity score smoothing and likelihood calibration of properties absent in the training set (in orange) shown by the second row are further to those of properties present (in blue) compared with the pure cosine similarity scores in the first row.

better results. Nonetheless, our evaluations indicate that, even in cases where the target property is not explicitly a label in the training set of the property extractor, it can generalize its discriminating capabilities to the target property. This fact permits adversaries to leverage pre-trained models as property extractors for initiating attacks, thereby substantially reducing the associated attack costs while achieving a reasonable degree of attack effectiveness.

4.3 Similarity Computation

In this stage, we compute the similarity between the data with the target property and the generated data to determine whether the target property is used to train the target model. The process of computing similarity scores is detailed in Algorithm 1. Specifically, for each image with the target property collected by the adversary which is referred to as the anchor image, we compare its cosine similarity with all generated images after property extraction (Lines 12-14 in Algorithm 1). Subsequently, the summation of the K-largest computed similarity scores among all generated images is designated as the similarity score for that anchor image (Lines 11-23 in Algorithm 1). The chosen K-largest values (top K) represent generated images most likely to be influenced by the corresponding target property. Similarity scores of each anchor image in the entire dataset D_A collectively constitutes the

derived similarity score for the given target property. During the computation of property similarity scores, we employ two operations, namely *similarity score smoothing* and *likelihood calibration*, to mitigate uncertainties arising from anchor images and generated images.

Similarity Score Smoothing. During our evaluations, we found that some anchor images tend to have fairly high (or low) similarities with all generated images. According to recent studies [3], memorized images tend to have abnormally high similarities among the whole similarity distribution. Inspired by this, we further adopt a smoothing method to polish our similarity scores (Line 20 in Algorithm 1). In contrast to a mere similarity comparison, a more effective indicator of the property's presence within a training set is the discernible pattern where a specific anchor image exhibits markedly higher similarity to a limited set of generated images as opposed to the rest. This indicates that the anchor image has evidently captured distinctive property characteristics within these conspicuously generated images with high similarity. Therefore, to mitigate the uncertainty of anchor images, we initially sub-

ject all resultant values to a softmax smoothing operation, followed by selecting the K-largest values.

Likelihood Calibration. Without a well-crafted input from the adversary to control the generating process, images randomly generated from a pre-defined latent space [12, 18] also exhibit comparable uncertainty of diverse similarity score distributions with images in the overall dataset. In order to mitigate this uncertainty, we introduce a likelihood test to calibrate the similarity score by approximating the similarity distribution. Rather than the whole similarity distribution of the overall dataset, we focus on the reference out-distribution which is the distribution of similarity scores between certain generated images and the D_{out} as mentioned in section 3.3.

The reference out-distribution indicates a general level of similarity for data with the out-properties and helps to mitigate the bias of the similarity introduced by the individual characteristics of generated images. For each generated image specially, we calculate the cosine similarity between the generated image and the data from the D_{out}. It is assumed that the reference out-distribution follows a Gaussian distribution and the data sampled from D_{out} is used to calculate its mean and variance (Lines 2-10 in Algorithm 1). For each anchor image, we calculate the corresponding probabilities under the reference out-distributions of all generated images (Lines 16-19 in Algorithm 1) and add them up when calculating the similarity score (Lines 21-22 in Algorithm 1). Aiming for a higher probability of the existing image with the target property present in the training set, we take the negative of the likelihood as likelihood calibration. We use a hyperparameter α to balance the weight of the original similarity and the likelihood calibration.

Figure 1 plots the frequency distribution histogram of the similarity scores of the properties present (blue) and absent (orange) in the training set of CelebA-HQ [22] and ImageNet [7], respectively. The first line illustrates the results obtained without utilizing similarity score smooth and likelihood calibration, whereas the second line showcases the results under these methods. It can be noticed that the gap between the two distributions of similarity scores in the second row is larger than that in the first row, indicating the effectiveness of reducing uncertainty.

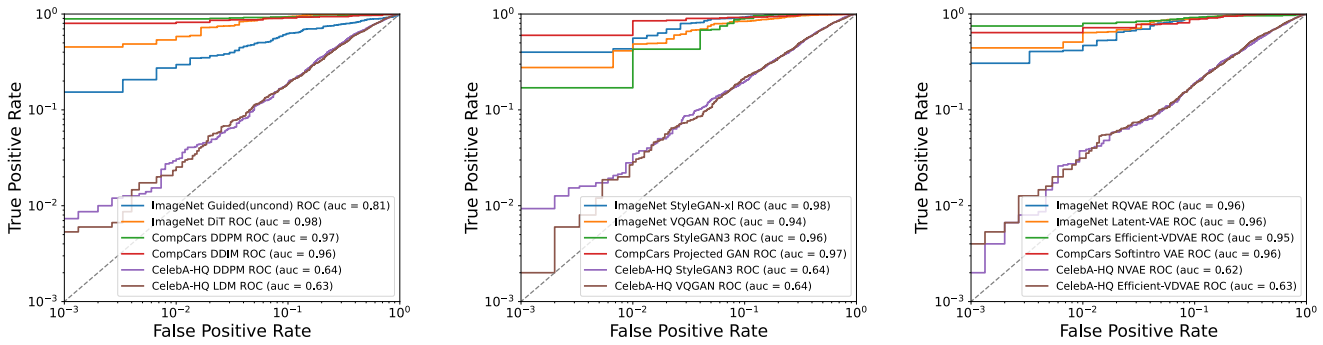
4.4 Distinguishing Test

After obtaining the similarity scores for the target property, we select a threshold to decide the result. If the similarity score exceeds the threshold, we predict the samples with the target property as used to train the target model; otherwise, we predict it as not used. In this stage, we first train shadow models with the training set sampled from D_{out}. Next, we select the properties used for training and those not used to obtain their corresponding similarity scores. We model the scores of these two types of properties as Gaussian distributions $\mathcal{N}(\mu_0, \sigma_0^2)$ and $\mathcal{N}(\mu_1, \sigma_1^2)$. The adversary can choose thresholds based on different false positive rate requirements. In our evaluations, we adopt the method of [4] to set the threshold as one of the following to minimize both two test errors:

$$\mathrm{T} = \frac{(\mu_0\sigma_1^2 - \mu_1\sigma_0^2) \pm 2\sigma_1\sigma_0\sqrt{\left(\frac{\mu_1-\mu_0}{2}\right)^2 + (\sigma_0^2 - \sigma_1^2)\log\left(\frac{\sigma_0}{\sigma_1}\right)}}{\sigma_1^2 - \sigma_0^2} \tag{3}$$

We set the $\mathrm{T} = \frac{\mu_0+\mu_1}{2}$ when $\sigma_0 = \sigma_1$.

In this paper, we do not require the adversary to possess any prior knowledge about the model structure or training algorithm of the target model. In our evaluation, we note that the optimal T obtained on different models is similar and does not have a significant impact on the effectiveness. We keep the proportion of samples with different properties fixed at 0.05% when training the shadow models and we demonstrate that when the proportion of the target property is larger than we expected (even larger than 10%), the attack effect will not worsen. In fact, the higher the proportion of property, the better the resulting effect. We provide detailed proof and explanation in the Appendix A.2.



5 Evaluation

5.1 Evaluation on Generative Models

Datasets and Property Extractors. We adopt the following three datasets to investigate the property existence inference and clarify the property extractor used for each dataset.

CelebA-HQ [22] The CelebA-HQ dataset is a CelebFaces Attributes dataset which contains 30,000 face images. CelebA-HQ is the high-resolution version of the CelebA [28] which consists of more than 200,000 RGB face images. In our evaluations, we employ the CelebA-HQ dataset with a resolution of 256×256 to train the target generative models and use the identity as target properties. In our evaluations, we randomly select a group of 1,500 individuals from CelebA-HQ as in-properties and another set of 1,500 individuals from CelebA but not in CelebA-HQ as out-properties. For each property, we randomly sample three images with this property from CelebA as anchor images to create D_A. We also collect an extra 4,500 images from CelebA to form the D_{out}. Furthermore, we assume that the attacker could generate 10,000 images from target models trained on CelebA-HQ to conduct their attack. For all generated and original images, we employ pre-trained facenet [40] as our property extractor to generate embeddings.

ImageNet [7] ImageNet is a large-scale visual dataset consisting of 14,197,122 annotated images according to the WordNet hierarchy used for the Large Scale Visual Recognition Challenge (ILSVRC). We use the version of ImageNet2012 containing 1,000 classes to train target models and ImageNet2010 as the extended dataset to select out-properties. In

(a) Diffsuion Models (DMs). (b) GANs. (c) VAEs.

Figure 2: The ROC curve plot for DMs, GANs, and VAEs showcases a pair of models for both CompCars, ImageNet, and CelebA-HQ in each individual graph.

our evaluations, we randomly select 300 classes from ImageNet2012 to serve as in-properties and another 300 classes from the class difference between ImageNet2012 and ImageNet2010 as out-properties. We sample 5 images for each property to compose D_A. Moreover, we sample 46,000 images from the rest classes of ImageNet2010 to compose D_{out} and resize all the data of ImageNet to 256×256. To extract embeddings, we use the clip fine-tuned on Laion2B[1].

CompCars [53] CompCars is a widely utilized benchmark in computer vision research for tasks of fine-grained object recognition and retrieval. It comprises diverse images of cars captured from various angles, lighting conditions, and occlusions. The dataset includes annotations for car make, model, and year. In our evaluations, we adopt the attributes of models as target properties and select 50,000 images with the resolution of 256×256 to train the target generative models. For in/out-properties, we randomly select 200 models of cars each, ensuring that the data with any selected in-properties constitute no more than 0.1% of the training dataset. We sample 5 images to create D_A for each model of cars and sample 10,000 images from CompCars to obtain D_{out}. We train the property extractor with the network backbone of [19] under VGG16 [43] which has been demonstrated to perform well on fine-grained classification tasks.

Target Models. Among state-of-the-art generative models for each dataset, we select two models as target models for each of the three types of models, e.g., DMs, GANs, and VAEs. For DMs, we adopt the DDPM [18] and LDM [36] trained on CelebA-HQ, DIT [34] and Guided Diffusion [8] trained on ImageNet, DDPM [18] and DDIM [45] trained on CompCars as the target models. For GANs, we adopt the styleGAN3 [23] and VQGAN [10] trained on CelebA-HQ, styleGAN-xl [39] and VQGAN [10] trained on ImageNet, Projected Gan [38] and styleGan3 [23] trained on CompCars as the target models. For VAEs, we adopt the NVAE [51] and Efficient-VDVAE [15] trained on CelebA-HQ, Latent VAE [30] and RQVAE [25] trained on ImagNet, Efficient-VDVAE [15] and Softintro Vae [6] trained on CompCars as the target models. We use the pre-trained models mentioned above for CelebA-HQ and ImageNet, and we train the target models of CompCars by ourselves.

Metrics. The property existence inference can be regarded as a binary classification task to distinguish whether the target property is an in- or out-property. Therefore, we measure the property existence inference with the metrics of Area under the ROC Curve (AUC) and Accuracy (ACC), which are widely used for the evaluation of binary classification tasks. We also use the True Positive Rate (TPR) at 1% False Positive Rate (FPR) to focus on the in-properties that can be confidently inferred. The larger the metrics mentioned above, the better the property existence inference performs. To measure the quality of the generated images, we use the Fréchet Inception Distance (FID) metric [16], where a lower FID indicates better quality of the generated images.

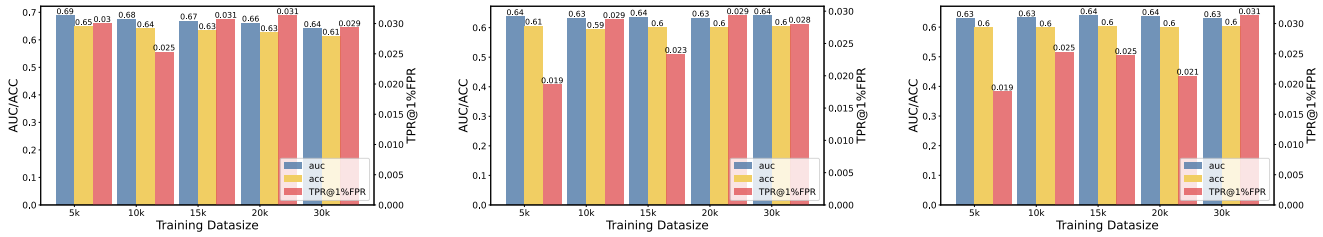
Baseline. Since we consider property existence inference as an extension of property inference, we added the method of [57] as a baseline in our evaluations. [57] predicts the proportion of images with a target property in the training set by evaluating the proportion of generated images that have the target property. We slightly modified this method to align with the goals of property existence inference: for each generated image, we classify it into a specific property category. The number of images classified under the target property is considered as the score for that property. We use those scores to calculate the metrics.

Results. For various models of corresponding datasets under the property existence inference, we show metrics of AUC, ACC, and TPR achieved at 1% FPR in Table 1. We depict the ROC curves in Figure 2, from left to right denoting models of DMs, GANs, and VAEs. Horizontally, there is no particularly

[1] https://mmpretrain.readthedocs.io/en/latest/papers/clip.html

Table 1: The AUCs, ACCs and TPRs achieved at 1% FPR for the effectiveness of property existence inference obtained from our method (PEI) and the baseline method [57] (PIA).

Dataset		Model	FID	PEI (Ours)			PIA (Baseline)		
				AUC	ACC	TPR@1%FPR	AUC	ACC	TPR@1%FPR
ImageNet	DMs	DiT	2.27	0.98	0.92	53.7%	0.81	0.79	4.6%
		guided	4.59	0.81	0.78	27.3%	0.67	0.68	0%
	GANs	styleGAN-xl	2.30	0.98	0.92	43.3%	0.82	0.79	2.4%
		VQGAN	5.2	0.94	0.88	41.3%	0.76	0.73	3.0%
	VAEs	Latent VAE	9.34	0.96	0.91	51.0%	0.72	0.69	0.7%
		RQVAE	4.45	0.96	0.90	41.7%	0.78	0.79	1.7%
CompCars	DMs	DDPM	9.75	0.97	0.95	89.0%	0.87	0.86	64.7%
		DDIM	12.85	0.96	0.92	80.0%	0.81	0.77	19.0%
	GANs	StyleGAN3	28.87	0.96	0.92	17.0%	0.66	0.63	19.4%
		Projected GAN	8.47	0.97	0.94	60.0%	0.86	0.80	30.0%
	VAEs	Efficient-VDVAE	78.12	0.95	0.91	75.0%	0.72	0.71	34.7%
		Softintro VAE	75.81	0.96	0.90	64.0%	0.77	0.74	25.4%
CelebA-HQ	DMs	DDPM	20.25	0.64	0.61	2.9%	0.59	0.58	2.2%
		LDM	19.82	0.63	0.60	2.3%	0.54	0.54	3.2%
	GANs	StyleGAN3	15.68	0.64	0.60	2.8%	0.58	0.57	2.4%
		VQGAN	19.32	0.64	0.60	2.7%	0.59	0.57	2.4%
	VAEs	NVAE	44.31	0.62	0.59	3.7%	0.53	0.53	1.3%
		Efficient-VDVAE	23.55	0.63	0.60	3.1%	0.54	0.54	2.3%



large difference in the performance of different generative models under inferences on the same dataset. In specific, the three aforementioned metrics are consistently close among all models such as for CelebA-HQ, with only a 0.01 fluctuation for AUC, and a 0.02 fluctuation for ACC and TPR achieved at 1% FPR. Vertically for a single model, the property existence inference can get advantages in the three datasets with ImageNet and CompCars considerably high compared to CelebA-HQ, which indicates that ImageNet and CompCars are more susceptible to the property existence inference. For instance, the ROC curves of ImageNet and CompCars with almost all AUCs around 0.95 located far above those of CelebA-HQ whose AUCs fall within a lower range of 0.63 to 0.64. Compared to the baseline, our method outperforms it in almost all metrics on each dataset, except for two values of metric TPR achieved at 1% FPR. Our method demonstrates significant improvement over the baseline in terms of AUC and ACC metrics. For example, our method improves the average AUC by 0.18, 0.18, and 0.07 on ImageNet, CompCars, and CelebA-HQ, while the average ACC improves by 0.14, 0.17, and 0.02, respectively.

Summary I: Most of the generative models we evaluated are vulnerable to the property existence inference and property existence inferences perform similarly against generative models trained on the same dataset.

5.2 Effect of Training Datasize

As mentioned in previous works, the size of the training set is a critical factor in determining the performance of inference attacks [5, 27, 41]. The size of a training set has a direct impact on how a model overfits it. In general, overfitting is reduced as the training set size increases. We also investigate effectiveness of property existence inference with different sizes of training sets.

Setup. We select DMs (DDPMs), GANs (styleGAN3s), and VAEs (Efficient-VDVAEs) as the target models to be trained with different sizes of training sets. We randomly selected 5k, 10k, 15k, 20k, and 30k samples from the CelebA-HQ dataset to train the target generative models, and subsequently conduct property existence inferences in those models. For each model, we randomly select 1,500 in-properties and 1,500 out-properties based on different identities and sample three images with each property to compose D_A. In addition, we generate 10,000 images from each target model to carry out the inferences. To ensure evaluation fairness, we train all

(a) DMs. (b) GANs. (c) VAEs.

Figure 3: The bar charts of AUC (blue), ACC (yellow), and TPR achieved at 1% FPR (red) for Diffusion models, GANs, and VAEs trained on the CelebA-HQ dataset with training set sizes of 5k, 10k, 15k, 20k, and 30k.

models within a certain type with similar FID values.

Results. Figure 3 shows the changes of AUC, ACC, and TPR achieved at 1% FPR across the different sizes of training sets in DMs, GANs, and VAEs respectively. With the exception of the attacks in DDPMs, which exhibit a slight decrease in AUC (i.e., from 0.69 to 0.64) when the training data size increases, attacks in GANs and VAEs do not show significant changes in AUC and ACC as the size of training set increases. In contrast to the general conclusion regarding MIAs [27,42,58], it is surprising that the effectiveness of property existence inferences seems to be insensitive to the change of sizes of the training set. When analyzing the uniqueness of DDPMs, we find that the increase in the replication behavior of DDPMs towards the training set, as the size of the training set decreases, results in an additional advantage for attacks.

Summary II: The primary reason for the effectiveness of the property existence inference is not overfitting, and increasing the size of the training set is not an effective way to prevent property existence inference.

5.3 Effect of Adversary Knowledge

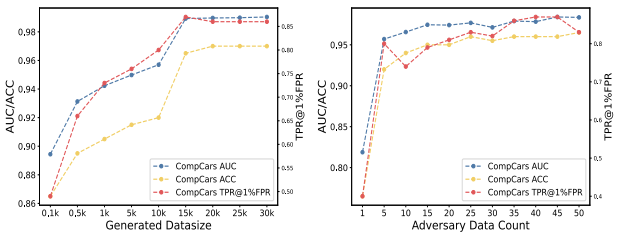


Figure 4: The changes in AUC (blue), ACC (yellow), and TPR achieved at 1% FPR (red) obtained from conducting property existence inferences on the DDIM vary with the increase in the number of the generated images (left), and the number of the data with target property (right).

In our attack scenario, we assume that the adversary can (1) generate a certain amount of images from the target model, (2) choose the target property and collect a specific number of images with the target property as anchor images to conduct property existence inferences. In this section, we evaluate the effect of the amount of both the generated images and the anchor images used by the adversary.

Setup. We investigate the effect of the adversary knowledge by performing property existence inferences against the diffusion model (DDIM) on the CompCars. In our basic settings, we randomly select 200 in-properties and 200 out-properties in CompCars based on the model of cars. To conduct the inference, the adversary samples 5 images for each property as anchor images and generates 10,000 images from the target model. We change these basic settings from two aspects while keeping other settings constant to evaluate the effect of the adversary knowledge. To evaluate the effect of the amount of the generated images, we let the adversary to generate images in the range of 0.1k to 30k from the target model. To evaluate the effect of the amount of the anchor images, we increase the number of the anchor images every 5 from 1 to 50.

Results. Figure 4 illustrates the changing trend of inference performance metrics on DDIM as the adversary knowledge changes. We show the trend of AUC, ACC, and TPR achieved at 1% FPR with a growing number of generated images and anchor images used by the adversary respectively on the left and right of Figure 4. It's clear that with a growing size of generated images and anchor images, the attack metrics will grow until they reach a threshold.

To further simulate real-world scenarios, we conducted the evaluations on CelebA-HQ by supplementing it with anchor images from social media, which are potential sources for adversaries to collect anchor images. The result is attached in the Appendix A.1. We get the same results as CompCars when the number of the generated images increases. However, we find a peak in metrics as the number of the anchor images increases. The peak in the figure signifies that as the number of the anchor images with target property increases, the gap in similarity scores between in-properties and out-properties

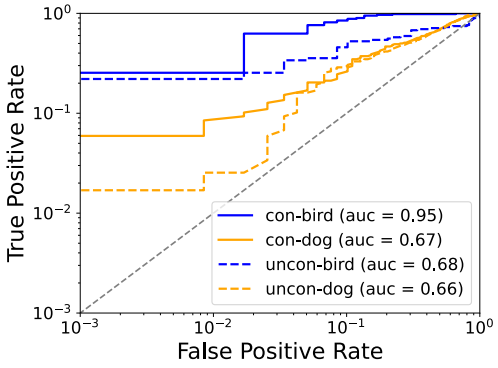

Figure 5: ROC curves for the fine-grained evaluations. “con” and “uncon” stands for the different types of the target models.

rapidly increases until reaching the optimum and finally decreases. Hence, we suggest the adversary train shadow models to select the appropriate number of anchor images for performing property existence inferences.

Summary III: 1) For the same training dataset, the adversary will get better performance of the property existence inference when the number of the generated images and anchor images increases. 2) For different training datasets, there exists an optimal quantity of anchor images that maximizes the attack performance.

5.4 Effect of Property Granularity

As we rely on manual labeling to determine the properties, samples can be classified into properties at different levels of granularity. For instance, an image of a canary may be classified as a fine-grained canary, a coarse-grained bird, or even a coarser-grained animal. In this section, we investigate the effectiveness of the property existence inference under different property granularities. It is worth mentioning that in the previous overall evaluations, we have adopted “identity”, “models of cars”, and the original label class in ImageNet as target properties, which may differ in granularities across different datasets. To better compare the effects of different granularities for the same dataset, we further conduct the property existence inference of ImageNet based on classification criteria under WordNet, a hierarchical tree-like structure with basic relations of synsets and hypernyms for fine-grained categorization. For instance, the synset "animal" is a hypernym of "dog" and the synset "dog" is further a hypernym of more fine-grained synsets such as "poodle", "labrador" and "bulldog", representing the "is-a" relationship.

Setup. To study the effectiveness of the property existence inference with different property granularities, we collect original synsets with hypernyms of birds and dogs from ImageNet2012 respectively as our in-properties and extract the other synsets from ImageNet as out-properties under the same hypernyms, ensuring that the in- and out-properties are not hypernyms of each other in the WordNet. In brief, we find out other children as out-properties sharing the same father as in-properties but not in one branch with in-properties. For birds and dogs, we use 100 and 300 classes of in-/out- properties respectively, and samples D_{out} from the rest classes. We use the Guided Diffusion [9] trained on ImageNet2012 as the target models and use the EfficientNet-b1 [50] pre-trained by torchvision as our property extractor.

Results. As shown in Figure 5, the ROC curves of the birds lie above those of the dogs under conditional and unconditional Guided Diffusions. In the conditional model, we get AUCs of 0.95 and 0.67 for birds and dogs respectively while in the unconditional model, we get AUCs of 0.68 and 0.66 respectively, which indicates that there still exists property existence information leakage in the fine-grained properties. Compared to attacks at a coarse level (e.g., ImageNet) in Figure 2 with AUCs of 0.81 and 0.98 at conditional and unconditional diffusion models, we can conclude that the finer the granularity of the properties, the harder it is to infer their existence information. Between the two fine-grained properties, it’s observed that the bird species are relatively easier to infer, due to the larger intra-class diversity of birds. Though the overall AUCs between conditional and unconditional models differ a lot, we observe close TPR at 1% FPR of 0.25 and 0.22 for birds evaluations. This indicates that there are indeed some properties whose features are more easily manifested in the generated images, regardless of whether it is in conditional or unconditional models.

Summary IV: Property existence inferences prove effective in the context of fine-grained datasets, and selecting properties at a finer granularity level results in higher inference difficulty.

5.5 Why Our Attacks Work

In previous sections, we present the effectiveness of our approach to perform the property existence inference under various settings from different generative models, different datasets to different granularities. To gain a deeper understanding of property existence inference, we further investigate which type of generated data contributes to the leakage of the property existence information.

How generated samples leak the property existence information. On left of the Figure 6, we display the performance of our attacks under DDPM trained on CelebA-HQ. According to Algorithm 1, we mainly focus on those generated samples most similar to each anchor image of target properties, since they are used to calculate the similarity scores during the attack. Specifically, we collect the top 20 generated samples with the highest similarity scores corresponding to each anchor image. In brief, we call these samples as chosen generated samples and the anchor image as their corresponding anchor image. Each chosen generated sample can have many corresponding anchor images and each anchor image

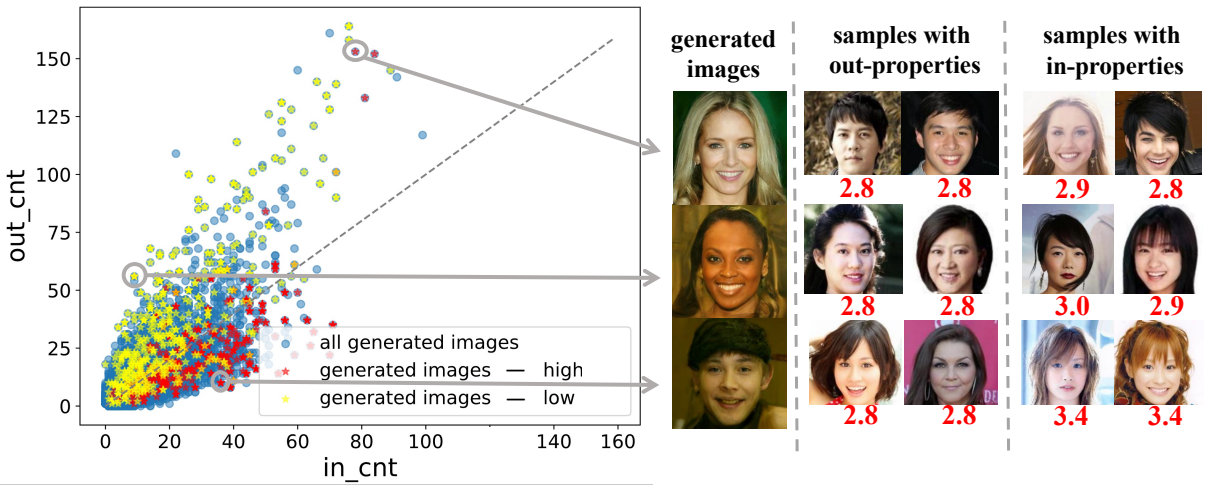

Figure 6: Figure in the left plots the top 20 generated samples collected with the highest similarity scores corresponding to each anchor image. The right side displays generated images of three chosen points representing generated data with high risks, low risks, and nearly no risks of property existence information leakage. For each chosen point, the corresponding anchor images with the highest similarity scores are plotted on the right. Below each anchor image marks their similarity scores ($\times 1,000$). For each chosen generated sample (blue dots), the x-axis and y-axis indicate the total number of their corresponding anchor images with in- and out-properties respectively. Most points with the lowest similarity scores (yellow stars) lie above the gray line while those with the highest scores (red stars) lie below, indicating that generated samples prone to leaking property existence information are more similar to relatively large amounts of anchor images with in-properties. From the bottom up, the difference in similarity scores between corresponding anchors with in- and out-properties and the chosen generated sample gradually decreases, indicating the weakened ability of the generated sample to distinguish in- and out-properties.

corresponds to 20 chosen generated samples. By intuition, it's considered that the riskiest generated sample should share markedly high similarities with more anchor images of in-properties compared with those of out-properties. So we further analyze the statistical difference between corresponding anchor images of in-properties and out-properties for each chosen generated image from the following two dimensions.

- **Quantity**: The relative number of anchor images with in- and out-properties.
- **Value**: The absolute value of similarity scores with anchor images of in- and out-properties.

To explore the dimension of **Quantity**, we count the number of corresponding anchor images with in-properties and out-properties respectively for each chosen generated sample. The result is displayed in Figure 6 where each blue point denotes a certain chosen generated sample. Among all corresponding anchor images of that sample, the total number of anchor images with in-properties is shown in the x-axis and that with out-properties is shown in the y-axis. The points on the grey line which separates the figure into two parts represent those chosen generated samples with an equal number of corresponding anchor images between in- and out-properties. To find generated samples that are easier and harder to leak property existence information, we mark chosen generated samples with the highest similarity scores in red stars and those with the lowest similarity scores in yellow stars. It's interesting to notice that most chosen generated samples with the lowest similarity scores lie above the gray line while those with the highest similarity scores lie below. Statistically speaking, it indicates that generated samples more prone to leaking property existence information tend to have more corresponding anchors of in-properties than out-properties.

To explore another dimension of **Value**, we choose three points in each representative area in the left figure and display the chosen generated samples along with their corresponding anchor images of in/out-properties with the highest similarity scores in the right of Figure 6. Below each anchor image marks its similarity score with the leftest chosen generated sample. From the bottom up, the similarity scores of the corresponding anchor images with out-properties remain the same but those of corresponding anchors with in-properties gradually decrease. It indicates that the difference in similarity scores between corresponding anchor images with in- and out-properties of the chosen generated sample gradually decreases and converges to 0. Moreover, it illustrates that the chosen generated sample gradually loses the ability to distinguish anchor images of in-properties and out-properties from the bottom up. From this point, we can say that the three points from the bottom up respectively represent generated samples with the highest risks, low risks, and nearly no risks

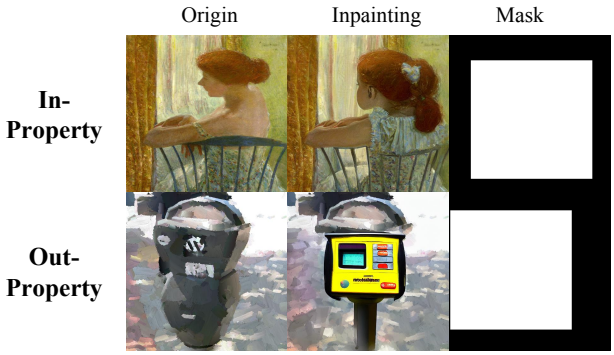

Figure 7: The visualized strategies of the inpainting evaluation. The first row belongs to the evaluation of image with in-property and the second row belongs to the evaluation of image with out-property generated by applying style transform to image in ImageNet2012. We apply the mask in the third column to the original image in the first column and inpaint the masked part with Stable Diffusion to acquire the inpainting image in the second column.

of property existence information leakage. Consequently, generated samples with high risks of leaking property existence information tend to have abnormally high similarity scores with anchor images of in-properties.

5.6 Case Study: Stable Diffusion

In order to investigate the effectiveness of the property existence inference in generative models for real-world scenarios, we perform attack on the open-source model Stable Diffusion [36] which is trained on LAION [41] with 5.85 billion CLIP-filtered image-text pairs.

Setup *Attack Goal.* As a means of distinguishing in/out-properties, we utilize the artistic style of works and assess whether any given artist's pieces are present in LAION. *Datasets.* We use the WikiArt [2] dataset which included 195 artists to select the in-properties. Inspired by the research of the Memorization about the diffusion models [3], we consider that the property of an artist's style is an in-property when the style of the generated images with their names mentioned in the prompt is very close to that of their real paintings. We finally found 100 in-properties under this method. As for the out-properties, the large data scale of LAION and the possibility that images obtained from the internet may not be labeled with artists' names make it infeasible to determine that none of an artist's pieces are present in LAION. Therefore, We seek a substitute method to acquire the out-properties, which applies style transformation [59] to real-world images (i.e., ImageNet in our evaluation) and produces the oil-painting style images. Then we apply clustering algorithms to divide the generated oil paintings, which are pre-processed by a property extractor trained on WikiArt to differentiate between different artistic styles, into distinct properties which are used as the out-properties to evaluate the performance of attacks in this evaluation.

[2] https://www.wikiart.org/

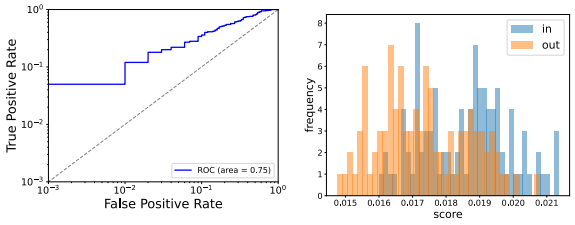

Figure 8: (Left) The ROC curve for attacks on Stable Diffusion. (Right) The frequency distribution histogram of the similarity scores for in-properties (blue) and out-properties (yellow).

Attack procedure. Because the out-properties lack clear information about the artists used in the prompts to query Stable Diffusion, we adopt the inpainting method to obtain the generative samples. Specifically, we randomly crop $3/4$ part (i.e., 384×384) of the images with the target property of original size 512×512 and use the Stable Diffusion to inpaint such cropped part. Similar to our previous assumption about the generative models, we expect that Stable Diffusion will have a better reconstruction performance on the images with in-properties. Therefore, We calculate the sum of cosine similarity of the embedding vectors of the before-cropped images with the target property and the after-inpainted images as the score of this property. Then we predict that properties that achieve scores greater than the set threshold are in-properties. In Figure 7, we visualized evaluations on the image with in/out-property separately. We observed that the style of the inpainted image with in-property is more similar to the original image compared to images with out-property.

Results. On the left of Figure 8, we depict the ROC curves of the inference against the Stable Diffusion, with an AUC score of 0.75. We also depict the frequency distribution histogram of the scores for those two types of properties in the right. It can be observed that the distribution of the scores of in-properties is more concentrated towards the right compared to out-properties. The results indicate that Stable Diffusion indeed memorizes some properties included in the training set and generates images based on those properties. The results of the evaluation also demonstrate that property existence inference is effective for models trained on large-scale training sets in real-world scenarios.

6 Related Work

Property Existence Inference. In the literature, there are already several studies investigating the topics related to the

property existence inference. [13] proposes distributional membership inferences that aim to determine whether a given party with a specific distribution contributes to the training set of classification models and conducts evaluations on the synthetic dataset. [32, 49] aim to determine if samples with the target property emerge in the training set under the setting of collaborative learning. [4] conducts property existence inferences on the classification models through poisoning. Compared to the aforementioned works, the target model in this paper focuses on image generative models rather than classifiers. Additionally, this paper assumes that the adversary cannot intervene in the training process of the target model nor manipulate the training set of the target model.

Inferences against Generative Models. Multiple studies have demonstrated the potential for extracting information from the training sets of generative models. [5, 14, 17, 58] focus on the membership inference which aims to determine whether a specific sample is used to train the target model. [57] aims to extract the overall distribution information of the training set, i.e., estimate the proportion of the data with target property in the training set. [3, 44] investigate the duplication phenomena about the diffusion models that the model directly generates the data in the training set. The focus of this paper differs from the aforementioned works. It does not center around specific samples or the overall distribution of the training set, but rather on the existence of samples with specific properties within the training set.

Property Inference against Discriminative Models. [1] first introduced property inference as a binary classification task on Hidden Markov Models and Support Vector Machines to extract the global information of the training set distribution. Subsequent works primarily focus on property inference against neural networks [11, 56]. These works launch inferences by training a binary classifier to distinguish the behavior of discriminative models trained on training sets with different property proportions. Recent works increase the behavioral gap of models trained on properties with different proportions through poisoning [4, 31]. In this paper, we focus on the information of more personalized properties and selects generative models as the target models.

7 Discussion

In this section, we discuss the possibility of less costly property existence inference under a partial black-box setting and analyze potential reasons for the performance on CelebA-HQ.

For unconditional generative models, obtaining specific outputs corresponding to particular inputs is unfeasible so the only viable approach to perform property existence inference is generating a substantial volume of data under our black-box setting. In Section 5.3, 15,000 generative images are needed to achieve the best performance of CompCars. Under the partial black-box setting, [57] reduces the number of required generated images by modifying the latent variables as inputs of GANs to obtain outputs with the target property through gradient descent. However, we observed that generative models (e.g., DDPM) with more powerful generative capabilities are able to produce images remarkably similar to specific properties. Moreover, the computational overhead incurred by gradient propagation is extremely high for diffusion models. Therefore, modifying the latent variables to reduce the number of generated images for all types of generative models is not feasible. We leave the challenge to reduce the required number of generated images under different settings from [57] as future work.

In Section 5.1, it can be observed that the effectiveness of our method on the CelebA-HQ is significantly inferior to that on ImageNet and CompCars. We analyze this difference and conclude that it may be caused by the following two reasons:

- Higher similarity between properties of CelebA-HQ: for CelebA-HQ, we choose identities as target properties, which may result in smaller gaps between different properties in evaluations compared to ImageNet (use different classes of the dataset) and CompCars (use different models of cars). We utilize CLIP to extract features from images with different properties in all datasets and compute the average differences between the two properties which are 9.94 in CelebA-HQ, 13.09 in ImageNet, and 10.30 in CompCars. Therefore, the selected properties in the CelebA-HQ appear to be the most similar.
- Limitations of the adversary knowledge: the number of anchor images corresponding to each property in CelebA-HQ is less than the others. Appendix A.1 shows that increasing the number of anchor images leads to an improved AUC value exceeding 0.74 for CelebA-HQ.

8 Conclusion

In this paper, we present property existence inference against generative models to determine whether any samples with target property are contained in the training set of the target model. We launch the attack by exploiting the difference in similarities between the generated images and anchor images with the in/out-properties. Furthermore, we enhance the attack performance by separately removing the uncertainties of the generated images and the anchor images. We have demonstrated through a comprehensive set of evaluations that property existence inference can effectively extract property existence information in generative models including large-scale models like Stable Diffusion. We discovered that the effectiveness of property existence inference is closely related to the number of anchor images and generated images, as well as the granularity of the target property. However, it is not highly sensitive to the size of the training set. Our research further reveals that there is an increased risk of property existence information leakage for the generated image that closely resembles a larger number of anchor images.

Acknowledgments

We would like to express our sincere gratitude to the anonymous reviewers and Shepherd for their invaluable feedback and constructive comments, which greatly contributed to the enhancement of this paper. This work was supported by National Natural Science Foundation of China (62102353).

A Appendix

A.1 The Effect of the Adversary Knowledge in Real-world scenarios

Figure 9 shows the change of the metrics of attacks when changing the adversary knowledge.

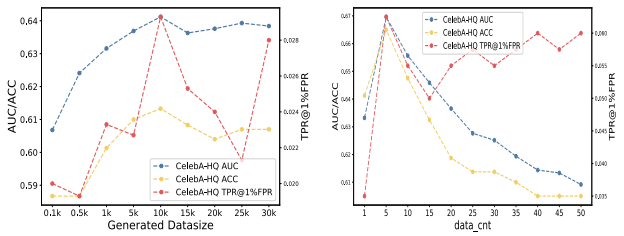

Figure 9: The change of attack performance with varying adversary knowledge. Left: Effect change with increasing generated images. Right: Effect change with increasing anchor images.

A.2 The Inference Effect when the Property Proportion is Large

Table 2: The mean (μ) and variance (σ) of similarity scores that obtained from the properties with different proportions.

proportion	1%	2%	5%	10%
μ	0.102	0.102	0.112	0.115
$\sigma \times 10^{-5}$	11.61	6.82	3.81	3.71

In our attack procedure, we compute similarity scores for each in/out-property and model the similarity score distribution as a Gaussian distribution. Table 2 shows that as the proportion of in-properties in the training set increases, the mean of the in-property similarity score distribution increases and the variance decreases. Based on this finding, we will demonstrate that using the same shadow model, the attack effect increases as the proportion of in-property increases.

Optimal threshold chosen by the shadow model. We assume that the similarity score distribution of in-properties obtained by the shadow model follows the Gaussian distribution $\hat{X} \sim N(\hat{\mu}, \hat{\sigma})$ and the similarity score distribution of out-properties follows distribution $X_0 \sim N(\mu_0, \sigma_0)$. Therefore, $\hat{\mu} > \mu_0$ and $\hat{\sigma} < \sigma_0$. The threshold T is chosen by minimizing the sum of the probabilities of making Type-I and Type-II errors which satisfies the condition as follows:

Claim 1. *Given two Gaussian distributions $X_0 \sim N(\mu_0, \sigma_0)$ and $\hat{X} \sim N(\hat{\mu}, \hat{\sigma})$ such that $\hat{\mu} > \mu_0$, $\hat{\sigma} < \sigma_0$ and objective function $J(\mathrm{T}) = \Pr[X_0 > \mathrm{T}] + \Pr[\hat{X} < \mathrm{T}]$, the threshold T that minimizes J must satisfy:*

$$\mathrm{T} \leq \hat{\mu}$$

Proof. On contradiction, assume the minimum value of $J(\mathrm{T})$ is taken under $\mathrm{T} > \hat{\mu}$. Therefore, $J(\mathrm{T})$ can be re-written as follows:

$$\begin{aligned} J(\mathrm{T}) &= \Pr[X_0 > \mathrm{T}] + \Pr[\hat{X} < \mathrm{T}] \\ &= 1 - \Pr[X_0 < \mathrm{T}] + \Pr[\hat{X} < \mathrm{T}] \\ &= 1 - \Phi\left(\frac{\mathrm{T}-\mu_0}{\sigma_0}\right) + \Phi\left(\frac{\mathrm{T}-\hat{\mu}}{\hat{\sigma}}\right) \end{aligned} \tag{4}$$

Consider a special point of $J(\mathrm{T})$ when T takes $\hat{\mu}$, we can express $J(\hat{\mu})$ as follows:

$$\begin{aligned} J(\hat{\mu}) &= 1 - \Phi\left(\frac{\hat{\mu}-\mu_0}{\sigma_0}\right) + \Phi\left(\frac{\hat{\mu}-\hat{\mu}}{\hat{\sigma}}\right) \\ &= 1.5 - \Phi\left(\frac{\hat{\mu}-\mu_0}{\sigma_0}\right) \end{aligned} \tag{5}$$

To compare the value between $J(\mathrm{T}|_{\mathrm{T}>\hat{\mu}})$ and $J(\hat{\mu})$, we take the difference D between Equation 4 and Equation 5:

$$\begin{aligned} D =& J(\mathrm{T}) - J(\hat{\mu}) \\ =& \Phi\left(\frac{\mathrm{T}-\hat{\mu}}{\hat{\sigma}}\right) - \Phi\left(\frac{\mathrm{T}-\mu_0}{\sigma_0}\right) \\ &+ \Phi\left(\frac{\hat{\mu}-\mu_0}{\sigma_0}\right) - 0.5 \end{aligned} \tag{6}$$

To consider the monotonicity of D, we compute the derivative of D with respect to T:

$$\frac{\partial D}{\partial \mathrm{T}} = \frac{1}{\hat{\sigma}}\phi\left(\frac{\mathrm{T}-\hat{\mu}}{\hat{\sigma}}\right) - \frac{1}{\sigma_0}\phi\left(\frac{\mathrm{T}-\mu_0}{\sigma_0}\right) \tag{7}$$

Equation 7 can be regarded as the difference between the $\hat{X}$ and X_0. The intersection points x of these two PDFs can be obtained as:

$$\begin{aligned} &\frac{1}{\sqrt{2\pi}\sigma_0} e^{-\frac{(x-\mu_0)^2}{2{\sigma_0}^2}} = \frac{1}{\sqrt{2\pi}\hat{\sigma}} e^{-\frac{(x-\hat{\mu})^2}{2\hat{\sigma}^2}} \\ &\Rightarrow \ln(\sigma_0 e^{-\frac{(x-\mu_0)^2}{2{\sigma_0}^2}}) = \ln(\hat{\sigma} e^{-\frac{(x-\hat{\mu})^2}{2\hat{\sigma}^2}}) \\ &\Rightarrow \left(\hat{\sigma}^2 - {\sigma_0}^2\right) x^2 + 2\left({\sigma_0}^2\hat{\mu} - \hat{\sigma}^2\mu_0\right) x + \hat{\sigma}^2{\mu_0}^2 \\ &\quad - {\sigma_0}^2\hat{\mu}^2 - 2{\sigma_0}^2\hat{\sigma}^2 \ln\frac{\sigma_0}{\hat{\sigma}} = 0 \end{aligned} \tag{8}$$

Therefore the two Gaussian function curves can have at most two intersection points. We focus on the monotonicity of D when $T > \hat{\mu}$.

$$\left.\frac{\partial D}{\partial \mathrm{T}}\right|_{\mathrm{T}=\hat{\mu}} = \frac{1}{\hat{\sigma}}\phi\left(\frac{\hat{\mu}-\hat{\mu}}{\hat{\sigma}}\right) - \frac{1}{\sigma_0}\phi\left(\frac{\hat{\mu}-\mu_0}{\sigma_0}\right) > 0 \tag{9}$$

$$\begin{aligned}
\left.\frac{\partial D}{\partial \mathrm{T}}\right|_{\mathrm{T}\to+\infty} &= \lim_{T\to+\infty} \frac{1}{\hat{\sigma}}\phi\left(\frac{\mathrm{T}-\hat{\mu}}{\hat{\sigma}}\right) - \frac{1}{\sigma_0}\phi\left(\frac{\mathrm{T}-\mu_0}{\sigma_0}\right) \\
&= \lim_{T\to+\infty} \frac{1}{\sigma_0}\phi\left(\frac{\mathrm{T}-\mu_0}{\sigma_0}\right)\cdot\left(\frac{\frac{1}{\hat{\sigma}}\phi\left(\frac{\mathrm{T}-\hat{\mu}}{\hat{\sigma}}\right)}{\frac{1}{\sigma_0}\phi\left(\frac{\mathrm{T}-\mu_0}{\sigma_0}\right)} - 1\right) \\
&= \lim_{T\to+\infty} \frac{1}{\sigma_0}\phi\left(\frac{\mathrm{T}-\mu_0}{\sigma_0}\right)\left(\frac{\sigma_0}{\hat{\sigma}} e^{\frac{(T-\mu_0)^2}{2\sigma_0^2} - \frac{(T-\hat{\mu})^2}{2\hat{\sigma}^2}} - 1\right) \\
&= \lim_{T\to+\infty} \frac{1}{\sigma_0}\phi\left(\frac{\mathrm{T}-\mu_0}{\sigma_0}\right)\left(\frac{\sigma_0}{\hat{\sigma}} e^{\frac{(\hat{\sigma}^2-\sigma_0^2)\mathrm{T}^2}{2\sigma_0^2\hat{\sigma}^2}} - 1\right) < 0
\end{aligned} \tag{10}$$

Similarly,

$$\left.\frac{\partial D}{\partial \mathrm{T}}\right|_{\mathrm{T}\to-\infty} < 0 \tag{11}$$

According to the intermediate zero theorem, there must be two zero points located in intervals $(-\infty,\hat{\mu})$ and $(\hat{\mu},+\infty)$ respectively.

Since 8 indicates that Equation 7 have at most two zero points, there is exactly one zero point within $(-\infty,\hat{\mu})$ and $(\hat{\mu},+\infty)$ respectively. We assume zero point $T = x^*$ in the interval $(\mu,+\infty)$. Therefore, The value of D increases monotonically in the interval $\mathrm{T} \in (\hat{\mu},x^*)$ and decreases monotonically in the interval $\mathrm{T} \in (x^*,+\infty)$. Hence, at $\mathrm{T} \to \hat{\mu}^+$ or $\mathrm{T} \to +\infty$, D reaches its minimum value when $\mathrm{T} > \hat{\mu}$:

$$\begin{aligned}
\min D|_{\mathrm{T}>\hat{\mu}} &= \min(D|_{\mathrm{T}\to\hat{\mu}^+}, D|_{\mathrm{T}\to+\infty}) \\
&= \min(0^+, \Phi\left(\frac{\hat{\mu}-\mu_0}{\sigma_0}\right) - 0.5) > 0
\end{aligned} \tag{12}$$

For all $\mathrm{T} > \hat{\mu}$, we can obtain:

$$D = J(\mathrm{T}) - J(\hat{\mu}) \geq \min D > 0 \tag{13}$$

This contradicts with our assumption that there is the optimal solution of $J(\mathrm{T})$ under $\mathrm{T} > \hat{\mu}$ since that $J(\hat{\mu})$ is always smaller. So the assumption is wrong. And the optimal threshold value T we choose must satisfy $T \leq \hat{\mu}$.

□

Increased proportion with decreased error. Using the same shadow model means that the threshold T chosen by the adversary remains unchanged and it has the property of $\mathrm{T} \leq \hat{\mu}$ by Claim 1. We assume that the similarity score distribution of in-properties follows distribution $X_1 \sim N(\mu_1,\sigma_1)$ and the similarity score distribution of the out-properties follows distribution $X_0 \sim N(\mu_0,\sigma_0)$. Another similarity score distribution of in-properties with lower proportion such as that of our shadow model follows distribution $\hat{X} \sim N(\hat{\mu},\hat{\sigma})$. So the means and variances have the relationship: $\mu_0 < \hat{\mu} < \mu_1$, $\sigma_0 > \hat{\sigma} > \sigma_1$. The attack effectiveness under property distributions with different proportions can be measured by the objective function $J(X)$, the sum of probabilities of two types of error, where X is a random variable of the similarity score. With an increased proportion of in-properties, the attack error decreases as follows:

Claim 2. *Given three Gaussian distributions $X_0 \sim N(\mu_0,\sigma_0)$, $X_1 \sim N(\mu_1,\sigma_1)$ and $\hat{X} \sim N(\hat{\mu},\hat{\sigma})$ such that $\mu_0 < \hat{\mu} < \mu_1$, $\sigma_0 > \hat{\sigma} > \sigma_1$ and objective function $J(X) = \Pr[X_0 > \mathrm{T}] + \Pr[X < T], X \sim N(\mu,\sigma)$ where T is a constant satisfying $T \leq \hat{\mu}$, then the objective function of $\hat{X}$ and X_1 must satisfy:*

$$J(\hat{X}) > J(X_1)$$

Proof.

$$\begin{aligned}
J(X) &= \Pr[X_0 > \mathrm{T}] + \Pr[X < \mathrm{T}] \\
&= \Pr[X_0 > \mathrm{T}] + \Phi\left(\frac{\mathrm{T}-\mu}{\sigma}\right)
\end{aligned}$$

As the proportion of in-property increases, the similarity score distribution of out-property does not change. Therefore, $\Pr[X_0 > \mathrm{T}]$ is a constant.

To compare $J(\hat{X})$ and $J(X_1)$, we compute the partial derivative of $J(X)$ with respect to μ and σ respectively:

$$\frac{\partial J}{\partial \mu} = -\frac{1}{\sigma}\phi\left(\frac{\mathrm{T}-\mu}{\sigma}\right)$$

$$\frac{\partial J}{\partial \sigma} = -\frac{\mathrm{T}-\mu}{\sigma^2}\phi\left(\frac{\mathrm{T}-\mu}{\sigma}\right)$$

where $\frac{1}{\sigma}\phi\left(\frac{\mathrm{T}-\mu}{\sigma}\right)$ denotes the PDF of X. Obviously, $\frac{\partial J}{\partial \mu} < 0$. So as μ increases, the probability of making two types of errors decreases. Since $\mathrm{T} \leq \hat{\mu} < \mu_1$, $\frac{\partial J}{\partial \sigma} \geq 0$. So $J(X)$ is monotonically increasing with respect to σ.

According to the relationship $\mu_0 < \hat{\mu} < \mu_1$, $\sigma_0 > \hat{\sigma} > \sigma_1$ and the monotonicity, there is $J(\hat{X}) > J(X_1)$.

Hence, as the proportion of the target properties increases in the training set, its variance decreases and its mean increases. Using the same shadow model, the effectiveness of the property existence inference will be improved.

□

Based on the above explanation, we conclude that with the same shadow model to obtain the threshold, the larger the proportion of the target property, the better the attack effect.

SDFuzz: Target States Driven Directed Fuzzing

Abstract

Directed fuzzers often unnecessarily explore program code and paths that cannot trigger the target vulnerabilities. We observe that the major application scenarios of directed fuzzing provide detailed vulnerability descriptions, from which highly-valuable program states (*i.e.*, target states) can be derived, *e.g.*, call traces when a vulnerability gets triggered. By driving to expose such target states, directed fuzzers can exclude massive unnecessary exploration.

Inspired by the observation, we present SDFuzz, an efficient directed fuzzing tool driven by target states. SDFuzz first automatically extracts target states in vulnerability reports and static analysis results. SDFuzz employs a selective instrumentation technique to reduce the fuzzing scope to the required code for reaching target states. SDFuzz then early terminates the execution of a test case once SDFuzz probes that the remaining execution cannot reach the target states. It further uses a new target state feedback and refines prior imprecise distance metric into a two-dimensional feedback mechanism to proactively drive the exploration towards the target states.

We thoroughly evaluated SDFuzz on known vulnerabilities and compared it to related works. The results show that SDFuzz could improve vulnerability exposure capability with more vulnerability triggered and less time used, outperforming the state-of-the-art solutions. SDFuzz could significantly improve the fuzzing throughput. Our application of SDFuzz to automatically validate the static analysis results successfully discovered four new vulnerabilities in well-tested applications. Three of them have been acknowledged by developers.

1 Introduction

Directed grey-box fuzzing (DGF) usually drives the testing towards highly-valuable target site locations. Though being widely used in crash reproduction and vulnerability validation [3, 7, 16, 26, 42], one primary problem of prior directed fuzzers is that they often explore a large number of program code and paths that cannot trigger the crashes. In the exploration stage of DGF, most existing approaches follow AFLGo's solution [26] and use coverage feedback for expanding the exploration of different code areas. Many code areas are irrelevant and unrequired for reaching the target sites [32]. Such code areas are still unnecessarily explored. In the exploitation stage, prior directed fuzzers utilize the distance metrics based on the control-flow graph (CFG) and call graph (CG) [3, 7, 26]. The distance metrics do not consider the path conditions, such as control-flow and data-flow conditions. As a result, executions that cannot trigger the vulnerabilities at the target sites because of unsatisfiable control-flow or data-flow conditions might still gain short distances and be overly favored [14, 16, 44]. Excessive testing efforts are thus wasted [44].

A solution to mitigate the above-mentioned problem is to first identify the required program code/paths for triggering the crashes and fuzz only the required one(s). SieveFuzz analyzes the inter-procedural control-flow graph (ICFG) to identify required functions for reaching the target sites and terminates the executions once they reach unrequired functions [32]. Beacon computes the preconditions to reach the target sites via a backward interval analysis and early terminates the executions that fail to satisfy the preconditions [14]. SelectFuzz [20] statically identifies the control- and data-dependent code to the target sites. However, they over-approximate the set of allowed program code and paths, significantly restricting their performance. This is because their analysis is conservative. They only consider the control-flow reachability but fail to analyze other conditions for triggering the vulnerabilities, *e.g.*, the expected reaching order of the target sites [16]. Hawkeye [3] and CAFL [16] include call traces in their designs of distance metrics. However, they do not use them to exclude unrequired code/paths.

We mitigate the problem of unnecessary exploration in DGF with a new finding of *target states, which include the expected call traces and reaching order of the target sites for triggering the vulnerabilities.* In particular, the major tasks of

DGF, such as crash reproduction and vulnerability validation, all provide detailed descriptions of vulnerabilities, such as the target site locations and the associated vulnerability information, *e.g.*, crash dumps, backtraces [10], and source-sink flows [35]. Target site locations describe where the vulnerabilities would occur; the vulnerability information additionally explains the interesting program states (namely target states) about how to trigger the vulnerabilities. The goal of directed fuzzing is not only to reach the target site locations but also to dynamically expose the vulnerabilities. Inspired by this, we aim to drive the fuzzing towards not only the target sites but also the interesting target states. *Thus, besides excluding the exploration that cannot reach target sites, we further avoid the unnecessary executions that cannot reach the target states*.[1]

We thereby design SDFUZZ, a target State driven Directed Fuzzer. We first formalize the target state of a vulnerability as an ordered list of program execution events (*i.e.*, the stack of function invocations at the vulnerability site). SDFUZZ then automatically extracts the target states from vulnerability reports and static analysis results. It takes a selective instrumentation technique to reduce the fuzzing scope to the code required for reaching the target states. In particular, based on the functions in the target states, SDFUZZ analyzes the calling relationship in the inter-procedural control-flow-graph (ICFG) to identify (un)required code. Unlike prior works that directly terminate all executions on unrequired code (identified based on target sites), SDFUZZ still preserves all code of the software but instead removes the code coverage feedback from unrequired code (identified based on target states). The unrequired code is hidden from the fuzzer's perspective, SDFUZZ thus would not assign excessive energy to overly test it. This design choice gets rid of the acute side effects of false code elimination and is fault tolerant: executions can go through (wrongly identified) unrequired code to target sites without being (wrongly) terminated.

SDFUZZ early terminates the execution of a test case once it probes that the remaining execution cannot lead to the target states. One challenge we face is *how to determine if an execution cannot ultimately lead to the target states without completing the execution*. We solve the problem by monitoring runtime program state. At runtime, SDFUZZ maintains the runtime program state, periodically compares it to the target state, and probes if there is any deviation. Situations with any deviation that *cannot be recovered in the subsequent execution of a test case* can be terminated immediately. A deviation can be recovered if there is a program path on the ICFG, through which the deviation function call can possibly be updated to the expected function call specified in the target state.

Besides reducing resource consumption by avoiding unnecessary exploration, SDFUZZ further employs a two-dimensional feedback mechanism to *proactively* drive the testing towards target states. In the first dimension, SDFUZZ calculates a novel target state feedback by computing a similarity score from the best runtime program state of a fuzzing trial to the target states. This dimension aims to favor test cases with better runtime program states. In the second dimension, SDFUZZ refines the widely-adopted distance metrics in DGF. Instead of using an empirically configured constant coefficient (*e.g.*, 10 in AFLGo [26]) as the inter-procedural distance between functions in CG, SDFUZZ uses a new weighted inter-procedural distance by approximating the chance for the caller function to invoke the callee function. The two-dimensional feedback is then used for the power scheduling and seed selection.

We thoroughly evaluated SDFUZZ to assess its capability. We first show that SDFUZZ could generate target states for the majority of bugs in the Magma dataset [13,21], demonstrating its applicability to real-world cases. Besides, on 45 known vulnerabilities, we compared SDFUZZ to four related state-of-the-art directed fuzzers, *i.e.*, AFLGo [26], WindRanger [7], Beacon [14], and SieveFuzz [32]. The results show that SDFUZZ exposed eight, seven, ten, and four more vulnerabilities, respectively, and achieved an average[2] speedup of 2.83×, 2.65×, 1.29×, and 1.81×, respectively, above them. SDFUZZ achieved the best performance for 77.8% of the evaluated vulnerabilities. Our ablation study confirmed the essence of target states to the performance of SDFUZZ. It also showed the benefit of each technique in SDFUZZ, especially the selective instrumentation and execution termination techniques. For instance, on average, SDFUZZ eliminated 48.18% of unrequired functions and early terminated 56.23% of executions. Furthermore, we applied SDFUZZ to automatically extract target states from the results of a static analysis tool—SVF [35]—and validate the results. SDFUZZ successfully identified four new vulnerabilities in three well-tested file processing applications (*e.g.*, `libjpeg`). Three of them have been promptly acknowledged by the developers. We plan to open-source SDFUZZ to facilitate future research.

In summary, this paper makes the following contributions:

- We proposed a new concept of target states and demonstrated their benefits for DGF.
- We designed SDFUZZ, an efficient directed fuzzing system driven by target states.
- We incorporated DGF with static analysis to fully automatically validate the results.
- With SDFUZZ, we discovered four new vulnerabilities.

2 Background and Motivation

In this section, we present the background of directed grey-box fuzzing and its representative use examples. We then analyze existing DGF approaches to motivate our solution.

[1] By the term of reaching target states, we mean the execution could exhibit such target program states.

[2] The average values are computed using the geometric mean instead of arithmetic mean throughout this paper.

2.1 Directed Grey-Box Fuzzing

DGF differentiates itself from general coverage-guided grey-box fuzzing in specializing in testing specific code locations. DGF employs an exploration stage driven by the code coverage feedback to expand the covered code locations. Additionally, DGF has an exploitation stage, where past practices mainly employ distance metrics for providing runtime feedback to guide testing direction [7, 16, 26]. For instance, AFLGo defines the distance of a basic block as the harmonic mean of its shortest path lengths to all target sites [26]. In a shortest path, the path length is the sum of the weighted inter-procedural CG distance from the caller function to the target function and the intra-procedural CFG distance from the basic block to the call site's basic block. During a fuzzing trial, a directed fuzzer obtains the execution trace of a test case and computes the average distance of the executed basic blocks as the seed distance. It then uses the distance for seed selection and power scheduling.

2.2 Use Examples of DGF

Directed fuzzers can generally be used to test particular target sites. We show some representative use examples of DGF below.

Reproducing crashes. Software developers often accept vulnerability reports from users. Automated crash report systems [11] collect crash reports from end users and send them to the developers. Since the crash inputs usually convey sensitive user data (*e.g.*, confidential cookies for browser crashes), such systems by default do not attach the crashing proof-of-concept (PoC) inputs [6]. They instead often provide the crash dumps, which contain the crash types and locations, and the involved call traces when the crashes occur. DGF is then helpful for the developers to reproduce the crash specified in the crash dumps. Even if PoC inputs are available, developers may still want to use DGF to comprehend the vulnerabilities and patches.

DGF can address the limitations of symbolic execution based crash reproduction tools. For instance, Star [4], JCharming [28], and BugRedux [15] perform symbolic execution on the slices to target sites. However, they usually collect non-linear, incomplete, and complex path constraints and do not handle external environments, rendering PoC generation through constraint solving difficult [41]. DGFs can address such complex issues by efficient input mutation.

Validating vulnerabilities. Static analysis screens the source code of the program and outputs potential vulnerabilities. The analysis results commonly include vulnerability locations and assumed suspicious flows for the vulnerabilities [29,33,34,39]. To reduce the huge number of false positives, developers can leverage DGF to proactively find PoCs on the suspicious flows and validate the results. Instead of considering all possible flows and paths, a desired DGF ought to focus on only the suspicious flows in the results.

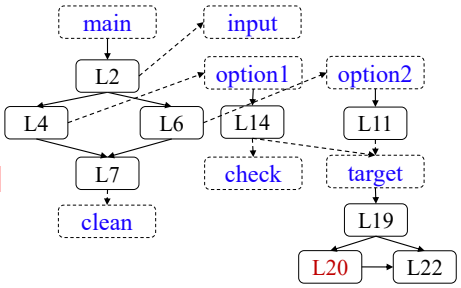
2.3 Existing Approaches and Limitations

Directed fuzzers often unnecessarily test code and paths that cannot trigger the vulnerabilities. This occurs in both the exploration and exploitation stages. We illustrate it with a motivating example shown in Figure 1. There is an assertion failure at `L20`, which is often set as the target site in DGF. The execution through `L4` in function `main()` (namely execution ①) can reach the target site and possibly trigger the assertion failure. The execution going through `L6` (namely execution ②) can only reach the target site.

Unnecessary exploration stage testing on unrequired code. DGF has the goal of reaching target sites and triggering the vulnerabilities there. Its exploration stage directly adopts the conventional coverage metric to expand the covered code, which would favor the executions/test cases that increase the coverage (*i.e.*, new code discovery). However, a large proportion of code is not required for reaching the target sites and would negatively interfere the exploration direction of DGF. For instance, the function `clean()` is not helpful for reaching `L20`.

Unnecessary exploitation stage testing on (un)reachable executions. Even after narrowing down the fuzzing scope to the required code, the exploitation stage still causes unnecessary resource consumption on both executions that can or cannot reach the target sites, *i.e.*, reachable and unreachable executions. As we mentioned in §2.1, DGFs use distance metrics in the exploitation stage [3, 16, 26]. The distance metrics are simply based on the ICFG without analyzing path conditions. Thus paths with unsatisfiable conditions can be regarded as feasible ones. The corresponding executions might obtain short distances and get overly favored.

2.3.1 Prior Mitigations



A solution to mitigate this problem is to identify the unrequired code/paths for triggering the vulnerabilities. Beacon [14] statically identifies unrequired code based on the reachability to target site locations. It immediately terminates executions through assertions once the executions trigger unrequired code. SieveFuzz [32] further integrates a dynamic analysis to identify unrequired code and then accordingly terminates executions. SelectFuzz [20] identifies the data- and control-dependent code to the target sites. However, they merely leverage the reachability to the target site locations to drive their required code identification. They could not sufficiently exclude other unrequired code.

Beacon also inserts assertion checks to early terminate executions unsatisfying the preconditions for reaching the target sites through a backward interval analysis. However, the current design of Beacon has two foundational problems. First, to terminate the executions early, the backward interval

```
1  void main() {
2      int x = input();
3      if(x < 10)
4          option1(x); //(1)
5      else
6          option2(x); //(2)
7      clean();
8  }
9
10 void option2(int opcode) {
11     target(opcode);
12 }
```

```
13 void option1(int opcode) {
14     check();
15     target(opcode + 5);
16 }
17
18 void target(int arg) {
19     if (arg <= 20) {
20         assert(arg < 5);
21     }
22     ...
23 }
```

(a) Code example.

(b) ICFG.

Figure 1: A motivating example. The starting line number of a basic block is used as its name in Figure 1(b).

analysis produces complex preconditions, which introduce significant runtime overhead [32]. Second, the preconditions merely embed the control-flow reachability to the target sites without considering additional important information such as call traces and the reaching order of the targets [16]. As a result, Beacon would not terminate reachable executions like execution ②.

Summary. The majority of distance-based DGFs do not leverage any method to exclude unnecessary exploration. They unnecessarily test code and paths in both the exploration and exploitation stages. Prior mitigation approaches [14, 20, 32], however, only consider the reachability to the target sites, yet still keep many unnecessary executions. In this work, we tackle these problems and improve the effectiveness of DGF by exploiting target states.

3 Target States

DGFs specify the target sites—code locations of interest. The target sites often come from two sources: 1) vulnerability reports and 2) static analysis results. We find that from the two sources, we can additionally identify target states, which include the expected call traces and reaching order of the target sites. The target states are helpful for improving directed fuzzing.

3.1 Vulnerability Reports

Software developers often accept vulnerability reports from users. Most vulnerability reports in the wild contain associated crash dumps to help developers confirm the vulnerabilities timely. For example, Figure 2 presents the crash dump (call trace) for the assertion failure in Figure 1. It captures a list of function calls that are currently active in the thread and the invocation locations when the crash is triggered. The `libc` in the crash dump means the library that starts the execution of the main function. Prior DGFs often set the erroneous locations at the top of the crash dump (*i.e.*, crash points) as the

```
1 0x... in target      file.c:20
2 0x... in option1     file.c:15
3 0x... in main        file.c:4
4 0x... in in __libc_start_main
```

Figure 2: Crash dump.

fuzzing target sites, *e.g.*, `file.c:20` in this example.

However, the crash point is only a part of the crash dump. The crash dump pinpoints a highly-valuable call trace about the reported crash, through which the vulnerability can be easily reproduced. With only the target site locations, directed fuzzers would unnecessarily explore many infeasible program states (*e.g.*, execution ②). Driving a directed fuzzer to invoke the list of functions conforming to the crash dump could enable it to trigger the vulnerability quickly. Furthermore, for multi-target vulnerabilities (*e.g.*, use-after-free), there can be associated call traces for each involved target site, and their expected reaching order can be inferred [16]. *In this work, we define the expected call traces and the reaching order of target sites as target states.* No prior directed fuzzer has used the target states to eliminate unnecessary exploration. Prior solutions [14, 32] only use the target site locations and partially exclude exploration that could not reach the target sites.

Crash dumps are available in most of the vulnerability reports, from which target states can be extracted. We studied four popular file processing applications such as `swftophp` and `lrzip`, to which fuzzing has been widely applied [14, 26]. We examined all historical crashes in the applications and summarized an unbiased dataset of 259 crashes. We found that crash dumps existed in 191 (73.75%) cases. This demonstrates that target states can be obtained in most cases. A solution that requires the target states still has wide applicability.

3.2 Static Analysis Results

Static analysis is based on heuristics and often outputs detailed information for analysts to comprehend the analysis

results. Static analysis tools report the vulnerable flows to the target sites where the conditions of the heuristics are met. For instance, Joern [39]—a taint analysis tool—would report the vulnerable flow from the untrusted external data sources to the target sites. SVF [34, 35] for memory-safety issues would report vulnerable program flows of improper memory usage.

Prior directed fuzzers often set the memory operations in the reported flows as the target sites. This would make DGF explore all possible paths to the target sites. However, there are abundant flows that do not meet the conditions of the heuristics. Testing them causes non-negligible resource waste. To efficiently validate the vulnerability, a fuzzer ought to focus on exhibiting the vulnerable flows instead of all possible ones. Similar to vulnerability reports, we can derive the expected target states from such commonly provided vulnerable flows in static analysis results.

3.3 Formalization

We define a general representation of program states used in this work, as shown in Formula 1. We learn from examples (*e.g.*, Figure 2) that the crash dumps contain a sequence of ordered function calls and the invocation locations. We thus formalize a program state (PS) as the stack of function invocations (call sites). Each item in the program state is a tuple of the function name and the invocation location (`(Func, Loc)`). The target state (`TS`) of a vulnerability or a bug is the program state when it is triggered. To reach a target state, the functions in it ought to be reached or called in the right order. Therefore, Formula 1 captures the expected call traces and their reaching order. For example, we can formalize the crash dump in Figure 2 as the target state (`TS1`) shown in Figure 4(a). For multi-target vulnerabilities, we can usually derive one target state per target site and sort them to obey the required target reaching order (`TSs`) [16]. Similarly, the target states of static analysis results can be formalized using program states.

$$\begin{aligned} PS &= [(Func_1, Loc_1), (Func_2, Loc_2), ..., (Func_n, Loc_n)] \\ TSs &= [TS_1, TS_2, ..., TS_m] \end{aligned} \tag{1}$$

4 SDFuzz

4.1 Overview

We advance DGF using target states. In the vast exploration space of a program, a significant proportion cannot trigger the target vulnerabilities. Testing all of it would cause unnecessary resource consumption. Fortunately, target states describe interesting program states where the vulnerabilities would (likely) occur. Our intuition is to drive the fuzzing to exhibit these interesting target states instead of merely reaching the target site locations. We use the target states from vulnerability reports and static analysis results to *exclude unnecessary exploration that cannot reach the target states*. We further design new techniques to proactively guide the testing. Hawkeye [3] and CAFL [16] also use call traces in their distance design to guide the exploration. They still consider the whole exploration space of a program. SDFuzz starts from a different angle by proactively removing unnecessary testing.

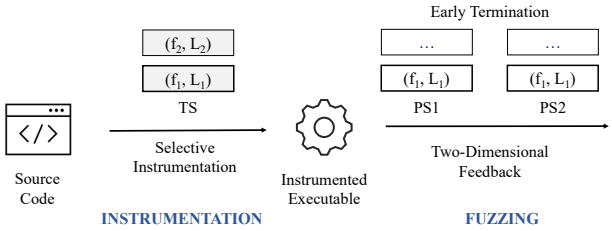


Figure 3: The workflow of SDFuzz.

We thereby develop a new directed fuzzing system, SDFuzz, based on the target states. The workflow of SDFuzz is depicted in Figure 3. SDFuzz first automatically extracts target states and parses them into specified formats. SDFuzz then identifies the required code for reaching the target states and removes other unrequired code from fuzzing. It particularly advances prior solutions [14, 32] in using the target states instead of target sites. SDFuzz early terminates the executions once it probes that the remaining execution of a test case cannot reach the target states, thereby increasing the fuzzing throughput (*i.e.*, number of executions per unit time). SDFuzz uses a two-dimensional feedback mechanism to proactively guide the testing towards the target states. In the first dimension, SDFuzz measures the similarity between the best runtime state of a test case and the target states, and favors the ones with higher similarity. In the second, SDFuzz adopts a new precisely-weighted inter-procedural distance metric.

4.2 Extracting Target States

To extract the target states, SDFuzz requires either vulnerability reports or static analysis results. For the latter, SDFuzz employs an existing static analysis tool to analyze the program's source code.

Vulnerability reports. The crash dump consists of the records of the active function calls when a vulnerability is triggered, as shown in Figure 2. Each record contains: 1) function name (*e.g.*, `option1`) and 2) invocation location (*e.g.*, `file.c:15`). Therefore, we first search the vulnerability reports about descriptions containing such information using regular expressions. After extraction, we further parse them to decide if they match the formats defined in Formula 1. We also automatically sort the target states based on the vulnerability types and the descriptions. For example, a use-after-free vulnerability often contains multiple target states. We would

Algorithm 1: Required code identification.

```
   input  : TSs, ICFG
   output : requiredFuncs
1  initRequiredFuncs ← [ ]
2  requiredFuncs ← [ ]
3  for TS ∈ TSs do
4      for f ∈ TS do
5          initRequiredFuncs.insert(f)
6          funcs ← backwardAnalysis(f, ICFG) // get
             functions with intra-procedural dependencies
7          initRequiredFuncs.insert(funcs)
8      end
9  end
10 while ! initRequiredFuncs.empty() do
11     f ← initRequiredFuncs.remove()
12     if f ∉ requiredFuncs then
13         requiredFuncs.insert(f)
14         callees ← getCallees(f, ICFG) // get callees
             of f
15         initRequiredFuncs.insert(callees)
16     end
17 end
18 return requiredFuncs
```

sort the target states sequentially by the free and the use site.

Static analysis results. SDFuzz also automatically extracts the target states from the static analysis results. Since different static analysis tools take diverse ways to represent their results, naturally, the automated extraction has to be specially designed for each static analysis tool. We currently develop SDFuzz to coordinate with one popular static analysis tool, SVF [34, 35]. To the best of our knowledge, target states can be extracted from other static analysis tools such as CodeQL [9] and Joern [39] with only additional efforts to parse the results. The program's source code is usually required for running such static analysis tools.

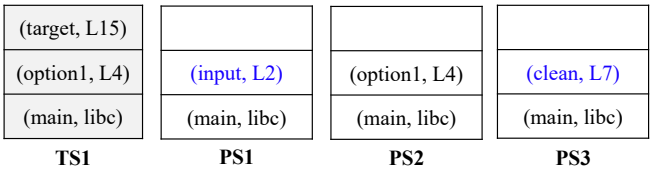
4.3 Selective Instrumentation of Required Code

SDFuzz reduces the fuzzing scope by selectively instrumenting only the required code for coverage feedback in the exploration stage of DGF. SDFuzz first identifies what part of the code is required and then deliberately excludes the other unrequired code from the fuzzing process. Our solution preserves the code required for reaching the target states, which is a subset of the code for reaching the target sites as preserved in SieveFuzz and Beacon. This is because the target states further constrain the paths to reach target sites. It thus can help filter out much more code and improve fuzzing throughput. Our solution selectively instruments the required code for code coverage feedback instead of directly removing it from the source or executable.

We propose a function-level algorithm shown in Algorithm 1 to identify the required code. It takes as inputs a set of target states (`TSs`) and the ICFG of the target program (`ICFG`). The functions appearing in the target states (namely target state functions) are related to the vulnerabilities and are directly included as the required functions (line 5). Besides, these target state functions might depend on other functions. Our algorithm first performs a backward intra-procedural analysis to identify the functions that a target state function depends on (line 6). A function is included if there is an intra-procedural path between the basic block that has a function call site and the basic block of a target state function. For instance, function `check()` is included because function `target()` at `L15` depends on it. Additionally, those newly included functions might invoke other functions to accomplish their functionalities. Therefore, our algorithm analyzes the CG and includes those functions on the CG paths outing from the initially included functions (lines 14-15). In this way, SDFuzz expands the set of functions required for realizing the target states. The callee functions of `check()` are added to the required code for this.

Instead of directly removing the code from the target executable, SDFuzz employs an instrumentation-based method to exclude unrequired code. We find that DGF requires collecting code coverage feedback, which reveals the existence of code areas. SDFuzz thus selectively instruments only the identified required code for code coverage feedback, which hides the other unrequired functions from the fuzzer and reduces the fuzzing scope. This design is fault-resilient. Even if some code areas are wrongly identified as unrequired, executions can still go through such code areas to further approach the target sites and states. SDFuzz would not assign testing energy to explore the paths that are not instrumented. Thus it gets rid of the critical downside caused by false code elimination in prior solutions [14, 32]. It also reduces the overhead caused by the instrumented coverage tracking code.

4.4 Early Termination of Executions



We develop a new fuzzing technique that early aborts the executions that cannot reach the target states. If some executions are known to be unable to reach the target states, we terminate them early to save the exploration resources. This can dramatically increase the fuzzing throughput by terminating unnecessary executions early. Unlike prior reachability-based execution termination approaches [14, 32], SDFuzz also terminates reachable executions that cannot reach the target states.

To perform the early termination of executions, we have to predict if the execution can ultimately reach the target states or not. This is difficult because the program state is dynamically updated along the program execution, *e.g.*, via function invocations and returns. Given the high complexity of modern programs, the program state space they can exhibit can be huge [1].

```
TS1=[(main, libc), (option1, L4), (target, L15)]

PS1=[(main, libc), (input, L2)]
PS2=[(main, libc), (option1, L4)]
PS3=[(main, libc), (clean, L7)]
```

(a) A target state and selected program states.

(b) Target state and selected program states, with the root deviations are in blue.

Figure 4: A target state and selected program states.

Runtime program state monitoring. SDFuzz monitors the runtime function invocations and records the stack of function invocations. These functions are pushed or popped from the stack with function invocations or returns. The function invocation locations enable SDFuzz to distinguish the same function invoked at different locations. Program state tracking might potentially lead to state explosion [38] and can cause heavy overhead. We mitigate this issue by tracking the states for only the functions relevant to the target states. In particular, SDFuzz only updates and checks the program state for early termination when the program calls or returns from the functions in target states.

An unrecoverable deviation based solution. As mentioned in §3.3, the target states for a multi-target vulnerability are an array of ordered lists of function call invocations, each for a target site. Our algorithm (shown in Algorithm 2) thus takes as inputs the current program state (`PS`) at a point in time, previously reached target states (`reachedTSs`), the ordered target states (`TSs`), and the `ICFG`. It iterates over the target states to find the first target state that has not been reached during a fuzzing trial of a test case (lines 3-6). If all target states have been reached, the algorithm directly returns (lines 7-8). Otherwise, it then checks the deviation function calls, especially the first deviation—*root deviation* through `rootDeviation` function (line 10). The root deviation denotes where the program state starts to deviate from the unreached target state. This is done by iteratively comparing the call sites (lines 20-26) to find the first deviation.

If there is any deviation (line 11), our algorithm further measures if the remaining execution can recover the deviations to reach the target state based on the ICFG (line 12). If an execution has unrecoverable deviations in its program state, it can be immediately terminated. Our algorithm checks the ICFG of the program and probes if there is a program path from the root deviation code location to the expected function call in the target state. Such a path means the deviations might be recovered in the future execution because the execution can return from the root deviation function call and run to the expected one. Accordingly, the execution that might recover the deviation would not be terminated.

We illustrate the workflow of our algorithm with three program states of an execution (namely `PS1`-`PS3`) listed in Figure 4. `PS1` is observed when the execution reaches right after line 2. The program state deviates from the target state (*i.e.*, `TS1`) in the second item, *i.e.*, `(input, L2)` *v.s.* `(option1, L4)`. The deviation is possibly recoverable because subsequent execution might return from the function `input()` and run next to the expected function `option1()` at `L4`. From the perspective of ICFG, this can be reflected as the existence of a program path from the deviation location (*e.g.*, `L2`) to the expected one (*e.g.*, `L4`). Thus the execution would not be terminated at `PS1`. At `PS2`, the program state is exactly the prefix of `TS1` without additional deviations and does not deviate from `TS1`. The execution would not get terminated. However, in the case of `PS3`, it deviates at `(clean, L7)` against the `(option1, L4)` in `TS1`, and there is no path from `L7` to `L4`. The execution would get terminated. Beacon's solution [14], on the other hand, is not able to terminate the execution in the middle.

4.5 Two-Dimensional Feedback

4.5.1 Target State Feedback

SDFuzz also compares the runtime program states to the target states and computes a similarity score to proactively guide the exploration. The feedback favors test cases with more similar program states to the target states. Some recent works such as CAFL [16], LOLLY [17], and Hawkeye [3] also use the runtime program behaviors. However, the mechanism in SDFuzz is tailored to target states and considers calling contexts.

The workflow is also shown in Algorithm 2. After finding the first unreached target state (`nextTS`) at lines 3-6, SDFuzz uses the index of the root deviation to compute the similarity score. If the current program state does not fully match the first unreached target state (`nextTS`), SDFuzz first measures how well the current program state fits it by computing the ratio of matched `deviationIdx` over its size (line 13). Our algorithm also considers previously reached target states and sums a score of the ratio and the size of `reachedTSs`. The score is further normalized using the number of target states and returned. If the current program state matches `nextTS`, our algorithm directly returns the proportion of reached target states (line 16). Since the algorithm might be invoked multiple times for the execution of a test case, we assign the best score as the result of the test case.

Algorithm 2: Execution termination and target state similarity.

```
   input  : PS, TSs, reachedTSs, ICFG
   output : score, termination, reachedTSs
1  nextTS ← null
2  termination ← false
3  for TS ∈ TSs\reachedTSs do
4  |  nextTS ← TS // find next target state
5  |  break
6  end
7  if nextTS = null then
8  |  return 1, false, reachedTSs
9  end
10 deviationIdx ← rootDeviation(PS, nextTS)
11 if deviationIdx ≠ nextTS.size then
12 |  termination ← ! ICFG.path.exists(PS[deviationIdx],
   |    nextTS[deviationIdx]) // check if recoverable
13 |  score ← (deviationIdx / nextTS.size + reachedTSs.size)
   |    / TSs.size
14 else
15 |  reachedTSs.insert(nextTS) // no deviation
16 |  score ← reachedTSs.size / TSs.size
17 end
18 return score, termination, reachedTSs
19
20 function rootDeviation(PS, TS):
21 |  index ← 0
22 |  for index<min(PS.size, TS.size) & PS[index]=TS[index]
   |    do
23 |  |  index ← index + 1
24 |  end
25 |  return index
26 end
```

4.5.2 Distance Feedback

SDFuzz also uses a distance metric to guide the fuzzing process. Prior distance metrics are imprecise because they consider every edge in CG equally. They empirically configure a constant weight (*e.g.*, 10 in AFLGo-based directed fuzzers) to approximate the chance for reaching the target functions [3, 26]. Therefore, executions exhibiting long call chains, even with high chances to reach the target functions, are possibly assigned with large distance values and get deprioritized. Distinct functions ought to be evaluated differently.

SDFuzz mitigates the imprecision with precise edge weights when computing inter-procedural distances. The edge weight is expected to reflect the chance for the caller function to invoke the callee function. SDFuzz computes the edge weight based on the call-site weights. We define the *call-site weight* for a caller function to invoke a callee function as the intra-procedural distance from the start of the caller function to the call site of the callee (*i.e.*, the basic block distance on the shortest path as in AFLGo [26]). Since there might be multiple call sites to the same callee function, the inter-procedural *edge weight* is the shortest call-site weight ($weight(f_i, f_j)$) between the caller function $f_i()$ and the callee function $f_j()$. This is also shown in Formula 2, where $d_{f_i}()$ computes the intra-procedural distance in function f_i. For the function `option1()` in Figure 1, since the function start and the call site of the function `check()` reside in the same basic block, their edge weight is `0` instead of `10` as in AFLGo.

$$weight\left(f_i, f_j\right) = min\left(d_{f_i}\left(BB_{f_i-start},\ BB_{f_j-call-site}\right)\right) \tag{2}$$

The edge weights between callers and callees form a weighted CG. This allows SDFuzz to compute precise CG distance between two arbitrary functions. We formalize the method to compute inter-procedural distance in Formula 3. If there is at least one path from function f_s to function f_e in the CG, their distance is calculated as the sum of edge weights in the shortest path. Otherwise, if there is no path from function f_s to function f_e, the distance is considered as not available or infinite. We explain how we construct CG in §5.

$$interDistance\left(f_s, f_e\right) = min\left(\sum_{(f_i,f_j)\in path} weight\left(f_i, f_j\right)\right) \tag{3}$$

4.5.3 Seed Selection and Power Scheduling

SDFuzz incorporates the two dimensions of feedback to guide the seed selection and power scheduling. To drive the fuzzing towards the target states quickly, SDFuzz sorts the seeds in the corpus sequentially by two attributes—target state feedback and seed distance. Generally, SDFuzz prefers seeds with better target state feedback and shorter distances. It uses target state feedback as the primary sorting attribute and distance as the secondary. The reason is that the target state feedback capturing the runtime context is more precise, and could better help approach target states. SDFuzz also refines the power scheduling algorithm of AFLGo to assign energy to the seeds according to the two-dimensional feedback.

5 Implementation

We implement a prototype of SDFuzz to fuzz C/C++ programs. We first use static analysis to build a program representation to facilitate the required code identification and execution termination. We then employ a compile-time analysis to instrument the target program, which inserts the necessary code for tracking coverage, maintaining program states, computing seed distances, *etc.* Besides, we develop a runtime library to retrieve runtime program states and perform selective execution termination. The main fuzzing component was implemented atop AFLGo [26].

Static analysis. We statically analyze the target program to identify the required functions (§4.3). The analysis leverages Andersen's points-to analysis to identify the call targets for indirect calls [31]. Our implementation currently reuses the associated pipeline of SVF [34]. This results in the CFG and CG for our analysis. We also discuss the potential issues of static analysis in §7.

Instrumentation. We maintain the list of interesting functions obtained from §4.3 and selectively instrument them for code coverage feedback. Other functions not in the list are still preserved but are not instrumented for code coverage feedback. As a result, they can still be executed. The instrumentation component is realized by modifying AFL's LLVM compiler.

Runtime state tracking. We implement a runtime library for program state maintenance and selective execution termination. In the library, we track only a set of functions that are relevant to the target states and maintain the stack of function invocations. At runtime, the library periodically compares the program state to the target state(s) to determine early execution termination. Besides, it also scores the runtime program states to provide target state feedback. We modify the `update_bitmap_score()` and `cull_queue()` functions in AFL to achieve our seed selection strategies.

6 Evaluation

In this section, we extensively evaluate SDFuzz to answer the following questions.

- How well can SDFuzz generate target states in practice?
- What is the capability of SDFuzz in exposing vulnerabilities?
- How much unnecessary exploration can SDFuzz reduce?
- How do the techniques in SDFuzz contribute to its performance?
- How effective is SDFuzz in discovering new vulnerabilities?

6.1 Target State Generation Capability

We first assess if SDFuzz can automatically extract target states for real-world vulnerabilities. We choose Magma [13, 21], a widely-used fuzzing benchmark containing 138 bugs along with their corresponding reports. We check the crash dumps for the included bugs and then apply SDFuzz to extract target states. After that, we manually verify the correctness of the extracted target states.

The results show that SDFuzz could successfully extract correct target states for 127 out of 138 cases, where the crash dumps are included in the bugs' reports. This suggests the high applicability of SDFuzz for real-world bugs. SDFuzz could not generate target states for the cases without available crash dumps. The vulnerabilities have diverse target states, *e.g.*, the number of targets ranges from one to three, and the number of function invocations ranges from two to six. Empirically, we have not observed an impact of target states on the performance of SDFuzz.

6.2 Performance of SDFuzz

We then evaluate the performance of SDFuzz on a set of known vulnerabilities.

Experimental Setup. We construct a comprehensive dataset. In particular, we include the programs and vulnerabilities evaluated by other recent DGFs [7, 14, 20, 32]. Google Fuzzer Test Suite [12] and AFLGo's Test Suite [27] are also included. In total, we include 45 unique vulnerabilities in our dataset, and we list them in Table 1. Other vulnerabilities evaluated by recent DGFs are excluded from our evaluation mainly because of compilation issues such as obsolete and missing dependencies and incompatible compilation environments. The included vulnerabilities span a comprehensive set of vulnerability types such as buffer overflow, heap overflow, *etc.*, and can well evaluate the capability of SDFuzz. All the experiments are conducted on a server running Ubuntu 18.04 with two 18-core Intel Xeon Gold 6140 CPUs and 256GB RAM.

We prepare the target states and the seed inputs for the experiments. We first find the origin of the vulnerability report and extract the target states. SDFuzz successfully extracted the target states for all the cases. We then use SDFuzz to test the vulnerabilities for five runs, each with a 24-hour time limit. For the vulnerabilities in Google's Fuzzer Test Suite, we use the seed inputs (if available) provided in the repository; we use empty seed inputs for other cases.

Required code identification. Our selective instrumentation technique can significantly reduce the fuzzing scope to the required code. We first analyze the proportion of the required code that SDFuzz identified for the 45 evaluated vulnerabilities. In particular, SDFuzz eliminated 48.18% of unrequired functions on average and narrowed down the fuzzing scope to the other 51.82% of required functions. For several cases (*e.g.*, #24 in re2), SDFuzz could even eliminate over 80% of unrequired functions and trigger the vulnerabilities.

Vulnerability exposure. We measured the time used for exposing the known vulnerabilities and presented the evaluation results in Table 1. SDFuzz could reproduce 44 out of the 45 vulnerabilities within the time limit of 24 hours (1,440 minutes). This demonstrates the high effectiveness of SDFuzz in exposing known vulnerabilities.

6.3 Comparison with Other Approaches

We compared SDFuzz to existing directed fuzzers on the same dataset. We thoroughly investigated the literature and included the state-of-the-art open-sourced directed fuzzers as the comparison targets: AFLGo [26], WindRanger [7], and SieveFuzz [32]. Beacon [14] is publicly available in the form of binary [40]. We additionally used the provided binary and included it in the comparison. We could not add some other related works (*e.g.*, Hawkeye [3], CAFL [16]) mainly because they are not open-sourced. We ran these fuzzers also for five

Table 1: Vulnerability exposure results. `Factor` is the ratio of time used by a tool compared to that of SDFuzz. `CE` denotes compilation error. `TO` denotes that a tool reaches the time limit (timeout) before triggering a vulnerability. The best result of a case is underlined.

24-hour runs and reported the average vulnerability exposure time. Since these works do not use target states, we acknowledge that our comparison with them can hardly be perfectly fair. Nevertheless, we tried our best to conduct a fair comparison by strictly following the instructions provided by the compared tools, and using the same hardware environments and initial seeds.

Vulnerability detection. The comparison results are shown in Table 1. SDFuzz *generally outperformed other directed fuzzers with more vulnerabilities exposed*. Specifically, AFLGo, WindRanger, Beacon, and SieveFuzz exposed 36, 37, 34, and 40 vulnerabilities, respectively. The numbers of the exposed vulnerabilities are fewer than SDFuzz's. Note that we failed to compile several cases in our evaluation, shown as `CE` in Table 1.

We characterize the time each tool used for triggering the vulnerabilities. SDFuzz *used a shorter time than the compared directed fuzzers in most of the exposed cases*. We compute a factor value as the ratio of the time used by a tool to that of SDFuzz in each case. The factor value describes the performance speedup between tools. The factor value is not available (shown as - in Table 1) if a fuzzer does not trigger the vulnerability. We further compute the average speedup as the geometric mean of the factor values for those exposed vulnerabilities (excluding `CE` and `TO` cases).[3] In general, SDFuzz achieved an average speedup of

[3] Excluding `TO` cases actually under-approximates the speedup factors

2.83×, 2.65×, 1.29×, and 1.81× above AFLGo, WindRanger, Beacon, and SieveFuzz, respectively. SDFuzz also outperformed AFLGo, WindRanger, Beacon, and SieveFuzz by up to 18.60×, 12.55×, 4.25×, and 8.80×, respectively. The best result per vulnerability is underlined in Table 1. We observe that SDFuzz performed the best in 35 out of the 45 cases (77.8%), demonstrating the effectiveness of our new techniques.

We further employed a Mann-Whitney U test [22] on vulnerability exposure time to measure the statistical significance of our experiment results. We find that our results are significant in the majority of the cases under the significance level of 0.05 (*i.e.*, most cases in Table 1 have a p-value less than 0.05). Therefore, given the high diversity of the vulnerabilities in our dataset, we confidently conclude that SDFuzz could trigger vulnerabilities more quickly.

We observe that several vulnerabilities were significantly hard for prior directed fuzzers to trigger, which SDFuzz successfully triggered. For instance, cases #11 and #15 were not exposed by all other four evaluated directed fuzzers; cases #20 and #23 were not triggered by three of the other evaluated directed fuzzers. We investigated the source code and the historical input queue and identified the reason why SDFuzz could more easily trigger them. These cases generally have a significantly large number of paths on the CG from the entry function to the target function(s). A large proportion of them is not feasible dynamically due to the unsatisfiable path constraints. For example, in case #11, a buffer overflow vulnerability, other directed fuzzers could not reproduce it within the time limit. They favored wrong paths and tested this vulnerability in a wrong direction, where the vulnerability-triggering conditions were hardly achieved. SDFuzz, however, chose a feasible path that was more likely to approach the target state. The analysis suggests that the target states provided additional guidance, which directed SDFuzz to trigger the vulnerabilities, whereas the other fuzzers easily got stuck in wrong directions.

Code elimination. SieveFuzz [32] uses a code elimination technique based on target site locations and is open-sourced. We also investigated how well SieveFuzz eliminated code. It removed around 31.53% of unrequired code on average, which is 43.29% less than what SDFuzz eliminated. This demonstrates the benefits of the target state information for code elimination. We were not able to check such statistics for Beacon [14] since the authors only released its binary, and we could not enhance it to obtain such internal statistics.

Path pruning and fuzzing throughput. The effectiveness of path pruning can be reflected in the fuzzing throughput, *i.e.*, number of executions per unit time. We find that SDFuzz *achieved a much higher fuzzing throughput.* Since different programs normally have distinct processing time, we thereby calculate a throughput factor value as the ratio of the throughput of a tool to that of AFLGo in each case. We then compute the geometric mean on all cases as the average throughput. On average, SDFuzz, WindRanger, Beacon, and SieveFuzz had the throughput factor value of 9.32, 0.93, 1.43, and 8.09, respectively. This shows that fuzzers employing execution termination techniques have higher throughput compared to the ones with only distance metrics. For instance, SDFuzz, Beacon, and SieveFuzz had higher throughput than the other two. Besides, SDFuzz, driven by target states, achieved the highest fuzzing throughput in the evaluated vulnerabilities. This could be explained as its execution termination to also abort some reachable executions. As for WindRanger, it underperformed AFLGo mainly because of its taint analysis overhead.

Vulnerability-triggering paths. *We found that other fuzzers mostly triggered the vulnerabilities through the identical paths that* SDFuzz *derived from the target states*. Specifically, we replayed the crashing input that a fuzzer generated to expose a vulnerability and analyzed the triggered program path. We then correlated such paths to the ones in the target states. SDFuzz triggered the vulnerabilities through these paths. On the other hand, AFLGo, WindRanger, Beacon, and SieveFuzz ultimately took the paths in the target states for 28, 20, 25, and 30 cases, respectively. Such an observation has two implications. First, SDFuzz could directly drive the exploration towards such paths without sparing too much effort on other paths. This is the root reason why SDFuzz could have superior performance compared to other directed fuzzers. Second, by driving towards the target states, though SDFuzz could potentially overlook some other paths, this would not significantly undermine the performance of SDFuzz. Therefore, we believe SDFuzz could significantly benefit state-of-the-art crash reproduction.

6.4 Component-Wise Analysis

We conduct an ablation study on the same dataset to understand how each technique in SDFuzz contributes to the performance. First, to assess the effect of the target states, we design a variant of SDFuzz, namely SDFuzz$_{bl}$, that utilizes only the bug locations (target sites)—the reduced target states. We add a variant of SDFuzz—SDFuzz$_{-si}$—by disabling its selective instrumentation. Additionally, we design four variants for the component-wise evaluation. Since SDFuzz is built atop AFLGo, each variant enables one key technique over AFLGo. In particular, AFLGo$_{+si}$, AFLGo$_{+et}$, AFLGo$_{+sf}$, and AFLGo$_{+df}$ further enables selective instrumentation, execution termination, target state feedback, and distance feedback, respectively, atop AFLGo.

We use the same experimental setup in §6.2 to run the variants. We measure the average time used to trigger the vulnerabilities for successful runs. We show the speedup of each variant above the baseline tool, AFLGo, in Table 2. We cannot compute the speedup for several cases when AFLGo

SDFuzz could achieve.

Table 2: Speedup of vulnerability exposure time above AFLGo. We use ✓ to denote the situation that the variant (or SDFuzz) triggers the vulnerability, but the speedup factor is not available because AFLGo does not trigger it.

ID	AFLGo$_{+si}$	AFLGo$_{+et}$	AFLGo$_{+sf}$	AFLGo$_{+df}$	SDFuzz$_{-si}$	SDFuzz$_{bl}$	SDFuzz

or the variant does not trigger the vulnerability, and we use ✓ to denote them. Generally speaking, the results validate the effectiveness of the four key techniques. We next analyze the results in detail.

Effect of target states. Target states are the indispensable factor for SDFuzz's superior performance. With only the bug location—a reduced target state, we could observe a significant performance decrease in SDFuzz$_{bl}$, compared to the full-fledged SDFuzz. SDFuzz$_{bl}$ exposed 36 vulnerabilities and SDFuzz$_{bl}$ on average achieved a speedup of 1.87× above AFLGo. We found that SDFuzz$_{bl}$ could not expose several vulnerabilities that even AFLGo could do, *e.g.*, #3. This is because by using only the bug location, SDFuzz$_{bl}$ could not precisely terminate executions. Besides, it would sometimes wrongly terminate the executions because it incorrectly determines the (un)recoverable executions. This demonstrates the necessity of using target states in our approach.

Selective instrumentation. AFLGo$_{+si}$ and SDFuzz share the same required code identification step. Therefore, AFLGo$_{+si}$ could eliminate the same proportion of code as SDFuzz. We have shown the results in §6.2 that SDFuzz

could eliminate 48.18% of unrequired functions on average, demonstrating its high effectiveness. On the contrary, SDFuzz$_{-si}$ would still explore the whole code base.

From Table 2, we found AFLGo$_{+si}$ improved AFLGo by exposing two additional vulnerabilities and triggered 38 out of the 45 vulnerabilities in total. AFLGo$_{+si}$ improved the performance of AFLGo, with an average speedup of 1.56× on the 36 vulnerabilities AFLGo exposed. We also found that SieveFuzz [32] had a similar average performance on vulnerability exposure time as AFLGo$_{+si}$ even though AFLGo$_{+si}$ eliminated more unrequired code. SieveFuzz also achieved an average speedup of 1.56× above AFLGo according to the results in Table 1. The reason is two-fold. First, AFLGo$_{+si}$ sacrifices a bit performance for fault tolerance by its instrumentation-based code elimination. Second, SieveFuzz also employs other techniques such as diversity heuristics that AFLGo$_{+si}$ currently does not support. Integrating such techniques would definitely improve our solution.

We further analyze another variant SDFuzz$_{-si}$ with selective instrumentation disabled atop SDFuzz. SDFuzz$_{-si}$ triggered 43 vulnerabilities and achieved an average speedup of 2.11×. This further confirms the benefit of the selective instrumentation technique.

Early termination of executions. The execution termination technique in AFLGo$_{+et}$ is highly effective. In the 24-hour experiments on the 45 vulnerabilities, AFLGo$_{+et}$ early terminated 56.23% of the executions on average. This also confirms that executions that cannot reach the target states are widespread in real-world programs. We could not measure the proportion of terminated executions in Beacon because it is close-sourced. Besides, AFLGo$_{+et}$ also improved the fuzzing throughput by 8.71× on average, compared to AFLGo. In terms of vulnerability exposure, AFLGo$_{+et}$ triggered five more vulnerabilities than AFLGo, exposing a total of 41 vulnerabilities. AFLGo$_{+et}$ achieved an average speedup of 1.94× above AFLGo on the vulnerabilities AFLGo triggered.

Feedback mechanism. The feedback mechanism guides the testing to trigger the vulnerabilities. AFLGo$_{+sf}$ triggered one more vulnerability compared to AFLGo. It also accelerated the vulnerability exposure by 1.32×. The rationale lies in that AFLGo$_{+sf}$ appropriately spares the testing efforts to desired paths specified in target states. However, we notice that AFLGo$_{+sf}$ performed slightly worse than AFLGo in several cases like #5 and #19. The reason mainly came from the runtime overhead caused by the program state maintenance. Since the cases are relatively simple to trigger, the overhead turned to take a significant proportion in the total used time.

Similarly, the precisely-weighted distance metric feedback in AFLGo$_{+df}$ also improved fuzzing effectiveness. Compared to AFLGo, AFLGo$_{+df}$ achieved an average speedup of 1.24×. However, we notice that the performance improvement of AFLGo$_{+df}$ is slightly less significant than that of AFLGo$_{+sf}$. Our manual analysis found that the target state feedback could offer more benefits in optimizing the exploration direction compared to the new distance metric.

Table 3: Vulnerability discovery results.

Program	Statically Reported	SDFuzz Validated
libjpeg	46	2
tinyexr	22	1
pugixml	59	1
ffmpeg	32	0
Total	159	4

6.5 New Vulnerability Discovery

We further evaluate the efficacy of SDFuzz in discovering new vulnerabilities. In particular, we explore the feasibility of applying SDFuzz to automatically validate the analysis results of SVF [35]. We apply SVF to a set of well-tested applications that handle or process different types of files, such as libjpeg [37], tinyexr [36], pugixml [43], and ffmpeg [8]. Some of the applications have been well-tested by the related tools [7, 26].

We employed the saber checker [35] of SVF to identify memory leakage and double-free vulnerabilities. In total, SVF reported 159 suspicious cases, and we leveraged SDFuzz to validate them. SVF provided a program flow for each suspicious case, which SDFuzz converted to a target state for directed fuzzing. Given the large number of cases, we ran SDFuzz for 12 hours for each case, resulting in a total CPU time of around 2,000 hours. To date, SDFuzz successfully identified four new vulnerabilities. We have responsibly reported the new vulnerabilities to the vendors and are in the process of applying for new CVE IDs. Three of the vulnerabilities have been acknowledged. The detailed vulnerabilities can be found in Table 3. Given this, we believe that SDFuzz can be applied in practice as a fully automated solution for vulnerability validation.

To understand the efficacy of target states, we further replayed the crashing inputs generated by SDFuzz on the four vulnerabilities and analyzed the triggered program paths. Our investigation revealed that the four vulnerabilities were triggered through the exact paths reported by SVF (*i.e.*, paths derived from the target states). This confirmed that the target states could help validate the static analysis results.

7 Discussion and Limitations

In this section, we discuss the limitations of SDFuzz and future work.

Requirement of target states. SDFuzz requires target states from two sources—vulnerability reports and static analysis results. This requirement can be satisfied in practice as most of the vulnerability reports provide such target states (§3).

Even if vulnerability reports are not available, SDFuzz can still leverage existing static bug analysis techniques to identify the target states. Compared to exploring all paths, the paths in static analysis results often convey the suspicious flows that better deserve testing. We have already demonstrated the feasibility in §6.5.

We admit that some application scenarios such as patch testing might not provide available target states. Our solution can extract the target states from the vulnerability where the patch applies by analyzing the vulnerability report. It can also analyze the patch change logs to identify the target reaching order [16]. However, it currently cannot directly derive complete target states from only the patch change logs, *e.g.*, find the problematic program paths in the patches. To mitigate this problem, one possible direction is to employ advanced program analysis techniques such as symbolic execution [2,5] to synthesize feasible target states for a patch. We leave this as future work.

States other than target states. A downside of our approach is that it might potentially overlook some valuable paths that are not included in the target states, only in crash reproduction. In fact, as shown in our evaluation, SDFuzz could trigger the vulnerabilities in a significantly shorter time. This suggests that overlooking other states would not undermine the performance of SDFuzz.

We believe driving to target states is a reasonable trade-off for two reasons. First, infeasible paths for triggering the vulnerabilities dominate the program paths [44]. The paths stated in the target states are preferred working ones. Our solution would mostly exclude unnecessary exploration and guide the fuzzer towards these guaranteed working directions. Second, the paths in target states are likely to be the best or simplest ones to trigger the vulnerability as they correspond to the first cases when a vulnerability gets triggered or reported in real world. Other fuzzers ultimately triggered the vulnerabilities also through the paths in the target states. This confirms the rationale of using target states.

In the application scenario of validating static analysis results, the task of applying directed fuzzing is to test the reported suspicious flows. Therefore, our strategy of focusing on the target states (suspicious flows) is reasonable for achieving this goal.

Incomplete call graph. We notice that the call graph might not be complete because some call targets cannot be statically inferred using SVF. SDFuzz might incorrectly assess the state recovery capability because of wrong path existence judgment. To mitigate the issue, we can incorporate dynamic tracing to monitor function invocations, and accordingly add additional call edges to the call graph. We can also leverage other advanced type inference methods to refine the call graph [18, 19].

8 Related Work

Eliminating unnecessary explorations can improve fuzzing effectiveness. Beacon [14], SieveFuzz [32], and SelectFuzz [20] are three typical examples considering the reachability to the target sites. As we discussed in §2.3, SDFuzz can further exclude unnecessary reachable executions that cannot reach the target states.

The distance metric is also an important factor in directed fuzzing. AFLGo [26] and SemFuzz [41] were the first lines of research about directed fuzzing. They initially proposed the concept of distance metrics to drive the coverage-guided fuzzing towards a direction. Hawkeye [3] further used adjacent-function distance, which considered the number of times a function is called. ParmeSan [24] directed the testing towards locations with more sanitization checks. WindRanger [7] pointed out that only deviation basic blocks were necessary for distance computation. MC2 [30] approached a new randomized search algorithm to optimize the fuzzing exploration. SDFuzz differentiates itself from these tools by considering the target states for triggering vulnerabilities. Additionally, LOLLY [17] analyzed the execution trace of a test case after its execution and used that as feedback. Its analysis was purely offline, *i.e.*, it did not capture the runtime program behaviors like the calling contexts. It also introduced heavy overhead in recording the complete execution trace in every fuzzing trial. SDFuzz instead selectively monitors the runtime program states with minimal overhead. CAFL [16] measured the order dependency among targets—a part of the target states. SDFuzz considers a comprehensive set of the target states for the feedback.

Unlike SDFuzz, some related works improve DGF from other angles or apply DGF to other scenarios. FuzzGuard [44] used deep learning to predict unreachable test cases and filtered them out from the testing. As for binary programs, UAFuzz [23] considered the target reaching order and detected UAF vulnerabilities; 1dVul [25] analyzed binary patches to identify one-day vulnerabilities.

9 Conclusion

Directed grey-box fuzzing would often unnecessarily explore code and paths that cannot trigger the vulnerabilities. In this paper, we presented SDFuzz, an efficient directed fuzzer driven by target states to mitigate this problem. SDFuzz excludes unnecessary explorations by eliminating unrequired code and early terminating executions that cannot reach the target states. SDFuzz further employs a two-dimensional feedback mechanism to proactively guide the testing direction. Our evaluation results demonstrated that SDFuzz could trigger the vulnerabilities faster and outperformed the prior works. SDFuzz also discovered four previously unknown vulnerabilities, proving its practical value in automated vulnerability validation.

Abstract

Newly submitted commits are prone to introducing vulnerabilities into programs. As a promising countermeasure, directed greybox fuzzers can be employed to test commit changes by designating the commit change sites as targets. However, existing directed fuzzers primarily focus on reaching a single target and neglect the diverse exploration of the additional affected code. As a result, they may overlook bugs that crash at a distant site from the change site and lack directness in multi-target scenarios, which are both very common in the context of commit testing.

In this paper, we propose WAFLGo, a direct greybox fuzzer, to effectively discover vulnerabilities introduced by commits. WAFLGo employs a novel critical code guided input generation strategy to thoroughly explore the affected code. Specifically, we identify two types of critical code: path-prefix code and data-suffix code. The critical code first guides the input generation to gradually and incrementally reach the change sites. Then while maintaining the reachability of the critical code, the input generation strategy further encourages the diversity of the generated inputs in exploring the affected code. Additionally, WAFLGo introduces a lightweight multi-target distance metric for directness and thorough examination of all change sites. We implement WAFLGo and evaluate it with 30 real-world bugs introduced by commits. Compared to eight state-of-the-art tools, WAFLGo achieves an average speedup of 10.3×. Furthermore, WAFLGo discovers seven new vulnerabilities including four CVEs while testing the most recent 50 commits of real-world software, including libtiff, fig2dev, and libming, etc.

1 Introduction

Software vulnerabilities can pose a significant security threat, making security testing on programs crucial. Within the thousands of lines of code that a program comprises, newly introduced code through commits for functional upgrades and bug patching can be critical, as such code has the potential to introduce new vulnerabilities to a program. For instance, recent studies have shown that nearly four in five bug reports in OSSFuzz [4] were regression bugs, indicating that the bug was introduced by a historical commit rather than the original codebase [39]. This emphasizes the need to comprehensively test commits, helping discover vulnerabilities introduced through code modifications early on.

While traditional coverage-based fuzzing [15, 21, 24–26] has proven to be highly effective in discovering security vulnerabilities in real-world software systems, it lacks efficiency in identifying vulnerabilities introduced through commits. This is because coverage-based fuzzing treats all parts of the code equally and does not specifically target the commit changes. By contrast, directed fuzzing [5, 14, 19, 27, 30, 38] is more suitable for commit testing scenarios as it focuses on testing specific parts of a program. Intuitively, one can guide the fuzzer to prioritize testing the new code and its affected areas by designating the commit change sites as targets.

However, in the specific context of commit testing, existing directed greybox fuzzers (DGFs) still encounter several problems. First, *existing DGFs primarily focus on quickly reaching the target (change site) while not guiding the fuzzer to thoroughly test the affected code.* Consequently, these fuzzers may fail to discover newly introduced vulnerabilities where the crash site differs from the change site, as they may not trigger crashes or even reach the crash site. In particular, the complexity of a program implies that a single modified line in a commit can significantly impact the entire program. For example, if a commit modifies the index of an array, all the code that uses that index to access the array is affected. As a result, an out-of-bounds vulnerability may occur at a location far away from the commit change site. By analyzing the issues of real-world programs on GitHub, we observe that over *half* of the crash sites associated with a bug introduced by a commit are different from the commit change site (refer to Table 1 "DiffLoc" for details). Moreover, existing techniques

✉Xuhong Zhang and Wenhai Wang are the corresponding authors.

even introduce counteractions to the affected code exploration. For instance, AFLGo [5] prioritizes inputs with shorter distances, resulting in the generation of inputs that follow similar paths and thus reduce the input diversity. Similarly, SelectFuzz [23] only considers and instruments the relevant code before the target, thus lacking important feedback to generate high-quality input after reaching the target. Thus, we need a new technique to discover commit introduced bugs that not only reach the change site but also thoroughly test the actually affected code.

Second, existing DGFs struggle to effectively handle the multi-targets problem, which is common in commit testing where a single commit can introduce multiple change sites. When testing a commit, it is crucial to comprehensively test every change site and its affected code. However, as the number of targets increases, existing DGFs experience a decrease in directness. In the worst case, their effectiveness may degrade to coverage-based fuzzing, lacking targeted guidance. The DGFs derived from AFLGo [5, 7, 11, 17] aggregate all target distances using the harmonic mean, which will overlook certain targets and compromise individual directness. On the other hand, DGFs based on path pruning [14, 23] aggregate the reachability analysis for all targets, which significantly decreases the pruned path ratio for each individual target. While there are some multi-target directed fuzzers like Parmesan [27] and FishFuzz [38], they primarily focus on sanitizer-marked targets, which often involve a large number of unrelated targets, unlike the commit targets that are interconnected.

To overcome the aforementioned problems, this work aims to propose an efficient directed greybox fuzzing for commit testing. There are two primary challenges: *1) How to quickly and thoroughly test the affected code?* Like existing works, we should first efficiently reach the change site (target). Once the target is reached, we have to maintain the reachability, and then generate diverse inputs to explore different program states of the affected code. *2) How to handle multiple site changes in a smart and lightweight manner?* An intuitive approach is to test each change site separately. However, this becomes impractical when a commit has numerous change sites. Moreover, this approach neglects important information, such as the fact that change sites within a commit often share the same context (e.g., being in the same function), resulting in a delay in bug discovery and inefficient utilization of resources.

To address the first challenge, we propose a novel critical code guided input generation strategy. The core design includes a critical code identification method, a target edge selection, and a mutation masking mechanism. Our key insight here is to generate inputs that explore diverse program states while preserving the execution of the critical code. Specifically, we identify two types of critical code: *path-prefix* code and *data-suffix* code. The path-prefix code refers to the control-flow prefix that can affect the change site, and the data-suffix code represents the code that has data dependency with the critical variables used in the change site. When mutating a seed, we check if it executes any critical code. If critical code is identified, we generate a mutation mask for the seed and apply fine-grained mutation to maintain its execution in the generated input. Otherwise, we resort to coarse-grained mutation to enhance the diversity of the seeds. Additionally, during the fuzzing process, we select the target edge based on whether the seeds reach the target. If the seed does not reach the target, we select the "closest" edge to the target among the executed path-prefix code of the seeds as the target edge. By mutating only the input bytes that do not deviate from the target edge, we gradually generate inputs that are closer to the target. If the seed already reaches the target, we select the rarest executed edge from both the path-prefix and data-suffix as the target edge for comprehensive testing of the affected code. The rare path-prefix indicates new paths toward the target, and the rare data-suffix indicates new data values that can impact the affected code. This approach allows our fuzzer to explore diverse program states that reach the target and thoroughly test the affected code.

To address the second challenge, we propose a new lightweight distance metric that maintains the directness of each target. Furthermore, we adjust the input generation strategy to optimize the exploration of the affected code. Specifically, we compute and record the distance for each target individually. To ensure that each target is guided effectively and receives sufficient testing attention, we only consider the distance of the rarest executed target when calculating the distance for an input. As for generating inputs to explore the affected code, we identify the critical code separately for each target and apply target edge masking accordingly. In addition, we simplify the complexity of testing targets by grouping them based on their common preconditions. Specifically, we employ the dominator tree concept to merge change sites within the same function into a merged target. These approaches allow our fuzzer to sufficiently test all the change sites.

In order to fairly compare our design with existing state-of-the-art fuzzers, we construct a benchmark dataset from the GitHub repository. This dataset consists of 30 real-world bugs from eight widely used C programs that have been tested in prior works [5, 11, 14, 23]. For each bug we manually identify its bug-inducing commit. In our evaluation, we compare the performance of WAFLGo with three categories of fuzzers. The first category includes directed fuzzers such as AFLGo [5]. The second category consists of coverage-based fuzzers like AFL [1]. The third category comprises regression fuzzers, specifically AFLChurn [39]. The experimental results demonstrate the superiority of WAFLGo compared to the other fuzzers. In general, WAFLGo achieves an average speedup of 10.3×. Besides, WAFLGo outperforms other fuzzers by successfully reproducing the highest number of bugs. Furthermore, we apply WAFLGo to test the newly submitted commits in real-world projects, including libtiff,

fig2dev, and libming, and successfully discover seven new bugs, including four CVEs. This real-world application of WAFLGo further validates its effectiveness in identifying bugs in newly committed code.

In summary, this paper makes the following contributions:

- We highlight the significance of thoroughly fuzzing the affected code in the context of commit testing, as solely reaching the commit change sites is insufficient for discovering newly introduced bugs.
- We propose a commit directed greybox fuzzer that utilizes a novel critical code guided input generation strategy and a new distance metric. These designs enable the generation of diverse inputs for thorough testing of all the commit change sites and their affected code, facilitating the discovery of newly introduced bugs.
- We implement a prototype of WAFLGo and make the source code available for future research at https://github.com/NESA-Lab/WAFLGo.
- We construct a dataset with 30 real-world bugs, and manually identify their bug-inducing commits (BICs). On the dataset, we evaluate WAFLGo through extensive experiments, and compare it with existing fuzzers. The comparison with existing fuzzers demonstrates its superiority. With WAFLGo, we successfully detect seven new vulnerabilities, including four CVEs.

2 Background

2.1 Greybox Fuzzing

Greybox fuzzing is an automated technique used to discover vulnerabilities in a project by generating and feeding inputs into the target program. Two prominent branches of greybox fuzzing are coverage-based greybox fuzzing and directed greybox fuzzing.

Coverage-based Greybox Fuzzing. Coverage-based fuzzing has emerged as a popular approach within the field of greybox fuzzing. Its main objective is to maximize code coverage and explore various execution paths to identify potential vulnerabilities. Coverage-based fuzzing has been enhanced with lots of techniques (e.g., static and dynamic program analysis [13, 18, 21], intelligent optimal strategies [10, 24, 36]), and has successfully discovered numerous vulnerabilities in real-world scenarios.

However, for real-world programs, the codebase is often large and complex, and a significant portion of the code remains unchanged over time. Fuzzing this large but unchanged code is less effective in finding vulnerabilities. Research by Zhu et al. [39] highlights that about four out of five reported bugs in OSSFuzz are introduced by recent code changes. While fuzzing the entire codebase is undoubtedly important, it is necessary to consider the limited availability of resources and the higher likelihood of newly added code introducing vulnerabilities. Therefore, prioritizing efficient fuzzing of the newly added code is crucial to effectively detect bugs.

Directed Greybox Fuzzing. Directed greybox fuzzing focuses on testing specific parts of a program, and there has been significant research dedicated to addressing challenges in target selection and improving the efficiency of reaching the target [14, 17, 30, 35].

For target selection, different applications require different settings. For patch testing, the target code can be manually specified as the patch site [17]. For crash reproduction, the target code can be set as the crash site [5]. For static analysis report verification, natural language processing techniques can be used to set the target code [35]. Additionally, the target code can be set as potential buggy points indicated by various sanitizers [27]. In the context of finding bugs introduced by commits, our work straightforwardly sets the commit change sites as the original targets.

Many existing approaches aim to improve the efficiency of reaching the target in directed greybox fuzzing. AFLGo [5], one of the pioneering works in this field, defines a distance metric to measure the proximity of the testing inputs to the target code. It calculates the distance between a testing input and a target code by averaging the distances between executed blocks and the target. This approach helps identify inputs that are closer to the target, and a power scheduling scheme is proposed to prioritize these inputs. Several subsequent works [7, 11, 17] have followed this line of research.

Taking account of the reachability analysis may also improve the fuzzing efficiency. By identifying inputs that cannot reach the target and, therefore, cannot trigger the correlated vulnerability, these inputs can be discarded. Some works employ deep learning methods to pretrain a model that predicts whether an input can reach the target [40]. Other works use static analysis to identify inputs that are path-wise or constraint-wise not reachable or relevant to the target, and subsequently discard them [14, 23].

DGF for Commit Testing. As highlighted by regression greybox fuzzing (RGF) [39], new commits are often prone to introducing bugs into a program. Therefore, it is crucial to efficiently detect whether a commit has introduced a bug or not. As a promising countermeasure, DGF can be leveraged to address this objective. However, there are two main problems in applying DGF to this task.

The first problem is that the crash sites of the introduced bugs may not be the same as the commit change sites. In our analysis, we found that over *half* of the commit-introduced bugs have change sites different from the crash sites, as depicted in Table 1. Existing approaches primarily focus on reaching the target, while not providing substantial assistance for thoroughly testing the target after it has been reached, thus resulting in miss detection of the potentially introduced bugs. The second problem arises from the fact that a commit often modifies multiple sites, resulting in multiple targets for

```
1  static int correct_orientation(struct i *image, ...){
2    //...
3    rotateImage(image, ..., True); // can toggle
4  }
5  static int processCropSelections(struct i *image, ...){
6    // only cropped image sections are rotated
7    rotateImage(image, ..., False); < can't toggle
8    if(img_mode == COMPOSITE_IMAGES){
9      //...
10   }else{
11     // read data from image
12     extractSeperateRegion(image, ...); < crash site
13   }//...
14 }
15 static int createCroppedImage(struct i *image,...){
16   rotateImage(image, ..., True); // can toggle
17   //...
18 }
19 static int rotateImage(struct i *image,..., int rotIP){
20   if(rotIP){
21       res_temp = image->width;
22       image->width = image->length;
23       image->length = res_temp;
24   }
25   //...
26 }
```

Figure 1: Motivating example.

DGF. However, existing approaches may overlook certain targets and compromise the individual directness required to thoroughly test each target.

2.2 Motivating Example

To better illustrate the aforementioned problems, we provide an excerpt, as shown in Figure 1, highlighting a specific issue (i.e., #519) related to the `rotateImage` function in the libtiff library [2]. In Figure 1, the bold texts are patch codes.

In the `rotateImage` function, there is a problem where the width and length parameters of the main image are mistakenly toggled, causing issues in subsequent executions (Figure 1, line 12). Specifically, when calling the `extractSeparateRegion` function, the main image's dimensions are incorrectly modified by the previous call of the `rotateImage` in line 7. Due to this modification, the program ends up reading data from the main image using the incorrect width and length parameters. As a consequence, a heap buffer overflow is triggered during the subsequent function call to `extractContigSamplesBytes` (not shown in Figure 1 for brevity).

If the fuzzer only focuses on reaching the toggle code in lines 21 - 23 of the `rotateImage` function, it will struggle to trigger the bug. This is because distance-based fuzzers will prioritize fuzzing other functions (`correct_orientation` in line 1 and `createCroppedImage` in line 15) that are closer in distance, generating more seeds that can reach the target but not trigger the bug. This loss of diversity can limit the effectiveness of bug detection.

Similarly, reachability-based fuzzers will fail to find the bug due to their design limitations in testing the affected code beyond the target site. Recent work, such as SelectFuzz [23], also struggles to trigger the bug because it only instruments target-related code before reaching the target, losing important feedback to generate or save inputs that explore the *else* branch at line 10.

The developer fixed this issue by adding a new parameter called *rotIP*, which serves to determine whether the image should be toggled or not. Now, when testing whether this patch commit introduces any bug, we face the challenge of dealing with multiple targets. In the given code, lines 3, 7, 16, and 19 - 24 all represent different change sites (targets) that need to be thoroughly tested for potential bugs.

To overcome these challenges, improved approaches are needed to prioritize input diversity, extend assistance beyond target reaching, and handle multi-target scenarios. By doing so, we can enhance the effectiveness and efficiency of directed fuzzing in identifying newly introduced bugs.

3 Design of WAFLGo

In this section, we present the design details of WAFLGo, a directed fuzzer specifically designed to efficiently identify bugs introduced by commits. First, we describe how to select fuzzing targets from the commit diff and calculate distance for each target. Second, we discuss how to define and identify the critical code. Finally, we discuss how to use the critical code to guide our tool during fuzzing. The overall architecture of WAFLGo is illustrated in Figure 2.

3.1 Target Selection and Distance Calculation

When testing a commit to discover potential vulnerabilities, it is necessary to test every change site and its affected code thoroughly. However, commits often consist of numerous change sites, resulting in multiple fuzzing targets. Handling each change site separately would be impractical and inefficient as it disregards some connections between them. For example, the similar preconditions shared by change sites within the same function. On the other hand, treating all change sites as a single target, as done in existing works [5,7,17], leads to the oversight of certain change sites and compromises individual directness.

In this work, we propose a novel multi-targets distance metric for commit testing. This distance metric merges the multiple change sites into a smaller set of function-level targets. The rationale behind this consolidation is to leverage shared preconditions among the same group of changes. Next, the distance metric calculates an individual distance for each merged target, ensuring the preservation of directness for each target, and pay more attention to the rarely executed targets.

1) Target Merging. We select the commit change sites as the initial targets. The functions that contain these initial targets are referred to as *target functions*. As the changes in one function share lots of similar preconditions, we merge all the change sites in the same function as one. We first

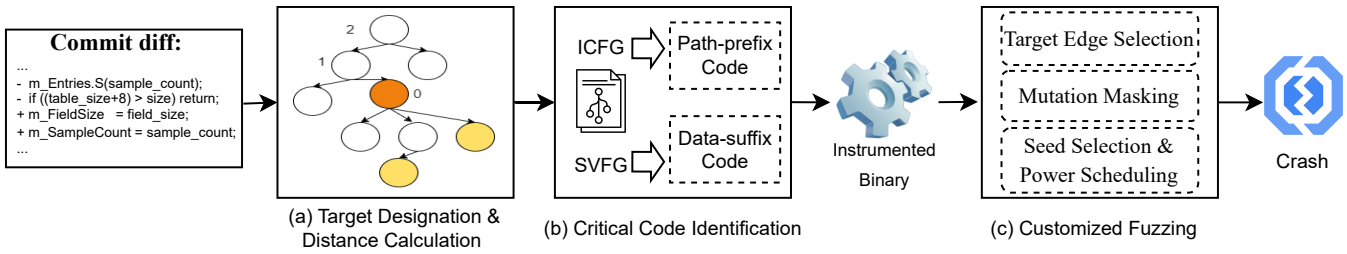

Figure 2: Architecture of WAFLGo.

construct the dominator trees of the target functions and then set the immediate dominator of each initial target in the target function as the merged target for that function. This ensures that each target function has only one target, simplifying the distance calculation phase and making it more efficient. The initial targets then become the descendants of the merged target, which will be marked and explored in the fuzzing phase.

2) Distance Computation. The basic blocks that contain merged targets are referred to as *target blocks* T_b. The *block distance* $d_b(m, T_b)$ determines the distance from a basic block m to each target block T_b. More formally, we define the distance $d_b(m_1, m_2)$ between two basic blocks m_1 and m_2 as the minimum number of basic blocks along the shortest path between them. As we have built the inter-procedural control flow graph (ICFG), we can more precisely compute the distance across functions than AFLGo [5]. Additionally, we assign an *edge distance* $d_e(e, T_b)$ to every edge e by calculating its distance to the target block T_b. Specifically, for an edge e_{ij}, where i and j respectively denote its head and tail nodes, we compute its distance as follows:

$$d_e(e, T_b) = d_b(j, T_b) \tag{1}$$

Taking Figure 3 as an example, we set line 14 as the target. In this case, we define $d_{e_{ab}}(e_{ab}, g) = d_b(b, g) = 2$. The edge distance is used for target edge selection in Sec 3.3.1.

Let $\delta(s)$ be the execution trace of a seed s. This trace contains the executed basic blocks of s. For each target T_b, we define the input distance $d_s(s, T_b)$ for a seed s as:

$$d_s(s, T_b) = \frac{\sum_{m \in \xi(s)} d_b(m, T_b)}{|\xi(s)|} \tag{2}$$

$$\xi(s) = \{m \mid m \in \delta(s) \text{ and } d_b(m, T_b) \neq \text{NaN}\} \tag{3}$$

The input distance of $s : a \to b \to d$ in Figure 3 is $\frac{3+2}{2} = 2.5$. In the multi-targets scenario, to ensure that each target receives sufficient testing attention, when using input distance for power scheduling in Sec 3.3.2, we focus on the rarest executed target T_r by using $d_s(s, T_r)$ as the input distance.

3.2 Critical Code Identification

WAFLGo highlights that in the context of commit testing, the successful identification of new vulnerabilities requires more than simply reaching the commit change site (target). It is crucial to conduct thorough testing of the affected code by employing diverse inputs. This is because the target can be accessed through various program states, including different paths and data values. Furthermore, the impact of the target may extend throughout the entire program, potentially leading to vulnerabilities that manifest at distant locations.

To ensure thorough testing of the commit change site, it is crucial to extract additional information both before and after the target. This information serves two key purposes: guiding the fuzzer toward the target change site and providing guidance for generating high-quality inputs that explore different program states and the affected code. Specifically, we identify code that is control- or data-dependent on the initial change sites as critical code. This critical code is further classified into two categories: *path-prefix* code and *data-suffix* code.

1) Path-prefix code. The path-prefix code refers to all the code that can lead to the execution of the target code. It includes the code blocks that are directly or indirectly connected to the target code in the ICFG. Consequently, the code that acts as a data-prefix (i.e., data-dependency predecessor) is inherently included within the path-prefix code. For instance, in Figure 3, the path-prefix code for target g consists of code blocks a, b, e, and f.

2) Date-suffix code. The data-suffix code includes the code that depends on the critical variables used in the initial targets. To identify the data-suffix code, we employ the following strategy in conjunction with data-flow analysis.

We exclusively consider variables used in the target that are **written** as sources for taint analysis. In the context of Figure 3, which features two variables, namely x and y, our focus for tracking the data-suffix code is limited to variable x due to its being written. For the inter-procedure taint analysis, when a tainted variable is employed as formal parameters, we taint both the callee's actual arguments and the callee's return values. Similarly, if a tainted variable is utilized as a return value, we taint the corresponding variable at the caller's call site.

Subsequently, we collect the corresponding basic blocks that use the tainted variables, constituting the data-suffix code. For instance, in Figure 3, the data-suffix code comprises code blocks i and k.

It's noteworthy that the data-suffix code yields more comprehensive and meaningful insights compared to the path-

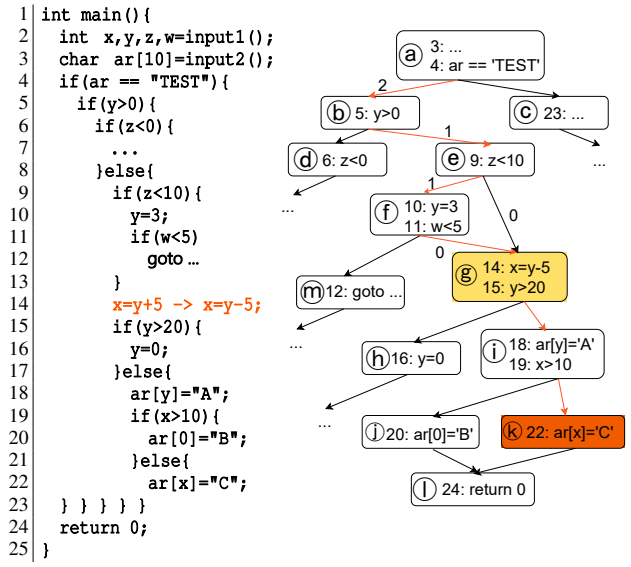

Figure 3: Illustration example. Line 14 is the change site (target) where we change $x = y+5$ to $x = y-5$. Line 22 is the crash site.

suffix code which often used for code coverage measurement. This distinction arises because not all the path-suffix code reached by the target is affected by it (e.g., blocks h, j and l in Figure 3). Conversely, the data-suffix code directly reflects the impact of the target on the program by focusing on the specific data changes by the target.

3.3 Critical Code Guided Fuzzing

Algorithm 1 sketches out our fuzzing procedure. In this subsection, we will demonstrate our target edge selection mechanism (line 7), and the practical application of the modified mutation operations through mutation masking (line 9). Then, we present our adaptive seed selection and power scheduling mechanisms (line 4 and line 8).

3.3.1 Input Generation Strategy

In fuzzing, the generation of inputs that can trigger crashes is highly prioritized. However, in the context of commit testing, two additional criteria are crucial for generating high-quality inputs. First, it is essential to generate inputs that can efficiently reach the target. Second, once the target is reached, we have to maintain the reachability, and then generate diverse inputs to explore different program states and the affected code.

To meet the criteria, WAFLGo utilizes a novel critical code guided input generation strategy that involves target edge selection and mutation masking. Specifically, WAFLGo selects a target edge for each input based on its trace and generates a mask for the input to maintain the execution of the target edge. Our insight is that when we have a seed that

Algorithm 1 WAFLGo Algorithm

Input: *Prog*, *Seeds*
Output: *potential bugs*

```
1:  function FuzzOne(Prog, Seeds)
2:      Queue ← Seeds
3:      while true do
4:          input = SelectOne(Queue)
5:          test_target = GetRarestTarget(Prog, input)
6:          test_edge =
7:                  GetTargetedge(Prog, input, test_target)
8:          score = AssignEnergy(input)
9:          mask = ComputeMask(Prog, input, test_edge)
10:         for i = 1 to score do
11:             newinput = Mutate(input, mask)
12:             Execute(Prog, newinput)
13:         end for
14:     end while
15: end function
```

exercises critical code, we aim to generate diverse inputs from this seed while ensuring the execution of the critical code. This means that our fuzzer should be aware of the important preconditions established by the seed and avoid unintentional side-effects during seed mutation that could deviate from our target.

1) Target Edge Selection. Based on the execution of the input being fuzzed, the target edge selection process varies. If the input does not reach the target, WAFLGo enters the target reaching stage. If the input reaches the target, WAFLGo enters the comprehensive testing stage. Algorithm 2 outlines how WAFLGo select target edge.

Target reaching stage. We leverage the path-prefix code identified in Sec 3.2 to systematically guide the fuzzer toward the target in a gradual and incremental manner. To achieve this, we take a step forward by preserving all incoming edges of the path-prefix code, denoted as "Prefixes" in Algorithm 2. This decision is motivated by the fact that edge execution state provides fine-grained information compared to basic blocks. For example, when inputs execute either edge e_{eg} or e_{fg}—both leading to the execution of block g—they correspond to distinct program states. The edges within the "Prefixes" list are organized in ascending order based on their edge distance. In the Figure 3, the "Prefixes" is $(e_{fg}, e_{eg}, e_{ef}, e_{be}, e_{ab})$.

If an input has not triggered any of the targets (Algorithm 2, lines 2 - 12), our approach aims to guide the fuzzer first to reach the rarest target. To achieve this, we select the *closest* edge that has been *triggered* by the input as the target edge. We systematically examine each edge in the "Prefixes" list. To avoid repeatedly generating inputs to execute the same edge, if an edge has been selected more times than a specified threshold (line 3), we consider it fully tested and skip to the next edge. We determine if the input has triggered each edge by evaluating its trace bitmap, which is a shared memory holds by fuzzer to record all the edges an input exercised. Once

Algorithm 2 Target edge Selection in WAFLGo

Input: *Prog*, *input*, *test_target*,
Prefixes, // prefix edges of each target in ICFG, sorted by distance
Suffixes // suffix edges of each target in data-flow
Output: *target_edge for input*

```
1:  function GetTargetEdge(Prog, input, test_target)
2:      for edge ∈ test_target.Prefixes do
3:          if selectcount[edge] < threshold then
4:              if edge ∈ input.trace then
5:                  target_edge = edge
6:                  selectcount[edge]++
7:                  break
8:              end if
9:          end if
10:     end for
11:     if input not trigger target and ! target_edge then
12:         target_edge = -1
13:     else if input triggers target and ! target_edge then
14:         for edge ∈ test_target.Suffixes do
15:             if edge ∈ input.trace then
16:                 target_edge = min(hitcount[edge])
17:             end if
18:         end for
19:     end if
20:     return target_edge
21: end function
```

we find a triggered edge, we designate it as the "triggered-closest" edge, which becomes the target edge for further mask generation. If none of the edges in the "Prefixes" list have been executed and the target has not been triggered, we assign the value of -1 to the *target_edge* variable. This indicates that the seed is considered highly irrelevant to the target. As a result, no mask is generated for this input, and only havoc mutation is performed.

Take Figure 3 as an example, if we have a seed A with the input trace: $a \to b \to e \to f \to m$, we first select e_{ef} as the target edge. If the $selectcount[e_{ef}]$ exceeds $threshold$, we will select e_{be} as the target edge and so on.

Comprehensive testing stage. In this stage, we leverage both the path-prefix code and the data-suffix code to enhance input diversity. Simultaneously, we utilize the data-suffix code to direct the fuzzer towards the affected code. Similar with "Prefixes", we define "Suffixes" as a set of all incoming edges of the data-suffix code. In Figure 3, the "Suffixes" is $\{e_{gi}, e_{ik}\}$.

If an input has triggered one target, we still prioritize selecting the "triggered-closest" edge, as we aim to generate diverse inputs that can reach the target. Then, if all the executed edges of the input in the "Prefixes" list have been triggered with sufficient frequency, we proceed to steer the fuzzer toward low-frequency code that is affected by the target. Specifically, we identify the rarest hit edge among the previously discovered "Suffixes" that the input executed (lines 13 - 18). This rarest hit edge is then designated as the target edge for subsequent mask generation.

Consider Figure 3 as an example. Suppose we have a seed B with the input data: $x = 0, y = 16, z = 11, w = 0$, and $ar =$'TEST', leading to the input trace: $a \to b \to e \to g \to i \to j \to l$. Initially, we select e_{eg} as the target edge, followed by e_{be} and e_{ab}. Subsequently, we choose the rare hit edge e_{ik} in the "Suffixes" as the new target edge.

2) Mutation Mask. To maintain the execution of the target edge, we incorporate a mutation mask mechanism inspired by techniques employed in FairFuzz [18] and GreyOne [13]. Specifically, WAFLGo employs a byte-by-byte mutation process on the input using a predefined set of mutation operators, which includes bit-flip, insertion, and deletion. After each mutation, WAFLGo checks whether the target edge is still executed. If the target edge is still hit, WAFLGo identifies the corresponding byte in the input as mutable and updates the input's mask accordingly. In subsequent mutations, such as the havoc mutation, the mutable bytes of the input will be mutated with higher probability to generate new inputs.

3.3.2 Seed Selection and Power Scheduling

The traditional strategy of appending new inputs to the end of the seed queue and selecting them sequentially can prove inefficient, particularly when a significant portion of the inputs in the queue are unrelated to the target, as discussed in [23]. To overcome this inefficiency, expedite target reachability, and ensure thorough testing of the affected code, we introduce a prioritization approach. This approach emphasizes seeds that trigger new critical code during seed selection. Specifically, we maintain a favored queue with higher priority and add seeds that meet this criterion to it. During the fuzzing phase, WAFLGo has a greater chance of selecting a seed from the favored queue.

Regarding power scheduling, relying solely on the distance metric of "Prefixes" as traditional works may reduce the diversity of the generated inputs, as it consistently prioritizes closer inputs. WAFLGo assigns energy to input differently based on whether the input reaches the target. For inputs that do not reach the target, WAFLGo adopts the simulated annealing algorithm proposed in AFLGo, with a modification in the energy calculation using the new seed distance metric. Specifically, it gradually assigns more energy to inputs that are closer to the rarest executed target, facilitating faster target reaching. On the other hand, for inputs that reach the target, WAFLGo adjusts its approach by disregarding the distance metric for energy assignment. Instead, it focuses on the code coverage of the data-suffix code. This means that more energy is assigned to inputs that cover more data-suffix code, resulting in the generation of more inputs for thorough testing of the affected code.

4 Implementation

The implementation of WAFLGo mainly consists of two parts: the static analysis module and the dynamic fuzzing module. For the static analysis module, we utilize the SVF static analysis framework [31] to construct an ICFG and an inter-procedural static value-flow graph (SVFG) from LLVM IR. The static analysis module is implemented with about 1,200 lines of C/C++ code. The dynamic fuzzing module is implemented based on AFLGo [5], with about 2,000 lines of C code. Next, we discuss a few important implementation details.

Initial Target Acquisition. When a commit is submitted, WAFLGo utilizes the `git diff` command to retrieve the differences between commits. For added lines, the change site is directly stored as "filename:linenum", indicating the precise location of the added code. For deleted lines, WAFLGo selects nearby code lines for further analysis. Next, to ensure effective testing of the commit, WAFLGo filters out change sites that are not relevant to the program's functionalities, such as comments or changes pertaining to other programs within the project. To achieve this, a simple script is employed to perform a straightforward reachability analysis, determining if the commit changes can be reached from the entry point of the tested program. In the end, only the change sites that truly affect the tested program are tested.

Inter-procedural Data-flow Analysis. In the critical code identification phase, WAFLGo utilizes a forward inter-procedure data-flow analysis to identify the data-suffix code. The process involves identifying the variables used in the change sites and then traversing the SVFG to collect the code that exhibits data dependency on these variables. However, due to the potential presence of multiple callers for a callee, it is essential to accurately propagate the data dependency to the appropriate call site. In this regard, WAFLGo implements a *context-sensitive* propagation strategy that selectively propagates the data dependency to the call site responsible for transferring the data-dependent parameters to the callee. This ensures that only the relevant call site is marked as data-dependent, enhancing the accuracy of the critical code identification process.

Extra Feedback Utilization. Existing fuzzers often discard inputs that do not execute any new branches, assuming that they are not valuable for further exploration. However, in the context of directed fuzzing, the branches executed by non-target reaching inputs can still be valuable if they are executed by target reaching inputs. WAFLGo acknowledges the importance of the new feedback provided by target reaching inputs. Therefore, WAFLGo constructs an additional trace bitmap to record the execution traces of the inputs that successfully reach the targets. This allows WAFLGo to leverage the information from target reaching inputs and further guide the exploration process for more effective bug detection.

Table 1: Real-world benchmark programs. "DiffLoc" and "SameLoc" are used to denote whether the change sites of the BIC are distinct from or identical to the crash sites, respectively. "BIC Hash" represents the bug-inducing commit hash.

Project	Program	Diff Loc	Same Loc	BIC Hash	Total	Path-prefix	Data-suffix

5 Experimental Setup

5.1 Research Questions

RQ1 How effective is WAFLGo in discovering bugs introduced by commits?

RQ2 Does the guidance toward critical code improve the efficiency of fuzzing?

RQ3 Does the multi-target optimizations improve the efficiency of fuzzing?

RQ4 Can WAFLGo detect new vulnerabilities in real-world programs?

5.2 Commit Dataset

5.2.1 Commit Dataset for Testing Known Bugs

We construct a commit dataset to answer the RQ1, 2, and 3.

Real-world Target Programs. We conduct our evaluation in real-world programs that have been frequently evaluated in the existing fuzzing frameworks [5, 11, 13, 14], which are shown in Table 1. The selected programs exhibit diverse functionalities and vary in size, allowing us to demonstrate the effectiveness and scalability of our approach in different contexts.

Bug Selection Criteria. To ensure the reliability and relevance of our commit benchmark subjects from real-world

Table 2: Compared fuzzers.

Fuzzer	Category	Description
AFLGo	Direct	Sophisticated seeds prioritization
Windranger	Direct	Deviation basic blocks
SelectFuzz	Direct	Selective path exploration
FishFuzz	Direct	Multi-targets fuzzing
AFL	Coverage	Evolutionary mutation strategies
AFL++	Coverage	Optimization of overall fuzzing framework
FairFuzz	Coverage	Mask mutation strategy
AFLChurn	Regression	Code history based strategy

programs, we establish the following criteria to collect the most recent closed and reproducible issues (as of Sep'10).

- Fixed Issue. The selected issue must be marked as "fixed", with the bug-fixing commit identified and linked.This aids in identifying the BIC of the bug.
- Executable Proof-of-Concept (PoC). The issue should have an accompanying executable PoC, enabling the verification and reproducibility of the bug. This ensures that the bug can be tested and verified in a practical manner.

DGF Target Code Designation. For each issue listed in Table 1, we manually identify its BIC, and designate the targets as the change sites of its BIC. The process begins by manually finding a good commit (*GoodC*) in the commit history where the bug is absent. Then we use `git bisect` to systematically locate the first crash commit (*FirstC*) triggered by the PoC. Following this, we perform a manual verification to confirm whether *FirstC* indeed serves as the BIC. This verification entails an examination of the bug-fixing commit and its relationship with *FirstC*. We also use debugging tools like gdb to understand how changes in *FirstC* impact the execution of the PoC. In instances where `git bisect` fails to accurately identify *FirstC*, which occurs due to configuration problems in some cases, we resort to an alternative method. We manually trace the blame information for the change sites of the bug-fixing commit to determine the BICs for these particular cases.

5.2.2 Commit Dataset for Finding New Bugs

To answer the RQ4, we apply WAFLGo to detect new vulnerabilities.

We include the projects evaluated in recent fuzzing works as our testing objects and compile their programs using default configurations. We test the latest 50 commits of these projects and designate specific commit change sites as the target code. To accommodate practical constraints, we allocated a maximum of 24 hours for testing each commit.

5.3 Compared Tools

We compare WAFLGo with the fuzzers listed in Table 2.

Directed Fuzzing Tools. We implement commit-directed fuzzing into AFLGo. In order to evaluate the effectiveness of our approach, we select AFLGo as our baseline for comparison. Besides, we add the state-of-the-art DGFs for comparison, including Windranger [11], SelectFuzz [23] and FishFuzz [38] which stand for distance-based, reachability-based and multi-target DGFs, respectively.

Coverage-based Fuzzing Tools. In order to compare commit-directed fuzzing to traditional coverage-based fuzzing, we choose the base AFL [1], state-of-the-art tool AFL++ [12] and innovative tool Fairfuzz [18] for comparison. AFL and AFL++ demonstrate the effectiveness of coverage-based fuzzers in detecting newly introduced bugs through commits. FairFuzz utilizes a novel mutation mask that biases mutations toward producing inputs that hit a given rare branch, which is similar to the mask design we used in our approach.

Regression Fuzzing Tools. We add AFLChurn [39] to our comparison because it leverages the observation that recently modified code in commits should receive more attention from the fuzzer. AFLChurn introduces a new power scheduling mechanism to effectively test the modified code.

5.4 Configuration

In this subsection, we present some necessary configurations.

Initial Seeds. The initial seeds can greatly affect the efficiency of the fuzzing process. To ensure a fair comparison, we apply the same seeds per bug across different fuzzers. In our experiment, we utilize the seeds provided by the project itself and those available in UNIFUZZ [20] for the corresponding input formats.

Time Budget. We limit each experiment to a time budget of 24 hours and repeat it five times. This decision is justified by the need for rapid iteration and security left-shifting in the development process. The goal is to conduct thorough testing of the code before it is merged, prioritizing early detection of potential issues rather than relying solely on post-merge testing. Considering the practical constraints and the need for efficient bug detection, testing a commit for more than 24 hours would be impractical.

Infrastructure. All experiments are conducted in a docker container configured with 1 CPU core of 2.40GHz E5-2680 V4 and the 64-bit Ubuntu 16.04 LTS. In total, we spend several weeks running evaluations on four servers, each of which has an Intel Xeon E5-2650 v4 (2.2GHZ, 48cores) CPU, and 256 GB memory.

6 Performance Evaluation

6.1 Efficiency of WAFLGo

We measure the time used by WAFLGo to reproduce the issues. We present the evaluation results in the 4th column of Table 3. In general, WAFLGo effectively reproduces 21 issues out of the 30 cases, achieving the highest success rate

Table 3: The average crash exposure time of WAFLGo and the compared fuzzers. Time-to-Exposure indicates the reproduction time (hour) averaged over five runs. T.O. indicates the fuzzer cannot reproduce the issue within the given time budget, 24 hours. For the timeout cases, we take the Time-to-Exposure time as 24 hours to calculate the speedup.

No.	Issue-id	Program	Time-to-Exposure(hour)									Factor							
			WAFLGo	AFLGo	Wind.	Selc.	Fish.	AFL	AFL++	Fair.	AFLC.	AFLGo	Wind.	Selc.	Fish.	AFL	AFL++	Fair.	AFLC.

#Reproduced / Average			21	15	17	16	15	15	17	18	16	9.1	5.4	5.7	25.8	9.9	7.2	11.2	8.0

among all the compared fuzzers. As the second most successful fuzzer, FairFuzz, reproduces 18 issues out of the 30 cases. For all the reproduced issues, WAFLGo outperforms other fuzzers, achieving an average speedup of 10.3×. WAFLGo fails to reproduce nine issues (i.e., Bento4 issue #679 and #652, Mujs issue #166, #141 and #65, Poppler issue #1282, #1305 and #1381 and Libxml2 issue #550), within the time budget of 24 hours, while other fuzzers could not trigger them, neither. The main reason is that these bugs require satisfying complex path constraints, which is beyond the scope of our approach. We further analyze these issues and find that none of the test cases generated by any of the fuzzers are able to reach the change site, let alone trigger the crashes.

Comparison with Directed Fuzzers. Compared with the baseline tool AFLGo, which WAFLGo is built upon, WAFLGo identifies six more bugs, with an average speedup of 9.1×. As for other state-of-the-art directed greybox fuzzers, namely Windranger, SelectFuzz, and FishFuzz, WAFLGo identifies four, five, and six more bugs, with an average speedup of 5.4×, 5.7×, and 25.8×, respectively.

Comparison with Coverage-based Fuzzers. We compare WAFLGo with three coverage-based tools listed in Table 2, namely AFL, AFL++, and FairFuzz. In total, WAFLGo identifies six, four, and three more bugs compared to them, with an average speedup of 9.9×, 7.2× and 11.2×, respectively. Our results show that our tool is more effective at detecting commit-inducing bugs compared to existing coverage-based fuzzers. This can be attributed to WAFLGo's capability of drawing more energy to test the code regions affected by commit changes.

Comparison with Regression Fuzzers. The evaluation results of AFLChurn are listed in the 12th column in Table 3. WAFLGo outperforms AFLChurn by successfully reproducing five more bugs. On average, WAFLGo achieves a speedup of 8.0×. The improved performance of WAFLGo is the result of its capability to identify fine-grained changes in the code compared to AFLChurn.

Directed Fuzzers v.s. Coverage-based Fuzzers. We notice that, in certain cases, directed fuzzers exhibit inferior performance compared to their coverage-based counterparts. There are two main reasons. First, in some scenarios, certain bugs are relatively easy to trigger, as demonstrated by cases such as issues #498, #732, and #535. These bugs can be successfully exploited within a short time frame of approximately one minute of fuzzing, as indicated in Table 3. Upon analysis, we find that the main reason for this is that the initial seed used for fuzzing is already in close proximity to the target location. This proximity allows for the generation of inputs that can effectively trigger the bug through simple mutations. In such cases, directed fuzzing-based tools may appear less effective, as the bug-triggering process does not require additional guidance or sophisticated mutation strategies. Second, some bugs, as exemplified by issue #519, have easily accessible target locations. This means that the majority of generated inputs can readily reach these targets. When the target is readily reached, the challenge shifts from reaching the targets to conducting thorough code testing, aligning more with a coverage-based testing task. Therefor, coverage-based fuzzers, such as AFL++

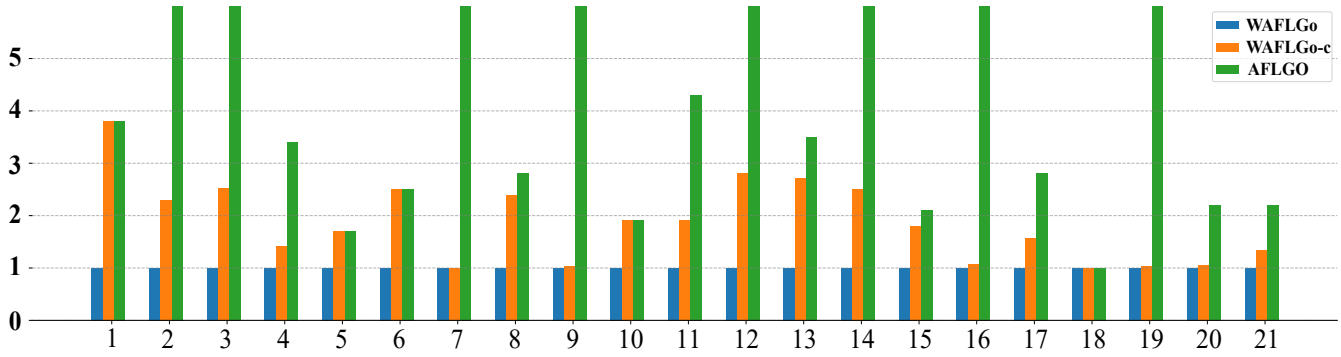

Figure 4: The component-wise effectiveness of WAFLGo. The y-axis represents the ratio of reproduction time, with WAFLGo as the baseline.

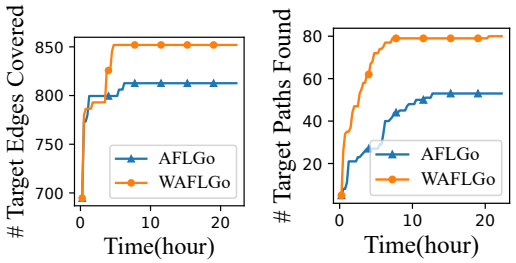
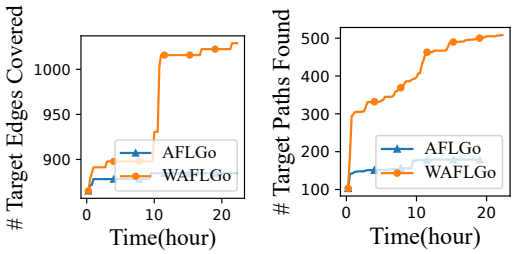


and FairFuzz, tend to excel in such scenarios. For example, in the case of issue #519, it is worth noting that more than 90% of seeds generated by all the fuzzers can successfully reach the target.

6.2 Impacts of Critical Code Guidance



To effectively direct WAFLGo toward and thoroughly test the target and its affected code, we introduce a novel critical code guided input generation strategy. The core design includes a critical code identification method, a target edge selection and a mutation masking mechanism. To evaluate how the strategy contributes to the efficiency of WAFLGo, we created a variant of WAFLGo in which these mechanisms were disabled. We refer to this variant as WAFLGo-*c*, and we conducted a set of experiments to compare its performance with that of the original WAFLGo.

Bug Triggering Time. The experimental results are depicted in Figure 4. Overall, WAFLGo outperforms WAFLGo-*c* to reproduce the bugs with an average speedup of 2.1×. These results demonstrate the effectiveness of the critical code guidance. Notably, our strategy has shown remarkable effectiveness in certain cases, such as case No.1. Both WAFLGo-*c* and AFLGo fail to reproduce this bug. To further evaluate its performance, we extend the fuzzing time for AFLGo on case No.1 to 48 hours. As a result, AFLGo successfully detects the bug at 37.1 hours. However, we observe that even though AFLGo reaches the target within the first hour, the coverage of affected basic blocks in the subsequent fuzzing period increases very slowly. This indicates that after reaching the target, AFLGo does not pay much attention to testing the affected code, leading to the bug not being triggered within the given time budget.

Coverage of Affected Code. To further demonstrate the effectiveness of our target testing, we present the edge coverage achieved by AFLGo and WAFLGo, along with the count of paths that reach the targets in Figure 5. We exclude the coverage of inputs that do not reach the targets from our analysis, as they are unlikely to discover bugs introduced by the targets. Due to space limitations, Figure 5 showcases the results for

(a) Tcpreplay #718

(b) Poppler #1289

Figure 5: The edge coverage and the number of target-reached paths.

two issues: No. 15 (Tcpreplay #718) and No. 19 (Poppler #1289). We will make all of our data available on our website for further analysis and reference. From the results, we observe that WAFLGo achieves an average increase of 11.7% in edge coverage after 24 hours compared to AFLGo. Furthermore, WAFLGo discovers nearly 2× (181.5%) more paths than AFLGo after 24 hours. It is worth noting that during the initial three hours, WAFLGo discovered a greater number of paths reaching the target compared to AFLGo, which aligns with the findings shown in Figure 4, where WAFLGo identifies the bugs at a faster rate than AFLGo.

6.3 Impacts of Multi-Target Optimization

To address the multi-target challenge, we have proposed several optimizations, which include the distance calculation methods, the adjusted input generation strategy and the seed scheduling mechanism.

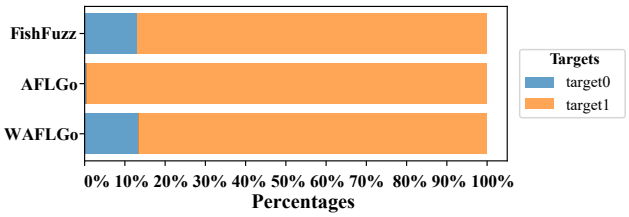


Figure 6: Target reached seeds.

Table 4: New vulnerabilities detected by WAFLGo

Program	Bug Type	Status	ID
tiffcrop	segmentation fault	patched	CVE-2023-3618
fig2dev	null pointer dereference	patched	CVE-2023-34629
fig2dev	segmentation fault	patched	CVE-2023-34630
fig2dev	memory leak	patched	CVE-2023-34631
swftophp	heap buffer overflow	reported	issue-271
swftophp	heap buffer overflow	reported	issue-270
swftophp	heap buffer overflow	reported	issue-269

Bug Triggering Time. In evaluating the effectiveness of our proposed optimization methods, we conducted a series of experiments involving WAFLGo-*c* and AFLGo. The experimental results shown in Figure 4 demonstrate that WAFLGo-*c* is faster than AFLGo for discovering bugs, achieving an average speedup of 4.3×. This improvement is attributed to the generation of high-quality seeds for each target using our multi-target optimizations. All 30 issues in our dataset have multiple targets, and 21 of them have more than 10 targets. Our target merging process reduces the number of targets by a factor of 6.72, and after the merging process, 20 of the issues have fewer than five targets.

Quality of Generated Seeds. To further understand the effectiveness of our multi-target optimization, we conducted an analysis of the seeds generated by AFLGo and WAFLGo for issue #1289. In this case, the BIC of issue #1289 modified one file with 31 additions and two deletions, resulting in changes to 32 basic blocks. Following our target merging process, WAFLGo identifies two targets. From Figure 6, we observe that nearly all the seeds generated by AFLGo reach target1 but ignore target0. However, it is target0 that represents the key change introducing the bug. Therefore, AFLGo fails to reproduce this bug. Furthermore, we analyze the seeds generated by FishFuzz, a fuzzer designed for multi-target scenario. Interestingly, we found that the seed distribution in FishFuzz is similar to that of WAFLGo, further highlighting the effectiveness of our approach in handling multi-target situations.

6.4 Detecting New Vulnerabilities

In this subsection, we employ WAFLGo to detect new vulnerabilities by applying them to various programs. WAFLGo successfully identifies seven new vulnerabilities during the time budget as listed in Table 4. It is noteworthy that WAFLGo demonstrated its effectiveness in uncovering vulnerabilities even in complex software such as *libtiff*. We promptly reported all identified vulnerabilities to the respective developers. As of the time of writing, four vulnerabilities have been patched and receive CVE IDs, showcasing the impact and value of our approach in contributing to the improvement of software security.

We further analyse the newly discovered vulnerabilities and found that the CVE-2023-34631 is introduced by the fixing commit (6678ad8) for CVE-2023-34630. The vulnerability originates from the code at `fig2dev/gengbx.c:1135` [3], where a linked list pointer is dereferenced without checking the existence of the next pointer. This led to a null pointer dereference bug (CVE-2023-34630). To address the vulnerability, the *sanitize_lineobject()* function in `fig2dev/read.c` was modified to include a check for the presence of the next pointer in the linked list. However, this adjustment affected the length of the linked list and disrupted other code logic, resulting in CVE-2023-34631 with invalid memory access. In order to resolve the vulnerability, the developers opted to revert the fix commit (6678ad8) and perform a careful refactoring of the linked list length handling in the *sanitize_lineobject()* function. It is worth noting that the change site of the bug-introducing commit is far away from the crash site, and it was not even evident in the stack trace of the crash. This observation further validates our hypothesis that effective fuzzing of newly committed code requires a focus not only on the changed code itself but also on the code that is affected by the changed code. By considering the broader code context, we can uncover potential vulnerabilities and bugs that may have cascading effects beyond the immediate scope of the modifications.

7 Discussion and Limitation

In this section, we discuss the limitations of WAFLGo and the possible future works.

Reaching Target Failure. WAFLGo proposes a comprehensive approach that focuses on thoroughly testing commit modifications and their affected code throughout the entire program. The first step in achieving this goal is to reach the modification sites. However, the task of reaching the target locations itself remains a significant challenge in the current research landscape of directed greybox fuzzing. As discussed in Section 6.1, there are instances where WAFLGo, along with existing fuzzers, fails to reach the modified sites and trigger the associated bugs. This limitation primarily stems from WAFLGo's difficulty in efficiently generating high-quality inputs that satisfy complex path constraints.

To address this challenge, incorporating advanced static analysis techniques could be highly beneficial. We plan to integrate other advanced static analyses (e.g., concolic symbolic

execution similar to [8, 16, 37]) into WAFLGo to mitigate this limitation.

Semantic Affected Code Identification. In WAFLGo, we collect all the code that exhibits a data dependency with the written variables used in the targets (commit changes) and consider it as the data-suffix code. However, not all variables in the commit changes hold the same level of importance regarding the potential introduction of bugs. For instance, a freed pointer variable is more critical than an arithmetic variable, as it could potentially lead to null pointer reference bugs in the suffix code logic of the program. Additionally, if we treat the data-suffixes with different levels of importance, the bug discovery process will be enhanced. Semantic information plays a significant role in determining the relevance of data dependencies. Factors such as data flow to a global value or memory write rather than memory reads carry more significance.

To enhance the precision and value of affected code targeting for vulnerability discovery in the commit-introducing changes, WAFLGo can collect and learn from the semantic information of the codes like [22]. By incorporating this semantic knowledge, one can achieve more accurate identification of affected code, ultimately improving the efficacy of vulnerability detection.

Incremental Testing. Different from traditional greybox fuzzing approaches, WAFLGo focuses on newly submitted commits to uncover newly introduced bugs. The ultimate goal is to shift commit security testing left in the Continuous Integration/Continuous Deployment (CI/CD) pipeline, ensuring that bugs are detected before a commit is merged into the main branch and released to the public. While our evaluation results demonstrate that we can discover a significant number of bugs within two hours, there are still instances where bug detection requires more than 12 hours (e.g., No. 5). This extended duration may not be feasible or acceptable in practical commit testing scenarios.

To address this challenge, an intuitive solution is to explore incremental testing. We could leverage historical testing data to guide WAFLGo more efficiently to the change site, similar in [25, 29]. Additionally, program analysis techniques such as under-constraint symbolic execution [6, 28, 34] and program slicing [9] can be utilized to further optimize the testing process. We consider these topics as future work, with the potential to enhance the efficiency and effectiveness of WAFLGo in the context of commit testing.

8 Related Work

In this section, we discuss the closely related works.

Improvement of Directed Greybox Fuzzing. Many approaches have been proposed to optimize directed greybox fuzzing and improve its effectiveness in discovering program bugs. Inspired by distance-guided fuzzer AFLGo [5], Hawkeye [7] introduces augmented distance metrics to enhance directness, while Windranger emphasizes precise distance calculation through the deviation of basic blocks. Reachability-based fuzzers like FuzzGuard [40] train models to predict and discard inputs that cannot reach the target, while Beacon [14] stops inputs that cannot reach the target. SelectFuzz [23] selectively instruments relevant code of the target to explore the program more efficiently. Parmesan [27] and FishFuzz [38] address the multi-target problem, while their targets are sanitizer-marked locations.

Different from existing works primarily focusing on quickly reaching the target, WAFLGo aims to thoroughly test the commit change sites and their affected code. Recognizing the importance of the commit's impact on the entire program, WAFLGo goes beyond reaching the target commit change sites and extensively tests the affected code with diverse inputs. By combining targeted testing with a comprehensive exploration of affected code, WAFLGo enhances its ability to uncover vulnerabilities introduced by code changes and contributes to more effective bug detection.

Verifying New Code. When a new commit is submitted to a program, it becomes crucial to verify whether this commit has introduced any new vulnerabilities. In the defect prediction community, lots of approaches [32–34] have been proposed to address this concern. For instance, UC-KLEE [28] utilizes under-constrained symbolic execution to directly check individual functions for potential crashes and to verify the new code. Symbolic execution provides a high level of certainty in code verification as it exhaustively explores the input space. However, it can be computationally intensive.

Regarding the fuzzing scope, AFLChurn [39] proposes simultaneous testing of all commits, assigning more energy to the inputs that execute the recent modified code area. In this work, we adopt a similar objective of targeting every commit change and addressing the multi-target challenge carefully. The aim is to identify newly introduced bugs as early as possible during the development process.

9 Conclusion

This work addresses the challenges faced in testing commits to discover newly introduced bugs and proposes WAFLGo, a directed fuzzer designed to efficiently reach change sites and thoroughly test their affected code. WAFLGo employs a critical code guided input generation strategy and a multi-target distance metric to enhance its effectiveness. We curate a dataset containing 30 real-world bugs, and identify their BICs manually. Through a meticulous evaluation of this dataset, we demonstrate the effectiveness of WAFLGo compared to existing fuzzers. Furthermore, WAFLGo successfully identifies and reports seven new vulnerabilities, including four CVEs, in real-world programs, showcasing its practical applicability.

Toward Unbiased Multiple-Target Fuzzing with Path Diversity

Abstract

Directed fuzzing is an advanced software testing approach that systematically guides the fuzzing campaign toward user-defined target sites, enabling efficient discovery of vulnerabilities related to these sites. However, we have observed that some complex vulnerabilities remain undetected by directed fuzzers even when the flawed target sites are frequently tested by the generated test cases, because triggering these bugs often requires the execution of additional code in related program locations. Furthermore, when fuzzing multiple targets, the existing energy assignment in directed fuzzing lacks precision and does not ensure the fairness across targets, which leads to insufficient fuzzing effort spent on some deeper targets.

In this paper, we propose a novel directed fuzzing solution named AFLRun, which features *target path-diversity metric* and *unbiased energy assignment*. Firstly, we develop a new coverage metric by maintaining extra virgin map for each covered target to track the coverage status of seeds that hit the target. This approach enables the storage of waypoints that hit a target through interesting path into the corpus, thus enriching the path diversity for each target. Additionally, we propose a corpus-level energy assignment strategy that ensures fairness for each target. AFLRun starts with uniform target weight and propagates this weight to seeds to get a desired seed weight distribution. By assigning energy to each seed in the corpus according to such desired distribution, a precise and unbiased energy assignment can be achieved.

We built a prototype system and assessed its performance using a standard benchmark and several extensively fuzzed real-world applications. The evaluation results demonstrate that AFLRun outperforms state-of-the-art fuzzers in terms of vulnerability detection, both in quantity and speed. Moreover, AFLRun uncovers 29 previously unidentified vulnerabilities, including 8 CVEs, across four distinct programs.

*Corresponding author.

1 Introduction

Fuzzing is a testing technique that examines a program's behavior by subjecting it to a range of generated inputs, identifying any anomalous behaviors that arise and reporting inputs causing such anomalies. In recent years, coverage-guided fuzzing [1,3,4,19] has made a significant stride in uncovering software vulnerabilities. However, coverage-guided fuzzing is designed to test all code regions within a program, but in certain security scenarios, such as static analysis report verification [14] and patch testing [10], the focus is on fuzzing specific code locations known as *target sites*. As a result, directed fuzzing [11], building upon coverage-guided fuzzing, has emerged as an alternative, receiving a lot of research attention [12, 18, 23, 29, 34, 43, 44]. The key idea of directed fuzzing is to approach and test the target sites by prioritizing the seeds (stored test cases) whose execution traces get to the vicinity of the target sites. This is achieved by evaluating the seeds using a distance oracle and assigning more *energy* (which determines the effort spent on fuzzing a given seed) to those coming closer to the targets than others. In this way, the fuzzer is expected to quickly discover the test cases capable of reaching the target sites and activating the security flaws (the vulnerabilities) at these sites (i.e., triggering the crash).

Listing 1 Example of Preconditioned Trigger

```
1  const char* get_string() {
2    if (/*Easy Constraint*/) return "default";
3    ... // Constaints solvable by genetic approach
4    return get_input(); // Get attacker-controllable input
5  }
6  void foo() {
7    char victim[128];
8    const char* p = get_string();
9    if (/*Hard Constraint*/)
10     strcpy(victim, p); // Potential Overflow
11 }
```

Limitations and challenges. However, directed fuzzing today are impeded by the limitations of techniques, rendering it less effective than expected in discovering vulnerabilities.

Specifically, as observed in our research, oftentimes, hitting a target site does not necessarily trigger the vulnerability it carries: that is, the fuzzing fails to produce a detectable crash. Instead, to activate the flaw, the execution trace needs to cover some other code locations, which could be far away from this target site. For example, in Listing 1, the flaw at the target site (Line 10) can only be activated when the seed's execution goes through Line 4, instead of Line 2, since receiving a long input is the *precondition* for overflowing the vulnerable buffer at the target site. We call such a scenario, in which a unique path needs to be covered before hitting the vulnerable target site for triggering such vulnerability at the target, *preconditioned flaw activation* or *PFA*. To sum up, PFA captures bugs requiring certain previous paths to trigger. Another scenario is that at the target site only the *root cause* of a security flaw is present while the flaw can only be activated in a different program location: as illustrated by the example in Listing 2, the target site (Line 15-20) introduces an uninitialized pointer, which has only be dereferenced (thereby causing a crash) at Line 28 and 29. We call this scenario *post-target activation* or *PTA*, which captures bugs triggered at certain paths following the root cause.

Moreover, in the presence of multiple target sites, a directed fuzzer is supposed to generate test cases to fuzz these sites in an unbiased way. However, today's energy assignment strategy relies primarily on a scalar distance oracle that determines a seed's priority using average. As pointed by the prior work [28, 40, 43], this strategy fails to take into account the dynamic status of each target (e.g., whether it is easier than others to reach), causing global optimum discrepancy, which could lead to *a bias against certain targets or even favor the seed unable to reach any target*. As a result, deeper target sites may receive insufficient fuzzing effort, potentially leaving some vulnerabilities at these locations undiscovered. Prior attempts to address the problem mostly focus on design of different distance oracles to mitigate the bias [12, 28]. These approaches, however, are still less effective due to their continued use of aggregate information like average across all targets, thereby missing the individual information of each target, such as the extent to which the paths to a specific target have been covered by the current corpus. Even the most recent approach, FishFuzz [43], which utilizes a vector-based oracle instead of a distance oracle, still does not pay enough attention to the path diversity, ignoring the seed that hits a target visited frequently but is associated with the paths much less traversed than others.

Solutions. To address those limitations, we developed a new directed fuzzer by enhancing the greybox fuzzer with two innovative techniques. First, we introduce *target path-diversity metric*. More specifically, our fuzzer, called AFLRun, aims at generating the seeds not only reaching a given target site but covering as many paths involving the target as possible. The criticality of these paths in activating bugs is emphasized by the fact that enhancing path diversity can effectively address both PFA and PTA. For this purpose, AFLRun maintains an extra virgin map for each target to record the coverage status of all seeds that hit the target. When deciding whether a mutated test case should be used to fuzz a program again (that is, storing the test case into the fuzzer's corpus as a seed), AFLRun not only checks its execution trace with the virgin map of the coverage-guided fuzzer to evaluate its potential to improve the total code coverage, but also with our extra virgin maps to determine its capability of diversifying the execution paths involving the target site. It is important to note that the extra virgin map associated with the target captures coverage both before and after execution reaches the target. This approach enables the comprehensive capture of both PFA and PTA.

Second, we introduce *unbiased energy assignment* to enable fair exploration and exploitation of each target. AFLRun first assigns each target block (the basic block containing the target site) a weight, which takes the same value to ensure their fair chance to be visited. Then it propagates the weights from the targets to a set of *critical blocks*, which include both the target blocks visited before and a set of *critical boundary blocks*: that is, a visited block leading to a target via the inter-procedural control flow graph (ICFG), with none of other blocks (including the target) from the block to the target being covered before. For a given seed, our approach computes its energy (which determines its mutation priority) by adding the weights of the critical blocks it covers. In this way, AFLRun always prioritizes the seeds with the highest potentials to get to a new target site and the seeds that cover any target sites, and also ensures each target to have a fair chance to be tested. When applied together with the targeted path-diversity metric, the energy assignment strategy can further improve the path diversity of each target.

We implemented AFLRun on top of AFL++ [19] and AFLGo [11], and evaluated it on a standard benchmark Magma [21] and real-world programs intensively fuzzed by the OSS-Fuzz project [6]. Our evaluation on the Magma benchmark shows that compared with state-of-the-art fuzzers (AFL++ [19], AFLGo [11], Parmesan [34], FishFuzz [43], Hawkeye [12], WindRanger [18] and MOpt [30]), AFLRun achieves an average speedup of 168%, 109%, 235%, 183%, 147%, 157% and 78%, and triggers 38%, 20%, 138%, 29%, 24%, 14% and 50% more vulnerabilities. In addition, AFLRun has discovered 29 previously unknown vulnerabilities in real-world programs, with 8 CVE IDs assigned so far.

Contributions. We have made the following contributions:

• *New techniques*. To the best of our knowledge, we present the first directed fuzzing technique that improves path diversity and fairness in energy assignment for each target at the same time, in a systematic way. Serving this purpose are two new techniques, including a new coverage metric that captures both PFA and PTA to improve the chance to activate the flaws related to target sites, and a new energy assignment

strategy that ensures the target fairness and prioritizes testing of the new paths involving the targets. Both are found to be highly effective.

• *Implementation, evaluation and findings*. We implemented a prototype system and released its code at https://github.com/Mem2019/AFLRun. AFLRUN has discovered 29 zero-day vulnerabilities from the real-world software that have been intensively fuzzed before, which provides evidence to the efficacy of our techniques.

2 Background

In this section, we introduce the basic concepts and overall workflow of coverage-guided fuzzing (§2.1) and directed fuzzing (§2.2).

2.1 Coverage-guided Fuzzing

The workflow of the current coverage-guided fuzzing technique can be summarized as follows: (1) At the beginning of a fuzzing campaign, one or more inputs are provided as the initial seed corpus. (2) The fuzzer selects a seed from the corpus, which is then mutated to create a test case that is executed by the program under test (PUT); this mutation and execution process is repeated several times for each selected seed. (3) If the test case triggers any new behavior not yet triggered by the current corpus, it is stored as a seed for future mutation. (4) The fuzzer repeats steps 2-3 in an infinite loop. Since our approach focuses on improving energy assignment and seed storage by modifying steps 2 and 3 in AFL++ [1,19], we will discuss how AFL++ implements these two steps in greater detail.

In AFL++, the fuzzer process and the PUT process share a segment of memory to record the execution path of the PUT, allowing the fuzzer to access this information. Each byte in the shared memory represents an edge connecting two basic blocks. The PUT is instrumented so that each time an edge is traversed during execution, the corresponding byte is incremented by one[1]. In the shared memory, the fuzzer obtains a bitmap that abstractly represents the execution path of a single run. In this paper, we refer to this bitmap as the *execution trace*. Additionally, AFL++ maintains a global bitmap to record all bits covered by at least one execution trace of seeds in the corpus so far. We refer to this bitmap as the *virgin map* in this paper. Specifically, the virgin map is an array with the same length as the execution trace, initialized with all bits set to 1. When a new seed covers a new bit, the corresponding bit in the virgin map is set to 0. Each time a mutated test case is executed, AFL++ compares the generated execution trace with the virgin map. If the execution trace covers a new bit that has not been covered by any previous seeds' execution traces, the test case will be added to the corpus as a seed. By incrementally adding new seeds into corpus, total coverage of the PUT can be improved.

In addition, AFL++ maintains a record of the best seed for each edge using an array, based on metrics such as the seed's length and execution time. We refer to this array as the *top-rated array* in this paper. When a new seed is added to the corpus, AFL++ attempts to update the top-rated array based on the seed's edge coverage and metrics. If any updates occur, a process called *queue culling* selects a subset of seeds from the corpus to be marked as favored, and these favored seeds are chosen for fuzzing more frequently than the others.

2.2 Directed Fuzzing

Directed fuzzing, built upon coverage-based fuzzing, focuses on testing a specific set of user-defined target sites rather than all code regions. The main concept involves using a seed oracle (i.e., dynamic information gathered by executing the PUT with the seed as input) to determine the proximity between the seed and the target sites. This oracle is then used to assign energy for preferentially testing these sites. The energy assigned to a seed is defined by the number of times the fuzzer is going to mutate the seed and execute the PUT using the mutated test case as input.

The seed oracle is commonly referred to as the *distance* in the context of directed fuzzing. To achieve such an oracle, both static analysis and dynamic information are required. Static analysis of the PUT computes the distance from each code location (e.g., basic block) to all target sites, typically averaged using the harmonic mean. During a fuzzing campaign, each time the PUT is executed with a particular seed as input, the seed's distance value to target sites (i.e., seed oracle) can be obtained by calculating the arithmetic mean of the distance values of the relevant code locations covered during the execution.

With this seed oracle, directed fuzzing assigns energy to each seed such that seeds with lower distance values receive higher amounts of energy. By adjusting energy assignment to favor seeds closer to the target sites, the fuzzing campaign focuses on testing these specific sites.

3 Motivation

In this section, we present a PTA vulnerability as our motivating example and discuss the directed fuzzing scenario intended to discover such a vulnerability. (§3.1) We also examine how current directed fuzzing approaches fail to find it, while AFLRUN is capable of successfully detecting it. (§3.2)

[1] AFL++ classifies value of each non-zero byte according to 8 predefined ranges, each corresponding to a bit in the byte. Ultimately, the byte is set to the bit corresponding to the classified range. The comparison between the execution trace and the virgin map is performed at bit level.

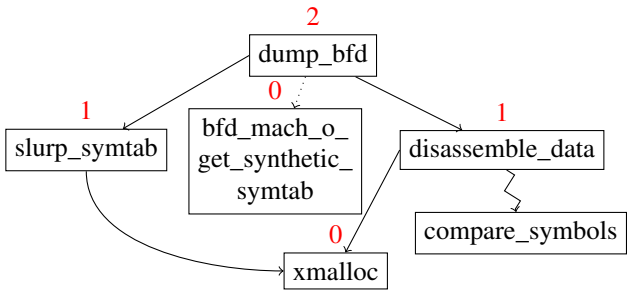

Figure 1: Partial call graph that involves the critical functions to trigger the vulnerability. Another target in `xmalloc` is also included. The distance value of each function is annotated above the rectangular in red.

3.1 Vulnerability and Fuzzing Scenario

We use the discovery of a zero-day vulnerability (CVE-2023-25588) in `binutils` as an example to demonstrate the limitations of existing techniques and motivate the ideas of AFLRun. Listing 2 shows the simplified vulnerable code snippet. The `dump_bfd` function invokes the `bfd_get_synthetic_symtab` function pointer (Line 10) to create synthetic symbols for indirect symbols and invokes the `disassemble_data` function (Line 11) to disassemble the contents of an object file. When processing a Mach-O executable, the function pointer points to the `bfd_mach_o_get_synthetic_symtab` function (Line 15-21), in which an array of the `asymbol` structure is allocated without initialization for its `the_bfd` pointer field. A pointer to the allocated array is stored in the global variable `synthsyms`. The `disassemble_data` function performs complex logic and finally calls the `compare_symbols` function to sort symbols. During comparison, the `the_bfd` field of the elements stored in the `synthsyms` array will be dereferenced, resulting in access of uninitialized pointer.

Figure 1 illustrates the partial call graph involving the critical functions needed to trigger the vulnerability. In the figure, the solid lines represent normal function calls linking caller and callee, the dashed line indicates a indirect call unable to be identified by static distance computation, and the zigzag line shows multiple normal calls with omitted intermediate nodes. As depicted, in order to trigger the vulnerability at the location of dereference (Line 28 in `compare_symbols`), a test case must cover this location after executing the location of allocation (Line 17 in `bfd_mach_o_get_synthetic_symtab`, the root cause location of the vulnerability). It is important to note that these two locations are distant from each other in the code base.

Consider a security scenario that utilizes directed fuzzing to verify a report from static analysis. An aggressive, yet comprehensive and scalable static checker might identify potential risks if it detects a function that allocates a piece of heap memory without initializing the content within the function scope.

Listing 2 Simplified vulnerable code snippet.

```
1  typedef struct bfd_symbol {
2    struct bfd *the_bfd;
3    /* other fields are omitted */
4  } asymbol;
5
6  asymbol *synthsyms;
7  long *(bfd_get_synthetic_symtab)(...);
8
9  void dump_bfd (...) {
10   bfd_get_synthetic_symtab(..., &synthsyms);
11   disassemble_data(...);
12 }
13
14 /* bfd_get_synthetic_symtab for Mach-O executable */
15 long bfd_mach_o_get_synthetic_symtab(..., asymbol **ret) {
16   size_t size = count * sizeof(asymbol) + 1;
17   char *s_start = bfd_malloc(size);
18   *ret = (asymbol *) s_start;
19   /* intialize each field of the asymbol structure,
20      except for the the_bfd pointer field */
21 }
22
23 /* disassemble_data finally calls compare_symbols */
24 int compare_symbols(const void *ap, const void *bp) {
25   /* a and b point to the elements in synthsyms. */
26   const asymbol *a = * (const asymbol **) ap;
27   const asymbol *b = * (const asymbol **) bp;
28   /* code to dereference a->the_bfd and b->the_bfd,
29      resulting in access of uninitialized pointer */
30 }
31
32 /* Another target site detected by static analysis */
33 void * xmalloc (size_t size) {
34   void *newmem = malloc (size);
35   return (newmem);
36 }
```

When employing such a checker on `binutils`, it reports multiple program locations, which are treated as target sites for directed fuzzing. The root cause of this vulnerability, located at Line 17, is one of these target sites. Additionally, there are other false positive target sites, including Line 34 at `xmalloc`, which is simply a wrapper for the `malloc` function. Figure 1 also includes some functions that invoke `xmalloc`. For simplicity, we only show two functions that call `xmalloc`, as it is a utility commonly used by numerous functions. Thus, an ideal directed fuzzer should be able to discover the vulnerability by generating a test case that both creates and dereferences the uninitialized variable, despite the interference from false positive target sites like Line 34. Besides, it is worth noting that these target locations conform to the format used by AFLGo [11], instead of targets with explicit dependency information required by some works [26, 33].

3.2 Limitations and Solutions

However, the current state-of-the-art directed fuzzer struggles to efficiently trigger this bug under the scenario we described earlier, even if the flawed target site at `bfd_mach_o_get_synthetic_symtab` is already covered

by the corpus during the fuzzing campaign. We outline two limitations that contribute to this issue and explain how our approaches address them.

First, current directed fuzzers still rely on the coverage metric of coverage-guided fuzzing, which is designed to improve the total code coverage of the corpus. Specifically, once a constraint is solved, the edge of the constraint will be marked as non-virgin in the virgin map, meaning that subsequent test cases that cover the same edge will not be stored in the corpus. In this example vulnerability, if the constraints on the path to Line 28 (i.e., the dereference of `the_bfd`) are solved with a seed that cannot cover Line 17 (i.e., the location that creates the uninitialized pointer), the edges of these constraints are no longer considered virgin. Consequently, if a test case that covers the target site of uninitialized pointer allocation later solves any of these constraints, it will not be stored in the corpus. As a result, seeds that cover this target site cannot make progress on these constraints by taking advantage of the genetic approach employed by the greybox fuzzer, which ultimately restricts the subsequent fuzzing campaign from discovering this potential crash.

We have observed that, in order to trigger this bug, path diversity of the target site with the uninitialized pointer allocation is crucial. In other words, we aim to maximize the total code coverage given the target site Line 17 is covered, in order to increase the likelihood of executing the code location that accesses the uninitialized pointer. Our approach, by maintaining an additional virgin map for this target site, does store test cases that improve path diversity of this target site in the corpus, even if the original coverage metric of AFL++ would deem the test case uninteresting.

Second, the energy assignment in existing directed fuzzing, which relies on the scalar distance oracle, may be biased toward certain targets, resulting in inadequate fuzzing efforts spent on the vulnerable target site. In this particular example scenario, we demonstrate the bias toward the target Line 34. For simplicity, we only consider these two target sites and part of the program illustrated in Figure 1, and assume there are only two categories of seeds in the corpus: S_a and S_b. Seeds in S_a can visit target site Line 17, while those in S_b cannot. Both categories of seeds are able to cover `xmalloc` through `slurp_symtab` and `disassemble_data`. Since Line 17 is an uncommonly covered target, S_a makes up only a small proportion of the corpus. To avoid loss of generality, we calculate the seed distance values using a simplified method that approximately represents current directed fuzzing approaches [11, 12, 34]: the distance value of each block is computed by the average of minimum distances to all targets that it can reach via the graph. Using the distance value of each function in Figure 1, we can calculate the distance values of S_a and S_b as $\frac{2+1+1+0+0}{5} = 0.8$ and $\frac{2+1+1+0}{4} = 1$, respectively. It is worth noting that covering Line 17 only contributes one additional term and does not significantly influence the average scalar value. As a result, the final energy assigned to each seed in S_a and S_b does not differ greatly. However, since the size of S_a is small, the total energy assigned to seeds in S_a is also low, causing the fuzzing campaign to lose directness toward target site Line 17 and become biased toward Line 34.

Instead, as we do not know which target site contains the vulnerability beforehand, the importance of each target is unknown a priori. Therefore, a best scheme is to treat each target (e.g., Line 17 and Line 34) equally during the fuzzing campaign. Our approach achieves this by assigning a uniform weight to each target and propagating such weight to seeds for energy assignment. To be specific, the weight assigned to S_a is $\frac{1}{|S_a|} + \frac{1}{|S_a|+|S_b|}$, and the weight assigned to S_b is $\frac{1}{|S_a|+|S_b|}$.[2] Since $|S_a|$ is a much smaller value than $|S_b|$, the weight assigned to each seed of S_a is significantly greater than that of S_b. Therefore, even though S_a comprises only a small set of seeds in the corpus, Line 17 will still be assigned an equal amount of weight as the others, ensuring that it receives enough energy to trigger the bug.

4 Design Overview

In this section, we provide a brief design overview of AFLRun, including its workflow (§4.1) and the fuzzing loop (§4.2).

4.1 Workflow

Figure 2 illustrates the workflow of AFLRun. In the static stage, AFLRun first takes the program source code and target sites for static analysis and instrumentation. The static analysis generates a partial ICFG with vertices representing basic blocks that can reach at least one of the target blocks, along with distance values to these target blocks for each vertex. Each of these blocks is instrumented with our runtime callback function. In the dynamic stage, our unbiased energy assignment generates energy values for all seeds, which determine the number of mutations and executions for each seed. For each execution of a mutated test case, we employ our target path-diversity metric to determine whether the test case should be stored in the corpus. If so, we also use it to update critical blocks and target clusters. Target clusters are utilized to group targets exhibiting similar behavior, thereby reducing the runtime overhead, particularly when the number of targets is substantial (discussed in §5.2).

4.2 Fuzzing Loop

Algorithm 1 provides a high-level overview of the fuzzing loop in AFLRun. Each iteration of the outermost loop constitutes one cycle, during which all seeds in the corpus are

[2] Here, we assume that the seeds in $|S_a|$ and $|S_b|$ have equal importance; however, in reality, the energy assignment among seeds in such set is not uniform. See §6.3 for more details.

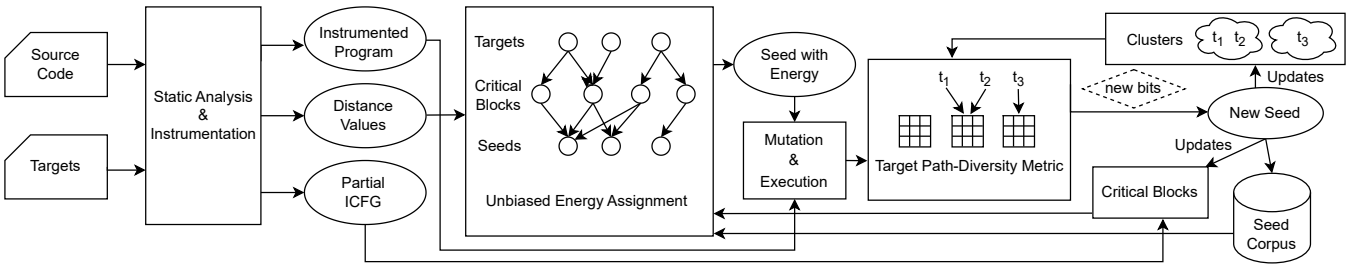

Figure 2: Workflow of AFLRUN.

Algorithm 1 Fuzzing Loop of AFLRUN

Require: Initial *corpus*
repeat
  seed_energy := assign_energy(E, corpus)
  for $(seed, energy) \in seed\_energy$ in descending order **do**
    for i from 1 to *energy* **do**
      s' := mutate_input(*seed*)
      t' := execute(s')
      if t' crashes **then**
        add s' to *crashes*
      else if has_new_coverage(t') **then**
        add s' to *corpus*
        if t' updates critical blocks **then**
          break the outermost loop
        end if
      end if
    end for
  end for
until timeout reached or abort-signal
return *crashes*

supposed to be selected for fuzzing once. At the beginning of each cycle, the `assign_energy` function, our unbiased energy assignment, is invoked to assign an energy value to each seed. Unlike other greybox fuzzing approaches, including directed ones, our energy assignment algorithm operates globally for the entire corpus rather than locally for individual seeds. This global perspective is crucial for ensuring unbiased energy assignment.

In the second loop, we iterate through each seed-energy pair returned from `assign_energy` in descending order based on energy, which allows AFLRUN to fuzz seeds with higher energy first. The seed is mutated using `mutate_input`, the mutation algorithm from AFL++ [19], and executed by the PUT with our instrumentation using `execute`. The execution results t' are examined similarly to other greybox fuzzing methods. However, `has_new_coverage` is now replaced by our target path-diversity metric, rather than the previous coverage metric used in AFL++. Additionally, if a new seed updates the current critical blocks, the cycle is immediately halted to restart the next cycle. This is because our unbiased energy assignment depends on critical blocks; thus, if any updates occur with them, AFLRUN should discard the obsolete energy results and re-assign energy using the updated critical blocks.

5 Target Path-Diversity Metric

In this section, we will discuss how our coverage metric improves the path diversity of already-covered targets. We introduce our multiple virgin maps in §5.1 and explain how we reduce overhead through clustering in §5.2.

5.1 Virgin Maps for Target Path Diversity

Algorithm 2 Coverage Metric for Test Case

Require: *path_trace* and *virgin_maps*
store := **false**
data := set()
for i := 1 **to** N **do**
  if path_trace[i] = 1 **then**
    updates := set()
    for map $\in$ virgin_maps **do**
      if map[i] = 1 **then**
        map[i] := 0
        store := **true**
        updates.insert(map)
      end if
    end for
    if $|updates| \neq 0$ **then**
      data.insert(updates)
    end if
  end if
end for
return store, data

Given a particular corpus state during a fuzzing campaign, the path diversity of a target is defined by the total coverage of seeds that cover this target. To enhance this path diversity, we propose to introduce an extra set of virgin maps. As we discussed in §2.1, AFL++ [19] uses a virgin map to store the coverage information of the current seed corpus. When the execution trace of a test case covers any new bits not yet covered by the corpus, the virgin map is updated, and the test case is stored to the corpus. In our approach, rather than using a single virgin map, we maintain and compare the execution trace of each test case against multiple virgin maps. These multiple virgin maps consist of the original virgin map used by AFL++, referred to as *primary virgin map*, and a set of extra virgin maps derived from all targets covered by the test case, referred to as *target virgin maps*. After executing each

test case, besides comparing its execution trace with primary virgin map like AFL++, we also compare it with our extra target virgin maps. If any of these virgin maps indicate that new bits have been covered, the test case will be stored to the corpus, and the bits of corresponding virgin map will be marked as non-virgin.

This approach is detailed in Algorithm 2. The parameter *path_trace* is a bit array of length N, which is the execution trace of test case that has just been executed. The parameter *virgin_maps* is a set of virgin maps including primary virgin map and target virgin maps, each of which is also a bit array of length N. The algorithm is somewhat similar to the original one of AFL++, except we compare execution trace with multiple virgin maps instead of a single virgin map. Furthermore, for each bit location where an update occurs, we record all the virgin maps that have experienced an update at that bit location. While this information is not useful for determining whether to store the test case, it is useful for target clustering, which will be discussed later.

5.2 Target Clustering

Another question to consider is how to obtain the set of target virgin maps from a set of targets covered by a test case. A naive approach would be to maintain a target virgin map for each of the targets that have been covered by seeds in the corpus. However, this approach could suffer from performance overhead: since comparing the execution trace with virgin maps is a frequent event, a large number of targets covered by each test case would require comparisons with a correspondingly large number of virgin maps, resulting in a non-negligible overhead. Initially, we implemented this naive approach and, by observing how each target virgin map was updated with new bits from the execution trace, we discovered that some virgin maps frequently update the same bits simultaneously. The general idea is that we can cluster these virgin maps into a single virgin map. This can reduce the overhead caused by repeated comparisons while still maintaining the desired path diversity.

Obtaining clusters. To select the set of clusters corresponding to the execution of a test case, AFLRun merges all clusters containing the targets covered during the execution. Each cluster corresponds to one virgin map and vice versa. By assembling these clusters together with the primary cluster, we can get the set of virgin maps used in Algorithm 2. For an in-depth depiction, refer to Appendix G of our arXiv version [36].

Association rule mining. Before discussing the details of our clustering algorithm, we will first introduce some concepts related to association rule mining used in this paper, which differ slightly from the original definitions. Assume we have a given set of items $I = \{i_1, i_2, ..., i_n\}$ and a database $D = \{t_1, t_2, ..., t_m\}$. Each element t in D is defined as a subset of I (i.e., $\forall_{t \in D}\ t \subseteq I$). In other words, the database consists of multiple subsets of items. In this paper, we define an association rule [8] between two items, denoted as $i_a \Rightarrow i_b$, where $i_a \in I$ and $i_b \in I$. Intuitively, this rule suggests that when i_a appears in a set t within the database, i_b is also likely to appear. Several metrics have been defined to measure the extent to which a given rule holds in a given database. The support count of an itemset $X \subseteq I$ is the number of times the itemset appears in the database. In other words, the support count, denoted as $\sigma(X)$, is the number of $t \in D$ such that $X \subseteq t$. The confidence of a rule $i_a \Rightarrow i_b$ is a ratio measuring the frequency of i_b appearing given that i_a appears, calculated by $\frac{\sigma(\{i_a, i_b\})}{\sigma(i_a)}$. In this paper, we consider a rule $i_a \Rightarrow i_b$ to be valid if both its support count $\sigma(\{i_a, i_b\})$ and its confidence are larger than a specified threshold.

When a new target is covered by the corpus, a new cluster containing only that target is created. At this point, the virgin map selection for this target is equivalent to the naive implementation mentioned earlier. As the fuzzing campaign progresses, more dynamic information is gathered, enabling us to merge clusters together. Specifically, we use *data* from all seeds in the corpus, collected through Algorithm 2, as a database for association rule mining [8]. This allows AFLRun to identify target virgin maps that can be clustered together. In Algorithm 2, we can observe that *data* consists of sets of clusters, as each virgin map corresponds to a cluster. We treat each cluster as an item and consider the union of *data* from all seeds in the corpus as the database in the context of association rule mining. Additionally, since our dataset is constructed by joining the dataset of each individual seed, we denote the dataset of a single seed s, which is a subset of the entire dataset, as I_s.

Algorithm 3 outlines the process of updating support count after a new seed is added to the corpus. The parameter *data* comes from the return value of Algorithm 2, and the parameter *support_count* is a global map used to record the support count of each itemset with one or two elements. For each set in *data*, we count both single items and pairs of items by $\frac{1}{|data|}$ instead of 1. This design choice is made to prevent bias caused by some seeds that trigger many new bits. (Remember that each element in *data* corresponds to a new bit.) As a result, we only assign a total support count of 1 for each seed, which is then distributed uniformly among all sets of items it contains.

Algorithm 3 Support Count Update for Each New Seed

Require: *data* and *support_count*
1: **for** items ∈ data **do**
2: **for** each single item $i \in$ items **do**
3: support_count[$\{i\}$] += $\frac{1}{|data|}$
4: **end for**
5: **for** each pair of items $\{i_a, i_b\} \subseteq$ items **do**
6: support_count[$\{i_a, i_b\}$] += $\frac{1}{|data|}$
7: **end for**
8: **end for**

Using the support count from Algorithm 3, we can calculate the confidence value of a given rule $i_a \Rightarrow i_b$ using the formula described earlier.

Clustering. Given an association rule $i_a \Rightarrow i_b$, if both its support count and confidence are higher than the threshold values, we can consider it to be valid. This semantically implies that if the execution trace of a new seed covers a new virgin bit in i_a, it will typically also cover the same new virgin bit in i_b. In other words, the behavior of virgin bit updates in i_a is very similar to that of i_b, so we can merge such redundant cluster i_a into i_b to reduce overhead while keeping the capability of improving path diversity of covered targets. Finally, it is important to note that the primary cluster cannot be merged into any other cluster, but other clusters can be merged into it.

6 Unbiased Energy Assignment

In this section, we describe the definition of critical blocks for each target (§6.1) and the process of selecting favored seeds (§6.2). We then introduce how AFLRUN assigns energy among seeds at the beginning of each cycle with such information (§6.3).

6.1 Critical Blocks

We firstly define a set R as the set of all basic blocks that have been covered by the current seed corpus, with $v \in R$ denoting a covered block within the set. Next, we define *critical blocks* C_t for each target t as a subset of R. The underlying idea is to identify a set of blocks for each target at a given state, so that we should concentrate our fuzzing energy on seeds that cover these blocks, ultimately enabling more efficient exploration or exploitation of the target. In this section, we introduce this concept.

For covered targets. During a fuzzing campaign, we can categorize the set of all targets into two groups: one set consists of targets already covered by the current corpus (i.e., $t \in R$), and the other set contains targets not yet covered by the current corpus (i.e., $t \notin R$). If a target is already covered, the critical block for this target is simply the target block itself. Consequently, to fuzz this target, we should focus on fuzzing seeds that cover such a target.

For uncovered targets. If a target is not yet covered, we should instead attempt to find a seed that covers the target by fuzzing seeds in the current corpus. Drawing on the intuition from [37], we define the critical blocks for such a target as the blocks that lie at the *boundary between the explored parts and unexplored parts of the path toward the target* in the ICFG, known as critical boundary blocks.

We firstly need to define some notations to introduce the exact definition of critical blocks. Given a target basic block

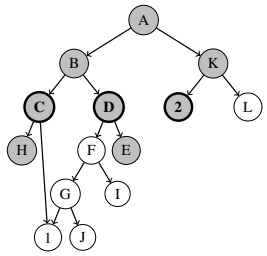

Figure 3: Inter-procedural Control Flow Graph

t, we can define a path[3] toward the target in the ICFG as follows:

$$v_1 \to v_2 \to \ldots \to v_n \to t$$

In the path above, v_i with $i \in \{1, \ldots, n\}$ are basic block vertices in the ICFG, and each arrow is either a control flow edge or a call edge that connects two adjacent vertices in the ICFG. The idea behind critical boundary blocks is to find each block visited by the corpus such that there exists a path from this block to target, and all vertices along this path are basic blocks not yet visited by the corpus except for the block itself. This definition aligns with the intuition of finding covered blocks at the boundary mentioned earlier, with the uncovered blocks considered as the unexplored part. Formally, critical blocks of an uncovered target t can be defined as all blocks $v_1 \in R$ such that there exists a path from v_1 to t with $\forall_{v \in \{v_2, v_3, \ldots, v_n, t\}} v \notin R$.

Example. We provide an example to illustrate concept of critical blocks. Figure 3 is the ICFG of a program, with 1 and 2 as target blocks. We now have three seeds in corpus with paths $A \to B \to C \to H$, $A \to B \to D \to E$ and $A \to K \to 2$. We mark basic blocks covered by the corpus in gray. Among these blocks, C and D are critical blocks of target 1, because we can have two paths to target $C \to 1$ and $D \to F \to G \to 1$ respectively, with F, G, 1 not yet covered by the corpus. Furthermore, 2 itself is the critical block of target 2, because the target has already been covered by the corpus.

6.2 Favored Seed Selection

Besides a target virgin map for each cluster introduced in §5.2, AFLRUN also maintains a top-rated array for each cluster, similar to the original top-rated array discussed in §2.1. When a new seed is added to the corpus, a set of top-rated arrays are selected, and we update these top-rated arrays using the same method as AFL++.

Using these top-rated arrays, we can select a set of favored seeds. We can apply the queue culling algorithm, similar to AFL++, on top-rated arrays of all clusters to select the favored seeds. For each top-rated array, we use the queue

[3] Here, the term "path" does not refer to the program's execution path. Instead, it refers to the concept of a path as defined in graph theory.

culling algorithm from AFL++ to select a set of favored seeds, and we then take the union of each set of favored seeds from each top-rated array to obtain the total set of favored seeds.

6.3 Energy Assignment

In this section, we will introduce the method for assigning energy among seeds using critical blocks of each target. In previous directed fuzzing works, a distance-to-target metric for each seed is used as the oracle for energy assignment. By contrast, instead of using such distance oracle, we utilize *critical blocks covered by each seed* as the oracle for energy assignment. The primary concept behind our algorithm involves distributing uniform weight from targets through critical blocks to seeds. Our goal is to assign energy to each seed at the beginning of a cycle so that the total energy of each seed after assignment can approach the proportion of such seed weight as much as possible.

Target weight. As mentioned earlier, AFLRUN starts with uniform weight values for all target basic block. Specifically, we have a vector of ones representing the weight for each target, denoted as $\mathbf{1}$. However, our approach does allow users to specify a customized weight value for each target. We provide a detailed description of this by-product in Appendix A.

Block weight. In this part, we discuss how we distribute weight from each target to its critical blocks. For each target t, we have a set of critical blocks $C_t \subseteq R$. By taking the union of C_t for all targets, we obtain the set of all critical blocks $C \subseteq R$, where R is the set of all covered blocks defined earlier. We can now define a matrix B for weight distribution: each column of B represents a corresponding target, and each row of B represents a block in C. An element of the matrix at row b and column t is defined as follows:

$$B_{b,t} = \begin{cases} \frac{1}{distance[b,t]+k} & \text{if } b \in C_t \\ 0 & \text{otherwise} \end{cases}$$

In the equation, the term $distance[b,t]$ represents the distance from the basic block b to the target t, computed using the method described in Appendix B, because this distance computation is only an auxiliary component of our approach. The constant k is a positive value that controls how significantly the distance value influences the preference for a block. The larger the value of k, the smaller the effect will be. Next, the matrix B is normalized to $\hat{B}$, ensuring that each column of the matrix sums to 1. Now, the distribution of the set of critical blocks can be obtained by calculating the product $\hat{B}\mathbf{1}$, which distributes weight from each target to each critical block.

Seed weight. The process of distributing weight from each critical block to seeds is quite similar to the distribution mentioned earlier. We also have a matrix S for this distribution: each column of S represents a critical block in C, while each row of S represents a seed in the corpus. An element at row s and column b can be defined as follows:

$$S_{s,b} = \begin{cases} score[s] & \text{if favored } s \text{ covers } b \\ 0.05 \cdot score[s] & \text{if unfavored } s \text{ covers } b \\ 0 & \text{otherwise} \end{cases}$$

Next, matrix S is also normalized to $\hat{S}$ to ensure that the sum of each column is equal to 1. The term $score[s]$ represents the energy assigned to seed s when fuzzed in coverage-guided mode, as computed by the algorithm from AFL++. This energy can, in some sense, represent the preference of a seed from AFL++'s perspective. We utilize this preference when distributing weight from each critical block to seeds. Additionally, AFL++ skips unfavored seeds with a 95% probability. We also follow this design by calculating an expected energy for unfavored seeds. The favorability of a seed is determined using the favored seeds selected. Finally, we can calculate the seed weight vector by computing $\hat{S}\hat{B}\mathbf{1} + c$. This final seed weight vector is also normalized to r, representing the final ratio to be approached.

Preventing local optima. One problem of our energy assignment based on critical blocks is the potential for local optima. To mitigate such issue, during the calculation of the seed weight vector, we add a vector c, which represents the energy assignment of each seed in coverage-guided fuzzing. The sum of c is calculated by multiplying the total energy (i.e., the number of targets) by a small fraction.

Seed energy assignment. Now, AFLRUN can assign energy to seeds using the obtained r. AFLRUN also maintains a vector b representing the energy that has been assigned to each seed previously. Given a total energy value E for this cycle, we assign energy E to each seed in the form of vector x, such that $x+b$ can approach the ratio r as closely as possible, under the constraint $\sum_i x_i = E$. Instead of using a general algorithm of mathematical optimization, we develop an algorithm with a worst-case complexity of $O(n^2)$ that guarantees the optimal solution. We discuss this algorithm in Appendix A of our arXiv version [36], as it is unrelated to fuzzing.

7 Evaluation

In this section, we explore the following research questions through experiments. **RQ1**: How effective is AFLRUN at triggering vulnerabilities compared to other fuzzers and ablated versions of AFLRUN? (§7.1 and Appendix E) **RQ2**: How effective is AFLRUN in ensuring fairness for each target? (§7.2) **RQ3**: What is the runtime overhead incurred by AFLRUN during fuzzing campaign? (§7.3) **RQ4**: Can AFLRUN discover new zero-day vulnerabilities in programs extensively fuzzed by OSS-Fuzz using state-of-the-art industrial fuzzers? (§7.4) **RQ5**: Do the extra seeds generated by AFLRUN assist in triggering vulnerabilities? (Appendix D)

Experiment setup. Unless otherwise specified, all experiments were conducted on an Ubuntu 20.04.5 LTS machine equipped with an Intel(R) Xeon(R) Gold 5318S CPU featuring 96 logical cores and 256 GB of RAM.

7.1 Fuzzer Comparison

We use two sets of vulnerabilities for experiments. Firstly, to compare AFLRun with other fuzzers, we employ the Magma [21], a benchmark commonly used by many fuzzing works, to evaluate multi-target directed fuzzing for bug reproduction. Additionally, to demonstrate the individual contribution from each component of AFLRun, we use another set of vulnerabilities in a real-world bug discovery scenario to conduct an ablation study.

Settings. We set the confidence threshold to 100% to only cluster target blocks that consistently dominate each other, because the target sites do not cause significant overhead in these experiments. We also individually remove two key components from AFLRun, resulting in variations denoted as AFLRun- and AFLRun*. AFLRun- refers to AFLRun devoid of the target path-diversity metric, while AFLRun* denotes AFLRun employing AFL++'s energy assignment rather than our unbiased energy assignment. Following the fuzzing papers' general experimental approach, we ran each fuzzing campaign for 24 hours and repeated 10 times. To prevent interference between experiments, we left some CPU cores unused, in line with previous research practices.

7.1.1 Evaluation on Magma

Magma operates by reintroducing multiple 1-day bugs into real-world programs using patches, enabling us to set multiple targets based on these patches and simultaneously fuzz multiple bugs. We excluded some bugs that can be found in less than ten minutes by coverage-guided fuzzers, as these bugs can also be discovered by directed fuzzers while still in coverage-guided mode, which would not effectively demonstrate the efficacy of directed fuzzing.

Fuzzers for comparison. We compare AFLRun with seven fuzzers: AFL++ [19], AFLGo [11], Hawkeye [12], Parmesan [34], FishFuzz [43], WindRanger [18] and MOpt [30]. We chose AFL++ because it is the grey box fuzzer upon which we build AFLRun, and selected AFLGo and Parmesan as they are open-source directed fuzzers commonly used for comparison. MOpt was chosen due to its outstanding performance on the Magma benchmark, where it currently leads as the most effective fuzzer. We also included Hawkeye, FishFuzz and WindRanger, as they all attempt to address the global optimum discrepancy problem. However, since Hawkeye is not open-source, we implemented our own prototype based on the approaches described in the paper. We exclude works that are orthogonal to our approach [23, 29, 38, 44], because these works can be applied on top of AFLRun without modifying both methods.

More fine-grained ablation study. In addition to AFLRun-, we introduced a more fine-grained ablation variant named AFLRun--. This ablated version not only removes the target path-diversity metric but also discards the concept of critical block. Instead of applying critical blocks, AFLRun-- assigns energy using all previously covered blocks that can reach the target via the ICFG. The purpose of this ablation study is to underscore the impact of the critical block design.

Target locations. Magma inserts one or more `MAGMA_LOG` macros into the tested program for each bug to notify when the bug is covered or triggered during execution. We set the locations of these macros as targets for each bug. Furthermore, Magma patches the program to invert the commits that fix the bugs, and we set these locations as targets as well.

Results. The results are presented in Table 1. Each entry in the table represents the average exposure time required for the fuzzer to trigger the vulnerability, calculated using survival analysis. We also computed p-values using the Mann-Whitney U test [32], employing the alternative hypothesis that AFLRun has a shorter exposure time. P-values are included in the parenthesis. T.O. indicates that the bug was not triggered in any fuzzing campaign. Note that Parmesan and WindRanger failed to run on some programs at either compile time or runtime, even after we fixed some of the bugs, so we mark those entries as N/A. We observe that AFLRun(-) outperforms other counterparts in most cases. On average, using the geometric mean, AFLRun achieves speedup factors of 168%, 109%, 235%, 183%, 147%, 157%, 78% and 56%, and discovers 38%, 20%, 138%, 29%, 24%, 14%, 50% and 16% more vulnerabilities compared to AFL++, AFLGo, Parmesan, FishFuzz, Hawkeye, WindRanger, MOpt and AFLRun--, respectively. Besides, according to the results, AFLRun can discover a bug that other fuzzers so far have not triggered, LUA002. We observe that the effectiveness of AFLRun-- diminished with the ablation; however, it still outperforms other fuzzers. This demonstrates that the design of the critical block indeed contributes to its enhanced effectiveness. Moreover, the fact that AFLRun-- still surpasses other fuzzers highlights the value of its unbiased energy assignment, even in the absence of the critical block design.

7.1.2 Evaluation on Real Scenario

The results from the Magma benchmark reveal that AFLRun does not significantly outperform AFLRun-. Upon further investigation, we discovered that most bugs in Magma are quite simple, probably because Magma requires easy detection of bug trigger. However, our target path-diversity metric is designed to handle complex bugs that require path diversity for triggering, thus the benchmark results fail to fully illustrate the impact of our method. Moreover, the Magma experiments are designed to test bug reproduction capability when the bug

sites are known. Yet, in real vulnerability discovery scenario such as the one detailed in §3.1, numerous false positive targets might also exist. This situation has not been evaluated in the aforementioned benchmarking experiment.

To address this deficiency of Magma benchmark, we conduct an additional experiment in a different setting, using some bugs that align with our scenario. To demonstrate the impact of encountering false-positive targets (emulating real-world bug detection), we carry out the experiment under two

conditions: with and without the introduction of false-positive targets. Those false-positive targets are randomly chosen from the bug reports detected by Clang static analyzer [2].

We did not include AFLRun-- in this experiment as its primary goal was to demonstrate AFLRun's effectiveness on complex bugs that require path diversity for activation. In contrast, AFLRun-- was designed to demonstrate the contributions of different components of unbiased energy assignment in the Magma experiment.

The bug triggering time results are displayed in Table 2. We observe that AFLRun significantly outperforms AFLRun-. Furthermore, with the introduction of false-positive targets, AFLRun generally exhibits superior bug-triggering capability compared to AFLRun*. This indicates that the unbiased energy assignment indeed helps in managing the seed explosion caused by the increased target count.

These results are further elucidated by graphing the path diversity curves from several experiments. For the corpus created by each fuzzing campaign, we track the increase in path diversity of basic block coverage necessary to trigger the vulnerability over time. For each set of repeated experiments, we compute the mean and the corresponding confidence interval. The outcomes are depicted in Figure 4. As seen in the figure, the target path-diversity metric significantly enhances the path diversity of the target.

7.2 Target Fairness Comparison

In this experiment, we evaluate the effectiveness of AFLRun in balancing each target compared to its counterparts, addressing RQ2. We aim to scale up the total number of targets by utilizing recently introduced commits as target sites for each program in the Magma benchmark [21]. We also disable the bugs introduced by Magma, as we are not concerned with their triggering in this experiment. Furthermore, since the primary goal of this experiment is to assess the effectiveness of our unbiased energy assignment, we have ablated the target path-diversity metric (i.e., we use AFLRun-).

We conducted the experiment for three directed fuzzers: Hawkeye, FishFuzz, and AFLRun-. For each fuzzer, we carried out an 8-hour fuzzing campaign, repeating each experiment 10 times. We recorded the energy assigned (i.e., the number of mutations and executions performed) to each seed. Additionally, we used a modified version of `afl-showmap` to determine the target coverage of each seed. With this information, we computed the total energy spent on fuzzing each target. We sorted the energy for each target and plotted a graph similar to the one in FishFuzz [43]. The results are illustrated in Figure 5. The x-axis represents all targets ordered incrementally by energy spent on them, and the y-axis is the corresponding energy. We can see that AFLRun generates flatter curves compared to other counterparts, indicating a more balanced energy assignment for each target, especially for `libtiff` and `libxml2`.

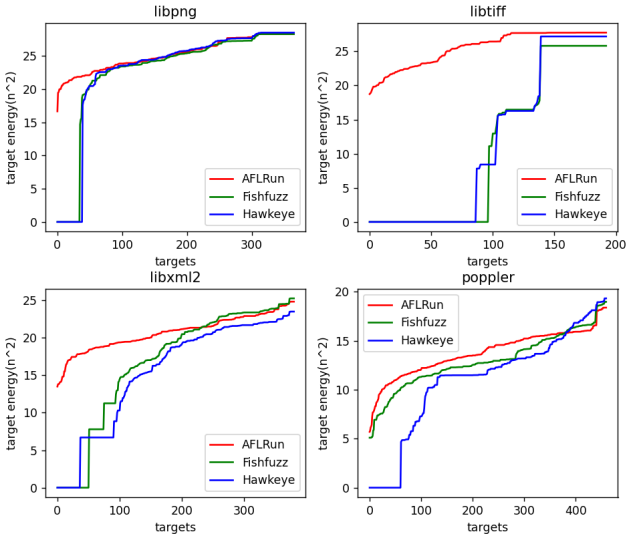

Figure 5: Energy spent on each target

7.3 Overhead Measurement

To evaluate the overhead incurred by AFLRun at runtime in response to RQ3, we also scale up the total number of targets by utilizing target sites of recent commits from §7.2. Similarly, the fuzzing campaign is conducted with the vulnerabilities introduced into these programs disabled.

To demonstrate the effectiveness of our clustering algorithm, we conducted overhead experiments under five different configurations: for three of them, we enabled target clustering with varying confidence threshold values of 50%, 70%, and 90% and a consistent support count threshold value of 500; for one of them, the clustering was disabled, meaning each target corresponds to a distinct virgin map and top-rated array; for the last one, we removed our path diversity component (AFLRun-). We ran each experiment for 3 hours, which was repeated 20 times. We recorded the number of clusters at the end of each fuzzing campaign and calculated the arithmetic mean across all repeated experiments for each configuration. Similarly, we profiled the proportion of time spent in AFLRun process to total time for each fuzzing campaign and calculated the mean. The results are shown in Table 3. Additionally, we measured the overhead incurred by the instrumented code. However, such overhead is negligible: it occupies less than 0.01% of total time in every fuzzing campaign.

Each row in the table represents a different configuration. The first three columns represent experiments with varying confidence threshold values; the fourth column represents an experiment without the clustering algorithm; and the last column represents an experiment with AFLRun-. Each entry displays a pair of values: the upper value represents the average number of clusters when the fuzzing campaigns terminate, and the lower value is the average ratio of time spent execut-

Table 3: Overhead Results: The upper values of each program are average number of clusters; the lower values are time ratio spent in the PUT.

ing the PUT over the total time of each fuzzing campaign. We can observe that the overhead incurred by the AFLRUN process is not significant compared to the time spent in executing the PUT. Additionally, the clustering algorithm that reduces the total number of virgin maps significantly does decrease some overhead spent in the fuzzer process.

7.4 Vulnerability Discovery

Lastly, we present all vulnerabilities found by AFLRUN to answer RQ4. We use AFLRUN to fuzz the latest versions of some famous programs that have been continuously fuzzed by the OSS-Fuzz project [6] using powerful Google machines. We integrate AFLRUN into OSS-Fuzz to simplify fuzzing each program without struggling with the environment. Since AFLRUN is a directed fuzzer, we set target locations using two approaches. First, we attempt to fuzz recently introduced commits by setting recently changed code locations as targets. The intuition behind this is that recently modified code may be more error-prone because older code has already been thoroughly fuzzed by OSS-Fuzz, while new code is less fuzzed. Second, we use the static analysis tool to identify suspicious code locations. Specifically, we write CodeQL [16] queries to find potentially vulnerable code locations as our targets.

Table 4: Zero-day vulnerabilities found by AFLRUN.

Project	ID	Type	Status
wabt	CVE-2022-44407	Out-of-bounds Read	Fixed
wabt	CVE-2022-44408	Type Confusion	Fixed
wabt	CVE-2022-44409	Out-of-bounds Read	Fixed
skia	issue-40045089	Uncontrolled Recursion	Accepted
freetype	issue-1159	Uncontrolled Recursion	Fixed
binutils	CVE-2023-25585	Access of Uninitialized Pointer	Fixed
binutils	CVE-2023-25587	NULL Pointer Dereference	Fixed
binutils	CVE-2023-25588	Access of Uninitialized Pointer	Fixed
binutils	CVE-2023-25586	Use of Uninitialized Variable	Fixed
binutils	CVE-2023-25584[4]	Out-of-bounds Read	Fixed

[4]This CVE consists of a group of 20 vulnerabilities in total. We conduct a case study for this CVE and list each of the individual vulnerability IDs in the Appendix C of our arXiv version [36].

We discovered 29 previously unknown vulnerabilities in these programs, which are listed in Table 4. We responsibly reported them to the vendors. All vulnerabilities marked as Fixed have already been addressed by the developers in the upstream. At the time of writing, 28 vulnerabilities have been fixed, and 8 CVE IDs have been assigned.

8 Discussion

In this section, we discuss the scope and limitation of AFLRUN, and the potential enhancements that could be applied to our work in the future to address any limitations.

8.1 Scope

Target path-diversity metric. Our target path-diversity metric aims to address PFA and PTA, as previously stated. In cases where the bug does not require extra paths for activation and can be triggered through mutations of seeds covering the buggy target location only, extra seeds aimed at enhancing path diversity become redundant. If this information is known in advance, users may choose to exclusively utilize the unbiased energy assignment (i.e., AFLRUN-).

Unbiased energy assignment. The scope of unbiased energy assignment is significantly broader by comparison. This method can be applied to nearly all scenarios of directed fuzzing. The scenario in which AFLRUN may become less effective occurs when the buggy target location is shallow and easily reachable, whereas false-positive target locations are deep and challenging to reach. In such instances, the biased energy assignment utilized by other directed fuzzing approaches might coincidentally bias to the correct target.

8.2 Limitations and Potential Solutions

Seed explosion. Similar to other works that propose a more fine-grained coverage metric [13, 15, 31, 39], our technique also suffers from problem of seed explosion. This phenomenon can lead to substantial overhead when the target count reaches into the thousands, given that the cost associated with processing each new seed is significant. In the current design, each target cluster corresponds to a virgin map that is exactly the same as the primary virgin map. However, as noted in [29], not all edges are relevant to targets, and these irrelevant edges can be discarded through static analysis. Consequently, their orthogonal approach could be integrated with our work to potentially mitigate the seed explosion problem.

Local optimum. In the current design, the critical boundary block requires that the path toward the target should not include any previously covered blocks. However, this can lead to directed fuzzing getting stuck in a local optimum, since progress toward the target may not necessarily result from mutating the seed that covers the boundary block. Although

the addition of a vector c to seed weight vector as a mitigation strategy is proposed in §6.3, it fails to tackle the root of the issue. A potential solution could involve relaxing the restriction on the number of non-covered blocks in the path: rather than insisting that no blocks can be covered, permitting a small number, n, of blocks to be covered might be a viable approach.

Clustering algorithm. Currently, AFLRun employs a simple and naive clustering algorithm based on a simplified version of association rule mining. However, more accurate clustering algorithms in the context of association rule mining exist [20]. As a future direction, the clustering algorithm could be improved by adopting a more sophisticated approach without sacrificing efficiency.

9 Related Work

9.1 Improving Coverage Metric

Numerous studies aim to enhance fuzzing effectiveness by refining the coverage metric. Angora [13] considers call context under which each edge is covered to make coverage metric context-sensitive. MemFuzz [15] uses address of memory access as extra coverage metric. Ankou [31] designs a new fitness function based on distance between execution paths of test cases, and their approach also allows to store extra seeds that do not achieve new coverage. Ijon [9] improves coverage metric to explore deep state in specific tested program by taking advantage of the guidance of user-defined annotations marked on important data in the program. AFL-Hier [39] proposes a multi-level coverage metric and a reinforcement-learning-based hierarchical scheduler in order to handle seed explosion problem introduced by more fine-grained coverage metric.

Some other works also have proposed coverage metric in order to find domain-specific bugs. SlowFuzz [35] uses number of executed instructions as metric to find bugs caused by worst case of algorithm complexity. PerfFuzz [27] similarly uses maximum count of each program location as storage metric of new seed to also find complexity bugs. MemLock [41] proposes memory usage as guidance to store extra seeds in order to find uncontrolled memory consumption bugs. Krace [42] designs a coverage tracking metric specially designed to find bugs caused by data races in kernel file system.

All of these works have developed new coverage metrics for coverage-guided fuzzing, while in contrast, AFLRun introduces a new coverage metric specifically for directed fuzzing. To the best of our knowledge, we are the first to primarily focus on this task, utilizing the coverage metric based on multiple virgin maps for targets. Moreover, some of the mentioned works [31,39] devise novel seed scheduling algorithms to address the seed explosion problem caused by their new coverage metrics. Similarly, AFLRun also proposes a new energy assignment algorithm for directed fuzzing, which not only serves the path diversity but also tackles the seed explosion problem.

9.2 Directed Fuzzing

AFLGo [11] firstly proposes directed greybox fuzzing to guide greybox fuzzing toward a set of user-defined targets. It proposes a distance oracle for each seed, which is used for energy assignment to favor seed closer to targets. However, such distance oracle is a very crude metric representing preference of seed with respect to targets. Hawkeye [12] improves directed fuzzing on top of design of AFLGo based on several desired properties it should hold. Parmesan [34] finds targets using information from compiler sanitizer passes, and it also proposes some methods of directed fuzzing such as dynamically constructing ICFG during fuzzing campaign. WindRanger [18] improves distance computation from a seed to targets by only considering basic blocks that deviate from path toward targets. However, it does not take multiple targets into account when obtaining such blocks. In addition, their definition of deviation block is local and is based on only one seed, while our critical blocks are global and take all seeds in corpus into account. LeoFuzz [28] is the first work that realizes the problem of using harmonic average distance of all targets, and it proposes a method based on target sequence in order to solve it. FishFuzz [43] also addresses such problem by using a distance vector for each seed instead of an average distance. By contrast, energy assignment of AFLRun not only solves such problem in a more fine-grained way, but also serves for our path diversity component. Finally, CAFL [26] takes sequence of locations with constraints as target, but such sequence requires more manual effort than other directed fuzzers.

There are other works that try to improve performance of directed fuzzing by trimming redundant parts considered irrelevant to targets in fuzzing campaign. FuzzGuard [44] uses deep learning to filter out test case considered to be unhelpful for reaching target, so it is not executed by tested program beforehand. BEACON [23] applies static analysis to terminate program early if current program state is guaranteed to be unable to reach any targets. SieveFuzz [38] also terminates the program early by restricting fuzzing to search space guaranteed relevant to reaching targets. SelectFuzz [29] selectively instruments and explores only target-relevant code, and it also proposes a novel distance metric from a basic block to target based on multi-path reaching probability. These works about trimming are considered orthogonal to our approach.

10 Conclusion

We proposed AFLRun, which includes target path-diversity metric and unbiased energy assignment. Through evaluation, we demonstrated the effectiveness of AFLRun in triggering known and zero-day bugs.

A Target Weight Calculation

At compile time, AFLRun can be provided with a set of target locations with their corresponding weight. Target location is a pair of file name and line number, usually in format `file.c:123`. Target basic block, on the other hand, is the basic block in tested program that contains at least one target location. We show how we compute weight of target block from weight of target location in this section. Each target location can be contained by one or more target basic blocks, and each target block can also contain one or more target locations. With such information, we distribute weight from target locations to target blocks using distribution matrix. Each column of the matrix represent a target location, and each row of the matrix represent a target block. We define matrix Φ as follows:

$$\Phi_{b,l} = \begin{cases} \frac{1}{N_l} & \text{if target block } b \text{ contains target location } l \\ 0 & \text{otherwise} \end{cases}$$

N_l is the total number of target blocks that contain target location l, and we should note that each column of this matrix sums to 1. Finally, we can multiply Φ by weight vector of target locations to obtain weight of each target block. At this point, we can discard these target locations, and unless otherwise specified, we use target to denote target basic block instead of target location in this paper.

B Static Distance Computation

We have developed an efficient method for computing the distance from each block to each target in $O(|T||E| + |T||V|log|V|)$, where V and E represent vertices and edges of the ICFG, and $T \subset V$ denotes the target blocks. We firstly define the weight of each edge from vertex v_{src} to vertex v_{dst} as follows:

$$W(v_{src}, v_{dst}) = \begin{cases} log_2(N_{out}(v_{src})) & \text{for control-flow edge} \\ 0 & \text{for call edge} \end{cases}$$

The term $N_{out}(v_{src})$ represents the number of control-flow outgoing edges of vertex v_{src}. The rationale behind this weight definition is to assign higher weight to edges that are less likely to be traversed after executing the basic block v_{src}. As a result, the weight of both call edges and unconditional control-flow edges should be 0, while the weight of conditional control-flow edges grows logarithmically with respect to the number of outgoing edges.

After obtaining the weight for each edge, we can define the distance from block v to target t as the sum of weight along the shortest path from v to t. This can be computed using Dijkstra's algorithm [17]. A naive approach involves applying Dijkstra's algorithm for each $v \in V$, as done by AFLGo [11]. However, this method has a time complexity of $O(|V||E| + |V|^2 log|V|)$, which can be very slow for large ICFGs. Instead, we compute this distance by *reversing each edge* of the ICFG and applying Dijkstra's algorithm for each $t \in T$, since the shortest distance from v to t in the ICFG is equal to the shortest distance from t to v in the transposed ICFG. As the set of targets T is usually much smaller than the set of basic blocks V in directed fuzzing, this method is significantly more efficient than the naive one. We describe this method in Algorithm 4.

Algorithm 4 Distance Computation

Require: *ICFG*
1: ICFG' = transpose(ICFG)
2: distance: $V \times T \to \mathbb{R}$
3: **for** $t \in T$ **do**
4: **for** (b, d) ∈ Dijkstra(ICFG', t) **do**
5: distance[b, t] = d
6: **end for**
7: **end for**
8: **return** distance

C Implementation

We have implemented AFLRun, a prototype based on the ideas presented, using the source code from AFL++ [19] and

AFLGo [11], totaling over 5,000 lines of C/C++ code. In this section, we will discuss some implementation details.

Static analysis and instrumentation. The compilation stage of AFLRUN is built upon the LLVM [25] Link Time Optimization (LTO) pass [5] by modifying the AFL++ LTO compiler [22]. First, we identify all target basic blocks. Then, using information from LLVM, we construct the ICFG of the PUT. With the ICFG, we gather all basic blocks that can reach at least one of the target blocks, including the target blocks themselves, and calculate their distances to each target block using the method described in Appendix B. Each of these basic blocks is assigned a unique ID. Moreover, to obtain critical blocks at runtime, we record the subgraph of the ICFG with these blocks as vertices. These blocks are instrumented with a function at the beginning, which will be called with the block ID as an argument when the block is executed.

Virgin map comparison. In AFL++, when comparing the execution trace with the virgin map, it avoids inefficiently comparing each bit individually. Instead, it compares 64 bits at a time by casting pointers into 64-bit arrays. For each 64-bit value in the execution trace and virgin map, AFL++ calculates their bitwise `AND` value, and a non-zero result indicates new bit coverage by the execution trace. We employ the same technique for efficient comparisons with multiple virgin maps by calculating the bitwise `AND` value between the execution trace and each virgin map. Each non-zero `AND` value at each location for each virgin map is also recorded and used to obtain *data* in Algorithm 2.

Target clusters. We assign each cluster an ID, and each cluster contains a set of targets recorded using an array indexed by the cluster ID. In addition to recording the set of targets in each cluster, we also need to map each target to its respective cluster. This is achieved using hash map [7].

Association rule mining. We implement `support_count` in Algorithm 3 using two data structures: one for counting 1-itemsets and another for counting 2-itemsets. We record 1-itemset support counts using an array indexed by cluster ID, while 2-itemset support counts are recorded using hash map [7], utilizing order-insensitive pairs as keys.

Covered blocks. For efficiency, we only consider covered blocks that can reach at least one target in the ICFG, each of which is assigned an ID during static analysis. To trace the set of blocks covered by the execution of a test case, we use a shared memory with n bits, where n is the number of blocks assigned with an ID. Each bit in memory represents a distinct block. In the instrumented function for each block, the block ID is obtained from the argument, allowing instrumented code to set the corresponding bit in the shared memory to 1 to indicate that the block is covered during execution. Furthermore, similar to the virgin map, we also have a virgin block bitmap with n bits to record each block covered by the corpus, enabling AFLRUN to determine whether a new seed covers any new blocks.

Table 5: Statistics about Unique Crashes

Program	No. Diversity Crashes	No. Total Crashes	Ratio
libpng	1336	1437	92.97%
libsndfile	97	169	57.40%
libtiff	4485	5476	81.90%
libxml2	3711	4448	83.43%
lua	430	584	73.63%
openssl	31	38	81.58%
php	943	1084	86.99%
poppler	753	1076	69.98%
sqlite3	675	1395	48.39%

Energy assignment. The energy assignment algorithm discussed in §6.3 involves matrix multiplication. However, since the related matrices are typically sparse, computing matrix multiplication explicitly can be inefficient. To address this, we represent each weight vector as a hash map [7] and use the relevant information to directly distribute weight from one hash map to another.

D Quality of Extra Seeds

In this appendix section, we address RQ5 by counting the number of unique crashes that are mutated from the extra seeds generated by our target path-diversity metric and calculating its ratio over the total number of crashes. We continued to use the results from the Magma benchmark [21] and enabled the fatal canary feature in Magma, causing any bug trigger to result in a crash. For each seed generated during the fuzzing campaign, AFLRUN annotates its filename with the factor contributing to its storage. Specifically, if a seed covers any new bits in the primary virgin map, AFLRUN marks a `cov` flag in its filename, and similarly adds a `div` flag if any new bits are covered in the target virgin map. Moreover, each unique crash is marked with the seed ID from which the unique crash is mutated, also known as the source seed. Using this information, we can track the flags of the source seed for each unique crash. We consider a unique crash to be mutated from the extra seed only if its source seed contains solely the `div` flag. We denote such unique crash as the diversity crash. The results are presented in Table 5. We observe that for the majority of programs, more than half of the unique crashes are mutated from our extra seeds, demonstrating the ability of these extra seeds to discover vulnerabilities.

E Additional Experiments

In addition to the Magma benchmark, we conducted further experiments to evaluate the effectiveness of AFLRUN compared to other fuzzers using a set of vulnerabilities used in the evaluations of previous directed fuzzing works [23, 24]. All fuzzers in §7.1.1 are included in this experiment except

for AFLRun--, the ablated version of AFLRun that does not contain the target path-diversity metric and critical blocks for evaluating the effectiveness of critical blocks in our energy assignment method, a task we have already accomplished using the Magma benchmark. However, we still include AFLRun- for its descent ability to find the vulnerabilities that do not require path diversity to trigger.

The experimental setup was identical to that described in §7.1.1: each fuzzing campaign was conducted 10 times, with each lasting 24 hours. However, we directly used the buggy version of the tested program instead of reintroducing old bugs into newer versions. Additionally, we lacked the automatic vulnerability trigger time recording feature provided by Magma. To overcome this limitation, each fuzzer was configured to record the time when a crashing input is saved. After each fuzzing campaign ends, we executed the files in the crash directory and identified the specific vulnerability that causes each crash, based on the execution's output. This allows us to determine the triggering time of a vulnerability in each fuzzing campaign. For the initial fuzzing setup, we utilized the same seed corpus as the previous work [24]. However, the target locations were different: we adjusted the target locations to the root-cause locations instead of the vulnerability-trigger locations commonly used in previous works; besides, similar to §7.1.1, we utilized multiple-target settings to find multiple vulnerabilities simultaneously. These two differences in target locations align with the two main issues addressed in our work.

The results are presented in Table 6, formatted similarly to Table 1. Compared to AFL++, AFLGo, Parmesan, FishFuzz, Hawkeye, WindRanger, and MOpt, AFLRun(-) achieves speedups of 164%, 77%, 819%, 319%, 136%, 118%, and 194% respectively. We observe the deviation of the results from those obtained from Magma: AFLGo instead of MOpt becomes the best performer among all non-AFLRun fuzzers, and the effectiveness of Parmesan drops significantly (even when excluding unrunnable campaigns due to its buggy implementation). Furthermore, our results also differ from those of previous studies, as AFLGo outperforms the works that followed it. We believe this inconsistency arises from our different configuration of the target locations mentioned earlier. Nevertheless, AFLRun still outperforms the other tested fuzzers, demonstrating its superiority across a diverse set of bugs without any overfitting.

SymBisect: Accurate Bisection for Fuzzer-Exposed Vulnerabilities

Abstract

The popularity of fuzzing has led to its tight integration into the software development process as a routine part of the build and test, i.e., continuous fuzzing. This has resulted in a substantial increase in the reporting of bugs in open-source software, including the Linux kernel. To keep up with the volume of bugs, it is crucial to automatically analyze the bugs to assist developers and maintainers. Bug bisection, i.e., locating the commit that introduced a vulnerability, is one such analysis that can reveal the range of affected software versions and help bug prioritization and patching. However, existing automated solutions fall short in a number of ways: most of them either (1) directly run the same PoC on older software versions without adapting to changes in bug-triggering conditions and are prone to broken dynamic environments or (2) require patches that may not be available when the bug is discovered. In this work, we take a different approach to looking for evidence of fuzzer-exposed vulnerabilities by looking for the underlying bug logic. In this way, we can perform bug bisection much more precisely and accurately. Specifically, we apply under-constrained symbolic execution with several principled guiding techniques to search for the presence of the bug logic efficiently. We show that our approach achieves significantly better accuracy than the state-of-the-art solution by 16% (from 74.7% to 90.7%).

1 Introduction

In recent years, large-scale programs such as the Linux kernel are being continuously fuzzed for the purpose of improving code quality and security [23, 11, 42, 19, 31, 24]. Such continuous fuzzing systems have been shown highly effective in identifying new bugs, e.g., syzbot [22] reports thousands of bugs in the Linux kernel.

While fuzzing is highly effective, this poses large workload to software developers and maintainers, as the continuous stream of bugs requires various analysis, e.g., bug triage and patching, that is often done largely manually today [27]. This is a hard problem as we already see over 8,000 bugs found by syzbot are auto-closed due to the lack of human investigations [22]. Thus, automating the analysis of fuzzer-exposed bugs is a worthwhile goal.

One important analysis that needs automation is bug bisection, i.e., the process of identifying commit that introduced a bug (also called vulnerability-contributing commits, or bug-inducing commits). It proves instrumental in various aspects. For example, it can help developers and maintainers understand the bug and facilitate patch development [7]; it can also pinpoint the vulnerable software versions to inform users about whether they need to worry about updating their software [12, 4].

To achieve this goal, researchers have proposed several automated approaches, but unfortunately they all have significant shortcomings.

The first type of approach directly executes the original PoC on older software versions to see which version would still crash after running the PoC. However, it is reported that such a dynamic solution suffers from several issues [3]: 1) Broken dynamic environment (e.g., build or runtime errors) leading to versions being skipped. 2) Accidental triggering of unrelated bugs. 3) Changes in the underlying bug-triggering condition.

The second type of approach requires patches, which may not be available at the time of the bug discovery. Even if the patches are available, such static solutions rely on heuristics which are inherently imprecise [9, 34]. This category includes the SZZ algorithm and its variants [12, 40], as well as most vulnerable code clone detection [26, 45]. For example, when given the code diff in a patch, their solutions consider the bug-inducing commit to be the one that introduces one or more lines in the code diff [12, 45]. However, such a solution does not take into account the bug-triggering conditions and can miss important details that are outside of the scope of the code diff in the patch.

There are also other methods, such as information

retrieval-based bisection [10, 47, 43], which are usually based on bug reports. However, they either have low accuracy or require manual analysis.

Motivated by the above deficiencies, we take a different approach from the traditional methods. In particular, we aim to reason about the *presence of vulnerability logic* through static code analysis. Fundamentally, our approach investigates many more possible inputs beyond what's included in the original PoC. Furthermore, static methods can effectively circumvent a series of problems caused by the broken dynamic environments such as build errors. Finally, it does not require the development of patches in advance. To this end, we leverage **symbolic reasoning** which is the most precise way of confirming the presence of a vulnerability statically. A crucial characteristic of this approach is that it can automatically distinguish significant changes from vulnerability-irrelevant changes and effectively eliminate the influence of vulnerability-irrelevant changes on the results.

More specifically, we apply under-constrained symbolic execution [32] in different software versions to precisely identify the presence/absence of the same *vulnerablility logic* that is inherited from the released PoC. Then with a simple binary search algorithm, we can pinpoint the commit that introduced the vulnerability. To address the scalability challenges of symbolic execution, we leverage the trace associated with the PoC to guide the symbolic execution.

Following the methodology proposed in this paper, we apply it to the context of Linux kernel and the corresponding continuous fuzzing platform syzbot [22]. We show that it significantly outperforms state-of-the-art approaches in terms of accurately determining the vulnerable versions of bugs found with fuzzing. We summarize our contributions as follows:

- We developed a novel and drastically different solution of an automatic bisection tool called SYMBISECT, targeting fuzzer-exposed vulnerabilities. Our method is precise as it relies on looking for the presence of key vulnerability logic represented by symbolic formulas. We have implemented SYMBISECT for Linux kernel bugs reported on syzbot. We open-sourced the solution to facilitate the reproduction of results and further research [2].
- We proposed a new method to address the scalability problem in under-constraint symbolic execution in the Linux kernel. Our insight is that in the specific context of fuzzing results, we are able to use the knowledge of the vulnerability from the PoC to guide the symbolic execution in a principled fashion.
- We evaluated the performance of SYMBISECT against other state-of-the-art methods. We demonstrate that it not only achieves much higher accuracy than the PoC-based bisection but even outperforms the methods dependent on the presence of patches. Specifically, it can identify 83% of the vulnerable versions that elude detection in the PoC bisection implemented by Syzbot.

2 Background and Motivation

In recent years, fuzzing has played a significant role in discovering vulnerabilities in the Linux kernel [22, 23]. However, manual analysis of the extensive results generated by fuzzing has placed a tremendous burden on maintainers [1]. Automatic analysis of fuzzing results, such as identifying vulnerable versions and simultaneously identifying when vulnerabilities were introduced, is highly beneficial for understanding the logic of vulnerabilities, developing patches, notifying the respective maintainers, and backporting patches to vulnerable Long-Term-Support branches. For example, Rui Abreu *et al.* observed that automating bug bisection that pinpoints the bug-inducing commits can speed up fixing fuzzer-exposed bugs in Google's proprietary code on average by a factor of 2.23 [7]. In this paper, we define **bug-inducing commit** as a commit that introduces a software bug into a codebase [10]. It is possible that multiple commits (e.g., commit1 and commit2) contribute to the bug, and the last commit (commit2) makes the bug triggerable. In such cases, we consider the last commit the BIC because that is when a vulnerability is considered to exist.

Previous researchers have developed various types of methods for identifying bug-inducing commits, including PoC-based, Patch-based, and other approaches. However, each has its own limitations. Next, we will introduce them separately.

PoC-based bisection. The most straightforward approach is to dynamically re-execute the PoC that triggered the bug on older commits. This method is employed by the continuous fuzzing platform syzbot [22]. Specifically, syzbot starts bisection by running the same PoC with the commit on which the bug was discovered, ensures that it can reproduce the bug, and then goes back release-by-release (e.g., v5.4 to v5.3) to pinpoint the earliest release without the kernel crash (again using the same PoC). The predicate for bisection is binary (crash vs. no crash), not trying to differentiate between different crashes. This is intentional because bugs can manifest in a different ways (under different bug titles) [3]. However, this inevitably introduces false positives as unrelated bugs can sometimes be triggered. In fact, a small-scale analysis showed that unrelated bugs being triggered contributed to 66% of incorrect bisection [4]. In addition, such an approach also leads to false negatives, i.e.,

failing to report a kernel version being affected by the bug during bisection. They can be due to build/boot errors, bugs that are difficult to reproduce, and failing to account for changes in bug-triggering conditions (no adaptation in the original PoC). Overall, a previous small-scale study conducted by the syzbot team concludes that the bisection accuracy is only about 50% [4], highlighting the need for a better solution.

Patch-based bisection. This family of solutions is based on patches, including *SZZ algorithm and its variants*[40, 12] and most vulnerable code clone detection solutions [26, 45, 56, 37]. The basic idea of SZZ is to identify the bug-inducing commit by tracing the modified lines in the patch back to the most recent commit that introduced the lines. This method is static and effectively assumes the source lines removed or changed by the patch are responsible for introducing the bug. The SZZ algorithm has many variations, among which VSZZ [12] is the latest improvement aimed specifically at vulnerabilities (instead of general bugs). VSZZ modifies SZZ slightly by tracing back the commit history to the earliest commit (as opposed to the most recent) that introduces the deleted lines of a patch. However, such methods require patches input, which are not available at the time of bug discovery. Furthermore, the SZZ algorithm and its variants are fundamentally heuristics and their accuracies are limited [9]. Finally, they are unable to handle patches with only added lines [12], which are quite common in security patches (e.g., adding a bounds check).

Vulnerable code clone detection statically identifies sections of code that are similar or identical to known vulnerable code fragments [25, 36, 26, 28, 45, 49]. These methods rely on similarity comparisons of vulnerability-related code to determine the presence of a given vulnerability in the target program. The basis of similarity could be in terms of text, tokens, Abstract Syntax Trees (AST), Control Flow Graphs (CFG), or Program Data Graphs (PDG) [55]. Even though not originally intended for bisection, they can be directly applied to identify the earliest version similar to the known vulnerable version. V0Finder [45] represents the state-of-the-art in this category. In general, these methods are not designed to distinguish small changes made to the code base (e.g., via a bug-inducing commit). Besides, such methods still require an initial input of vulnerable code. The "vulnerable code" is generally defined as the whole patch function or a subset of lines within it. For example, VUDDY [26] uses the entire patch function, while others, like MVP [49], extract "relevant lines" through methods such as slicing, using deleted/added lines in the patch as slicing criteria. The "vulnerable code" can also be manually extracted, such as in HiddenCPG [44].

Other bisection. There are some other methods such as Information Retrieval (IR) approaches, that take bug information (usually from the bug report) as input and statically rank prior commits according to their "relevance to the bug" [10, 43, 13]. The advantage of IR-based methods is that they do not require patches and can still locate the buggy code based on bug reports or code coverage. Nevertheless, such methods still do not fundamentally attempt to verify the presence of vulnerability logic and instead only approximate them. As a result, the accuracy is also limited. They are usually good at identifying the top-N suspected bug-inducing commits. However, their accuracy declines significantly when N=1. Specifically, for Fonte [10], the state-of-the-art method in this category, the accuracy drops to only 36% when N=1, which is lower than the accuracy of PoC/Patch-based methods. Therefore, we do not consider such methods as the baseline for comparison.

Our insight. We observe that existing approaches have significant shortcomings. First and foremost, none of the above methods attempts to reason about the vulnerability logic when determining whether a particular version is affected by a bug. This motivates us to develop a solution that looks for the presence of the vulnerability logic in target software versions.

Specifically, we propose to leverage under-constrained symbolic execution to effectively address the shortcomings of existing solutions. Compared to PoC-based bisection, our solution (1) is static, thus sidestepping the challenges stemming from broken dynamic environments; (2) focuses on the specific vulnerability, allowing it to overlook other unrelated bugs; (3) considers more possible inputs and execution paths, alleviating the concern of changes in the underlying bug-triggering conditions.

Compared to the existing patch-based methods, our solution (1) does not require patches, which are not available when a fuzzer first finds the bugs; (2) looks for the presence of vulnerability logic as opposed to syntatic information such as the presence of certain source lines or tokens; (3) inspects the vulnerability logic beyond the scope of patch functions, allowing a much more complete and informed validation compared to heuristics that concentrate on only the code diff or the functions involved in patches.

3 Overview

In this section, we begin with a motivating example to provide a concise overview of why existing methods fall short and the intuition behind SYMBISECT. We will also discuss the main challenges of implementing our solution. Following that, we introduce the overall architecture of SYMBISECT.

The Bug-inducing Commit:

```
static struct bpf_map *htab_map_alloc(...)
1  - cost = S1*C1 + S2*S3;
     ......
2  - cost += S2*C2
3  - err = bpf_map_charge_init(..., cost);
4  - if (err)
   -     goto free_htab;
     ......
5    err = prealloc_init(...);

int bpf_map_charge_init(...,u64 size)
     ......
6    if (size >= U32_MAX - PAGE_SIZE)
        return -E2BIG;
```

The Patch:

```
static int prealloc_init(...)
     S3 = S3 + C2;
     ......
7  - htab->elems =bpf_map_area_alloc(S2*S3,
8  + htab->elems =bpf_map_area_alloc((u64)S2*S3,
```

```
S1: (u64)htab->n_buckets     C1: sizeof(struct bucket)
S2: (u64)htab->elem_size     C2: num_possible_cpus()
S3: htab->map.max_entries
```

Figure 1: The Bug-inducing commit and Patch of a vulnerability from syzbot

3.1 Motivating Example

Figure 1 illustrates an integer overflow vulnerability that leads to an out-of-bounds memory access. Specifically, the **bug-inducing commit** modifies the function `htab_map_alloc()`, which in turn calls function `bpf_map_charge_init()` and function `prealloc_init()`. Prior to this commit, the function `bpf_map_charge_init()` had a check at line 6, which checked the variable `size` to prevent any potential integer overflow in `prealloc_init()`. However, the removal of this safeguard paved the way for the occurrence of an integer overflow. To mitigate this vulnerability, the subsequent **patch** introduced a type-casting operation at line 8 within `prealloc_init()`, effectively preventing the risk of integer overflow.

Prior PoC-based tool executed the released PoC in versions preceding the patch. However, in this case, it triggered an unrelated bug, leading the kernel to crash before it could access the function `htab_map_alloc()`. Consequently, this resulted in an imprecise bisection result — syzbot thinks the kernel version is vulnerable and keep checking even earlier versions.

Prior Patch-based tools derive various forms of signatures, primarily syntactic, from the patch function `prealloc_init()`. In this case, the bug-inducing commit does not alter the patch function. Consequently, these solutions are unable to capture the commit and fail to differentiate versions preceding and following the bug-inducing commit. This leads to incorrect identification

Symbolic execution trace (partly):

```
...... -> htab_map_alloc() -> bpf_map_charge_init()
                           -> prealloc_init() -> ......
```

Before inducing commit:

```
Line1  Assignment: cost = S1*C1 + S2*S3
Line2  Assignment: cost +=  S2*C2
Line6  Constraint  S1*C1 + S2(S3+C2) < U32_Max - 4096
Line7  Overflow condition: S2(S3+C2) > U32_Max
Not solvable => Not vulnerable
```

After inducing commit (before patch):

```
Line8  Overflow condition: S2(S3+C2) > U32_Max
Solvable => Vulnerable
```

Figure 2: Vulnerability detection via symbolic execution

of the bug-inducing commit.

Our solution symbolically executes the relevant functions until it reaches the target source line and evaluates the symbolic constraints to check whether an out-of-bound memory access can occur — we know it is an out-of-bound bug from the bug report. Specifically, the symbolic execution starts from the syscall entry that triggered the bug (available from the call stack in the bug report). By enlarging the analysis scope, our solution effectively explores more of the state space and is not confined to the patch function. It effectively addresses both the limitation of patch-based bisection and potential changes in the bug-triggering conditions. Additionally, by disregarding unrelated bugs, it resolves the issues associated with PoC-based bisection.

Figure 2 illustrates a portion of the symbolic execution process. In the non-vulnerable version (prior to the bug-inducing commit), the variable `cost` is assigned in lines 1 and 2, with a subsequent check at line 6. While there are two branches in line 6, only one of them leads to the vulnerability point. Within this path, symbolic execution identifies a crucial constraint: S2(S3+C2) + S1*C1 <U32_Max - 4096. This constraint ensures that the overflow condition S2(S3+C2) >U32_Max is never satisfied, preventing any subsequent out-of-bounds occurrences (the OOB section isn't depicted in the figure). Consequently, this version is deemed non-vulnerable, which is correct. In contrast, in the vulnerable versions, the critical check against the cost is removed. As a result, the overflow condition becomes solvable by the symbolic execution engine, leading to an out-of-bounds (OOB) situation later on. Accordingly, our solution correctly classified this version as vulnerable.

3.2 Challenges and Insights

Despite the advantages of using symbolic execution to confirm the presence of vulnerability logic precisely, symbolic execution also faces its own challenges.

Scalability concerns. In the motivating example, we showed only a segment of the symbolic execution in Figure 2. In reality, our solution will encounter many more

functions (i.e., starting from the syscall entry) and accumulate many more symbolic constraints. This can lead to the classic scalability challenge for symbolic execution, as the number of forked states may grow exponentially as the execution progresses. This makes the solution seemingly ill-suited for a large scope of analysis, especially against large-scale software such as the Linux kernel. Previous methods deal with this problem by confining the scope of symbolic execution to one specific function [54] or utilizing concolic execution[15]. Nevertheless, these methods are unsuitable for our purpose: the existence of a vulnerability is not determined by a single function, and we do not want to over-constrain the possible inputs through concolic or concrete execution.

Key observation. We observe that, to overcome the above challenge, it is possible to leverage fine-grained trace-level information about how the vulnerability is manifested (e.g., where the vulnerability is triggered, and which functions are involved) in the reported version to guide the exploration in the target version. This information allows us to distinguish the key statements from the unrelated ones for a specific vulnerability. As an illustration, coverage data can help de-prioritize less relevant execution paths. By utilizing this approach, SYMBISECT effectively narrows the scope of exploration, thus enhancing efficiency and mitigating the scalability challenge of symbolic execution.

3.3 System Architecture

As illustrated in Figure 3, our tool, denoted as SYMBISECT, requires three essential inputs for its operation:

- The source code of the program on which the bug was reported – we refer to it as the reference version. This version should be compilable and bootable as the fuzzer has successfully found the bug on this version.
- Proof of Concept (PoC): This is the executable or script that can reliably trigger the vulnerability in the reference version of the program.
- The source code of the program in potentially vulnerable target versions: These are the other versions of the program that we want to assess for the same vulnerability.

SYMBISECT is designed for vulnerabilities found through fuzzing. So both the compilable and bootable source code of the reference program and the PoC are naturally available when a vulnerability is found via fuzzing. With such inputs, SYMBISECT bisects the bug in a fashion similar to syzbot (except that SYMBISECT is completely static). It first evaluates historical versions backwards – one major release version at a time (e.g., v5.5 and then v5.4). Through this iterative process, SYMBISECT can identify the boundary or range for which the bug-inducing commit falls under (e.g., between v5.4 and v5.5). Subsequently, SYMBISECT follow a simple binary search procedure to pinpoint the specific commit that introduced the bug.

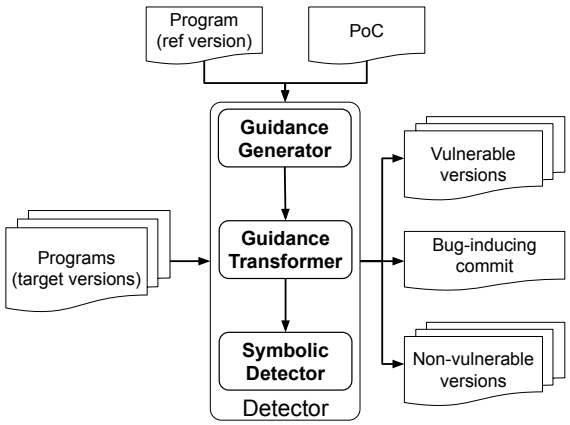

Figure 3: Overview of SYMBISECT

SYMBISECT consists of three primary components, designed to accurately identify vulnerabilities while also addressing scalability issues:

Guidance Generator. SYMBISECT first runs a PoC to trigger the specific vulnerability in the reference version of the program, thereby collecting essential execution traces. Utilizing these traces, SYMBISECT systematically produces three primary categories of guidance for subsequent symbolic detection. Firstly, SYMBISECT attempts to align the call stack trace (also called call trace in the syzbot bug report) of the execution on the target version to the one on the reference version (referred to as **Call Stack Guidance**) This effectively steers the exploration of symbolic execution towards the function where the vulnerability is observed. Secondly, besides the call stack trace, SYMBISECT also secondarily attempts to align the execution path down to the basic block level (referred to as **Path Guidance**). This is useful when there are a large number of possible execution paths that follow the same call stack. Lastly, SYMBISECT reuses the callees involved in indirect calls (referred as **Indirect Call Guidance**), thereby informing the symbolic detector to focus on a limited number of indirect call targets (as opposed to all possible ones computed using static analysis). More details are in §4.1.

Guidance Transformer. Upon identifying the above three kinds of guidance, SYMBISECT transforms them from the reference version into the target versions of the program. This enables a more efficient symbolic execution and a more accurate vulnerability detection process on these target versions. It's important to highlight that guidance translation between versions is done at the

source code level, which remains stable and unaffected by compiler optimizations. To enhance the precision and robustness of those guidance when applied to differing target versions of the program, SYMBISECT employ multiple optimizations during the guidance transformer phase. More details about the guidance transformer will be provided in §4.2.

Symbolic Detector. The symbolic detector is a form of detector that can capture (or re-capture) the bugs that were reported by a fuzzer. The detector is applied to a target version, where it tracks all variables, especially symbolic variables, including the symbolic sizes of allocated objects. However, instead of attempting to find all possible bugs during the exploration (which is clearly not scalable), we narrowly focus on the specific bug at hand, with the help of the aforementioned guidance. Throughout the execution, the symbolic detector leverages guidance from preceding phases. Specifically, it dynamically adjusts the execution state schedule, aiming to alleviate path explosion. Additionally, the detector refines the callees of indirect function calls based on prior indirect call guidance. For vulnerability detection, the symbolic detector relies on call trace guidance to ensure accurate detection of the same vulnerability previously identified. More details about the under-constrained symbolic detector can be found in §4.3.

4 SYMBISECT Design

In this section, we delve into the intricacies of SYMBISECT's design by dissecting each component, discussing the challenges encountered, and illustrating our corresponding solutions.

4.1 Guidance Generator

Overall, this components attempts to guide SYMBISECT when SYMBISECT executes the PoC in the reference version of the program to trigger a specific vulnerability and collects the execution trace. Then, SYMBISECT produces three categories of guidance from the execution traces, which we explain below.

Call Stack Guidance. The call stack guidance represents the state of the call stack at the moment a vulnerability is triggered. This information can be readily collected when the corresponding bug is triggered in the reference version of the software under investigation. Utilizing the call stack guidance serves multiple purposes. First, it assists in identifying an appropriate **entry function** as the starting point for our symbolic detector. Second, it assists in pinpointing **the target line** where the vulnerability is triggered, allowing the symbolic detector to focus on the same vulnerability rather than any arbitrary vulnerability. We use call stack guidance to constrain the exploration of a target version so that it only explores the basic blocks that can potentially lead to the same stack trace. Correspondingly, we translate call stack guidance into basic-block-level priorities to guide the exploration.

- Highest Priority: basic blocks that dominate the basic blocks in the call stack will receive the highest priority. This indicates that their execution is essential for reaching the bug while maintaining the same call stack. The set of such basic blocks can be identified through the dominator analysis on the control flow graph of functions in the call stack.
- Lowest Priority: basic blocks, upon the execution of which can cause deviations from the call stack, will receive the lowest priority. Consequently, a symbolic detector should avoid executing any of these blocks. They can be identified through reachability analysis.

Path Guidance. In addition to the call stack guidance, we will need more fine-grained guidance if there are still too many possible execution paths that follow the same call stack. Specifically we propose to prioritize the execution path directly at the basic block level. The idea is that a basic block in the target version is likely to be non-critical if (1) the basic block is not executed in the reference version and (2) it remains unchanged in both the reference and target versions of the program. Therefore, the symbolic execution should prioritize the exploration of branches whose basic blocks have higher priority. Note that when there are conflicts, path guidance must yield to call stack guidance because the most critical goal is to ensure the vulnerable function being reached. We translate path guidance into the basic-block-level priorities as follows:

- High Priority: basic blocks covered by the execution trace in the reference version of the program will receive high priority (lower than the highest priority).
- Low Priority: basic block not covered by the execution trace in the reference will receive low priority.

Indirect Call Guidance. The indirect call guidance records the callee functions associated with each indirect function call encountered in the execution trace. Its primary role is to facilitate the accurate resolution of indirect function calls during the symbolic execution process, particularly in the target versions of the software under analysis.

4.2 Guidance Transformer

To enhance both the efficiency of symbolic execution and the precision of vulnerability detection in target program versions, it is essential to translate the three categories

of guidance collected from a reference version. Specifically, one fundamental task is to map basic blocks from the binary form in the reference version, where execution traces are collected, to the LLVM IR in the target version, where symbolic execution is executed. One potential solution is first to map the binary-level basic blocks from reference to target. However, due to compiler optimizations, even if the source code lines are identical, their binary basic blocks may differ, making this solution undesirable.

Our solution employs source code as an intermediate representation to improve the mapping accuracy between the reference and target versions. The transformation sequence for basic blocks begins with the binary form in the reference version, moves to its source code, transitions to the source code in the target version, and ends in the LLVM IR of the target version. To facilitate these mappings, we use the debug information to transition between binary and source code and between source code and LLVM IR. Additionally, Git is employed for source code mapping between the reference and target versions. During the transformation sequence, we take care of multiple corner cases to enhance the precision (more details in §5.1).

After transforming the call stack to the target version, we verify the presence of the target line triggering the vulnerability. If absent, the target version is deemed non-vulnerable. If present, we examine whether there is a potential path from the entry to the target function in the call graph. A missing path directly results in a negative outcome.

Otherwise, the exploration of the target version will follow the aforementioned guidance. Finally, if there are basic blocks unique to the target version (never seen in the reference), we will assign a neutral priority level to them as it is unknown whether these basic blocks will be useful in triggering the vulnerability:

- Medium Priority: basic blocks unique to the target version, which do not map to any basic blocks in the reference version, will receive medium priority. Compared to the low priority basic blocks – the ones seen in reference version yet not exercised, we are less certain about the utility of such basic blocks; therefore we prefer to explore them with a higher priority compared to the basic blocks that were seen in both reference and target versions but not exercised in the reference.

Then, all the guidance (call stack, five lists of varying priorities, and indirect call mapping) are forwarded to the subsequent component.

4.3 Symbolic Detector

After generating guidance for the target version of the program under analysis, the symbolic detector conducts under-constrained symbolic execution on these targeted versions. Specifically, the detector monitors all variables within the program to identify potential vulnerability patterns, such as use-after-free or out-of-bound access errors. We propose multiple improvements to enhance the ability of under-constrained symbolic execution, including but not limited to handling symbolic addresses, and symbolic sizes of allocated memory. The details are described in §5.2. Throughout this execution, the symbolic detector utilizes the guidance generated in prior stages to enhance its effectiveness.

Call Stack Guidance. Symbolic execution is initiated at a selected entry function, determined by examining the call stack. Specifically, execution starts at the first meaningful function in the call stack — we choose to start at the syscall handler [24] (which is typically several layers behind the generic syscall entry). The symbolic execution process ends upon detecting a vulnerability (resulting in a positive output) or upon hitting a time constraint (yielding a negative output). Importantly, the detector only checks for vulnerabilities upon reaching the specified target line in the guidance, avoiding hitting any unrelated bugs accidentally. Also, the basic blocks with the lowest priority are prohibited from execution.

Path guidance. When symbolic execution encounters a symbolic condition, it forks to explore both true and false branches. This forking behavior primarily contributes to the path explosion in symbolic execution. The path guidance is employed to address this. This approach prioritizes exploration by first traversing branches with higher priority. When two branches have the same priority, one is randomly selected to be explored first.

Indirect Call Guidance. During symbolic execution, if we observe the indirect call target being assigned explicitly to a function pointer, we can unambiguously determine the indirect call target. Otherwise, we initially refer to the indirect call guidance to identify the indirect call target. If we find a match for the specific indirect call, we use the specific target from the guidance directly. Otherwise, we utilize the state-of-the-art type-based analysis [29] to resolve indirect calls (which may produce multiple targets).

5 Implementation

In total, the implementation of SYMBISECT has 4,726 LoC Python code for the Guidance Generator and Guidance Transformer and 4,347 LoC of C++ for the Symbolic Detector atop KLEE [16]. In the following sections, we will delve into further details regarding

the Guidance Transformer (§4.2), and Symbolic Detector (§4.3). In summary, SymBisect collects the original trace at the binary level, the generated guidances are at the source code level, and the symbolic execution engine is based on LLVM IR.

5.1 Guidance Transformer

Code formatting. Because we employ source code as an intermediate representation during the guidance transformer, we require each source code line to be associated with only a single basic block. To achieve this, we develop a simple source code formatter that divides composite lines into simpler ones. For instance, splitting "} else if(cond){" into two distinct lines. This is done for both the reference version and the target version at the beginning.

Accurate coverage collector. SYMBISECT leverage KCOV mechanism to discern which sections of the code have been covered. Syzkaller offers a tool to save the coverage data from KCOV. However, this operation is not always reliable. When the kernel crashes, some coverage can be lost. To improve this, SYMBISECT modifies the kernel to record the KCOV buffer in a log upon a kernel crash.

Refine guidance. The source code level guidance is generated using DWARF debug information, which may not always be accurate. Specifically, compiler optimizations (compiling the Linux kernel with -O0 is generally not supported), e.g., function inlining, and reordering, can lead to inaccuracies when mapping basic blocks in binary instructions into their corresponding source code lines with debug information – we find that the coverage of many basic blocks can be lost. To mitigate such impact, we implement an analysis of the basic blacks with the control flow graph and the dominator tree. We recover potentially lost basic block coverage under the following two conditions: 1) Should a line within a BB be marked as covered by a test case, it is necessary to mark all lines within that same BB as covered as well. 2) In instances where a covered BB is dominated by another BB (indicating that it is invariably executed after the dominating BB), it's essential that the dominator BB is also marked as covered.

5.2 Symbolic Detector

The types of vulnerabilities supported by SYMBISECT are determined by symbolic engine and detectors. SYMBISECT currently support bugs that exhibit out-of-bound (OOB) memory access and use-after-free (UAF) errors. This is because OOB/UAF vulnerabilities are the ones that are generally considered more security-critical and commonly exploited [57, 15, 48]. Note that the root causes of these vulnerabilities can vary, e.g., the underlying causes might be integer overflow and type confusion but they exhibit OOB memory access as an error. Given that syzbot categorizes vulnerabilities based on their security impact, we follow the same categorization. Currently, SYMBISECT has a few limitations: (1) it does not support race condition bugs (that are not supported by KLEE), and (2) it does not support bugs that require reasoning across multiple syscalls (instead the detector focuses on the last syscall that triggered the bug). Below, we discuss some modifications made to KLEE to achieve more accurate results.

Under constraint symbolic variables. We choose to symbolize all variables without concrete values in static environments, including global variables and arguments of system calls. This approach allows us to explore a broader range of potential execution paths during our analysis.

Symbolic address. In its original form, KLEE does not adequately support under-constrained symbolic addresses. When it encounters read/write operations to a symbolic address, KLEE typically generates a specific concrete address based on the current constraints.

The logic KLEE employs for dealing with under-constrained symbolic addresses is not reliable, particularly when faced with a multitude of such addresses. There might be instances where a symbolic address does not map onto any existing object. In such cases, arbitrarily concretizing this address to an existing object and proceeding with read/write operations can lead to incorrect outcomes.

Instead, we apply an improved mechanism in UCKLEE [18] to deal with symbolic addresses that have not been encountered before. When attempting to write/read to such a novel symbolic address, our system allocates a new object. Besides that, we maintain mappings between symbolic and concrete addresses. Therefore, subsequent attempts to access the same symbolic address will, in reality, be directed toward the corresponding concrete object as per the mapping. This procedure ensures that each symbolic address is consistently linked to a unique concrete object, thereby improving the precision of read-/write operations and overall analysis.

Symbolic size. The original way KLEE allocates a new object with symbolic size is also not suitable for our situation. Specifically, if the size is symbolic, it generates a specific concrete size, and then KLEE tries to half its size until the size is no larger than a small constant (i.e., 128 in KLEE v2.2).

In our under-constraint cases, it will result in many objects with small sizes, such automatic concretization may result in the inaccuracy of the results. For example, if there is a path that can only be explored with a size larger than the constant, it will always be skipped.

Instead, we implement a solution similar to the previous work[41] to handle this issue. We choose to track the symbolic sizes. We allocate the object with a large constant size in memory to make sure that the intended access to the object won't be missed and log the symbolic size. When there is a check against the size of an object, we always use the symbolic size.

Function modeling. To improve the scalability of symbolic execution, we manually model more general library functions belonging, such as strcpy(), malloc().

Vulnerability checker. The under-constraint nature of our symbolic execution will introduce some false positives when asserting the presence of vulnerability logic. To mitigate the problem, we concentrate on detecting the vulnerability on the corresponding line (called target line) in the target version where the vulnerability is triggered – we require the same line to be present in the reference and target version.

Once reaching the target line, for each read/write operation, we extract the address (usually symbolic) and find the corresponding object. If no corresponding object is found (usually happens in UAF cases), instead of allocating new under-constrained memory, we report the vulnerability directly. Otherwise, SYMBISECT compares the offset with the size of the object under current constraints. If the offset can be larger than the size (usually happens in OOB cases), SYMBISECT reports the vulnerability and terminates the execution. Finally, if none of these is detected, SYMBISECT keeps exploring various execution paths until a time limit is reached or runs out of paths to explore, leading to a negative result.

6 Evaluation

In this section, we evaluate SYMBISECT based on the following three research questions.

- RQ1: How precisely does SYMBISECT identify the vulnerable versions for a specific vulnerability? How precisely does it determine the exact bug-inducing commit? What factors influence the accuracy?
- RQ3: How effective is SYMBISECT, when compared with state-of-the-art (PoC-based/patch-based) bug-inducing commit identification methods?
- RQ4: How efficient is SYMBISECT in conducting its analysis? Specifically, how does the provided guidance/exploration strategy improve efficiency?

Evaluation Target and Vulnerability Dataset. We assess SYMBISECT on Linux kernel bugs reported on syzbot [22]. This choice is made due to several factors. First, syzbot is among the earliest and most mature continuous fuzzing platforms and the Linux kernel is among the most popular open source software. Second, the Linux kernel is the largest software that is being continuously fuzzed today. Third, there are a variety and a large number of bugs reported on syzbot continuously, which require bisection. Specifically, in our evaluation, we utilize SYMBISECT to conduct bisection on the Linux mainline branch. We believe our solution generalizes beyond the Linux kernel as it is likely more complex than most other software.

We consider adding support for other types an important but orthogonal exercise (see discussion in §7). As mentioned, SYMBISECT currently supports bugs that exhibit OOB and UAF impact (and no race conditions involved). Therefore, we randomly sampled 50 bugs from syzbot reports that meet the following requirements: 1) reported in the last 4 years. 2) labeled to have OOB or UAF impact. 3) not race conditions (which our symbolic detector currently does not support). 4) with PoCs and the bugs can be reproduced. 5) the corresponding patch has a "Fixes:" tag (to be explained below).

A "Fixes:" tag is included in a patch that points to one or more previous commits that are considered to introduce the corresponding bug. We treat it as the ground truth because we verified that they are consistent with our definition of bug-inducing commits (see later for "ground truth verification"). Note that SYMBISECT does not require the presence of a "Fixes:" tag to operate; we choose such bugs to merely simplify the evaluation process.

For each vulnerability, our tool begins with the released vulnerable version and inspects every major release version (e.g., v5.10) until the oldest version, v4.20, in our dataset. Versions prior to v4.20 present compatibility issues with the Clang/LLVM toolchain. While more engineering work might address this, it diverts from our primary focus. If the released vulnerable version is not on the Linux mainline branch, we find the corresponding commit (with the same Linux kernel version) as the starting point on the mainline. In total, our dataset consists of 645 bug-version pairs. We will determine whether each version is affected by a bug (vulnerable vs. non-vulnerable). We evaluate the accuracy of SYMBISECT against these bug-version pairs. Subsequently, to evaluate bug-inducing commit identification, we retained the bugs introduced after v4.20 (32 in total): SYMBISECT employs a binary search between the latest non-vulnerable version and version on which the bug was reported by syzbot to pinpoint the exact bug-inducing commit.

All experiments are conducted in Ubuntu-20.04 with 1TB memory and Intel(R) Xeon(R) Gold 6248 20 Core CPU @ 2.50GHz * 2. For each bug-version pair, we allocate a single CPU core for a maximum of 10,000 seconds of symbolic execution.

Comparison Targets. We compare SYMBISECT with the three following lines of work:

Tools	TP	FP	TN	FN	Accuracy	Precision	Recall	F-1 Score
SYMBISECT	237	29	348	31	90.7%	89.1%	88.4%	88.7%
Syzbot(PoC)	146	27	350	122	76.9%	84.4%	54.5%	66.2%
V0Finder	138	0	377	130	79.8%	100.0%	51.5%	68.0%
VSZZ	250	145	232	18	74.7%	63.4%	93.3%	75.4%

Table 1: **The results of vulnerable versions detection**

Tools	correct	incorrect	Accuracy
SYMBISECT	24	8	75%
Syzbot	16	16	50%
V0Finder	11	21	34.375%
VSZZ	18	14	56.25%

Table 2: **The results of bug-inducing commit identification**

- PoC-based bisection. Syzbot bisects bugs with PoCs to find the commit that introduced the bug [3]. We employ a crawler to directly retrieve results from the website. In instances where bisection results are unavailable, we execute the PoC on the target kernels to get the results.
- Patch-based bisection with SZZ algorithm. As described in §2.2, this line of research assesses vulnerability-(un)affected versions by locating the vulnerability-introducing commit with SZZ and its variants. In this line of work, VSZZ [12] is the state-of-the-art tool and it's open source. We set up VSZZ with their default options according to the tutorials[6].
- Patch-based bisection with vulnerable code clone detection. These methods are based on code similarity comparison. V0Finder [45] is a recent vulnerable code clone detector that is used to discover the first version where a vulnerability is introduced. We set up V0Finder with their default options according to the tutorials[5].

Evaluation metrics. For the evaluation of determining the vulnerable versions for a specific vulnerability, for each bug-version pair, we will get a verdict as true positives (TP), true negatives (TN), false positives (FP), or false negatives (FN). Then we calculate the corresponding accuracy, precision, recall, and F1 score. For pinpointing the precise bug-inducing commit, we received a binary result (either identifying the correct bug-inducing commit or not) from which we calculated the accuracy.

Ground truth verification. To ensure that the "Fixes:" tag is consistent with the bug-inducing commit we defined, we carried out the following verification for all such tags in our dataset: 1) If the PoC triggers the reported bug in the target version, then that version is deemed vulnerable. 2) If the path from the entry function to the target line is absent in the target version (for example, if the target function or line does not exist), then it is considered not vulnerable. 3) For versions that cannot be verified through the previous two steps, we manually analyze the logic of the vulnerability to determine if it exists in the target version.

After the verification, we found that the vast majority of "fixes" tags are consistent with the bug-inducing commit we defined. The only exception was a vulnerability introduced by two adjacent commits. The first commit defined a function related to the vulnerability, and the second introduced the caller of this function. According to our definition, the second is the bug-inducing commit, but the "fixes" tag pointed to the first. Interestingly, we noted that these two adjacent commits were merged into the Linux mainline branch together in a single merge commit, thus not affecting our evaluation results.

6.1 Accuracy of SYMBISECT (RQ1)

Accuracy of vulnerable version detection. As shown in Table 1, SYMBISECT achieves an overall accuracy of 90.7% over 645 versions, higher than all existing tools. Note that this evaluation is performed on a per-bug-version-pair basis.

Accuracy of bug-inducing commit identification. Table 2 shows the results of bug-inducing commit identification, SYMBISECT outperformed all the other cases with an accuracy of 75%. The reason the accuracy is lower (than vulnerable version detection) is that it aggregates the results from all kernel versions for a single bug. For example, if the vulnerability was introduced in v5.3, we might correctly label v5.4 as vulnerable; however, if we mistakenly labeled v5.3 as non-vulnerable, then we still will end up with an incorrect bisection result for the specific bug (FN). Upon manual inspection, we discovered that among these eight cases of inaccuracy, five were due to FPs, and three resulted from FNs.

False positives in SYMBISECT. SYMBISECT has 29 false positives (misidentifying non-vulnerable versions as vulnerable). The FPs generated by SYMBISECT tool arise from the intrinsic characteristics of under-constrained symbolic executions. For example, global variables are symbolized in our approaches, allowing the constraints to represent them as potentially holding any

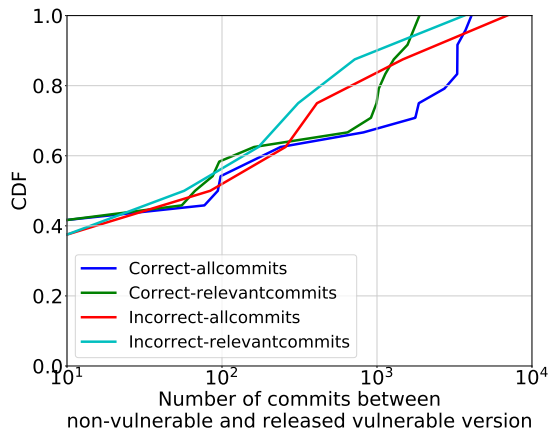

Figure 4: Comparison of commit number between correct and incorrect cases

value of the specified type. However, such a variable could be hard-coded somewhere that symbolic execution cannot access. Consequently, such under-constraining can lead to SYMBISECT concluding infeasible behaviors in practice.

As an example false positive, we find an OOB bug that arises from a lack of checks against socket types. In the kernel, different types of sockets possess different sizes. The mappings between the socket type and the corresponding structure sizes are stored as global variables in the kernel, which are symbolized in our detectors. When under-constrained, the symbolized mapping can produce any sizes from a given socket type, leading to false positives.

False negatives in SYMBISECT. Our evaluation records 31 false negatives (misidentifying vulnerable versions as non-vulnerable). The primary cause of FNs is the scalability issue. Certain vulnerabilities can be triggered only via a specific path, which might not be covered in the symbolic execution due to the time threshold, despite our effort to apply principled guidance during exploration. Moreover, the guidance may not be complete due to differences between the reference and target versions. If the symbolic execution lacks accurate guidance, it is likely to encounter scalability issues due to the complexity of kernels.

An example of this challenge occurs when a vulnerability site is influenced by a check against a pivotal variable. The vulnerability can be triggered only when this variable is set to a particular value in preceding functions. Yet, the distance between this value assignment and the condition check is substantial, with many functions with many state forks interspersed. Even with our guidance, satisfying such a nuanced condition in a limited time to activate the vulnerability proves challenging, resulting in false negatives.

Factors that influence accuracy. We hypothesize there are certain factors that affect the bisection accuracy. For instance, a plausible factor is the distance between the bug-inducing commit and the commit on which the bug is discovered. This is because the farther away the two commits are, the more changes may occur to the underlying bug-triggering condition.

To evaluate the distance factor, we counted the total number of commits between the released vulnerable version and the non-vulnerable version (the version before the bug-inducing commit) on the Linux mainline branch. Note that on the Linux mainline branch, a merge commit may combine updates from multiple commits on other branches, and we did not break down this merge commit to recount the number of commits. Another variation of the distance factor is to count only the "relevant commits" — commits that modify the files within the call stack responsible for triggering the bug — between the vulnerable and non-vulnerable versions.

We investigated the two aforementioned factors, and the results are presented in Figure 4. Contrary to our expectations, there appears to be little correlation between the two distance metrics and the accuracy of bisection in our dataset. Specifically, as illustrated in the figure, 37.5% (3 out of 8) of the incorrect cases (Incorrect-all commits) had very limited space (fewer than 10 commits in total) between bug-inducing commit and vulnerability-finding commit. This proportion is close to that of the correct cases (Correct-all commits), where 41.7% (10 out of 24) also had limited space.

We analyzed bugs that have more than 100 "relevant commits" (i.e., with large distances), which constitutes 14 bugs in total. The accuracy of SYMBISECT was 71.4% (10 out of 14). In general, we find that our method is effective in eliminating the influences of unrelated code changes. Even if those commits modified files included in the call stack (or even directly modified the corresponding functions), as long as they do not affect the existence of the vulnerability logic, our symbolic execution-based methods often can exclude their impact on the results.

6.2 Comparison (RQ3)

As shown in Table 1, SYMBISECT outperforms other tools effectively. It achieves higher accuracy (90.7% compared to the 77.1% average of preceding tools) and higher F1 scores (88.7% as opposed to 69.8%) than all previous tools. As expected, we observed that the main reasons for inaccuracies in existing PoC-based methods are the broken dynamical environment, inadvertent triggering of unrelated bugs, and evolving bug-triggering conditions as the code progresses. The fail-

Reason	FN	FP	Solved in SYMBISECT
Hard to reproduce	38	0	15
Detector not introduced	8	0	8
Build/boot errors	14	0	14
Config disabled	9	0	9
Trigger another bug	0	27	27
Over-constraint on inputs	53	0	53
Total	149		126

Table 3: **The reasons of PoC-based method failed**

ures of patched-based tools are due to their dependence on unreliable syntactic information and only consider a limited portion of bug-related code. In comparison, our solution based on static symbolic reasoning aims to capture the logic of the specific vulnerability and extend its scrutiny to a much broader context beyond the confines of the patched function.

Improvements over syzbot bisection. Table 3 outlines the reasons for the PoC-based method's failures in our dataset. The first five types are cited from the official syzbot documentation[3], while the final reason, "over-constraint" is a reason we observed. In fact, we find that it is the most common reason for inaccuracies. Notably, SYMBISECT has effectively addressed 83% of the inaccuracies associated with the PoC-based approach. We will now detail the causes of each failure and how SYMBISECT addressed them, as follows:

- Vulnerability with low probability of triggering. PoC-based approach often struggles to reproduce bugs that have a very low probability of triggering even in the released version that corresponds to the PoC. At present, for every target version, syzbot conducts testing only 10 times [3]. It is probable that vulnerabilities may not be triggered within these limited attempts. The under-constraint feature of SYMBISECT enhances its capability to fulfill the preconditions necessary for triggering the bug. As a result, SYMBISECT yields accurate results for 15 of the 38 cases within the given time threshold.
- Detector not introduced. The PoC-based approach is dependent on specific detectors, like the KASAN sanitizer. Until these detectors are integrated into the kernel, PoCs cannot detect vulnerabilities effectively. In contrast, SYMBISECT is equipped with its own symbolic execution detector, eliminating the need for reliance on sanitizers in the Linux kernel.
- Build/boot errors. As we discussed in §2, the static feature of SYMBISECT bypasses the problem resulting from kernel boot errors.
- Config disabled. As PoC-bisection goes back in time, certain kernel configs may be forcefully disabled when they conflict with the other config options. In contrast, since our solution does not require the compilation of the entire kernel, we can simply force other config conflicts to be disabled and make sure the vulnerable modules involved are compiled into LLVM bitcode for our analysis.
- Accidental triggering of unrelated bugs. The PoC has the potential to activate unrelated kernel bugs that break the program. Current syzbot does not look at the exact crash, nor does it attempt to distinguish between different types of crashes, leading to some FPs. In contrast, our tool focuses on the specific bug only upon reaching the target line (and analyze its associated operations). This allows us to effectively sidestep this issue.
- Over-constraint on inputs. This is essentially due to changes in the underlying bug-triggering conditions. Executing the original PoC does not always activate the bug in some vulnerable versions. Input mutations become necessary under these circumstances. The under-constrained symbolic execution approach treats all potential entry function arguments and global values comprehensively, effectively addressing these false negatives.

  Figure 5 presents an OOB vulnerability. Specifically, in function `mpol_parse_str()` if the str variable starts with "=", the flags variable will reference the first byte of str. If a certain condition at line 2 is met, the program skips to line 4. Here, a write operation occurs that exceeds the boundaries of str, leading to an out-of-bounds write. The PoC-based syzbot bisection incorrectly pinpoints a bug-inducing commit which modified the function `shmem_parse_one`—the caller of the `mpol_parse_str()` function. Prior to this misidentified commit, another check at line 8 was in place against the opt variable. The initial PoC fails this check, causing syzbot to label versions before this commit as non-vulnerable. However, by using a different input that bypasses this check, the bug remains exploitable. Instead, SYMBISECT symbolizes the inputs, making it easier to bypass such checks as long as a feasible solution exist.

Improvements over V0Finder. V0Finder failed to discover 107 vulnerable versions out of 230 cases, resulting in a low recall of 46.5%. The main reason is that V0Finder does a strict syntactic similarity comparison for the whole function. Specifically, after normalization and abstraction, it concludes that the target version is vulnerable only if the patch functions are strictly the same as those in the released version. Thus it cannot detect the vulnerable cases that are syntactically different, but convey the same vulnerable functionality.

The vulnerable function:

```
int mpol_parse_str(char *str,...)
1   char *flags = strchr(str, '=');
2   if(condition)
3       goto out
    ......
4   if (flags)
5       *flags++ = '\0';
    ......
out:
6   if (flags)
7       *--flags = '=';
```

The incorrect Bug-inducing Commit (Identified by Syzbot Bisection):

```
static int shmem_parse_one(...)
    ......
8 - else if (!strcmp(opt, "mpol")) {
  -     ......
9 -     if (mpol_parse_str(value, &ctx->mpol))
        ......
10+ if (IS_ENABLED(CONFIG_NUMA)) {
  +     ......
11+     if (mpol_parse_str(param->string, &ctx->mpol))
```

Figure 5: Case study of syzbot FN

The Patch:

```
int qrtr_endpoint_post(...)
    struct qrtr_cb *cb;
1 - unsigned int size;
2 + size_t size;
    ......
3   if (len != ALIGN(size, 4) + hdrlen)
    goto err;
```

The incorrect Bug-inducing Commit (Identified by V0Finder):

```
int qrtr_endpoint_post(...)
    ......
+   if (cb->type == QRTR_TYPE_NEW_SERVER) {
+       const struct qrtr_ctrl_pkt *pkt = data + hdrlen;
+       qrtr_node_assign(node, le32_to_cpu(pkt->server.node));
+   }
```

Figure 6: Case study of V0Finder FN

In Figure 6, we see an illustrative example. Here, a 4-byte size variable is prone to an overflow at line 3. To address this, the patch modifies the variable's size to 8 bytes. However, the bug-inducing commit pinpointed by V0Finder is actually a feature enhancement commit, unrelated to the vulnerability. This commit introduces multiple lines into the patched function. Due to this, V0Finder incorrectly designates all preceding versions as non-vulnerable, leading to a multitude of false negatives.

SymBisect, instead of syntactic comparison, extracts accurate semantic information. Thus it can distinguish vulnerability-irrelevant changes from significant changes effectively. Furthermore, it does not rely on patches. Whether the patch changes a function or not is irrelevant to SymBisect. As a result, SymBisect can eliminate a large number of FN cases of V0Finder. This significant advantage is largely due to the differing

The Patch:

```
int squashfs_read_data(...)
1 - TRACE("Block @ 0x%llx, %scompressed size %d\n", index,
2 + TRACE("Block @ 0x%llx, %scompressed size %d\n", index - 2,
        compressed ? "" : "un", length);
      }
3 + if (length < 0 || length > output->length ||
  +         (index + length) > msblk->bytes_used) {
4 +     res = -EIO;
5 +     goto out;
  +   }
```

The incorrect Bug-inducing Commit :

```
    ...... (initialize the file)
6 +  TRACE("Block @ 0x%llx, %scompressed size %d\n", index,
```

The correct Bug-inducing Commit :

```
int squashfs_read_data(...)
    ......
7   TRACE("Block @ 0x%llx, %scompressed size %d\n", index,
  -         compressed ? "" : "un", length);
8 - if (length < 0 || length > output->length ||
  -         (index + length) > msblk->bytes_used)
9 -     goto block_release;
```

Figure 7: Case study of VSZZ FP

foundational design principles of the two systems.

Improvements over VSZZ. VSZZ processes a patch as input and identifies the vulnerability-introducing commit by backtracing the patch's deleted lines through the code commit history to the earliest instance, facilitated by line matching. The earliest commit where these deleted lines were initialized is then marked as the commit that induced the bug. When multiple deleted lines originate from different commits, VSZZ selects the earliest of those commits as the bug-inducing commit. If the patch does not have any deleted lines, VSZZ identifies the commit that initialized the file mentioned in the patch as the bug-inducing commit.

Figure 7 illustrates a typical scenario where the underlying assumption fails, leading to a false positive. The deleted line 1 in the patch function is not created by the vulnerability-inducing commit, leading to backtracing to an earlier point. All commits situated between the commit identified by VSZZ and the actual inducing commit will be marked as FPs. In detail, the vulnerability was brought into the codebase by a commit that removed a certain validation check at line 8, then the vulnerability was patched by putting the check back in. However, the line they removed from the patch was just for logging that is not really related to the vulnerability. VSZZ traced this logging line back to when the whole function was first added, resulting in some FPs.

Basically, the commit that introduces the vulnerability may not alter the patch function at all, as demonstrated in our motivating example. Even if it does alter the patch function, it may not modify the deleted lines in the patch, just as in the above example. Furthermore, even

Strategy	Implementation
SYMBISECT	Exploration + Indirect call + Stack + Path
Pure Exploration	Exploration + Indirect call
Pure Re-tracing	Indirect call + Stack + Path
Stack	Exploration + Indirect call + Stack
Path	Exploration + Indirect call + Path

Table 4: **The relationship between strategy and guidance**

if the bug-introducing commit does change the deleted lines, it may only modify them rather than create them. In such cases, VSZZ may backtrace beyond the actual bug-introducing commit. These factors contribute to 112 false positives, a significantly higher figure than those seen with the other methods.

In contrast, our semantic method does not hinge on such a strong assumption. The symbolic execution engine accurately extracts semantic information, clarifying their relationship with the vulnerability.

6.3 Scalability of Different Exploration Strategies (RQ4)

To understand how the guidance helps with the overall results, we conduct a comparative study against alternative strategies. Fundamentally, SYMBISECT balances the exploration (i.e., allowing execution of the basic blocks in the medium-priority list) with re-tracing (i.e., aligning the execution trace with the one in the reference version). Therefore, we consider the following strategies that fall under various places in the spectrum: (1) pure exploration without any re-tracing or guidance (no consideration of basic block priorities), (2) pure re-tracing strictly following path guidance (i.e., when a branch leads to a high/highest priority exists, the other branches are prohibited from execution), (3) exploration with call stack guidance only. (4) exploration with path guidance only.

Table 4 shows the relationship between various strategies and specific guidance. "Indirect call", "Stack", and "Path" represent indirect call guidance, call stack guidance, and path guidance, respectively. For strategies with a combination of exploration and certain guidance, we assign different priorities to different paths based on guidance as defined in §4.1. In general, we prioritize the execution of higher priority branches, and do not prohibit the execution of branches unless the basic blocks are marked as the lowest priority (which can never reach the target line). In contrast, "Pure Re-tracing", when one branch leads to a high/highest priority basic block, the execution of other branches is prohibited. For all strategies, we employ the same entry function and target line and activate the indirect call guidance to ensure a fair comparison.

Results. The results are presented in Figure 8. The X-axis represents the symbolic execution time required to reach the target line, while the Y-axis shows the percentages of cases where the execution time falls within the range [0, X]. We have the following observations:

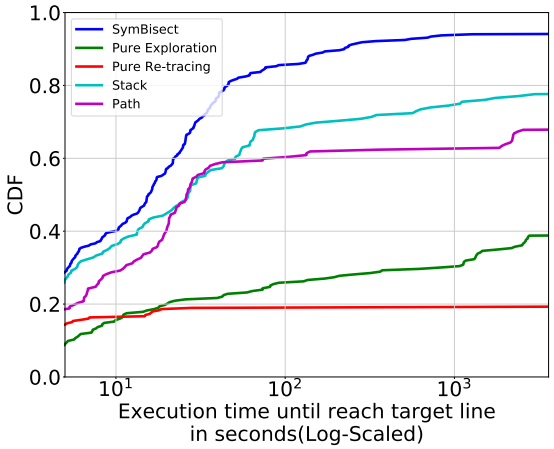

Figure 8: Scalability Evaluation

We can see that SYMBISECT performs the best. Pure re-tracing performs the worst, as it often fails to account for changes in the underlying bug-triggering condition and cannot reach the target line (e.g., the symbolic exploration is killed earlier than expected). Pure exploration performs second to last because it has too many execution paths to cover, resulting in path explosion. The remaining two strategies with limited guidance perform better than pure exploration but worse than SYMBISECT. When comparing call stack guidance against path guidance, we find that the former performs slightly better than the latter. This is consistent with our strategy in SYMBISECT where call stack guidance takes precedence over path guidance. In other words, guiding the execution toward the target function is more aligned with the end goal of reaching the target line of code.

7 Discussion

Exploration range. As discussed in §2, Relying solely on patch functions presents inherent disadvantages, prompting us to explore entire traces in order to gather comprehensive information relevant to vulnerabilities within the program. However, these traces may encompass thousands of functions, with the majority of them unrelated to the vulnerability at hand. Consequently, achieving a balance between scalability and accuracy primarily relies on determining the appropriate exploration range. While we employ specific heuristics to limit the range, there is still room for a more systematic approach to this decision-making process. For ex-

ample, we envision one can apply static analysis (less precise but more scalable) to identify the vulnerability-related functions in advance, then skipping the unrelated functions when applying symbolic execution. Developing such a solution would significantly improve our capability to identify and address vulnerabilities without overwhelming our resources.

Support more bug types. The types of vulnerabilities supported by SYMBISECT depend on the symbolic engine it is based on (currently KLEE) and the detectors built on top of it (or provided by KLEE itself). SYMBISECT currently supports bugs that manifest as OOB and UAF, including type confusion and integer overflow bugs that manifest as OOB. There are a few types of bugs that are interesting to support for future improvements: (1) additional bug types such as use-before-initialization [52], (2) bugs that require precise reasoning across multiple syscalls, and (3) race conditions bugs. For (1), it requires additional symbolic detectors to recognize other bug types. For (2), symbolic execution across multiple syscalls is feasible but presents an additional scalability challenge. For example, in some OOB cases, the allocation and use of the vulnerable object occur in different system calls. Without analyzing the allocation, the analysis of the subsequent syscall on use will be under-constrained and therefore potentially lead to false positives. This means we will need to first collect the symbolic expression for the object size (in one syscall), and then reason about whether the use can go out-of-bounds (in another syscall). We envision an optimization to terminate the symbolic execution of the allocation syscall earlier, as soon as the object size info is collected and leave other unexplored variables under-constrained. For (3), there are specialized symbolic detectors that can detect specific race condition bugs, e.g., multi-reads and double-fetch [50]. In the context of bisection, we envision that a more general approach is to recognize the interleaving points [51] and record the desired interleaving during the execution of the PoC in the reference version and use it to guide the execution of the target version.

Support bugs without PoCs. When a fuzzer discovers bugs, it usually generates a corresponding PoC, but there are exceptions. In some cases, syzakaller only produces a bug report. We wish to point out that our tool does not necessarily have to rely on PoCs. Instead, as long as we can obtain traces that trigger the vulnerability, it would be sufficient to guide the symbolic execution. For example, with hardware support (e.g., Intel Processor Trace [21]), we envision bug reports can be accompanied with corresponding control flow information.

8 Related Work

Under-constrained symbolic execution in OS kernels. UCKLEE [33] represents the initial implementation of an under-constrained symbolic execution virtual machine based on KLEE. It is primarily utilized for patch verification as well as rule-based generalized checks, encompassing areas such as memory leaks, uninitialized data, and user input vulnerabilities. UBITect [52] and IncreLux [53] utilize under-constrained symbolic execution to identify feasible paths and mitigate false positives in static analysis when detecting Use-Before-Initialization (UBI) bugs. SID [46] aims to distinguish security-related patches from other bug fixes, which is different from our work. It attempts to set up a model for several types of vulnerabilities with the help of under-constraint symbolic execution, rather than simply extracting and comparing characteristics. Besides, previous studies that attempted to perform symbolic execution on operating system kernels addressed the scalability issues using the following methods: 1) Decrease the scope of symbolic execution when analyzing operating system kernels. For example, performing intra-procedural analysis on a specific function such as the patch function [54] [46]. However, the approach may not be suitable for our purposes. The existence of a vulnerability is not determined by a single function. 2) Concretizing symbolic inputs and global variables [15, 48]. In our cases, it will result in an over-constraint problem.

Dynamic vulnerable version identification. The information about the affected versions of a vulnerability is quite important [38]. Dai et al. [17] proposed a PoC migration approach that takes a PoC as input and migrates the PoC to verify other affected versions. However, it specifically targets user-space programs. Furthermore, as demonstrated in § 6, over-constraint on inputs is only one of the causes of failure.

Code clone detection. If two code fragments are highly similar, with only minor modifications, or identical due to copy-paste, then one fragment may be considered a code clone of the other [55]. Code clone detection is widely used in software engineering tasks such as program understanding, plagiarism detection, copyright infringement investigation, and code compaction [8, 35, 36, 39, 20]. These techniques are designed to detect general code clones with high accuracy and scalability. However, they do not aim to precisely reason about security properties of the code, which may be influenced by small changes while still preserving "similarity". In addition, vulnerable code clone detection [26, 25, 14, 49, 56, 14, 45] usually perform code clone detection on what they define as vulnerability-related code (a few lines within the patch function or the entire function, sometimes manually extracted [44]). However,

the lack of vulnerability logic reasoning makes them imprecise, as demonstrated in our evaluation.

Information-retrieval-based bisection. Locus [43] was the initial method to pinpoint bugs at the software change level using token similarities from bug reports. ChangeLocator [47] determines Bug-Inducing Commit (BIC) using crash call stack information. Orca [13] ranks commits based on bug symptoms, like exception messages or customer feedback. Bug2Commit [30] aggregates features from bug reports and commit, averaging their vector representations. FONTE [10] identifies BIC via test coverage. It ranks commits by the suspiciousness of their modifications. Despite their scalability, these methods fall short in accuracy. As mentioned in the Background section, The state-of-the-art, Fonte, only reaches a 36% accuracy rate.

9 Conclusion

The identification of vulnerable versions of Open Source Software and pinpointing bug-inducing commits are crucial for vulnerabilities uncovered through fuzzing. In response to this, we introduce SYMBISECT, a precise methodology grounded in symbolic analysis. The central principle is that detailed symbolic information tends to be more stable compared to both the original PoC and syntactic similarity assessments during software evolution. Our experimental results confirm that SYMBISECT not only significantly surpasses the existing PoC-based approach in terms of accuracy, but also outperforms methods that rely on patches. With the insights gained from SYMBISECT about vulnerable versions, developers can precisely locate the bug-inducing commit. This empowers them to address the potential threats brought about by fuzzing vulnerabilities, thus promoting a more secure software ecosystem.

Abstract

Code coverage is crucial for fuzzing. It helps fuzzers identify areas of a program that have not been explored, which are often the most likely to contain bugs. However, code coverage only reflects a small part of a program's structure. Many crucial program constructs, such as constraints, automata, and Turing-complete domain-specific languages, are embedded in a program as constant data. Since this data cannot be effectively reflected by code coverage, it remains a major challenge for modern fuzzing practices.

To address this challenge, we propose data coverage for guided fuzzing. The idea is to detect novel constant data references and maximize their coverage. However, the widespread use of constant data can significantly impact fuzzing throughput if not handled carefully. To overcome this issue, we optimize for real-world fuzzing practices by classifying data access according to semantics and designing customized collection strategies. We also develop novel storage and utilization techniques for improved fuzzing efficiency. Finally, we enhance libFuzzer with data coverage and submit it to Google's FuzzBench for evaluation. Our approach outperforms many state-of-the-art fuzzers and achieves the best coverage score in the experiment. Furthermore, we have discovered 28 previously-unknown bugs on OSS-Fuzz projects that were well-fuzzed using code coverage.

1 Introduction

Code coverage is an essential part to software testing. In any case, code must be executed to trigger the underlying bug. This is particularly important in the case of guided fuzzing, a type of automated testing that identifies potential bugs and vulnerabilities by maximizing code coverage with novel test cases. The use of code coverage in guided fuzzing has been shown to be highly effective, leading to its widespread adoption in both industry [30,35] and academia [29,34,38]. In fact, the use of code coverage in guided fuzzing has been responsible for the discovery of over 40,000 bugs in 650 popular projects [1]. Most academic papers on fuzzing also rely on code coverage as a key component of their testing strategy.

However, code coverage is *not* sufficient to fully reflect a program's semantics. As Niklaus Wirth [36] pointed out, "algorithms + data structures = programs." In other words, *programs* are concrete formulations of abstract *algorithms* based on particular representations and structures of *data* [36]. This can also be seen from the perspective of programming language implementation: when a compiler converts source code into machine code, the algorithms are transformed into *machine instructions*, while the data structures are encoded as *constant data*.

In addition to code, constant data plays a crucial role in program constructs. There are two physical forms of constant data: immediate values and static values.

- *Immediate values* are simple, directly embedded in code, and commonly found in programs. For example, in the C programming language, the code `*ptr = 0x1234abcd` would lower to the x86 machine code c7 00 cd ab 34 12, with the immediate value 0x1234abcd embedded as the last four bytes of the machine code.

- *Static values* are more complex and expressive. In the C programming language, string literals, `static` variables, and global variables are all examples of static values. These values can encode complex structures and convey intricate semantics, including arrays, linked lists, lookup tables, and even graphs.

Data-intensive program constructs are often difficult to test with code coverage guided fuzzing. To illustrate this point, consider the scenario of testing a parser for a highly-structured input format such as SQL. In this case, the programmer writes a grammar specification and uses a tool like YACC to automatically generate the parser code. The transition rules derived from the grammar are encoded as large arrays, while a small

*Corresponding author.

piece of template code is used to drive the transition. Therefore, code coverage only reflects the superficial logic of "how to run *any* automata," while data coverage reflects the real logic of "how *this* SQL automata runs." This is why data coverage is so important for fuzzing: it allows fuzzers to fully test data-intensive program constructs.

According to the definition of constant data symbols, data coverage can have varying granularities, such as variable, array, field, or bit coverage, similar to code coverage's function, line, and branch coverage. However, a trade-off exists between the precision of the data coverage measurement and the overhead it introduces. For instance, achieving perfect data coverage would require symbolizing the program's address space into a bit vector and collecting the constant data symbols that contribute to the program's output. While this would provide highly precise measurements, it also significantly slow down the program's execution and reduce the overall fuzzing throughput.

We optimize data coverage for real-world fuzzing practices. Our techniques aim to retain accuracy while maintaining high performance. They consist of three stages:

1. Before fuzzing begins, we perform static analysis and instrument potential data accesses. To remove unnecessary instrumentation, we divide data accesses into 6 categories and instrument them differently.
2. During fuzzing, when a data access is intercepted, the runtime library translates the different kinds of data accesses into tuples of (address, length). We store the novel ones in a novel set for further inspection.
3. After the execution of a test case, the fuzzer checks the novel data coverage set. Code and data features are used to jointly adjust the fuzzer's exploration direction.

To demonstrate the effectiveness of data coverage, we implemented a reference fuzzer based on libFuzzer and conducted third-party evaluation on Google's FuzzBench. Our evaluation incorporates many classic fuzzers and fully replicates the original FuzzBench paper's setup [23]. The results indicate that data coverage significantly boosts libFuzzer's normalized coverage score from 87.65 to 98.31, resulting in an improved rank for the fuzzer from 9th place to 1st place among the 12 fuzzers tested. Interestingly, we found that the introduction of data coverage alone outperforms the combination of many advanced fuzzing strategies, including AFL++ [9], the default fuzzer for Google's continuous fuzzing service OSS-Fuzz.

Moreover, when we applied data coverage to real-world programs on OSS-Fuzz, we discovered 28 previously-unknown bugs despite continuous fuzzing by thousands of machines in Google's cluster. These findings indicate that data coverage can uncover novel program states and bugs even when a program is continuously fuzzed with code coverage guidance.

In summary, this paper makes the following contributions:

- We propose a data coverage approach for guided fuzzing. It helps to solve the limitations of code coverage when applied to data-intensive program constructs.
- We present optimization techniques for using data coverage in fuzzing, including novel methods for coverage maintenance, representation, and utilization.
- We implement a reference fuzzer based on data coverage and evaluate its effectiveness. Experiments show that it achieves the highest coverage and stability among all the evaluated fuzzers. It also found 28 previously-unknown bugs on well-fuzzed OSS-Fuzz projects.

For open, reproducible research, we publish the source code[1], the raw experiment data[2], and the detailed evaluation report on FuzzBench[3].

2 Towards Data Coverage

2.1 Limitations of Code Coverage

Although code coverage is a valuable tool for fuzzing, it has limitations when it comes to exploring data-intensive program constructs. One such construct involves immediate values used in predicates, which determine the truth value of a proposition. A common example of this type of construct can be found in the widely-used color management engine, LCMS, which accepts ICC color profiles as input data. As illustrated in Figure 1, LCMS performs a sanity check on the ICC file by verifying the magic number. While the predicate `magic != 0x61637370` is relatively simple to understand and reason about, using code coverage to explore it can be challenging.

```
#define cmsMagicNumber  0x61637370     // 'acsp'

// Validate file as an ICC profile
if (_cmsAdjustEndianess32(Header.magic) != cmsMagicNumber) {
  cmsSignalError(... "not an ICC profile, invalid signature");
  return FALSE;
}
```

Figure 1: Predicate in LCMS testing for magic numbers.

In the code snippet provided, code coverage can only determine whether the check passes or fails. However, when the check fails, the code coverage remains the same regardless of how close the guessed value is to the correct value. Without effective guidance, the fuzzer must "guess" the values blindly, which means that the likelihood of a successful guess is 2^{-32}. In other words, to achieve a success rate of 50%, the fuzzer

[3]The evaluation report is available at https://www.fuzzbench.com/reports/experimental/2022-10-08-wingfuzz.

would need to try 3×10^9 times, which would take over a month assuming 1,000 executions per second.

2.2 Limitations of Constraint Solving

Constraint solving is an effective way to solve simple branches. Two popular solving approaches are concolic execution [7, 27, 33] and intelligent branch solving [3, 19, 20, 28].

Concolic execution represents the constraint as symbolic expressions, enabling solvers such as SMT solvers to solve them. We can represent the input bytes as a sequence of 8-bit vectors, with each byte declared as SMT-LIB clause `(declare-fun inputX () (_ BitVec 8))`. As the program executes, we gradually update the symbolic representations of all values based on the `inputX` variables. To solve the failed predicate, we add an assertion that mandates all bytes to be equal to the expected values: `(assert (and (= input0 #x61) ...))`. By querying this assertion, we request the SMT solver to provide concrete input values satisfying the constraints.

Intelligent branch solving identifies which input bytes are used by the constraint and employs a tailored mutation strategy on these bytes [3, 26]. For instance, to solve the branch in Figure 1, we can record the operands of the failed predicates and match them against the input data. In this example, we find that the first 4 bytes of the input impact the branch and are expected to be `0x61637370`. Therefore, we can simply replace the bytes with the expected value to solve the branch.

However, there are limitations for data-intensive program constructs, particularly for static values with rich semantics. For static values, it is inefficient for solvers to resolve one constraint. Moreover, the fuzzer may fail when the semantics of static values are not constraints.

2.2.1 Inefficiency in Constraint Solving

Even simple string comparisons can be challenging for constraint solvers. For example, LCMS implements case-insensitive string comparison on its own for portability, as shown in Figure 1. Neither concolic execution nor intelligent branch solving can effectively solve this constraint.

```
int cmsstrcasecmp(const char* s1, const char* s2) {
  // [...]
  while (toupper(*us1) == toupper(*us2++))
    if (*us1++ == '\0')
      return 0;
}
```

Figure 2: Manual string comparison in LCMS.

Concolic execution can solve this constraint by enumerating paths in the program systematically, but it fails to distinguish useful differences among paths from superficial ones. For instance, in this case, the `toupper` function may contain several branches to handle the non-ASCII, lower-cased, or upper-cased scenarios. Thus, there could be 8 paths to handle in one iteration, assuming two cases for the first `toupper`, two cases for the next `toupper`, and two cases for the equality comparison. If the loop runs for m iterations, there would be 8^m paths to solve! Even with modern optimizations that merge similar paths, it can still incur high overhead in symbolization and solver invocations.

Table 1: Hard-Coded Buffer Comparison Routines in AFL++

Program	Count	Example
C++	4	`operator==(string&, char*)`
C	10	`strcmp`
apache	3	`ap_cstr_casecmp`
busybox	1	`memcmpct`
curl	5	`Curl_safe_strcasecompare`
glib	9	`g_strcasecmp`
lcms	1	`cmsstrcasecmp`
libxml	7	`xmlStrcasecmp`
openssl	4	`OPENSSL_memcmp`
samba	1	`strcsequal`
Total	45	

Intelligent branch solving cannot solve this constraint without human intervention. Because the comparison of a single character is easy to succeed, the `while` branch is quickly marked as solved and not inspected further. Consequently, the constraint for the remaining characters is never passed to the solver. As a remedy, state-of-the-art fuzzers tend to work around this issue with per-program optimizations. For instance, AFL++ implements "CmpLog" instrumentation to record the operands of failed comparison routines to solve them with heuristics. Rather than instrumenting individual branches in a program-agnostic manner, it hard-codes a curated list of comparison routines and treats each invocation as an abstract branch. As shown in Table 1, more than two-thirds of the optimizations are focused on individual programs. Obviously, this approach does not scale.

In conclusion, constraint solvers cannot effectively solve static value-based branches. Although it is technically possible to solve this branch with concolic execution, it is inefficient in fuzzing practices. Intelligent branch solving also requires manual optimizations for individual programs.

2.2.2 Challenges in Non-Constraints

Complex structures, such as lookup tables, binary trees, and directed graphs, can be represented as static data. However, their semantics are not simple constraints, which makes them unsuitable for constraint solvers [2]. For example, libpcap supports customized packet filtering with user-provided expressions, which is implemented using a flex-based lexer and a bison-based parser. As Figure 3 shows, the lexer encodes the complex transition table in constant arrays and drives the machine using simple logic [18].

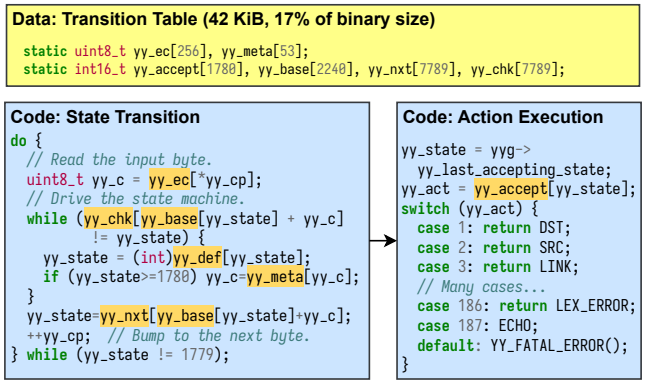

Figure 3: Finite-state machine implementation of libpcap. Based on the predefined *transition table* (shown in top), the *transition logic* (shown in the left) alters the machine's state according to input. When a final state is entered, the *execution logic* (shown in the right) performs user-defined actions. Data references in code are highlighted in yellow.

To explore the libpcap program, the fuzzer needs to trigger novel state transfers within the automaton, reach new accepted states, and execute new program logic in the end. However, the simplicity of the machine's logic results in saturated code coverage on the left and coverage plateau on the right. Since the fuzzer's coverage is stranded in the switch statement on the right, the fuzzer seeks help from the constraint solver. Concolic execution fails to symbolize indirect memory accesses, falling back to a concrete version of `yy_act`, which is unsolvable. Intelligent branch solving also fails since the predefined mutation strategy is inapplicable, as the value of `yy_act` is not directly related to input data. Therefore, none of the solvers can efficiently explore the state machine and trigger novel actions.

2.3 Benefits of Data Coverage

2.3.1 Benefits for Static Values

Static values are objects with static storage duration and predefined values. In the C programming language, string literals, `static` variables, and global variables are all examples of static values. A common implementation of these values is to convert the data to a binary form and store it in data segments. At runtime, these segments can be efficiently mapped to the process's address space.

The complexity of static values provides rich semantics. Complex structures, such as lookup tables, binary trees, and directed graphs, can be represented as static data. As demonstrated in the automaton example of Figure 3, the semantics of static values can be much more complex than constraints, where existing techniques such as constraint solving simply do not work. In this case, data coverage can be a crucial complement to code coverage. By tracking constant data usages, the fuzzer can distinguish 1,780 intermediate states and gradually explore them, executing novel actions as it does so.

2.3.2 Benefits for Immediate Values

Immediate values are simple values that are embedded directly inside instructions. For example, in the statement `*ptr = 0x1234abcd`, the value `0x1234abcd` is an immediate value. When this statement is compiled to x86 machine code, the instruction will be represented as c7 00 cd ab 34 12 (or `movl $0x1234abcd, (%eax)` in assembly). The immediate value is encoded as the last four bytes of the movl instruction. Immediate values can take up a significant amount of space in machine code. For example, in the above `movl` instruction, 67% of the machine representation is pure data.

Similar to constraint solving techniques, data coverage can be a crucial complement to code coverage. We can understand how data coverage helps to solve this scenario by the "short-circuiting" nature of predicates. Essentially, a predicate divides the input domain into two equivalence classes. Since the returned value is only one bit, not all bits of information are required to compute the result. In Figure 1's example, the least significant bit of immediate value `0x61637370` is 0. When the processor performs the comparison, it can immediately terminate the comparison and return "true" for any odd value (i.e., any value with a least significant bit of 1) because of the mismatch. This means that only one bit of the 32-bit immediate value is effectively used in the comparison.

To detect these subtle changes in integer predicates, we can use data coverage at bit-level precision. Specifically, we can guide fuzzing by maximizing the effectively used bits in predicates. When all 32 bits of the immediate value are effectively used, the predicate will flip and new code will emerge automatically.

3 Data Coverage in a Nutshell

Figure 4 illustrates how we guide fuzzing with data coverage. Before fuzzing starts, we instrument the program for various kinds of data access primitives. During fuzzing:

1. The fuzz engine generates a test case and executes the target program with it.
2. During the test case execution, the instrumented fuzz target records data coverage. In this case, the instrumentation code intercepts a 16-bit switch at 0x404a1c and passes its condition and case values to the runtime library.
3. The runtime abstracts the switch according to its semantics, treating it as two integer accesses. The first one (omitted in the figure) reads 4 bits from 0x404a19, while the next one (shown in the figure) reads 15 bits from 0x404a20.
4. With the access tuple, we detect novel coverage by comparing it to the known coverage database. In this case, the

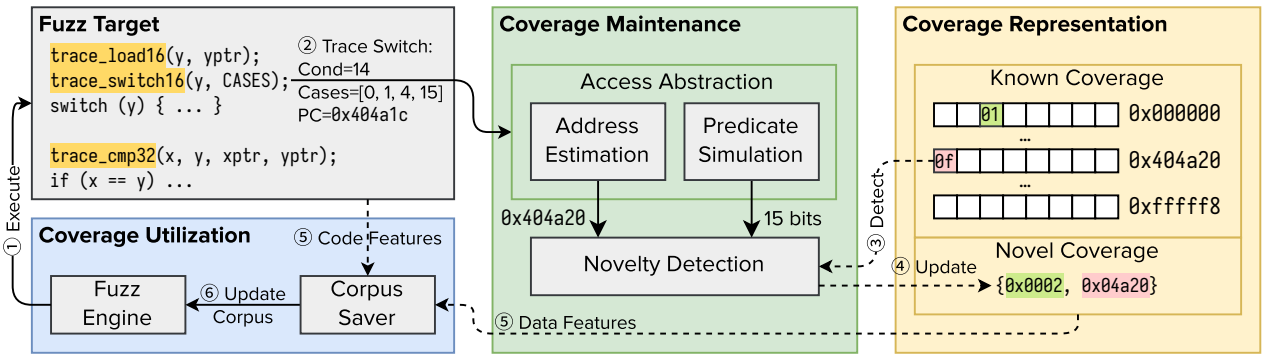

Figure 4: Fuzzing with data coverage. The *fuzz target* is instrumented during compilation. During program execution, the *coverage maintenance* component intercepts the program's data accesses and updates the coverage representation. After the test case execution completes, the *coverage utilization* component adjusts the fuzzing directions based on the novel coverage.

access to 0x404a20 improves the previously known coverage length to 15 bits. We add its address to the set of novel coverage and continue the program's normal execution.

5. After the test case execution is completed, we collect the complete code coverage and the set of novel data features.
6. The corpus saver analyzes both code and data features. In this case only novel data coverage is detected, thus the saver replaces an existing seed with the current test case.

3.1 Coverage Maintenance

We model each data access as a region, represented as a tuple of **(address, length)**. The address is based on byte granularity, whereas the length is measured in bits. We intercept and convert all the program's data accesses to such tuples. There are several special cases worth mentioning.

3.1.1 Load Filtering

Static values must be used by loading their values to registers. Therefore, we instrument load instructions to intercept static value usages. However, not all load operations are based on static values: the address can also be derived from the stack or the heap.

To filter load addresses, we analyze the runtime memory layout. The layout is obtained from the operating system's dynamic linker, which is responsible for loading a binary's segments to the program's address space and managing shared objects. For example, the dynamic linker of GNU libc provides the `dl_iterate_phdr` function to iterate through all the program headers (`dl_phdr_info`) of loaded objects. With this information, we can construct the runtime memory layout of the current process at the segment level, including the segment's type, address, and length. We use the layout to determine whether an address belongs to the program's binary. To improve efficiency, we pre-compute the valid memory range when the program starts. This design only requires two integer comparisons for each check.

3.1.2 Program Counter for Address Estimation

Immediate values are designed to be embedded in instructions. Typically, their addresses are implementation-defined and cannot be directly accessed. For example, the ARM64 architecture has a fixed 4-byte instruction encoding, which means that a 32-bit integer is spread across two instructions. Tracking the precise address of immediate values is costly and does not provide any benefits for fuzzing.

To estimate the address of immediate values, we use the *program counter*. Specifically, when instrumentation is needed, we insert a call to the runtime library *before* the parent instruction of the immediate value. When the program calls the runtime library, it saves the program counter in the manner specified by the application binary interface (ABI). Because the saved program counter is adjacent to the parent instruction and the contained immediate value, we read the value following the platform ABI and use it as an approximation of the immediate value's address.

3.1.3 Predicate Emulation

Over approximation may occur if we directly treat the data's storage bits as the access length. As discussed in §2.3.2, predicates compress the input domain into a boolean value. Therefore, not every bit of information is used in the decision process. For example, when testing `x == 0`, the processor may terminate the comparison as soon as a non-zero bit is found.

To determine the number of effectively used bits of information in predicates, we emulate predicates based on the following observation: predicates require more information to complete as the operands become more similar to each other. For example, when testing `0b0001 == 0b1110`, we can easily return "false" if *any* of the four bits is selected; however, when testing `0b1110 == 0b1110`, *every* bit must be compared to draw a conclusion. Therefore, *we define the "effectively-used bit" of equivalence relations as the number of equal bits in the corresponding positions for both operands.*

However, this measurement cannot be applied to partial order relations. Unlike equivalence relations, which treat all bits equally, the predicates of partial order relations scan from the most significant bit to the least significant bit. For example, when testing `0b0001 > 0b1110`, the result can be obtained by looking at the most significant bits alone. As a solution, we add a constraint to the original measurement, requiring that the measurement starts from the most significant bit. Therefore, *we define the "effectively-used bit" of partial order relations as the number of consecutive equal bits of both operands starting from the most significant bit.*

Since the measurement of effectively used bits is used frequently, we accelerate the operation with bit manipulation. Suppose that we are measuring the actually used bits between `x` and `y`, we first compute the different bits `diff = x xor y`. A bit in `diff` would be 0 if the corresponding bits in `x` and `y` are equal. Therefore, the final measurement would be the number of zeros in `diff` for equivalence relations and the number of *leading* zeros of `diff` partial order relations. We compute the results with the compiler intrinsic `__builtin_popcount` and `__builtin_clz` for potential hardware acceleration.

3.2 Coverage Representation

We represent the known coverage as an 8-bit integer array. For each access tuple, the lowest 24 bits of the address are used as the array index, and the length is stored directly as the element's value. For example, as shown in Figure 4, if the program reads 15 bits at 0x404a20, then the array's 0x404a20-th element is accessed to obtain the known access length. If the known length is less than 15, we update the value to 15 and mark the access as novel.

The design of known coverage reduces the overhead of instrumentation. First, most memory access primitives (e.g., load instructions and `memcpy`) touch multiple adjacent bytes. This design merges all accesses into one byte, reducing the extra memory accesses issued by instrumentation. Second, unnecessary predicate emulations are reduced.

Predicate emulation improves the tracking precision to the bit level, but slow bit manipulations are involved. We use `0xff` as a saturation mark to represent whether the maximum possible length has been reached. In this way, we can directly skip predicate simulation if the saturation mark is found.

We represent the novel coverage as a set, which contains the base addresses of novel access tuples. To minimize the impact on program execution, we implement the set as a dynamic-sized array. As the instrumentation logic identifies a novel access tuple during execution, the address is immediately appended to the array. Following each execution, we convert the array to a set through sorting and de-duplication processes.

The design of the novel coverage set removes the expensive post-execution coverage scan. Existing code coverage pipelines typically scan the coverage array after each execution to detect new coverage. If we reuse this pipeline to handle data coverage, then it would take too many cycles: to prevent collisions and the accompanying inaccuracy, we store the known coverage in a large 16 MiB array. Our new design solves this problem by delegating the maintenance of novel coverage to the instrumentation logic during program execution. Therefore, the post-execution coverage discovery is essentially an $O(1)$ access to the array's length.

3.3 Coverage Utilization

When a test case finishes execution, we determine the fuzzing exploration direction with both code and data features. Algorithm 1 presents the potential actions. The most common case in fuzzing is a boring trial where no novel data or code features are found. In this case, we directly ignore this test case and proceed to the next trial. Next, we refine an existing seed if the trial discovers novel data features but no novel code features. The overall idea is to reduce the number of saved seeds, since the space of data coverage is much larger than code coverage. For example, for the same static value, if the new data access reads 8 bits while the old one reads 7 bits, we directly replace the 7-bit seed with the new one. Finally, if the refinement fails to proceed, we save the current test case as a new seed and update the data-seed mapping.

Algorithm 1: Refinement-based Corpus Update

```
Input: novel code coverage C
Input: novel data coverage D
Input: code feature summaries S
Input: testcase t and code feature summary s
Data: M: maps a data feature to the saved seed
if C = ∅ ∧ D = ∅ then                          // No discovery.
    return;
if C = ∅ then
    // Data discovery only: try refinement.
    for f ∈ D do
        if S_{M_f} = s then
            ReplaceSeed(M_f, t);
            for f' ∈ D do
                M_{f'} ← M_f;
            return;
// Refinement is not possible: save a new seed.
n ← SaveSeed(t, s);
for f ∈ D do
    M_f ← n;
```

We maintain two extra data structures for efficient seed refinement. M maps a feature to the last seed saved in the corpus that demonstrates that feature. With this mapping, we can quickly enumerate the seeds for an access with the maximal access length. S maps a seed to the summary of its code features. It is used to prevent discarding already-discovered code features because of refinement. We ensure that the new

and old input shares the same code feature summary before performing the replacement.

4 Data Access Interception

We classify a program's data accesses into six categories according to their semantics. Table 2 lists an example code snippet for each category. Based on the classification, we design customized instrumentation and collection strategies to balance precision and overhead.

4.1 Integer Comparison

Integer comparisons are simple predicates. We insert a runtime library call for each integer comparison. The runtime estimates the address using the program counter. The runtime also determines the length via predicate emulation following the scheme presented in §3.1.3.

4.2 Switch Statement

Switch statements are predicates that directly determine the control flow. They are usually implemented as jump tables for efficiency [4]. Despite this, their semantics are equivalent to a series of `if-then-goto` statements using immediate values.

We emulate the semantics of switch statements accordingly. At compile time, for each switch statement we collect the case values, sort them, and store them inside a static array. We also insert a runtime library call before the switch statement, passing the condition value together with the case value array. Specifically, the function converts the switch statement into two or three integer comparisons.

If the condition value v is too large or small, we try to guide the value back to the case value range. We expand the switch as if the original code tests for `v == min` and `v == max`. In this case, a switch expands to two predicates targeted at different case values. To provide unique data coverage storage for each case, we slightly modify the program counter estimation technique when determining the address of immediate values. Specifically, for a switch executed at p, we assume the i-th case's immediate value is stored at $p+i$.

When the condition value v falls inside the range of a switch statement, we try to locate the case i such that $v \in [c_i, c_{i+1})$. Because the original case value array is sorted at compile time, we perform binary search to locate the index. If the condition value v matches the i-th case exactly, we emulate $v \neq c_i$ to reflect that the data of c_i has been completely covered. In addition to that, we also guide fuzzing towards adjacent cases, emulating $v \neq c_{i-1}$ and $v \neq c_{i+1}$ if possible. If the condition value v falls between c_i and c_{i+1}, then we emulate $v \neq c_i$ and $v \neq c_{i+1}$ to guide the condition to both cases.

For example, the switch statement in Figure 4 is located in 0x404a1c and the condition value is 14. The condition value fits between the 3rd case 4 and the 4th case 15. Therefore, we simulate $14 \neq 4$ at 0x404a1c + 3, yielding an access tuple of (0x404a1f, 8). We also simulate $14 \neq 15$ at 0x404a1c + 4, yielding an access tuple of (0x404a20, 15).

4.3 Trivial Value

Instead of instrumenting the immediate values, we rely on the existing code coverage pipeline to measure their coverage. This is because immediate values are directly embedded in instructions, and covering an immediate value implies that the parent instruction has been executed, which further implies that the basic block of the instruction has been covered. Therefore, using the existing code coverage pipeline allows us to assess the coverage of these values without introducing additional implementation complexity or execution overhead, while still maintaining completeness.

4.4 Load-Based Comparison

Load-based comparisons are a type of integer comparison, whose operator is loaded from a static value. These comparisons have the same value semantics as plain integer comparisons (see §4.1), but they have different data access semantics. To determine the access address of a load-based comparison, we must find the origin of the comparison operand.

To estimate the origin address of a value, we use intra-procedural analysis. The basic idea is to decompose the value into its dependent values recursively until we reach a load instruction. The specific rules for decomposition are shown

Table 2: Data Access Semantics and Their Address-Length Estimations

Data	Access Semantics	Example	Address Estimation	Length Estimation
Immediate Value	Integer Comparison	`x == 0`	Program Counter	Predicate Emulation
	Switch Statement	`switch (x) case 1:`	PC + Case Index	Switch Emulation
	Trivial Value	`y = x + 2`	Not Available (Represented by Code Coverage)	
Static Value	Load-Based Comparison	`p[x * y] - 1 > z`	Static Analysis	Predicate Emulation
	Region Comparison	`memcmp(p, q, 5)`	Base Pointer	Region Emulation
	Simple Load	`*p`	Pointer	Data Size

in Figure 5. During the decomposition, we remove unrelated numeric operations, such as casting (`(long)short_value`), intrinsic functions (`__builtin_bswap`), and binary operators (`x + 1` and `x | 1`). Once we have decomposed the value, we treat the load target address as the origin.

```
originOf (Load ptr)              = ptr
originOf (Cast value)            = originOf value
originOf (Intrinsic value operation)
    | operation is numeric       = originOf value
    | otherwise                  = ()
originOf (BinaryOperator lhs rhs) =
  case (originOf lhs, originOf rhs) of
    (lptr, ())                  -> lptr
    ((), rptr)                  -> rptr
    (lptr, rptr)                -> lptr
originOf (Argument _)            = ()
originOf (Constant _)            = ()
originOf (Instruction _)         = ()
```

Figure 5: Rules for deriving the origin of a value.

To instrument load-based comparisons, we use the above origin analysis to assist us. For each non-immediate comparison in the form of `lhs CMP rhs`, we insert a runtime call `trace_cmp(T lhs, T rhs, T* lptr, T* rptr)`, where `lptr` and `rptr` are the origin analysis results for `lhs` and `rhs`, respectively. For example, when instrumentation the comparison `p[x * y] > z`, we insert the runtime call `trace_cmp(p[x * y] - 1, z, p + x * y, NULL)`. The runtime function filters out non-static addresses according to the design described in §3.1.1. With the addresses filtered and the length computed through predicate emulation, we can update the data coverage at the end.

4.5 Region Comparison

Algorithm 2: Maintenance for Region Comparisons

Input: base pointer x and y, length l
Data: coverage database K
Data: novel set N
Output: comparison result
$r \leftarrow \text{OriginalComparison}(x, y, l)$;
$p \leftarrow \text{EstimateAddress}(x, y)$;
if $K_p = MAX$ **then**
  return r;
if r *is saturated* **then**
  $n \leftarrow MAX$;
else
  $m \leftarrow \text{PrefixBytes}(x, y, l)$;
  $n \leftarrow 8m + \text{UsedBits}(x_m \not\equiv y_m)$;
if $n > K_p$ **then**
  $K_p \leftarrow n$;
  $N \leftarrow N \cup \{p\}$;
return r;

Region comparisons, such as `memcmp`, are a specialized type of load-based comparison. Because data accesses in these comparisons occur in the operating system's C language runtime library, they cannot be directly intercepted by instrumenting the program's load instructions. To ensure that these data accesses are not missed, we use libFuzzer's weak hook infrastructure to reimplement these utility functions.

Specifically, C runtime libraries provide default implementations of utility functions that are marked as *weak* symbols. Since *regular* symbols take precedence over weak symbols according to linkage semantics, we provide our own versions of these functions as regular symbols, replacing the default implementations in the C runtime library. The specific logic of the interception function is shown in Algorithm 2.

First, we invoke the original C runtime library's function to compute the return value quickly. Next, we try to locate the access address and remove non-static-data accesses. Based on the comparison semantics, we mark the current comparison as saturated and skip the slow emulation if possible. If not, we compute the length in two steps: the common prefix m determines the size of the equal region at the byte level quickly, while the predicate emulation determines the number of effectively used bits for the first unequal byte precisely. We combine these results to obtain the total number of effectively used bits n and update the coverage accordingly.

4.6 Simple Load

To improve the precision of coverage tracking, we try to promote individual loads to load-based comparisons when instrumenting the program. If the promotion fails, we instrument the load as-is to ensure completeness. In such cases, we simply treat the bit width of the load instruction as the access length. However, most load instructions are not based on constant data and thus do not provide any benefits when instrumented. To avoid these cases, we use static analysis to prune them: before instrumenting a load instruction, we first locate the base memory object of the address and only proceed if the pointer is based on a static value.

5 Implementation

To assess the effectiveness of our data coverage approach, we developed a new fuzzer named WingFuzz. The fuzzer is built on top of libFuzzer from LLVM 14. We added runtime support and corpus saving logic for data coverage, and implemented instrumentation and static analysis using a compiler plugin based on the LLVM infrastructure [16].

Despite the invitation for integrating data coverage into AFL++ [11], we decided to use libFuzzer for fast prototyping when writing the paper. AFL++ is a complex fuzzer that incorporates numerous incremental research efforts. A simple integration of data coverage would potentially jeopardizing the validity of AFL++'s parameters derived from over 150 fine-tune experiments conducted on FuzzBench.

6 Evaluation

We used the classic code coverage approach and submitted WingFuzz to FuzzBench [23], the evaluation service developed by Google. FuzzBench follows the golden standard of fuzzing evaluation and publishes the results for open and reproducible science. With more than 400 experiments involving 100 fuzzers and their variants on a variety of real-world programs, it has become the de facto standard for evaluating fuzzing performance in both academia and industry.

Our evaluation follows the default setup of FuzzBench. It uses 19 target programs, runs for 23 hours, and repeats each trial for 20 times. Each trial runs on a single-core instance on Google Compute Engine with 3.75GB of memory available [23]. The baseline fuzzers used in the evaluation fully replicates the original FuzzBench paper's configuration, which includes classic works from academia and the default fuzz engines from OSS-Fuzz [1].

Through our empirical evaluation, we aim to answer the following research questions:

RQ1: Can data coverage improve fuzzing performance?
RQ2: Is data coverage orthogonal to prior techniques?
RQ3: How does individual component contribute?
RQ4: What is the runtime overhead of data coverage?
RQ5: Will the extra guidance cause state explosion?

6.1 Overall Fuzzing Performance

The evaluation summary from FuzzBench is presented in Table 3. The median branch coverage of all the 20 trials is used to calculate the metrics, where the fuzzer with the highest number of explored branches receives 100 points. The "average score" column represents the average score across all benchmarks, while the "average rank" column indicates the average of a fuzzer's relative rankings of scores.

Table 3: FuzzBench Evaluation Summary

Fuzzer	Average Score	Average Rank
WingFuzz	**98.31**	3.08
AFL++ [9]	96.91	**3.06**
Honggfuzz [31]	96.26	4.12
Entropic [5]	94.71	4.03
MOPT [21]	93.10	5.79
Eclipser [8]	92.86	6.31
AFLSmart [25]	92.84	5.28
AFL [37]	92.30	5.16
AFLFast [6]	88.77	7.70
libFuzzer [32]	87.65	7.09
LAFIntel [15]	86.47	8.17
FairFuzz [17]	84.67	7.44

- WingFuzz is based on libFuzzer.
- The full report can be found at https://www.fuzzbench.com/reports/experimental/2022-10-08-wingfuzz.

Our results demonstrate that the use of data coverage significantly enhances the average score, increasing it from 87.65 for libFuzzer to 98.31 for WingFuzz, thereby improving its rank by 9 places (12 in total). Furthermore, WingFuzz achieved the 2nd-lowest average rank (3.08), just 0.02 points behind AFL++, a sophisticated fuzzer that combines multiple incremental optimizations from the research community. An analysis of the individual benchmark ranks indicates that WingFuzz is resilient against various program types, with the minimum worst ranking of 8, while AFL++'s worst ranking was 10. Additionally, WingFuzz consistently delivers impressive results and had the lowest standard deviation (3.17) among all the fuzzers we evaluated.

To understand how data coverage assists code coverage guided fuzzer on individual programs, we compare the raw coverage improvements of individual programs between WingFuzz and its baseline version, libFuzzer. We present the raw data in Table 4, where the rows are sorted according to the gains in data coverage.

Table 4: Performance of WingFuzz Compared to libFuzzer

Benchmark	libFuzzer 23h Cov.	WingFuzz 23h Cov.	WingFuzz's Cov. Gains	Hours to 23h Cov.
sqlite3	11449.5	18142.0	+58.45%	0.25
freetype2	8173.5	12019.5	+47.05%	1.00
libxslt	8526.0	11446.0	+34.25%	0.25
woff2	987.0	1155.0	+17.02%	0.25
openthread	2247.0	2585.0	+15.04%	7.75
curl	8185.5	9046.5	+10.52%	0.25
libjpeg	1865.5	2046.5	+9.70%	1.00
libxml2	7885.0	8548.5	+8.41%	2.25
harfbuzz	7206.5	7760.0	+7.68%	1.00
mbedtls	2367.5	2527.5	+6.76%	0.50
php	15880.5	16785.5	+5.70%	0.25
proj4	4360.0	4512.0	+3.49%	4.00
bloaty	5723.0	5766.5	+0.76%	19.75
jsoncpp	519.0	518.0	-0.19%	/
re2	2566.0	2555.0	-0.43%	/
zlib	463.0	461.0	-0.43%	/
Average			+13.99%	2.96

We observe that data coverage significantly improves the coverage of a majority of programs by an average of 14%. In addition to improving code coverage, data coverage also accelerates fuzzing and reduces the time cost. On average, WingFuzz only requires 2.96 hours to achieve the same level of coverage as libFuzzer, which takes 23 hours.

In particular, data coverage performs exceptionally well on programs with large chunks of static data. For example, SQLite3 uses a static value-based table to encode parsing rules, freetype2 contains a complicated string processors for Type1 fonts, and libxslt consists of XML parsing logic. Take libxslt for a closer look. The semantics of input data are determined by predefined keys such as `<?xml`, `version`, and

`encoding`, providing more opportunities for our data coverage techniques to enhance fuzzing efficiency. However, we also observe minor regressions (-0.35% on average) on small, algorithm-oriented programs like zlib. For zlib, despite its complex in-memory operations, it uses straightforward constants such as 0 and 1 to maintain efficiency in its compression algorithms, which limits the effectiveness of advanced data coverage strategies.

> Data coverage significantly improves the overall fuzzing performance. It improved the code coverage of libFuzzer by 14%, lifting it to the 1st place in coverage score and 2nd place in average rankings. It also consistently delivers good results and has the lowest standard deviation.

6.2 Orthogonality to Prior Techniques

One valid concern about data coverage is that it could be similar to existing data-sensitive fuzzing techniques. For example, AFL++ [9] is a state-of-the-art fuzzer which constantly delivers superb performance on FuzzBench because it combines dozens of incremental research efforts including intelligent branch solving. In this section, we use AFL++ to showcase how data coverage differs from data-sensitive techniques.

First, we discovered that WingFuzz and AFL++ covered different sets of the same program in fuzzing. We assessed the raw coverage data from FuzzBench, comparing the differential "extra coverage" offered by both WingFuzz and AFL++ against the "baseline coverage" of libFuzzer across all programs. As Figure 6 shows, of all the additionally covered branches, 3,171 were detected by both, whereas 1,636 branches were exclusively uncovered by WingFuzz and 484 by AFL++. This indicates that over 34% of the additional coverage achieved by WingFuzz is unique and not replicated by AFL++, showcasing its distinctive advantage in tracking data coverage. In comparison, WingFuzz's data coverage methodology captures about 77% of the advancements AFL++ has over libFuzzer, leaving AFL++'s complex optimizations accounting for the remaining 23%.

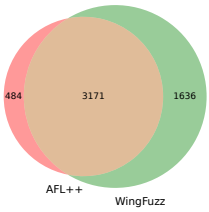

Figure 6: Extra coverage of WingFuzz and AFL++ over the baseline libFuzzer.

For a better understanding of the orthogonality between WingFuzz and AFL++, we conducted an ensemble fuzzing experiment, using the 20-hour corpus snapshot from FuzzBench for AFL++. We compared the performance of WingFuzz and AFL++ on three large benchmarks: freetype2, php, and libxslt, since these benchmarks are among the largest programs in FuzzBench, with more than 10,000 branches each. They allow for a meaningful comparison of the tools' ability to explore new code paths. We conducted fuzzing sessions for both tools on each benchmark, running for a duration of 3 hours and measured the number of unique branches discovered by each tool. The results show that WingFuzz significantly outperformed AFL++, discovering an average of 133 additional branches per benchmark compared to AFL++'s 16 (specifically, 35 v.s. 69 for freetype2, 8 v.s. 172 for php, and 6 v.s. 159 for libxslt) In other words, WingFuzz is 7x more efficient than AFL++ when fuzzing a saturated program.

Second, we found that WingFuzz can discover previously-unknown bugs in well-fuzzed programs, including AFL++. For instance, we identified two new bugs (issue #373 and #374) in the Little-CMS color management library. It's worth noting that Little CMS is a well-used package, which is integrated into widely-used software like Chromium, Firefox, and OpenJDK. These bugs eluded detection for an astonishing 14 years, even with Google OSS-Fuzz's continuous fuzzing with AFL++ and a variety of other fuzzers since 2016 and a manual audit in 2018 (refer to Issue #171). As demonstrated in Figure 7, the bug in Little-CMS pertain to its handling of ANSI/CGATS.17, a highly-structured color specification language that employs key-value pairs extensively. We adhered to established responsible disclosure guidelines: after assessing the impact of vulnerabilities, we notified the stakeholders and collaborated on mitigation to avoid misuse.

```
// BUG happens here.
nSamples = satoi(cmsIT8GetProperty(it8, "NUMBER_OF_FIELDS"));

const char* cmsIT8GetProperty(cmsHANDLE hIT8, const char* Key) {
  IsAvailableOnList(GetTable(it8)->HeaderList, Key, ...)
}

bool IsAvailableOnList(KEYVALUE* p, const char* Key, ...) {
  // Enumerates the input data by walking a linked list.
  for (; p != NULL; p = p->Next) {
    // String camparison, see Figure 2.
    if (cmsstrcasecmp(Key, p->Keyword) == 0) break;
  }
}
```

(a) Buggy code: linked list walk using static data.

NUMBER_OF_FIELDS 4 S BEGIN_DATA_FORMAT	I R G B END_DATA_FORMAT I NUMBER_OF_FIELDS 8

(b) Bug-triggering input with multiple key-value records.

Figure 7: Case study: previously-unknown bug of Little-CMS.

The library's parsing code heavily relies on data structures, featuring a linked-list walk and manually-implemented string comparison. This very characteristic facilitated the unearthing

of these bugs using our proposed data coverage approach. On the contrast, conventional fuzzers usually get lost in the same branch for different constant data references.

To further analyze how data coverage works on a variety of program types, we performed fuzzing on Serenity OS, a popular project on GitHub with over 24,500 stars. Google's OSS-Fuzz cluster continuously fuzzed it for more than two years [14], and more than 140 bugs have been discovered by code coverage-based fuzzers [24]. We conducted a bug-finding experiment on it, ensuring consistent compiler settings (`O2`, `fsanitize=address`), using default initial seeds from OSS-Fuzz, and setting an equal duration of 23 hours. The results underscore the efficacy of data coverage: WingFuzz successfully discovered 26 bugs in 17 components in the newest version of the OS (commit `4f496e97` on 2023-03-20), as depicted in Table 5. In contrast, AFL++ and libFuzzer detected 4 and 0 bugs, respectively.

Table 5: New Bugs in Serenity OS Detected by WingFuzz

Kind	Issue ID
Assertion failure	17936, 17938, 17939, 18303, 18305–18307, 18310, 18316–18321
Resource exhaustion	17937, 18309, 18312–18315
Memory safety	18036, 18044, 18302, 18304, 18324–25
Total	26 bugs

Data coverage is different from state-of-the-art techniques optimized for solving branches. For example, over 34% of the additional coverage achieved by WingFuzz is unique and not replicated by AFL++. It also found 28 previously-unknown bugs on programs well-tested by OSS Fuzz.

6.3 Contribution of Data Guidance Types

To further understand the impact of each guidance type, we conducted a controlled study using WingFuzz variants with varying levels of instrumentation. As Table 6 lists, we start with a minimal level of guidance (WingFuzz-Imm and WingFuzz-Static), and gradually restore the removed guidance until it matches the full version of WingFuzz.

Table 6: Fuzzing Guidance of WingFuzz Variants

Variant	Data Guidance		Code Guidance		Coverage
	Static	Immediate	Spatial	Temporal	
WingFuzz-Imm		Partial			60.78
WingFuzz-Static	✓				71.91
WingFuzz-Data$^-$	✓	Partial			79.25
WingFuzz-Data$^+$	✓	✓	✓		93.73
WingFuzz	✓	✓	✓	✓	94.48

One issue we encountered is related to trivial immediate values. As stated in §4.3, we use code coverage as a proxy of data coverage on trivial immediate values. However, this approach introduces code coverage, which may not be desired. Therefore, for strict control of variables, we partially collect the immediate values for WingFuzz-Imm, removing the dependency of code coverage. Similarly, we design two versions of WingFuzz-Data: WingFuzz-Data$^-$ is free from code coverage but may result in reduced data coverage of trivial values; WingFuzz-Data$^+$ is collects complete data coverage, but uses code coverage. Additionally, we disable temporal code coverage for WingFuzz-Data$^+$ to minimize the amount of information used.

We followed the evaluation best practices [13] and ran multiple 24-hour trials for 10+ benchmark programs. For unified measurement throughout this paper, we used the median value of all trials as the basis and computed the normalized coverage of each variant and presented the data in Figure 8.

WingFuzz-Imm and WingFuzz-Static only use immediate or static values for fuzzing guidance. WingFuzz-Imm only discovered an average of 61% of the maximal known coverage among all trials (14% – 84%, std = 20%). WingFuzz-Static discovered 72% coverage (39% – 92%, std = 18%), which is 11% more than WingFuzz-Imm. In fact, among all the 14 evaluated benchmarks, WingFuzz-Static outperforms WingFuzz-Imm

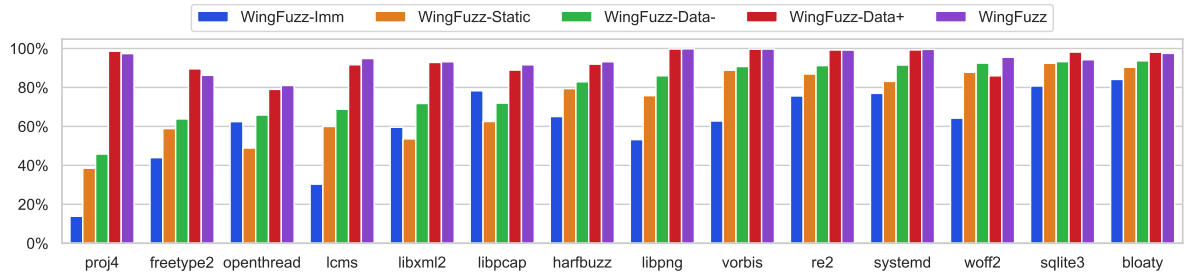

Figure 8: Normalized coverage of WingFuzz variants (see Table 6). Higher bars indicate better performance. The baseline fuzzer WingFuzz-{Static,Imm} only has static/immediate value as fuzzing guidance. The remaining fuzzers gradually enable immediate value (partial) and spacial/temporal feature of code coverage, respectively. The X axis is sorted by WingFuzz-Data$^-$.

on 11 benchmarks. This indicates that static values have rich semantics and can reflect a program's code behavior to some extent. For instance, SQLite3 is an embedded SQL engine that parses SQL using static-value-based automatons. It has 1,958 entries in the `yy_action` table. With pure static value coverage, we successfully explored 1,728 entries. With a high coverage of 88% for the action table, we obtained a high score of 92% for the overall program coverage.

WingFuzz-Data$^-$ offers a more complete view of data coverage, enabling partial immediate value guidance. Unlike static values, immediate values only carry simple semantics and are mostly trivial values. However, this scheme lacks the accounting for trivial values, which leads to a modest improvement of the coverage score to 79% (46% – 94%, std = 15%). Despite this limitation, the gains are consistent across all programs, with improvements ranging from 1% to 18%.

WingFuzz-Data$^+$ is the complete data coverage. Compared to WingFuzz-Data$^-$, it also detects trivial value usages, but introduces code coverage as a side effect. It further improves the score from 79% to 94% (79% – 100%, std = 6%). From the perspective of data coverage, the improvement can be explained by the characteristics of trivial values. Trivial values are the most common among all the three types of immediate values. For example, proj4 is a library for geodetic coordinate conversions. The computation involves a large number of trivial immediate values, such as the diameter of the Earth. When accounting for trivial values, the coverage score increased from 46% to 99%.

Surprisingly, WingFuzz-Data$^+$ outperforms the original WingFuzz on five programs, including sqlite3, freetype2, proj4, bloaty, and re2 (as shown in Figure 8). Unlike the original WingFuzz, which uses edge frequency as a guidance signal, WingFuzz-Data$^+$ leverages data coverage as a fuzzing signal, resulting in a superior signal-to-noise ratio. This approach provides strong and intuitive semantics, guiding the fuzzer to explore novel data references. In contrast, edge frequency may create noise by saving too many seeds and reducing overall efficiency.

> Data coverage is effective with or without code coverage. The use of code coverage along with data coverage can result in an additional 14% coverage, while using only static data coverage can achieve 72% of the maximum coverage observed. The number can be further increased to 94% if full data coverage is collected.

6.4 Memory and Execution Overhead

One potential drawback of using data coverage in fuzzing is the instrumentation overhead. In our implementation, we do incur a one-time memory overhead of 80 MiB. This allocation includes 16 million (2^{24}) slots for data coverage, since we limit the pointers to the last 24 bits. For each slot, we use 1 byte to store the data coverage information and an additional 4 bytes for the seed map. It is important to note that the 80 MiB allocation is performed once at program startup rather than for each seed. Instead of storing the raw coverage for each seed, we utilize a global storage mechanism to detect new coverage. This approach helps us reduce memory consumption by avoiding redundant storage of coverage information for each individual seed, enabling us to evaluate using FuzzBench, which limits the memory usage to 3.75GB.

Besides memory overhead, the collection of data coverage can also slow down fuzzing, which creates a negative impact particularly for shorter trials. To measure the actual impact of fuzzing, we extracted and analyzed the FuzzBench 15-minute snapshot, which is the earliest possible snapshot provided by FuzzBench. According to the 15-minute data, we found that WingFuzz achieved the best coverage score of 97.0 and the best average rank of 2.5. For the second-best fuzzer AFL++, is had the coverage score of 96.0 and an average rank of 2.7. As for the baseline libFuzzer, it only had 87.7 points of coverage score and had an average rank of 7.2. Therefore, data coverage is highly effective in discovering new program states, making the benefits of data coverage outweigh the overhead.

To further understand the overhead introduced by instrumentation, we measure the execution time of several differently instrumented target programs. To reduce the randomness of fuzzing, we collect the seeds of a fuzz campaign and use the same set of seeds on all programs. Figure 9 decomposes the execution duration of our instrumentation scheme, normalized to the baseline, non-instrumented program.

The blue bars of Figure 9 show the overhead introduced by code coverage instrumentation. Across the 14 programs we evaluated, the median overhead was 6% (0% – 33%, std = 8%). The red bars represent the overhead of our WingFuzz instrumentation, which includes both code and data coverage. We observed a median overhead of 61% (9% – 125%, std = 75%) for this instrumentation. This means that the introduction of data coverage reduces the fuzzing throughput by 34% compared to convention code coverage-guided fuzzing. The overhead mainly comes from the instrumentation of immediate and static values. Specifically, using immediate value tracking alone (orange bars) introduces a median overhead of 15% (-5% – 70%, std = 20%), while using static value tracking alone (green bars) introduces a median overhead of 26% (0% – 130%, std = 42%).

> The overhead of data coverage does not affect end-to-end fuzzing performance, even for short trials. In fact, data coverage yielded the highest coverage score in the shortest 15-minute evaluation. However, it did result in a reduction of throughput by 34%. This decrease is primarily due to the added overhead of collecting static values, which increases the execution duration by 26%.

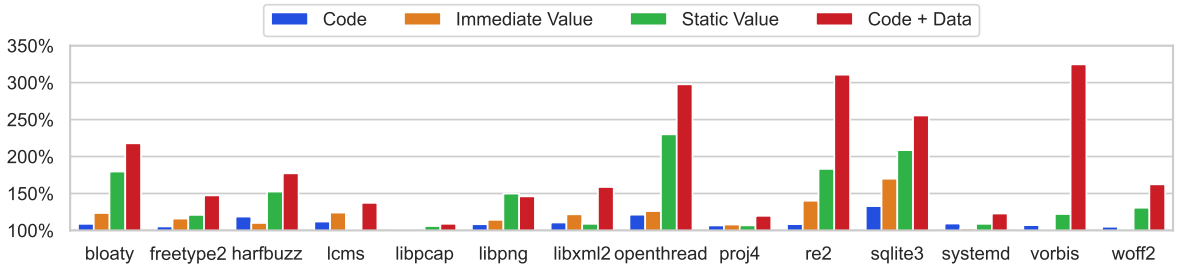

Figure 9: Normalized execution duration of programs in different instrumentation modes. Lower bars indicate better performance. For example, a value of "200%" indicates that the program executes at half the speed of the baseline version.

6.5 Queue Size and State Explosion

Fuzzers may tend to retain overly similar test cases when given very fine-grained data coverage feedback, which can hinder their ability to effectively explore and exploit the program state space within a bounded time frame. To address this issue, we employed a seed refinement strategy in WingFuzz and conducted an investigation using hourly corpus snapshots from the original FuzzBench experiment. For each duration, we normalized the queue size to the baseline of libFuzzer for each benchmark and plotted the mean value along with the error band of 95% confidence interval in Figure 10.

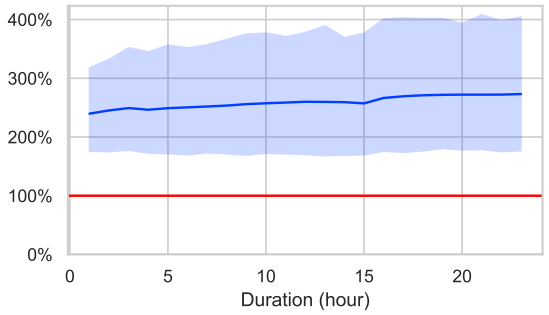

Figure 10: Temporal trend of normalized queue sizes using mean estimator with error band of 95% CI. The red horizontal line (100%) marks the queue size of libFuzzer.

Inside Figure 10, although we observed an increase in the queue size due to enhanced data coverage, it did not lead to unmanageable queue expansion. Among all trials from the FuzzBench experiment, WingFuzz discovered 139%, 150%, 159%, and 173% more seeds than libFuzzer at 1h, 6h, 12h, and 23h, respectively. This indicates a sustainable linear growth pattern rather than exponential explosion, suggesting that WingFuzz effectively balances between depth and breadth of state exploration. This analysis demonstrates the capability of WingFuzz to maintain a manageable queue size while achieving significant seed discovery rates compared to the baseline libFuzzer.

7 Related Work

Dataflow Guided Fuzzing While data coverage and dataflow-guided fuzzing share similar terminology, they represent distinct methodologies. Data coverage pertains to the analysis of a program's constant data utilization, whereas dataflow-guided approaches focus on capturing the data dependencies within code through def-use pairs.

For instance, in the context of the automaton depicted in Figure 3, where transitions are expressed as constant data, efficient exploration can be achieved through data coverage. However, distinguishing transitions becomes challenging for dataflow-guided techniques such as DDFuzz [22] and datAFLow [12]. These approaches primarily detect def-use pairs of code locations representing value definitions and usages. When the actual value is obscured behind a constant array instead of being directly associated with a code location, the differentiation of transitions becomes impractical.

Furthermore, the variance in design choices results in notable performance discrepancies. Our approach focuses solely on constant data, thereby minimizing the overhead in coverage collection to approximately 51%. In contrast, existing dataflow-guided techniques necessitate extensive instrumentation, leading to overheads as high as 10 times, as reported in datAfLow. Similarly, DDFuzz, when integrated with AFL++, exhibits decreased performance, as indicated in the FuzzBench evaluation [4].

Value Profile Introduced by libFuzzer in 2016, the "Value Profile" feature converts each comparison operation into a feature, leveraging the instruction and hamming distance between operands. Like our approach, which aims to maximize code coverage, libFuzzer endeavors to cover more value features. This technique bears some resemblance to our predicate emulation technique (see §3.1.3). However, our data coverage approach differs from Value Profile in two significant ways.

[4]The evaluation of DDFuzz and AFL++ on FuzzBench is available at https://www.fuzzbench.com/reports/experimental/2021-09-02-datadependency.

Firstly, while Value Profile diversifies discovered value features for code branches, our approach focuses on maximizing coverage for constant data. With our method, if a later execution covers more bits in a constant data operand used in the same comparison instruction, the prior seed is discarded since the newly discovered seed strictly covers more constant data than the previous one. In contrast, the Value Profile approach retains both seeds, potentially leading to seed explosion. Secondly, our data coverage approach targets constant data coverage more broadly, rather than focusing solely on immediate values used in branches. As shown in Figure 8, targeting overall static data coverage alone achieves a coverage score of 72 points, whereas the immediate-value-only variant (similar to Value Profile) only reaches 61 points.

The key distinction is that our approach aims to maximize coverage of all constant data, rather than solely solving individual branches. Interestingly, while our data coverage technique improves fuzzing performance, Value Profile actually reduces the coverage score of the original algorithm by 4 points, as reported in the original libAFL paper [10]. Indeed, among all evaluated techniques targeting fuzzing roadblocks, Value Profile performs the poorest. This broader perspective on constant data operands, rather than solely immediate values in branches, proves to be a more effective fuzzing strategy.

8 Discussion

Integration with Other Fuzzing Guidance In this paper, we delve into the concept of data coverage, presenting a novel coverage collection mechanism and scheduling strategy. While our enhancements to libFuzzer have yielded significant performance gains, the integration with other fuzzers and mechanisms is an area ripe for exploration.

Firstly, the concept of data coverage naturally aligns with more advanced code coverage forms such as context-sensitive edge coverage and branch n-grams. These approaches augment conventional code coverage by providing deeper guidance to the fuzzer. However, beyond simply introducing new guidance, it is crucial to adapt the scheduler to mitigate potential challenges, such as the seed explosion problem. For instance, when mutating a pathological input, numerous new coverage points may be generated in data coverage or n-gram code coverage. Yet, if these mutated inputs predominantly exhibit similar or identical program behaviors, blindly saving them as seeds would inundate the corpus with pathological cases, diverting resources from other potentially fruitful avenues.

Secondly, our seed replacement mechanism presents a promising solution to this challenge. Initially developed to address the seed explosion stemming from the extensive state transition table of SQLite's embedded state machine, this mechanism proved effective in curbing the proliferation of seeds, preventing out-of-memory errors caused by excessive seed generation. It remains to be seen whether this approach can be extrapolated to enhance the performance of fuzzers utilizing advanced code coverage feedback in diverse scenarios. By replacing seeds strategically, we can potentially mitigate the impact of seed explosion, enabling fuzzers to explore a broader spectrum of program behaviors efficiently.

Design of Data-Access Categories In this paper, we present an efficient coverage collection mechanism which categories the data access into six categories. While the categorization may appear detailed, it is crucial for striking the right balance between precision and practical applicability in real-world scenarios.

Our design, as outlined in Table 2, revolves around the core idea of differentiating these categories based on semantic distinctions to optimize data handling in terms of both address and length estimation. For example, if code coverage already reflects the coverage to an immediate value, we bypass instrumentation. However, for comparisons where individual bits might remain unused during execution, we employ sophisticated compile-time analysis and runtime instrumentation. This strategy minimizes operational overhead to 51%, compared to the typical 10x overhead seen in prior techniques such as datAFLow.

It is important to note that the optimal trade-off between precision and efficiency remains an ongoing exploration. The six-category design presented here is one of several possible approaches that have proven effective in practice. However, it may not be exhaustive, reflecting the design trade-offs we made between precision and efficiency. While this approach has shown efficacy within our system's context, we remain open to exploring additional data collection techniques to further enhance understanding and application.

9 Conclusion

In this paper, we explored how can data coverage assist guided fuzzing. We found that constant data encodes complex semantics that cannot be reflect by code coverage, neither can the challenge be resolved with constraint solvers. To enhance fuzzing with the guidance from constant data usages with reasonable fuzzing throughput, we designed an instrumentation based data coverage collection scheme. It also outperformed many advanced fuzzing strategies and achieved the best coverage score in the FuzzBench evaluation. We investigated the properties of data coverage with experiments. The major improvement comes from the static data, a sophisticated form of constant data with rich semantics.

I/O-Efficient Dynamic Searchable Encryption meets Forward & Backward Privacy

Abstract

We focus on the problem of I/O-efficient Dynamic Searchable Encryption (DSE), i.e., schemes that perform well when executed with the dataset on-disk. Towards this direction, for HDDs, schemes have been proposed with good *locality* (i.e., low number of performed non-continuous memory reads) and *read efficiency* (the number of additional memory locations read per result item). Similarly, for SSDs, schemes with good *page efficiency* (reading as few pages as possible) have been proposed. However, the vast majority of these works are limited to the *static* case (i.e. no dataset modifications) and the only dynamic scheme fails to achieve forward and backward privacy, the de-facto leakage standard in the literature. In fact, prior related works (Bost [CCS'16] and Minaud and Reichle [CRYPTO'22]) claim that I/O-efficiency and forward-privacy are two *irreconcilable* notions. Contrary to that, in this work, we "reconcile" for the first time forward and backward privacy with I/O-efficiency for DSE both for HDDs and SSDs. We propose two families of DSE constructions which also improve the state-of-the-art (non I/O-efficient) both asymptotically and experimentally. Indeed, some of our schemes improve the in-memory performance of prior works. At a technical level, we revisit and enhance the *lazy de-amortization* DSE construction by Demertzis et al. [NDSS'20], transforming it into an I/O-preserving one. Importantly, we introduce an oblivious-merge protocol that merges two equal-sized databases without revealing any information, effectively replacing the costly oblivious data structures with more lightweight computations.

1 Introduction

Searchable encryption has been the topic of a huge line of research (e.g., [14, 15, 19–23, 26, 29, 30, 34, 36, 40, 45, 48, 52, 53, 60–63, 66, 67, 69–72]). At the same time, it has been proposed for use in a number of different applications, e.g., for encrypted relational and graph databases [16, 18, 28, 44], annotated image search [2], encrypted email [54], or maintaining a secure gun registry service [43]. In fact, very recently, MongoDB announced support for a mode called *queryable* encryption, using techniques inspired by this line of research. The approach followed by most works is to strive for a high performance at the cost of well-defined *leakages* observed by the server storing the encrypted dataset. I.e., although it is required that the server never accesses decrypted data, *search* query on the data allows the server to learn some information that typically includes which entries are accessed for a query (*access pattern leakage*), which queries are for the same term (*search pattern leakage*), and how many entries are returned (*volume pattern leakage*). Dynamic Searchable Encryption (DSE) schemes have additional leakage considerations related to updates, i.e., do not reveal any connection of newly modified entries to previous ones, or do not reveal information of deleted entries during queries that take place after the deletion. DSE schemes that protect against both these leakages are called *forward-and-backward private* [12].

I/O overhead of DSE schemes. Existing state-of-the-art DSE schemes achieve extremely low computational overhead for search and update queries, typically in the order of a few milliseconds or even microseconds, even for massive datasets [14, 26]. The key reason for this is that they employ extremely lightweight symmetric-key cryptographic techniques, mainly pseudorandom functions (PRF) and symmetric key encryption. At a high level, most existing schemes use some variation of an *encrypted map* index [14], a key-value storage data structure where the values are encrypted tuples of the form (w, id) (where w is a keyword/term, and id is the identifier of a record from the dataset, and the tuple attests to "w appears in id)[1] and keys are computed *pseudo-randomly* with a PRF. This not only simplifies subsequent searches significantly, but also, due to the PRF usage, tuples are placed in random-looking positions in the index, which is crucial for minimizing the information revealed to the server about structure of the underlying dataset.

While this random placement does not significantly affect DSE performance when the encrypted index is stored in RAM

[1] In our constructions the tuple also contain the operation type: *(w,id,op)*.

Scheme	Storage	Search			Update	FP / BP	HDD / SSD /
		Locality	Read Efficiency	Page Efficiency	Cost		
LayeredSSE [55]	$O(N)$	$O(n_w/p+\log N)$	$O(\log\log N)$	$O(\log\log N)$	$O(n_w)$	✗ / ✗	SSD
Local[LayeredSSE] [55]*	$O(N)$	$O(1)$	$\tilde{O}(\log\log N)$	$\tilde{O}(\log\log N)$	$O(n_w)$	✗ / ✗	HDD
SD_a[1C [6]]	$O(N)$	$O(\log N)$	$O(\log N)$	$O(\log N)$	$O(\log N)(am.)$	✓ / II	HDD
SD_a[2C [6]]*	$O(N)$	$O(\log N)$	$O(\log N)$	$O(\log N)$	$O(\log^2 N)(am.)$	✓ / II	HDD
SD_a[NlogN [6]]	$O(N\log N)$	$O(\log N)$	$O(\log N)$	$O(\log N)$	$O(\log^2 N)(am.)$	✓ / II	HDD/SSD
SD_a[sN [31]]	$O(sN)$	$O(N^{\frac{1}{s}}+\log N)$	$O(\log N)$	$O(N^{\frac{1}{s}}/p+\log N)$	$O(s\log N)(am.)$	✓ / II	HDD/SSD
SD_a[Tethys/Pluto [10]]	$O(N)$	$O(n_w/p+\log N)$	$O(p)$	$O(\log N)$	$O(N\log N)(am.)$	✓ / II	SSD
L-SD_d[1C [6]]	$O(N)$	$O(\log N)$	$\tilde{O}(\log N)$	$\tilde{O}(\log N)$	$O(\log^2 N)$	✓ / II	HDD
L-SD_d[2C [6]]*	$O(N)$	$O(\log N)$	$\tilde{O}(\log N)$	$O(\log N)$	$O(\log^2 N)$	✓ / II	HDD
L-SD_d[NlogN [6]]	$O(N\log N)$	$O(\log N)$	$O(\log N)$	$O(\log N)$	$O(\log^3 N)$	✓ / II	HDD/SSD
L-SD_d[sN [31]]	$O(sN)$	$O(N^{\frac{1}{s}}+\log N)$	$O(\log N)$	$O(N^{\frac{1}{s}}/p+\log N)$	$O(s\log^2 N)$	✓ / II	HDD/SSD

Figure 1: Comparison of different *locality-aware* and *page-efficient* DSE schemes. For any function $f(N)$ the nonation $\tilde{O}(f(N))$ denote $O(f(N)(\log f(N))^x)$ for some constant x; n_w denotes the number of updates for a keyword w, and p denotes memory page size and *am.* stands for amortized complexity. **FP** and **BP** stands for forward privacy and backward privacy respectively; all the schemes except the schemes from [55] satisfy **FP** and **BP-II**. The sources of the schemes that $SD_a[\cdot]$ and L-$SD_d[\cdot]$ are instantiated with are cited inside the brackets. The schemes marked with * restrict keyword-lists' size to be at most $N^{1-1/\log\log N}$.

it can have a major negative impact, when it is stored on hard-disk. To see why, we need to consider that the I/O-related overhead of accessing disk data consists also of moving the disk head (a "mechanical" component). When using DSE to retrieve a result of R tuples, due to their random placement, causes (close to) R such head "jumps" (i.e. disk seeks in HDDs) if the index is sufficiently large. In this case, this turns out to be the main DSE bottleneck! Reading data from consecutive location costs orders of magnitude less than reading from random positions. In the relevant literature, the number of such jumps required for one DSE search query is referred to as *locality*. Cash and Tessaro [17] identified different interesting trade-offs between *locality* and *read efficiency*, i.e., the number of extra data that needs to be retrieved beyond the result itself (e.g., if we just want to minimize locality we can just retrieve and locally decrypt the entire dataset; clearly not a favorable trade-off in this case). Subsequent works [6,27,31] proposed improved schemes both from a theoretical perspective [6] and with good practical performance [6, 31]. For the case of SSDs, recent works [10, 55] indicate that the search performance depends on another metric which is called *page efficiency*, which is the ratio of the number of pages retrieved for the encrypted results to the number of pages that would have been retrieved for the plaintext result.

Unfortunately, all of these schemes with bounded *locality* and *page efficiency* are restricted in the *static* dataset case, without support for updates. The work closest to ours is the recent work of Minaud and Reichle [55] from CRYPTO'22, which suffers from two important drawbacks. First, its updates are very inefficient–the overhead of adding a single (w,id) tuple is proportional to the number of entries that already contain w. This is as costly as running a search for w, whereas prior DSE achieve constant or, at worst, logarithmic cost w.r.t the dataset size. Second, and arguably most important, the DSE of [55] *is not forward-private*. In practice, it stores all tuples for the same keyword directly in consecutive locations in the encrypted index (which very naturally gives it good locality), so just looking at the location a new entry is stored during an update, the server infers information about whether it is related to prior entries. Forward privacy has been shown to be very important in practice, not only because it allows the dataset to be incrementally built but also because it impairs existing privacy attacks against DSE [73].

Forward-privacy AND "good" locality? At first glance, these two properties seem inherently contradicting. Forward-privacy seeks to "eliminate" any information about new entries that can be inferred from where they are placed in the encrypted index (e.g., using random placement). On the other hand, good locality requires that entries for the same keyword are placed close to each other, ideally in contiguous disk locations! Indeed, the authors of [55] claim that the two properties, *locality* and *forward privacy*, *"seem to be fundamentally at odds."* Prior to this, Bost [11] claimed that the two are *"irreconcilable notions."*

Our results: I/O Efficient DSE with forward and backward privacy. Based on the above observation, it may seem that we cannot hope to achieve both of these properties. In this work, we disprove this by proposing the first DSE schemes that reconcile the two properties achieving bounded (logarithmic or polylogarithmic) *locality* and *page efficiency*, good overall practical performance, and forward-and-backward privacy! Our results can be summarized as follows. First, we observe that the generic "static-to-dynamic" transformation of Demertzis et al. [26], called SD_a, also works as a locality-preserving compiler that can produce forward and backward private DSE from existing *locality-aware*[2] static schemes

[2]Schemes with good locality are referred as *locality-aware* schemes

with just an extra logarithmic overhead for locality. This approach yields the first such DSE in the literature, albeit with "amortized" updates, as the client needs to periodically merge indexes into larger ones. In practice, while most updates are fast, some of them are significantly more resource-consuming.

Second, aiming for schemes with de-amortized updates, we begin with the de-amortized version of SD_a presented as the SD_d scheme in [26]. SD_d relies on oblivious dictionaries [68], [57] for the de-amortization, which makes updates computationally intensive and requires multiple rounds of interaction. In this work, we revisit this de-amortization strategy and *refine* it to make it work for a variety of schemes based on our computationally lighter approach of *oblivious-merge*. Our *oblivious-merge* merges encrypted indexes into bigger ones through multiple oblivious passes and oblivious-sort [5] and compaction operations in order to compute important metadata, decide about the placement of the input-elements, adjust properly the required dummy records and do the final placement. These operation require to operate on elements in chunks/batches, as opposed to the individual, one-by-one manner of SD_d. This necessitates multiple oblivious passes on these chunks and de-amortized oblivious-sort and compaction implementations in a manner that preserves forward and backward privacy. We named this new *locality-aware-deamortized* SD_a to be $\mathsf{L\text{-}SD}_d$. Using *oblivious sorting* based *oblivious merge*, instead of oblivious dictionaries as [26], asymptotically improves our update overhead by a logarithmic factor and also reduces the amount of interaction.

Third, we instantiate our two transformations $\mathsf{SD}_a[\cdot]$ and $\mathsf{L\text{-}SD}_d[\cdot]$ with several static schemes with (i) good *locality* (i.e. *locality-aware schemes*), well suited for HDD storage, i.e., the One Choice Allocation (1C), Two Choice Allocation (2C), NlogN from [6] and [31]; (ii) and with good *page efficiency*, well suited for SSD storage, i.e., the NlogN, [31] and Tethys/Pluto from [10]. While $\mathsf{SD}_a[\cdot]$ can be instantiated with any static SE scheme, $\mathsf{L\text{-}SD}_d[\cdot]$ can be instantiated only with One-Choice-Allocation, Two-Choice-Allocation and NlogN schemes. Figure 1 provides an overview of the asymptotic performance of the multiple schemes we achieve in this way from the literature [26,55]. Interestingly, not only our schemes are the *first* to combine I/O efficiency with forward and backward privacy, but they also asymptotically *outperform* prior (non forward-private) works.

Finally, we experimentally evaluate all of the proposed new DSE in HDD, SSD, and RAM for variable dataset and result sizes, considering both synthetic and real datasets [1]. We plan to make our code publicly available after publication. Our experimental results are very encouraging; it shows DSE with good I/O performance and strong privacy is not only possible but yields schemes with good practical performance. Below, we discuss our evaluation in more detail.

Experimental evaluation. We implemented all of our schemes and compare their search and update computation time with the state-of-the-art forward/backward private DSE schemes in HDD and SSD settings (Section 4). In particular, we implement 1C, 2C, NlogN schemes with $\mathsf{SD}_a[\cdot]$ and $\mathsf{L\text{-}SD}_d[\cdot]$[3], and compared them with the original PiBAS based SD_a and SD_d of [26]. In terms of search, SD_a[NlogN] has the best performance among the schemes at the cost of more storage. However, all of our amortized (SD_a[1C], SD_a[2C], and SD_a[NlogN]) and de-amortized ($\mathsf{L\text{-}SD}_d$[1C] and $\mathsf{L\text{-}SD}_d$[NlogN]) schemes with "good-locality" outperform PiBAS based SD_a and SD_d. I.e., they are up to **two** and **three** orders of magnitude faster in SSD and HDD settings respectively. Regarding the update computation time, PiBAS based SD_a has the worst update time. Turning to the de-amortized schemes, $\mathsf{L\text{-}SD}_d$[1C] has the best performance in memory and disk and is up to **4**× and **179**× faster than SD_d[PiBAS][4] respectively. Although we do asymptotic comparisons of our schemes with LayeredSSE and Local[LayeredSSE] [55] in Figure 1, we did not implement them, as these schemes are rather a theoretical work.

Comparison with additional prior works. Minaud and Reichle [56] independently and concurrently presented two theoretical page-efficient DSE schemes that are forward private. The selection of the construction is based on a relationship between the number of entries, page size, and number of keywords, which leaks more information than our approaches do (setup leakage). In addition, their constructions target only SSDs (and cannot be used for HDDs) require up to $O(N)$ client storage and its updates are very inefficient (similar to [55]). The concept of using oblivious sorting periodically and then de-amortizing it to equalize average and worst-case scenarios has been adopted in previous works, such as in the rebuilding of square-root ORAM [36] and hierarchical ORAMs [60] when inputs exceed trusted client memory. We are not the first to employ and de-amortize oblivious sort. Oblivious-sort was utilized also by [64]. However, their construction does not achieve backward privacy. Their solution was tailored to ensure quasi-optimal search time (i.e., search time independent of the deleted records), which is not our primary objective. Oblivious sort is used to avoid contiguous memory locations of deleted entries through binary search and to obliviously-sort/permute their indexes with sublinear available client memory (mirroring challenges faced by hierarchical and square-root ORAMs in prior works).

Limitations. A parallel line of research concentrates on leakage-abuse attacks for SE [9, 13, 25, 41, 49–51], as well as on defenses and mitigation techniques [28, 42, 65]. Our work does not offer new insights into leakage-abuse attacks or mitigation techniques. Instead, it adheres to the standard forward and backward privacy leakage profile for DSE.

[3] Referred as SD_a[1C],SD_a[2C], $\mathsf{L\text{-}SD}_d$[NlogN] etc.

[4] SD_d is the original version of [26] based on PiBAS, and SD_d[PiBAS] is our new framework instantiated with PiBAS, which are equivalent.

2 Preliminaries

Notation. Let $(x';y') \leftrightarrow P(x;y)$ denote a protocol execution between a client and a server, which may consist of multiple rounds of communication, and $(x';y') \leftarrow A(x;y)$ denote an algorithm execution, with no communication between client and server—x and x' are the input and output for the client, and y and y' are the input and output for the server. We denote by $\lambda \in \mathbb{N}$ a security parameter and by $v(\lambda)$ a negligible function in λ. PPT stands for Probabilistic Polynomial-Time. $\mathcal{D}$ is a collection of n documents with identifiers $id_1, \ldots, id_n$. A document contains a set of keywords from a dictionary Δ. Let DB consist of N tuples of the form (w, id, op)–file id contains keyword w, and op is either add or del, which denotes whether the tuple is for an insertion or deletion. $DB(w)$ is the set of identifiers of documents that contain keyword w. We use n_w to denote $|DB(w)|$, i.e. the result size of keyword w. The aforementioned tuples can be expanded to $(w, id, op, rank, n_w)$, where $0 \leq rank < n_w$. EDB denotes the encrypted database/index stored in the server.

Pseudo Random Functions (PRFs) [46]. A PRF function $F : \{0,1\}^{\lambda} \times \{0,1\}^* \rightarrow \{0,1\}^*$ is a two input function where the first input is the *key* and the second is the input x. F can be distinguished from a truly random function by a PPT adversary only with negligible probability $v(\lambda)$.

Dynamic Searchable Encryption (DSE). A DSE scheme Σ consists of a `Setup` algorithm, and (possibly interactive) protocols `Search` and `Update`–$\Sigma = (\texttt{Setup}, \texttt{Search}, \texttt{Update})$.

- $(K, \sigma; EDB) \leftarrow \texttt{Setup}(\lambda, N)$ takes as input the security parameter λ and N. Returns EDB to the server, and the secret key K and local state σ to the client.
- $(res, K, \sigma; EDB) \leftrightarrow \texttt{Search}(K, w, \sigma; EDB)$ is a protocol for searching keyword w. The output of this protocol is the query result res (i.e., $DB(w)$). The protocol may or may not modify K, σ and EDB.
- $(K, \sigma; EDB) \leftrightarrow \texttt{Update}(K, (w, id, op), \sigma; EDB)$ is a protocol that inserts/removes (w, id) to/from the DB–$op = add/del$. The protocol may modify K, σ and EDB. This protocol modifies EDB and may modify K and σ.

The `Search` and `Update` algorithm/protocols for the schemes presented in section 3.2 also include an additional parameter Γ, which is an instance of a static SE scheme[5]

Following [11, 12, 26, 35], we start from an empty database. Given an input DB of size N, the client populates EDB by calling the `Update` protocol N times. Other works [33, 47] equivalently modeled updates in document granularity, i.e., inserting or deleting an entire document. We focus on retrieving only the document identifiers upon `Search`; the client may retrieve the documents separately if needed. This leads to a straightforward leakage formulation and is more natural for database queries (e.g., [28, 32, 44]).

DSE–Leakages & Forward/Backward privacy. The standard security of a DSE scheme is parametrized by a leakage function $\mathcal{L} = (\mathcal{L}^{Stp}, \mathcal{L}^{Srch}, \mathcal{L}^{Updt})$. $\mathcal{L}^{Stp}$ corresponds to the leakage during the setup phase–in our case it reveals size of the database N; $\mathcal{L}^{Srch}$ corresponds to the leakage during search queries; $\mathcal{L}^{Updt}$ corresponds to the leakage during update queries. *Search pattern* leakage reveals which searches are related to the same w, and *access pattern* leakage reveals $DB(w)$ during a search for w. *Access pattern* leakage is unavoidable if the client retrieves the actual files with an additional round of communication with the server; schemes that avoid this leakage (e.g. by storing files in oblivious data structures) are referred as *result hiding* schemes.

A secure DSE scheme with leakage $\mathcal{L}$ should reveal nothing to an adaptive PPT[6] adversary about the database DB other than the leakage $\mathcal{L}$. This is formally captured by a standard real/ideal experiment presented in the extended version—for more details see [12, 35, 64].

Forward and backward privacy [12, 64] have become the de-facto security guarantees for modern DSE.

Forward privacy (**FP**): limits the information revealed due to updates. In particular, an $\mathcal{L}$-adaptively secure DSE is forward private *iff* the update leakage function $\mathcal{L}^{Updt}$ can be written as: $\mathcal{L}^{Updt}(op, w, id) = \mathcal{L}'^{Updt}(op, id)$ where $\mathcal{L}'$ is a stateless function, $op = add/del$, and id is a file identifier. Particularly, it should be impossible to tell whether an insertion is for a new keyword or a previously inserted/searched one.

Backward privacy (**BP**): ensures that during searches the server does not learn the identifiers of deleted documents that contained the searched keyword w. Bost et al. [12] proposed various formulations for this property. Here, we target backward private schemes that reveal the identifiers of (non-deleted) documents currently containing w (known as $TimeDB(w)$ leakage) and the timestamps and type (i.e. insertion and deletion) of all prior updates for w (known as $Updates(w)$ leakage). This corresponds to the **BP-II** definition from [12] (see the extended version for more details). $TimeDB(w)$ accounts for the leakage from retrieving the actual files; but we focus only on retrieving the document identifiers during `Search`, and we never use it in our proofs as none of our constructions explicitly leaks $TimeDB(w)$.

Definition 1 ([12]). *A DSE scheme Σ is $\mathcal{L}$-adaptively-secure with forward and backward privacy, iff $\mathcal{L}^{Updt}(op, w, id) = \mathcal{L}'(op)$ and $\mathcal{L}^{Srch}(w) = \mathcal{L}''(TimeDB(w), Updates(w))$* ***and*** *iff for any adaptive PPT adversary Adv issuing polynomially many queries q, there exists a stateful PPT simulator $\mathsf{Sim} = (SimSetup, SimSearch, SimUpdate)$ such that $|\Pr[\mathsf{Real}^{\mathsf{DSE}}_{Adv}(\lambda, q) = 1] - \Pr[\mathsf{Ideal}^{\mathsf{DSE}}_{Adv, Sim, \mathcal{L}}(\lambda, q) = 1]| < v(\lambda)$,*

[5] Γ is a static searchable encryption scheme such that $\Gamma = (\texttt{KeyGen}, \texttt{Setup}, \texttt{Search})$..

[6] An adaptive PPT decides its next step based on its previously observed leakages/search results.

where $\mathcal{L}'$ and $\mathcal{L}''$ are stateless functions; op is insertion or deletion, and id is a file identifier.

DSE for HDDs: Locality/Read-Efficiency/Update Locality/Update Cost/Space. To scale SE to big data using external memory (i.e., HDD drives), SE schemes with "small" locality and read efficiency have been proposed before. *Locality* is defined as the number of *non-contiguous* memory accesses made during the search by the server. *Read-efficiency* is the ratio of the total amount of data read/retrieved during the search over the actual query result size (for querying a keyword w)—see [17] for formal definitions. Cash and Tessaro [17] proved that any secure SE scheme with both optimal locality $O(1)$ and optimal read efficiency $O(1)$ requires $\omega(N)$ space. For locality-aware DSE schemes, in addition to the "search" and "static" efficiency, i.e., (i) locality, (ii) read-efficiency and (iii) space, we focus on two update metrics: (iv) update-locality, i.e., the number of *non-contiguous* memory accesses during an update and (v) update asymptotic cost, i.e., the asymptotic cost of one update (i.e., insert/delete one (w,id,op) tuple). See the extended version for the exact definitions.

DSE for SSDs: Page-Efficiency/Space. Bossuat et al. [10] proposed a new I/O-efficiency dimension for SSDs, which is called *page efficiency*—SSD performance mainly depends on page efficiency, aiming at reading as few memory pages as possible. More formally, *page efficiency* is the ratio of the total number of pages that the server accesses (using SE) over the optimal number of accessed pages in a plaintext case. For page-efficient DSE schemes, in addition to the "search" and "static" efficiency dimensions, i.e., (i) page-efficiency and (ii) space, we focus on (iii) update efficiency, i.e., the number of pages accessed during one update (i.e., insert/delete one (w,id,op) tuple) and (iv) update asymptotic cost (i.e., asymptotic cost of insert/delete of one (w,id,op) tuple). See the extended version for the exact definitions.

Oblivious sort. An oblivious sorting algorithm sorts an array of N elements without leaking information about the relative ordering of the input elements [4, 8, 38, 59]. We use the oblivious bucket sort [5], which has $O(N\log N)$ time complexity, and uses a temporary client storage of two buckets, where one bucket contains 512 elements. We can decompose bucket sort into $N\log N/\gamma$ rounds of $O(\gamma)$ work per round (e.g., for $\gamma = O(\log N)$ the oblivious bucket sort can be completed in N rounds). We highlight that fetching $O(\gamma)$ elements from disk requires always $O(1)$ locality, since accesses are performed on a bucket granularity, and on consecutive buckets— see the extended version for more details.

Oblivious compaction. Given an array of N elements, some of which are tagged with bit 1, and the rest with bit 0, an oblivious compaction [37, 39, 58] generates an output in which all the elements tagged with bit 1 appear before all the elements tagged with bit 0, without leaking the information of which elements were tagged with bit 1 or 0. Our constructions need the compaction to be order preserving, i.e. the relative ordering of the elements tagged with bit 1/0 do not change after the compaction. We use the oblivious bucket sort [5] mentioned above for performing order preserving compaction.

Oblivious Maps(OMAP) [24,68]. An oblivious map is a data structure that supports oblivious read/get and write/put functionality for encrypted $(key, value)$ pairs (i.e., oblivious hash map). That is, all same-length operation sequences appear indistinguishable. OMAP has the following algorithms/protocols: (i) OMAP.`Setup` initializes an empty data structure with maximum capacity N blocks, (ii) OMAP.`put` adds/overwrites a $(key, value)$ pair, and (iii) OMAP.`get` returns the *value* of a given *key*. We have used the AVL tree based implementation by Wang et al. [68] on top of PathORAM [65]. For a map with capacity N, each oblivious access requires $O(\log^2 N)$ operations/accessed-blocks, $O(\log N)$ roundtrips, and $O(\log^2 N)$ locality—see [68] for more details.

One-Choice Allocation. Asharov et al. [6] presented the One-Choice Allocation scheme (we will refer to it as 1C) that offers optimal locality, optimal space overhead and $O(\log N \log\log N)$ read efficiency. Given a database of size N, this scheme allocates an array of $m = N/\log N\log\log N$ bins, each of size $3\log N\log\log N$[7]. For each keyword w it computes a hash value $h(w)$, and stores the i^{th} document identifier in the bin $(h(w)+i) mod\ m$. Bins are filled up with *dummy* entries, if not full. The formal description of 1C is provided the extended version.

Two-Choice Allocation. Asharov et al. also presented the Two-Choice Allocation (2C) in [6]. For a database of size N, this scheme offers optimal locality and space overhead and $O((\log\log N)^A(\log\log\log N)^2)$ read efficiency assuming keyword list sizes $< N^{1-1/(\log\log N)^A}$, for a constant $A \geq 1$. This scheme allocates an array of $m = N/(\log\log N)^A(\log\log\log N)^2$ bins, each bin with size $z\cdot(\log\log N)^A\ (\log\log\log N)^2$, where $2 \leq z \leq 4$ (we use $A = 1$). The keyword lists are padded to be nearest power of 2 and stored in decreasing length order. For list for w, first it divides bins into groups of $sb = \frac{m}{n_w}$ *superbins*; i.e. each *superbin* consists of n_w bins. Then two superbins are chosen with two hash functions: $h_1(w)\%sb$ and $h_2(w)\%sb$. Finally, the superbin that has minimal load stores the list for w. The formal description of 2C is provided the extended version.

NlogN Scheme. The third scheme presented by Asharov et al. in [6] offers optimal locality and read efficiency at the cost of $O(\log N)$ storage overhead, i.e. a total of $O(N\log N)$ storage. We highlight this scheme provides optimal page efficiency. This scheme consists of $(\log N + 1)$ hash tables, each of size N. The keyword-lists are padded so that their length becomes nearest power of 2. The k^{th} hash-table stores lists of size 2^k. The pseudocode and more details of the NlogN scheme are

[7] The bins overflow with negligible probability when the bin size is set to $3\log N\log\log N$ for 1C.

provided in the extended version. Demertzis et al. [31] proposed a variation of the NlogN scheme in which only s of the above mentioned hash tables are stored; s is evenly distributed (i.e. the server stores the levels $\{0, x, 2x, \ldots (s-1)\cdot x\}$, where x is set to be $\lceil \frac{\log N+1}{s} \rceil$). In the worst case, a keyword-list is divided into smaller $O(N^{\frac{1}{s}})$ chunks. This scheme achieves optimal read efficiency, $O(N^{\frac{1}{s}})$ locality and has a $O(s)$ space overhead, and $O(\min\{N^{\frac{1}{s}}/p, p\})$ page efficiency (p denotes the memory page size). We refer to this scheme as sN.

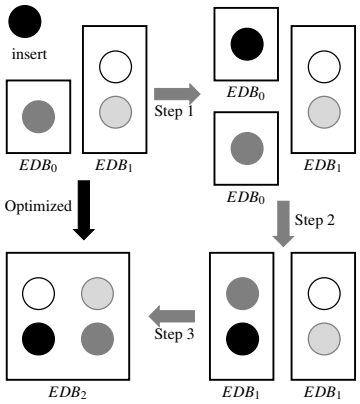
Encrypted dictionary. In our DSE constructions (in section 3) along with the encrypted index we have an encrypted dictionary. The encrypted dictionary maintains a keyword to keyword-counter mapping, i.e. keyword w maps to $|DB(w)|$. To perform searches in 1C, 2C, NlogN, and sN schemes the keyword-counter is required (to know how many bins to fetch, or which levels to search). We will refer to the encrypted dictionary as EDB.DICT and the encrypted index as EDB.IND. For an index with N entries the size of EDB.DICT is at most N, as there can be at most N distinct keywords.

3 DSE—I/O efficiency meets Forward/Backward Privacy

This section introduces our I/O efficient DSE schemes, which are the first to simultaneously achieve good I/O performance and forward/backward privacy. In Section 3.1, we apply the SD_a transformation, as proposed by Demertzis et al. [26], in conjunction with I/O efficient static SE schemes. In Section 3.2, we address the more challenging task of offering de-amortized I/O efficient constructions that ensure forward/backward privacy. Here, we introduce a novel *oblivious merge* framework to meet these objectives and present three implementations of this framework: the dynamic de-amortized 1C, 2C, and NlogN schemes.

3.1 Amortized Constructions using SD_a [26]

Overview of $\mathsf{SD}_a[\cdot]$. Demertzis et al. [26] introduced a compiler, SD_a, that converts any result hiding static SE scheme into a forward/backward private DSE scheme. The essence of SD_a is to store the results of N updates across $\log N$ indexes (ranging from $0th$ to $(\log N-1)th$). The ith index (EDB_i) has a size of 2^i. With each update, the client initializes the static SE scheme (using SE's `Setup`) to produce and upload an encrypted index with size 1 (EDB_0). When two same-sized indexes emerge (in server), the client downloads, decrypts and combines them into a doubled size index, amortizing the cost of updates. Searches are performed in each index independently. Figure 2 shows an update example using SD_a. The optimized pseudocode for SD_a, as depicted in Figure 2, can be found in the extended version.



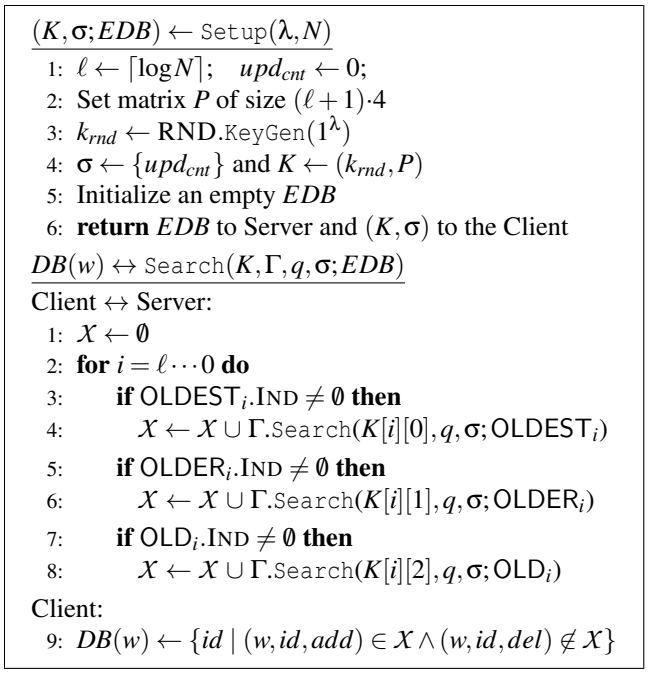


Figure 2: Update in SD_a. Before the insertion of the new (black) entry three previous consecutive insertions have created EDB_0. and EDB_1. After the fourth insertion, two EDB_0 indexes exist (Step 1), which are downloaded and merged to a single EDB_1 of size 2 (Step 2). Now, two EDB_1 indexes exist, which are downloaded and merged to a single EDB_2 of size 4 (Step 3). The black arrow shows an optimized version of SD_a where the intermediate steps are skipped.

In [26], the authors use PiBAS [14] as the underlying static SE scheme. PiBAS maps every (w, id, op) tuple to a pseudorandom location (using a counter cnt_w that is maintained locally for each keyword). During search for w, all locations for counter values $1, \ldots, cnt_w$ are accessed to retrieve the results. The results are decrypted and the deleted entries are filtered locally at the client. While this gives us a very simple and lightweight scheme, when it comes to I/O overhead, due to the pseudorandom placement, the number of disk head movements (HDD case) and the number of fetched pages (SDD case) is equal to the result size. In other words, $\mathsf{SD}_a[\cdot]$ when applied to PiBAS gives a DSE with the worst possible *search locality* and *page efficiency*.

I/O-efficient $\mathsf{SD}_a[\cdot]$. Our main observation here is that when applied to an *I/O-efficient* static scheme, the SD_a transformation gives dynamic schemes with "good" I/O performance. In fact, in the extended version we prove two theorems that state that the resulting $\mathsf{SD}_a[\Gamma]$ transformation will retain same *space-overhead* as that for Γ, where as for *locality*, *read-efficiency* (for HDDs) and *page-efficiency* (for SSDs) an additional factor of $O(\log N)$ is introduced as each index is queried independently

Locality-aware $\mathsf{SD}_a[\cdot]$ (for HDDs). There exist various candidates for static locality-aware schemes, the 1C and 2C schemes from [6] achieve optimal *locality*, storage, and poly-logarithmic *read-efficiency*. The NlogN scheme from [6] provides optimal *locality* and *read-efficiency* but increases storage. Other recent schemes are also introduced in [7, 27, 31].

Page-Efficient $\mathsf{SD}_a[\cdot]$ (for SSDs). Tethys [10] and NlogN [6] are candidates for static page-efficient schemes. Table 1

$(K,\sigma;EDB) \leftarrow \texttt{Setup}(\lambda,N)$

1: $\ell \leftarrow \lceil \log N \rceil$; $upd_{cnt} \leftarrow 0$;
2: Set matrix P of size $(\ell+1)\cdot 4$
3: $k_{rnd} \leftarrow \text{RND}.\texttt{KeyGen}(1^\lambda)$
4: $\sigma \leftarrow \{upd_{cnt}\}$ and $K \leftarrow (k_{rnd}, P)$
5: Initialize an empty EDB
6: **return** EDB to Server and (K,σ) to the Client

$DB(w) \leftrightarrow \texttt{Search}(K,\Gamma,q,\sigma;EDB)$

Client $\leftrightarrow$ Server:

1: $\mathcal{X} \leftarrow \emptyset$
2: **for** $i = \ell \cdots 0$ **do**
3: **if** $\mathsf{OLDEST}_i.\text{IND} \neq \emptyset$ **then**
4: $\mathcal{X} \leftarrow \mathcal{X} \cup \Gamma.\texttt{Search}(K[i][0], q, \sigma; \mathsf{OLDEST}_i)$
5: **if** $\mathsf{OLDER}_i.\text{IND} \neq \emptyset$ **then**
6: $\mathcal{X} \leftarrow \mathcal{X} \cup \Gamma.\texttt{Search}(K[i][1], q, \sigma; \mathsf{OLDER}_i)$
7: **if** $\mathsf{OLD}_i.\text{IND} \neq \emptyset$ **then**
8: $\mathcal{X} \leftarrow \mathcal{X} \cup \Gamma.\texttt{Search}(K[i][2], q, \sigma; \mathsf{OLD}_i)$

Client:

9: $DB(w) \leftarrow \{id \mid (w,id,add) \in \mathcal{X} \wedge (w,id,del) \notin \mathcal{X}\}$

Figure 3: SD_a/$\mathsf{L\text{-}SD}_d$: from Γ=(KeyGen, Setup, Search) to DSE (de-amortized version).

shows various SD_a instances from *locality-aware* and *page-efficient* static schemes. In this work, we emphasize the most practical I/O-efficient static SE schemes: 1C and 2C (suitable for HDDs) and NlogN(compatible with both HDDs and SSDs). The security and forward/backward privacy of the DSE schemes resulting from the $\mathsf{SD}_a[\cdot]$ transformation are directly derived from [26, Theorem 1]. In the extended version we provide a more detailed discussion for $\mathsf{SD}_a[\cdot]$.

3.2 De-amortized constructions: $\mathsf{L\text{-}SD}_d[\cdot]$

Although $\mathsf{SD}_a[\cdot]$ provides a clean way to transform a static SE scheme to a dynamic one, its drawback is that it has amortized update cost. In the worst case an update may require rebuilding an index of size N at once. Figure 16 illustrates the above weakness of schemes with amortized update cost. In this section, we construct I/O efficient DSE schemes with de-amortized updates and with forward and backward privacy. Our starting point is the de-amortization strategy that Demertzis et al. [26] proposed for SD_a, called SD_d (which is tailored on PiBAS [14]; pseudocode of PiBAS can be found in the extended version. In this work, we introduce $\mathsf{L\text{-}SD}_d$, which is simpler than SD_d and separates the static-to-dynamic transformation from the underlying static SE scheme. We highlight that $\mathsf{L\text{-}SD}_d$ is not a compiler; it is specifically tailored for certain schemes, namely 1C, 2C, and NlogN schemes. We present $\mathsf{L\text{-}SD}_d$ primarily as a framework for the sake of clarity and concise presentation. Below, we explain the new $\mathsf{L\text{-}SD}_d$:

Overview of $\mathsf{L\text{-}SD}_d[\cdot]$. The main idea of $\mathsf{L\text{-}SD}_d[\cdot]$ framework is to split construction steps of index level i over the previous 2^i insertions. We use a static SE scheme Γ=(KeyGen, Setup, Search). For dataset size N, $\mathsf{L\text{-}SD}_d[\Gamma]$ keeps $\log N$ index levels. Every ith index level has 4 indexes (a.k.a. NEW_i, OLD_i, OLDER_i and OLDEST_i); every index stores 2^i real entires. The $\mathsf{L\text{-}SD}_d[\Gamma].\texttt{Search}$ simply queries the OLD_i, OLDER_i and OLDEST_i indexes by individually calling $\Gamma.\texttt{Search}$ for all $\log N$ levels as a black box (see Search in Figure 3). Index NEW_i is used as a temporary buffer for moving elements between levels $i-1$ and i during $\mathsf{L\text{-}SD}_d[\Gamma].\texttt{Update}$. Below, we explain $\mathsf{L\text{-}SD}_d[\Gamma].\texttt{Update}$ in three rules:

(Rule 1): An update for (w,id,op) (insert or delete) is performed by creating NEW_0 (i.e. an encrypted index NEW_0.IND and an encrypted dictionary NEW_0.DICT) by calling $\Gamma.\texttt{KeyGen}$ and $\Gamma.\texttt{Setup}$ in a black-box manner (see lines 11-12 in Figure 4)—this instantly triggers the next rule.

(Rule 2): If NEW_i.IND is full, then NEW_i is moved[8] to the oldest *empty* index among OLDEST_i,OLDER_i, and OLD_i (see lines 13-15 for level 0 and lines 5-10 for level i in Figure 4). At the end of 2^i updates (equivalently moving $2\cdot 2^{i-1}$ elements from level $(i-1)$) NEW_i.IND becomes full, which triggers two actions in level $(i-1)$: OLD_{i-1} is moved to OLDEST_{i-1}, and OLDER_{i-1} is set to be empty (line 6).

(Rule 3): If both OLDER_{i-1}.IND and OLDEST_{i-1}.IND are full, all the elements of OLDER_{i-1}.IND $\cup$ OLDEST_{i-1}.IND are moved to NEW_i.IND over the next 2^i updates. Thus, at the end of these 2^i updates NEW_i.IND is full, and hence NEW_i is moved to the oldest *empty* index in level i using Rule 2.

We demonstrate the above $\mathsf{L\text{-}SD}_d[\Gamma]$ rules graphically in Figure 5. So far, all the actions needed for enforcing the Rules 1 and 2 during $\mathsf{L\text{-}SD}_d[\Gamma].\texttt{Update}$ and $\mathsf{L\text{-}SD}_d[\cdot].\texttt{Search}$ are either agnostic to the static SE scheme Γ, or are using Γ in a black-box manner. We mention that the actions needed for $\mathsf{L\text{-}SD}_d[\Gamma].\texttt{KeyGen}$ are also agnostic to Γ (see Figure 3).

We would like to emphasize that up to this point, $\mathsf{L\text{-}SD}_d$ is identical to SD_d [26]. Below, we detail how $\mathsf{L\text{-}SD}_d$ differs from SD_d. Rule 3 gradually builds NEW_i by moving elements from OLDER_{i-1}.IND and OLDEST_{i-1}.IND, i.e. $\Gamma.\texttt{Setup}$ for NEW_i needs to be executed in an incremental fashion. In other words, $\Gamma.\texttt{Setup}$ cannot be used as a black-box here. To overcome this obstacle, we define a new *oblivious merge* protocol as follows:

$$\mathsf{NEW}_i \leftarrow \texttt{oblMerge}_i(K,\sigma,\mathsf{OLDEST}_{i-1},\mathsf{OLDER}_{i-1})$$

For each index level i, an instance of *oblivious merge* (denoted as $\texttt{oblMerge}_i$) needs to be executed. The $\texttt{oblMerge}_i$ protocol takes as input a structure of necessary keys as K (created and maintained from $\mathsf{L\text{-}SD}_d[\cdot]$), client's local state σ, OLDEST_{i-1} and OLDER_{i-1}, and creates NEW_i. We claim that if a static $\Gamma.\texttt{Setup}$ can be transformed to an $\texttt{oblMerge}_i$ with the following three properties then it can be used in conjunction with the $\mathsf{L\text{-}SD}_d$'s update functionality to de-amortize

[8] $\mathsf{OLDEST}_i \leftarrow \mathsf{NEW}_i$ is syntactic sugar for (OLDEST_i.IND, OLDEST.DICT) $\leftarrow$ (NEW_i.IND, NEW_i.DICT)

$\underline{(K,\sigma;EDB) \leftrightarrow \texttt{Update}(K,(w,id,op),\Gamma,\sigma;EDB)}$

Client $\leftrightarrow$ Server:

1: Parse K as (k_{rnd},P) ▷ k_{rnd} is encryption key, P is an array of PRF keys
2: **for** $i=\ell,\ldots,1$ **do**
3: **if** $\mathsf{OLDEST}_{i-1}.\textsc{Ind} \neq \emptyset \wedge \mathsf{OLDER}_{i-1}.\textsc{Ind} \neq \emptyset$ **then** ▷ Γ is {PiBAS,1C,2C,NlogN}
4: Execute the next γ steps of $\Gamma.\texttt{oblMerge}(K,\sigma,\mathsf{OLDEST}_{i-1},\mathsf{OLDER}_{i-1})$ and update NEW_i
5: **if** $\mathsf{NEW}_i.\textsc{Ind}$ is full **then** ▷ Client can deduce this from upd_{cnt}
6: Server sets $\mathsf{OLDEST}_{i-1} \leftarrow \mathsf{OLD}_{i-1}$ and $\mathsf{OLDER}_{i-1} \leftarrow \emptyset$
7: **if** $\mathsf{OLDEST}_i.\textsc{Ind} = \emptyset$ **then** server sets $\mathsf{OLDEST}_i \leftarrow \mathsf{NEW}_i$ and client sets $P[i][0] \leftarrow P[i][3]$
8: **else if** $\mathsf{OLDER}_i.\textsc{Ind} = \emptyset$ **then** server sets $\mathsf{OLDER}_i \leftarrow \mathsf{NEW}_i$ and client sets $P[i][1] \leftarrow P[i][3]$
9: **else** server sets $\mathsf{OLD}_i \leftarrow \mathsf{NEW}_i$ and client sets $P[i][2] \leftarrow P[i][3]$
10: Client sets $P[i][3] \leftarrow \Gamma.\texttt{KeyGen}(1^\lambda)$
11: Client sets $P[0][3] \leftarrow \Gamma.\texttt{KeyGen}(1^\lambda)$
12: Client runs $\Gamma.\texttt{Setup}(P[0][3], (w,id,op))$ and sends the output to server who stores it as NEW_0
13: **if** $\mathsf{OLDEST}_0.\textsc{Ind} = \emptyset$ **then** server sets $\mathsf{OLDEST}_0 \leftarrow \mathsf{NEW}_0$ and client sets $P[0][0] \leftarrow P[0][3]$
14: **else if** $\mathsf{OLDER}_0.\textsc{Ind} = \emptyset$ **then** server sets $\mathsf{OLDER}_0 \leftarrow \mathsf{NEW}_0$ and client sets $P[0][1] \leftarrow P[0][3]$
15: **else** Server sets $\mathsf{OLD}_0 \leftarrow \mathsf{NEW}_0$ and client sets $P[0][2] \leftarrow P[0][3]$
16: Client sets $upd_{cnt} \leftarrow upd_{cnt}+1$
17: **return** EDB to Server and (K,σ) to Client

Figure 4: SD_d/L-SD_d: from Γ=(KeyGen, Setup, Search) to DSE (de-amortized version).

the corresponding $\mathsf{SD}_a[\Gamma]$ construction (maintaining forward and backward privacy). These properties are:

- (P1): *Obliviousness*—$\texttt{oblMerge}_i$ has to be oblivious—an algorithm/protocol is oblivious iff for any two same-sized sequence of memory accesses their resulting access patterns are indistinguishable for anyone but the client. In other words, we assume the existence of a simulator, $\texttt{Sim-oblMerge}_i$, which takes as an input only the size of the ith index (i.e. 2^i) and is indistinguishable from $\Gamma.\texttt{oblMerge}_i$ by any PPT adversary (later, we prove that our $\Gamma.\texttt{oblMerge}_i$ is oblivious for $\Gamma \in \{\text{1C},\text{2C},\text{NlogN}\}$).
- (P2): *Input-Output Indistinguishability*—A PPT adversary can recover a "mapping" between the encrypted input entries (contained in $\mathsf{OLDEST}_{i-1}.\textsc{Ind}$ and $\mathsf{OLDER}_{i-1}.\textsc{Ind}$) and the corresponding output ones (in $\mathsf{NEW}_i.\textsc{Ind}$) after the execution of $\texttt{oblMerge}_i$ only with a negligible advantage.
- (P3): *Decomposability*—Given $\texttt{oblMerge}_i$ that requires $s(2^i)$ steps to produce NEW_i, can be decomposed into $s(2^i)/\gamma$ rounds/steps of γ work at a time (i.e., per update).

We need (P1) in order to achieve forward privacy. If $\texttt{oblMerge}_i$ is oblivious, then nothing is leaked about the elements that we are moving from level $(i-1)$ to level i, i.e., during an individual update/movement the leakage function $\mathcal{L}^{Updt}$ can be written as: $\mathcal{L}^{Updt}(op,w,id) = \mathcal{L}'^{Updt}(op,id)$ where $\mathcal{L}'$ is a stateless function. (P2) is not required for the security of L-$\mathsf{SD}_d[\Gamma]$, e.g., the original PiBAS-based L-SD_d in [26] does not achieve (P2) (explained later). However, we will see that (P2) is byproduct of (P1) when Γ is I/O efficient, as well as it simplifies the security analysis of our L-$\mathsf{SD}_d[\Gamma]$ (the simulator can use the search simulator of Γ in black box).

Regarding (P3), every algorithm/protocol naturally can be decomposed into instructions (e.g., CPU instructions), or sets of instructions. By maintaining a state locally (e.g. a counter for each ith level), and running a set of instructions at a time, we guarantee the correct execution of the algorithm/protocol. (P3) allowed us to describe L-$\mathsf{SD}_d[\Gamma]$ independent to the used static scheme Γ and simplify the presentation of $\Gamma.\texttt{oblMerge}_i$.

The original Update protocol of SD_d in [26], which was PiBAS-specific SD_d, achieves properties (P1) and (P3). We can also transform PiBAS (and its setup) to an oblMerge protocol in order to fit to the the new L-$\mathsf{SD}_d[\cdot]$ transformation. For completeness, we provide PiBAS.oblMerge in the extended version. Both versions, SD_d presented in [26] and SD_d[PiBAS] fail to achieve (P2) (i.e. *input-output indistiguishability*). For moving each input entry e (from $\mathsf{OLDEST}_{i-1}.\textsc{Ind} \cup \mathsf{OLDER}_{i-1}.\textsc{Ind}$)—one by one, it simply does two oblivious accesses to an oblivious dictionary, and it performs a "write" in a random position in NEW_i (using a PRF), i.e. the server can see the corresponding chosen positions in NEW_i. However, the security does not fail since the positions in NEW_i are chosen randomly. We can also construct L-SD_d[PiBas] that achieves all the properties, including (P2). This construction improves the update cost of the original SD_d by a logarithmic factor (the pseudocode provided in the extended version). The proof has been omitted because it can be derived from the L-SD_d proof, as it is based on a subset

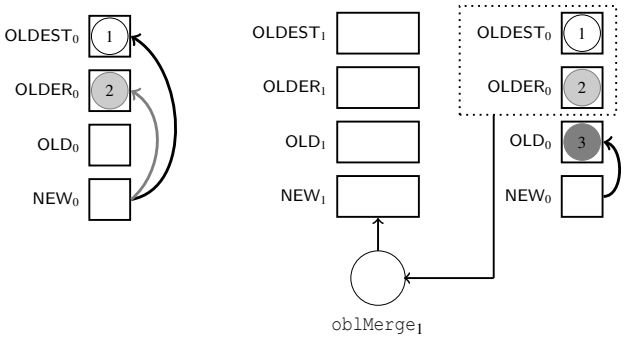

Figure 5: SD$_d$/L-SD$_d$[Γ] framework. (a) The first element inserted to NEW$_0$ (Rule 1). NEW$_0$ becomes full and it is moved to OLDEST$_0$ (Rule 2). Similarly, the second inserted element to NEW$_0$ (Rule 1) is moved to OLDER$_0$ (Rule 2). (b) During the third insertion, both OLDEST$_0$ and OLDER$_0$ are full and Γ.oblMerge$_1$ is called (Rule 3) to move elements from OLDEST$_0$ ∪ OLDER$_0$ to NEW$_1$. The third insertion is moved to OLD$_0$ (Rules 1 and 2).

of the computations required by L-SD$_d$. In our experimental evaluation, we refer to this construction as L-SD$_d$[PiBas].

Phases of `oblMerge` framework. Now we will present our `oblMerge` framework that ensures properties (P1), (P2), and (P3) for the static SE scheme $\Gamma \in \{1C, 2C, NlogN\}$, in detail. Similar to SD$_a$, we have L-SD$_d$[1C] and L-SD$_d$[2C] (suitable for HDDs), as well as L-SD$_d$[NlogN] (compatible with both HDDs and SSDs). The corresponding is presented in Figure 6. Some of the steps are not necessary for all the schemes in {1C, 2C, NlogN}, but we needed them in order to create the general `oblMerge` framework. Towards the end of this section we discuss some optimization specific to each scheme. Here, we also would like to point out, the temporary client storage cost is upper bounded by the update cost (e.g. $O(\log^2 N)$ for L-SD$_d$[1C]), while the permanent client storage is constant.

The high level idea is, instead of moving elements directly from OLDER$_{i-1}$.IND ∪ OLDEST$_{i-1}$.IND to NEW$_i$.IND (using oblivious dictionaries, as done in [26]), move them to a buffer $\mathbf{BUF}_1$ first. This step will ensure property (P2). Then with oblivious operations, re-order the entries of $\mathbf{BUF}_1$ to satisfy the I/O efficiency requirements of scheme Γ, and then move $\mathbf{BUF}_1$ to NEW$_i$.IND. This step and the previous step together ensure property (P1). The buffer, $\mathbf{BUF}_2$, is used to create the keyword dictionary, NEW$_i$.DICT, in an oblivious fashion as well. The references to OLDER$_{i-1}$ and OLDEST$_{i-1}$ are passed as parameters to the `oblMerge`$_i$ protocol. Each `oblMerge`$_i$ instance runs in four phases. Below we discuss the four phases in detail. Refer to Figure 6 for the pseudocode. If a step in the pseudocode does not mention who is performing it (i.e. Client or Server), it means multiple rounds of communication happens between the client and the server to perform that step. Finally, at the end of 2^i calls to `oblMerge`$_i$ it returns NEW$_i$ (i.e. NEW$_i$.IND and NEW$_i$.DICT).

Phase 1. Entries of OLDER$_{i-1}$.IND ∪ OLDEST$_{i-1}$.IND are first copied (not moved) to $\mathbf{BUF}_1$. Next, $\mathbf{BUF}_1$ is obliviously sorted based on the lexicographic order of the keywords (line 3). The sort places entries for the same keyword adjacent to each other in $\mathbf{BUF}_1$, and the dummy entries are placed at the end. Each entry of $\mathbf{BUF}_1$ is then assigned a *rank* and an n_w value via two linear scans (line 4). Next, each keyword-list in $\mathbf{BUF}_1$ is padded to make their lengths to be nearest power of 2 (line 5). Another oblivious sort is performed on $\mathbf{BUF}_1$, based on the lexicographic order of the keywords, as well as descending order of the n_w values (line 6). This sort places same keyword entries adjacent to each other and entries with higher n_w values are placed before entries with lower n_w values in $\mathbf{BUF}_1$. We provide a more detailed pseudocode for lines 4 and 5 in the extended version.

Phase 2. This phase prepares the elements in $\mathbf{BUF}_1$ for NEW$_i$.IND by adding proper position tags to them (lines 12-13), and prepares $\mathbf{BUF}_2$ for creating NEW$_i$.DICT (lines 9-11). For every entry in $\mathbf{BUF}_1$ $(w, id, op, rank, n_w)$ an entry is appended to $\mathbf{BUF}_2$. When $rank = 0$, a real entry (w, n_w, p) is appended to $\mathbf{BUF}_2$. In all other cases a dummy entry $(\perp, \perp, \perp)$ is added (line 11) (because we can neither reveal the length of each keyword-list, nor the number of unique keywords). Here, p is a uniformly generated random key of λ bit. The `Map` function of Γ is called for each entry of $\mathbf{BUF}_1$, which returns a pair $(level, pos)$. For every $\Gamma \in \{1C, 2C, NlogN\}$ the pseudocode for the corresponding `Map` function is provided in the extended version. For 1C and 2C the value of *level* indicates the bin number assigned to this entry, and *pos* is 0 by default. Whereas, for NlogN scheme $level (\in \{0, \ldots, i\})$ indicates the array level, and position indicates the position $pos (\in \{0, \ldots, (2^{i-level}\text{-}1)\})$ in the array level. The encrypted entry $(w, id, op, level, pos)$ replaces the existing $(w, id, op, rank, n_w)$ entry in $\mathbf{BUF}_1$.

Phase 3. This phase adds dummy elements (lines 14-15) to $\mathbf{BUF}_1$, beacuse every bin needs to be filled up to their maximum capacity. For 1C and 2C if bin size is b_i then the dummy element $(\perp, \perp, \perp, bin, 0)$ is appended to $\mathbf{BUF}_1$ b_i times. This step is repeated for each bin number *bin*. For NlogN scheme, array level k contains 2^{i-k} lists of size 2^k. Hence, the dummy entry $(\perp, \perp, \perp, k, pos)$ is appended 2^k times for each $pos \in \{0, \ldots, (2^{i-k} - 1)\}$. This step is repeated for levels $k \in \{0, \ldots, i\}$. We add a total of $3 \cdot 2^i$ dummy elements for 1C and 2C and $2^i \cdot \log 2^i$ dummy elements for NlogN. The goal is to add dummy entries for every vacant positions of the bins/levels. But we want to hide the number of real elements in each bin/level, and so the number of dummy elements we add is equal to the index size. Extra dummy elements are discarded in Phase 4.

Phase 4. This phase consists of few steps. The oblivious sort on line 16 sorts $\mathbf{BUF}_1$ based on $(level, pos)$ values. Dummy elements come last, as usual. But now we have more elements assigned to each bin/level than their capacity. Hence, with a linear scan (line 17) unnecessary elements are tagged with

$\Gamma \in \{\mathsf{1C}, \mathsf{2C}, \mathsf{NlogN}\}$
If $\Gamma = \mathsf{1C}$, $N' = 3{\cdot}2^i, m_i = \lceil \frac{2^i}{\log 2^i \log\log 2^i} \rceil$, $\forall level \in \{0 \ldots m_i - 1\}$ $b_{level} = 3{\cdot}\log 2^i \log\log 2^i$ and $c_{level} = 0$
If $\Gamma = \mathsf{NlogN}$, $N' = 2^i{\cdot}\log(2^i + 1)$, $m_i = (i+1)$, $\forall level \in \{0 \ldots m_i - 1\}$ $b_{level} = 2^{level}$ and $c_{level} = 2^{i-level}$
If $\Gamma = \mathsf{2C}$, $N' = z{\cdot}2^i, m_i = \lceil \frac{2^i}{(\log\log 2^i)(\log\log\log 2^i)^2} \rceil$, $\forall level \in \{0 \ldots m_i - 1\}$ $b_{level} = z{\cdot}(\log\log 2^i)(\log\log\log 2^i)^2$ and $c_{level} = 0$, $2 \le z \le 4$

$\mathsf{NEW}_i \leftrightarrow \Gamma.\texttt{oblMerge}_i(K, \sigma; \mathsf{OLDEST}_{i-1}, \mathsf{OLDER}_{i-1})$
Client $\leftrightarrow$ Server:

//** Phase 1 - Preparing sorted input array **//
1: Client parses K as (k_{rnd}, P) ▷ all encryptions and decryptions are done with key k_{rnd}, P is an array of PRF keys
2: Server initializes arrays $\mathbf{BUF}_1$ of size $3{\cdot}N'$, and $\mathbf{BUF}_2$ of size N' to be empty at Server
3: Copy $\mathsf{OLDEST}_{i-1}.\textsc{Ind} \cup \mathsf{OLDER}_{i-1}.\textsc{Ind}$ to $\mathbf{BUF}_1$; obliviously sort $\mathbf{BUF}_1$ w.r.t. lexicographic order of keywords
4: Perform two linear scans (one in reverse and one in correct order) on $\mathbf{BUF}_1$, to add the *rank* and n_w values to each entry of keyword w. The entries now look like $(w, id, op, rank, n_w)$, where $0 \le rank < n_w$.
5: Linearly scan $\mathbf{BUF}_1$ and pad each keyword-list with dummy elements so that its size is nearest power of 2, hide list lengths by padding total size to $2N'$
6: Perform oblivious sort on $\mathbf{BUF}_1$ w.r.t. lexicographic order of the keywords and descending order of the n_w values. Keep first N' elements.

//** Phase 2—Prepare index elements and prepare keyword counters **//
7: **for** each $j = 1 \ldots |\mathbf{BUF}_1|$ **do**
8: Client decrypts $(w, id, op, rank, n_w) \leftarrow \text{RND}.\texttt{Dec}(k_{rnd}, \mathbf{BUF}_1[j])$
9: Client generates $p \leftarrow^{\$} \{0,1\}^\lambda$
10: **if** $rank = 0$ **then** Client appends $(\text{RND}.\texttt{Enc}(k_{rnd}, (w, n_w, p)))$ to $\mathbf{BUF}_2$
11: **else** Client appends $(\text{RND}.\texttt{Enc}(k_{rnd}, (\perp, \perp, \perp)))$ to $\mathbf{BUF}_2$
12: Client generates $((level, pos), \sigma) \leftarrow \texttt{Map}(P[i][3], w, rank, n_w, \sigma)$ ▷ $pos = 0$ for 1C and 2C
13: Client writes $(\text{RND}.\texttt{Enc}(k_{rnd}, (w, id, op, level, pos)))$ to $\mathbf{BUF}_1[j]$

//** Phase 3—Add dummies **//
14: **for** $level = 0 \ldots m_i - 1$ **do**
15: for every $pos \in \{0 \ldots c_{level}\}$ call Client appends $(\text{RND}.\texttt{Enc}(k_{rnd}, (\perp, \perp, \perp, level, pos)))$ to $\mathbf{BUF}_1$ b_{level} times

//** Phase 4—Final placement **//
16: Perform oblivious sort on $\mathbf{BUF}_1$ w.r.t. the integer values of $(level, pos)$ in ascending order
17: Linearly scan $\mathbf{BUF}_1$, and tag **first** b_{level} entries for each $level \in \{0, \ldots, \Sigma.m_i - 1\}$ and $pos \in \{0, \ldots, c_{level}\}$ with 1, and with 0 the rest of them (the existing $(level, pos)$ tags are replaced with 0/1 tags, the entries now look like (w, id, op, x), where $x \in \{0,1\}$)
18: Perform order preserving oblivious compaction on $\mathbf{BUF}_1$; keep first N' entries; discard the 0/1 tags
19: Perform oblivious sort on $\mathbf{BUF}_2$ w.r.t. the random keys in ascending order; keep first 2^i entries; discard random keys
20: Server moves $\mathbf{BUF}_1$ to $\mathsf{NEW}_i.\textsc{Ind}$ ▷ elements in each bin/pos is randomly shuffled
21: **for** each $s \in \mathbf{BUF}_2$ **do**
22: Client decrypts $(w, cnt_w) \leftarrow \text{RND}.\texttt{Dec}(k_{rnd}, s)$
23: Client generates $(key, value) \leftarrow \text{PiBAS}.\texttt{Map}((P[i][3], k_{rnd}), w, cnt_w, 1)$ ▷ parameter 1 is used by the PRF F
24: Client writes $\mathsf{NEW}_i.\textsc{Dict}[key] \leftarrow value$
25: **return** NEW_i

Figure 6: `oblMerge` framework of $\Gamma \in \{\mathsf{1C}, \mathsf{2C}, \mathsf{NlogN}\}$

a 0; and the entries to be kept are tagged with a 1. This tag replaces the existing $(level, pos)$ tags. Next, an order preserving oblivious compaction (line 18) is performed so that all elements tagged with 0 come at the tail of the output and can be discarded altogether. We use another round of oblivious bucket sort (which is order preserving) for the compaction. NEW_i.IND is created with the remaining entries of $\mathbf{BUF}_1$ (line 20). $\mathbf{BUF}_2$ is also obliviously sorted (line 19) based on the random keys in ascending order. The dummy entries with $p = \perp$ will be placed at the end of the sorted buffer. There can be at most 2^i entries such that $p \neq \perp$, as there can be at most 2^i distinct keywords at index level i. Hence, the first 2^i elements are used to create NEW_i.DICT (lines 21-24).

Locality-aware $\mathsf{L\text{-}SD}_d[\cdot]$. The search-*locality* and search-*read efficiency* of $\mathsf{L\text{-}SD}_d[\Gamma]$ depends on the same of the static SE scheme Γ. For both *locality* and *read efficiency*, a $\log N$ factor is added due to querying $3 \cdot \log N$ dictionaries and calling Γ.Search on $3 \cdot \log N$ indexes (for OLDEST, OLDER, and OLD). For example, 1C offers $O(1)$ *locality* and $O(\log N \log\log N)$ *read efficiency*, whereas $\mathsf{L\text{-}SD}_d$[1C] offers $O(\log N)$ *locality* and $O(\log N \log\log N + \log N)$ *read efficiency*. Similarly, $\mathsf{L\text{-}SD}_d$[NlogN] offers $O(\log N)$ *locality* and $O(\log N)$ *read efficiency*, as opposed to optimal *locality* and *read-efficiency* that is offered by NlogN.

Page-efficient $\mathsf{L\text{-}SD}_d[\cdot]$. We can instantiate $\mathsf{L\text{-}SD}_d[\cdot]$ on SSDs with static page efficient schemes like NlogN [6] and its variations i.e. sN [31]. The *page efficiency* of $\mathsf{L\text{-}SD}_d$[NlogN] is $O(\log N)$ vs. the optimal *page efficiency* offered by NlogN, whereas for $\mathsf{L\text{-}SD}_d$[sN] *page efficiency* is $O(N^{\frac{1}{s}}/p + \log N)$.

Security and efficiency. We formally state and prove the security of $\mathsf{L\text{-}SD}_d[\Gamma]$ (for $\Gamma \in \{1C, 2C, \mathsf{NlogN}\}$) in the extended version. The security of SD_d[PiBAS] is already proven in [26]. We prove also that when we instantiate a locality-aware static scheme Γ with $\mathsf{L\text{-}SD}_d[\cdot]$, it retains its space overhead, but for *locality* and *read-efficiency* an additional $3\log N$ factor is introduced as $3\log N$ indexes are queried (similar proof for the *page-efficient* $\mathsf{L\text{-}SD}_d[\cdot]$ transformation can be proven)—see the extended version.

1C **Optimization.** In 1C scheme we do not need to make the keyword-lists' sizes to be of power of 2. We also do not need to store the larger keyword-lists into the bins before the smaller lists. Hence the lines 5 and 6 in Figure 6 are not required for 1C. The two linear scans that add *rank* and n_w values to each entry can be also removed (line 4). This is because, after the first oblivious sort the entries for the same keyword are all placed together in adjacent locations. In Phase 2, with the help of a single counter one can count how many occurrences of a particular keyword has been seen. Based on this counter value $\mathbf{BUF}_2$ can be updated accordingly. The same counter value can be used in 1C.Map function to compute the bin numbers.The counter needs to be reset to 0 every time a new keyword is observed. We provide the optimized pseudocode for 1C.oblMerge in the extended version.

Scheme	Size(GB) for $\lvert DB\rvert = 2^{23}$	Size(GB) for $\lvert DB\rvert = 2^{26}$
$\mathsf{L\text{-}SD}_d$[NlogN]	49	436
$\mathsf{L\text{-}SD}_d$[1C]	7.5	60
SD_d[PiBAS]	5	40

Figure 7: Needed storage for a dataset and encrypted index.

NlogN **Optimization.** Here the order of storing lists does not matter. Thus, the second oblivious sort (line 6) can be omitted in Phase 1 for the NlogN scheme. This can be further optimized by storing only s evenly distributed arrays, instead of $\ell = \log N + 1$ arrays, which is essentially the Ns scheme.

2C **Optimization.** For 2C scheme, the client needs to maintain a map to remember which bin has how many entries. This is because, placement of a keyword-list into a superbin depends on how full the superbin is. There are can be maximum of $m = \lceil N/\log\log N(\log\log\log N)^2 \rceil$ bins. But in $\mathsf{L\text{-}SD}_d$ there are $\log N$ index levels. Hence, to maintain this information the required client storage is $O(m \cdot \log N)$. To achieve a constant client storage, this map can be stored at the server in oblivious maps (see section 2).

Update cost. The oblMerge framework shown in Figure 6 mainly consists of three types of building blocks: bucket oblivious sorts, basic **for** loops and linear scans. Linear scans are realized with basic **for** loops. The costliest operation among these is the bucket oblivious sort [5], which can be decomposed into N steps of $O(\log N)$ work per step, assuming an index contains at most N entries (recall the ith index contains 2^i elements). In the extended version we explain how to deamortize the bucket oblivious sort in detail. Even the **for** loops can be executed for $O(\log N)$ iterations during a particular call of $\mathtt{oblMerge}_i$ (for the ith index). Overall, an $\mathtt{oblMerge}_i$ protocol can be decomposed into N steps of at most $O(\log N)$ work per step. There are $\log N$ levels in $\mathsf{L\text{-}SD}_d[\cdot]$. Hence, the *worst case* update cost is $O(\log^2 N)$ for $\mathsf{L\text{-}SD}_d$[1C], and $\mathsf{L\text{-}SD}_d$[2C]. For $\mathsf{L\text{-}SD}_d$[NlogN] the update cost is $O(\log^3 N)$, because it has at most $\log N$ levels per index.

4 Experimental Evaluation

We report the performance of our schemes and compare them with previous state-of-the-art works.

We implemented SD_a[1C], SD_a[2C], SD_a[NlogN], SD_a[sN], $\mathsf{L\text{-}SD}_d$[1C] and $\mathsf{L\text{-}SD}_d$[sN] with approximately $31K$ lines in C++. We used OpenSSL-AES [3] PRF evaluation and semantically secure encryption. We also used Oblivious MAP of [26] for the SD_d[PiBAS] implementation, and merge-sort as the last step in the implementation of bucket oblivious sort [5]. We ran our experiments on a machine with Intel Xeon E-2174G 3.8GHz processor, 128GB RAM, 1TB SSD, and 5TB HDD running Ubuntu 20.04 LTS (limited to one

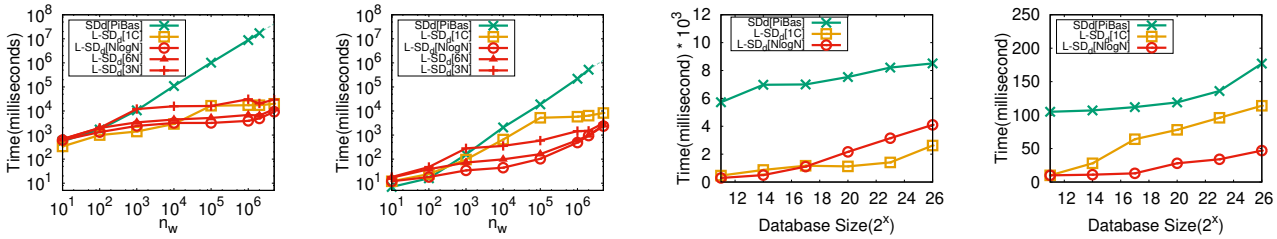

Figure 8: Search computation time for $|DB| = 2^{23}$ and variable result size for (a) $|block| = 32$B in (a) HDD, (b) SSD. Search computation time for variable database size and $n_w = 1K$ in (c) HDD, (d) SSD.

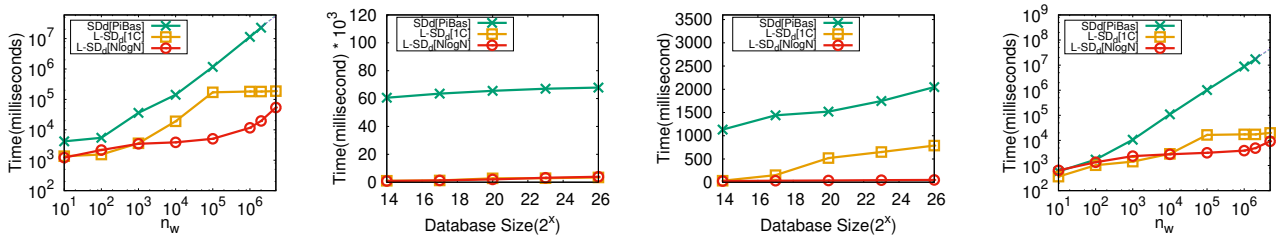

Figure 9: Search computation time for $|DB| = 2^{23}$ and variable result size for (a) $|block| = 512$B in HDD. Search computation time for variable database size and $n_w = 10K$ in (b) HDD, (c) SSD. (d) Search computation time for $|DB| = 2^{23}$, $|block| = 32$B in HDD and variable result size for WAN machines with 24.7ms network delay and 2.5Gbps bandwidth.

CPU core for our experiments). Our code is available online.[9]

We focus on the computation time for Search and Update queries and measure these parameters for variable-size synthetic datasets with $|DB| = 2^{11}$-2^{26} records randomly shuffled before insertion, each time setting the total number of distinct keywords $|W|$ to $|DB|/100$. Likewise, we report results for varying result size n_w between 10 and $5M$ documents. We also consider two block sizes: 32B and 512B. To highlight the significance of I/O in a memory-constrained environment, we conduct our experiments in a cold cache setting, but we also provide two sets of experiments to show the effect of cache on the performance of our schemes. In the first one, we keep the different ratios of datasets in the memory (as cache) and respond to the queries for those encrypted data from memory. Note that we normalize the cache for each scheme. In other words, we fix the cache size and load as much as data we can in that memory. In the second, we assume there are many users (200 for HDD and 75 for SSD) each of which has her own dataset with size 2^{20} and they execute their own search queries randomly when the cache in the system is enabled.

Experiments were repeated five times, and the average result is reported. We also provide a comparison between the needed storage on the server for each de-amortized scheme in Figure 7 for a dataset with $|block| = 32B$ where $|DB| = 2^{23}$ and $|DB| = 2^{26}$. Note that we focus on small client storage schemes. Therefore, client storage is constant.

We also repeated the search experiments on a real dataset consisting of 22 attributes and 6,123,276 records of reported crime incidents in Chicago [1]. We used two different attributes, containing 34 and 170 distinct keywords, respectively, and keyword frequency ranging from 1 record to 1,631,721 records. Finally, we simulated the search and update time of our schemes when run over WAN with 24.7ms delay and 2.5Gbps bandwidth on AWS (between two machines on Ireland and Frankfurt zones).

[9] https://github.com/jgharehchamani/DSE-with-IO-Locality

4.1 Search Performance

Our first set of experiments focuses on search performance and we demonstrate the impact of variable data block sizes, variable result sizes, variable database sizes, and cache size on all our schemes and compare them with SD_a[PiBAS] [26] and SD_d[PiBAS] [26]. We do not provide the big-block experiments for SSD due to disk space limits.

Variable Block and Result Sizes. Figure 8 (a,b) and Figure 9 (a) show the search computation time of a dataset with size 2^{23} $|block| = 32$B as the result size n_w changes. Similar results for our amortized schemes are in Figure 10 (a),(b),(e).

The conclusions from these experiments are: (i) As expected, SD_a[PiBAS] and SD_d[PiBAS] have the worst performance among all other schemes for large result sizes due to their poor locality (in HDD) and page efficiency (in SSD). They need to change the position of the hard-drive head or bring different pages of the results, stored at random locations, which leads to significant slowdown. (ii) The SD_a[NlogN]

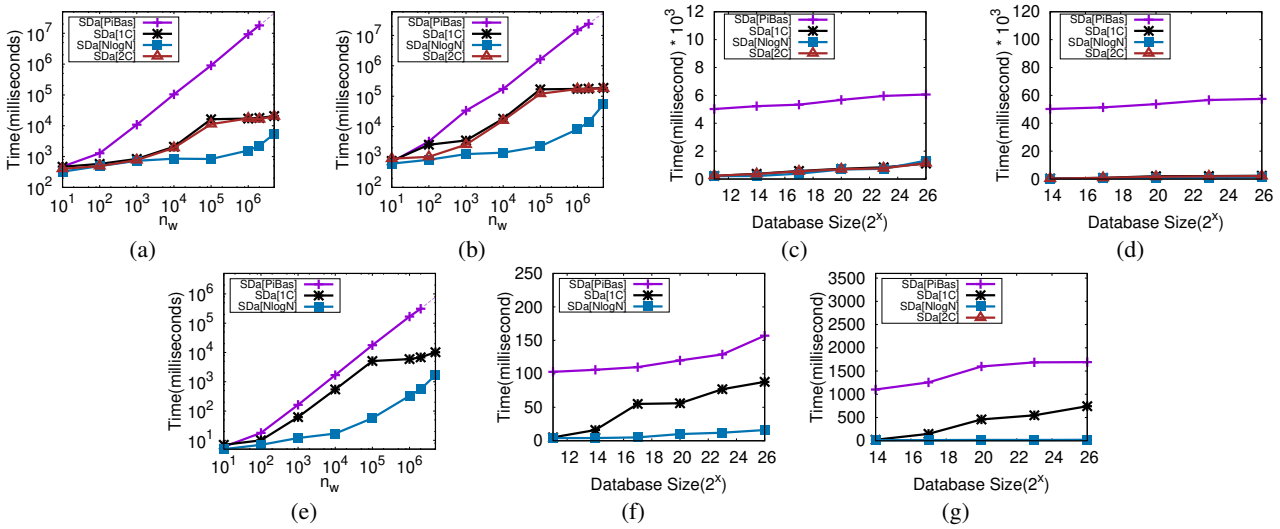

Figure 10: Search computation time for $|DB| = 2^{23}$ and variable result size for (a) $|block| = 32$B in HDD, (b) $|block| = 512$B in HDD. Search computation time for variable database size and (c) $n_w = 1K$ in HDD, (d) $n_w = 10K$ in HDD. Search computation time for $|DB| = 2^{23}$ and variable result size for (e) $|block| = 32$B in SSD. Search computation time for variable database size and (f) $n_w = 1K$ in SSD, (g) $n_w = 10K$ in SSD.

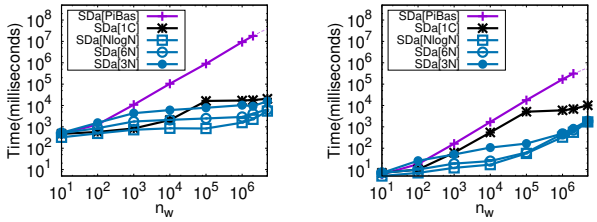

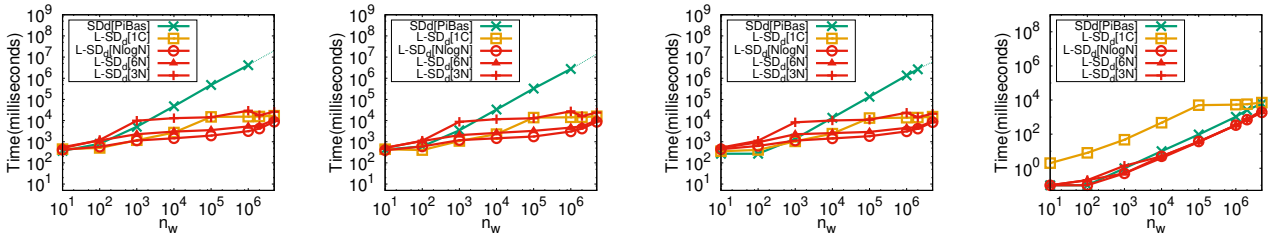

Figure 11: Search computation time for $|DB| = 2^{23}$, variable result size, and $|block| = 32$B for different NlogNsettings in (a) amortized HDD, (b) amortized SSD.

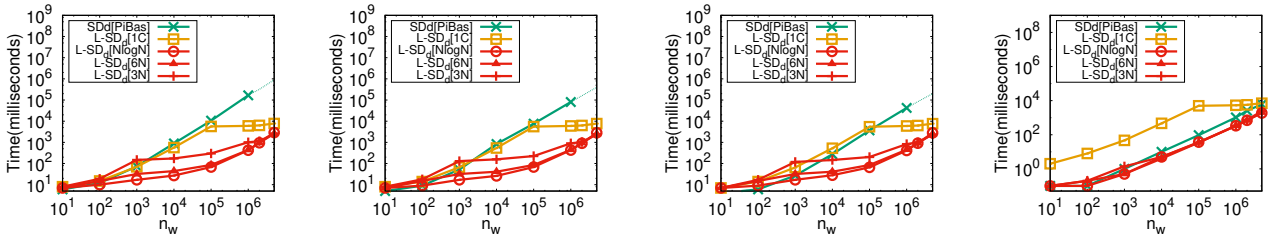
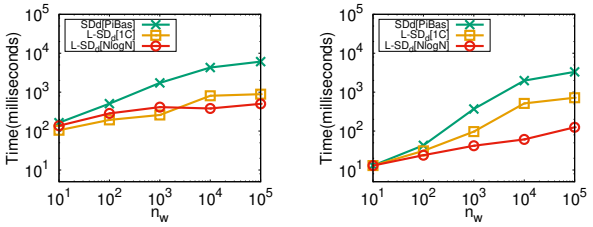
and L-SD$_a$[NlogN] schemes achieve the best performance in the amortized and de-amortized setting, at the cost of extra storage. The number of indexes searched in L-SD$_a[\cdot]$ is three times than that of SD$_a[\cdot]$, hence the search time of L-SD$_a$[NlogN] is slightly more than SD$_a$[NlogN]. (iii) SD$_a$[2C] performs better than SD$_a$[1C] for small result sizes. However, their performance is the same for result sizes more than the bin's threshold, since, after the threshold entries are stored using SD$_a$[1C] (therefore we ignored this scheme in SSD experiments). (iv) The execution time for SD$_a$[1C] for result sizes bigger than 10^5 remains approximately constant, as at this point the database is read in its entirety (i.e. all bins contain results). (v) When the block size is increased from 32B to 512B, the search time of all schemes increases, but the gap between SD$_a$[2C]/SD$_a$[1C] and SD$_a$[PiBAS] decreases. This is due to the increase in the volume of the data read for blocks of size 512B, which becomes the dominant factor in the performance. (vi) Amortized and de-amortized versions of PiBAS, 1C, and NlogN have similar performance. Finally, all our schemes have excellent performance in practice. E.g., SD$_a$[1C] and SD$_a$[NlogN]/L-SD$_d$[NlogN] are up to three orders of magnitude faster than SD$_a$[PiBAS]/SD$_d$[PiBAS] (for $|n_w| = 10^5$ and $|DB| = 2^{23}$ SD$_a$[1C], SD$_a$[NlogN], and SD$_a$[PiBAS] take 16s, 0.8s, and 903s respectively).



Variable Database Size. Figures 8 (c,d) and Figures 9 (b),(c) show the effect of database size on search computation. (Results for the amortized schemes are in Figures 9 (c),(d),(f),(g)). For small blocks it varies search time for variable database sizes between $2^{11} - 2^{26}$ and for result size n_w=1K in HDD and SSD. As the figures show, the search time of all schemes increases as the database size increases, because of the added levels in the data structures. However, all our schemes are significantly faster than SD$_a$[PiBAS] and SD$_d$[PiBAS]. For instance, the amortized schemes SD$_a$[1C], SD$_a$[2C], and SD$_a$[NlogN] are faster than SD$_a$[PiBAS] by $2-136\times$, $5-159\times$, and $4-209\times$ respectively. Also, the de-amortized schemes, L-SD$_d$[1C] and L-SD$_d$[NlogN] are faster than SD$_d$[PiBAS] by $2-58\times$ and $3-70\times$ respectively.

Effect of the value of s on SD$_a$[NlogN] and L-SD$_d$[NlogN]. The previous experiments showed that our NlogN-based schemes have the best performance at a cost of more (i.e. log$N$ times) storage. However, as discussed in Section 3.2, these schemes can be used more "cleverly" to reduce the storage overhead. In Figure 8 (a,b), we measured the effect of keeping s intermediate levels instead log$N$ levels for the de-amortized schemes (e.g., L-SD$_d$[3N] refers to keeping 3 levels). Similar experiments for amortized schemes are presented in Figure 11. If the level that a keyword-list should be stored does not exist, we split the list into multiple equal-sized



(a) (b) (c) (d)

Figure 12: Search computation time for $|DB| = 2^{23}$ and variable result size for $|block| = 32$B in HDD, (a) 25% Caching, (b) 50% Caching, (c) 75% Caching, (d) 100% Caching.

Figure 13: Search computation time for $|DB| = 2^{23}$ and variable result size for $|block| = 32$B in SSD, (a) 25% Caching, (b) 50% Caching, (c) 75% Caching, (d) 100% Caching.

(a) (b)

Figure 14: Search computation time for $|DB| = 2^{20}$ for each user and variable result size for $|block| = 32$B with caching enabled in (a) HDD where 200 users exist in the system (b) SSD where 75 users exist in the system

chunks (last chunk is padded, if necessary) and store them in the next closest existing level. The experiment shows that even when keeping fewer levels than $\log N$, SD_a[NlogN]/L-SD_d[NlogN] outperform PiBAS and 1C based schemes in terms of search time, due to its practical locality and page efficiency, while also reducing storage to $3s \times N$. E.g., when storing every 8th level (SD_a[3N]/L-SD_d[3N]), the achieved scheme is up to 30× and 1949× faster than SD_a[1C] and SD_a[PiBAS] and up to 8× and 833× faster than L-SD_d[1C] and L-SD_d[PiBAS] for big result sizes.

Cache Experiment. Figures 12 and 13 show the effect of cache on the search time. They represent the search computation time over a dataset with size 2^{23} and $|block| = 32B$ for variable result sizes and variable cache sizes on HDD (Figure 12) and SSD (Figure 13). As explained above, for these experiments we fix the cache size in memory according to the SD_d[PiBAS] scheme which has the smallest storage size in the de-amortized schemes (e.g., 25% of the encrypted dataset of SD_d[PiBAS]), and we use the same cache size as for other schemes for fairness. The figures show that: i) as the cache size increases, all schemes' perform better and their search time reduces. However, SD_d[PiBAS] benefits more from the cache than others (i.e., its search time improves up to 8× while L-SD_d[1C] and L-SD_d[NlogN] only improve up to 2.4× and 2×) due to the smaller needed storage. ii) all our schemes still outperform SD_d[PiBAS] for big enough result sizes (>1K). Even when 75% of data is cached in SD_d[PiBAS], L-SD_d[1C] and L-SD_d[NlogN] are up to 191× and 641× faster. iii) When all data is cached (assuming it fits entirely in memory), L-SD_d[NlogN] outperforms other schemes (as expected) because it has the best locality and needs minimal cryptographic operations. On the other hand, L-SD_d[1C] becomes worse than SD_d[PiBAS] in big result sizes because in these queries the dominant overhead comes from crypto and L-SD_d[1C] needs to execute Sim3× more decryptions than the other schemes due to padding.

In a second experiment (Fig. 14) we emulate a scenario with multiple users (200 for HDD and 75 for SSD) each with her own independent dataset (of size 2^{20}). With cache enabled, we executed random queries among users. As the figure shows, due to the size of datasets being larger than the memory (encrypted indexes for HDD and SSD were 1.8TB and 675GB), we see a similar trend as Figures 8 (a, b).

Search Over Real Datasets. We evaluated search times on two attributes of the crime dataset [1], with (a) 34, and (b) 170 distinct keywords. We measured the search time for differ-

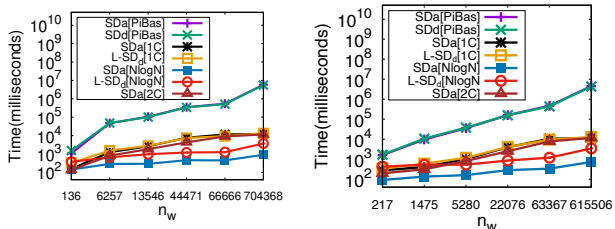

Figure 15: Crime Dataset—Search computation time vs variable result size for an attributed with (a) $|W| = 34$, (b) $|W| = 170$.

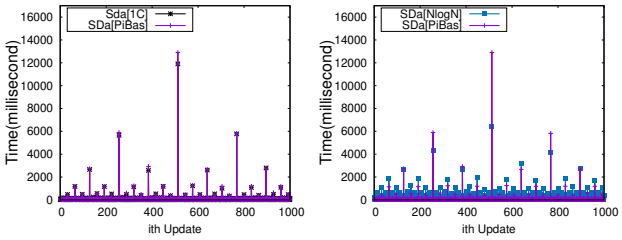

Figure 16: Update computation time of amortized schemes for 1K updates starting from an empty dataset (a) SD_a[1C] vs SD_a[PiBAS] (b) SD_a[NlogN] vs SD_a[PiBAS]

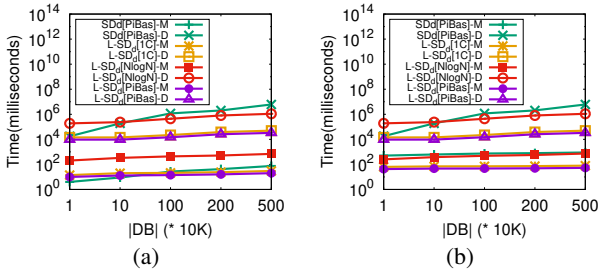

Figure 17: Update computation time for variable database sizes (a) over single machine (b) over WAN machines with 24.7ms network delay and 2.5Gbps bandwidth.

ent keywords associated with increasing numbers of results. Our experiments show that our schemes clearly outperform both SD_a[PiBAS] and L-SD_d[PiBAS], and we reach similar conclusions as previously (Figure 15).

Search Over WAN We also simulated the end-to-end search time when client and server are located on two different machines. Our testbed was two AWS machines in Ireland and Frankfurt (with 24.7ms delay and 2.5Gbps bandwidth). Our experiments show a similar trend as the single machine case due to the constant roundtrip number and high network bandwidth, so our schemes outperform SD_a[PiBAS] and SD_d[PiBAS] (see Fig. 10 (d)).

4.2 Update Performance

Next, we report the update performance of our schemes via two sets of experiments: (i) update cost of the amortized scheme, (ii) update cost of the de-amortized schemes.

Update Cost of Amortized schemes. In the first experiment, we measured the update time for 1K consecutive updates. Each time, the client fetches and merges some previously built levels and then uploads them to the server. Clearly, the update cost depends on the number of previously inserted indexes and it increases when more indexes need to be merged. We repeated the same experiment for SD_a[NlogN] and saw the same behaviour (see Figure 16). It is clear that SD_a[PiBAS] has the best update cost for small merges (due to storing fewer entries) and the worst update cost for big merges (as random I/Os increases). The minimum and maximum observed time for SD_a[PiBAS] is 2ms and 12905ms, while for SD_a[NlogN] they are 58ms and 6421ms.

Update Cost of De-Amortized schemes. To measure the update performance of our de-amortized schemes, first we measured the update computation time for variable database sizes in memory. According to our experiment (Figure 17 (a)), L-SD_d[1C] outperforms other schemes for database sizes above $100K$ which is compatible with its better asymptotics (e.g., L-SD_d[1C] is up to $2.5\times$ faster than SD_d[PiBAS] for database size of 5M). Furthermore, L-SD_d[NlogN] has the worst performance in the memory setting due to the large number of layers it needs to create for each level of the de-amortized framework. We also provided L-SD_d[PiBAS] update time to show our framework is applicable to SD_d[PiBAS] and can reduce its cost from $O(\log^3 N)$ to $O(\log^2 N)$. Finally, we re-executed this using HDD storage. We observe that L-SD_d[1C] is still the most efficient scheme in all database sizes. On the other hand, L-SD_d[NlogN] becomes better than SD_d[PiBAS] in bigger database sizes due to its better locality (e.g., L-SD_d[1C] and L-SD_d[NlogN] are $123\times$ and $5\times$ faster than SD_d[PiBAS] for size 5M).

Update Over WAN. We measured end-to-end update times when client and server are located on different AWS machines, as above (Figure 17 (b)). The performance of memory-based SD_d[PiBAS] worsens due to the round trips for OMAP access and the amount of data that must be transferred over the network (L-SD_d[1C] is $8-11.3\times$ and L-SD_d[NlogN] is $1.2-2\times$ faster than SD_d[PiBAS]). That said, the performance of disk-based schemes is similar to the single-machine case as the disk overhead is the dominant cost and the bandwidth is high enough to "cover" for the network overhead.

5 Conclusion

In this work, we proposed the first I/O efficient DSE schemes with forward/backward privacy by re-visiting prior "static-to-dynamic" compilers. First, we came up with a new *oblivious merge* framework, that enabled us to place entries for the same keyword close to each other (preserving locality). Moreover, we optimized performance by replacing oblivious data

structures for more lightweight and easier-to-implement oblivious sorting algorithms and linear scans. We implemented both amortized and de-amortized transformations with I/O-efficient static schemes, such as 1C, 2C, NlogN, and sN (for s = 3 and 6), and compared their search and update times with prior works, overall showcasing our schemes' superior performance in various settings and configurations.

Abstract

Asymmetric Searchable Encryption (ASE) is a promising cryptographic mechanism that enables a semi-trusted cloud server to perform keyword searches over encrypted data for users. To be useful, an ASE scheme must support expressive search queries, which are expressed as conjunction, disjunction, or any Boolean formulas. In this paper, we propose a *fast* and *expressive* ASE scheme that is adaptively secure, called FEASE. It requires only 3 pairing operations for searching any conjunctive set of keywords independent of the set size and has linear complexity for encryption and trapdoor algorithms in the number of keywords.

FEASE is based on a new fast Anonymous Key-Policy Attribute-Based Encryption (A-KP-ABE) scheme as our first proposal, which is of independent interest. To address optional protection against keyword guessing attacks, we extend FEASE into the first *expressive* Public-Key Authenticated Encryption with Keyword Search (PAEKS) scheme.

We provide implementations and evaluate the performance of all three schemes, while also comparing them with the state of the art. We observe that FEASE outperforms all existing expressive ASE constructions and that our A-KP-ABE scheme offers anonymity with efficiency comparable to the currently fastest yet non-anonymous KP-ABE schemes FAME (ACM CCS 2017) and FABEO (ACM CCS 2022).

1 Introduction

Outsourcing data storage to third-party providers offers an efficient way for clients with limited resources or expertise to manage and disseminate large volumes of encrypted data. However, traditional public or private key encryption methods hinder the ability to selectively retrieve specific data segments. To address this limitation, Searchable Encryption (SE) emerges as a cryptographic solution [15, 52]. SE empowers a user to securely outsource data to a server in an encrypted form and perform search operations on the data without revealing the plaintext to the server. SE finds diverse applications including cloud storage, secure messaging and email, healthcare, finance, academic and research databases, Internet of Things security, and more.

SE can be classified into two categories: Symmetric Searchable Encryption (SSE) [26, 55] and Asymmetric Searchable Encryption (ASE) [13]. In SSE, a user employs a secret key to encrypt a set of documents and keywords and uploads the resulting ciphertext to a cloud server. Later, the same secret key is used to generate a trapdoor for a specific search query containing one or more keywords. This trapdoor is sent to the server, which matches it with the ciphertext and returns the searched documents. In ASE, the distinction lies in that a data sender encrypts the document and keywords by using a public key and a data receiver subsequently generates the trapdoor by using the corresponding secret key.

A related field known as "Stream Encryption with Pattern Matching" (SEPM) [16, 17, 22], has emerged in recent years. SEPM achieves functionalities similar to traditional SE but is tailored for searching patterns [1] within encrypted streams. This means that data senders only need to encrypt data streams, eliminating the need for encrypting a keyword set as indexes. SEPM schemes share a similar syntax with ASE schemes that are usually constructed in a public-key setting. They find valuable applications in fields such as deep packet inspection, genomic data, medical data analysis, and more.

It is widely recognized that SSE offers high efficiency and has been extensively studied for its dynamic capabilities [33], allowing for efficient addition and deletion of keywords or documents in the encrypted dataset. ASE simplifies key management, offering strong security arguments and flexibility that can be extended to facilitate fine-grained access control on data receivers [61]. SEPM shares similar advantages with ASE but stands out for its capabilities for searching patterns instead of exact keywords [2]. In this paper, our focus is on ASE schemes, which find practical applications in various fields such as cloud storage [44], email filtering [13], cloud-based healthcare [21], smart grids [60], etc.

[1] E.g., a pattern "ab**cd" means any 6-character string with the first two letters "ab" and the last two letters "cd".

[2] A comparison for these three fields is given in our full version [43].

When designing an ASE scheme, the expressiveness of keyword search queries is usually considered a critical aspect. A search query is called *expressive* if contained keywords can be represented as a conjunctive, disjunctive, or any monotonic Boolean formula. For example, in the email filtering use case [13], a typical search query may be: "(Sender: Tom **AND** Subject: Rent) **OR** Priority: Urgent", which asks the email server to return emails sent from Tom with the subject "Rent", or emails with an "urgent" priority.

The efficiency of an ASE scheme is also crucial in large-scale applications. For an ASE scheme to be efficient, the communication overhead *and* computational overhead must be small. For instance, in a cloud-based healthcare system [21], a slow ASE scheme can delay access to critical patient information, which can lead to serious consequences. In the email filtering use case [13], an inefficient ASE scheme can result in slower email retrieval time, the requirement of more storage space, and thus higher resource utilization and higher costs.

In the literature, we observe that most of the existing ASE schemes that support expressive search queries [21, 37, 42, 44, 53, 57] are derived from Anonymous Key-Policy Attribute-Based Encryption (A-KP-ABE) schemes. Informally, Attribute-Based Encryption (ABE) is a form of public-key encryption enabling fine-grained access control. In ABE, ciphertexts and secret keys are linked to sets of attributes, and access policies specify which attributes are required for decryption. Typically, ABE schemes use linear secret-sharing techniques [6] to support expressive access policies. In a Key-Policy ABE (KP-ABE) scheme, a data sender encrypts a message with an attribute set $\mathbb{S}$ to create a ciphertext ct, and each data receiver owns a secret key sk tied to an access structure $\mathbb{A}$. The decryption is successful only if $\mathbb{S}$ in ct satisfies $\mathbb{A}$ in sk. However, KP-ABE prioritizes message privacy over attribute privacy. This is inadequate for applications where attributes, such as those in healthcare and E-commerce, contain sensitive information. To address this, A-KP-ABE schemes are developed to conceal attribute information within the ciphertext. Due to the similarity in syntax, expressiveness, and security properties, an A-KP-ABE scheme can be transformed into an expressive ASE scheme by treating attributes as keywords [3].

Nevertheless, existing expressive ASE schemes [21, 34, 37, 42, 44, 53, 57] suffer from significant drawbacks. The scheme in [34], based on inner-product encryption, experiences a superpolynomial blowup in both ciphertext and trapdoor size. The schemes in [37] and [42], relying on bilinear pairings over composite-order groups, are highly inefficient. Expressive ASE schemes proposed in prime-order groups, such as [21, 44, 53, 57], offer better efficiency than [37, 42]. Unfortunately, these schemes suffer from either insecure constructions that are vulnerable to attacks or intricate designs leading to inefficiency [4]. These limitations severely restrict their practicality in real-world applications. Given these challenges, a natural question arises: *Can we construct a fast and expressive ASE scheme by initially constructing a fast and expressive A-KP-ABE scheme?*

Continuing our research on ASE security. Typically, an ASE scheme is designed to achieve semantic security, protecting the privacy of the keyword sets encrypted within the ciphertext. This property, referred to as Indistinguishability against Chosen Keyword Attacks (IND-CKA), is foundational. However, this property does not guarantee the confidentiality of keywords in a trapdoor. Research has revealed a vulnerability in ASE schemes known as Keyword Guessing Attacks (KGA) [18]. In this scenario, a cloud server acting as an adversary can generate ciphertext for every possible keyword and test if it matches a trapdoor. If the number of potential keywords is polynomially bounded, the adversary can deduce the keyword hidden in the trapdoor. Several approaches have been proposed to counter such attacks, such as fuzzy keyword search [58], designated server [49], dual server [19], registered keyword search [56], public-key authenticated keyword search [31], secure-channel free keyword search [5], etc.

Among these countermeasures, Public-key Authenticated Encryption with Keyword Search (PAEKS) [31] stands out as a promising technique. The fundamental concept behind PAEKS is to enable a data sender to encrypt keywords with his own secret key sk_s and a data receiver's public key pk_r, while a data receiver generates a trapdoor by using his own secret key sk_r and a data sender's public key pk_s. In this case, a PAEKS scheme is required to simultaneously achieve "Ciphertext Indistinguishability" [5], and "Trapdoor Indistinguishability (TI)", where the latter ensures that a trapdoor does not reveal any keyword value. Crucially, since the cloud server lacks access to the secret keys sk_r and sk_s, it is unable to generate ciphertext for keywords and test them, effectively preventing KGA. In the literature of PAEKS [20, 24, 31, 40, 41, 45, 47, 48], we observe that they only focus on supporting equality search queries and lack expressiveness. Motivated by the situation, our second question arises: *Can we construct a fast and expressive PAEKS scheme?*

Contributions. In summary, we have the following contributions in this paper:

- We introduce a fast and expressive A-KP-ABE scheme, serving as the foundation for our research and it is independent of interest.
- Our primary achievement is to transform our A-KP-ABE scheme into FEASE – a *Fast* and *Expressive* ASE scheme.
- Building upon FEASE, we further extend it to create the first expressive PAEKS scheme, which is secure under the state-of-the-art security model [6].
- Our three schemes share the following features:

[3] This is intuitive from the transformation from anonymous IBE to ASE supporting equality queries [2]. See Sec. 4.2 for details.

[4] Details of the literature are given in Sec. 2.1.

[5] CI in PAEKS is similar to IND-CKA in traditional ASE schemes.

[6] The literature of this model is reviewed in our full version [43]. The detail of this model is introduced in Sec. 5.3 in the PAEKS field.

1. They support expressive search queries (or access policies) that are conjunctive, disjunctive or any monotonic Boolean formulas.
2. They have a linear complexity for both communication and computational overhead in the encryption and trapdoor/key generation algorithm, and require only 3 pairing operations for searching/decrypting any conjunctive set of keywords/attributes independent of the set size.
3. They are constructed in the prime-order group with the efficient Type-III pairing.
4. They have no restrictions on the size of keywords (attributes) or policies and allow any arbitrary string to be used as a keyword (attribute).
5. They satisfy the adaptive security in the generic group model and random oracle model [7].

- The implementation results show that our three schemes have almost the same efficiency and achieve the best performance in their corresponding fields. We stress that our A-KP-ABE scheme is even comparable to state-of-the-art non-anonymous KP-ABE schemes FAME [3] and FABEO [50] in terms of their efficiency. For 100 keywords/attributes, our schemes run around 0.07s for encryption, 0.24s for trapdoor/key generation, and 0.012s for searching a conjunctive set of 100 keywords. Compared to FAME, our A-KP-ABE is 2 times faster for key generation and 4 times faster for encryption. Compared to FABEO, our A-KP-ABE is 0.7 times slower for key generation and 0.1 times slower for encryption. This shows that anonymity in KP-ABE can be achieved without noticeable degradation in efficiency.

2 Related work

In this section, we first review the literature on ASE, SSE, and SEPM and provide a comprehensive comparison between these three fields. Then we review PAEKS and A-KP-ABE schemes. Due to the page limit, we only present the literature of ASE field here. The rest is shown in our full version [43].

2.1 ASE schemes

The concept of ASE traces back to Boneh et al [13]. They started up the ASE research with the first construction. Subsequently, Abdalla et al. [2] formalized ASE consistency and explored the relationship between ASE and Anonymous Identity-Based Encryption (AIBE). Several ASE constructions based on different techniques were proposed later in [7,23,35]. These ASE schemes primarily supported equality search and lacked expressiveness. Advancements came with Park et al. [46] and Golle et al. [27], who introduced ASE schemes capable of handling conjunctive search queries. Hwan and Lee [32] enhanced these schemes, optimizing ciphertext and secret key sizes and extending the techniques to multi-user scenarios. Zhang et al. [59] studied the cases where the keyword numbers in search queries formed subsets of those in ciphertexts. Boneh and Waters [14] introduced a comprehensive framework for analyzing and constructing Searchable Public Key Encryption (S-PKE) schemes, a generalization of ASE, supporting diverse families of predicates and arbitrary conjunctions.

In 2008, Katz et al. [34] introduced the concept of Inner-Product Encryption (IPE) that paved the way for the construction of the first expressive ASE scheme capable of handling both conjunctive and disjunctive keyword queries. However, this solution faced a superpolynomial increase in both ciphertext and trapdoor sizes. Addressing this, Lai et al. [37] and Lv et al. [42] presented expressive ASE schemes, ensuring linear complexity in ciphertext size concerning the number of keywords, which is a significant improvement over the superpolynomial complexity. Nevertheless, their schemes relied on inefficient bilinear pairings over composite-order groups. Though there exist techniques [25] to convert pairing-based schemes from composite-order groups to prime-order groups, there is still a significant performance degradation due to the required size of the special vectors [51].

In 2016, Cui et al. [21] proposed the first expressive ASE scheme in the prime-order groups that significantly improves the performance over existing schemes and proves the selective security of their scheme in the standard model. After that, Meng et al. [44] improved the construction of [21] to achieve constant-size ciphertext and seven pairings in the search algorithm without depending on the number of keywords. However, their scheme has a quadratic trapdoor size $O(\ell^2+\ell)$ where ℓ represents the number of keywords in the keyword policy. Additionally, this scheme requires all keywords that appeared in the ciphertext must be a part of the search query, otherwise, the search will fail. These trade-offs hugely decrease the practicality of their scheme. In 2019, Shen et al. [53] proposed a generic transformation from an A-KP-ABE scheme to an expressive ASE scheme, then they proposed an A-KP-ABE scheme and transformed it into an expressive ASE scheme. Recently, Tseng et al. [57] proposed a fast A-KP-ABE scheme and transformed it into an expressive ASE scheme that achieves only two pairings in the search algorithm without depending on the number of keywords. Unfortunately, the A-KP-ABE schemes in [53] and [57] bring the construction of KP-ABE schemes from [51] and [30] respectively with only removing the exposed attributes in the ciphertext. Their constructions do not satisfy the anonymity of an A-KP-ABE scheme [8]. Therefore, [21] and [44] remain at the forefront of the expressive ASE field.

As shown in Table 1, we compare different features between our FEASE and PAEKS and other ASE schemes. For expres-

[7] The use of random oracle is fairly common in many cryptographic protocols such as Full Domain Hash signatures [8] and OAEP encryption [9].

[8] The reasons are the same as in FABEO, as introduced in Sec. 4.1.

Scheme	Expressiveness	Group	Pairing	KGA	Security	Universe	Efficiency
BCOP04 [13]	AND	Prime	Type I	No	Full, RO	Large	-
KSW08 [34]	AND, OR	Composite	-	No	Sel., STD	Small	*
LZDLC13 [37]	AND, OR	Composite	-	No	Full, STD	Small	**
LHZF14 [42]	AND, OR, NOT	Composite	-	No	Full, STD	Small	**
CWDWL16 [21]	AND, OR	Prime	Type I	Partial	Sel., STD	Large	***
MZNLHS17 [44]	AND, OR	Prime	Type III	Partial	Sel., STD	Large	***
FEASE	AND, OR	Prime	Type III	No	Full, GGM & RO	Large	****
Our PAEKS	AND, OR	Prime	Type III	Yes	Full, GGM & RO	Large	****

Table 1: A property-wise comparison of the various ASE schemes for different features. "KGA" represents the security against the keyword guessing attack, "RO" stands for "Random Oracle", "STD" stands for "Standard Model", "GGM" stands for "Generic Group Model". The more number of "*", the better the efficiency (lower running time and communication overhead).

siveness, [13] is the first ASE scheme and it supports only equality queries, other schemes support at least any monotonic Boolean formulas [9]. For the bilinear pairing group, [34,37,42] are using composite-order groups, and other schemes are built on the prime-order group. For pairing type, [13,21] are using the Type I pairing, and other schemes are using the faster Type III pairing. For stronger security requirements, [21,44] can partially protect against KGA since they allow a designated server to perform KGA, and our PAEKS can fully prevent the KGA from any cloud server. For the security model, [13] is fully secure under the random oracle model. [37,42] satisfies full security under the standard model, while [21,34,44] are selectively secure in the standard model. Our FEASE and PAEKS are fully secure under the generic group model and random oracle model. For the restriction of keyword space, except from [34,36,42], all other schemes support a large universe of keywords and hence do not need to restrict the number of keywords in the system. Finally, we rate the level of efficiency of all the expressive ASE schemes in a qualitative way.

3 Preliminaries

In this section, we define the notation, access structures, monotone span programs for providing expressiveness, the partially hidden structure, and hardness assumptions.

3.1 Notation

For integers m, n where $m < n$, $[m, n]$ denotes the set $m, m+1, ..., n$. For $m = 1$, we simply write $[n]$. For a prime p, let $\mathbb{Z}_p$ denote the set $[0, ..., p-1]$ where addition and multiplication are computed modulo p. The set $\mathbb{Z}_p^*$ is same as $\mathbb{Z}_p$ but with 0 removed. Let λ denote the security parameter.

For a set S, $s \xleftarrow{\$} S$ denotes that s is sampled uniformly and independently at random from S. $y \leftarrow \mathcal{A}(x)$ denotes that y is the output of running algorithm $\mathcal{A}$ on input x with uniformly random bits. An adversary is a probabilistic algorithm. A probabilistic algorithm is called probabilistic polynomial time (PPT) if its running time is bounded by some polynomial in the length of its input.

We use bold letters to denote vectors and matrices, with the former in lowercase and the latter in uppercase. By default, a vector $\mathbf{v}$ is treated as a column vector. $\mathbf{v}_k$ denotes the k-th element of $\mathbf{v}$ and $\|$ denotes concatenation of vectors. M_i and $\mathrm{M}_{i,j}$ denote the i-th row and the (i, j)-th element of a matrix M, respectively. We use M^{T} for the transpose of M.

3.2 Access structures

In this paper, *access structures* and *attribute sets*, *keyword policy* and *keyword set* are defined in the same way. Below we only provide the definition of the former set of terms.

Definition 1. *Definition 2.1 (Access structure). If $\mathcal{U}$ denotes the universe of attributes, then an access structure $\mathbb{A}$ is a collection of non-empty subsets of $\mathcal{U}$, i.e., $\mathbb{A} \subseteq 2^{\mathcal{U}} \setminus \{0\}$. It is called monotone if for every $B, C \subseteq \mathcal{U}$ such that $B \subseteq C$, $B \in \mathbb{A} \Rightarrow C \in \mathbb{A}$.*

Monotone means that an authorized user who acquires more attributes will not lose any privileges. A (monotone) Boolean formula consists of **AND** and **OR** gates, where each input is associated with an attribute in $\mathcal{U}$. A set of attributes $S \subseteq \mathcal{U}$ satisfies a Boolean formula if we set all inputs of the formula that map to an attribute in S to true and the others to false and the formula evaluates to true.

Monotone span programs (MSP) (or linear secret sharing schemes [6]) are a more general class of functions and include Boolean formulas. We encode an access structure by a policy (M, π) where M of size $\ell \times n$ over $\mathbb{Z}_p$ and a general mapping function $\pi : \{1, ..., \ell\} \to \mathcal{U}$. In [39], Lewko and Waters describe a simple and efficient method to convert any (monotone) Boolean formula F into an MSP(M, π) such that every row of M corresponds to input in F and the number of columns is same as the number of **AND** gates in F. Furthermore, each entry in M is either a 0, 1, or -1.

Let $\mathbb{S} = \{u_i\}_{i \in [m]} \subseteq \mathcal{U}$ be a set of m attributes and $I = \{i \,|\, i \in \{1, ..., \ell\}, \pi(i) \in \mathbb{S}\}$ be the set of rows in M that belong to $\mathbb{S}$. We say that (M, π) accepts $\mathbb{S}$ if there exists

[9] [42] supports non-monotonic queries (e.g., ''NOT gate'') as well.

a linear combination of rows in I that gives $(1, 0, ..., 0)$. This means, there exist constants $\gamma_i \in \mathbb{Z}_p$ for $i \in I$ such that $\sum_{i \in I} \gamma_i \mathbf{M}_i = (1, 0, ..., 0)$. These constants can be computed in time polynomial in the size of M. It is worth noting that if Lewko and Water's method is applied to Boolean formulas, then it is always possible to pick coefficients that are either 0 or 1 for the resulting MSPs, irrespective of the set $\mathbb{S}$.

3.3 Partially hidden structures

We apply the partially hidden structure for an attribute set (keyword set) and an access policy (keyword policy) for our proposed schemes. This structure is firstly proposed in [36] for an anonymous CP-ABE and then applied in the expressive ASE schemes [21,44]. Taking A-KP-ABE as an example, the structure works as follows: Each attribute is divided into a generic attribute name and an attribute value. The attribute values used in both the secret key and ciphertext are not disclosed to the cloud server, whereas a partially hidden access structure and attribute set with only attribute names are included in a secret key and ciphertext respectively. The decryption algorithm matches the attribute names first and then decrypts the ciphertext by testing if the attribute values match.

More specifically, we define an attribute set $\mathbb{S} = \{u_i\}_{i \in [m]}$ has m attributes with each attribute belonging to a different category. Let n_i and v_i denote the attribute name and attribute value of an attribute u_i respectively, i.e., $u_i = \{n_i, v_i\}$. We express an access policy as $\mathbb{A} = (\mathrm{M}, \pi, \pi(i))$, where M is a $\ell \times n$ share-generating matrix, M_i denotes the i^{th} row of M, π is a mapping function from M_i to an attribute $\pi(i)$. Let $n_{\pi(i)}$ and $v_{\pi(i)}$ denote the attribute name and attribute value of attribute $\pi(i)$ respectively, i.e., $\pi(i) = \{n_{\pi(i)}, v_{\pi(i)}\}$. In our schemes, the attribute values $v_{\pi(i)}$ of an access policy $(\mathrm{M}, \pi, \{\pi(i)\})$ and the attribute values v_i of an attribute set $\mathbb{S}$ are not exposed in the ciphertext or secret key, while $(\mathrm{M}, \pi, n_{\pi(i)})$ and attribute names n_i are disclosed.

Using our notation, a user's attribute set $\mathbb{S} = \{u_i\} = \{n_i, v_i\}$ satisfies an access policy $(\mathrm{M}, \pi, \pi(i) = \{n_{\pi(i)}, v_{\pi(i)}\})$ if and only if there exists $I \subseteq \{1, ..., \ell\}$ and constants $\{\gamma_i\}_{i \in I}$ such that

$$\sum_{i \in I} \gamma_i \mathrm{M}_i = (1, 0, ..., 0) \text{ and } \pi(i) = x_i \text{ for } \forall i \in I.$$

Similar to the scheme in [36], our schemes have the restriction that each attribute name can only be used once in an access policy. We can obtain a partially hidden access structure where attribute names are used multiple times (up to a constant number of uses fixed at setup) from a one-use scheme by applying the generic transformation given in [38]. While the transformation does incur some cost in key size, it does not increase the size of the ciphertext.

3.4 Bilinear maps

Bilinear maps. Let GroupGen be a PPT algorithm that takes as input a security parameter 1^λ and outputs a set of group parameters $\mathsf{par} = (p, \mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, e, g_1, g_2)$, where p is a prime of $\Theta(\lambda)$ bits, $\mathbb{G}_1$,$\mathbb{G}_2$ and $\mathbb{G}_T$ are cyclic groups of order p, g_1 and g_2 are the generators of $\mathbb{G}_1$ and $\mathbb{G}_2$ respectively. $e : \mathbb{G}_1 \times \mathbb{G}_2 \to \mathbb{G}_T$ is a bilinear mapping that satisfies the following properties:

- Computable: Given $g_1 \in \mathbb{G}_1$, $g_2 \in \mathbb{G}_2$, there is a polynomial time algorithm to compute $e(g_1, g_2) \in \mathbb{G}_T$.
- Bilinear: For all $g_1 \in \mathbb{G}_1$, $g_2 \in \mathbb{G}_2$ and any integers $a, b \in \mathbb{Z}_p$, we have $e(g_1^a, g_2^b) = e(g_1, g_2)^{ab}$.
- Non-Degenerate: There exists $g_1 \in \mathbb{G}_1$ and $g_2 \in \mathbb{G}_2$ such that $e(g_1, g_2) \neq 1$.

In this work, we only consider asymmetric (or Type-III) pairing groups where there exists no efficiently computable homomorphism between $\mathbb{G}_1$ and $\mathbb{G}_2$. Remark that while our constructions are using bilinear maps the security of our constructions will be proven to hold in the generic group model rather than under standard assumptions in pairing-based cryptography.

4 Our proposed schemes

Our research begins with FABEO [50], the fastest KP-ABE scheme known for its linear complexity in key size and ciphertext size, and a constant 2 pairing operations in the decryption process. As shown in Fig. 1, our design strategy unfolds in stages. Initially, we transform from the FABEO KP-ABE scheme into an A-KP-ABE scheme as a solid foundation. Subsequently, this A-KP-ABE scheme serves as the basis for creating FEASE as our primary achievement. Building upon FEASE, we extend its capabilities to craft the first expressive PAEKS scheme. Notably, all our schemes maintain the same level of expressiveness and efficiency as FABEO, inheriting the strengths of its construction. In this section, we guide you through the step-by-step evolution of our designs, starting from FABEO and progressing through each scheme outlined in our roadmap.

4.1 Transform from FABEO KP-ABE into anonymous KP-ABE

First, we show the syntax of an (anonymous) KP-ABE scheme. A KP-ABE (or A-KP-ABE) scheme consists of the following algorithms:

- $(\mathsf{pk}, \mathsf{msk}) \leftarrow \mathsf{Setup}(1^\lambda)$. The setup algorithm Setup is run by a key generation center (KGC). The algorithm takes as input a security parameter 1^λ. It outputs a system public key pk and a master secret key msk.
- $\mathsf{sk} \leftarrow \mathsf{KeyGen}(\mathsf{pk}, \mathsf{msk}, \mathbb{A})$. The key generation algorithm KeyGen is run by the KGC. The algorithm takes as input a public key pk, a master secret key msk, and an access structure $\mathbb{A}$. It outputs a secret key sk.

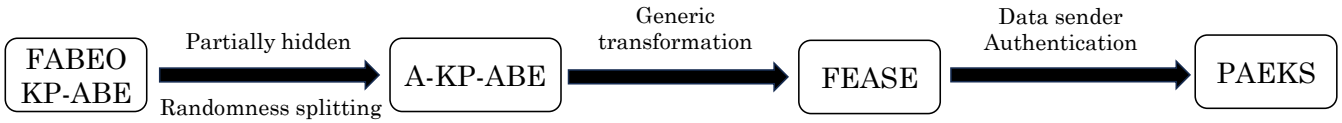

Figure 1: The technical roadmap of our proposed schemes. The texts on the arrows indicate the main techniques we used for the transformation from the left scheme to the right one.

- $\mathsf{ct} \leftarrow \mathsf{Enc}(\mathsf{pk}, \mathbb{S}, \mathsf{msg})$. The encryption algorithm Enc is run by the data sender. The algorithm takes as input a public key pk, a set of attributes $\mathbb{S}$, and a message msg. It outputs a ciphertext ct.
- $\mathsf{msg}/\perp \leftarrow \mathsf{Dec}(\mathsf{ct}, \mathsf{sk})$. The decryption algorithm Dec is run by the data receiver. The algorithm takes as input a ciphertext ct associated with an attribute set $\mathbb{S}$ and a message msg, and a secret key sk associated with an access policy $\mathbb{A}$. It outputs the message msg if $\mathbb{S}$ satisfies $\mathbb{A}$, or outputs a $\perp$ otherwise.

The concrete construction of FABEO KP-ABE scheme [50] is presented in Fig. 2. Note that the $\pi(i)$ is the attribute in $\mathbb{A}$ and u_i is the attribute in $\mathbb{S}$, following the notation defined in Sec. 3.2. Besides, the r value in sk_1 would have been a vector $\mathbf{r}'$, and the original version should be $\mathsf{sk}_{1,j} = g_2^{\mathbf{r}'[j]}$ where $j \in [\tau]$ indicates the number of attribute re-use. In this paper, we simplify it and let $j = 1$ since it is easier for further illustrations.

Why the FABEO KP-ABE does not ensure anonymity? In terms of the anonymity of an A-KP-ABE scheme defined in the Sec. 5.1, a close inspection of the FABEO construction reveals two fundamental issues:

1. Exposed attribute set: The ciphertext in FABEO includes the exposed attribute set $\mathbb{S}$ as an element, making it directly accessible to potential attackers.
2. Attribute guessing attack: Even if the exposed attributes are removed from the ciphertext, anonymity is not guaranteed. Specifically, when provided with two attributes, u_0 and u_1, and a ciphertext $(\mathsf{ct}_{1,u_b}, \mathsf{ct}_2)$ where $b \in \{0, 1\}$, attackers can determine b from the equation $e(\mathsf{ct}_{1,u_b}, g_2) = e(\mathsf{H}(u_b), \mathsf{ct}_2)$.

To address the above vulnerabilities, we apply the following techniques to transform FABEO KP-ABE into an A-KP-ABE scheme. The A-KP-ABE construction is shown in Fig. 3. We highlight the differences between the two schemes in red fonts.

Partially hidden structure. To consider how to conceal the exposed attribute set, the choice of the privacy level becomes pivotal. If the objective is to safeguard the complete privacy of the attribute set without any information leakage, the existing technique, Inner Product Encryption (IPE) by Katz et al. [34], is an option. However, it suffers from a significant drawback: a super-polynomial increase in both ciphertext and trapdoor size, making it highly inefficient. Considering our goal of developing a fast ASE scheme, a more viable alternative is the widely used

$\underline{(\mathsf{pk}, \mathsf{msk}) \leftarrow \mathsf{Setup}(1^\lambda)}$.
Run $\mathsf{GroupGen}(1^\lambda)$ to obtain the group parameters $\mathsf{par} := (p, e, \mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, g_1, g_2)$. Pick $\alpha \xleftarrow{\$} \mathbb{Z}_p$ and a hash function $\mathsf{H} : \{0,1\}^* \to \mathbb{G}_1$. Compute the public key pk and master secret key msk as

$$\mathsf{pk} = (\mathsf{par}, \mathsf{H}, e(g_1, g_2)^\alpha), \mathsf{msk} = \alpha.$$

$\underline{\mathsf{sk} \leftarrow \mathsf{KeyGen}(\mathsf{pk}, \mathsf{msk}, \mathbb{A} = (\mathbf{M}, \pi, \{\pi(i)\}_{i\in[\ell]}))}$.
Pick $r \xleftarrow{\$} \mathbb{Z}_p^\tau, \mathbf{v} \xleftarrow{\$} \mathbb{Z}_p^{n-1}$. Compute

$$\mathsf{sk}_1 = g_2^r, \mathsf{sk}_{2,i} = g_1^{\mathbf{M}_i(\alpha \| \mathbf{v})^\top} \cdot \mathsf{H}(\pi(i))^r.$$

Output $\mathsf{sk} = (\mathbb{A}, \mathsf{sk}_1, \{\mathsf{sk}_{2,i}\}_{i\in[\ell]})$.

$\underline{\mathsf{ct} \leftarrow \mathsf{Enc}(\mathsf{pk}, \mathbb{S} = \{u_i\}_{i\in[m]}, \mathsf{msg})}$. Pick $s \xleftarrow{\$} \mathbb{Z}_p$. Compute

$$\mathsf{ct}_{1,i} = \mathsf{H}(u_i)^s, \mathsf{ct}_2 = g_2^s, \mathsf{ct}_3 = e(g_1, g_2)^{\alpha s} \cdot \mathsf{msg}.$$

Output $\mathsf{ct} = (\mathbb{S}, \{\mathsf{ct}_{1,i}\}_{i\in[m]}, \mathsf{ct}_2, \mathsf{ct}_3)$.

$\underline{\mathsf{msg}/\perp \leftarrow \mathsf{Dec}(\mathsf{ct}, \mathsf{sk})}$.
If $\mathbb{S}$ satisfies $\mathbb{A}$, there exists constants $\{\gamma_i\}_{i\in I}$ s.t. $\sum_{i\in I}\gamma_i \mathbf{M}_i = (1, 0, ..., 0)$ and reconstruct the message msg by computing:

$$\mathsf{msg} = \frac{e(\prod_{i\in I}(\mathsf{ct}_{1,\pi(i)})^{\gamma_i}, \mathsf{sk}_1) \cdot \mathsf{ct}_3}{e(\prod_{i\in I}(\mathsf{sk}_{2,i})^{\gamma_i}, \mathsf{ct}_2)}.$$

Figure 2: The FABEO KP-ABE scheme.

method known as the "partially hidden structure", illustrated in Sec. 3.3. The essence of this structure lies in the division of each attribute into a generic attribute name and an attribute value. While the attribute values remain undisclosed in both the private key and ciphertext, a partially hidden access structure and attribute set expose only the attribute names. For instance, considering an access structure like "(Sender: Tom **AND** Subject: Rent) **OR** Priority: Urgent" and an attribute set "[Sender: Bob, Subject: Meeting, Priority: Medium]", the partially hidden access structure becomes "Sender **AND** (Subject **OR** Priority)" and the partially hidden attribute set is "[Sender, Subject, Priority]". During decryption, the algorithm first matches the attribute names and then tests if the attribute values match.

As highlighted in Fig. 3, each attribute $\pi(i)$ in an access

structure $\mathbb{A}$ is separated into a name $n_{\pi(i)}$ and a value $v_{\pi(i)}$, in which $n_{\pi(i)}$ is exposed with (M, π) in sk. Similarly, each attribute u_i in an attribute set $\mathbb{S}$ is separated into a name n_i and a value v_i, in which n_i is disclosed in ct.

This technique, although leaking a certain level of information (i.e., attribute names), provides high efficiency. Attribute names, being less sensitive than attribute values, allow for efficient matching without involving pairing or exponentiation operations. This efficiency improvement is critical, enabling a fast location of specific attribute values under corresponding names, thereby significantly enhancing decryption efficiency.

$(\mathsf{pk}, \mathsf{msk}) \leftarrow \mathsf{Setup}(1^\lambda)$.

Run $\mathsf{GroupGen}(1^\lambda)$ to obtain the group parameters $\mathsf{par} := (p, e, \mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, g_1, g_2)$. Pick $\alpha, b_1, b_2 \xleftarrow{\$} \mathbb{Z}_p$ and a hash function $\mathsf{H} : \{0,1\}^* \to \mathbb{G}_1$. Compute the public key pk and master secret key msk as

$$\mathsf{pk} = (\mathsf{par}, \mathsf{H}, g_2^{b_1}, g_2^{b_2}, e(g_1, g_2)^\alpha), \mathsf{msk} = (\alpha, b_1, b_2).$$

$\mathsf{sk} \leftarrow \mathsf{KeyGen}(\mathsf{pk}, \mathsf{msk}, \mathbb{A} = (\mathsf{M}, \pi, \{\pi(i)\}_{i\in[\ell]})$.

Remind that $\{\pi(i)\}_{i\in[\ell]} = \{n_{\pi(i)}, v_{\pi(i)}\}_{i\in[\ell]}$. Pick $r \xleftarrow{\$} \mathbb{Z}_p$, $\mathbf{v} \xleftarrow{\$} \mathbb{Z}_p^{n-1}$. Compute $\mathsf{sk}_1 = g_2^r$,

$$\mathsf{sk}_{2,i} = (g_1^{\mathsf{M}_i(\alpha\|\mathbf{v})^\top} \cdot \mathsf{H}(\pi(i))^r)^{\frac{1}{b_1}}, \mathsf{sk}_{3,i} = (g_1^{\mathsf{M}_i(\alpha\|\mathbf{v})^\top} \cdot \mathsf{H}(\pi(i))^r)^{\frac{1}{b_2}}.$$

Output $\mathsf{sk} = ((\mathsf{M}, \pi, \{n_{\pi(i)}\}_{i\in[\ell]}), \mathsf{sk}_1, \{\mathsf{sk}_{2,i}, \mathsf{sk}_{3,i}\}_{i\in[\ell]})$.

$\mathsf{ct} \leftarrow \mathsf{Enc}(\mathsf{pk}, \mathbb{S} = \{u_i\}_{i\in[m]} = \{n_i, v_i\}_{i\in[m]}, \mathsf{msg})$.

Pick $s_1, s_2 \xleftarrow{\$} \mathbb{Z}_p$, let $s = s_1 + s_2$. Compute

$$\mathsf{ct}_{1,i} = \mathsf{H}(u_i)^s, \mathsf{ct}_2 = g_2^{b_1 s_1}, \mathsf{ct}_3 = g_2^{b_2 s_2}, \mathsf{ct}_4 = e(g_1, g_2)^{\alpha s} \cdot \mathsf{msg}.$$

Output $\mathsf{ct} = (\{n_i\}_{i\in[m]}, \{\mathsf{ct}_{1,i}\}_{i\in[m]}, \mathsf{ct}_2, \mathsf{ct}_3, \mathsf{ct}_4)$.

$\mathsf{msg}/\perp \leftarrow \mathsf{Dec}(\mathsf{ct}, \mathsf{sk})$.

Tests if there is any subset I that matches the attribute names $\{n_i\}_{i\in[m]}$ in ct with $(\mathsf{M}, \pi, \{n_{\pi(i)}\}_{i\in[\ell]})$ in sk. If not, return $\perp$. Otherwise, it finds constants $\{\gamma_i\}_{i\in I}$ s.t. $\sum_{i\in I} \gamma_i \mathsf{M}_i = (1, 0, ..., 0)$ and reconstruct the message msg by computing:

$$\mathsf{msg} = \frac{e\left(\prod_{i\in I}(\mathsf{sk}_{2,i})^{\gamma_i}, \mathsf{ct}_2\right) \cdot e\left(\prod_{i\in I}(\mathsf{sk}_{3,i})^{\gamma_i}, \mathsf{ct}_3\right)}{e\left(\prod_{i\in I}(\mathsf{ct}_{1,\pi(i)})^{\gamma_i}, \mathsf{sk}_1\right) \cdot \mathsf{ct}_4}.$$

If the equation holds, return 1. Otherwise, continue to find another subset of I and repeat the checking. If the above equation does not hold for all subsets, return 0.

Figure 3: Our A-KP-ABE scheme.

Randomness splitting technique. We observe that the attribute guessing attack is available as $\mathsf{ct}_{1,u}$ and ct_2 sharing the same randomness s. To counter this problem, we introduce a technique to split the randomness in the ciphertext. Specifically, we divide the randomness s into two distinct components $s_1, s_2 \in \mathbb{Z}_p$ and let $s = s_1 + s_2$. As highlighted in Fig. 3, the ciphertext components are now structured as $\mathsf{ct}_{1,i} = \mathsf{H}(u_i)^s$, $\mathsf{ct}_2 = g_2^{b_1 s_1}$, and $\mathsf{ct}_3 = g_2^{b_2 s_2}$, where $g_2^{b_1}$ and $g_2^{b_2}$ are parts of the public key. At the secret key side, to recover s and eliminate the b_1, b_2 terms, the secret key element $g_1^{\mathsf{M}_i(\alpha\|\mathbf{v})^\top} \cdot \mathsf{H}(\pi(i))^r$ is doubling and exponentiation by $\frac{1}{b_1}$ and $\frac{1}{b_2}$ separately. By correctness, ct_4 remains the same as the ct_3 in FABEO. In this case, given two attributes, u_0 and u_1, and a ciphertext $(\mathsf{ct}_{1,u_b}, \mathsf{ct}_2, \mathsf{ct}_3, \mathsf{ct}_4)$ where $b \in \{0,1\}$, an attacker who owns $g_2^{b_1}$ and $g_2^{b_2}$ can no longer discern the attribute u_b. Consequently, the ciphertext successfully conceals the attribute value.

4.2 FEASE: A Fast and Expressive ASE scheme

In this section, we demonstrate how to convert the A-KP-ABE scheme proposed in Sec. 4.1 into the FEASE, which is our main research target. We first introduce the syntax of an expressive ASE scheme, which includes the following four algorithms:

- $(\mathsf{pk}, \mathsf{sk}) \leftarrow \mathsf{KeyGen}(1^\lambda)$. The key generation algorithm KeyGen is run by the data receiver. The algorithm takes as input a security parameter 1^λ. It outputs a public key pk and a secret key sk.
- $\mathsf{td} \leftarrow \mathsf{Trap}(\mathsf{pk}, \mathsf{sk}, \mathbb{P})$. The trapdoor generation algorithm Trap is run by the data receiver. The algorithm takes as input a public key pk, a secret key sk, and a keyword policy structure $\mathbb{P}$. It outputs a trapdoor td.
- $\mathsf{ct} \leftarrow \mathsf{Enc}(\mathsf{pk}, \mathbb{W})$. The encryption algorithm Enc is run by the data sender. The algorithm takes as input a public key pk, and a set of keywords $\mathbb{W}$. It outputs a ciphertext ct.
- $1/0 \leftarrow \mathsf{Search}(\mathsf{ct}, \mathsf{td})$. The search algorithm Search is run by the cloud server. The algorithm takes as input a keyword ciphertext ct and a trapdoor td. It outputs a bit 1 if the search is successful, or a bit 0 if the search is failed.

In addition to the keyword ciphertext described in our syntax, the data owner also encrypts documents using a public-key encryption scheme. However, it is essential to highlight that our focus in this paper is solely on the encryption of keywords.

It is easy to see that an A-KP-ABE scheme shares a similar syntax as an expressive ASE scheme. In A-KP-ABE, a ciphertext can only be decrypted with a secret key if the attributes in the ciphertext satisfy the policy in the key. In expressive ASE, keywords can only be searched if the keywords in the ciphertext satisfy the policy associated with the trapdoor. Besides, the semantic security of ASE (IND-CKA) (defined in Sec. 5.2) aligns with the same level of security as the anonymity in A-KP-ABE (defined in Sec. 5.1). Therefore, we can convert our A-KP-ABE to FEASE by using the following generic transformation:

Generic transformation from A-KP-ABE to expressive ASE. An ASE scheme $\mathsf{ASE} = (\mathsf{KeyGen}, \mathsf{Enc}, \mathsf{Trap}, \mathsf{Search})$ can be constructed from an A-KP-ABE scheme $\mathsf{A\text{-}KP\text{-}ABE} = (\mathsf{Setup}, \mathsf{KeyGen}, \mathsf{Enc}, \mathsf{Dec})$ by the following steps:

- $(\mathsf{pk}, \mathsf{sk}) \leftarrow \mathsf{ASE.KeyGen}(1^\lambda)$. On input of a security parameter 1^λ, this algorithm executes as follows: (1) Run $(\mathsf{pk}, \mathsf{msk}) \leftarrow \mathsf{A\text{-}KP\text{-}ABE.Setup}(1^\lambda)$. (2) Set $\mathsf{sk} \leftarrow \mathsf{msk}$ and output $(\mathsf{pk}, \mathsf{sk})$.

- $\mathsf{td} \leftarrow \mathsf{ASE.Trap}(\mathsf{pk}, \mathsf{sk}, \mathbb{P})$. On input of pk, sk and a keyword policy $\mathbb{P}$, this algorithm executes as follows: (1) Run $\mathsf{sk} \leftarrow \mathsf{A\text{-}KP\text{-}ABE.KeyGen}(\mathsf{pk}, \mathsf{sk}, \mathbb{P})$. (2) Set $\mathsf{td} \leftarrow \mathsf{sk}$ and output td.

- $\mathsf{ct} \leftarrow \mathsf{ASE.Enc}(\mathsf{pk}, \mathbb{W})$. On input of pk and a set of keywords $\mathbb{W}$, this algorithm executes as follows: (1) Set a message $\mathsf{msg} = 1$. (2) Run $\mathsf{ct} \leftarrow \mathsf{A\text{-}KP\text{-}ABE.Enc}(\mathsf{pk}, \mathbb{W}, \mathsf{msg})$ and output ct.

- $1/0 \leftarrow \mathsf{ASE.Search}(\mathsf{ct}, \mathsf{td})$. On input of td and ct, this algorithm executes as follows: (1) Set $\mathsf{sk} \leftarrow \mathsf{td}$. Run $\mathsf{msg}' \leftarrow \mathsf{A\text{-}KP\text{-}ABE.Dec}(\mathsf{ct}, \mathsf{sk})$. (2) If $\mathsf{msg}' = 1$, the algorithm outputs 1, else 0.

Based on this transformation, the resulting construction of FEASE is shown in Fig. 4. We highlight the differences between FEASE and our A-KP-ABE scheme. Note that $n_{\pi(i)}$ and $v_{\pi(i)}$ represent the keyword name and value in the keyword policy $\mathbb{P}$ respectively. n_i and v_i are the keyword name and value in the keyword set $\mathbb{W}$ respectively. We can see that FEASE's construction mirrors our A-KP-ABE scheme by treating attributes as keywords and setting the message as a known value.

4.3 Fast and Expressive PAEKS scheme

After obtaining FEASE, we extend it into the first expressive PAEKS scheme that has security against Keyword Guessing Attack (KGA). Traditional ASE schemes cannot resist KGA because 1) the data sender encrypts the keyword with only a data receiver's public key. The cloud server can generate ciphertext and exhaustively test the keywords within an existing trapdoor, and 2) the trapdoor does guarantee keyword privacy: Given two keyword policies, a cloud server can discern a trapdoor is generated from which policy. Thus, to defend against KGA, the following security requirements should be satisfied:

1. The cloud server is not capable of matching an existing trapdoor by generating a ciphertext.

2. Ciphertext Indistinguishability (CI): A ciphertext should not reveal the keyword values in the keyword set.

3. Trapdoor Indistinguishability (TI): A trapdoor should not reveal the keyword values in the keyword policies.

$\underline{(\mathsf{pk}, \mathsf{sk}) \leftarrow \mathsf{KeyGen}(1^\lambda)}$.

Run $\mathsf{GroupGen}(1^\lambda)$ to obtain the group parameters $\mathsf{par} := (p, e, \mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, g_1, g_2)$. Pick $\alpha, b_1, b_2 \xleftarrow{\$} \mathbb{Z}_p$ and a hash function $\mathsf{H} : \{0,1\}^* \to \mathbb{G}_1$. Compute the public key and secret key as

$$\mathsf{pk} = (\mathsf{par}, \mathsf{H}, g_2^{b_1}, g_2^{b_2}, e(g_1, g_2)^\alpha), \mathsf{sk} = (\alpha, b_1, b_2)$$

$\underline{\mathsf{td} \leftarrow \mathsf{Trap}(\mathsf{pk}, \mathsf{sk}, \mathbb{P} = (\mathrm{M}, \pi, \{\pi(i)\}_{i\in[\ell]}))}$.

Remind that $\{\pi(i)\}_{i\in[\ell]} = \{n_{\pi(i)}, v_{\pi(i)}\}_{i\in[\ell]}$. Pick $r \xleftarrow{\$} \mathbb{Z}_p$, $\mathbf{v} \xleftarrow{\$} \mathbb{Z}_p^{n-1}$. Compute $\mathsf{td}_1 = g_2^r$

$$\mathsf{td}_{2,i} = (g_1^{\mathrm{M}_i(\alpha\|\mathbf{v})^\top} \cdot \mathsf{H}(\pi(i))^r)^{\frac{1}{b_1}}, \mathsf{td}_{3,i} = (g_1^{\mathrm{M}_i(\alpha\|\mathbf{v})^\top} \cdot \mathsf{H}(\pi(i))^r)^{\frac{1}{b_2}}$$

Output $\mathsf{td} = ((\mathrm{M}, \pi, \{n_{\pi(i)}\}_{i\in[\ell]}), \mathsf{td}_1, \{\mathsf{td}_{2,i}, \mathsf{td}_{3,i}\}_{i\in[\ell]})$.

$\underline{\mathsf{ct} \leftarrow \mathsf{Enc}(\mathsf{pk}, \mathbb{W} = \{w_i\}_{i\in[m]} = \{n_i, v_i\}_{i\in[m]})}$.

Pick $s_1, s_2 \xleftarrow{\$} \mathbb{Z}_p$, let $s = s_1 + s_2$. Compute

$$\mathsf{ct}_{1,i} = \mathsf{H}(w_i)^s, \mathsf{ct}_2 = g_2^{b_1 s_1}, \mathsf{ct}_3 = g_2^{b_2 s_2}, \mathsf{ct}_4 = e(g_1, g_2)^{\alpha s}$$

Output $\mathsf{ct} = (\{n_i\}_{i\in[m]}, \{\mathsf{ct}_{1,i}\}_{i\in[m]}, \mathsf{ct}_2, \mathsf{ct}_3, \mathsf{ct}_4)$.

$\underline{1/0 \leftarrow \mathsf{Search}(\mathsf{ct}, \mathsf{td})}$.

Tests if there is any subset I that matches the keyword names $\{n_i\}_{i\in[m]}$ in ct with $(\mathrm{M}, \pi, \{n_{\pi(i)}\}_{i\in[\ell]})$ in td. If not, return 0. Otherwise, it finds constants $\{\gamma_i\}_{i\in I}$ s.t. $\sum_{i\in I}\gamma_i \mathrm{M}_i = (1, 0, ..., 0)$ and computes:

$$\mathsf{ct}_4 = \frac{e\left(\prod_{i\in I}(\mathsf{td}_{2,i})^{\gamma_i}, \mathsf{ct}_2\right) \cdot e\left(\prod_{i\in I}(\mathsf{td}_{3,i})^{\gamma_i}, \mathsf{ct}_3\right)}{e\left(\prod_{i\in I}(\mathsf{ct}_{1,\pi(i)})^{\gamma_i}, \mathsf{td}_1\right)}.$$

If the equation holds, return 1. Otherwise, the cloud server continues to find another subset of I and repeats the checking. If the above equation does not hold for all subsets, return 0.

Figure 4: Our FEASE scheme.

The formal definitions of CI and TI are defined in the Sec. 5.3. In a PAEKS scheme, the data sender is allowed to have a public key and a secret key. The keywords are encrypted by using the data sender's secret key and the data receiver's public key. The trapdoor is generated by using data receiver's secret key and the data sender's public key. Since the cloud server does not hold any of the secret keys, it cannot generate a ciphertext to match with an existing trapdoor. Borrowing the semantic security of FEASE, it is feasible to preserve CI in the PAEKS. Thus, our main target is to develop TI in our PAEKS design.

The syntax of an expressive PAEKS scheme is defined with the following algorithms:

- $\mathsf{pp} \leftarrow \mathsf{Setup}(1^\lambda)$. The Setup algorithm is run by a trusted party. The algorithm takes as input a security parameter 1^λ. It outputs the global public parameter pp.

- $(\mathsf{pk}_s, \mathsf{sk}_s) \leftarrow \mathsf{KeyGen}_s(1^\lambda)$. The KeyGen_s algorithm is run by a data sender. This algorithm takes as input a security parameter 1^λ. It outputs the sender's public key pk_s and secret key sk_s.

- $(\mathsf{pk}_r, \mathsf{sk}_r) \leftarrow \mathsf{KeyGen}_r(1^\lambda)$. The KeyGen_r algorithm is run by a data receiver. This algorithm takes as input a security parameter 1^λ. It outputs the receiver's public key pk_r and secret key sk_r.

- $\mathsf{td} \leftarrow \mathsf{Trap}(\mathsf{pp}, \mathsf{pk}_s, \mathsf{sk}_r, \mathbb{P})$. The trapdoor generation algorithm Trap is run by the data receiver. The algorithm takes as input the public parameter pp, the sender public key pk_s, the receiver secret key sk_r, and a keyword policy structure $\mathbb{P}$. It outputs a trapdoor td.

- $\mathsf{ct} \leftarrow \mathsf{Enc}(\mathsf{pk}_r, \mathsf{sk}_s, \mathbb{W})$. The encryption algorithm Enc is run by the data sender. The algorithm takes as input the public parameter pp, the receiver public key pk_r, the sender secret key sk_s, and a set of keywords $\mathbb{W}$. It outputs a keyword ciphertext ct.

- $1/0 \leftarrow \mathsf{Search}(\mathsf{ct}, \mathsf{td})$. The search algorithm Search is run by the cloud server. The algorithm takes as input a keyword ciphertext and a trapdoor td. It outputs a bit 1 if the search is successful, or a bit 0 if the search is failed.

Data sender authentication. We first analyze why the trapdoor construction of FEASE does not guarantee keyword privacy. Considering the TI security model defined in the Sec. 5.3: Given two keyword policies that contain keywords $\pi(i)_0$ and $\pi(i)_1$ separately, and a trapdoor $(\mathsf{td}_1, \mathsf{td}_{2,\pi(i)_b}, \mathsf{td}_{3,\pi(i)_b})$ where $b \in \{0, 1\}$, a cloud server can test the keywords $\pi(i)_0$ and $\pi(i)_1$ separately into the equation $e(\prod_{i\in I}(\mathsf{td}_{2,i})^{\gamma_i}, g_2^{b_1}) = e(g_1, g_2)^{\alpha} \cdot e(\prod_{i\in I}\mathsf{H}(\pi(i)_b)^{\gamma_i}, \mathsf{td}_1)$ where the γ_i can be easily calculated since there is no policy for a single keyword. Even to distinguish two sets of keywords, the server can try different policies together with γ_i and hash values. Since the number of keywords and policies is polynomially bounded, the server can discern the keywords hidden in the trapdoor.

The concrete construction of our PAEKS scheme is shown in Fig. 5. We highlight the difference between the PAEKS and FEASE. Our idea to extend from FEASE to PAEKS is to embed a data sender's secret key $\frac{1}{c} \in \mathbb{Z}_p$ in the keywords term to be distinguished in the ciphertext: $\mathsf{H}(w_i)^{\frac{s}{c}}$, and eliminate $\frac{1}{c}$ by the corresponding pairing element g_2^{cr} in trapdoor, where g_2^c is the data sender's public key. The reasons are listed as follows:

- Multiplying a random number $\frac{1}{c}$ to s does not affect the construction for the ciphertext, thus the CI security is inherited from the IND-CKA security of FEASE.

$\mathsf{pp} \leftarrow \mathsf{Setup}(1^\lambda)$. Run $\mathsf{GroupGen}(1^\lambda)$ to obtain group parameters $\mathsf{par} := (p, e, \mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, g_1, g_2)$. Pick a hash function $\mathsf{H}: \{0,1\}^* \to \mathbb{G}_1$. The global public parameter is

$$\mathsf{pp} = (\mathsf{par}, \mathsf{H}).$$

$(\mathsf{pk}_r, \mathsf{sk}_r) \leftarrow \mathsf{KeyGen}_r(1^\lambda)$. Pick $\alpha, b_1, b_2 \leftarrow \mathbb{Z}_p$. Compute

$$\mathsf{pk}_r = (g_2^{b_1}, g_2^{b_2}, e(g_1, g_2)^{\alpha}), \mathsf{sk}_r = (\alpha, b_1, b_2).$$

$(\mathsf{pk}_s, \mathsf{sk}_s) \leftarrow \mathsf{KeyGen}_s(1^\lambda)$. Pick $c \leftarrow \mathbb{Z}_p$. Compute

$$\mathsf{pk}_s = g_2^c, \mathsf{sk}_s = c.$$

$\mathsf{td} \leftarrow \mathsf{Trap}(\mathsf{pp}, \mathsf{pk}_s, \mathsf{sk}_r, \mathbb{P} = (\mathrm{M}, \pi, \{\pi(i)\}_{i\in[\ell]}))$.

Remind that $\{\pi(i)\}_{i\in[\ell]} = \{n_{\pi(i)}, v_{\pi(i)}\}_{i\in[\ell]}$. Pick $r \xleftarrow{\$} \mathbb{Z}_p$, $\mathbf{v} \xleftarrow{\$} \mathbb{Z}_p^{n-1}$. Compute $\mathsf{td}_1 = g_2^{cr}$

$$\mathsf{td}_{2,i} = (g_1^{\mathrm{M}_i(\alpha\|\mathbf{v})^\top} \cdot \mathsf{H}(\pi(i))^r)^{\frac{1}{b_1}}, \mathsf{td}_{3,i} = (g_1^{\mathrm{M}_i(\alpha\|\mathbf{v})^\top} \cdot \mathsf{H}(\pi(i))^r)^{\frac{1}{b_2}}.$$

Output $\mathsf{td} = ((\mathrm{M}, \pi, \{n_{\pi(i)}\}_{i\in[\ell]}), \mathsf{td}_1, \{\mathsf{td}_{2,i}, \mathsf{td}_{3,i}\}_{i\in[\ell]})$

$\mathsf{ct} \leftarrow \mathsf{Enc}(\mathsf{pk}_r, \mathsf{sk}_s, \mathbb{W} = \{w_i\}_{i\in[m]} = \{n_i, v_i\}_{i\in[m]})$.

Pick $s_1, s_2 \xleftarrow{\$} \mathbb{Z}_p$, let $s = s_1 + s_2$. Compute

$$\mathsf{ct}_{1,i} = \mathsf{H}(w_i)^{\frac{s}{c}}, \mathsf{ct}_2 = g_2^{b_1 s_1}, \mathsf{ct}_3 = g_2^{b_2 s_2}, \mathsf{ct}_4 = e(g_1, g_2)^{\alpha s}$$

Output $\mathsf{ct} = (\{n_i\}_{i\in[m]}, \{\mathsf{ct}_{1,i}\}_{i\in[m]}, \mathsf{ct}_2, \mathsf{ct}_3, \mathsf{ct}_4)$.

$1/0 \leftarrow \mathsf{Search}(\mathsf{ct}, \mathsf{td})$.
Tests if there is any subset I that matches the keyword names $\{n_i\}_{i\in[m]}$ in ct with $(\mathrm{M}, \pi, \{n_{\pi(i)}\}_{i\in[\ell]})$ in td. If not, return 0. Otherwise, it finds constants $\{\gamma_i\}_{i\in I}$ s.t. $\sum_{i\in I}\gamma_i \mathrm{M}_i = (1, 0, ..., 0)$ and computes:

$$\mathsf{ct}_4 = \frac{e\left(\prod_{i\in I}(\mathsf{td}_{2,i})^{\gamma_i}, \mathsf{ct}_2\right) \cdot e\left(\prod_{i\in I}(\mathsf{td}_{3,i})^{\gamma_i}, \mathsf{ct}_3\right)}{e\left(\prod_{i\in I}(\mathsf{ct}_{1,\pi(i)})^{\gamma_i}, \mathsf{td}_1\right)}.$$

If the equation holds, return 1. Otherwise, the cloud server continues to find another subset of I and repeats the checking. If the above equation does not hold for all subsets, return 0.

Figure 5: Our PAEKS scheme.

- g_2^{cr} is a single element that is not related to the number of keywords, thus the efficiency of trapdoor generation remains almost the same as FEASE.

- After changing the term from g_2^r to g_2^{cr}, the cloud server is not capable of attacking the trapdoor since it only has the knowledge of g_2^c and g_2^{cr} instead of g_2^r.

5 Security definitions

In this section, we introduce the formal security definitions and models of expressive A-KP-ABE, ASE, and PAEKS schemes.

5.1 Security definitions of A-KP-ABE

The security model for an A-KP-ABE scheme with a partially hidden structure addresses the property that a ciphertext does not reveal any information about the encrypted message, which we call "Indistinguishability against Chosen Plaintext Attack (IND-CPA)" security and that a ciphertext does not reveal any information about the encrypted attribute set, which we call "Anonymity (Anon)".

IND-CPA Security. We model the adaptive IND-CPA security in a game $\prod$ that is running between an adversary $\mathcal{A}$ and a challenger $\mathcal{C}$ as follows:

- **Setup.** $\mathcal{C}$ runs $\mathsf{Setup}(1^\lambda)$ to obtain a public key pk and a master secret key msk. It sends pk to the adversary and keeps msk secret.
- **Phase 1.** $\mathcal{A}$ issues queries to a key generation oracle for polynomial many times:
  - Key generation oracle: Given an access structure $\mathbb{A}$, the oracle generates a secret key $\mathsf{sk} \leftarrow \mathsf{KeyGen}(\mathsf{pk}, \mathsf{msk}, \mathbb{A})$ and returns sk to $\mathcal{A}$.
- **Challenge.** $\mathcal{A}$ outputs a challenge attribute set $\mathbb{S}^*$ and two equal-length messages msg_0^*, msg_1^* with the restriction that $\mathbb{S}^*$ cannot satisfy any access structure $\mathbb{A}$ that has been queried in Phase 1. Then $\mathcal{C}$ selects a random bit $b \in \{0, 1\}$, runs the algorithm $\mathsf{ct}_b^* \leftarrow \mathsf{Enc}(\mathsf{pk}, \mathbb{S}^*, \mathsf{msg}_b^*)$ and returns the challenge ciphertext ct_b^* to $\mathcal{A}$.
- **Phase 2.** Same as Phase 1 with the restriction that any input access structure $\mathbb{A}$ cannot be satisfied by $\mathbb{S}^*$.
- **Guess.** $\mathcal{A}$ outputs $b' \in \{0, 1\}$ and wins the game if $b' = b$.

An A-KP-ABE scheme is adaptively IND-CPA secure if the advantage function refers to the security game $\prod$

$$\mathsf{Adv}_{\Pi,\mathcal{A}}^{\mathsf{CPA}}(\lambda) = \left| \Pr[b' = b] - \frac{1}{2} \right|$$

is negligible in security parameter λ for any PPT adversary $\mathcal{A}$.

Anonymity. Then we model the anonymity property in a game $\prod$ that is running between an adversary $\mathcal{A}$ and a challenger $\mathcal{C}$ as follows:

- **Setup.** $\mathcal{C}$ runs $\mathsf{Setup}(1^\lambda)$ to obtain a public key pk and a master secret key msk. It gives pk to adversary $\mathcal{A}$ and keeps msk secret.
- **Phase 1.** The adversary $\mathcal{A}$ issues queries to a key generation oracle for polynomial many times:
  - Key generation oracle: Given an access structure $\mathbb{A}$, the oracle generates a secret key $\mathsf{sk} \leftarrow \mathsf{KeyGen}(\mathsf{pk}, \mathsf{msk}, \mathbb{A})$ and returns sk to $\mathcal{A}$.
- **Challenge.** $\mathcal{A}$ outputs a message msg^* and two equal-size attribute sets $\mathbb{S}_0^* = \{n_i, v_{i0}\}_{i\in[m]}$, $\mathbb{S}_1^* = \{n_i, v_{i1}\}_{i\in[m]}$ with the restriction that $\mathbb{S}_0^*, \mathbb{S}_1^*$ have the same attribute names $\{n_i\}_{i\in[m]}$ and neither of them satisfies any access structure $\mathbb{A}$ that has been queried in Phase 1. $\mathcal{C}$ selects a random bit $b \in \{0, 1\}$, runs the algorithm $\mathsf{ct}_b^* \leftarrow \mathsf{Enc}(\mathsf{pk}, \mathbb{S}_b^*, \mathsf{msg}^*)$ and returns the challenge ciphertext ct_b^* to $\mathcal{A}$.
- **Phase 2.** Same as Phase 1 with the restriction that any input access structure $\mathbb{A}$ cannot be satisfied by $\mathbb{S}_0^*$ and $\mathbb{S}_1^*$.
- **Guess.** $\mathcal{A}$ outputs $b' \in \{0, 1\}$ and wins the game if $b' = b$.

An A-KP-ABE scheme is anonymous if the advantage function refers to the security game $\prod$

$$\mathsf{Adv}_{\Pi,\mathcal{A}}^{\mathsf{Anon}}(\lambda) = \left| \Pr[b' = b] - \frac{1}{2} \right|$$

is negligible in security parameter λ for any PPT adversary $\mathcal{A}$.

5.2 Security definitions of expressive ASE

The security model for an expressive ASE scheme with a partially hidden structure addresses the property that a ciphertext does not reveal any information about the keyword values, which we call Indistinguishability against Chosen Keyword Attacks (IND-CKA) defined here for keyword sets.

IND-CKA security. We model the adaptive IND-CKA security in a game $\prod$ that is running between an adversary $\mathcal{A}$ and a challenger $\mathcal{C}$ as follows:

- **Setup.** The challenger $\mathcal{C}$ runs $\mathsf{KeyGen}(1^\lambda)$ to obtain a public key pk and the a secret key sk. It gives the public key pk to adversary $\mathcal{A}$ and keeps sk to itself.
- **Phase 1.** The adversary $\mathcal{A}$ adaptively issues queries to a trapdoor oracle for polynomial many times:
  - Trapdoor oracle: Given a keyword policy structure $\mathbb{P}$, the oracle generates a trapdoor $\mathsf{td} \leftarrow \mathsf{Trap}(\mathsf{pk}, \mathsf{sk}, \mathbb{P})$ and returns td to $\mathcal{A}$.
- **Challenge.** $\mathcal{A}$ outputs two equal-size keyword sets $\mathbb{W}_0^* = \{n_i, v_{i0}\}_{i\in[m]}$, $\mathbb{W}_1^* = \{n_i, v_{i1}\}_{i\in[m]}$ with the restriction that $\mathbb{W}_0^*$, $\mathbb{W}_1^*$ have the same keyword names $\{n_i\}_{i\in[m]}$, and neither of them satisfies any trapdoor that has been queried in Phase 1. $\mathcal{C}$ selects a random bit $b \in \{0, 1\}$, runs the algorithm $\mathsf{ct}_b^* \leftarrow \mathsf{Enc}(\mathsf{pk}, \mathbb{W}_b^*)$ and returns the challenge ciphertext ct_b^* to the $\mathcal{A}$.
- **Phase 2.** $\mathcal{A}$ continues to issue queries to the trapdoor oracle for polynomial times with the restriction that any $\mathbb{P}$ input by $\mathcal{A}$ cannot be satisfied by $\mathbb{W}_0^*$ and $\mathbb{W}_1^*$.

- **Guess.** $\mathcal{A}$ outputs its guess $b' \in \{0, 1\}$ and wins the game if $b' = b$.

An expressive ASE scheme is adaptively IND-CKA secure if the advantage function refers to the security game $\prod$

$$\mathrm{Adv}^{\mathsf{CKA}}_{\prod,\mathcal{A}}(\lambda) = \left| \Pr[b' = b] - \frac{1}{2} \right|$$

is negligible in security parameter λ for any PPT adversary $\mathcal{A}$.

5.3 Security definitions of expressive PAEKS

The security model for an expressive PAEKS scheme with a partially hidden structure addresses the property that a ciphertext does not reveal any information about the keyword values, which we call "Ciphertext Indistinguishability (CI)" and the property that a trapdoor does not reveal any information about the keyword policy values, which we call "Trapdoor Indistinguishability (TI)". CI and TI are defined in two separate games that are running between an adversary $\mathcal{A}$ and a challenger $\mathcal{C}$. We refer to the state-of-the-art PAEKS security model proposed in [20], in which it addresses both the CI and TI in a multi-user, multi-challenge, and fully chosen setting. Intuitively, these terms indicate the following conditions in the CI/TI game:

1. Multi-user CI/TI: In the CI/ TI game, $\mathcal{A}$ can not only input a keyword set/keyword policy but also input a data receiver/data sender's public key [10] to the ciphertext/trapdoor oracle respectively.

2. Multi-challenge CI/TI: In the CI/TI game, $\mathcal{A}$ can choose two sets of keywords for challenge keyword sets/policies rather than only two single keywords respectively [11].

3. Fully-chosen CI/TI: In the CI/TI game, $\mathcal{A}$ can query ciphertext/trapdoor for the challenge keyword sets/keyword policies from the ciphertext/trapdoor oracle respectively.

Game 1: Ciphertext Indistinguishability

1. **Setup.** Given a security parameter λ, the challenger $\mathcal{C}$ generates the global system parameter pp. Then $\mathcal{C}$ generates a pair of sender's key $(\mathsf{pk}_s, \mathsf{sk}_s)$ and a pair of receiver's key $(\mathsf{pk}_r, \mathsf{sk}_r)$. It gives $(\mathsf{pp}, \mathsf{pk}_s, \mathsf{pk}_r)$ to the adversary $\mathcal{A}$.

2. **Phase 1.** $\mathcal{A}$ is allowed to adaptively issue queries to the following oracles for polynomial many times:

   - Trapdoor Oracle $O_T(\mathbb{P}, \mathsf{pk})$: Given a keyword policy structure $\mathbb{P}$ and a public key pk (not necessarily the sender's pk_s), the oracle computes a trapdoor $\mathsf{td} \leftarrow \mathsf{Trap}(\mathsf{sk}_r, \mathsf{pk}, \mathbb{P})$ and returns td to $\mathcal{A}$.
   - Ciphertext Oracle $O_C(\mathbb{W}, \mathsf{pk})$: Given a set of keywords $\mathbb{W}$ and a public key pk (not necessarily the receiver's pk_r), the oracle computes a ciphertext $\mathsf{ct} \leftarrow \mathsf{Enc}(\mathsf{sk}_s, \mathsf{pk}, \mathbb{W})$ and returns ct to $\mathcal{A}$.

3. **Challenge.** After Phase 1, $\mathcal{A}$ outputs two equal-size keyword sets $\mathbb{W}^*_0 = \{n_i, v_{i0}\}_{i\in[m]}$, $\mathbb{W}^*_1 = \{n_i, v_{i1}\}_{i\in[m]}$ with the restriction that $\mathbb{W}^*_0, \mathbb{W}^*_1$ have the same keyword names $\{n_i\}_{i\in[m]}$ and neither of them satisfies any trapdoor that has been queried for $O_T(\cdot, \mathsf{pk}_s)$ in Phase 1, and submits them to $\mathcal{C}$. $\mathcal{C}$ randomly chooses a bit $b \in \{0, 1\}$, computes $\mathsf{ct}^*_b \leftarrow \mathsf{Enc}(\mathsf{pk}_r, \mathsf{sk}_s, \mathbb{W}^*_b)$ and returns ct^*_b to $\mathcal{A}$.

4. **Phase 2.** $\mathcal{A}$ continues to issue queries to O_T and O_C as above, with the restriction that any trapdoor that is queried for $O_T(\cdot, \mathsf{pk}_s)$ should not be satisfied by $\mathbb{W}^*_0$ and $\mathbb{W}^*_1$.

5. **Guess.** $\mathcal{A}$ outputs $b' \in \{0, 1\}$ and wins the game if $b' = b$.

We define $\mathcal{A}$'s advantage of successfully distinguishing the ciphertext of PAEKS as

$$\mathrm{Adv}^{\mathrm{CI}}_{\mathcal{A}}(\lambda) = \left| \Pr[b' = b] - \frac{1}{2} \right|.$$

Definition 2. *A PAEKS scheme is fully CI secure if for any PPT adversary $\mathcal{A}$, $\mathrm{Adv}^{\mathrm{CI}}_{\mathcal{A}}(\lambda)$ is negligible for security parameter λ.*

Game 2: Trapdoor Indistinguishability

1. **Setup.** The challenger $\mathcal{C}$ generates pp, $(\mathsf{pk}_s, \mathsf{sk}_s)$ and $(\mathsf{pk}_r, \mathsf{sk}_r)$ as in Game 1. It then gives $(\mathsf{pp}, \mathsf{pk}_s, \mathsf{pk}_r)$ to the adversary $\mathcal{A}$.

2. **Phase 1.** $\mathcal{A}$ issues queries to oracles $O_T(\mathbb{P}, \mathsf{pk})$ and $O_C(\mathbb{W}, \mathsf{pk})$ as in Game 1.

3. **Challenge.** After Phase 1, $\mathcal{A}$ chooses two equal size keyword policies $\mathbb{P}^*_0 = (\mathrm{M}^*, \pi^*, \{n_{\pi^*(i)}, v_{\pi(i)0}\}_{i\in[\ell]})$, $\mathbb{P}^*_1 = (\mathrm{M}^*, \pi^*, \{n_{\pi^*(i)}, v_{\pi(i)1}\}_{i\in[\ell]})$ with the restriction that $\mathbb{P}^*_0, \mathbb{P}^*_1$ have the same $(\mathrm{M}^*, \pi^*, \{n_{\pi^*(i)}\}_{i\in[\ell]})$ and neither of them are satisfied by any ciphertext that has been queried to $O_C(\cdot, \mathsf{pk}_r)$ in Phase 1, and submits them to $\mathcal{C}$ as the challenge keywords. $\mathcal{C}$ randomly chooses a bit $b \in \{0, 1\}$, computes $\mathsf{td}^*_b \leftarrow \mathsf{Trap}(\mathsf{pk}_s, \mathsf{sk}_r, \mathbb{P}^*_b)$ and returns td^*_b to $\mathcal{A}$.

4. **Phase 2.** $\mathcal{A}$ continues to issue queries to O_T and O_C as above, with the restriction that any ciphertext that is queried for $O_C(\cdot, \mathsf{pk}_r)$ should not be satisfied by $\mathbb{P}^*_0$ and $\mathbb{P}^*_1$.

5. **Guess.** $\mathcal{A}$ outputs $b' \in \{0, 1\}$ and wins the game if $b' = b$.

We define $\mathcal{A}$'s advantage of successfully distinguishing the trapdoors of PAEKS as

$$\mathrm{Adv}^{\mathrm{TI}}_{\mathcal{A}}(\lambda) = \left| \Pr[b' = b] - \frac{1}{2} \right|.$$

Definition 3. *A PAEKS scheme is fully TI secure if for any PPT adversary $\mathcal{A}$, $\mathrm{Adv}^{\mathrm{TI}}_{\mathcal{A}}(\lambda)$ is negligible for security parameter λ.*

[10] The public key is not necessary to be the challenged data sender or receiver, it could be anyone's public key including $\mathcal{A}$.

[11] This setting is not naturally preserved in a PAEKS scheme that only supports equality queries. But for an expressive PAEKS, this is a default setting.

6 Security Analysis of our schemes

In this section, we prove the security of our A-KP-ABE, FEASE, and PAEKS schemes under the Generic Group Model (GGM) and random oracle model. The reasons we use the generic group model can be summarized into the following aspects:

- The GGM is widely utilized in practical applications due to its sufficient security, supported by a deep understanding of pairing curves and widespread adoption. In practice, there is no significant difference observed between standard assumptions like SXDH and GGM security [50]. Real-world systems are more vulnerable to issues such as side-channel attacks or poor security practices, which are beyond the scope of GGM.
- The most efficient ABE schemes, such as FABEO [50] and BSW [10], are proven under GGM. Our proposed schemes, aimed at efficiency, utilize the same proof technique as [50], making GGM the natural choice.
- GGM serves as the base technique for proving the security of many well-known static assumptions like Diffie-Hellman (DH), Bilinear Diffie-Hellman (BDH), and their variants [11, 12, 54]. This underscores GGM's role in security proofs within various cryptographic contexts.

Theorem 1. *Our A-KP-ABE scheme is adaptively IND-CPA secure under the generic group model by modeling the hash function* H *as a random oracle.*

The proof of Theorem 1 is shown in our full version [43].

Theorem 2. *Our A-KP-ABE scheme is anonymous under the generic group model by modeling the hash function* H *as a random oracle.*

The proof of Theorem 2 is shown in our full version [43].

Theorem 3. *FEASE is adaptively IND-CKA secure under the generic group model by modeling the hash function* H *as a random oracle.*

The proof of Theorem 3 is shown in our full version [43].

Theorem 4. *The proposed PAEKS scheme is fully CI secure under the generic group model by modeling the hash function* H *as a random oracle.*

The proof of Theorem 4 is shown in our full version [43].

Theorem 5. *The proposed PAEKS scheme is fully TI secure under the generic group model by modeling the hash function* H *as a random oracle.*

The proof of Theorem 5 is shown in our full version [43].

7 Implementation and performance

We first introduce the roadmap of our experiments. Then we analyze the performance of the expressive ASE and KP-ABE schemes. Finally, we conduct an additional set of experiments for larger datasets.

7.1 Implementation roadmap

We implement our FEASE, PAEKS, A-KP-ABE schemes and the most efficient expressive ASE and ABE schemes in Python 3.9.16 using the Charm 0.5 framework [4] and the MNT224 curve for pairings because it is the best Type-III curve in PBC, the default pairing library in Charm. All running times below were measured on a PC with a 3.59 GHz AMD Ryzen 5 3600 6-Core Processor and 16GB RAM. The implementation code is available on GitHub [1].

In particular, we compare our FEASE and PAEKS scheme with the most efficient expressive ASE schemes CWDWL16 [21] and MZNLHS17 [44] and compare our A-KP-ABE scheme with the most efficient KP-ABE schemes FAME [3] and FABEO [50] [12]. Among these schemes, only CWDWL16 is constructed on a symmetric setting. In order to compare their efficiency on the same level, we transfer the construction of CWDWL16 to the asymmetric setting (presented in Appendix A). We choose not to compare FEASE with former expressive ASE schemes [34, 37, 42] since they are all based on the inefficient composite order groups. According to the analysis in [25, 29], in terms of the pairing-friendly elliptic curves, prime order groups have a clear advantage in both parameter size and computational efficiency over composite order groups.

For the expressive ASE schemes, we first choose random words from the English vocabulary to form keyword names and randomly assign a positive integer between 1 - 100 as a keyword value to each keyword name. Thus, every keyword is in the format of "Department: 2", "Professional: 6", "Hospital: 7", etc. The keyword values are the input of the trapdoor and encryption algorithm and the keyword names are exposed. We ensure that the keyword names in every trapdoor are included in the ciphertext, i.e., the keyword names can always match regardless of the policy, but the keyword values are chosen randomly for the trapdoor and ciphertext side. i.e., the keyword values only have little probability to match. In this way, we can simulate the worst case that the search has to traverse every subset of the matched keyword names to maximize the search time. On the ciphertext side, we test the encryption for 10, 20, ..., 100 keywords. On the trapdoor side, we choose 10, 15, ..., 50 keywords and assign "AND" and "OR" gates between the keywords to form policies.

For the KP-ABE schemes, We separate it into two cases: for our A-KP-ABE scheme, we create the attribute set and access policies in the way as the keyword set and keyword policies as stated above. For FAME and FABEO KP-ABE

[12] The reasons are separately shown in Sec. 2.1 and our full version [43].

Groups	Choose	Multiply	Exp.	Hash	Pairing
$\mathbb{G}_1$	0.58	0.02	0.57	0.04	3.68
$\mathbb{G}_2$	4.32	0.28	4.37	10.85	
$\mathbb{G}_T$	-	0.05	0.96	-	

Table 2: Average time (in milliseconds) for various operations on MNT224 curve.

Scheme	Setup	KeyGen_s	KeyGen_r	KeyGen_c

Table 3: Setup time and sender/receiver/server key generation time for various schemes (in milliseconds).

schemes, the partially hidden structure is not needed since they do not aim to protect attribute privacy. Thus, their attributes are straightforward and their policies are to use AND gate between any attribute because all the attributes are then required for decryption. We test these schemes against policies and attribute sets of size 10, 20, ..., 100 since large policy sizes are quite likely in typical use cases [28].

For both the keyword policies and access policies, we first convert the policies into a Boolean formula and then to an MSP using Lewko-Waters' method [39] (see Sec. 3.2 for a detailed discussion) so that the matrix M has only entries in $\{0, 1, -1\}$ and the reconstruction coefficients $\{\gamma_i\}$ are always 0 or 1, which reduces the number of exponentiations.

We present the setup times for the expressive ASE schemes and KP-ABE schemes in Table 3. Then we show the running times for the expressive ASE schemes in Fig. 6 and for the KP-ABE schemes in Fig. 7. These results are supported by our theoretical overview in Table 4 and Table 5 which lists the number of multiplications and exponentiations for each group as well as the number of hashing and pairing operations for each scheme. Additionally, we provide the number of group elements of trapdoor/secret key and ciphertext in Table 6. A more detailed explanation of running times and sizes is shown below.

7.2 Basic operation and initializations

Table 2 lists the average time taken by various operations on MNT224 in milliseconds. We can see that operations on group $\mathbb{G}_2$ are much more expensive than on $\mathbb{G}_1$, in which it has 8 times for choosing an element and exponentiation, 14 times for multiplication, and 271 times for hashing. Pairing is also a relatively expensive operation that is close to the cost of exponentiation on $\mathbb{G}_2$. It is also important to note that the size of an element in $\mathbb{G}_2$ is 3 times that of $\mathbb{G}_1$.

Setup time. In Table 3, we show the time of setup, data sender/data receiver key generation (only used in our PAEKS scheme), and cloud server key generation (used in CWDWL16 and MZNLHS17) of the schemes listed in our evaluation. Since all schemes support large universes of keywords/attributes, all of these schemes have a constant setup time and user/server key generation time and are almost equally fast. In specific, the setup time of FEASE/PAEKS is a bit faster than CWDWL16 and MZNLHS17, and the setup time for our A-KP-ABE lies between FAME and FABEO.

7.3 Expressive ASE schemes

The running times for expressive ASE schemes are shown in Fig. 6. For encryption, MZNLHS17 and our FEASE/PAEKS have a very close time around $0.06 \sim 0.07$s for encrypting 100 keywords, in which CWDWL16 is nearly 7 times slower. This result can be supported by Table 4: Although FEASE/PAEKS has two more exponentiations in $\mathbb{G}_2$, MZNLHS17 has 6 more exponentiations and $m+2$ multiplications in $\mathbb{G}_1$ and CWDWL16 has much more of them.

For the trapdoor generation algorithm, FEASE/PAEKS has the fastest 0.03s for generating a trapdoor with 50 keywords, followed by 3.76s from CWDWL16, and the MZNLHS17 runs a very inefficient 53.75s for 50 keywords. In terms of Table 4, almost all the multiplications and exponentiations of CWDWL16 and MZNLHS17 are calculated on $\mathbb{G}_2$. Instead, FEASE/PAEKS has less number of them and they happened in $\mathbb{G}_1$. Besides, MZNLHS17 has a quadratic increasing time regarding keyword numbers in a trapdoor, in which the trade-off is brought from the target of constant-size ciphertext.

For the search algorithm, we can see from Fig. 6 (c) that, all the schemes are linear to the number of matched keyword names subset. For the special case that we implement (each subset contains only one keyword), FEASE/PAEKS runs the fastest 0.1s for 10 subsets which is 2 times faster than CWDWL16 and MZNLHS17. Then Fig. 6 (d) shows that FEASE/PAEKS is the only one that remains a constant time around 0.011s for searching no matter how many keywords are included in a subset, while CWDWL16 and MZNLHS has a linear increase. We can see this in Table 5. First of all, FEASE/PAEKS has the least number of multiplications in $\mathbb{G}_T$ and pairings. Second, the pairing number of CWDWL16 is related to x_2 - the total number of keywords needed for search, which is why the search time is both related to x_1 - the matched subset number, and the number of keywords in each subset. Instead, the pairing number of MZNLHS17 and FEASE/PAEKS is only related to x_1. However, MZNLHS17 has extra calculations to multiply 4 components for each trapdoor element in each subset, before carrying out the pairing operations. This calculation is on the costly $\mathbb{G}_2$ group and is linear to x_2, which incurs a linear increase for their search time. Note that FEASE/PAEKS also has a linear increase regarding x_2 for multiplications in $\mathbb{G}_1$, but as shown in Table 2, it only takes 0.02ms for each hence it does not impact the search time for a limited number of keywords.

Schemes	Trapdoor/Secret Key						Encryption					
	$\mathbb{G}_1$			$\mathbb{G}_2$			$\mathbb{G}_1$			$\mathbb{G}_2$		
	Mul	Exp	Hash	Mul	Exp	Hash	Mul	Exp	Hash	Mul	Exp	Hash
CWDWL16 [21]	-	1	-	3ℓ	$8\ell+1$	-	$2m$	$6m+2$	-	-	-	-
MZNLHS17 [44]	-	1	-	3ℓ	$4\ell^2+4\ell+1$	-	$m+2$	$m+6$	-	-	-	-
FEASE (Fig. 4)	2ℓ	4ℓ	ℓ	-	1	-	-	m	m	-	2	-
PAEKS (Fig. 5)	2ℓ	4ℓ	ℓ	-	1	-	-	m	m	-	2	-
FAME [3]	$9\ell n+3n$	$9\ell+3n$	$6\ell+6n$	-	3	-	$3m$	$6m$	$6m$	-	-	-
FABEO [50]	ℓ	2ℓ	ℓ	-	1	-	-	m	m	-	1	-
A-KP-ABE (Fig. 3)	2ℓ	4ℓ	ℓ	-	1	-	-	m	m	-	2	-

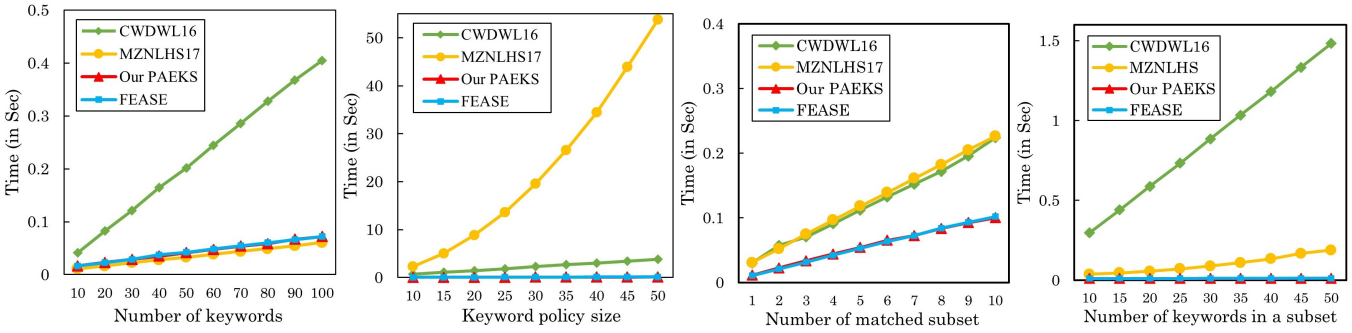
Table 4: Computational overhead for trapdoor/key generation and encryption between ASE (top)/KP-ABE (bottom) schemes. m denotes the number of keywords/attributes in the ciphertext, ℓ, and n are the number of rows and columns of the MSP matrix.

Schemes	Search/Decryption				
	$\mathbb{G}_1$	$\mathbb{G}_2$		$\mathbb{G}_T$	
	Mul	Mul	Exp	Mul	Pairing
CWDWL16 [21]	-	1	-	$5x_2$	$6x_2+1$
MZNLHS17 [44]	-	$7x_2-x_1+1$	-	5	$6x_1+1$
FEASE (Fig. 4)	$3x_2$	-	-	2	$3x_1$
PAEKS (Fig. 5)	$3x_2$	-	-	2	$3x_1$
FAME [3]	$6x_2$	-	-	6	6
FABEO [50]	$2x_2$	-	-	2	2
A-KP-ABE (Fig. 3)	$3x_2$	-	-	3	$3x_1$

Table 5: Computational overhead for search/decryption between ASE (top)/KP-ABE (bottom) schemes. x_1 denotes the total number of matched keyword/attribute names subset. x_2 denotes the total number of keywords/attributes under every matched names subset.

Schemes	Trapdoor/Secret key		Ciphertext	
	$\mathbb{G}_1$	$\mathbb{G}_2$	$\mathbb{G}_1$	$\mathbb{G}_2$
CWDWL16 [21]	1	$6\ell+1$	$5m+1$	-
MZNLHS17 [44]	1	$4\ell^2+2\ell+1$	6	-
FEASE (Fig. 4)	2ℓ	1	m	2
PAEKS (Fig. 5)	2ℓ	1	m	2
FAME [3]	3ℓ	3	$3m$	3
FABEO [50]	ℓ	1	m	1
A-KP-ABE (Fig. 3)	2ℓ	1	m	2

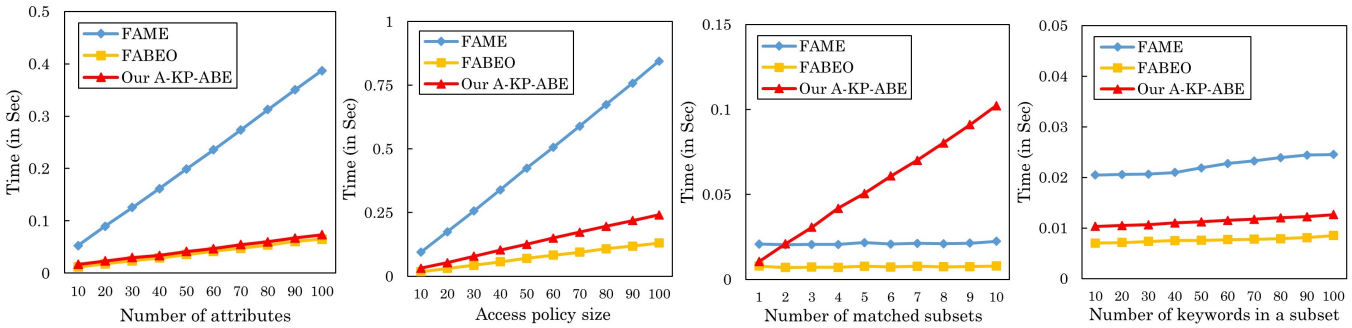
Table 6: Comparison of communication overhead between ASE (top)/KP-ABE (bottom) schemes. m denotes the number of keywords/attributes in the ciphertext, and ℓ is the number of rows of the MSP matrix.



Then we can see the comparison of the communication overhead in Table 6, which shows the number of group elements of trapdoor and ciphertext. Note that in general, elements in $\mathbb{G}_2$ are about 2 to 3 times the size of elements in $\mathbb{G}_1$. For ciphertext, MZNLHS17 has a constant of 6 ciphertext elements in $\mathbb{G}_1$. FEASE/PAEKS has m element in $\mathbb{G}_1$ and 2 elements in $\mathbb{G}_2$, which is less than CWDWL16 that has $5m+1$ elements on $\mathbb{G}_1$. For trapdoor, FEASE/PAEKS has 2ℓ elements in $\mathbb{G}_1$ and 1 element in $\mathbb{G}_2$ while CWDWL16 has $6\ell+1$ elements in $\mathbb{G}_2$ group and 1 element in $\mathbb{G}_1$. The worst one is MZNLHS17 that they have quadratic $4\ell^2+2\ell+1$ trapdoor elements in $\mathbb{G}_2$, which is a trade-off of their constant-size ciphertext.

7.4 KP-ABE schemes

We can see the running times for KP-ABE schemes in Fig. 7. For encryption, our A-KP-ABE scheme runs a very fast 0.07s for the encryption of 100 keywords, with only 0.01s slower than FABEO! FAME needs 0.38s in the same case, which is 5 times slower than our A-KP-ABE. Referring to Table 4, this is because our A-KP-ABE has the same m exponentiations and hashes in $\mathbb{G}_1$ as same as FABEO while FAME has $6m$. The only difference between our A-KP-ABE and FABEO is that we have one more exponentiation in $\mathbb{G}_2$.



For key generation, FABEO has the fastest 0.13s for a secret key with 100 attributes. Our A-KP-ABE doubles the time with 0.24s but it is 3.5 times faster than FAME. As Table 4 shows, all schemes mainly build elements in $\mathbb{G}_1$. FABEO has ℓ hashes and 2ℓ exponentiations in $\mathbb{G}_1$, our A-KP-ABE has double size calculations for them in order to build the D-LIN type construction. Nevertheless, it is more efficient than FAME since the number of exponentiations, hashes, and multiplications of FAME all depend on ℓ and n.

For decryption, the Fig. 7 (c) shows that FAME and FABEO all have a constant decryption time of 0.02s and 0.007s respectively while our A-KP-ABE has a linear increase with the number of matched attribute names subset x_1. Even in this case, our A-KP-ABE is only 0.08s slower than FAME and 0.093s slower than FABEO when $x_1 = 10$. We can see from Fig. 7 (d) that when $x_1 = 1$, our A-KP-ABE has a constant 0.012s no matter how many attributes are included in the subset, which is very close to FABEO and even two times faster than FAME. In other words, when $x_1 \leq 2$, our A-KP-ABE can decrypt at least as fast as FAME. Table 5 shows the reason that, when $x_1 = 1$, our A-KP-ABE has a constant 3 pairings that lie between FABEO (2 pairings) and FAME (6 pairings). The linear relation to x_1 is the main bottleneck between our A-KP-ABE and non-anonymous FAME and FABEO since the former protects anonymity by using the partially hidden structure while the latter does not. However, it is common sense that stronger security requirement leads to the degradation of efficiency. Compared to former A-KP-ABE schemes, our scheme already achieves the smallest gap between the anonymous ABE and non-anonymous ABE field, in which our A-KP-ABE scheme can even have comparable efficiency to the fastest non-anonymous KP-ABE schemes!

(a) ASE Encryption (b) ASE Trapdoor generation (c) ASE Search regarding matched subset number (assume only one keyword in each subset) (d) ASE Search regarding keyword number in a matched subset (assume there is only one matched subset)

Figure 6: Running times for ASE schemes.

(a) KP-ABE Encryption (b) KP-ABE Key generation (c) KP-ABE Decryption regarding matched subset number (assume only one attribute in each subset) (d) KP-ABE Decryption regarding keyword number in a matched subset (assume there is only one matched subset)

Figure 7: Running times for KP-ABE schemes.

To compare the communication overhead, we can go through Table 6. For ciphertexts, FABEO has only m elements in $\mathbb{G}_1$ and one element in $\mathbb{G}_2$, FAME is three times heavier than FABEO in every parameter. Our A-KP-ABE only adds one more element in $\mathbb{G}_2$ so it has a very similar ciphertext size as FABEO. For the secret key, FABEO has ℓ size elements in $\mathbb{G}_1$ and 1 element in $\mathbb{G}_2$, while FAME has thrice more again. Our A-KP-ABE doubles the size of elements in $\mathbb{G}_1$ of FABEO, so the communication overhead lies between FABEO and FAME.

7.5 Experiments with larger datasets

In the previous sections, we compared our schemes with the state-of-the-art expressive ASE and ABE schemes using 100 keywords. Despite being acknowledged as the fastest in the expressive ASE field, we recognized the importance of testing our schemes on a larger, more practical dataset size. Thus, we expand our dataset to 1000, 5000, and 10000 keywords for both our FEASE and PAEKS schemes. This decision was influenced by the fact that many state-of-the-art SSE schemes evaluate their efficiency on much larger datasets. This marks the first ASE work to explore datasets of such a substantial scale.

Schemes	Dataset	Setup	Trap	Enc	Search
FEASE	1000	0.018	2.17	0.62	0.068
	5000	0.018	14.13	3.28	1.5
	10000	0.018	35.64	6.61	6.76
PAEKS	1000	0.031	2.05	0.64	0.076
	5000	0.031	12.81	3.05	1.75
	10000	0.031	33.4	6.31	6.55

Table 7: The running time (in seconds) for our FEASE and PAEKS in larger datasets with 1000, 5000, and 10000 keywords for both the keyword sets and keyword policies.

Table 7 presents the setup, trapdoor generation, encryption, and search algorithms for both our FEASE and PAEKS schemes. These algorithms were tested with 1000, 5000, and 10000 keywords, considering "AND" gates between all keywords in the policy for simplicity. First, the setup time for both schemes remains constant and unaffected by the number of keywords [13]. In the case of FEASE, with a dataset containing

[13]The same considerations apply to the data sender key and data receiver

1000 keywords, trapdoor generation, and encryption take 2.17s and 0.62s, respectively. The search algorithm operates at 0.068s. As the dataset expands to 5000 keywords, these times increase to 14.13s, 3.28s, and 1.5s, respectively. For a dataset of 10,000 keywords, these times further rise to 35.64s, 6.61s, and 6.76s. Besides, the results from the PAEKS scheme mirror those of FEASE closely, given their similar constructions.

The diagrams in Figure 6 show a strict linear correlation between the running time of encryption and the number of keywords in the dataset. However, there are deviations in the running time of trapdoor generation and the search algorithm, exceeding the linear relation with the keyword count. This discrepancy arises because when the number of keywords surpasses 1000, the built-in recursive functions "evalStack" and "requiredAttributes" utilized in the trapdoor and search algorithm hit the maximum recursion depth of the program. Consequently, the program requires additional memory to execute, leading to increased running times. Addressing this issue and optimizing the program remain areas for our future work.

Based on the results of this experiment, it is evident that while the efficiency of ASE has not yet reached the same level as SSE, our FEASE demonstrates state-of-the-art efficiency in the expressive ASE field. In summary, the asymptotic performance of the expressive ASE field is developing from the fully hidden scheme using IPE [34] to partially hidden schemes in composite order groups [37, 42], and further to partially hidden schemes in prime order group [21, 44]. Furthermore, the foundation KP-ABE scheme is chosen from [38] for [37, 42], to [51] for [21, 44], and finally to the most efficient FABEO [50] for our FEASE and PAEKS. The progress in group settings, partially hidden structure, and KP-ABE schemes together form the efficiency enhancement for expressive ASE schemes. We anticipate that future research efforts will continue to explore novel techniques to further enhance ASE efficiency.

8 Conclusion

In this paper, we have proposed a fast and expressive asymmetric searchable encryption (FEASE) scheme and applied similar techniques to create two other fast and expressive applications: a public key authenticated encryption with keyword search (PAEKS) scheme and an anonymous key-policy attribute-based encryption (A-KP-ABE) scheme. The performance of these three schemes reaches the highest efficiency level in these three primitives, and it is comparable to the state-of-the-art non-anonymous ABE schemes FAME and FABEO. Compared to SSE, the lack of capabilities supporting dynamic updates is still a shortcoming of ASE schemes. In the future, we will carry on our research for the dynamism of the ASE field.

key generation algorithms in the PAEKS scheme. Therefore, we have omitted the running time for these two algorithms in our evaluation.

A CWDWL16 scheme in the Type-III setting

Fig. 8 shows [21] that we transformed into the Type-III setting.

$(\mathsf{pp}, \mathsf{sk}) \leftarrow \mathsf{KeyGen}(1^\lambda)$. Run $\mathsf{GroupGen}(1^\lambda)$ to obtain $\mathsf{par} := (p, e, \mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, g_1, g_2)$. Pick $u_1, h_1, \delta_1 \xleftarrow{\$} \mathbb{G}_1$, $u_2, h_2, \delta_2 \xleftarrow{\$} \mathbb{G}_2$, $\alpha, d_1, d_2, d_3, d_4 \xleftarrow{\$} \mathbb{Z}_p$, and a hash function $\mathsf{H}: \mathbb{G}_T \to \mathbb{G}_2$. Compute the public key and secret key as

$$\mathsf{pp} = (\mathsf{par}, \mathsf{H}, g_1, u_1, h_1, \delta_1, u_2, g_1^{d_1}, g_1^{d_2}, g_1^{d_3}, g_1^{d_4}, e(g_1, g_2)^\alpha)$$

$$\mathsf{sk} = (\alpha, g_2, h_2, \delta_2, d_1, d_2, d_3, d_4)$$

$(\mathsf{pk}_c, \mathsf{sk}_c) \leftarrow \mathsf{KeyGen}_c(\mathsf{pp})$. Pick $\beta \xleftarrow{\$} \mathbb{Z}_p$ and compute

$$\mathsf{pk}_c = g_1^\beta, \mathsf{sk}_c = \beta$$

$\mathsf{td} \leftarrow \mathsf{Trap}(\mathsf{pp}, \mathsf{pk}_c, \mathsf{sk}, \mathbb{P} = (\mathbb{M}, \pi, \mathbb{P} = (\mathbb{M}, \pi, \{\pi(i)\}_{i\in[\ell]}))$.

Pick $r, r', t_{1,1}, t_{1,2}, ..., t_{\ell,1}, t_{\ell,2} \xleftarrow{\$} \mathbb{Z}_p$, $\mathbf{v} \xleftarrow{\$} \mathbb{Z}_p^{n-1}$. Compute

$$\begin{aligned}
&\mathsf{td}_{1,i} = g_2^{\mathbb{M}_i(\alpha\|\mathbf{v})^\top} \cdot \delta_2^{d_1 d_2 t_{i,1} + d_3 d_4 t_{i,2}},\\
&\mathsf{td}_{2,i} = \mathsf{H}(e(\mathsf{pk}_c, \mathsf{td}_8)^r) \cdot g_2^{d_1 d_2 t_{i,1} + d_3 d_4 t_{i,2}},\\
&\mathsf{td}_{3,i} = (u_2^{\pi(i)} h_2)^{-d_2 t_{i,1}}, \mathsf{td}_{4,i} = (u_2^{\pi(i)} h_2)^{-d_1 t_{i,1}},\\
&\mathsf{td}_{5,i} = (u_2^{\pi(i)} h_2)^{-d_4 t_{i,2}}, \mathsf{td}_{6,i} = (u_2^{\pi(i)} h_2)^{-d_3 t_{i,2}},\\
&\mathsf{td}_7 = g_1^r, \mathsf{td}_8 = g_2^{r'}.
\end{aligned}$$

Output $\mathsf{td} = ((\mathbb{M}, \pi, \{n_{\pi(i)}\}_{i\in[\ell]}), \{\mathsf{td}_{1,i}, \mathsf{td}_{2,i}, \mathsf{td}_{3,i}, \mathsf{td}_{4,i}, \mathsf{td}_{5,i}, \mathsf{td}_{6,i}\}_{i\in[\ell]}, \mathsf{td}_7, \mathsf{td}_8)$.

$\mathsf{ct} \leftarrow \mathsf{Enc}(\mathsf{pk}, \mathbb{W} = \{w_i\}_{i\in[m]} = \{n_i, v_i\}_{i\in[m]})$.

Pick $\mu, s_{1,1}, s_{1,2}, ..., s_{m,1}, s_{m,2}, z_1, ..., z_m \xleftarrow{\$} \mathbb{Z}_p$ and compute

$$\begin{aligned}
&\mathsf{ct}_1 = g_1^\mu, \mathsf{ct}_{2,i} = \delta_1^{-\mu}(u_1^{w_i} h_1)^{z_i}, \mathsf{ct}_{3,i} = g_1^{d_1(z_i - s_{i,1})}, \mathsf{ct}_{4,i} = g_1^{d_2 s_{i,1}},\\
&\mathsf{ct}_{5,i} = g_1^{d_3(z_i - s_{i,2})}, \mathsf{ct}_{6,i} = g_1^{d_4 s_{i,2}}, \mathsf{ct}_7 = e(g_1, g_2)^{\alpha\mu}
\end{aligned}$$

Output $\mathsf{ct} = (\{n_i\}_{i\in[m]}, \mathsf{ct}_1, \{\mathsf{ct}_{2,i}, \mathsf{ct}_{3,i}, \mathsf{ct}_{4,i}, \mathsf{ct}_{5,i}, \mathsf{ct}_{6,i}\}_{i\in[m]}, \mathsf{ct}_7)$.

$1/0 \leftarrow \mathsf{Search}(\mathsf{pp}, \mathsf{sk}_c, \mathsf{ct}, \mathsf{td})$. Tests if there is any subset I that matches the keyword names $\{n_i\}_{i\in[m]}$ in ct with $(\mathbb{M}, \pi, \{n_{\pi(i)}\}_{i\in[\ell]})$ in td. If not, return 0. Otherwise, it finds constants $\{\gamma_i\}_{i\in I}$ s.t. $\sum_{i\in I}\gamma_i \mathbb{M}_i = (1, 0, ..., 0)$ and computes:

$$\begin{aligned}
\mathsf{ct}_7 = \prod_{i\in I} (&e(\mathsf{ct}_1, \mathsf{td}_{1,i}) e(\mathsf{ct}_{2,i}, \frac{\mathsf{td}_{2,i}}{\mathsf{H}(e(\mathsf{td}_7, \mathsf{td}_8)^\beta)}) e(\mathsf{ct}_{3,i}, \mathsf{td}_{3,i})\\
&e(\mathsf{ct}_{4,i}, \mathsf{td}_{4,i}) e(\mathsf{ct}_{5,i}, \mathsf{td}_{5,i}) e(\mathsf{ct}_{6,i}, \mathsf{td}_{6,i}))^{\gamma_i},
\end{aligned}$$

If the equation holds, return 1. Otherwise, the cloud server continues to find another subset of I and repeats the checking. If the above equation does not hold for all subsets, return 0.

Abstract

Dynamic Searchable Encryption (DSE) has emerged as a solution to efficiently handle and protect large-scale data storage in encrypted databases (EDBs). Volume leakage poses a significant threat, as it enables adversaries to reconstruct search queries and potentially compromise the security and privacy of data. Padding strategies are common countermeasures for the leakage, but they significantly increase storage and communication costs. In this work, we develop a new perspective on handling volume leakage. We start with *distinct search* and further explore a new concept called *distinct* DSE (*d*-DSE).

We also define new security notions, in particular Distinct with Volume-Hiding security, as well as forward and backward privacy, for the new concept. Based on *d*-DSE, we construct the *d*-DSE designed EDB with related constructions for distinct keyword (d-KW-*d*DSE), keyword (KW-*d*DSE), and join queries (JOIN-*d*DSE) and update queries in encrypted databases. We instantiate a concrete scheme BF-SRE, employing Symmetric Revocable Encryption. We conduct extensive experiments on real-world datasets, such as Crime, Wikipedia, and Enron, for performance evaluation. The results demonstrate that our scheme is practical in data search and with comparable computational performance to the SOTA DSE scheme (MITRA*, AURA) and padding strategies (SEAL, ShieldDB). Furthermore, our proposal sharply reduces the communication cost as compared to padding strategies, with roughly 6.36 to 53.14x advantage for search queries.

1 Introduction

Encrypted databases (EDBs) [46] have been developed to support privacy-preserving data storage and search services. They allow clients to outsource sensitive encrypted data to a server and then send search queries to the server who can return the corresponding data. These databases can adopt Searchable Symmetric Encryption (SE) [13, 51] and its Dynamic version [31] (DSE) to offer various types of privacy-preserving queries, such as keyword [16], range [17], SQL [27] queries, and updates. Note more related works for EDBs and DSE are presented in Appendix B and D, respectively.

Although easily inheriting Forward Privacy and Backward Privacy (FP&BP) guarantees from DSE [2,4], those EDBs are still vulnerable to volumetric attacks [1, 64]. The adversary can infer the underlying keywords from search queries [1, 36, 64] or even reconstruct the whole EDB [22, 32] by exploiting *volume leakage* (i.e., the length of the response).

Padding strategies [3, 15, 55] are popularly applied to mitigate the impact of volume leakage in EDBs. They work by adding "dummy" data to the original database to ensure uniform volume for each keyword. Thus, from the viewpoint of adversaries, volume leakage with regard to queries is now indistinguishable. This strategy, however, yields significant costs (see Tab. 1). It requires extra storage and computational resources to establish and update the EDB but also consumes huge communication bandwidth for query response. Note we provide more details on padding in Appendix C.

A new perspective - starting from *distinct search*. In line with the design of secure EDBs [18], we should minimize the leakage during search queries. It is natural to see that the SQL syntax 'SELECT DISTINCT'[1] can be used to eliminate duplicated search responses, which, to some extent, reduces the volume leakage. But we cannot simply apply distinct search in EDBs due to the fact that it still leaks information to the server. In the context of SQL queries, a distinct search retrieves distinct (unique) values from the corresponding columns in a database table, which allows us to eliminate "duplicate" values. The search process traverses only one copy of each value and ignores its duplicates. However, if the number of those "ignored" values (i.e., the number of duplicates) is leaked, it can reveal information about the quantities of all relevant values, leading to volume leakage. To mitigate this threat, it is crucial to design a mechanism that prevents the server from being aware of the repetition of values. We find that we can use the dummy tags to group all relevant values into an

[1]In ISO/IEC 9075-2:2016, the 'DISTINCT' predicate can apply with other syntax like 'SELECT', 'JOIN', 'GROUP BY' to retrieve distinct values from a database table.

Table 1: Comparison on related DSE, padding, and our scheme. N is the total number of keyword/value pairs. W and F are the total number of keywords and files, respectively. In Column **5**, ✓ indicates that padding strategies can be deployed in the schemes. For keyword $\mathbf{w}$, a_w is the total number of update operations, n_w is the current number of pairs, d_w is the number of deletion, d_{max} is the supported maximum number of deletions, and s'_w is the number of legal search tokens. For **SEAL**, x means the adjustable padding's parameter, and n^*_w denotes the number of the pairs currently containing w after padding. For **ShieldDB**, n_r and n_b separately represent the real and padding pairs of the streamed keyword w_i, $|B|$ means the padding dataset length, and f_w and f_{w_i} represent the maximum frequency and the streamed keyword w_i frequency, respectively. Backward privacy (**BP**) contains type-1/2/3 level (I/II/ III), including the special case $\mathrm{II}^{\mathrm{A}}, \mathrm{III}^{\mathrm{R}}, \mathrm{II}^{\mathrm{D}}$ extended from [4].

Schemes	Distinct Search	Computation			Communication			Client Storage	BP

*: SEAL only focuses on static database (indicating it cannot support update operations) while providing values retrieval with keyword. In SEAL we store the client's states locally.
⋆: ShieldDB is a dynamic document database. Its deletion is done through re-encryption, which does not clearly specify the backward privacy.

unsearchable dataset so that the server, in the Search stage, can only "see" a single copy of results, thereby concealing the volume of repetitive values and reducing the potential for volume leakage.

A trivial solution to transform DSE for volume-hiding. Recall that DSE focuses on searching file-identifiers instead of values. It may not be straightforward to replace the distinct identifiers with the unique/repeatable values. Here, we attempt to provide a *trivial transformation* to make DSE support "distinct search."

• In the Setup or Update stage, the client maps each value to a unique identifier and then initializes or updates the keyword-value pairs by a DSE instance.

• To perform the distinct search, the client utilizes the query protocol of the DSE to retrieve these identifiers. Afterward, the client restores the values based on the mapping of the identifiers and then extracts the distinct values locally.

We see that this transformation necessitates the client to maintain a local mapping table for translation between identifiers and values during each search. Furthermore, its security and efficiency heavily rely on the underlying DSE instance. We note that a regular DSE scheme could still be vulnerable to volume leakage (e.g., [60]), or it applies expensive padding strategies incurring significant bandwidth and storage costs (e.g., [15, 55]). This observation indicates that a trivial transformation could not be the best solution for both security and efficiency.

In response to this, we propose the *Distinct Dynamic Searchable Symmetric Encryption (d-DSE)* that enables clients to securely search for distinct values with volume-hiding. In this concept, we make use of the Distinct State, the Distinct Classifier, and the Distinct Constraint to determine distinct values and eliminate the volume difference. We instantiate a d-DSE scheme BF-SRE for non-interactive deletion and efficient search. We present a brief comparison between BF-SRE and related (D)SE schemes in Tab. 1.

Extension from "distinct" to "diverse" search. We notice that many works have demonstrated the feasibility of incorporating DSE to support secure queries in SQL syntax, such as keyword [15], range [17], and join [24, 50]. Fortunately, we find out that the distinct search can be integrated into secure SQL as well. Our core idea is to process a query by first obtaining the *distinct values* using the distinct search and subsequently restoring the quantity of each distinct value (i.e., *value's quantity*) by small client storage. Please see Sec. 4 for more details.

The above descriptions briefly introduce our technical roadmap from the beginning by distinct search, constructing secure distinct search (i.e., d-DSE), and fulfilling SQL search for EDBs. We summarize key contributions as follows.

• **Definition and models of *d*-DSE**. We underline the definition and models for secure distinct search. In particular, we propose a so-called Distinct with Volume-Hiding (DwVH) security that captures how a secure distinct search can mitigate volume leakage. We formalize the EDB context of distinct search, analyze security risks, and define the advantage in the models.

• ***d*-DSE designed EDB**. We leverage d-DSE to build EDBs with volume-hiding property. We first illustrate the EDB system enhanced by the d-DSE query model. Then we present three new constructions: d-KW-dDSE (for distinct keyword queries), KW-dDSE (for keyword queries), JOIN-dDSE (for join queries), and the corresponding row addition and deletion operations. We comprehensively expose the leakage functions [6, 26] under these constructions and interpret the pattern leakage from the EDB perspective. Finally, our analysis clari-

fies that they resist both SOTA passive [60] and active [64] volumetric attacks.

• **Concrete scheme for *d*-DSE**. To handle the distinct feature in *d*-DSE designed EDB, we utilize the Bloom Filter (BF) [53], producing Distinct State to control the tag generation for values. In this sense, we can effectively match the distinct values in the search. Based on the above, we propose our scheme, called BF-SRE, by applying Symmetric Revocable Encryption (SRE). The scheme enables the client to process the deletion locally, and thus, it is non-interactive and flexible to row update in encrypted databases. We also provide formal security analysis to demonstrate that the scheme satisfies the FP&BP as well as the DwVH security.

• **Evaluations**. We extensively perform evaluations on our proposals and prior work under diverse real-world datasets, including the Crime reports, Wikipedia, and the Enron email datasets. Concretely, under equivalent security parameters, we compare BF-SRE with the SOTA MITRA* [20], AURA [53], SEAL [15], and ShieldDB [55] in terms of the time and communication costs. Our evaluation demonstrates that BF-SRE stands as a competitive solution compared to the aforementioned schemes. For example, on the Enron dataset, its costs of time and communication for searching the highest-volume keyword are 8.25s and 83.82KB, outperforming others by a factor of approximately 29.27x and 30.54x, respectively.

2 Backgrounds

We first describe the encrypted database that supports recording the keyword/value pairs. In this context, we introduce the parties in distinct search with the corresponding interactions. After that, we propose the threat in distinct search.

2.1 Encrypted Database Description

We use EDB to represent an encrypted database in the context of DSE. This database stores repeatable keyword/value pairs (w,v) (e.g., for relational table structure, an attribute's value in one column as a keyword with a foreign-key in another as a value) in sequence and supports secure addition, deletion, and search operations. Specifically, the client can search keywords to retrieve the matching values, add new keyword/value pairs, and delete all specified repetitive (w,v) pairs. Note that the search operation incorporates the distinct search predicate $TypeDB(w) = \{v_1,...,v_n | v \in (w,v)\ and\ \forall\ i,j \in [1,n]\ s.t.\ v_i = v_j \iff i = j\}$ to retrieve all matched distinct values given a keyword w. We call the number of distinct values in $TypeDB(w)$ as the *value's type*.

2.2 Parties

Two parties involve in the distinct search:

• Client: The client initializes the EDB by security parameter and outsources it to the server. The client sends an update token generated by the input $(w,v,op = \{add,del\})$ to add or delete the keyword/value pairs (w,v) on the EDB. The client sends the search token generated by the keyword w to find the corresponding distinct values.

• Server: The server hosts the EDB outsourced by the client. The server updates the EDB by the update token. In processing a search token, the server searches the distinct values corresponding to the keyword w and returns the result to the client.

2.3 The Threat in Distinct Search

A scheme for secure distinct search should protect the client's outsourced EDB against the probabilistic polynomial time (PPT) adversary from the *passive* [40,41,60] and *active* [64] attacks. Akin to [12], we propose the adversaries' observations during various client events that could reveal volumetric information for the aforementioned attacks.

Table 2: The adversaries' passive and active observations.

Client Event	Passive observations	Active observations
Setup: 1.Set up Secret Key; 2.Outsource the EDB.	1.The initial EDB.	
	1.Prior volume knowledge;	1.The deceptive set of keyword/value pairs; 2. Partial queries volume before injection.
Update: 1.Update ciphertexts in the EDB.	1.The updated EDB.	
	1.Updated queries in ciphertexts.	1. Updated queries generated from deceptive set.
Search: 1.Require distinct search.	1.Client search queries; 2.Search process; 3.The volume of search queries.	1. The after-injection volume of queries.

From Tab. 2, we state that the philosophy of volume-hiding countermeasure is to decouple the volumetric relationship speculated from the Setup and Search stage. The passive and active adversaries first get the baseline of volume through prior knowledge (e.g., outdated keyword frequency [40]) and partial queries observed before injection, respectively. Then they both consult the observation in the Update stage to achieve maximum fit in the Search stage, such as minimizing objective functions [41, 60] and manufacturing binary volume [64]. To mitigate the fitting, padding strategies produce uniform volume through dummy data at initialization. Our perspective is to prevent the search leakage containing predicable volume distribution, which is our security goal for distinct search.

We also require Forward Privacy and Backward Privacy (FP&BP) [2,4] to protect the update and distinct search function from serious privacy disclosure. To capture the leakage from distinct search, the security for volume leakage [42] should be defined.

3 Distinct DSE

We define Distinct Dynamic Searchable Symmetric Encryption (*d*-DSE), which includes its scheme and security guarantees, to tackle the distinct search threat.

3.1 Notations

$\lambda \in \mathbb{N}$ is the security parameter. $r \xleftarrow{\$} \mathcal{R}$ means randomly sampling r from the space $\mathcal{R}$. $a||b$ is the concatenation between a and b. $\{0,1\}^{\lambda}$ is a λ-bit length string. $\{0,1\}^{*}$ is an arbitrary-bit length string. F is a secure Pseudo Random Function (PRF). Σ is the Dynamic Searchable Symmetric Encryption (DSE) scheme. The frequently used notations & concepts, the symmetric encryption, Bloom Filter (BF) [53], and Symmetric Revocable Encryption (SRE) [53], are introduced in Appendix A.

3.2 The *d*-DSE Scheme

Definition 1 (The Distinct DSE) *A Distinct Dynamic Searchable Encryption is a triple* $(\mathsf{Setup}, \mathsf{Search}, \mathsf{Update})$ *consisting of three protocols:*

- $\mathsf{Setup}(\lambda)$ *is a protocol that takes as input the* security parameter λ. *It invokes the* DSE setup protocol $\Sigma.setup$ *and generates the* Distinct State σ^D, *outputting* $K, \mathbf{st} = \{\sigma, \sigma^D\}$ *for the client and outsourcing* EDB *for the server respectively, where K is the* master secret key, EDB *is the* encrypted database, *and* **st** *is the* client's internal state.

- $\mathsf{Search}(K, \mathbf{st}, w; \mathrm{EDB})$ *is a protocol between the client with inputs K,* **st**, *and a search query restricted to a* keyword w, *and the server with input the* EDB. *It invokes the* DSE search protocol $\Sigma.search$ *with input modified by the Distinct State* σ^D. *At the end, the client gets a search result set included* ***distinct values*** *from the* EDB.

- $\mathsf{Update}(K, \mathbf{st}, op, \mathrm{in}; \mathrm{EDB})$ *is a protocol between the client with K and* **st** *as above, and an* operation op *with its input* in, *where op is from the set {add, del}* (i.e. addition, deletion) *and* in *is parsed as the* keyword/value pair (w, v); *and the server with input* EDB. *It invokes the* DSE update protocol $\Sigma.update$ *with input modified by the Distinct State* σ^D. *At the end, the client updates its internal* $\mathbf{st}'$, *and the server renews the* EDB.

Correctness. *Except with negligible probability, the d-DSE scheme is correct if the* Search *protocol returns (current) correct results for the keyword being searched. For the formalism, we follow the case where the client should not delete a keyword with a retrieval value that is not present in* EDB.

Remark on the *d*-DSE search protocol. The retrieval searched by d-DSE and DSE is different [4]. In DSE, the client eventually needs to obtain the outsourced data through the file-identifier, and the volume leakage is not considered by Forward Privacy and Backward Privacy (FP&BP) [60]. In our context, the client is allowed to search the EDB to retrieve outsourced distinct values by a keyword. To this end, we must refine the leakage on retrieving values.

3.3 Security Notions for Distinct Search

To address the leakage ($\mathcal{L}_D$) in d-DSE, we refer to the DSE security. The security contains FP&BP [2,4] under the Adaptive Security model [13], but it falls short in preventing volume leakage. Therefore, we define the Distinct with Volume-Hiding (DwVH) security. Note that we introduce the Sim-adaptive Security model instead of the Adaptive Security model to perceive FP&BP and the DwVH security.

We assume that the client is *honest* and should prevent the disclosure of sensitive information, e.g., underlying keywords and encrypted data. The server, which is *honest-but-curious*, should follow the protocols' instructions yet passively exposes some information. Similar to the *Real* and *Ideal* formulation [4,7], the Sim-adaptive security notions of d-DSE are defined as follows.

Definition 2 (Sim-adaptive Security of *d*-DSE) *Assume a d-DSE scheme is $\mathcal{L}$-adaptively secure iff for all sufficiently large security parameters $\lambda \in \mathbb{N}$ and PPT adversary $\mathcal{A}$, there is a set of efficient simulators $\mathcal{S}$ with a set of leakage functions $\mathcal{L}$ that has:*

$$\left| \mathbb{P}\left[\mathrm{Real}_{\mathcal{A}}^{\mathrm{d-DSE}}(\lambda) = 1 \right] - \mathbb{P}\left[\mathrm{Ideal}_{\mathcal{A},\mathcal{S},\mathcal{L}}^{\mathrm{d-DSE}}(\lambda) = 1 \right] \right| = negl(\lambda),$$

where the games $\mathrm{Real}_{\mathcal{A}}^{\mathrm{d-DSE}}(\lambda)$ *and* $\mathrm{Ideal}_{\mathcal{A},\mathcal{S},\mathcal{L}}^{\mathrm{d-DSE}}(\lambda)$ *are:*

- *Game* $\mathrm{Real}_{\mathcal{A}}^{\mathrm{d-DSE}}(\lambda)$*: the adversary controls the client to run real protocols. Firstly, it triggers the protocol* Setup *and gets the encrypted database* EDB. *Secondly, with the parameters of its choice, it adaptively triggers* Update, Search, *and then obtains the real transcript list* $Q = (q_1, q_2, ..q_n)$. *Finally, it outputs a bit b decided from the real sensitive information* $(\mathrm{EDB}, q_1, ...q_n)$.

- *Game* $\mathrm{Ideal}_{\mathcal{A},\mathcal{S},\mathcal{L}}^{\mathrm{d-DSE}}(\lambda)$*: all of the real protocols are replaced by the set of simulators $\mathcal{S}$. The adversary first triggers the simulator* $\mathcal{S}_{\mathsf{setup}}$ *and obtains the simulated database* $\mathrm{EDB}^{\mathcal{S}}$. *Secondly, with chosen parameters, it adaptively triggers* $\mathcal{S}_{\mathsf{Update}}$, $\mathcal{S}_{\mathsf{Search}}$, *and then gets the simulated transcript* $Q^{\mathcal{S}} = (q_1^{\mathcal{S}}, q_2^{\mathcal{S}}, ..q_n^{\mathcal{S}})$. *Finally, it outputs a bit b decided from the simulated sensitive information* $(\mathrm{EDB}^{\mathcal{S}}, q_1^{\mathcal{S}}, q_2^{\mathcal{S}}, ..q_n^{\mathcal{S}})$.

Common Leakage Functions. Akin to [4], we use the $sp(w)$ to represent the *search pattern*, i.e., which queries belong to the keyword w, and the $\mathsf{UpHist}(w)$ to represent the history of all updates on keyword w.

Forward Privacy (FP). As d-DSE holds FP, adversaries should not utilize the previous transcript to imply the newly added information before executing the Search protocol. Based on FP in [2], d-DSE must further preserve the value's information. This requirement prevents adversaries from deducing the equality among values, which will expose more information than just the distinct values.

Definition 3 (Forward privacy) *An $\mathcal{L}$-adaptively-secure d-DSE scheme has forward privacy if its* Update *leakage function $\mathcal{L}_D^{Upt}$ can be written as:*

$$\mathcal{L}_D^{Upt}(w,v,op) = \mathcal{L}'(op),$$

where $\mathcal{L}'$ is a state-less function.

Backward Privacy (BP). As d-DSE holds BP, adversaries should not use new transcripts to imply previous information after executing Search.

To capture the BP in d-DSE, we first propose the leakage function TimeDTS(w). TimeDTS(w) defines the list of all encrypted values v matching keyword w, excluding the deleted and repetitive ones, together with the timestamp u of when they were added in the database:

$$\begin{aligned}\text{TimeDTS}(w) = \{(u,v) | (u,w,v,add) \in Q \text{ and } \forall\, u', (u',w,v,del) \notin Q \\ \text{and } \forall\, (u,w,v_i,add) \in Q, (u,w,v_j,add) \in Q, \\ s.t.\ v_i = v_j \iff i = j\}.\end{aligned}$$

Update(w) defines the leakage of which timestamps have update queries on the keyword w. With the input w, Update(w) returns the set of the timestamps, in which each of them represents an update on w:

$$\text{Update}(w) = \{u \mid (u,w,v,add) \in Q \text{ or } (u,w,v,del) \in Q\}.$$

With the above functions, we define the BP of d-DSE:

Definition 4 (Backward privacy) *An $\mathcal{L}$-adaptively-secure d-DSE scheme has backward privacy if its* Update, Search *leakage functions $\mathcal{L}_D^{Upt}$, $\mathcal{L}_D^{Srch}$ can be written as:*

$$\begin{aligned}\mathcal{L}_D^{Upt}(w,v,op) &= \mathcal{L}'(w,op) \\ \mathcal{L}_D^{Srch}(w) &= \mathcal{L}''(sp(w), \text{TimeDTS}(w), \text{Update}(w)),\end{aligned}$$

where $\mathcal{L}', \mathcal{L}''$ are state-less functions.

We say that the aforementioned backward privacy is appropriate for d-DSE. That is inspired by the type-2 level of DSE [4]. Besides, the type-3 level discloses that multiple (w,v) additions can be associated with the corresponding deletion operations, revealing the number of identical values that may cause volume leakage.

3.4 Distinct with Volume-Hiding Security

We analyze the d-DSE leakage in consideration of volumetric attacks from the server. Previous works [42, 57] assume that the number of values associated with any single keyword should not be revealed, excluding the maximum volume. Accordingly, the leakage in *distinct search* should only infer the distinct values searched by keywords, and that cannot be pairwised with prior and current volume knowledge.

Inspired by the volume-hiding [42], we define the DwVH security, which aims to prevent adversaries from distinguishing the "signatures" of EDB. We say that a signature is defined as a sequence of uploaded keyword/value pairs $S = \{w, l(w), t(w)\}$, where $l(w)$ and $t(w)$ denote the number of distinct values (i.e., *value's type*) and the sum of value's quantities associated with keyword w, respectively. Under our security notion, the adversary is allowed to make two signatures S_0, S_1 for the challenger who randomly selects one of them $S_b, b \in \{0,1\}$ to generate the EDB. Afterward, the adversary collects leakages from update and search operations. Finally, it decides which signature is used to construct the EDB. We say that a d-DSE scheme is DwVH secure if this signature (chosen by the challenger) is indistinguishable from the adversaries, i.e., negligible advantages on the leakage from distinct values and d-DSE operations to restore volume information.

We let n denote the initial total number of keyword/value pairs in the EDB, and s represents the step $s = 1, 2, ...poly(\lambda)$. The DwVH security is defined as follows.

Definition 5 (DwVH Security) *An $\mathcal{L}$-adaptive secure d-DSE is called DwVH secure if for all $n \geq 1$ and all adversary $\mathcal{A}$ that execute at most s steps, the probability that $\mathcal{A}$ outputs 1 in* **DwVHGame**$_{\mathcal{A}}^{\mathcal{L}}((n,s),0)$ *is identical to that in* **DwVHGame**$_{\mathcal{A}}^{\mathcal{L}}((n,s),1)$. *The* **DwVHGame**$_{\mathcal{A}}^{\mathcal{L}}((n,s),b)$ *is:*

Game 1 DwVHGame$_{\mathcal{A}}^{\mathcal{L}}((n,s),b)$:

Prepare :

1: $\mathcal{A}$ generates two signatures $S_0 = \{w, l_0(w), t_0(w)\}_{w \in \mathcal{W}}$ and $S_1 = \{w, l_1(w), t_1(w)\}_{w \in \mathcal{W}}$, such that:
$l_0(w)_{w \in \mathcal{W}} < t_0(w)_{w \in \mathcal{W}} \leq n$; $l_1(w)_{w \in \mathcal{W}} < t_1(w)_{w \in \mathcal{W}} \leq n$;
$l_0(w)_{w \in \mathcal{W}} = l_1(w)_{w \in \mathcal{W}}$; $\Sigma_{w \in \mathcal{W}} t_b(w) = n$
2: $\mathcal{A}$ sends S_0 and S_1 to the challenger $\mathcal{C}$.
3: $\mathcal{C}$ computes keyword/value pairs by choosing $t_b(w)$ values for each keyword w, and each keyword w corresponds to $l_b(w)$ distinct values.
4: $\mathcal{C}$ updates all pairs and sends the corresponding leakages $\mathcal{L}_D^{Upt}$ to the adversary $\mathcal{A}$.

Queries :

1: $\mathcal{A}$ adaptively executes s step. In each step, it can perform:
• Update query: $\mathcal{A}$ adaptively performs the s-th update query about the step's keyword w_s, $\mathcal{C}$ computes $\mathcal{L}_D^{Upt}$ and sends it back.
• Search query: $\mathcal{A}$ adaptively performs the s-th search query about w_s, and $\mathcal{C}$ computes and returns $\mathcal{L}_D^{Srch}$.

Guess :

1: $\mathcal{A}$ guess the b input and outputs a bit $b' \in \{0,1\}$.

Compared to the volume-hiding definitions [42], d-DSE can fight against adversaries who enable challengers to adaptively perform update and search operations. The aim of the DwVH security is to show that the leakages from the update and distinct search do not reveal which signature is chosen to establish the EDB. In other words, the adaptive adversaries are consistent with our consideration in the FP&BP d-DSE so that they just leverage the d-DSE leakage of update and distinct search.

4 High Level of d-DSE Designed EDB

This section illustrates the practical application of d-DSE in bolstering foundational queries in EDB systems. We introduce the d-DSE query model, which encompasses update, distinct keyword, keyword, and join queries, effectively covering the

spectrum of fundamental queries pertinent to encrypted relational databases. Based on our d-DSE security model, we also conduct a leakage analysis to identify potential volumetric attacks for EDB. Note that we summarize the frequently used notations in Tab. 3 (see Appendix A).

4.1 Apply to EDB system

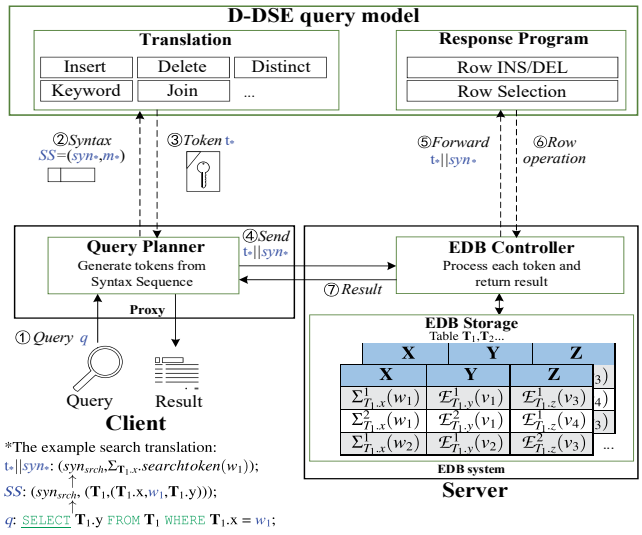

Figure 1: The high-level of d-DSE design EDB. $\Sigma^{c}_{\mathbf{T}_1.x}(w_1)$ and $\mathcal{E}^{c}_{\mathbf{T}_1.y}(v_1)$ denote that the keyword w_1 and value v_1 in table column $\mathbf{T}_1.x$ and $\mathbf{T}_1.y$ are encrypted by Σ and $\mathcal{E}$ with a counter c, respectively.

Like [45, 46], Fig. 1 depicts that d-DSE based EDB leverages the *EDB-proxy* architecture, including:

- **EDB Storage** ($\mathcal{EDB}_S$) organizes encrypted data into the table collection $\mathcal{T} = \{\mathbf{T}_1, ...\mathbf{T}_N\}$ *on disk*. Each $\mathbf{T}_*$ (e.g., $\mathbf{T}_1$.x) is represented by columns $\mathbf{T}_*.\star$ and their respective attribute types (e.g., constant-size string, integer, etc.). Tables include rows, where each row corresponds to the encrypted record $\mathbf{r} = (\Sigma^{c}_{\mathbf{T}_*.\star}(w), \mathcal{E}^{c}_{\mathbf{T}_*.\star}(v), ...)$ manufactured by the d-DSE query model.

- ***d*-DSE query model** includes a series of d-DSE constructions that support the following: (1) the *translation* from the functional equivalent syntax $SS = (syn_*, m_*)$ to the token t_*, where syn_* specifies the construction name, m_* includes the message of $\mathbf{T}_*$, $\mathbf{T}_*.\star$, and numeric or text data, and t_* contains the encrypted data generated from SS; (2) the *response program* for the EDB controller to perform the related construction operations (i.e., row insertion/deletion and selection) on $\mathcal{EDB}_S$ via the concatenation of the encrypted data and the name $t_*||syn_*$. We construct update, (distinct) keyword, and join query for the d-DSE query model (see the following subsections).

- **Query Planner** processes queries and forwards results. For a query q, the planner does the following: ① extracts it to SS (see the example in Fig. 1); ② forwards SS to the translation; ③ receives the t_*; ④ forwards the $t_*||syn_*$ to the EDB Controller and waits for response;

- **EDB Controller** processes the $t_*||syn_*$ and replies the corresponding results. Specifically, it follows operations from the response program to update rows in $\mathcal{EDB}_S$ and to copy encrypted data from $\mathcal{EDB}_S$ to the *controller's memory* for selection. We call the replicated encrypted data as $\mathtt{EDB}_C$. The EDB Controller works as: ⑤ forwards $t_*||syn_*$ to the response program; ⑥ follows the operations to update/select rows; ⑦ returns the operation results.

We leverage the EDB-proxy architecture as described in [45, 46] to map the original SQL syntax into a series of d-DSE tokens. This approach enables us to thoroughly analyze potential leakages within the N-size SS sequence (i.e., $\mathbf{SS} = (SS_1, .., SS_N)$) through the d-DSE query model. Our d-DSE query model can attain a *one-for-all* volume-hiding capability within EDB systems. We note that hereafter, we omit the subscript when describing a query in a table (e.g., $\mathbf{T}$).

4.2 Update Queries

We start with the basic update queries on table $\mathbf{T}$, e.g.

$$\texttt{INSERT INTO}\ \mathbf{T}\ (\mathbf{T}.x, \mathbf{T}.y)\ \texttt{VALUE}\ (w, v) \hookrightarrow SS_{ins} = (syn_{ins}, (\mathbf{T}, (\mathbf{T}.x, w, \mathbf{T}.y, v)))$$

$$\texttt{DELETE FROM}\ \mathbf{T}\ \texttt{WHERE}\ \mathbf{T}.x = w\ \texttt{AND}\ \mathbf{T}.y = v \hookrightarrow SS_{del} = (syn_{del}, (\mathbf{T}, (\mathbf{T}.x, w, \mathbf{T}.y, v))).$$

We can convert this syntax SS_{ins}/SS_{del} to the d-DSE Update protocol, which works for $\mathbf{T}$ (initialized by d-DSE Setup protocol) and receives keyword, value, and 'INSERT'/'DELETE' command as the (w, v, op) input from the Query Planner. We generate the update token through the Update protocol to append/delete the encrypted keyword and value in the corresponding row in $\mathbf{T}$, i.e., $\left(\Sigma_{\mathbf{T}.x}(w), \mathcal{E}_{\mathbf{T}.y}(v)\right)$, for subsequent distinct keyword queries. Note that we use the client's state $\mathbf{st}$ to mark deleted rows on $\mathcal{EDB}_S$ and then process deletion in batch for queries on $\mathtt{EDB}_C$.

Note that one should not separately analyze the leakage from the N-size update sequence (i.e., $\mathbf{op}_N = ((u_1, op_1)..(u_N, op_N))$, where u_* is the timestamp) since it is further refined by the leakage (Update(w), see Sec. 3.3) from search queries in the EDB system (see Sec 4.3).

4.3 Distinct Keyword Queries

A distinct keyword query retrieves distinct values from the column $\mathbf{T}.y$ of table $\mathbf{T}$ that corresponds to keyword w in column $\mathbf{T}.x$, i.e:

$$\texttt{SELECT DISTINCT}\ \mathbf{T}.y\ \texttt{FROM}\ \mathbf{T}\ \texttt{WHERE}\ \mathbf{T}.x = w \hookrightarrow SS_{Dsrch} = (syn_{Dsrch}, (\mathbf{T}, (\mathbf{T}.x, w, \mathbf{T}.y))).$$

Like [15, 27], the d-DSE Search protocol can implement SS_{Dsrch} by viewing w in $\mathbf{T}.x$ as keywords and data in $\mathbf{T}.y$ as values. d-DSE should allocate a local memory as Distinct

State σ^D to control the Update and Search protocols. For generating tokens t_* from SS, the Update and Search protocols should separately employ the Distinct Classifier and Distinct Constraint to pre-process SS in *translation* (Fig. 1):

• *Distinct Classifier* identifies whether the (w,v,op) from update queries is represented as distinct in retrieval, and subsequently, it tags the modified input.

• *Distinct Constraint* generates the constrained key for distinct search queries that limits the retrieval of distinct values from $\mathbf{T}.y$ based on w in $\mathbf{T}.x$.

We refer to this construction as d-KW-dDSE (distinct KeyWord queries from d-DSE). [2]

We notice that finding distinct values in a table requires a huge storage cost to store their state (i.e., distinct or repetitive). At the same time, the rows in a table do not support records that represent delete operations (e.g., the addition & deletion list of file-identifiers [20]). To this end, we apply the Bloom Filter (BF) to minimize local storage costs and the Symmetric Revocable Encryption (SRE) to enable non-interactive deletion. Our scheme for d-KW-dDSE is elaborated in Sec. 5.

Leakage analysis on d-KW-*d*DSE. We represent a N-size sequence of distinct keyword queries as $\mathbf{q}_{dis} = (\mathbf{i}, \mathbf{w})$, including the sequence of table name $\mathrm{i} \in \mathbf{i}$ for $\mathbf{T}_\mathrm{i}$ and searched keyword $w_* \in \mathbf{w}$, respectively. Akin to [24], in the EDB perspective, the leakage function [6, 8, 13] of d-KW-dDSE is:

$$\hat{\boldsymbol{L}}_{d-KW-dDSE}(\mathbf{q}_{dis}) = [(\mathrm{i}_1, \mathrm{t}_{w_1}, \mathcal{L}_D^{Srch}(w_1)) \ldots (\mathrm{i}_N, \mathrm{t}_{w_N}, \mathcal{L}_D^{Srch}(w_N))],$$

where t_{w_*} represents the token from w_*.

Similar to [15], the replacement of the Search protocol is carried out in a black-box manner. We gain the ability to detect and examine all the leakages present in the EDB, which stem from the search leakage in d-DSE.

To the best of our knowledge, passive [60] and active [64] attacks both source patterns revealed from the leakage function. We propose volumetric information [60] for d-KW-dDSE:

- **Update length pattern**, denoted as $ulen(w) = |\mathrm{Update}(\mathrm{w})|$ in $\mathcal{L}_D^{Srch}(w)$, outputs the number of updates made on keyword w.
- **Distinct response length pattern**, denoted as $drlen(w) = |\mathrm{TimeDTS}(w)|$, outputs value's type matching keyword w.
- **Query equality pattern** (a.k.a search pattern), denoted as $qeq(w_i, w_j) = \mathbf{1}(w_i = w_j)$, indicates whether two queries are targeting the same keyword. The predicate $\mathbf{1}(*)$ outputs 1 for $w_i = w_j$ and 0 otherwise.

We state that d-KW-dDSE does not have the insert/delete length pattern due to the type-2 BP of d-DSE. The file volume and response similarity pattern are both related to file retrieval instead of the constant-size distinct values protected by FP&BP.

[2] We give a detailed design for the d-DSE construction in Appendix F.

Potential attacks on d-KW-*d*DSE. d-KW-dDSE does not possess file volume (size) pattern leveraged by BVA [64] in injection attacks. For LAA, we find it difficult to perform similar volumetric attacks as in DSE [60]. Based on DwVH security, the value's quantity can express arbitrary distribution and integrate into the $ulen(w)$ of each keyword. Meanwhile, $drlen(w)$ does not reveal the sum of the value's quantities matching w, leading to the absence of the linear relationship between $drlen(w)$ and $ulen(w)$ [60].

4.4 Keyword Queries

The most common keyword query retrieves values from column $\mathbf{T}$.y for a keyword w in $\mathbf{T}$.x:

$$\texttt{SELECT}\ \mathbf{T}.y\ \texttt{FROM}\ \mathbf{T}\ \texttt{WHERE}\ \mathbf{T}.x = w \hookrightarrow SS_{srch} = (syn_{srch}, (\mathbf{T}, (\mathbf{T}.x, w, \mathbf{T}.y))).$$

The SS_{srch} is implemented by d-KW-dDSE along with certain client computations. Specifically, the client allocates a hash table to map the keyword w with the vector $\mathbf{d}$ constructed from (w,v,op) input. The dimensions of $\mathbf{d}$ record the value's quantities in the value's numerical (or lexicographical for string) order. We can first obtain the encrypted distinct values on column $\mathbf{T}$.y through d-KW-dDSE, decrypt them, and finally restore each value's quantity through $\mathbf{d}$ in their aforementioned order. The order from d-KW-dDSE can also help us to insert/auto-increment/delete a dimension in $\mathbf{d}$ for new/repetitive/deleted (w,v) input when updating encrypted data. We call this construction as KW-dDSE (KeyWord queries from d-DSE), which is a practical approach with $O(W)$ local storage cost to clients [2, 4, 20]. Note that this approach enables record recovery by treating duplicated records copied from multiple columns' data as values.

Leakage analysis on KW-*d*DSE. The KW-dDSE and d-KW-dDSE are identical except for the hash map on the honest client. For a keyword query sequence $\mathbf{q}_{kw} = (\mathbf{i}, \mathbf{w})$, the leakage function of KW-dDSE is:

$$\hat{\boldsymbol{L}}_{KW-dDSE}(\mathbf{q}_{kw}) = \hat{\boldsymbol{L}}_{d-KW-dDSE}(\mathbf{q}_{kw}).$$

Potential attacks on KW-*d*DSE. The potential attacks are identical to those on d-KW-dDSE, as the equation captures the same leakage function.

4.5 Join Queries

We implement the join query [24] between the foreign-key and primary-key, which is the fundamental query type for relational databases. A simple join query of two tables $\mathbf{T}_1/\mathbf{T}_2$ on the foreign/primary key $\mathbf{T}_1.z = \mathbf{T}_2.z$ returns all values on $\mathbf{T}_2.y$ from $\mathbf{T}_1$ and $\mathbf{T}_2$ that agree on $\mathbf{T}_1.z = \mathbf{T}_2.z$ & $\mathbf{T}_1.x = w$, i.e.,

$$\texttt{SELECT}\ \mathbf{T}_2.y\ \texttt{FROM}\ \mathbf{T}_1\ \texttt{JOIN}\ \mathbf{T}_2\ \texttt{ON}\ \mathbf{T}_1.z = \mathbf{T}_2.z\ \texttt{WHERE}\ \mathbf{T}_1.x = w. \hookrightarrow SS_{join} = (syn_{join}, (\mathbf{T}_1, \mathbf{T}_2, (\mathbf{T}_1.x, w, \mathbf{T}_1.z), (\mathbf{T}_2.z, 0, \mathbf{T}_2.y))).$$

It is straightforward to use multi KW-dDSE to capture the SS_{join}. We encrypt $\mathbf{T}_2$ with one KW-dDSE $T_2^{KW-dDSE}$ between column $\mathbf{T}_2$.y and $\mathbf{T}_2$.z and $\mathbf{T}_1$ with another $T_1^{KW-dDSE}$

between $\mathbf{T}_1$.z and $\mathbf{T}_1$.x. For the join query, we first invoke $T_1^{KW-dDSE}$ to get values $\mathbf{v}$ in $\mathbf{T}_1$.z corresponding to w in $\mathbf{T}_1$.x. Then we utilize $T_2^{KW-dDSE}$ to search values on $\mathbf{T}_2$.y by results from $T_1^{KW-dDSE}$. We call this construction as JOIN-dDSE (JOIN queries from d-DSE).

Leakage analysis on JOIN-*d*DSE. We find that the leakage of JOIN-dDSE on the EDB is caused by the process from $T_1^{KW-dDSE}$ and $T_2^{KW-dDSE}$. Since a join query consists of multi KW-dDSE processes (referred to the join equation), the leakage function of JOIN-dDSE for a sequence of join queries $\mathbf{q}_{join} = (\mathbf{i}, \mathbf{j}, \mathbf{w})$ is:

$$\hat{\boldsymbol{L}}_{JOIN-dDSE}(\mathbf{q}_{join}) = \hat{\boldsymbol{L}}_{KW-dDSE}\left((\mathbf{i}, \mathbf{w})||_l^{|\mathbf{v}|}(\mathbf{j}, v_l)\right),$$

where v_l is the value of l dimension in $\mathbf{v}$, $\mathbf{j}$ is the sequence of the second table name (i.e., $\mathbf{T}_2$), and $||_l^{|\mathbf{v}|}$ denotes concatenating the sequence of each value performing KW-dDSE on $\mathbf{T}_\mathbf{j}$.

Different from $\hat{\boldsymbol{L}}_{KW-dDSE}$, $\hat{\boldsymbol{L}}_{JOIN-dDSE}$ has an apparent search sequence between $\mathbf{T}_\mathbf{i}$ and $\mathbf{T}_\mathbf{j}$. To perform KW-dDSE on $\mathbf{T}_\mathbf{j}$, the keyword w in $\hat{\boldsymbol{L}}_{JOIN-dDSE}$ can query the same v, revealing that they have previously searched the same value in $\mathbf{T}_\mathbf{i}$.

Potential attacks on JOIN-*d*DSE. Although JOIN-dDSE resists volumetric attack inherited from KW-dDSE, it additionally leaks a 'generalized' access pattern [6] and reveals the co-occurrence matrix [36, 39] in certain situations (e.g., the plain dataset is partially exposed). To reduce the leakage, one could use the oblivious join [11,35] through indistinguishable join access, which heavily depends on Oblivious RAM (ORAM) and Bitonic-Sorted Network.

5 The BF-SRE Scheme

We describe the d-DSE scheme BF-SRE based on the Bloom Filter (BF), Symmetric Revocable Encryption (SRE), and the Forward Private DSE (FP-DSE) scheme for d-KW-dDSE. Inspired by AURA [53], the retrieval of BF-SRE is exactly the encrypted distinct values, which brings benefits for subsequent token execution. The security analysis depicts that BF-SRE attains FP&BP and DwVH security. The scheme also achieves non-interactive deletion and the sub-linear search.

Symmetric Revocable Encryption (SRE) [53]: (1) SRE.$KGen(\lambda)$ outputs the master secret key $msk = (sk, D)$ from the security parameter λ, where sk and D are the secret key and revoke structure, respectively; (2) SRE.$Enc(msk, s, t)$ outputs the ciphertext ct from msk, message s, and the tag t; (3) SRE.$Comp(D, t)$ compresses t into the revoke structure D and outputs the new one D'; (4) SRE.$ckRev(sk, D)$ takes as input sk and D and outputs sk_R; (5) SRE.$Dec(sk_R, ct)$ decrypts ct via sk_R if the related tag is not in D for sk_R.

Fig. 2 shows the Update and Search protocol of BF-SRE. BF-SRE uses BF for storing the Distinct State and the FP-DSE Σ_{add} to upload modified keyword/value pairs, while the SRE

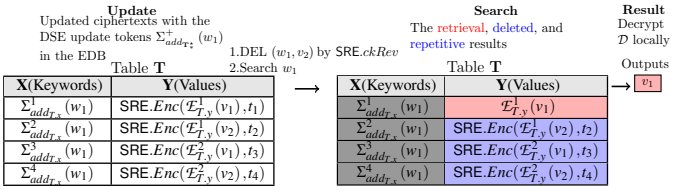

Figure 2: BF-SRE: the scheme overview. We use the blue color to represent the same revocation.

is used to revoke tags associated with deleted or repetitive values in the EDB. In Update protocol, the BF determines the real or dummy tag generation for SRE ciphertexts based on the first or repetitive inputs, respectively. The SRE ciphertext is uploaded with real tags if the BF outputs "false." Otherwise, BF-SRE uploads the SRE ciphertext with a dummy tag manufactured by revoking the corresponding SRE key. In the Search stage, if the SRE ciphertext is unrevoked, it will be decrypted by the constrained sub-key from SRE. Finally, the returned symmetric ciphertexts are decrypted locally.

The combination of BF and SRE can sufficiently deal with large-scale datasets, even for those with table structures. According the BF required bit size $b = -n \ln p / (\ln 2)^2$, where n and p are the maximum count and the tolerated false-positive probability, BF can expense a small storage cost to record whether keyword/value/op pairs appear (e.g., for $n = 2^{20}$ and $p = 10^{-5}$, b size is just 3MB [53]).

5.1 BF-SRE Description

Protocol 1 BF-SRE: Setup, bold lines 2-3 are Distinct State.

Setup(λ):

1: Initialize the DSE scheme $(\text{EDB}, \sigma, K_\Sigma) \leftarrow \Sigma_{add}.Setup(\lambda)$
2: Initialize the Bloom Filter $\mathbf{H}, \mathbf{B} \leftarrow \Phi.Gen(\lambda)$
3: Initialize empty maps MSK, UpCnt, C, D, $\text{EDB}_{\text{cache}}$
4: Randomly generate keys $K_s, K_t, K_c \xleftarrow{\$} \{0,1\}^\lambda$
5: Send EDB and the cache $\text{EDB}_{\text{cache}}$ to the server

Setup. The Setup protocol generates the encrypted database EDB, its internal state σ, secret key K_σ from a FP-DSE scheme Σ_{add}, and constructs secret keys K_s, K_t, K_c, the BF hash collection $\mathbf{H}$, the BF bit array $\mathbf{B}$, and four empty maps **MSK**, **UpCnt**, **C**, **D**. The K_c is used to encrypt values. The K_s generates the cache token tkn to get previous search results from the cache EDB ($\text{EDB}_{\text{cache}}$). The K_t is used to generate tags from inputs and **UpCnt**. The **C** counts the search on each w. The **MSK** and **D** are used to store each master key and revoked key structure associated keyword w, respectively.

Update. This protocol updates the EDB with the new internal state. At lines 1-7, the client loads the internal state on keyword w. At line 8, the client uses PRF to generate tags t and l. The t is the *real* tag for the first input of the $w||v$. The l is the *dummy* tag for the repetitive input. At line 9, the client uses the symmetric encryption to generate the retrieval s from the value v and the unique count cnt. At lines 10 and 22, the

Protocol 2 BF-SRE: Update, bold lines 11-19 are the Distinct Classifier.

Update$(K_\Sigma, \mathbf{st}, op, (w,v)$;EDB):
Client:
1: Read msk, D, i, and cnt from $\mathbf{MSK}[w]$, $\mathbf{D}[w]$, $\mathbf{C}[w]$, and $\mathbf{UpCnt}[w]$, respectively.
2: **if** msk is not initialized **then**
3: Set $msk \leftarrow \mathsf{SRE}.KGen(\lambda)$, where $msk = (sk, D)$
4: Set $\mathbf{MSK}[w] \leftarrow msk$, $\mathbf{D}[w] \leftarrow D$
5: Set $\mathbf{UpCnt}[w] \leftarrow 0$, $\mathbf{C}[w] \leftarrow 0$
6: Set $cnt \leftarrow 1$, $\mathbf{UpCnt}[w] \leftarrow cnt$
7: **end if**
8: Gen. the real/dummy tags $t \leftarrow F(K_t, w||v||0)$, $l \leftarrow F(K_t, w||v||cnt)$
9: Gen. the retrieval $s \leftarrow \mathcal{E}(K_c, v||cnt)$
10: **if** op == add **then**
11: **if** $\Phi.Check(\mathbf{H}, \mathbf{B}, t)$ **is false then**
12: **Update BF** $\Phi.Upd(\mathbf{H}, \mathbf{B}, t)$
13: $ct \leftarrow \mathbf{SRE}.Enc(msk, s, t)$
14: **Insert the EDB** $\Sigma_{add}.Update(K_\Sigma, add, w||i, (ct, t)$;EDB)
15: **else**
16: $ct \leftarrow \mathbf{SRE}.Enc(msk, s, l)$
17: **Insert the EDB** $\Sigma_{add}.Update(K_\Sigma, add, w||i, (ct, l)$;EDB)
18: **Puncture the dummy tag** $D' \leftarrow \mathbf{SRE}.Comp(D, l)$, $\mathbf{D}[w] \leftarrow D'$
19: **end if**
20: **else**
21: Puncture the real tag $D' \leftarrow \mathsf{SRE}.Comp(D, t)$, $\mathbf{D}[w] \leftarrow D'$
22: **end if**
23: $\mathbf{UpCnt}[w] \leftarrow cnt + 1$

client chooses to generate ciphertext or revoke the SRE key according to the input operation ('add' or 'del'). For addition, at line 11, the client executes the Distinct Classifier program to check whether the $w||v$ input appears for the first time. If so, the client updates the BF, generates SRE ciphertexts ct tagged t as the encrypted ciphertexts, and uploads it by the instance of DSE. Otherwise, the client generates dummy SRE ciphertexts, revokes the corresponding revoked key structure D, and uploads the dummy encrypted ciphertexts. For deletion, at line 21, the client revokes the SRE key structure corresponding to the tag t of the first input $w||v$. At line 23, the client updates the count $\mathbf{UpCnt}[w]$ for keyword w.

Protocol 3 BF-SRE: Search, bold lines 3-4 are the Distinct Constraint.

Search$(K_\Sigma, w, \mathbf{st}$;EDB):
Client:
1: Read i, sk, and D from $\mathbf{C}[w]$, $\mathbf{MSK}[w]$, and $\mathbf{D}[w]$, respectively.
2: **if** i is not valid, **then** $\perp$.
3: $sk_R \leftarrow \mathbf{SRE}.ckRev(sk, D)$
4: **Send** $(\mathbf{sk_R}, \mathbf{D})$ **and** $\mathbf{tkn} = \mathbf{F}(\mathbf{K_s}, \mathbf{w})$ **to the server**
5: $msk = (sk, D) \leftarrow \mathsf{SRE}.KGen(\lambda)$
6: Renew $\mathbf{C}[w] \leftarrow i + 1$, $\mathbf{MSK}[w] \leftarrow msk$, $\mathbf{D}[w] \leftarrow D$
Client and Server:
7: Run $\Sigma_{add}.Search(K_\Sigma, w||i, \sigma$;EDB), and the server gets the list $L = ((ct_1, t_1), (ct_2, t_2) ..., (ct_l, t_l))$
Server:
8: Set the new value list $NV \leftarrow \emptyset$
9: **for** $j \in [1, l]$ **do**
10: Get the encrypted value $V_j \leftarrow \mathsf{SRE}.Dec((sk_R, D), ct_j, t_j)$
11: **if** V_j is valid **then**
12: Update $NV \leftarrow NV \bigcup V_j$
13: **else**
14: Delete this ciphertext in EDB
15: **end if**
16: **end for**
17: Retrieve cache $OV \leftarrow \mathrm{EDB}_{\mathrm{cache}}[tkn]$
18: Return $S \leftarrow NV \bigcup OV$, and update $\mathrm{EDB}_{\mathrm{cache}}[tkn] \leftarrow S$
Client:
19: Extract each symmetric cipher s from S, and decrypt the s to get the value v from $v||cnt \leftarrow \mathcal{D}(K_c, s)$ as the search result

Search. The Search protocol finds the ciphertexts by keyword w and returns the distinct values. At lines 1-4, the client reads internal state, computes the Distinct Constraint program to get the SRE revoked key sk_R and the cache token tkn, and sends them to the server. At lines 5-6, the client renews the internal state for the next search on w. At line 7, the client and server run the Search protocol of Σ_{add}, and then the server gets the search list L. At lines 8-16, the server uses the sk_R to decrypt each ct in list L and remains the symmetric ciphertexts from the unrevoked SRE ciphertext. At line 17, the server retrieves previous results from the encrypted database cache $\mathrm{EDB}_{\mathrm{cache}}$ by tkn. At lines 18-19, the client obtains the search result S from the server and decrypts all symmetric ciphertexts to get the distinct values.

Remark on BF-SRE. To simplify the explanation, we illustrate the situation of retrieving distinct values from the specified column $\mathbf{T}.y$ based on the searched keyword in $\mathbf{T}.x$. To retrieve distinct values on other columns in $\mathbf{T}$, we do the following: (1) extend the value input as a vector (i.e., v to $\mathbf{v}$); (2) expand the dimension of $\mathbf{B}$ (i.e., $\mathbf{B}[w]$ to $\mathbf{B}[w].\star$) to record more state on other columns; (3) expand the dimension of $\mathbf{D}$ (i.e., $\mathbf{D}[w].\star$) for their corresponding revoked key structure; and (4) finally extend ct. After that, we switch to the right column's revoked key structure in $\mathbf{D}[w].\star$ for distinct values on arbitrary columns in $\mathbf{T}$. More functional extensions for BF-SRE are possible through replacing Σ_{add} with other FP-DSE schemes like range search [67].

5.2 Analysis on BF-SRE

Correctness. The BF-SRE scheme uses the FP-DSE to upload the modified keyword/value pairs in encrypted databases. With the polynomial-time algorithm of the PRF F, it always outputs a tkn from K_s. The BF's possibility of losing correctness is false positive and acceptable [53]. Hence, our scheme can correctly update and search distinct values.

Security Analysis. BF-SRE securely generates the ciphertexts, search tokens attached to the FP-DSE, the SRE, the PRF, and the symmetric encryption. As for the Update stage, the client modifies the input by **UpCnt** and the Distinct State, and the ciphertext is uploaded by the FP-DSE Σ_{add}. With regard to the Search stage, the client uploads the revoked SRE key to exactly retrieve the values attached to the real tags, which does not show auxiliary information about the volume.

Theorem 1 (Adaptive Security of BF-SRE) *Let F (the PRF) with a specific key be modelled as the random oracle $\mathcal{H}_F$, $\mathcal{L}_D = \left(\mathcal{L}_D^{Upt}, \mathcal{L}_D^{Srch}\right)$ is defined as:*

$$\mathcal{L}_D^{Upt}(w, v, op) = add$$
$$\mathcal{L}_D^{Srch}(w) = sp(w), \mathrm{TimeDTS}(w), \mathrm{Update}(w),$$

BF-SRE is $\mathcal{L}_D$-adaptively-secure.

Proof Sketch. The proof is conducted in the game hop like AURA [53]. We gradually replace the real cryptographic tools

used in the BF-SRE scheme with the bookkeeping tables or the corresponding simulators and obtain the BF-SRE simulator. The addition list L_{add} and the deletion set D are used in the $\mathcal{L}_D^{Srch}$ leakage function to retrieve the search result. We note that the BF determines the workflow of the simulator and does not affect the indistinguishability between each game hop.

Theorem 2 (DwVH Security of BF-SRE) *The leakage function of BF-SRE* $\mathcal{L}_D = (\mathcal{L}_D^{Upt}, \mathcal{L}_D^{Srch})$ *is Distinct with Volume-Hiding.*

Proof Sketch. The proof is analyzed from the leakage in the BF-SRE forward and backward privacy. To prove that $\mathcal{L}_D$ is Distinct with Volume-Hiding, we need to construct two signatures with the same size and the upper bound of maximum volume. Note that $\mathcal{L}_D^{Upt}$ consists the addition operations, and $\mathcal{L}_D^{Srch}$ includes value's type and timestamps of updates. The $\mathcal{L}_D^{Srch}$ is independent of the input keyword/value pairs because the real and dummy tags generation can always maintain identical response on value's type under the two signatures. Therefore, the leakage function reveals nothing about the volume. Both proofs are given in Appendix E.

Complexity. In the Setup stage, BF-SRE spends a constant time initializing Σ_{add}, internal state, and secret keys. In the Update stage, it consumes a constant time to update the internal state, execute Σ_{add}, test the BF, and generate ciphertexts. Hence, the Update protocol computation complexity is $O(1)$ with a one-way interaction and an $O(1)$ length ciphertext. In the Search stage, BF-SRE spends a constant time performing Σ_{add} and spends $O(a_w)$ time on search results, where a_w denotes all ciphertexts found by Σ_{add}. Hence, the Search protocol computation complexity is set as $O(n_w)$ with a one-way interaction, where n_w denotes the number of returned distinct values.

5.3 Optimization

In BF-SRE, the cryptographic tools determine the actual computation and communication costs. Recall that in the Search protocol, BF-SRE uses the DSE scheme to find all matched ciphertexts. A possible solution to improve the efficiency of the Search is to leverage the parallel Forward Private DSE [30, 33].

On the other hand, the SRE decryption affects the efficiency of finding the distinct values. In practice, SRE requires significant computational cost to determine the derived sub-key corresponding to SRE ciphertext. Fortunately, we can identify and implement the *Greedy* and *Default* optimization for the SRE decryption:

• *Greedy*: Temporarily store the sub-keys that are not applied in the previous SRE decryption and try using them in subsequent decryption. In practice, we can use a stack to store unused sub-keys, enabling a systematic approach to ejecting the keys one by one for the decryption of SRE ciphertexts. After decryption, the used sub-keys are discarded, while the (new) derivatives are added to the stack.

• *Default*: Pre-compute the sub-key space size of SRE decryption through the keyword frequency in the target dataset. In practice, we can utilize the estimated keyword frequencies, which are close to the real ones [55], to set the appropriate limitation of revoke operation corresponding to each keyword. After that, SRE decryption reduces the total computation of sub-keys, thereby achieving faster decryption speed.

Note we combine the two optimizations for BF-SRE.

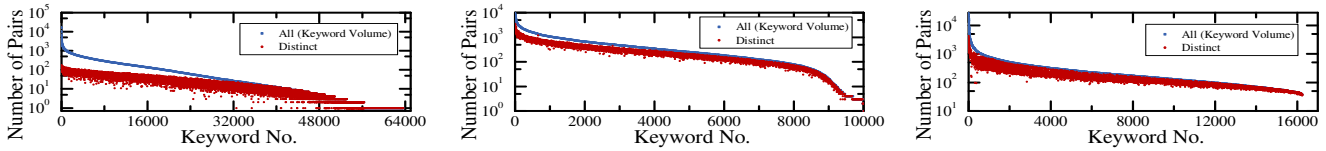
6 Evaluation

We first introduce datasets with different keyword/value distributions and experimental setup. Then, we evaluate the comparison between BF-SRE and MITRA* [20], AURA [53], SEAL [15], and ShieldDB [55]. Our scheme, under equivalent security parameters, exhibits comparable time costs and significant communication improvement. Our codes are publicly available in https://github.com/jd89j12dsa/ddse.

6.1 Dataset

Chicago Crimes Reports.[3] The Crime dataset is suitable for keyword/value pairs (in the context of SQL and EDB) [9, 15]. It includes 7,989,987 keyword/value pairs extracted from the reports (spanning from 1-1-1999 to 2-4-2024). We use street names and the corresponding IUCR codes as keywords and values in the Crime table, respectively. For testing join queries, we extract the whole IUCR table to search the PRIMARY_DESCRIPTION by IUCR codes from the Crime results.

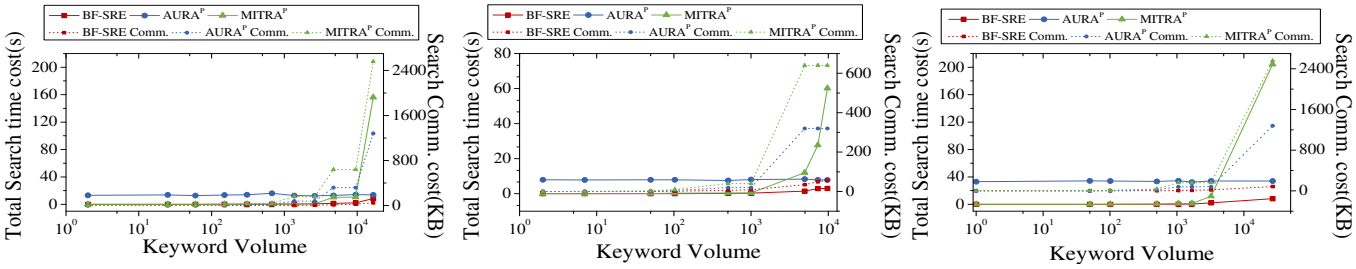
Wikipedia.[4] This is a large-scale document dataset for DSE evaluation [12, 33]. Through the Wikipedia extractor and Python NLTK package [33], we collect 4,565,948 pairs in our table structure, and we aim to find the distinct words by document names.



Enron.[5] Enron email dataset [33, 65] stores the texts converted from its email system. We use NLTK package and Porterstemmer [47] to extract 5,190,199 pairs, aiming to identify distinct words through email names.

Fig. 3 illustrates the number of keyword/value pairs associated with each keyword in descending order. We count the number of all keyword/value pairs as *Keyword Volume*. The repetitive-percentage/keyword-space/highest-keyword-volume of the Crime, Wikipedia, and Enron dataset are 80.15%/63,659/16,644, 42.04%/10,000/9,738, and 45.53%/16,241/26,946, respectively.

6.2 Experimental Setup



Our test platform is Intel® Xeon Gold 5120 CPU @ 2.20GHz, 128GB, Dell RERC H730 Adp SCSI Disk Device, Windows Server 2016 Standard. In our Python (v3.60) code, we utilize

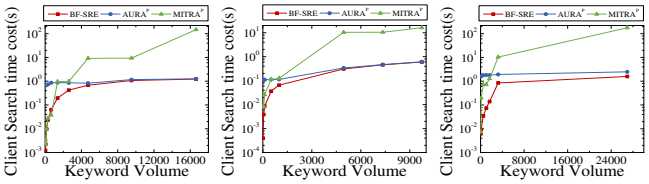
Figure 4: Comparison of the **total** search **time and communication** costs of BF-SRE, AURA^P, and MITRA^P **without deletion**.

the PYmysql package to perform at most 100 parallel queries on MySQL (Ver 14.14 Distrib 5.7.33).

We first compare the performance of BF-SRE with MITRA^P and AURA^P. Note BF-SRE uses DIANA [4] as the Forward Private DSE implementation. Our implementation makes Python modules from the SRE [53] source code with the *greedy* and *default* optimization mentioned in Sec. 5.3. We also implement MITRA^P and AURA^P from MITRA* [20] and AURA [53], along with the SEAL's adjustable padding strategy [15] for fair comparisons. Specifically, when initializing the EDB, we ensure that MITRA^P and AURA^P pad each keyword with dummy pairs until the volume of each keyword reaches the exponentiation of $x = 4$, respectively. For correctness, we prepare a translation map between keyword/value pairs and keyword/id pairs to restore search results mentioned in Sec. 1.

Then, we test the time and communication costs of BF-SRE, SEAL, and ShieldDB when processing queries in SQL syntax. SEAL is implemented through the tree-based ORAM [20][6] with the factor $a = 20, x = 4$. For ShieldDB in NL mode ($\alpha = 256$), we transform keyword/value datasets to the related file dataset and further compose keyword clusters uploading the stream data. We say that they can perform the queries via our basic Query Planner established from the PYmysql package and the transformation in Sec. 1.



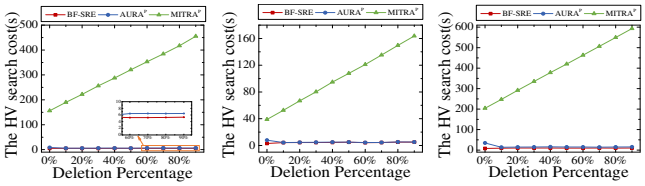
6.3 Compare with DSE

For BF-SRE, AURA^P, and MITRA^P, we document total/client search time, communication, and highest-volume keyword search time costs in deletion. Based on the equation in Sec. 5, the BF's size reaches an appropriate setting to delete on the highest-volume keyword, preserving the correctness of BF-SRE and AURA^P.

[6]The tree-based ORAM: https://github.com/jgharehchamani/SSE

6.3.1 Search performance

Total search time and communication costs. Fig. 4 illustrates that BF-SRE significantly outperforms AURA^P and MITRA^P in time and communication costs when the Keyword Volume > 10^3. Particularly, with regards to time costs, in Fig. 4c, BF-SRE exhibits a slower increase in cost, extending up to 8.25 seconds. This is more efficient, with a 4.12x and 29.27x reduction in time compared to AURA^P and MITRA^P. Meanwhile, the communication costs for BF-SRE are 83.82 KB with 15.27x and 30.54x advantage over AURA^P and MITRA^P. Both compared DSE schemes display significant ladder like mutations (of SEAL) in communication cost. All trends of Fig. 4a,4b,4c have similar increments. This result shows that the padding strategy requires AURA^P to initialize the large size BF to log the deletion of dummy pairs, while MITRA^P has to perform more "clean-up" operations (i.e., removing deleted pairs and re-encrypting the remaining pairs).

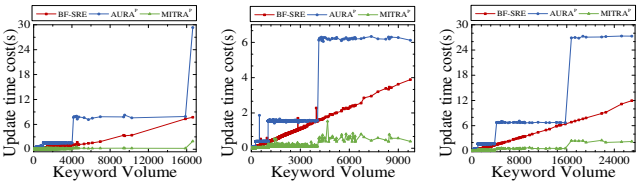


(a) Crime **(b)** Wikipedia **(c)** Enron

Figure 5: Comparison of search **time** costs of BF-SRE, AURA^P, and MITRA^P on **client without deletion**.

Search time cost on client. Fig. 5 shows that BF-SRE outperforms MITRA^P and presents a small advantage over AURA^P. For example, in Fig. 5a, the cost gap between BF-SRE and AURA^P is roughly 0.64-0.03s. We state that BF-SRE does not process dummy data while searching, thereby improving the client's performance.

Highest-Volume (HV) Search time costs. Fig. 6 provides



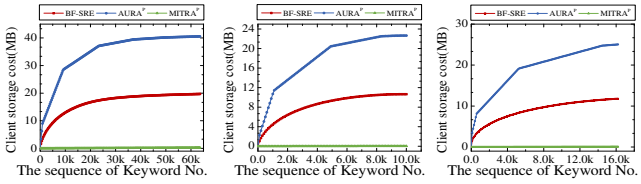
(a) Crime **(b)** Wikipedia **(c)** Enron

Figure 6: Comparison of **search time** costs of BF-SRE, AURA^P, and MITRA^P on the highest-volume (HV) keyword **with deletion** percentage (namely, delete 0-90% pairs).

the fact that BF-SRE is well-perform across all datasets. We notice that the costs associated with BF-SRE exhibit a slight increase in correlation with the rise in the deletion percentage. In Fig. 6b,6c, the costs slowly increase from 2.96s and 8.14s to 4.97s and 10.02s, respectively. The costs of MITRA^P climb up abruptly as its deletion requires traversing and re-encrypting all dummy data (under padding). AURA^P presents a declining cost trend on the costs but still cannot outperform BF-SRE. In Fig. 6c, the cost of AURA^P decreases from 34.31s to 15.33s since the deletion operations indirectly reduce its cost on decryption key generation.

6.3.2 Update performance

We compare update time costs for BF-SRE, AURA^P, and MITRA^P. Due to AURA^P and MITRA^P inheriting the batch update of padding strategies, we record the costs based on Keyword Volume. For BF-SRE, we record the average addition cost of all pairs associated with the keyword at a specific Keyword Volume. We also record the client storage cost when adding keyword/value pairs in the sequence of Keyword No. In other words, for the Crime dataset, we add the corresponding pairs in the order of Keyword No.1 to No.63659 shown in Fig. 3a.



(a) Crime **(b)** Wikipedia **(c)** Enron

Figure 7: Comparison of **update time** costs of BF-SRE, AURA^P, and MITRA^P.

Update time costs. Fig. 7 depicts that the costs of BF-SRE are at the same magnitude in all datasets. BF-SRE yields linear costs that grow in proportion to the Keyword Volume, while the AURA^P and MITRA^P both experience step-wise increases. In detail, for Fig. 7a, the costs of BF-SRE, AURA^P, and MITRA^P climb from $1.52{\cdot}10^{-4}$s, $2.72{\cdot}10^{-4}$s, and $8.8{\cdot}10^{-5}$s to 7.62s, 29.24s, and 1.94s, respectively. Both AURA^P and MITRA^P have the mutation at the Keyword Volume of 4096 and 15868, which is due to the use of SEAL's adjustable padding.

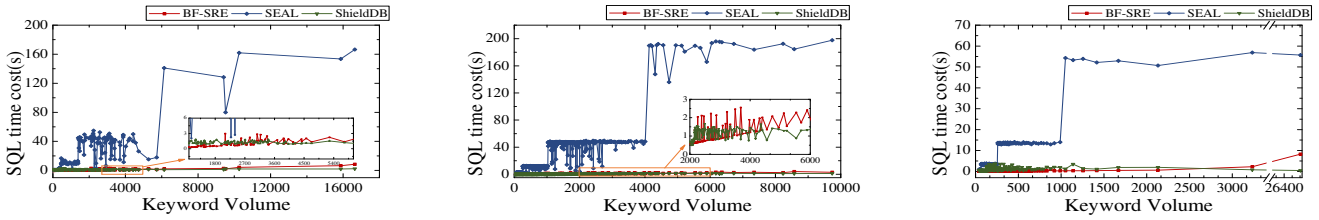
Client storage costs. Fig. 8 illustrates that the costs for BF-SRE fall between those of AURA^P and MITRA^P in all datasets.

(a) Crime **(b)** Wikipedia **(c)** Enron

Figure 8: Comparison of **client storage** costs of BF-SRE, AURA^P, and MITRA^P for update.

Due to the *Default* optimization, the BF-SRE costs eventually trend toward MITRA^P, roughly 1.47x less than AURA^P in Fig. 8a, 8b, 8c, respectively. In Fig. 8a, AURA^P exhibits noticeable inflections when the sequence of Keyword No. reaches 899, 9192, and 23351 (corresponding to Keyword Volumes of 1023, 255 and 63) due to the SEAL's adjustable padding.

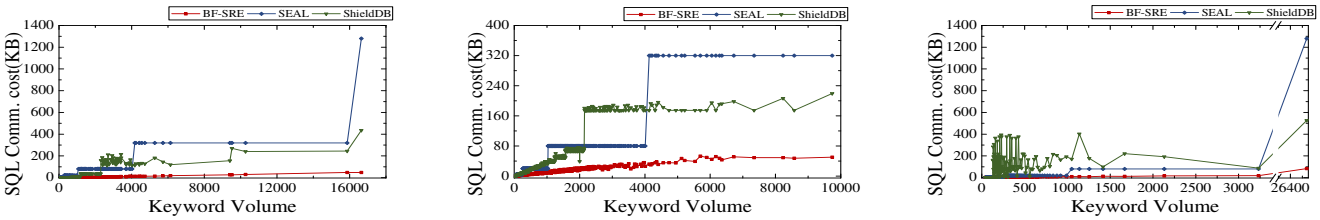
6.4 Compare with Padding Strategy



We test the time and communication costs for keyword and join queries in SQL syntax. As mentioned in Sec. 4, we first set up the constructions of BF-SRE, SEAL, and ShieldDB, respectively. Then, we use the Query Planner to extract original queries for each construction to retrieve values from the EDB.

For join queries, we use the Crime dataset to test time and communication costs about its Keyword Volume. We use Query Planner to request retrieving the relevant IUCR code through keyword (street name, see Sec. 6.1) in the Crime table, and then leverage each IUCR code result to find the PRIMARY_DESCRIPTION in the IUCR table. Finally, we let the planner restore the query combined from the two-stage results and log the related costs.

Keyword query time cost. Fig. 9 presents the costs of BF-SRE, SEAL, and ShieldDB. From the query results covering the entire keyword space, we see that BF-SRE provides advantage, nearly 10.89-180x, for SEAL when the Keyword Volume $> 10^3$. Its cost slightly exceeds that of ShieldDB when the Keyword Volume is greater than 4728, 4219, and 2712 in the Crime, Wikipedia, and Enron dataset, respectively. From our analyze, the numbers of keywords below these thresholds are accounted for approximately 95.0%, 96.5%, and 98.5%, revealing that the BF-SRE's cost is competitive among large keyword spaces. Note that some 'spikes' come from batch read operations [20] and cache retrieval [55] in SEAL and ShieldDB, respectively.



Keyword query communication costs. In Fig. 10, BF-SRE consumes much less communication costs than the padding strategies. Specifically, it reduces the highest-volume keyword cost up to 53.14x, 6.36x, and 15.27x on the Crime, Wikipedia, and Enron dataset, respectively. We recall that BF-SRE mainly concentrates on the retrieval of the values, while the padding has to deal with the dummy data.

Join query cost. Fig. 11 shows that BF-SRE performs the

(a) Time costs **(b)** Communication costs

Figure 11: Comparison of **time and communication** costs for SQL join queries on Crime.

best in the Crime dataset. Compared to executing SQL keyword queries, BF-SRE does not require a significant rise in the metrics. In contrast, SEAL and ShieldDB repeatedly eliminate the dummy data from the IUCR table locally, thereby sharply increasing their costs. The costs associated with BF-SRE are roughly 26.6x lower than those of ShieldDB w.r.t. the highest-volume keyword.

When considering overall costs, BF-SRE stands as a competitive performer in comparison to trivial-transformed instances from DSE. Moreover, it provides comparable time costs to the padding strategies while delivering significant advantages. It demonstrates the ability to efficiently handle various search queries and offers practical communication costs under the tested security parameters.

7 Discussions

Dataset. We notice that there are still a few datasets that have been used for DSE evaluations, e.g., Apache Lucene [64]. We can apply them to locate distinct words by document names, similar to the approach used in Wikipedia or Enron. We argue that using these datasets will not seriously affect the performance of our proposals because Crime/Wikipedia/Enron has a familiar data distribution to other table/document/email datasets [33].

Highest-volume keyword search in deletion. One may argue that using "highest-volume keyword" may not yield extensive results. It is important to note that the search results obtained from representative keywords exhibit minimal fluctuation. This is because the search process for these keywords consumes sufficient time and ensures accurate results. These keywords are more frequently used in practical databases and we use them to clearly highlight the advantage of our proposal. We note that interested readers may choose to use less-frequent keywords in the evaluation.

Other SQL databases. We use MySQL to store the ciphertexts of the EDB. We say that interested readers may use other SQL databases, such as PostgreSQL and Microsoft SQL Server, to implement the d-DSE schemes via the Python interfaces. The parallel capability of SQL databases is not a crucial aspect to consider when choosing among them, as their performance is largely dependent on disk storage.

The d-DSE storage cost. BF-SRE needs more client storage than MITRA^P, which is required by the underlying SRE revoke structure. We can apply other DSE schemes as building blocks consuming lower client storage.[7]

Threat from access pattern. Similarly to JOIN-dDSE, d-KW-dDSE could potentially be vulnerable to access pattern leakage [1], which is a concern associated with practical DSE constructions [12, 14, 43, 53]. In certain scenarios, the retrieval process could involve accessing memory, such as acquiring a constant-size file-identifier from a column, which could inadvertently reveal access patterns. One straightforward strategy to mitigate this issue is to combine d-KW-dDSE with ORAM [20] to obscure memory access, albeit at extra costs of time and storage. Specifically, we can first retrieve identifiers via d-KW-dDSE and then employ ORAM to re-

[7] In the full version [37], we provide an example based on MITRA and the Inner Product Encryption [34], obtaining distinct values via the distinct inner products between ciphertexts and search tokens.

trieve each identifier's data. When processing queries in batch, we leverage the multi-path ORAM (e.g., OBI [59]) to mitigate the high throughput.

Against frequency attacks. Although we mainly focus on volume leakage, a recent research [60] alerts the frequency(-matching) attack. The success of the attack hinges on the diversity of the query frequency that is exposed in BF-SRE and prior FP&BP DSE schemes [20, 53] through persistent frequency detection. To mitigate the attack, we can apply a general countermeasure - frequency-smoothing - also used in PANCAKE [21], on the top of d-DSE. It is compatible for combining d-DSE and frequency smoothing as: 1) they both leverage keyword/value pairs (KV pairs in their description); 2) their contexts (i.e., static and dynamic frequency distributions) are consistent.

Ciphertext de-duplication. Recall that ciphertext de-duplication [5, 38, 49, 63] is to eliminate the repetitive ciphertexts. In particular, this approach, inherited from convergent encryption [38], emphasizes the elimination of ciphertexts with identical contents across multiple clients in order to minimize storage costs. But this technique does not focus on ensuring secure value searches.

8 Conclusion

We explore the distinct search and propose d-DSE. Following the concept and definition of d-DSE, we propose the d-DSE designed EDB and develop BF-SRE, which satisfies the forward and backward privacy and DwVH security. We conduct extensive experiments to highlight the practical performance of our designs in run time, communication, storage, and effectiveness on volume leakage.

A Summary of Notations & Concepts

Table 3: Notations for d-DSE.

d-DSE designed EDB	Description
$\mathcal{EDB}_S$	The collection of encrypted tables stored on disk
$\mathtt{EDB}_C$	The replicated encrypted data from $\mathcal{EDB}_S$ on memory
q	The query
$\mathbf{q}_s$	The query sequence
SS	The functionally equivalent syntax
$\mathbf{t}_s$	The encrypted data generated from SS for queries
syn_s	The specific d-DSE construction name
$\mathcal{T}$	The table collection in EDB storage
$\mathbf{T}_s$	The table name
$\mathbf{T}_s.\star$	The table column
$\hat{\mathbf{L}}_s$	The leakage function of constructions
$\mathbf{d}$	The vector containing value's quantities
$ulen(w)$	The update length pattern
$drlen(w)$	The distinct response length pattern
$qeq(w)$	The query equality pattern
BF-SRE	**Description**
EDB	The encrypted database
$\text{EDB}_{\text{cache}}$	The cache encrypted database
$\mathbf{C}[w]$	The map counts the number of search on keyword w
$\mathbf{MSK}[w]$	The map records the master secret key about w
$\mathbf{UpCnt}[w]$	The map counts the update on w
$\mathbf{D}[w]$	The map records revoked key structure about w
K_c	The encryption key for values
K_s	The encryption key for $\text{EDB}_{\text{cache}}$
K_t	The encryption key for tag
t	The real tag
l	The dummy tag
$\mathbf{H}$	The Bloom Filter hash collection and bit array
$\mathbf{B}$	The Bloom Filter bit array
Σ_{add}	The Forward Private DSE scheme
Φ	The Bloom Filter scheme
$\mathcal{E}\&\mathcal{D}$	The encryption and decryption algorithm of the symmetric encryption

Symmetric encryption. Given a security parameter $\lambda \in \mathbb{N}$, message space $\mathcal{M} = \{0,1\}^*$, ciphertext space $\mathcal{C} = \{0,1\}^*$ and the key space $\mathcal{K} = \{0,1\}^\lambda$, a symmetric encryption scheme consists of two algorithm $(\mathcal{E}, \mathcal{D})$ the syntax in Algorithm 1.

Algorithm 1 Symmetric Encryption

- $\mathcal{E}(k,m)$: Input a symmetric key $k \in \mathcal{K}$ and a message $m \in \mathcal{M}$, output a ciphertext $c \in \mathcal{C}$.
- $\mathcal{D}(k,c)$: Input a symmetric key $k \in \mathcal{K}$ and a ciphertext $c \in \mathcal{C}$, recover a message $m \in \mathcal{M}$.

* For correctness $\mathcal{E}, \mathcal{D}$ should always make sense. For security, the requirement is INDistinguishability against Chosen Plaintext Attack (IND-CPA).

Bloom Filter [53]. A Bloom Filter (BF) Φ is a probabilistic data structure, which can rapidly and space-efficiently perform set membership test. A BF consists of three polynomial-time algorithms shown in Algorithm 2.

Algorithm 2 Bloom Filter

- $Gen(\lambda)$: It takes λ parsed as two integers $b, h \in \mathrm{N}$, and samples a collection of universal hash functions $\mathbf{H} = \{H_j\}_{j\in[h]}$, where $H_j : \{0,1\}^* \to [b]$, $[b]$ denotes a finite set. Finally, it outputs $\mathbf{H}$ and an initial b-bit array $\mathbf{B} = 0^b$ with each bit $\mathbf{B}[i]$ for $i \in [b]$ set to 0.
- $Upd(\mathbf{H}, \mathbf{B}, x)$: It takes $\mathbf{H} = \{H_j\}_{j\in[h]}$, $\mathbf{B} \in \{0,1\}^b$ and an element $x \in \mathcal{X}$, updates the current array $\mathbf{B}$ by setting $\mathbf{B}[H_j(x)] \leftarrow 1$ for all $j \in [h]$ and finally outputs the updated B. We use $\mathbf{B}_\mathsf{S} \leftarrow Upd(\mathbf{H}, \mathbf{B}, \mathsf{S})$ to denote the final array after inserting all elements in the set S one-by-one.
- $Check(\mathbf{H}, \mathbf{B}, x)$: It takes $\mathbf{H}, \mathbf{B}$ and an element x, and checks if $\mathbf{B}[H_j(x)] = 1$ for all $j \in [h]$. If true, it outputs 1 and 0 otherwise.

For correctness, a BF is *perfectly complete* if for all integers $b, h \in \mathbb{N}$, any set $S \in \mathcal{X}$, and $(\mathbf{H}, \mathbf{B}) \leftarrow Gen(\lambda)$ as well as $\mathbf{B}_\mathsf{S} \leftarrow Upd(\mathbf{H}, \mathbf{B}, \mathsf{S})$, it holds: $\mathbb{P}[\mathsf{Check}(\mathbf{H}, \mathbf{B}_\mathsf{S}, x) = 1] = 1$.

Symmetric Revocable Encryption [53]. Symmetric Revocable Encryption (SRE) is a primitive resembled from Symmetric Puncturable Encryption (SPE). With key space $\mathcal{K}_{SRE}$, message space $\mathcal{M}$ and tag space $\mathcal{T}$, SRE includes four polynomial-time algorithms shown in Algorithm 3.

Algorithm 3 Symmetric Revocable Encryption

- $\mathsf{SRE}.KGen(\lambda)$: It takes a security parameter λ as input and outputs a master secret key $sk \in \mathcal{K}_{SRE}$.
- $\mathsf{SRE}.Enc(sk, m, T)$: It takes as input a sk and a message $m \in \mathcal{M}$ with a list of tags $T \subseteq \mathcal{T}$, and outputs a ciphertext ct for m under tags T.
- $\mathsf{SRE}.KRev(sk, R)$: It takes as input sk and a revocation list $R = \{t_1, t_i, ..., t_\tau\} \subseteq T$, and outputs a revoked secret key sk_R, which can be used to decrypt only the ciphertext that has no tag belonging to R. For *compress revocation*, it takes $D \leftarrow \mathsf{SRE}.Comp(D, t_i)$ to make a revocation data structure D and takes $sk_R \leftarrow \mathsf{SRE}.cKRev(sk, D)$ to make the revoked secret key sk_R.
- $\mathsf{SRE}.Dec(sk_R, ct, T)$: It takes as input sk_R and ct encrypted under tags T, and outputs m or a failure symbol $\perp$.

For correctness, an SRE scheme is correct if the decrypt algorithm returns the correct result for every input of sk_R, ct, T, except with negligible probability. For security, SRE should provide the adaptive security of IND-REV-CPA and the selective security of IND-sREV-CPA [53].

B DSE

We notice that the majority of DSE schemes fail to consider the search and retrieval of the distinct values (which is a fundamental feature in relational databases). And none of existing works adequately address distinct search with well-defined security notions. DSE is commonly used for retrieving file-identifiers by keywords [13], and it is assumed that the client does not query the addition of the same pair of keyword and identifier [7,52]. Kamara et al. [31] conceptualized a database as a collection of files, each represented by a unique identifier. This assumption has been adopted by subsequent works, e.g., [23]. Stefanov et al. [52] used DSE to search the inverted index data structure for keyword/identifier pairs, while Cash et al. [7] revisited definitions from [13] to facilitate the storage of document-type data into databases using DSE. This philosophy has been widely embraced by subsequent works [2, 4, 10, 14, 53, 54, 61]. Xu et al. [62] proposed a robust DSE with an extension of backward security. Chen et al. [12] introduced a solution against key compromise in the context of DSE. Wang et al. [56] proposed a solution for keyword search on multi-writer encrypted databases. Recently, a volume-hiding DSE construction [66] was built on top of a padding strategy called dprfMM [42] (involving a dummy dataset). But its search complexity is proportional to the maximum response length [64].

C Padding Strategies

The padding strategy leverages false positive information as a means of performing obfuscation. Cash et al. [6] initially

proposed padding for keyword search to counter volume leakage. It is important to note that this technique relies on the distribution of the input dataset, making it susceptible to potential leakage even before a search query is initiated. Many works have been proposed to refine the padding [3, 28, 29]. SEAL [15] introduces an adjustable searchable encryption scheme that provides control over the amount of leaked access pattern information. This control is implemented through fine-tuning padding parameters to adjust leakage level. But SEAL does not support update operations, which is impractical in the EDB scenarios. ShieldDB [55] introduces a padding strategy that is explicitly tailored to accommodate a more realistic adversarial model, particularly within the context of databases undergoing continuous updates. This solution requires a large amount of dummy files to perform the padding on the batched data. We highlight that padding strategies, while effectively mitigating volume leakage, come with extra costs, impacting search efficiency and response time of queries. For example, during the initialization stage, they generate dummy data for the encrypted database, which can be computationally intensive, especially for large-scale databases. Padding strategies also tend to increase the amount of data transferred during search operations, thereby raising communication cost.

D Encrypted Databases

Over the past few years, notable efforts have been made in enhancing the security of search operations within encrypted databases. These advancements span a spectrum of dimensions, including bolstering data security, refining security schemes tailored to diverse functionalities, and optimizing the overall design of encrypted databases [18]. Encrypted databases have demonstrated capacity to execute a spectrum of secure functionalities, such as conjunctive search [43], keyword range search [67], and order-revealing encryption [58]. Researchers have leveraged structural encryption (e.g., [27] and [19]), private set intersection [44], private set union [25], and secure hardware [48] to delve into the realm of universal search within encrypted databases.

Table 4: Comparison of related EDBs.

EDB	Volume leakage	Tools for Security	Query mode
CryptDB [46]	✓	SQL aware Encryption	SQL
Arx [45]	✓	DSE	SQL
EnclaveDB [48]	✓	SGX	SQL
ShieldDB [55]	×	DSE + Padding	Keyword based

The SQL aware encryption used in CryptDB [46] is deterministic, which makes the EDB vulnerable to volumetric attacks. At present, researchers have used trusted hardware (SGX) [48] and DSE [45, 55] to safeguard the EDBs. Tab. 4 shows that current EDBs either overlook volume leakage or strongly rely on padding strategies (with significant storage and communication costs).

E Security analysis for BF-SRE

Theorem 1 (Adaptive Security of BF-SRE) *We define* $\mathcal{L}_D = \left(\mathcal{L}_D^{Upt}, \mathcal{L}_D^{Srch}\right)$ *as:*

$$\mathcal{L}_D^{Upt}(w, v, op) = op$$
$$\mathcal{L}_D^{Srch}(w) = sp(w), \text{TimeDTS}(w), \text{Update}(w),$$

BF-SRE is $\mathcal{L}_D$*-adaptively-secure.*

Proof 1 *We analyze the indistinguishability between BF-SRE and simulator* $\mathcal{S}_{BF-SRE}$*, and we use the game hop method to analyze indistinguishability.*

Game G_0**.** *This game is identical with the real BF-SRE:* $\mathbb{P}\left[\text{Real}_{\mathcal{A},\mathcal{S},\mathcal{L}}^{\text{BF-SRE}}(\lambda) = 1\right] = \mathbb{P}[G_0 = 1]$.

Game G_1*. We replace the calls of F with random strings. When each time a previous unseen call is input, we select a random output from this range space, and record it in tables Tokens, Tags, and Counts for* $F(K_s, w)$, $F(K_t, w||v)$*, and* $F(K_t, cnt)$*, respectively. Whenever F is recalled on the same input, the output value is retrieved directly from these tables. The distinguishing advantage between* G_0 *and* G_1 *is equal to that of PRF against an adversary making at most N calls to F:* $\mathbb{P}[G_1 = 1] - \mathbb{P}[G_0 = 1] \leq 3Adv_{F,\mathcal{B}_1}^{prf}(\lambda)$.

Game G_2*. We replace the Forward Private DSE instance* Σ_{add} *with the associate simulator* $\mathcal{S}_{add}^{DSE}$*. To construct this simulator, we use some bookkeeping to keep track of all the Update queries as they come, and postpone all addition and deletion operations to the subsequent Search query. This variant can be done because the additions leak nothing about their contents guaranteed by the forward privacy of* Σ_{add} *and the obliviousness of deletions to server.*

Moreover, a list Uphist is initialized and used in this game. The list Uphist in fact corresponds to the update history on w for the scheme Σ_{add} *and will be taken as the input of the simulator. The distinguishing advantage between* G_1 *and* G_2 *is reduced to the* $\mathcal{L}_{FS}$*-adaptive forward privacy of* Σ_{add}*. Therefor, there exists a PPT adversary* $\mathcal{B}_2$ *such that:* $\mathbb{P}[G_2 = 1] - \mathbb{P}[G_1 = 1] \leq Adv_{\Sigma_{add},\mathcal{S}_{add}^{DSE},\mathcal{B}_2}^{\mathcal{L}_{FS}}(\lambda)$.

Game G_3*. We only modify the generation of the ciphertext deletion. More precisely, we replace the values that were inserted previously and punctured later with constant 0.*

Since the modification above works only on the ciphertexts with revoked tags, we can see that the distinguishing advantage between G_2 *and* G_3 *is the IND-sREV-CPA security of the SRE scheme. The selective security is sufficient for the application here, because the reduction algorithm* $\mathcal{B}_3$ *can obtain the revoked tags from* $\text{Uphist}(w)$ *and simulate the encrypting process of non-deleted values with the revoked secret key. There for, there exists a reduction algorithm* $\mathcal{B}_3$ *such that:* $\mathbb{P}[G_3 = 1] - \mathbb{P}[G_2 = 1] \leq Adv_{SRE,\mathcal{B}_3}^{\text{IND-sREV-CPA}}(\lambda)$.

Game G_4*. We modify the way of constructing addition list* L_{add} *and the way of updating the compressed data structure D.* L_{add} *contains the addition entries and corresponds to the update history Uphist on w for the scheme* Σ_{add} *and is*

taken as the input of the simulator $\mathcal{S}_{add}^{DSE}$. In detail, we first compute the leakage information TimeDTS *and* Update *from the table* Uphist*, and then base the information to construct L_{add} and update D. This has no influence to the distribution of G_3: $\mathbb{P}[G_4 = 1] = \mathbb{P}[G_3 = 1]$.*

Game *G_5. We modify the generation of tags in a different way. In detail, we replace the tags with random strings directly, instead of computing them from keyword-value pairs and storing them in the table Tags. The distinguish between G_4 and G_5 is whether the tags will repeat. It is sufficient because each keyword/value/count pair was inserted/deleted at most once during the updates. We do not need to record every distinct tag for keeping consistence. Therefor, we have: $\mathbb{P}[G_5 = 1] = \mathbb{P}[G_4 = 1]$.*

Game *G_6. We replace the outputs from symmetric encryption to random strings on retrievals. The difference between G_5 and G_6 comes from the advantage: $\mathbb{P}[G_6 = 1] - \mathbb{P}[G_5 = 1] \leq Adv^{\text{IND-CPA}}_{\mathcal{E},\mathcal{B}_4}(\lambda)$.*

Simulator. *When building a simulator from G_6, we need to avoid directly using the keyword w as the protocols input. This can be done by replacing the input w with $\min sp(w)$. To construct L_{add} and collection D, we can properly take the leakage* TimeDTS *and* Update *as the input of* Search*, and the simulator does not need to keep the track of the updates anymore. In this condition, G_6 can be efficiently simulated by the simulator with the leakage function $\mathcal{L}$, so we have: $\mathbb{P}[G_6 = 1] = \mathbb{P}\left[\text{Ideal}^{\text{BF-SRE}}_{\mathcal{A},\mathcal{S},\mathcal{L}}(\lambda) = 1\right]$.*

Conclusion. *By combining all contributions from all games, there exists the adversary such that:*

$$|\mathbb{P}\left[\text{Real}^{\text{BF-SRE}}_{\mathcal{A}}(\lambda) = 1\right] - \mathbb{P}\left[\text{Ideal}^{\text{BF-SRE}}_{\mathcal{A},\mathcal{S},\mathcal{L}}(\lambda) = 1\right]| \leq$$
$$3Adv^{prf}_{F,\mathcal{B}_1}(\lambda) + Adv^{\mathcal{L}_{\mathcal{FS}}}_{\Sigma_{add},\mathcal{S}^{DSE}_{add},\mathcal{B}_2}(\lambda) + Adv^{\text{IND-sREV-CPA}}_{SRE,\mathcal{B}_3}(\lambda) + Adv^{\text{IND-CPA}}_{\mathcal{E},\mathcal{B}_4}(\lambda).$$

Theorem 2 (BF-SRE's DwVH Security) *The leakage function of* BF-SRE *$\mathcal{L}_D = (\mathcal{L}_D^{Upt}, \mathcal{L}_D^{Srch})$ is Distinct with Volume-Hiding.*

Proof 2 *Suppose an adversary $\mathcal{A}_D$ who can the distinguish signature from $\mathcal{L}_D$ and win the DwVH game with advantage $Adv^{DwVH}_{BF-SRE,\mathcal{A}_D}$. Then there exist a PPT algorithm $\mathcal{B}_D$ efficiently breaking all security guarantees from PRF F, Σ_{add},* SRE*, and the symmetric encryption $\mathcal{E}$, i.e.:*

$$MIN(Adv^{prf}_{F,\mathcal{B}_D}, Adv^{\mathcal{L}_{\mathcal{FS}}}_{\Sigma_{add},\mathcal{S}^{DSE}_{add},\mathcal{B}_D}, Adv^{\text{IND-sREV-CPA}}_{SRE,\mathcal{B}_D}, Adv^{\text{IND-CPA}}_{\mathcal{E},\mathcal{B}_D}) \geq Adv^{DwVH}_{BF-SRE,\mathcal{A}_D}.$$

$\mathcal{B}_D$ should perform like the simulator $\mathcal{S}$ with $\mathcal{L}_D$ that $\mathcal{A}_D$ can access in the DwVH game. Specifically, it contains four sub-program $\mathcal{B}_D^1$, $\mathcal{B}_D^2$, $\mathcal{B}_D^3$, and $\mathcal{B}_D^4$ to break the secure primitives from F, Σ_{add}, SRE*, and $\mathcal{E}$, respectively. With the guess from $\mathcal{A}_D$, the sub-programs leverage bookkeeping and embed the challenge message to break the above security primitives. We detail the DwVH security analysis in the full version [37].*

F High-level design for *d*-DSE

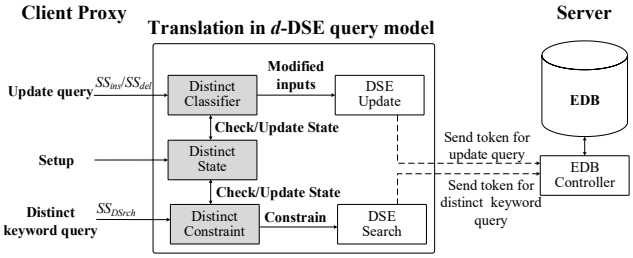

Figure 12: The high-level design of d-DSE construction.

Fig. 12 shows a high-level design for the d-DSE construction. The concrete construction should provide the components of Distinct Classifier, Distinct State, and Distinct Constraint in the Setup, Update, and Search protocols, respectively. The core of achieving secure distinct search is to: *promptly update the state of (w,v,op) inputs at the initial occurrence, and subsequently conceal the repetitive (w,v,op) inputs.*

F.1 Store the state of distinct inputs

The Setup protocol allocates local memory as Distinct State to record the state of whether the input has appeared. In previous work, the state is commonly used to achieve the forward and backward privacy and special properties such as non-interactivity [53] and robustness [62]. To clarify whether the input is distinct, Distinct State should efficiently store all updates that include distinct (w, v, op) pairs.

F.2 Tag distinct values

The Update protocol employs a program called Distinct Classifier to generate real or dummy tags for each input. The tags are used to identify whether the matched value is represented as distinct in the Search protocol. Based on the Distinct State, the inputs attach the real tag as the distinct. The repetitive inputs are replaced with bogus keyword/value pairs and tagged the dummy tag. The processed data will be updated to the EDB system.

We state that traditional dummy data generation like that in [15,55] is applicable to our requirement. The inputs marked by dummy tags will not affect the results of distinct values. Based on the Distinct State, the repetitive inputs can be replaced with random duplicated pairs to construct the arbitrary volume distribution on the EDB system.

F.3 Retrieve distinct values

The Search protocol employs the Distinct Constraint program to generate the constrained key and retrieves the distinct values. Under the requirement from the d-DSE security definitions, the tag can only reveal whether the corresponding value is distinct in the Search protocol. In the full version [37], we further discuss the roadmap to construct d-DSE.

MUSES: Efficient Multi-User Searchable Encrypted Database

Abstract

Searchable encrypted systems enable privacy-preserving keyword search on encrypted data. Symmetric systems achieve high efficiency (e.g., sublinear search), but they mostly support single-user search. Although systems based on public-key or hybrid models support multi-user search, they incur inherent security weaknesses (e.g., keyword-guessing vulnerabilities) and scalability limitations due to costly public-key operations (e.g., pairing). More importantly, most encrypted search designs leak statistical information (e.g., search, result, and volume patterns) and thus are vulnerable to devastating leakage-abuse attacks. Some pattern-hiding schemes were proposed. However, they incur significant user bandwidth/computation costs, and thus are not desirable for large-scale outsourced databases with resource-constrained users.

In this paper, we propose MUSES, a new multi-writer encrypted search platform that addresses the functionality, security, and performance limitations in the existing encrypted search designs. Specifically, MUSES permits single-reader, multi-writer functionalities with permission revocation and hides *all* statistical information (including search, result, and volume patterns) while featuring minimal user overhead. In MUSES, we demonstrate a unique incorporation of various emerging distributed cryptographic protocols including Distributed Point Function, Distributed PRF, and Oblivious Linear Group Action. We also introduce novel distributed protocols for oblivious counting and shuffling on arithmetic shares for the general multi-party setting with a dishonest majority, which can be found useful in other applications. Our experimental results showed that the keyword search by MUSES is two orders of magnitude faster with up to 97× lower user bandwidth cost than the state-of-the-art.

1 Introduction

Commodity cloud service (e.g., AWS IAM, Google Cloud IAM) provides data storage and sharing facilities for a large number of users. However, data outsourcing might lead to privacy concerns, especially for sensitive data (e.g., medical/financial). An adversarial cloud can access and exploit data illegitimately. Although end-to-end encryption permits confidentiality, it prevents data utility (e.g., querying, analytics), thereby invalidating the benefits of outsourcing services.

To address the data utilization and privacy dilemma, Searchable Encryption (SE) was proposed to enable keyword search over encrypted data while respecting the confidentiality of the data and the search query. There are two main SE models including Symmetric SE (SSE) [12, 27, 29, 40, 45, 49, 71] and Public-Key SE (PKSE) [4, 8, 10, 83]. While SSE offers high efficiency, forward/backward privacy [12, 40, 55, 55, 72, 75], and diverse queries (e.g., range [28, 52, 75]), it only supports a single user, where the data can only be searched by its owner. This strictly limits its practicality to apply for real-world settings, where the data can be contributed by multiple users. Moreover, SSE leaks statistical information including search/result/volume patterns, thus are vulnerable to leakage-abuse attacks [16, 46, 50, 54, 56, 59, 65–67, 81, 85]. To prevent these leakages, some oblivious SSE schemes (e.g., [27, 35, 45] were proposed using Oblivious RAM [70] or Private Information Retrieval (PIR) [41]; however, they incur significant overhead (bandwidth, computation) to the user [64].

On the other hand, PKSE enables multi-user encrypted search, in which one user (reader) can search on encrypted documents shared by the other users (writers) [58, 61, 82, 83]. However, PKSE has some security issues including lack of forward privacy and dictionary attacks. Recently, Wang et al. proposed Hybrid SE (HSE) [76], which elegantly combines SSE and PKSE to achieve the benefits of both models: forward privacy and search efficiency by SSE, and multi-writer capability by PKSE. Despite its merits, HSE inherits other security weaknesses of both models, including keyword-guessing vulnerabilities and pattern leakages. Given that all existing SE schemes pose certain fundamental security, functionality, and efficiency limitations, we raise the following question:

Can we design a new SE scheme that not only supports multi-writer search but also achieves concrete efficiency with high security and privacy guarantees simultaneously?

Table 1: Comparison of MUSES with prior encrypted search systems.

Scheme	#Servers L	Search Leakage $\mathcal{L}_{\mathsf{Search}}$	Forward Privacy	Backward Privacy	Multi-Writer	Search Complexity (per writer)		
						Server	Reader	Communication
PEKS [10]	1	$\{\mathsf{kw}, \mathsf{sp}(\mathsf{kw}), \mathsf{rp}(\mathsf{kw}), \mathsf{sv}(\mathsf{kw})\}$	✗	✗	✗	$O(d_w N^{\dagger})$	$O(\lambda)$	$O(\lambda + n_s)$
SSE [17]	1	$\{\mathsf{sp}(\mathsf{kw}), \mathsf{rp}(\mathsf{kw}), \mathsf{sv}(\mathsf{kw})\}$	✗	✗	✗	$O(n_s)$	$O(\lambda)$	$O(\lambda + n_s)$
NTRU-PEKS [8]	1	$\{\mathsf{kw}, \mathsf{sp}(\mathsf{kw}), \mathsf{rp}(\mathsf{kw}), \mathsf{sv}(\mathsf{kw})\}$	✗	✗	✗	$O(d_w N^{\dagger})$	$O(\lambda)$	$O(\lambda + n_s)$
DORY [27]	2	$\{\emptyset\}$	✓	✓	✗	$O(mN)$	$O(\log m + N)$	$O(\lambda \log m + N)$

AESM^2 [77]	1	$\{\mathsf{sp}(\mathsf{kw}), \mathsf{rp}(\mathsf{kw}), \mathsf{sv}(\mathsf{kw})\}$	✓	✗	✓	$O(\lvert W \rvert^{\ddagger})$	$O(\lambda)$	$O(\lambda + n_s)$
Q-μSE [20]	1	$\{\mathsf{sp}(\mathsf{kw}), \mathsf{rp}(\mathsf{kw}), \mathsf{sv}(\mathsf{kw})\}$	✓	✓	✗	$O(n_s)$	$O(n_s + n_u)$	$O(n_s + n_u)$
Our MUSES	≥ 2	$\{\emptyset\}$	✓	✓	✓	$O(mN)$	$O(\tau + N)$	$O(\lambda\tau + n_s)$

• $\mathcal{L}_{\mathsf{Search}}$: Search leakage function with kw as the input keyword; sp: Search pattern; rp: Result pattern; sv: Search volume (see §3 for more details).
• λ: Security parameter; N: Total number of documents; d_w: Number of keywords per document. n_u: Number of updates after previous search. W: Collection of all unique keywords in the database (keyword universe); m: Size of keyword representation *per* document; n_s: Number of matched results *per* keyword search.
• In practice, $d_w < m \ll W$, $n_s \leq N$.
• Number of servers L is considered as a constant number in complexity analysis. We assume document identifiers can be represented using a constant number of bits to skip this quantity in search complexity.
‡ $\tau = O(\log m)$ when $L = 2$, or $O(\sqrt{m})$ when $L \geq 3$.
† Public-key pairing operations.

1.1 Our Contributions

We answer the above question affirmatively by proposing MUSES, a new distributed multi-writer encrypted search system that achieves a high level of security with concrete efficiency. MUSES achieves the following desirable properties.

- **Multi-writer functionalities**: MUSES allows single-reader, multi-writer functionalities similar to other multi-writer SE schemes (e.g., [7, 58, 61, 76, 77, 82, 84]. MUSES enables the writers to update their data that can be searched by the reader. MUSES also permits the writers to revoke the reader's search permission with writer-efficiency.
- **Security against statistical attacks:** MUSES is not vulnerable to dictionary attacks, achieves forward/backward privacy, and hides all pattern leakages simultaneously. Thus, it has more security guarantees than most prior SE schemes [10, 51, 58, 61, 76, 77, 79, 83]. MUSES offers semi-honest security with dishonest majority. With L servers, it can achieve $L-1$ privacy threshold, meaning that the confidentiality of data and queries is protected as long as one server is honest.
- **User-driven efficiency**: MUSES is designed with user efficiency in mind, and therefore, it is highly favorable to thin users with resource constraints (e.g., mobile devices). In MUSES, the reader only performs lightweight computations (e.g., modular additions) and its bandwidth is constant, compared with linear (w.r.t. collection size) in prior oblivious SE schemes (e.g., [27, 35, 45]). Evaluation results indicate that MUSES achieves up to 97× lower user bandwidth than the state-of-the-art oblivious SE. MUSES permits the writer to revoke the reader's search permission efficiently by offloading all processing tasks to the servers. This is more efficient than prior systems that do not naturally support revocation [27, 76] and thus, the writer needs to rebuild the index itself, which incurs high bandwidth and computation.
- **Low server cost**: In MUSES, the servers only perform low-cost operations (e.g., modular addition, rounding over small modulus). It is more efficient than PKSE/HSE designs that incur costly pairing operations [4, 7, 10, 32, 58, 76, 77, 83, 84].
- **Fully-fledged implementation and evaluation**: We fully implemented MUSES and evaluated its performance on commodity servers. Under real environments, experimental results demonstrated that MUSES performs search 126.8×–631.8× and 1.6×–3.9× faster than state-of-the-art SE techniques [27, 76] in the multi-writer and single-writer settings, respectively. Our implementation is available at https://github.com/vt-asaplab/MUSES.

  Techniques: Multi-party Oblivious Count and Shuffle. To build MUSES, we construct several multi-party oblivious protocols that can be of independent interest. We design an L-party protocol to privately count how many elements in an additive secret-shared vector equal to a specific (small) value. Our protocol is novel as it does not require binary-arithmetic share conversion and/or costly comparison circuits. It operates in an online/offline model with a highly efficient online counting, where the parties only communicate in one round and perform lightweight computations (e.g., addition, circular shift) locally. We also design a new oblivious shuffle protocol for L parties to randomly permute an additive secret-shared vector such that one party learns the shuffled vector, while each other party learns a part of a permutation composition[1]. Although there exists an L-party secret-shared shuffle [33], it is designed for secure communication, thus its online phase outputs the shares instead of the shuffled vector. We design a new preprocessing in a way that the online protocol outputs the shuffled vector directly. For applications that need shuffled data as output, our protocol is more direct and round-efficient than [33], which incurs an additional round for opening.

[1] A permutation composition is formed by applying $L-1$ separate permutations $\pi_1, \ldots, \pi_{L-1}$ to shuffle a vector $\mathbf{d}$ as: $\pi_{L-1}(\pi_{L-2}(\ldots(\pi_1(\mathbf{d}))\ldots))$.

Table 1 compares MUSES with prior SE designs. To our knowledge, MUSES is the first multi-writer SE that can prevent all vulnerabilities and achieve high user efficiency (optimal bandwidth, low processing) simultaneously. Note that MUSES makes use of distributed servers to also mitigate inherent vulnerabilities in the multi-user setting (e.g., rollback attacks in Appendix B), albeit at the cost of additional processing overhead as a trade-off.

1.2 Technical Highlights

We present the technical highlights of our construction. MUSES is inspired by DORY [27] – an SSE scheme, and HSE [76] – a framework that shows how to adapt SSE to the multi-writer setting. We begin by giving DORY's overview and the challenges when adopting it to the multi-writer setting. We then present high-level ideas to address these challenges.

Brief Overview of DORY. DORY [27] is a (single-client) oblivious search scheme with dynamic update capability. Its search index is instantiated with a table structure, where columns represent keywords for performing search and rows represent documents with corresponding identifiers. To reduce the index size, Bloom Filter (BF) is employed to compress the keyword representation per document. The search index is row-wise encrypted with a symmetric key. To search for a keyword, the user computes its BF representation, and executes a PIR protocol based on the Distributed Point Function (DPF) [41] to privately retrieve K encrypted columns of the index, where K is a BF membership checking parameter. The user then decrypts these columns and aggregates them together to identify what document identifiers match the search query. To update a document, the user replaces its row in the index with a new encrypted BF representation.

In principle, DORY can be extended to support multi-writer (separate reader/writer) by incorporating public-key cryptography to distribute the symmetric key of the writer to the reader. However, due to its cryptographic protocol back-end, it may incur high processing complexity. Specifically, the reader's search complexity is linear to the number of documents N in the database in terms of both network bandwidth and computation overhead (due to PIR reconstruction, decryption, and aggregation sequence) to obtain the search result. This overhead is significant for thin readers to search on large data collections. Meanwhile, an efficient search should only return a small number of matched identifiers. Furthermore, as the key is shared with the reader directly, it is challenging to enable access control. For example, a writer may want to restrict the reader's search permission on her index temporarily. A potential solution is to re-encrypt the search index with a fresh key unknown to the reader. However, this requires the writer to download the entire encrypted index, re-encrypt it with a new key, and then transmit it back to the server. This incurs significant bandwidth/processing costs to the writer. *Can we address all these challenges while maintaining efficiency?*

Idea 1: Minimize reader overhead by delegating aggregation and decryption tasks to the server. Instead of decrypting and aggregating K PIR-retrieved encrypted columns on the reader side, we delegate all these processing tasks to the distributed servers securely. Specifically, we develop a protocol that incorporates Key-Homomorphic Pseudorandom Function (KH-PRF) [11] and DPF-based PIR [14, 15, 41] together, which permits the servers to partially decrypt the encrypted columns to obtain additive shares, and perform secure aggregation on the shares. Our protocol outputs the shares of the search result to the servers, which can be opened afterwards to return only matched document identifiers to the reader. This process ensures the servers do not learn anything during the partial decryption and aggregation (e.g., what columns are being aggregated/decrypted and decryption keys), given that at least one server does not collude with the others. However, although this strategy reduces the reader's processing and bandwidth costs, if we open the search result to the servers at this point, they can learn result patterns (i.e., what document identifiers match the query), volume patterns (i.e., the number of matched documents), thereby inferring search patterns (i.e., whether the same/different keywords are being searched). *Can we seal all these pattern leakages before opening while maintaining reader efficiency?*

Idea 2: Conceal all pattern leakages via oblivious padding and random shuffling. To hide volume information, we perform oblivious padding so that the search result always contains a fixed small number (n_s) of document identifiers[2]. We design an oblivious counting protocol based on linear group action [6], which permits the servers to privately count the current number of matched documents on the shares of the search result vector and open the count s to the reader. Next, the reader creates a padding vector of size n_s, which contains $n_s - s$ padded matched values and secret shares it with L servers. The servers then concatenate (the shares of) the search result vector and the padding vector together, forming a shared vector of size $(N + n_s)$. Our followed step is to design an L-party oblivious shuffle protocol based on the two-party scheme in [21], which enables L servers to randomly permute the concatenated vector on its shares, and open the permuted vector to one server while other $L-1$ servers obtain the permutation composition. Since the permuted vector contains exactly n_s document identifiers, all of which have been obfuscated due to oblivious shuffle, our strategy can conceal all volume, result, and search pattern leakages. To this end, the servers send obfuscated identifiers along with the permutation composition to the reader. The reader obtains the search result by applying the permutation inverses on the obfuscated list. Note that our padding and shuffle strategies require one more communication round in the search procedure; however, the optimal bandwidth complexity of $O(n_s)$ is maintained.

[2]This assumption is similar to that of volume-hiding SE schemes [5], where an effective search should only return a small number of results

Idea 3: Minimize writer overhead in revoking reader' permission via "key rotation" on the servers. To revoke the reader's search capability, we re-encrypt the writer's search index on the servers with fresh keys unknown to the reader. At a high level, we incorporate the homomorphic property of KH-PRF with random masking techniques, which enables the servers to "rotate" the index that is currently encrypted by the old KH-PRF keys to the new ones on behalf of the writer in a privacy-preserving manner. The writer only needs to share the old and the new fresh KH-PRF keys with the servers, and does not need to stay involved in the later process.

2 Preliminaries

Notation. $||$ denotes the concatenation operator. λ is the security parameter and $\mathbb{Z}_p$ is a ring of integers. We denote by $[n]$ the set $\{1,\ldots,n\}$. $x \xleftarrow{\$} [n]$ means x is selected uniformly at random from $[n]$. For integers q and p where $q \geq p \geq 2$, we define $\lfloor \cdot \rceil_p : \mathbb{Z}_q \to \mathbb{Z}_p$ as a rounding function as $\lfloor x \rceil_p = i$ where $i \cdot \lfloor q/p \rfloor$ is the largest multiple of $\lfloor q/p \rfloor$ that does not exceed x. Given an integer x, x^+ denotes $x+1$ while x^- denotes $x-1$. Bold small letters ($\mathbf{a}$) denote vectors, while capitalized bold letters ($\mathbf{M}$) denote matrices. We denote by $\langle \mathbf{a}, \mathbf{b} \rangle$ the dot product of two vectors $\mathbf{a}$ and $\mathbf{b}$. Given $\mathbf{M}$, $\mathbf{M}[u,*]$ and $\mathbf{M}[*,v]$ denote accessing the row u and column v of $\mathbf{M}$, respectively. $\mathbf{M}[u,v]$ denotes accessing the cell at row u and column v. We denote the execution of protocol A by L parties $(o_1; o_2; \ldots; o_L) \leftarrow A(i_1; i_2; \ldots; i_L)$, where the input/output of each party is separated by a semicolon (;).

Let $\Sigma = (\mathsf{Gen}, \mathsf{Enc}, \mathsf{Dec})$ be a public-key encryption: $(\mathsf{pk}, \mathsf{sk}) \leftarrow \Sigma.\mathsf{Gen}(1^\lambda)$ generating a public and private-key pair with security parameter λ; $c \leftarrow \Sigma.\mathsf{Enc}(\mathsf{pk}, m)$ encrypting plaintext m with public key pk; $m \leftarrow \Sigma.\mathsf{Dec}(\mathsf{sk}, c)$ decrypting ciphertext c with private key sk. Let $\mathsf{BF} = (\mathsf{Init}, \mathsf{Gen}, \mathsf{Vrfy})$ be a Bloom Filter (BF) [9]: $(H_1, \ldots, H_K) \leftarrow \mathsf{BF.Init}(m, K)$: generating K mappings $H_k : \mathcal{S} \to [m]$ $\forall k \in [K]$ with two parameters m (BF size) and K; $\mathbf{u} \leftarrow \mathsf{BF.Gen}(\mathcal{S})$: computing the BF representation $\mathbf{u} \in \{0,1\}^m$ of a given set $\mathcal{S}$; $\{0,1\} \leftarrow \mathsf{BF.Vrfy}(\mathbf{u}, s)$: checking if an element s belongs to the set represented by $\mathbf{u}$.

Secret Sharing. Secret sharing enables a secret to be shared among L parties. We denote $x^{(i)}$ as the additive share of a secret $x \in \mathbb{Z}_p$ to party i such that $x = \sum_{i=1}^{L} x^{(i)} \pmod p$.

Bit Operations. We denote $\oplus$ and $\otimes$ as the bit-wise XOR and AND operations, respectively. $x \lll t$ and $x \ggg t$ denote left-shift and right-shit operations by t bits of value x.

Table 2 summarizes the symbols and notation in our scheme.

2.1 Distributed Point Function

Distributed Point Function (DPF) [14,15,41] permits L parties to jointly evaluate a point function. For $a, b \in \{0,1\}^*$, let $P_{a,b} : \{0,1\}^{|a|} \to \{0,1\}^{|b|}$ s.t. $P_{a,b}(a) = b$ and $P_{a,b}(a') = 0^{|b|}$ $\forall\ a' \neq a$. A DPF scheme contains the following algorithms.

L	Number of parties (servers)
m	Number of columns of index (BF parameter)
K	Number of retrieved columns (BF parameter)
N	Number of rows of index (Number of documents)
n_s	Search output volume bound
w	Writer identifier
st_w	State of writer w
EIDX_w	Encrypted index of writer w
PTkn_w	Private token of writer w
STkn_w	Shared token of writer w
$\mathcal{P}_i$	Party (server) i
$x^{(i)}$	Secret share of x owned by $\mathcal{P}_i$
Σ	Public-key encryption
e	Rounding error of KH-PRF
z	Number of reserved bits for accumulated error
π/π^{-1}	Permutation/Permutation inverse
$\lll / \ggg$	Bitwise left/right shift operator
$\circlearrowright$	Circular shift right operator
x^+/x^-	$x^+ = x+1, x^- = x-1$
$[x]$	$\{1,\ldots,n\}$
$\lceil x \rceil, \lfloor x \rfloor$	Round up/down of x

Table 2: Summary of notation

- $(k^{(1)}, \cdots, k^{(L)}) \leftarrow \mathsf{DPF.Gen}(1^\lambda, a, b)$: Given security parameter λ, and values $a, b \in \{0,1\}^*$, it outputs L keys $k^{(1)}, \cdots, k^{(L)} \in \mathcal{K}$.
- $y^{(\ell)} \leftarrow \mathsf{DPF.Eval}(k^{(\ell)}, x)$: Given a key $k^{(\ell)} \in \mathcal{K}$ and $x \in \{0,1\}^{|a|}$, it outputs $y^{(\ell)}$ as the share of $P_{a,b}(x)$.

DPF can be used to realize Private Information Retrieval (PIR) on a database $\mathbf{B} = (\mathbf{b}_1, \mathbf{b}_2, \ldots, \mathbf{b}_m)$. The client creates L keys $(k^{(1)}, \ldots, k^{(L)}) \leftarrow \mathsf{DPF.Gen}(1^\lambda, j, 1)$, $j \in [m]$, for L parties, $k^{(1)}, \ldots, k^{(L)} \in \{0,1\}^n$ ($n = O(\lambda \log m)$ for $L = 2$, or $n = O(\lambda\sqrt{m})$ for $L \geq 3$) and $k^{(\ell)}$ is sent to party $\mathcal{P}_\ell \in \{\mathcal{P}_1, \ldots, \mathcal{P}_L\}$. Each party $\mathcal{P}_\ell$ returns $\mathbf{r}^{(\ell)} \leftarrow \sum_{i=1}^{m} \mathsf{DPF.Eval}(k^{(\ell)}, i) \times \mathbf{b}_i$ and the client reconstructs the retrieved item $\mathbf{b}_j \leftarrow \sum_{\ell=1}^{L} \mathbf{r}^{(\ell)}$.

2.2 Key-Homomorphic PRF (KH-PRF)

KH-PRF [11] enables distributed evaluation of a PRF function $F^* : \mathcal{K} \times \mathcal{X} \to \mathcal{Y}$ such that $(\mathcal{K}, *)$ and $(\mathcal{Y}, \bullet)$ are groups and for every $k_1, k_2 \in \mathcal{K}$, $F^*(k_1 * k_2, x) = F^*(k_1, x) \bullet F^*(k_2, x)$. An L-party KH-PRF scheme contains the following algorithms.

- $\mathbf{k} \leftarrow \mathsf{KH\text{-}PRF.Gen}(1^\lambda)$: Given a security parameter λ, it outputs a secret key $\mathbf{k} \in \mathcal{K}$.
- $(\mathbf{k}^{(1)}, \ldots, \mathbf{k}^{(L)}) \leftarrow \mathsf{KH\text{-}PRF.Share}(\mathbf{k})$: Given a key $\mathbf{k} \in \mathcal{K}$, it outputs L keys $\mathbf{k}^{(1)}, \ldots, \mathbf{k}^{(L)} \in \mathcal{K}$ s.t. $\mathbf{k}^{(1)} * \cdots * \mathbf{k}^{(L)} = \mathbf{k}$.
- $y \leftarrow \mathsf{KH\text{-}PRF.Eval}(\mathbf{k}, s)$: Given a key $\mathbf{k} \in \mathcal{K}$ and a seed $s \in \{0,1\}^*$, it outputs the evaluation $y = F^*(\mathbf{k}, s) \in \mathcal{Y}$.

We extend the 2-party (almost) KH-PRF scheme based on Learning with Rounding (LWR) under Random Oracle Model (ROM) by Boneh et al. [11] into L-party setting. Let $H_2 : \{0,1\}^* \to \mathbb{Z}_q^n$ be a hash function modeled as a random oracle. The KH-PRF function $F^* : \mathbb{Z}_q^n \times \{0,1\}^* \to \mathbb{Z}_p$ is defined as $F^*(\mathbf{k}, s) = \lfloor \langle H_2(s), \mathbf{k} \rangle \rceil_p$, where $\mathbf{k}^{(1)} + \cdots + \mathbf{k}^{(L)} = \mathbf{k}$, F^* is an almost key homomorphic such that $F^*(\mathbf{k}, s) = e + \sum_{\ell=1}^{L} F^*(\mathbf{k}^{(\ell)}, s) \pmod p$ where $e \in \{0, \ldots, L\}$.

2.3 Linear Group Action

Let $(\mathbb{G}, \circ, 1)$ be a group. A linear group action [6] of $\mathbb{G}$ on $\mathbb{Z}_p^n$ is a function $\psi : \mathbb{Z}_p^n \times G \to \mathbb{Z}_p^n$ satisfying:

$$\begin{aligned} \psi(\mathbf{x}, 1) &= \mathbf{x} && \forall \mathbf{x} \in \mathbb{Z}_p^n \\ \psi(\mathbf{x}, g_1 \circ g_2) &= \psi(\psi(\mathbf{x}, g_1), g_2) && \forall \mathbf{x} \in \mathbb{Z}_p^n, g_1, g_2 \in \mathbb{G} \\ \psi(\mathbf{x}+\mathbf{y}, g) &= \psi(\mathbf{x}, g) + \psi(\mathbf{y}, g) && \forall \mathbf{x}, \mathbf{y} \in \mathbb{Z}_p^n, g \in \mathbb{G} \\ r\psi(\mathbf{x}, g) &= \psi(r\mathbf{x}, g) && \forall r \in \mathbb{Z}_p, \mathbf{x} \in \mathbb{Z}_p^n, g \in \mathbb{G} \end{aligned}$$

Shuffle. We define $\psi : \mathbb{Z}_p^n \times \mathbb{G} \to \mathbb{Z}_p^n$ as follows:

$$\psi(\mathbf{x}, \pi) \leftarrow \pi(\mathbf{x})$$

where π is a permutation. For example, with $n = 4$, $\pi = (2,1,4,3)$ and $\mathbf{x} = (5,6,7,8)$, $\psi(\mathbf{x}, \pi) = \pi(\mathbf{x}) = (6,5,8,7)$.

Chase et al. [21] proposed a two-party Secret-shared Shuffle (TSS) protocol, which permits each party to obtain the share of $\pi(\mathbf{x})$. TSS consists of the following PPT algorithms.

- $(\mathbf{\Delta}; \mathbf{a}, \mathbf{b}) \leftarrow \mathsf{TSS.ShrTrns}(\pi; 1^\lambda)$: Given a permutation π for n elements from $\mathcal{P}_1$, and a security parameter λ from $\mathcal{P}_2$, it outputs $\mathbf{\Delta} = \mathbf{b} - \pi(\mathbf{a}) \in \mathbb{Z}_p^n$ to $\mathcal{P}_1$ and $\mathbf{a}, \mathbf{b} \in \mathbb{Z}_p^n$ to $\mathcal{P}_2$.
- $(\mathbf{x}'; \mathbf{b}) \leftarrow \mathsf{TSS.Shffl}(\pi, \mathbf{\Delta}; \mathbf{x}, \mathbf{a}, \mathbf{b})$: Given a permutation π and its corresponding $\mathbf{\Delta}$ from $\mathcal{P}_1$, a set $\mathbf{x}$ and masks $\mathbf{a}, \mathbf{b}$ from $\mathcal{P}_2$, it outputs $\mathbf{x}' = \pi(\mathbf{x}) + \mathbf{b} \in \mathbb{Z}_p^n$ as a masked permutation of $\mathbf{x}$ to $\mathcal{P}_1$, and the mask value $\mathbf{b}$ to $\mathcal{P}_2$.

Circular Shift. Let $\mathbb{G}$ be a group modulo n. We define $\psi : \mathbb{Z}_p^n \times \mathbb{G} \to \mathbb{Z}_p^n$ as follows:

$$\psi(\mathbf{x}, g) \leftarrow (\mathbf{x} \circlearrowright g)$$

where $\circlearrowright$ denotes circular shift operator, which rotates vector $\mathbf{x}$ to the right by g positions. For example, with $\mathbf{x} = (1,2,3,4)$ and $g = 1$, we have $\psi(\mathbf{x}, g) = \mathbf{x} \circlearrowright g = (4,1,2,3)$.

3 Models

System Model. Our system consists of an honest reader, n_w independent writers, and L servers. WLOG, we identify each writer as a member of $[n_w]$, i.e., $\mathcal{W} = [n_w]$. Each writer $w \in \mathcal{W}$ owns a collection of N documents (each identified as a member of $[N]$) and desires to share the collection with the reader. The reader would like to perform an encrypted keyword search over the collections of a writer subset $\mathcal{W}' \subseteq \mathcal{W}$. Also, the writer can revoke the permission of the reader if needed. The reader and writers are independent and they do not communicate directly with each other in any operations (i.e., search, update, revoke) after system setup.

Definition 1 (MUSES). *A MUSES scheme is a tuple of PPT algorithms defined as follows:*

- $(\mathsf{pk}, \mathsf{sk}) \leftarrow \mathsf{RSetup}(1^\lambda)$*: Given a security parameter* λ*, it outputs a public and private key pair* $(\mathsf{pk}, \mathsf{sk})$.
- $(\mathsf{EIDX}_w, \mathsf{st}_w, \mathsf{PTkn}_w, \mathsf{STkn}_w) \leftarrow \mathsf{WSetup}(1^\lambda, w, \mathsf{pk})$*:Given a security parameter* λ*, a writer identifier* w*, the reader's public key* pk*, it outputs an encrypted index* EIDX_w*, a state* st_w*, a private token* PTkn_w*, and a shared token* STkn_w *encrypted under* pk.
- $\mathfrak{s} \leftarrow \mathsf{SearchToken}(\mathsf{kw}, \mathcal{W}')$*: Given a keyword* kw*, and a subset of writers* $\mathcal{W}'$*, it outputs a search token* $\mathfrak{s}$.
- $O \leftarrow \mathsf{Search}(\mathfrak{s}, \mathsf{sk}, \{(\mathsf{EIDX}_w, \mathsf{STkn}_w, \mathsf{st}_w)\}_{w \in [n_w]})$*: Given a search token* $\mathfrak{s}$*, the reader's private key* sk*, encrypted search indices* EIDX_w*, shared tokens* STkn_w*, and states* st_w *of writers* $w \in [n_w]$*, it outputs the search result* O.
- $\mathfrak{u}_w \leftarrow \mathsf{UpdateToken}(\mathcal{V}_u, u, w, \mathsf{PTkn}_w, \mathsf{st}_w)$*: Given an updated document identifier* u*, a set of updated keywords* $\mathcal{V}_u$*, a writer identifier* w*, the writer's private token* PTkn_w *and state* st_w*, it outputs an update token* $\mathfrak{u}_w$.
- $(\mathsf{EIDX}'_w, \mathsf{st}'_w) \leftarrow \mathsf{Update}(\mathfrak{u}_w, \mathsf{EIDX}_w, \mathsf{st}_w)$*: Given an update token* $\mathfrak{u}_w$*, an encrypted index* EIDX_w *and a state* st_w *of writer* w*, it outputs updated index* EIDX'_w *and state* st'_w.
- $(\mathsf{EIDX}'_w, \mathsf{PTkn}'_w) \leftarrow \mathsf{RvkPrm}(w, \mathsf{PTkn}_w, \mathsf{EIDX}_w, \mathsf{st}_w)$*: Given a writer identifier* w*, the writer's private token* PTkn_w*, the writer's index* EIDX_w *and state* st_w*, it outputs an updated index* EIDX'_w *and updated token* PTkn'_w.

The correctness of MUSES is presented in our full version [57].

Threat and Security Models. We assume the adversary can corrupt up to $L-1$ servers and any number of writers. We assume the adversary is semi-honest, meaning that it is curious about the query of other honest writers/reader but follows the protocols faithfully.

We concentrate on the security of the search index and its related operations. Informally speaking, MUSES aims to achieve standard SE security properties including semantic security and forward and backward privacy. More importantly, in MUSES, we strive to conceal all pattern leakages during search, including search pattern sp, result pattern rp, and volume pattern sv. Due to space constraints, we present the formal definitions of all these properties in our full version [57].

Document access leakage. In this paper, we focus only on the security of the search index. Accessing document content from the collection after the search is out-of-scope. Sealing document access leakage is an independent study. Some oblivious file systems (e.g., [22, 23, 60, 62]) can be used orthogonally with our scheme for system-wide end-to-end security.

4 Our Proposed Scheme

4.1 Data Structures

Search Index. In MUSES, each writer $w \in \mathcal{W}$ has an independent index for keyword-document representation. We use a probabilistic data structure (i.e., BF) to create a compressed index for each writer. Suppose there are N documents, the writer extracts a set of unique keywords $\mathcal{V}_u$ for each document $u \in [N]$ and computes its BF representation as $\mathbf{v}_u \leftarrow \mathsf{BF.Gen}(\mathcal{V}_u) \in \{0,1\}^m$. The search index contains N BF vectors, which is interpreted as a $N \times m$ binary matrix

RSetup(1^λ):
1. $(\mathsf{pk},\mathsf{sk}) \leftarrow \Sigma.\mathsf{Gen}(1^\lambda)$
2. **return** $(\mathsf{pk},\mathsf{sk})$

WSetup($1^\lambda, w, \mathsf{pk}$):
1. For $v = 1$ to m
   (a) $\mathbf{r}_{w,v} \leftarrow \text{KH-PRF.Gen}(1^\lambda)$
   (b) $\mathsf{STkn}_{w,v} \leftarrow \Sigma.\mathsf{Enc}(\mathsf{pk}, \mathbf{r}_{w,v})$
2. $\mathsf{st}_w \leftarrow (\mathsf{st}_{w,1}, \mathsf{st}_{w,2}, \ldots, \mathsf{st}_{w,N})$, where $\mathsf{st}_{w,u} \leftarrow 0$, for $u \in [N]$
3. $\mathsf{EIDX}_w[u,v] \leftarrow F^*(\mathbf{r}_{w,v}, u || \mathsf{st}_{w,u})$, for $u \in [N]$ and $v \in [m]$
4. $\mathsf{PTkn}_w \leftarrow (\mathbf{r}_{w,1}, \mathbf{r}_{w,2}, \ldots, \mathbf{r}_{w,m})$
5. $\mathsf{STkn}_w \leftarrow (\mathsf{STkn}_{w,1}, \mathsf{STkn}_{w,2}, \ldots, \mathsf{STkn}_{w,m})$
6. **return** $(\mathsf{EIDX}_w, \mathsf{st}_w, \mathsf{PTkn}_w, \mathsf{STkn}_w)$

Figure 1: MUSES setup.

$\mathsf{IDX}_w = [\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_N] \in \{0,1\}^{N \times m}$. Searching a keyword incurs checking BF membership by reading K columns in IDX_w, where K is the BF parameter. Updating a document u recreates a new BF representation of the updated keywords and overwrites the corresponding row $\mathsf{IDX}_w[u,*]$.

IDX_w is encrypted for confidentiality. For reader efficiency, the writer encrypts her index in a way that the decryption can be delegated to the servers during search. MUSES employs KH-PRF function F^* for such delegation as follows.

First, the writer w interprets the index as a matrix $\mathsf{IDX}_w = \begin{bmatrix}\mathbf{c}_1 & \mathbf{c}_2 & \ldots & \mathbf{c}_m\end{bmatrix} \in \{0,1\}^{N \times m}$, where $\mathbf{c}_v \in \{0,1\}^N \ \forall v \in [m]$. For each column $v \in [m]$, the writer generates a KH-PRF key as $\mathbf{r}_v \leftarrow \text{KH-PRF.Gen}(1^\lambda) \in \mathbb{Z}_q^n$ for column-wise encryption. Since F^* is an almost KH-PRF, there exists a small error e (§2.2) during the KH-PRF evaluation. Thus, it is necessary to "reserve" several bits for the error in the column data before being encrypted with KH-PRF so that such error can be "ruled out" after KH-PRF decryption. Moreover, since the servers also perform secure addition of K columns after KH-PRF evaluations for BF membership verification, we need to reserve enough space for the accumulated error. Let $z = \lceil \log_2(e \cdot K) \rceil$ be the number of bits for the accumulated error when adding K columns encrypted by KH-PRF together. For each $u \in [N]$, the writer encrypts the element $\mathbf{c}_v[u]$ as

$$\hat{\mathbf{d}}_v[u] \leftarrow (\mathbf{c}_v[u] \lll z) + F^*(\mathbf{r}_v, u \,||\, \mathsf{st}_{w,u}) \pmod p \quad (1)$$

where $\mathsf{st}_{w,u}$ is the update state of document u (initialized with 0). The final encrypted index is $\mathsf{EIDX}_w = \begin{bmatrix}\hat{\mathbf{d}}_1 & \hat{\mathbf{d}}_2 & \ldots & \hat{\mathbf{d}}_m\end{bmatrix} \in \mathbb{Z}_p^{N \times m}$, where $\hat{\mathbf{d}}_v \in \mathbb{Z}_p^N \ \forall v \in [m]$.

Auxiliary Information. In MUSES, each writer w's index EIDX_w is associated with three auxiliary components:

- Private token PTkn_w: It contains KH-PRF keys $\mathbf{r}_v$ that are used to encrypt the search index.
- Shared token STkn_w: It contains information for the reader to search on EIDX_w, which are the KH-PRF keys $\mathbf{r}_v$, encrypted under the reader's public key. Specifically, $\mathsf{STkn}_w = (\mathsf{STkn}_{w,1}, \ldots, \mathsf{STkn}_{w,m})$, where $\mathsf{STkn}_{w,v} \leftarrow \Sigma.\mathsf{Enc}(\mathsf{pk}, \mathbf{r}_v)$ for $v \in [m]$ and $(\mathsf{pk},\mathsf{sk}) \leftarrow \Sigma.\mathsf{Gen}(1^\lambda)$ is the reader's public/private keys.
- Update state st_w: It contains public information concatenated with document identifier as seed value for KH-PRF evaluation. Specifically, $\mathsf{st}_w = (\mathsf{st}_{w,1}, \ldots, \mathsf{st}_{w,N})$, where $\mathsf{st}_{w,u}$ is the counter value (initialized with 0) for document u incremented after each update on that document happens.

Setup. Figure 1 presents the setup procedures as follows.

- Reader: It executes RSetup algorithm to generate a public/private key pair $(\mathsf{pk},\mathsf{sk})$ and broadcasts pk to all writers.
- Writer: Each writer w executes WSetup algorithm on reader's public key pk to generate four components: the encrypted index EIDX_w, a private token PTkn_w, a shared token STkn_w, and an update state st_w. The writer first generates m KH-PRF keys $(\mathbf{r}_{w,1}, \ldots, \mathbf{r}_{w,m})$ to encrypt m columns of the search index (step 1(a)). These KH-PRF keys are stored as the private token PTkn_w by the writer and also encrypted under the reader's public key pk as shared token STkn_w (steps 1(a)–1(b)) to grant search permission to the reader. The writer initializes a public update state st_w as zero values (step 2). Finally, the writer encrypts an empty search index cell-by-cell by evaluating KH-PRF function F^* with KH-PRF keys $\mathbf{r}_{w,v}$ and the seeds formed by row indices and update counters (step 3). Finally, the writer sends EIDX_w and its auxiliary components (st_w, STkn_w) to L servers while keeping PTkn_w private.

4.2 Search Procedure

We present the search protocol of MUSES in Figure 2. To search for a keyword kw on a writer subset $\mathcal{W}'$, the reader first computes its BF representation as column indices $(v_1, \ldots, v_K)$, and creates corresponding DPF keys $\{q_1^{(i)}, \ldots, q_K^{(i)}\}_{i \in [L]}$ (SearchToken, steps 1–2), and sends them to L servers, where each server $\mathcal{P}_i$ receives a search token $\mathfrak{s}_i = (\mathcal{W}', \{q_k^{(i)}\}_{k \in [K]})$. The servers then execute Search algorithm, which performs three main operations: (*i*) partial decryption, (*ii*) oblivious counting/padding, and (*iii*) oblivious shuffle.

4.2.1 Partial decryption

First, each server $\mathcal{P}_i$ evaluates DPF on two components of the writer: the search index EIDX and shared token STkn. The former is to privately retrieve $(\hat{\mathbf{d}}_{v_1}^{(i)}, \ldots, \hat{\mathbf{d}}_{v_K}^{(i)})$ as the additive shares of K requested columns in EIDX, while the latter is to privately retrieve $(\mathsf{STkn}_{v_1}^{(i)}, \ldots, \mathsf{STkn}_{v_K}^{(i)})$ as the additive shares of the K corresponding shared tokens (step 4).

The servers send the shares of the shared tokens to the reader to open the secret keys $\mathbf{r}_{v_k}$ (for $k \in [K]$) (steps 5(a)–5(b)). The reader then delegates the (partial) decryption to the servers by creating $(\mathbf{r}_{v_k}^{(1)}, \ldots, \mathbf{r}_{v_k}^{(L)})$ as the KH-PRF (additive) shares of each $\mathbf{r}_{v_k}$ (step 5(c)), and distributes each $\mathbf{r}_{v_k}^{(i)}$ to each server $\mathcal{P}_i$ (step 6). Each server performs KH-PRF evaluation to obtain the shares of the *decrypted* columns (step 7(a)) as:

$$\tilde{\mathbf{d}}_{v_k}^{(i)}[u] = \hat{\mathbf{d}}_{v_k}^{(i)}[u] - F^*(\mathbf{r}_{v_k}^{(i)}, u \,||\, \mathsf{st}_u) \pmod p \quad (2)$$

$\mathsf{SearchToken}(\mathsf{kw}, \mathcal{W}')$:

1. For each $k \in [K]$:
   (a) $v_k \leftarrow H_k(\mathsf{kw})$
   (b) $(q_k^{(1)}, \ldots, q_k^{(L)}) \leftarrow \mathsf{DPF.Gen}(1^\lambda, v_k, 1)$
2. $\mathfrak{s}_i \leftarrow (\mathcal{W}', \{q_k^{(i)}\}_{k\in[K]})$ for each $i \in [L]$
3. **return** $\mathfrak{s} \leftarrow (\mathfrak{s}_1, \ldots, \mathfrak{s}_L)$

$\mathsf{Search}(\mathfrak{s}, \mathsf{sk}, \{(\mathsf{EIDX}_w, \mathsf{STkn}_w, \mathsf{st}_w)\}_{w\in[n_w]})$:

Let $\mathfrak{s} = (\mathcal{W}', \{q_k^{(i)}\}_{k\in[K]})$. *For each writer* $w \in \mathcal{W}'$*, repeat the following process on its components* $\mathsf{EIDX} = \mathsf{EIDX}_w$, $\mathsf{STkn} = \mathsf{STkn}_w$, $\mathsf{st} = \mathsf{st}_w$*:*

4. For each $k \in [K]$, each server $\mathcal{P}_i$ locally computes:
   (a) $\hat{\mathbf{d}}_{v_k}^{(i)} \leftarrow \sum_{v=1}^m \mathsf{DPF.Eval}(q_k^{(i)}, v) \times \mathsf{EIDX}[*, v]$
   (b) $\mathsf{STkn}_{v_k}^{(i)} \leftarrow \sum_{v=1}^m \mathsf{DPF.Eval}(q_k^{(i)}, v) \times \mathsf{STkn}_v$
   (c) Send $\mathsf{STkn}_{v_k}^{(i)}$ to the reader.
5. For each $k \in [K]$, the reader computes:
   (a) $\mathsf{STkn}_{v_k} \leftarrow \sum_{i=1}^L \mathsf{STkn}_{v_k}^{(i)} \pmod p$
   (b) $\mathbf{r}_{v_k} \leftarrow \Sigma.\mathsf{Dec}(\mathsf{sk}, \mathsf{STkn}_{v_k})$
   (c) $(\mathbf{r}_{v_k}^{(1)}, \ldots, \mathbf{r}_{v_k}^{(L)}) \leftarrow \mathsf{KH\text{-}PRF.Share}(\mathbf{r}_{v_k})$
6. The reader sends $\{\mathbf{r}_{v_k}^{(i)}\}_{k\in[K]}$ to server $\mathcal{P}_i$ for each $i \in [L]$
7. For each $u \in [N]$, each server $\mathcal{P}_i$ locally computes:
   (a) $\tilde{\mathbf{d}}_{v_k}^{(i)}[u] \leftarrow \hat{\mathbf{d}}_{v_k}^{(i)}[u] - F^*(\mathbf{r}_{v_k}^{(i)}, u \,||\, \mathsf{st}_u) \pmod p$ for $k \in K$
   (b) $\mathbf{d}^{(i)}[u] \leftarrow \sum_{k=1}^K \tilde{\mathbf{d}}_{v_k}^{(i)}[u] \pmod p$
8. All servers jointly execute Π_{LOC} online protocol on shares $\mathbf{d}^{(i)}$ and obtain $(s^{(i)}, \mathbf{d}'^{(i)})$. Each $\mathcal{P}_i$ sends $s^{(i)}$ to the reader
9. The reader computes:
   (a) $s \leftarrow \sum_{i=1}^L s^{(i)} \pmod p$
   (b) Generates padding vector $\mathbf{p} = (\mathbf{1}^{n_s - s} \,||\, \mathbf{0}^s)$
   (c) Secret shares $\mathbf{p}$ as $\mathbf{p}^{(i)} \xleftarrow{\$} \mathbb{Z}_p^{n_s}$ such that $\sum_{i=1}^L \mathbf{p}^{(i)} = \mathbf{p}$
   (d) Sends $\mathbf{p}^{(i)}$ to each server $\mathcal{P}_i \in \{\mathcal{P}_1, \ldots, \mathcal{P}_L\}$.
10. Every $\mathcal{P}_i$ concatenates $\mathbf{o}^{(i)} = (\mathbf{d}'^{(i)} || \mathbf{p}^{(i)})$
11. All servers jointly execute Π_{LOS} online protocol on shares $\mathbf{o}^{(i)}$, which outputs permutation π_i to each $\mathcal{P}_i \in \{\mathcal{P}_1, \ldots, \mathcal{P}_{L-1}\}$ and shuffled vector $\hat{\mathbf{o}}$ to $\mathcal{P}_L$. $\mathcal{P}_L$ sends $O = \{u : \hat{\mathbf{o}}[u] = 1\}$ to the reader, and each $\mathcal{P}_i \in \{\mathcal{P}_1, \ldots, \mathcal{P}_{L-1}\}$ sends π_i to the reader
12. **return** $O' = \{u' : u' \le N \wedge u' = \pi_1^{-1}(\ldots(\pi_{L-1}^{-1}(u))\ldots) \forall u \in O\}$

Figure 2: MUSES search.

for each $u \in [N]$ and $k \in [K]$, where $\mathsf{st}_{i,u}$ is the (update) counter of document u. Finally, each server $\mathcal{P}_i$ aggregates the shares of K decrypted columns (step 7(b)) as $\mathbf{d}^{(i)} \leftarrow \sum_{k=1}^K \tilde{\mathbf{d}}_{v_k}^{(i)} \in \mathbb{Z}_p^N$ to obtain the share of the search result according to BF membership verification. Specifically, keyword kw appears in document u of the writer iff $\left(\sum_i \mathbf{d}^{(i)}[u]\right) \ggg z = K$, where $z = \lceil \log_2(e \cdot K) \rceil$ is the reserved space for accumulated error when aggregating K KH-PRF-evaluated columns together by Eq. (1). Since broadcasting $\mathbf{d}^{(i)}$ permits the servers to learn the plain search result leading to result/volume pattern leakages, the next steps are to perform oblivious padding and oblivious shuffle on the shares $\mathbf{d}^{(i)}$ before opening the search result.

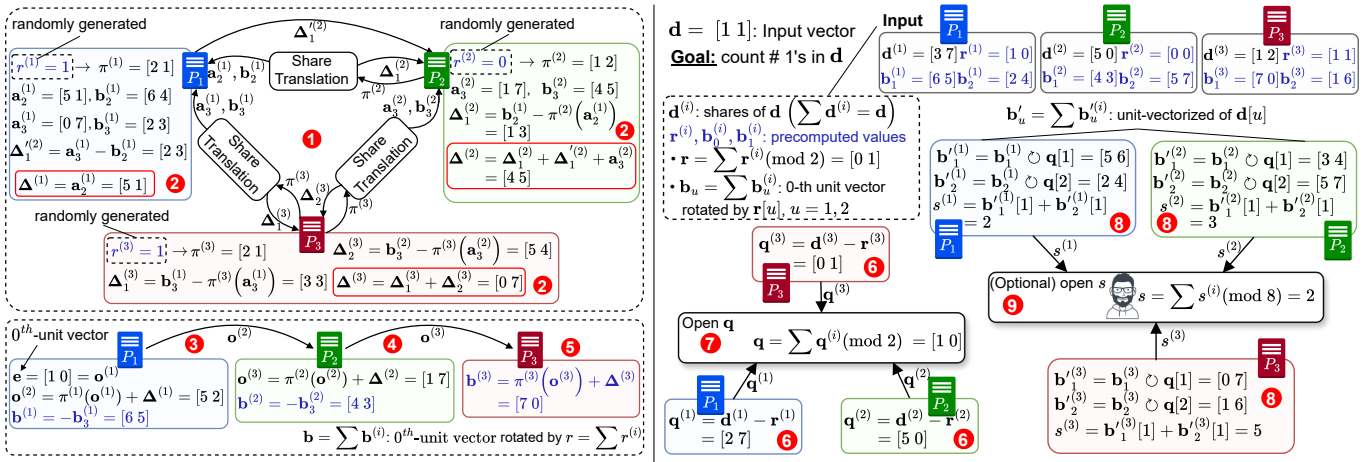
4.2.2 Oblivious padding

To seal the volume leakage, we perform oblivious padding so that the search result always returns n_s document identifiers. We first count s as the number of occurrences of K in the aggregated column $\mathbf{d}$ (Figure 2, step 8), and then create a padding vector containing $(n_s - s)$ elements of value K.

Protocol 1. Π_{LOC} – Multi-party Oblivious Count Protocol

Preprocessing:
Input: Security parameter λ and value to be counted K
Output: Each $\mathcal{P}_i$ obtains shares $r^{(i)} \in \mathbb{Z}_{K^+}, \mathbf{b}^{(i)} \in \mathbb{Z}_p^{K^+}$ s.t. $r = \sum_{i=1}^L r^{(i)}$, $\mathbf{b} = \sum_{i=1}^L \mathbf{b}^{(i)}$ is a unit vector with $\mathbf{b}[r] = 1$

1. Every $\mathcal{P}_i$ sets $r^{(i)} \xleftarrow{\$} \mathbb{Z}_{K^+}, \pi^{(i)} \leftarrow [K^+] \circlearrowright r^{(i)}$
2. For each $\mathcal{P}_i \in \{\mathcal{P}_1, \ldots, \mathcal{P}_{L-1}\}$, $\mathcal{P}_j \in \{\mathcal{P}_{i+1}, \ldots, \mathcal{P}_L\}$:
   (a) $\mathcal{P}_j \leftrightarrow \mathcal{P}_i$: $(\mathbf{\Delta}_i^{(j)}; \mathbf{a}_j^{(i)}, \mathbf{b}_j^{(i)}) \leftarrow \mathsf{TSS.ShrTrns}(\pi^{(j)}; 1^\lambda)$
3. Every $\mathcal{P}_i$ sends $\mathbf{\Delta}_i'^{(j)} \leftarrow \mathbf{a}_{j+1}^{(i)} - \mathbf{b}_j^{(i)}$ to each $\mathcal{P}_j \in \{\mathcal{P}_{i+1}, \ldots, \mathcal{P}_{L-1}\}$
4. $\mathcal{P}_1$ sets $\mathbf{\Delta}^{(1)} \leftarrow \mathbf{a}_2^{(1)}$. For $i = 2$ to $L-1$, $\mathcal{P}_i$ sets $\mathbf{\Delta}^{(i)} \leftarrow \sum_{j=1}^{i-1} \mathbf{\Delta}_j^{(i)} + \sum_{i=1}^{\ell-1} \mathbf{\Delta}_j'^{(i)} + \mathbf{a}_{i+1}^{(i)}$. $\mathcal{P}_L$ sets $\mathbf{\Delta}^{(L)} \leftarrow \sum_{j=1}^{L-1} \mathbf{\Delta}_j^{(L)}$
5. $\mathcal{P}_1$ initializes $\mathbf{e} \leftarrow \{0\}^{K^+}$, sets $\mathbf{e}[0] = 1$ and $\mathbf{o}^{(1)} \leftarrow \mathbf{e}$
6. Each $\mathcal{P}_i \in \{\mathcal{P}_1, \ldots, \mathcal{P}_{L-1}\}$ sets $\mathbf{b}^{(i)} \leftarrow -\mathbf{b}_L^{(i)}$ and sends $\mathbf{o}^{(i+1)} \leftarrow \pi^{(i)}(\mathbf{o}^{(i)}) + \mathbf{\Delta}^{(i)}$ to $\mathcal{P}_{i+1}$
7. $\mathcal{P}_L$ sets $\mathbf{b}^{(L)} \leftarrow \pi^{(L)}(\mathbf{o}^{(L)}) + \mathbf{\Delta}^{(L)}$



Online phase:
Input: Each $\mathcal{P}_i$ inputs $\mathbf{d}^{(i)} \in \mathbb{Z}_p^N$ as share of aggregated column with z-lower bit noise, N preprocessed shares $\{(r_u^{(i)}, \mathbf{b}_u^{(i)})\}_{u\in[N]}$
Output: Each $\mathcal{P}_i$ obtains shares $s^{(i)} \in \mathbb{Z}_p$, $\mathbf{d}'^{(i)} \in \mathbb{Z}_p^N$ s.t. $\sum_{i=1}^L \mathbf{d}'^{(i)} = \mathbf{d}'$, $\sum_{i=1}^L s^{(i)} = s$, $\mathbf{d}'[u] = ((\sum_{i=1}^L \mathbf{d}^{(i)}[u] \ggg z) \stackrel{?}{=} K)$, $s = \sum_{u=1}^N \mathbf{d}'[u]$

1. For each $u \in [N]$ in parallel:
   (a) Every $\mathcal{P}_i$ computes $\hat{r}_u^{(i)} \leftarrow -r_u^{(i)} \pmod{K^+}$ and sends $q_u^{(i)} \leftarrow (\hat{r}_u^{(i)} \lll z) + \mathbf{d}^{(i)}[u] \pmod p$ to all other parties
   (b) Every $\mathcal{P}_i$ computes $q_u \leftarrow \left(\sum_{j=1}^L q_u^{(j)}\right) \ggg z \pmod{K^+}$, $\mathbf{b}_u'^{(i)} \leftarrow \mathbf{b}_u^{(i)} \circlearrowright q_u$, and $\mathbf{d}'^{(i)}[u] \leftarrow \mathbf{b}_u'^{(i)}[K]$
2. Every $\mathcal{P}_i$ computes $s^{(i)} \leftarrow \sum_{u=1}^N \mathbf{b}_u'^{(i)}[K]$

Oblivious count protocol. Given a vector $\mathbf{v} \in \mathbb{Z}_m^N$, counting how many elements in $\mathbf{v}$ equal a specific value $x \in \mathbb{Z}_m$ can be done by transforming each $\mathbf{v}[u]$ to a one-hot vector $\mathbf{b}_u \in \{0,1\}^m$, where $\mathbf{b}_u[\mathbf{v}[u]] = 1$, and computing $\sum_{u=1}^N \mathbf{b}_u[x]$. With this unit-vectorization trick, we design an online/offline L-party oblivious counting algorithm (Protocol 1) to compute s (i.e., number of elements in the noise-free aggregated column $\mathbf{v} \in \mathbb{Z}_m^N$ equal x) in arithmetic secret-sharing. We present a toy example of our protocol in Figure 3.

Suppose $p = 2^\alpha$, $K^+ = K + 1 = 2^{\alpha'}$ for some integers $\alpha > \alpha'$ and $s < p$ (e.g., $p = 8, K = 1$ in Figure 3). In the preprocessing phase (Figure 3a), we precompute the share of N random roulette pairs $(\mathbf{b}_u, r_u)$, where $\mathbf{b}_u \in \{0,1\}^{K^+}$ is a random unit vector that $\mathbf{b}_u[r_u] = 1$, and $r_u \in \mathbb{Z}_{K^+}$ is a random circular shift. Let $\mathbf{b}_u^{(i)} \in \mathbb{Z}_p^{K^+}$ and $r_u^{(i)} \in \mathbb{Z}_{K^+}$ be the share of $\mathbf{b}_u$ and r_u, respectively. In the online phase (Figure 3b), the share of s is computed by masking each element $\mathbf{d}[u]$ with $\hat{r}_u^{(i)}$, where $\hat{r}_u^{(i)} \leftarrow -r_u^{(i)} \pmod{K^+}$ is the complement of circular shift value $r_u^{(i)}$ (step ❻), followed by opening the masked data (step ❼), and unmasking with the unit vector $\mathbf{b}_u$ (step ❽).

As z least significant bits (LSBs) of $\mathbf{d}[u]$ contain KH-PRF error (Eq. (1)), we left-shift the circular shift value $\hat{r}_u^{(i)}$ by z bits to only mask the actual data in $\mathbf{d}[u]$ as $q_u^{(i)} = \mathbf{d}^{(i)}[u] + \hat{r}_u^{(i)} \cdot 2^z \in \mathbb{Z}_p$. We then open and remove z LSBs of the masked data as $q_u = \left(\sum_{i=1}^L q_u^{(i)}\right) \ggg z \in \mathbb{Z}_{K^+}$. Finally, the share of s is

(a) Preprocessing (Π_{LOC}.Prep)

(b) Online phase (Π_{LOC}.Cnt)

Figure 3: A numerical example of Π_{LOC} with $p = 8$ and $K = 1$.

computed by unmasking the opened data with the share of $\mathbf{b}_u$ as $s^{(i)} = \sum_{u=1}^{N} \mathbf{b}'^{(i)}_u[K] \in \mathbb{Z}_p$, where $\mathbf{b}'^{(i)}_u = \mathbf{b}^{(i)}_u \circlearrowleft q_u$ (step 8). Moreover, as $\mathbf{d}[u] \ggg z$ contains aggregated values from 1 to K, it may reveal information about the search pattern when opened in the next search operation (i.e., oblivious shuffle). Meanwhile, the search only needs the information whether $\mathbf{d}[u] \ggg z \stackrel{?}{=} K$, which is available in $\mathbf{b}'_u[K]$. Thus, our online protocol also outputs the shares of $\mathbf{b}'_u[K]$ in the form of shared vectors $\mathbf{d}'^{(i)}[u] = \mathbf{b}'_u[K]$ for the next processing.

We now show how to compute a roulette pair $(\mathbf{b}, r)$ in the offline phase. Our idea is to employ the two-party shuffle in [21] and extend it to L-party setting. As $\mathbf{b}[r] = 1$, it can be written as linear group operations as $\mathbf{b} = \pi^{(L)}(\dots(\pi^{(1)}(\mathbf{e}))$, where $\mathbf{e} \in \mathbb{Z}_2^{K^+}$ is the unit-vector that $\mathbf{e}[0] = 1$, $\pi^{(i)} = [K+1] \circlearrowleft r^{(i)}$ is a random circular shift permutation with $r^{(i)} \xleftarrow{\$} \mathbb{Z}_{K^+}$ and $r = \sum_{i=1}^{L} r^{(i)} \in \mathbb{Z}_{K^+}$. Thus, L shares of $\mathbf{b}$ can be set as $\mathbf{b}^{(i)} \xleftarrow{\$} \mathbb{Z}_p^{K^+}$ for $i \in [L^-]$ and $\mathbf{b}^{(L)} = \pi^{(L)}(\dots(\pi^{(1)}(\mathbf{e})) - \sum_{i=1}^{L-1} \mathbf{b}^{(i)}$. That means $L-1$ parties $\mathcal{P}_i \in \{\mathcal{P}_1, \dots, \mathcal{P}_{L-1}\}$ can independently generate random circular shift and vector as the shares $r^{(i)}$ and $\mathbf{b}^{(i)}$, respectively, and interact with each other to help party $\mathcal{P}_L$ obtain $\mathbf{b}^{(L)} = \pi^{(L)}(\dots(\pi^{(1)}(\mathbf{e})) - \sum_{i=1}^{L-1} \mathbf{b}^{(i)}$ with its chosen random circular shift permutation $\pi^{(L)}$. Specifically, each party $\mathcal{P}_i$ computes a translation function $\mathbf{\Delta}^{(i)}$ such that

$$\pi^{(L)}(\dots(\pi^{(2)}(\mathbf{\Delta}^{(1)}) + \mathbf{\Delta}^{(2)})\dots) + \mathbf{\Delta}^{(L)} = \pi^{(L)}(\dots(\pi^{(2)}(\pi^{(1)}(\mathbf{e})))\dots) - \sum_{i=1}^{L-1} \mathbf{b}^{(i)}$$

The idea is to execute the two-party share translation protocol in [21] between $(\mathcal{P}_i, \mathcal{P}_j)$ for $i, j \in [L]$ and $i < j$ (with circular permutation $\pi^{(j)}$ chosen by $\mathcal{P}_j$, and random vectors $\mathbf{a}^{(i)}_j$, $\mathbf{b}^{(i)}_j$ chosen by $\mathcal{P}_i$) to generate $\mathbf{\Delta}^{(j)}_i = \mathbf{b}^{(i)}_j - \pi^{(j)}(\mathbf{a}^{(i)}_j)$ for $\mathcal{P}_j$ (step 1 in Figure 3a). Then, each $\mathcal{P}_i$, for $\mathcal{P}_i \in \{\mathcal{P}_1, \dots, \mathcal{P}_{j-1}\}$, sends $\mathbf{\Delta}'^{(j)}_i \leftarrow \mathbf{a}^{(i)}_{j+1} - \mathbf{b}^{(i)}_j$ to $\mathcal{P}_j$, for $\mathcal{P}_j \in \{\mathcal{P}_{i+1}, \dots, \mathcal{P}_{L-1}\}$. From $\mathbf{\Delta}^{(i)}_j$ and $\mathbf{\Delta}'^{(i)}_j$, each $\mathcal{P}_i \in \{\mathcal{P}_1, \dots, \mathcal{P}_L\}$ can compute $\mathbf{\Delta}^{(i)} = \mathbf{x}_{i+1} - \pi^{(i)}(\mathbf{x}_i)$ (step 2), where

$$\mathbf{x}_i = \begin{cases} \sum_{j=1}^{L-1} \mathbf{b}^{(j)}_L & \text{if } i = L+1 \\ \sum_{j=1}^{i-1} \mathbf{a}^{(j)}_i & \text{otherwise} \end{cases}$$

Next, $\mathcal{P}_1$ initializes the unit-vector $\mathbf{e}$ and sends $\mathbf{o}^{(2)} \leftarrow \pi^{(1)}(\mathbf{e}) + \mathbf{\Delta}^{(1)} = \pi^{(1)}(\mathbf{e}) + \mathbf{a}^{(1)}_2$ to $\mathcal{P}_2$ (step 3), who then computes $\mathbf{o}^{(3)} \leftarrow \pi^{(2)}(\mathbf{o}^{(2)}) + \mathbf{\Delta}^{(2)} = \pi^{(2)}(\pi^{(1)}(\mathbf{e})) + \sum_{i=1}^{2} \mathbf{a}^{(i)}_3$ (step 4) and forwards it to $\mathcal{P}_3$, and so on until the final party $\mathcal{P}_L$ who receives $\mathbf{o}^{(L)} = \pi^{(L-1)}(\dots(\pi^{(1)}(\mathbf{e}))\dots) + \sum_{i=1}^{L-1} \mathbf{a}^{(i)}_L$ from $\mathcal{P}_{L-1}$. Then, $\mathcal{P}_L$ computes the share as $\mathbf{b}^{(L)} \leftarrow \pi^{(L)}(\mathbf{o}^{(L)}) + \mathbf{\Delta}^{(L)} = \pi^{(L)}(\dots(\pi^{(1)}(\mathbf{e}))\dots) + \sum_{i=1}^{L-1} \mathbf{b}^{(i)}_L$ (step 5).

We argue correctness/security of Π_{LOC} in our full version [57].

Oblivious padding. Once the count s in the aggregated column is computed, the oblivious padding can be easily achieved. All servers send $s^{(i)}$ to the reader to open $s = \sum_{i=1}^{L} s^{(i)}$ (Figure 2, step 9(a)). The reader generates a padding vector $\mathbf{p} \in \{0,1\}^{n_s}$ containing $n_s - s$ elements of 1 and secret-shares it with L servers (steps 9(b)-9(d)). The servers form a concatenated vector from $\mathbf{p}$ and the vector $\mathbf{d}'$ output from the Π_{LOC} online protocol as $\mathbf{o} = (\mathbf{d}' || \mathbf{p})$ (step 10). To completely seal pattern leakages, $\mathbf{o}$ must be shuffled before opening to obtain the search result. In the next section, we present an oblivious shuffle protocol to shuffle $\mathbf{o}$ in L-party arithmetic secret-sharing.

4.2.3 Oblivious shuffle

We construct a new L-party random shuffle protocol to shuffle vector elements in arithmetic secret sharing.

***L*-party secret-shared shuffle.** Protocol 2 presents our L-party shuffle Π_{LOS} scheme. Similar to Π_{LOC}, Π_{LOS} is extended from the two-party shuffle in [21] to work with L-

Protocol 2. Π_{LOS} – Multi-party Oblivious Shuffle Protocol

Preprocessing:
Input: Security parameter λ and size n
Output: Preprocessing values, including $(\pi^{(1)}, \mathbf{\Delta}_1)$ for $\mathcal{P}_1$, $(\pi^{(i)}, \mathbf{\Delta}_i, \mathbf{a}_i^{(1)})$ for $\mathcal{P}_i$, with $i = 2, \ldots, L-1$, and $\mathbf{a}_L^{(1)}, \mathbf{b}_L^{(L-1)}$ for $\mathcal{P}_L$

1. For each $\mathcal{P}_i \in \{\mathcal{P}_1, \ldots, \mathcal{P}_{L-1}\}$, $\mathcal{P}_j \in \{\mathcal{P}_{i+1}, \ldots, \mathcal{P}_L\}$:
   (a) $\mathcal{P}_i$ generates a random $\pi^{(i)}$ for n elements
   (b) $\mathcal{P}_i \leftrightarrow \mathcal{P}_j$: $(\mathbf{\Delta}_j^{(i)}; \mathbf{a}_i^{(j)}, \mathbf{b}_i^{(j)}) \leftarrow \mathsf{TSS.ShrTrns}(\pi^{(i)}; 1^\lambda)$
2. Each $\mathcal{P}_i \in \{\mathcal{P}_3, \ldots, \mathcal{P}_L\}$ sends $\mathbf{\Delta}_i'^{(j)} \leftarrow \mathbf{b}_{j-1}^{(i)} - \mathbf{a}_j^{(i)}$ to each $\mathcal{P}_j \in \{\mathcal{P}_2, \ldots, \mathcal{P}_{i-1}\}$. Each $\mathcal{P}_i \in \{\mathcal{P}_1, \ldots, \mathcal{P}_{L-1}\}$ computes $\mathbf{\Delta}^{(i)} \leftarrow \sum_{j=i+1}^{L} \mathbf{\Delta}_j^{(i)}$. Each $\mathcal{P}_i \in \{\mathcal{P}_2, \ldots, \mathcal{P}_L\}$ computes $\mathbf{\Delta}^{(i)} \leftarrow \mathbf{\Delta}^{(i)} - \pi^{(i)}(\sum_{j=i+1}^{L} \mathbf{\Delta}_j'^{(i)} + \mathbf{b}_{i-1}^{(i)})$

Online phase:
Input: Secret shares $\mathbf{d}^{(i)}$ and preprocessing values including $(\pi^{(1)}, \mathbf{\Delta}^{(1)})$ for $\mathcal{P}_1$, $(\pi^{(i)}, \mathbf{\Delta}^{(i)}, \mathbf{a}_1^{(i)})$ for $\mathcal{P}_i$, with $i = 2, \ldots, L-1$, and $\mathbf{a}_1^{(L)}, \mathbf{b}_{L-1}^{(L)}$ for $\mathcal{P}_L$
Output: $\pi^{(i)}$ for each $\mathcal{P}_i \in \{\mathcal{P}_1, \ldots, \mathcal{P}_{L-1}\}$, shuffled vector $\mathbf{r}$ for $\mathcal{P}_L$

1. Each $\mathcal{P}_i \in \{\mathcal{P}_2, \ldots, \mathcal{P}_L\}$ sends $\mathbf{z}^{(i)} \leftarrow \mathbf{d}^{(i)} + \mathbf{a}_1^{(i)}$ to $\mathcal{P}_1$
2. $\mathcal{P}_1$ computes $\mathbf{o}^{(1)} \leftarrow \mathbf{d}^{(1)} + \sum_{i=2}^{L} \mathbf{z}^{(i)}$
3. Each $\mathcal{P}_i \in \{\mathcal{P}_1, \ldots, \mathcal{P}_{L-1}\}$ sends $\mathbf{o}^{(i+1)} \leftarrow \pi^{(i)}(\mathbf{o}^{(i)}) + \mathbf{\Delta}^{(i)}$ to $\mathcal{P}_{i+1}$
4. $\mathcal{P}_L$ computes $\mathbf{r} \leftarrow \mathbf{o}^{(L)} - \mathbf{b}_{L-1}^{(L)}$

party and arithmetic shares. However, unlike Π_{LOC} or prior works [33], the goal of Π_{LOS} is to output the shuffled vector directly, instead of its shares which may cost an additional communication round for opening. To achieve this, we design a new preprocessing protocol that permits all parties to compute precomputed materials for direct online shuffle. Specifically, we precompute translation functions for every $\mathcal{P}_i$ (except $\mathcal{P}_L$) with its chosen random permutation $\pi^{(i)}$ as $\mathbf{\Delta}^{(i)} = \mathbf{x}_{i+1} - \pi^{(i)}(\mathbf{x}_i)$ such that

$$\mathbf{x}_i = \begin{cases} \sum_{j=i+1}^{L} \mathbf{a}_i^{(j)}, & \text{if } i = 1 \\ \sum_{j=i}^{L} \mathbf{b}_{i-1}^{(j)}, & \text{otherwise} \end{cases}$$

where $\mathbf{a}_i^{(j)}, \mathbf{b}_i^{(j)}$ are random vectors chosen by $\mathcal{P}_j$.

With these precomputed materials, our online protocol can output the shuffled vector directly as follows. Let $\mathbf{d}^{(i)}$ be the share of the vector to be shuffled. Each $\mathcal{P}_i \in \{\mathcal{P}_2, \ldots, \mathcal{P}_L\}$ sends its masked share $\mathbf{z}^{(i)} \leftarrow \mathbf{d}^{(i)} + \mathbf{a}_1^{(i)}$ to $\mathcal{P}_1$. $\mathcal{P}_1$ computes $\mathbf{o}^{(1)} \leftarrow \mathbf{d}^{(1)} + \sum_{i=2}^{L} \mathbf{z}^{(i)}$ sends $\mathbf{o}^{(2)} \leftarrow \pi^{(1)}(\mathbf{o}^{(1)}) + \mathbf{\Delta}^{(1)} = \pi^{(1)}(\mathbf{d}) + \sum_{i=2}^{L} \mathbf{b}_1^{(i)}$ to $\mathcal{P}_2$, which in turn computes $\mathbf{o}^{(3)} \leftarrow \pi^{(2)}(\mathbf{o}^{(2)}) + \mathbf{\Delta}^{(2)} = \pi^{(2)}(\pi^{(1)}(\mathbf{d})) + \sum_{i=3}^{L} \mathbf{b}_2^{(i)}$ and forwards it to $\mathcal{P}_3$ and so on until $\mathcal{P}_L$ receives $\mathbf{o}^{(L)} = \pi^{(L-1)}(\ldots(\pi^{(1)}(\mathbf{d}))\ldots) + \mathbf{b}_{L-1}^{(L)}$ from $\mathcal{P}_{L-1}$. As $\mathcal{P}_L$ holds $\mathbf{b}_{L-1}^{(L)}$, it can compute $\mathbf{r} \leftarrow \mathbf{o}^{(L)} - \mathbf{b}_{L-1}^{(L)} = \pi^{(L-1)}(\ldots(\pi^{(1)}(\mathbf{d})))$.

To generate precomputed materials, we execute two-party share translation scheme in [21] between $(\mathcal{P}_i, \mathcal{P}_j)$ for $i, j \in [L]$ and $i < j$ (with random permutation $\pi^{(i)}$ chosen by $\mathcal{P}_i$, and random vectors $\mathbf{a}_i^{(j)}$, $\mathbf{b}_i^{(j)}$ chosen by $\mathcal{P}_j$) to compute $\mathbf{\Delta}_j^{(i)} = \mathbf{b}_i^{(j)} - \pi^{(i)}(\mathbf{a}_i^{(j)})$ for $\mathcal{P}_i$. Then, each $\mathcal{P}_i \in \{\mathcal{P}_2, \ldots, \mathcal{P}_{L-1}\}$ receives $\mathbf{\Delta}_j'^{(i)} = \mathbf{b}_{i-1}^{(j)} - \mathbf{a}_i^{(j)}$ from each $\mathcal{P}_j \in \{\mathcal{P}_{i+1}, \ldots, \mathcal{P}_L\}$. From $\mathbf{\Delta}_j^{(i)}$ and $\mathbf{\Delta}_j'^{(i)}$, $\mathcal{P}_i \in \{\mathcal{P}_1, \ldots, \mathcal{P}_{L-1}\}$ can compute $\mathbf{\Delta}^{(i)}$.

We argue correctness/security of Π_{LOS} in our full version [57].

$\mathsf{RvkPrm}(w, \mathsf{PTkn}_w, \mathsf{EIDX}_w, \mathsf{st}_w)$:

1. Writer w:
   (a) **parse** $\mathsf{PTkn}_w = (\mathbf{r}_{w,1}, \mathbf{r}_{w,2}, \ldots, \mathbf{r}_{w,m})$
   (b) For $v = 1$ to m
      i. $\mathbf{r}'_{w,v} \leftarrow \mathsf{KH\text{-}PRF.Gen}(1^\lambda)$
      ii. $(\mathbf{r}_{w,v}^{(1)}, \ldots, \mathbf{r}_{w,v}^{(L)}) \leftarrow \mathsf{KH\text{-}PRF.Share}(\mathbf{r}_{w,v})$
      iii. $(\mathbf{r}_{w,v}'^{(1)}, \ldots, \mathbf{r}_{w,v}'^{(L)}) \leftarrow \mathsf{KH\text{-}PRF.Share}(\mathbf{r}'_{w,v})$
   (c) $\mathsf{PTkn}'_w \leftarrow (\mathbf{r}'_{w,1}, \mathbf{r}'_{w,2}, \ldots, \mathbf{r}'_{w,m})$
2. Writer $w \to$ Server $\mathcal{P}_i \in \{\mathcal{P}_1, \ldots, \mathcal{P}_L\}$: $\{\mathbf{r}_{w,v}^{(i)}, \mathbf{r}_{w,v}'^{(i)}\}_{v \in [m]}$
3. Server $\mathcal{P}_i \in \{\mathcal{P}_1, \ldots, \mathcal{P}_L\}$:
   (a) For $u = 1$ to N, $v = 1$ to m do
      i. $x_{u,v} \xleftarrow{\$} \mathbb{Z}_p$, $\mathbf{M}^{(i)}[u,v] \leftarrow x_{u,v} \lll z$
      ii. $\mathbf{T}_1^{(i)}[u,v] \leftarrow \mathbf{M}^{(i)}[u,v] - F^*(\mathbf{r}_{w,v}^{(i)}, u \| \mathsf{st}_{w,u}) + \mathsf{max}_e \pmod p$
      iii. $\mathbf{T}_2^{(i)}[u,v] \leftarrow -\mathbf{M}^{(i)}[u,v] + F^*(\mathbf{r}_{w,v}'^{(i)}, u \| \mathsf{st}_{w,u}) \pmod p$
4. Server $\mathcal{P}_i \to$ Server $\mathcal{P}_j$: $\mathbf{T}_1^{(i)}, \mathbf{T}_2^{(i)}$, for $\mathcal{P}_i, \mathcal{P}_j \in \{\mathcal{P}_1, \ldots, \mathcal{P}_L\}$ and $\mathcal{P}_i \neq \mathcal{P}_j$
5. Server $\mathcal{P}_i \in \{\mathcal{P}_1, \ldots, \mathcal{P}_L\}$:
   (a) For $u = 1$ to N, $v = 1$ to m do
      i. $\mathbf{T}'[u,v] \leftarrow \mathsf{EIDX}_w[u,v] + \sum_{j=1}^{L} \mathbf{T}_1^{(j)}[u,v]$
      ii. $\hat{\mathbf{T}}[u,v] \leftarrow ((\mathbf{T}'[u,v] \ggg z) \lll z)$
      iii. $\mathsf{EIDX}'_w[u,v] \leftarrow \hat{\mathbf{T}}[u,v] + \sum_{j=1}^{L} \mathbf{T}_2^{(j)}[u,v] + \mathsf{max}_e \pmod p$
6. **return** $(\mathsf{EIDX}'_w, \mathsf{PTkn}'_w)$

Figure 4: MUSES permission revocation.

Obtaining final search result. Once the concatenated search vector $\mathbf{o}$ is randomly shuffled (Figure 2, step 11) and opened to $\mathcal{P}_L$ as $\hat{\mathbf{o}}$, it can extract n_s indices u such that $\hat{\mathbf{o}}[u] = 1$ and send them to the reader. All other servers send their permutations to the reader. The reader obtains the final search result by applying the permutation inverses on indices from $\mathcal{P}_L$ and removing padded indices (step 12).

4.3 Search Permission Revocation

MUSES permits a writer to revoke access permission of the reader on her search index. The idea is to re-encrypt the writer's index with refreshed (column) KH-PRF keys unknown to the reader. Figure 4 presents our revocation protocol, where the re-encryption operation is delegated securely to the servers for writer efficiency. Its high-level idea is as follows.

To re-encrypt EIDX_w, the writer w first parses the current secret column keys $\mathbf{r}_{w,v}$, for $v \in [m]$ (step 1(a)) and generates new secret column keys $\mathbf{r}'_{w,v}$ (step 1(b).i). Next, the writer creates secret-shares of these keys as $(\mathbf{r}_{w,v}^{(1)}, \ldots, \mathbf{r}_{w,v}^{(L)})$, $(\mathbf{r}_{w,v}'^{(1)}, \ldots, \mathbf{r}_{w,v}'^{(L)})$ (steps 1(b).ii–iii), then updates private token (step 1(c)) and sends $\{\mathbf{r}_{w,v}^{(i)}, \mathbf{r}_{w,v}'^{(i)}\}_{v \in [m]}$ to servers $\mathcal{P}_i \in \{\mathcal{P}_1, \ldots, \mathcal{P}_L\}$ (step 2).

Each server $\mathcal{P}_i$ computes $\mathbf{T}_1^{(i)}$ and $\mathbf{T}_2^{(i)}$, where $\mathbf{T}_1^{(i)}$ is the masked component to remove the shared encryption computed by the secret-shared key $\mathbf{r}_{w,v}^{(i)}$, and $\mathbf{T}_2^{(i)}$ is the component to unmask the value $\mathbf{M}^{(i)}$ added by $\mathbf{T}_1^{(i)}$ and add the shared encryption computed by the new secret-shared key $\mathbf{r}_{w,v}'^{(i)}$ (step 3(a)). The server $\mathcal{P}_i$ then distributes $\mathbf{T}_1^{(i)}$ and $\mathbf{T}_2^{(i)}$ to other servers (step 4). Next, each server $\mathcal{P}_i$ obtains the

UpdateToken($\mathcal{V}_u, u, w, \mathsf{PTkn}_w, \mathsf{st}_w$): ▷ Executed by writer w

1. **parse** $\mathsf{PTkn}_w = (\mathbf{r}_{w,1}, \mathbf{r}_{w,2}, \ldots, \mathbf{r}_{w,m})$
2. $\mathbf{u} \leftarrow \{0\}^m$, $\mathbf{u}' \leftarrow \{0\}^m$
3. For $\mathsf{kw}_j \in \mathcal{V}_u$, $k = 1$ to K: $\mathsf{cid}_{j,k} \leftarrow H_k(\mathsf{kw}_j)$, $\mathbf{u}[\mathsf{cid}_{j,k}] \leftarrow 1$
4. For $v \in [m]$: $\mathbf{u}'[v] \leftarrow (\mathbf{u}[v] \lll z) + F^*(\mathbf{r}_{w,v}, u \| (\mathsf{st}_{w,u}+1)) \pmod p$
5. **return** $\mathfrak{u}_w \leftarrow (w, u, \mathbf{u}')$

Update($\mathfrak{u}_w, \mathsf{EIDX}_w, \mathsf{st}_w$): ▷ Executed by each server $\mathcal{P}_i \in \{\mathcal{P}_1, \ldots, \mathcal{P}_L\}$:

6. **parse** $\mathfrak{u}_w = (w, u, \mathbf{u}')$
7. $\mathsf{EIDX}'_w[u, *] \leftarrow \mathbf{u}'$, $\mathsf{st}'_{w,u} \leftarrow \mathsf{st}_{w,u} + 1$
8. **return** $(\mathsf{EIDX}'_w, \mathsf{st}'_w)$

Figure 5: MUSES document update.

masked value with error denoted as $\mathbf{T}'$ (step 5(a).i), where $\mathbf{T}'[u,v] = (\mathsf{IDX}[u,v] \lll z) + \sum_{j=1}^{L} \mathbf{M}^{(j)}[u,v] + e_{u,v}$. The random mask $\mathbf{M}^{(j)}$ generated by each server $\mathcal{P}_j$ is to hide the plaintext data $(\mathsf{IDX}[u,v] \lll z)$ when the servers remove the current encryption by adding EIDX with $\sum_{j=1}^{L} \mathbf{T}_1^{(j)}$ to obtain $\mathbf{T}'$. By clearing z lower bits of each $\mathbf{T}'[u,v]$, the error part $e_{u,v}$ can be removed, and the servers now hold the masked plaintext value $\hat{\mathbf{T}}[u,v]$ (step 5(a).ii). To retrieve the final EIDX'_w encrypted by the new secret keys, each server $\mathcal{P}_i$ computes $\mathsf{EIDX}'_w[u,v]$ based on $\hat{\mathbf{T}}[u,v]$ and $\sum_{j=1}^{L} \mathbf{T}_2^{(j)}[u,v]$ (step 5(a).iii). The value $\mathsf{max}_e = L$ is the max error when using LWR-based KH-PRF. It is necessary for decryption in keyword search later. Finally, all servers hold the same updated EIDX'_w, which is encrypted with the new column keys.

4.4 Document Update

MUSES supports document update as other bitmap-based dynamic encrypted search schemes (e.g., [27, 45]). We present the update procedure of MUSES in Figure 5. Given an updated document with identifier u and a set of its keywords $\mathcal{V}_u$, the writer parses KH-PRF keys $\mathbf{r}_{w,v}$, for $v \in [m]$, from its private token PTkn_w (step 1). The writer computes the new BF representation $\mathbf{u} \in \{0,1\}^m$ of the updated document with input keywords $\mathcal{V}_u$ (steps 2–3). The writer encrypts $\mathbf{u}$ with KH-PRF keys and the incremented counter value as $\mathbf{u}'[v] \leftarrow \mathbf{u}[v] + F^*(\mathbf{r}_v, u \,||\, (\mathsf{st}_{w,u}+1)) \pmod p$, for each $v \in [m]$ (step 4). Finally, the writer sends $\mathfrak{u} = (w, u, \mathbf{u}')$ as the update token to the servers to update its search index accordingly as $\mathsf{EIDX}'_w[u, *] \leftarrow \mathbf{u}'$ and $\mathsf{st}'_{w,u} \leftarrow \mathsf{st}_{w,u} + 1$ (steps 6–7).

5 Analysis

Complexity. We analyze the online asymptotic cost of MUSES. We consider the number of servers (L) and BF parameters (m, K) as small constants. Let N be the number of documents. To search for a keyword kw in a writer's database, the reader creates a query of size $O(K \cdot \lambda \cdot \tau) = O(\lambda\tau)$, where $\tau = O(\log m)$ for $L = 2$, and $\tau = O(\sqrt{m})$ for $L \geq 3$. For each writer in $\mathcal{W}'$, the reader sends shares of KH-PRF keys to L servers, which costs $O(L \cdot K \cdot n \cdot \log q) = O(\lambda)$ in total (as $n, q = O(\lambda)$ are the LWR parameters of KH-PRF). Let n_s be the bound on the size of the search output. For oblivious padding, the reader receives secret shares of the count from servers, then creates secret shares of padding values with communication and computation costs are $O(L \cdot n_s) = O(n_s)$. To obtain the search result, the reader receives PRP seeds from $L-1$ servers, and shuffled output from $\mathcal{P}_L$, then re-generates the permutations $\pi^{(1)}, \ldots, \pi^{(L-1)}$, and reverses permutations to obtain the final search output, which incurs $O((L-1)\lambda + n_s) = O(\lambda + n_s)$ communication and $O((L-1) \cdot N) = O(N)$ computation cost. The overall reader's bandwidth cost is $O(\lambda\tau + |\mathcal{W}'|(\lambda + n_s))$.

For keyword search, each server incurs $(K \cdot N \cdot m) = O(N \cdot m)$ modulo additions and multiplications for retrieval. Each server performs $O(K \cdot N) = O(N)$ additions for KH-PRF evaluation, $O(N)$ additions and circular shift operations for oblivious counting, and $O(N + n_s)$ additions for oblivious shuffle. The overall server computation cost per search on the writer set $\mathcal{W}'$ is $O(|\mathcal{W}'| \cdot (N \cdot m + N + n_s)) = O(|\mathcal{W}'| \cdot N \cdot m)$.

To update a document, the writer creates a new BF representation of size $O(m)$ and re-encrypts it. Thus, the total writer's bandwidth cost and computation cost per document update are both $O(m)$. The server does not incur any computation other than replacing the writer's components (e.g., a row in the search index and a state value).

For permission revocation, the writer's bandwidth and computation cost are similar to the corresponding overhead in document update, which is $O(m)$ for both. Since the servers are responsible for updating the encrypted search index with the new secret keys on behalf of the writer, the computation and inter-server communication costs are $O(N \cdot m)$.

For storage, the reader and each writer store a private/secret key of size $O(\lambda)$. Although the index is encrypted by $O(m)$ KH-PRF keys, the writer does not need to store these keys separately for update/revocation as they can be regenerated from a (master) secret key using a key derivation function. The update state st is public and, therefore, can be maintained at the server and retrieved when needed. For each writer, the servers store an index of size $O(\log p \cdot N \cdot m) = O(N \cdot m)$, a state st of size $O(\lambda \cdot N)$, shared tokens STkn of size $O(m \cdot n \cdot \log q) = O(m \cdot \lambda)$. The total server cost is $O(n_w \cdot N \cdot m + n_w \cdot \lambda \cdot N + n_w \cdot m \cdot \lambda)$, where n_w is the number of writers.

Security. We state the security of MUSES as follows.

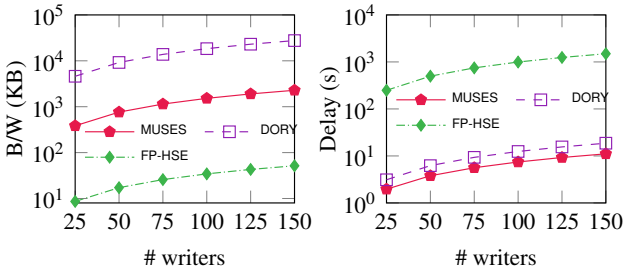
Theorem 1. *Assuming that the adversary corrupts at most $L-1$ out of the L servers and some writers, MUSES hides all pattern leakages during search, achieves $\mathcal{L}_{\mathcal{H}}$-adaptive security and forward and backward privacy, where $\mathcal{L}_{\mathcal{H}}^{\mathsf{Setup}}(1^\lambda) = \{w, N, m\}_{w \in [n_w]}$, $\mathcal{L}_{\mathcal{H}}^{\mathsf{CorruptWriter}}(w) = \{\mathsf{UpdateBy}(w)\}$, $\mathcal{L}_{\mathcal{H}}^{\mathsf{Search}}(\mathsf{kw}, \mathcal{W}') = \{\emptyset\}$, $\mathcal{L}_{\mathcal{H}}^{\mathsf{Update}}(w, u, \mathcal{V}_u) = \{w, \mathsf{up}(u)\}$, and $\mathcal{L}_{\mathcal{H}}^{\mathsf{Revoke}}(w) = \{w\}$, where $\mathcal{W}'$ is a writer subset.*

We present the proof in our full version [57].

6 Experimental Evaluation

Implementation. We fully implemented all our proposed techniques including MUSES, Π_{LOC} and Π_{LOS} in `C++` consisting of approximately 2,500 lines of code. We used standard cryptographic libraries, including `OpenSSL` [1] for IND-CPA encryption and hash functions, `libsecp256k1` [80] for public-key encryption in our scheme, and `EMP-Toolkit` [78] for IKNP OT protocol. We implemented KH-PRF from scratch. We used `libzeromq` [2] for network communication between servers and client. Our implementation is available and ready for public release. Our source code is available at: https://github.com/vt-asaplab/MUSES.

Hardware and network. We used EC2 `r5n.4xlarge` instances with 8-core Intel Xeon Platinum 8375C CPU @ 2.90 GHz and 128 GB memory as servers. For the user, we used a laptop with an Intel i7-6820HQ CPU @ 2.7 GHz and 16 GB RAM. The bandwidth between servers is 3 Gbps and the client bandwidth is 20 Mbps with 10ms RTT.



Dataset. We used the Enron email dataset [3] which includes about 500K emails of 150 employees. We extracted unique keywords using the standard tokenization method as described in [27]. Each email has an average of 73.18 keywords. The average number of keywords in each writer database is 11,017.

Counterparts and parameters selection. We compared MUSES with the state-of-the-art schemes including FP-HSE [76] and DORY [27]. We selected their parameters as follows.

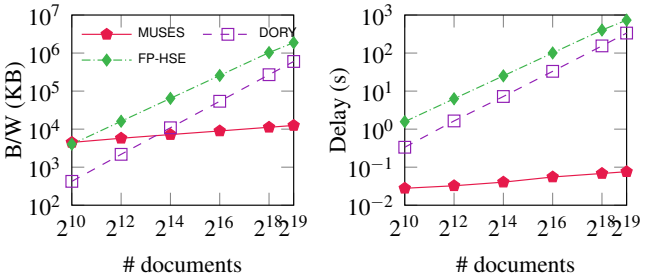
- **MUSES**: For KH-PRF, we selected $q = 2^{13}$, $p = 2^{10}$, $n = 256, l = 2$ as suggested in [31] for secure LWR with 126-bit security, where each KH-PRF key is of 1 KB. We used SHA-256 for the hash function. We used 256-bit keys for IND-CPA encryption and PRF/PRG seeds. Each folder in the dataset is considered as a writer. We created a reader that can perform a search over all databases for experiments. To cover the largest folder in the dataset which contains 28,229 documents, we let $N = 2^{15}$ be the bound on the number of documents. We chose BF parameters such that $N \times \text{FP rate} < 1$. For $K = 7$, we chose $m = 2000$ to achieve FP rate $\approx 3e^{-5}$. To evaluate the permission revocation, we used a varied number of documents N from 2^{10} to $2^{19}(\approx 500K)$ with the corresponding m from 1120 to 3120 (with $K = 7$) to achieve a low FP rate.

- **FP-HSE** [76]: We selected the original parameters with a 96-bit security level, where PRFs and keyed hash functions are instantiated with `HMAC-SHA-256`, and `MNT224` curve for pairings. Each folder in the dataset is a separate writer.

- **DORY** [27]. We run experiments with DORY in the semi-honest setting similar to our MUSES and FP-HSE. We configured BF parameters of DORY similar to our scheme as DORY uses DPF-based PIR scheme for oblivious search, and 256-bit keys for IND-CPA encryption, and PRG seeds.

(a) Reader's bandwidth **(b)** E2E delay

Figure 6: Keyword search performance (log scale on y-axis).



6.1 Overall Results

6.1.1 Keyword search

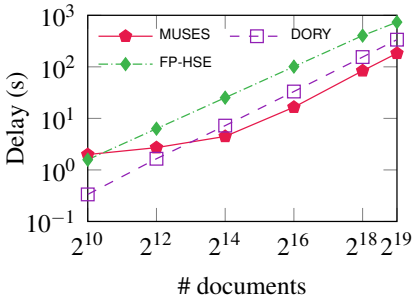
Reader's bandwidth. Figure 6a shows the search bandwidth between the reader and the servers of our MUSES, DORY and FP-HSE. In this experiment, we consider $L = 2$ servers and the search result size $n_s = 255$. The network overhead in MUSES increases from 0.4 MB to 2.2 MB, corresponding to the cases of 25 to 150 writers mostly due to transmitting KH-PRF key shares. For DORY, it incurs 4.6 MB–27.6 MB network overhead per search operation depending on the writer subset size, which is 11.9×–12.1× larger than the communication cost of MUSES. FP-HSE incurs the lowest bandwidth as the reader only sends a search token of 65 B to the server and receives the results. Although FP-HSE achieves the minimum bandwidth overhead among all schemes, it suffers from many vulnerabilities and leaks more information than the others.

Keyword search. Figure 6b illustrates the corresponding end-to-end delay in keyword search of our scheme under 2 servers and the search result size of 255, in comparison with DORY and FP-HSE. The latency of all schemes grows almost linearly to the number of writers. MUSES is about 126.8×–134.7× faster than FP-HSE, and 1.6×–1.7× faster than DORY. With 25 writers, MUSES takes approximately 2.0s to accomplish a search, and increases to about 11.1s for 150 writers. The overhead of FP-HSE mainly comes from pairing operations, in which decrypting each encrypted search token needs two pairing operations, while the overhead of our scheme mainly stems from KH-PRF evaluation. By contrast, the overhead of DORY is mostly due to network overhead.

Three factors contributing to the search delay include reader processing, communication latency, and server processing. Specifically, the reader processing is low, which only takes 13.6ms–69.4ms, while server processing and communication take 1.8s–10.1s and 0.2s–0.9s, respectively. Their corresponding portion in the total delay is 0.6%–0.7%, 90.9%–91.3%, and 8.0%–8.4% respectively.

(a) Writer's bandwidth **(b)** Writer's latency

Figure 7: Permission revocation performance (log scale on y-axis).



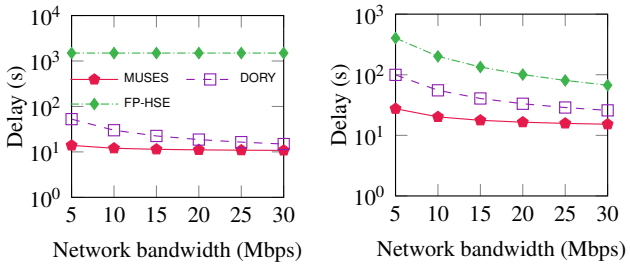


Figure 8: E2E permission revocation delay (log scale on y-axis).

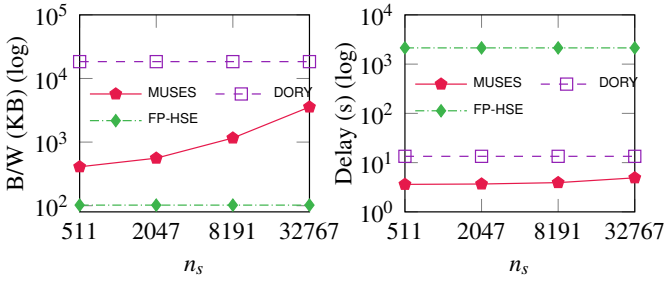
6.1.2 Permission revocation

We evaluate the performance of MUSES when a writer wants to update secret column keys to revoke search permission of the reader on her database, and compare it with other schemes. For DORY and FP-HSE, as these schemes do not offer permission revocation function for a user/writer's database by offloading re-encrypting work to the servers as ours, we measure their latency to re-encrypt a user/writer's search index on the user/writer side. For FP-HSE, the writer only re-encrypts her underlying SSE with another secret key and ignores updating encrypted search tokens to stop sharing her database.

Writer's bandwidth. Figure 7a demonstrates the bandwidth cost of all schemes in permission revocation. The bandwidth overhead of MUSES grows slightly when increasing BF size (from 1120 to 3120 corresponding to the cases from 1K to 500K documents) as the writer just needs to transmit secret-shares of KH-PRF keys, together with updated shared tokens while DORY and FP-HSE requires downloading and uploading the whole search index. MUSES incurs 4.4 MB–12.1 MB communication overhead, while DORY produces 0.4 MB–587.0 MB, which is 1.5×–48.2× larger than MUSES starting from 2^{14} documents. The network overhead of FP-HSE is 3.9 MB–1833.4 MB, which is 2.8×–150.4× larger than our MUSES. Its cost is high due to the transmission of the search index back and forth similar to DORY.

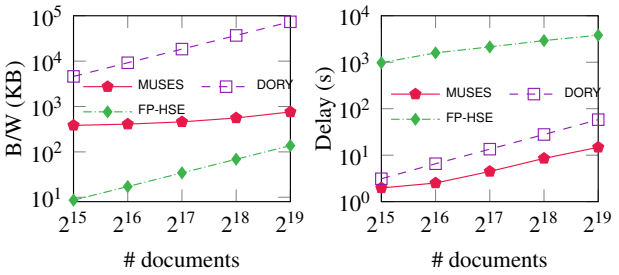
Writer's latency. Figure 7b presents the computing time on the writer side to re-encrypt her search index. MUSES requires the minimum amount of time on the writer side, which is 27.9ms–76.1ms for the database sizes increasing from 1K to 500K documents, where most overhead is for deriving the current and new secret column keys. By contrast, a user in DORY takes 0.3s–335.5s to download, re-encrypt the search index with a new secret key and upload it again, which is 11.9×–4407.6× larger than the computing time of the writer in MUSES. FP-HSE incurs longer latency on the writer side due to its larger search index size, where it takes 1.6s–734.3s, corresponding to 56.4×–9647.4× longer than our MUSES.



(a) Keyword search **(b)** Permission revocation

Figure 9: E2E delay w/ varying bandwidths (log scale on y-axis).

Permission revocation. Figure 8 illustrates the end-to-end delay to finish re-encryption of the search index of FP-HSE, DORY, and MUSES. It is noticeable that when increasing the number of documents, the end-to-end delay of all schemes grows linearly but by varying degrees. MUSES takes about 2.0s (resp. 183.1s) to update a search index including keyword representations of 1K (resp. 500K) documents. For DORY, its latency is around 0.3s and 336.6s, respectively, which is 1.6×–2.0× slower than MUSES starting from 2^{14} documents. FP-HSE incurs the largest overhead to re-encrypt the search index due to its larger index size. As a result, it takes 1.6s–736.1s, which is 2.3×–6.1× larger than MUSES.

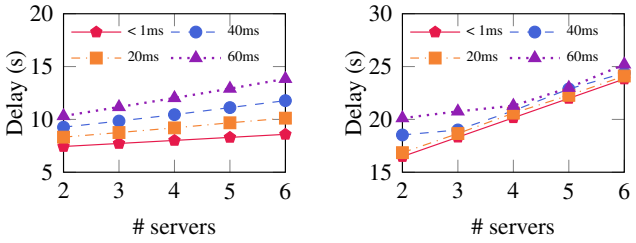


6.1.3 Performance under varied parameters

Varying network bandwidths. Figure 9 demonstrates the end-to-end latency of keyword search and permission revocation of different schemes w.r.t various connection bandwidths. The search delay (Figure 9a) is measured in the case of 150 writers and the permission revocation delay (Figure 9b) is measured in the typical case of $2^{16} \approx 64$ K documents. As search operations of FP-HSE incur the lowest communication overhead, its performance is barely affected by varying network bandwidths, where it takes around 1.5×10^3s to finish a search operation. The end-to-end delay of MUSES slightly decreases when increasing the network bandwidth, where it takes 13.9s with 5 Mbps, and decreases to 10.8s with 30 Mbps, while DORY takes 52.6s and 14.9s, respectively. In permission revocation, since both DORY and FP-HSE need to download and upload the search index again, their latency decreases significantly when the network bandwidth is higher, in which DORY takes 99.6s–25.8s, and FP-HSE takes 402.6s–67.2s, corresponding to the bandwidths 5 Mbps–30 Mbps. By contrast, MUSES incurs a delay of 27.5s–15.3s to finish a permis-

(a) Reader's bandwidth **(b)** E2E delay

Figure 10: Keyword search performance with varying n_s.



(a) Reader's bandwidth **(b)** E2E delay

Figure 11: Keyword search performance w/ varying database sizes.

sion revocation, where most communication overhead is for transmitting secret shares of KH-PRF keys to the servers.

Varying search result sizes. We present the performance of MUSES and other schemes with varying search result sizes n_s (from 511 to 32767) in Figure 10. We consider 25 writers each having $N = 2^{17}$ documents and the keyword universe of 94,549 (with the corresponding BF parameter $m = 2520$). The bandwidth of MUSES increases from 408.9 KB to 3558.9 KB, respectively, which is 5.2×–45.0× smaller than DORY (Figure 10a). The corresponding delay increases from 3.6s to 4.9s, which is 2.7×–3.7× and 435.2×–590.3× faster than DORY and FP-HSE, respectively (Figure 10b).

Varying database sizes. We present the search performance of MUSES and other schemes with varying dataset sizes N (from 2^{15} to 2^{19} documents per writer) in Figure 11. In this experiment, we fix the number of writers to be 25. When increasing the number of documents in the dataset, it also increases the size of the keyword universe (from 43,209 to 168,770) and the search result size (from 255 to 4095). As shown in Figure 11a, the bandwidth cost of MUSES slightly increases from 0.4 MB to 0.7 MB while DORY and FP-HSE increase from 4.5 MB to 71.9 MB and 8.6 KB–137.6 KB, respectively. That means MUSES incurs 12.0×–97.0× smaller bandwidth overhead than DORY and 5.5× larger than FP-HSE for 2^{19} documents. Figure 11b presents the corresponding search delay of MUSES. Specifically, MUSES takes about 2.0s–14.8s while DORY takes 3.1s–58.1s and FP-HSE takes 976.1s–3812.6s. Thus, MUSES is 1.6×–3.9× and 257.9×–631.8× faster than DORY and FP-HSE, respectively.

(a) Keyword search **(b)** Permission revocation

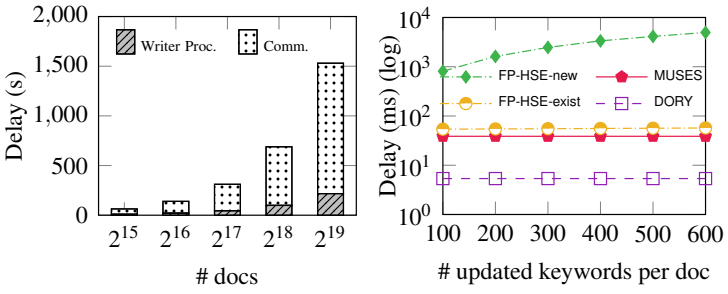


Figure 12: MUSES latency with varying numbers of servers.

Varying numbers of servers. To achieve a higher privacy threshold, more servers can be added to the system. Figure 12 illustrates the end-to-end delay of keyword search and permission revocation on 2^{16} documents of 100 writers with varying numbers of servers (from 2 to 6) and inter-server network latencies (from 1ms to 60ms). In MUSES, adding more servers does not significantly increase the online computation work of each server. Instead, it requires more communication rounds between the servers to forward and open the shuffled search output. In addition, a small amount of extra overhead in search operations is put on the reader to create and send more DPF keys, secret shares of KH-PRF keys, as well as padding values when there are more servers in the system. The server network latency does not significantly impact the search delay. As shown in Figure 12a, searching takes 7.4s-8.6s under 1ms network latency while it takes 10.3s-13.8s under 60ms latency. In permission revocation, having more servers increases network traffic of the system because the servers need to broadcast their components for updating encrypted index to each other. Also, the writer has to send the secret-shares of the previous and fresh KH-PRF keys to all servers. As shown in Figure 12b, revoking permission takes 16.5s-23.8s under 1ms latency (with 2 to 6 servers), while it takes 20.1s-25.2s under 60ms latency.

6.1.4 Setup Time and Document Update

Figure 13a shows the setup time of MUSES including writer processing time and communication delay. Specifically, the writer takes 9.0s–217.3s to create an encrypted index and its auxiliary components for a database of 2^{15}–2^{19} documents. Transmitting all these components to the servers takes 54.3s–1312.9s under network bandwidth 20 Mbps.

Figure 13b presents the update delay of MUSES, DORY, and FP-HSE. We measure the latency of FP-HSE in document update in two cases. The worst case is when all keywords of the updated document are new (FP-HSE-new), and the best case is when all keywords have appeared (FP-HSE-exist). For each new keyword, FP-HSE-new needs two public-key pairings to generate a new search token, thus its cost is linear to the number of new keywords, while DORY, FP-HSE-exist and our scheme remain nearly unchanged. MUSES takes about

(a) Setup time **(b)** Document update

Figure 13: E2E setup time and document update delay

38.7ms to update the index per document update, while FP-HSE-new takes 0.8s–4.9s for the cases increasing from 100 to 600 keywords, and DORY takes about 5.4ms. The update latency of FP-HSE-exist slightly grows from 53.9ms to 57.1ms as it does not incur pairing operations.

6.1.5 Storage overhead

In MUSES, each writer stores a 256-bit secret key and the reader stores a 256-bit private key. As MUSES utilizes LWR-based KH-PRF in [11], each bit of the search index is encrypted to a 10-bit ciphertext in $\mathbb{Z}_p$ where $p = 2^{10}$. Each column of the index is encrypted by a separate key of size 1 KB. Thus, for a database with 2^{15} documents, the size of EIDX, STkn, and st is approximately 78.1 MB, 2.05 MB, and 0.25 MB, respectively. In total, the server storage cost for each writer is approximately 80.4 MB, which goes up to 12.1 GB for 150 writers. For the largest database in our experiment (i.e., 2^{19} documents), the server storage cost per writer is approximately 2.0 GB, which goes up to 48.9 GB for 25 writers. Note that in MUSES, the storage cost depends on the number of documents N and the number of keywords per document, but not search result size n_s.

7 Related Work

SSE. Song et al. [69] were the first to propose and formalize SE. Secure SSE schemes permit encrypted search on encrypted data via an encrypted index with improved security (e.g., forward privacy [12, 55], backward privacy [13, 40, 72, 73]), efficiency (e.g., [19, 29]), query functionality (e.g., [52]) and/or updatability (e.g., [18, 42, 48, 49, 71]). Most SSE schemes are vulnerable to statistical inference attacks [16, 50, 66, 67, 81], some of which exploit fundamental leakage in SSE (e.g., search pattern [54, 59, 65], access pattern [46], volume pattern [56], file-injection [85, 86]). Recently, Xu et al. [81] showed that the desirable security properties of SSE (e.g., forward/backward privacy) may not be sufficient to prevent devastating leakage-abuse attacks.

While SSE mainly supports single-user queries, several attempts (e.g., [20, 51] have been proposed to enable multi-user functionalities. Chamani et al. [20] proposed a multi-user SSE scheme that supports data and query policy control along with verifiability using blockchain. The scheme in [51] permits a reader to query encrypted data without interacting with the data owner using some helper users. Some other schemes permit multi-user functionalities by requiring all users to be trusted [27] or using costly cryptographic protocols such as multi-party computation [35, 47]. The scheme in [47] uses two non-colluding custodians executing garbled circuit to generate search tokens for readers. Its search follows standard SSE so it leaks pattern information (e.g., search, volume, result). Leakage-suppression technique [39] can prevent some pattern leakage; however, it fits more in the single-user setting due to the costly rebuild process. When using it in multi-user settings (separate reader and writers), the writer needs to keep track of the reader's activities to rebuild its index accordingly for security. Multi-key SSE [51, 79] provides decentralization between users but does not prevent pattern leakages.

PKSE. PKSE schemes such as [7, 10, 32, 83] can support multi-writer setting, but they do not adapt to forward privacy, which might lead to injection attacks [86]. Although hybrid-based model [76] can ensure forward privacy, it requires each writer to be stateful and present to rebuild encrypted tokens periodically. In addition, most PKSE systems are vulnerable to KGA. Some PKSE schemes can prevent KGA, but they require a dedicated trusted third party [53, 58, 77].

Oblivious platforms. Some oblivious storage platforms employ ORAM and/or PIR primitives to hide search patterns during data operations (e.g., data sharing/access [22–24, 27, 60, 62], search [30, 35, 38, 45, 64]. However, these schemes incur a large communication overhead, which costs $O(N)$ with N is the number of documents in the collection. Differential Privacy-based technique [68] can obfuscate search access patterns, but it incurs high computation and latency.

Hardware-assisted SE. Trusted hardware (e.g., Intel SGX [25]) was used to build practical oblivious platforms with diverse functionalities (e.g., keyword search [37, 44, 63], SQL queries [34, 36], data storage [26, 43], oblivious memory [74]). These platforms require a security assumption on the hardware (e.g., isolation, tamper-free, side-channel resistance).

A Query-Independent Preprocessing

We analyze preprocessing cost of the search protocol in MUSES. The overhead mostly comes from executing Share Translation protocol (ST) between two servers: $(\mathbf{\Delta}; \mathbf{a}, \mathbf{b}) \leftarrow \mathsf{TSS.ShrTrns}(\pi; 1^\lambda)$, which lets one server obtain $\mathbf{a}, \mathbf{b}$, and the other server learn the corresponding translation function $\mathbf{\Delta} \leftarrow \mathbf{b} - \pi(\mathbf{a})$ without revealing the permutation π. As the input/output of the preprocessing is independent of search queries, the precomputed materials can be stored in a temporary memory and used when a search happens. The communication and computation complexity of the primitive Share Translation protocol in [21] is $O(n \log n)$ and $O(n^2)$, respectively, where n is the number of elements. We analyze the communication and computation cost of preprocessing for a search query happening on a writer subset $\mathcal{W}'$ as follows, in which the number of servers L is a small constant and omitted. As the preprocessing of Π_{LOS} executes ST $|\mathcal{W}'|$ times w.r.t. the number of elements $N + n_s$ (the total bound on the number of documents and padded values), the communication and computation cost for preprocessing of Π_{LOS} is $O(|\mathcal{W}'|(N+n_s)\log(N+n_s))$ and $O(|\mathcal{W}'|(N+n_s)^2)$, respectively. Similarly, the preprocessing of Π_{LOC} executes ST $|\mathcal{W}'|N$ times w.r.t. the number of elements $K+1$, where K is a BF parameter, the communication and computation cost for preprocessing of Π_{LOC} is $O(|\mathcal{W}'|N(K+1)\log(K+1))$ and $O(|\mathcal{W}'|N(K+1)^2)$, respectively.

B Preventing rollback attacks

In the "rollback" attacks, the malicious server can omit some writer's update, and present the outdated data to the reader. We present a (simple) extension to our semi-honest MUSES construction to prevent such attacks. The high-level idea is to employ additional servers and perform "pair-wise" checking of the responses from different subsets of servers in processing the reader's request. For simplicity, assume our original MUSES scheme uses two servers. We add one more server to detect rollback attacks as follows. Let $\mathcal{W}'$ be the writer subset and kw is the keyword that the reader would like to search. For each pair of servers $\mathcal{P}_i, \mathcal{P}_j \in \{\mathcal{P}_1, \mathcal{P}_2, \mathcal{P}_3\}$, the reader executes the following:

- $\mathfrak{s}_{ij} = (\mathfrak{s}_i, \mathfrak{s}_j) \leftarrow \mathsf{SearchToken}(\mathsf{kw}, \mathcal{W}')$
- $O_{ij} \leftarrow \mathsf{Search}(\mathfrak{s}_{ij}, \mathsf{sk}, \{(\mathsf{EIDX}_w, \mathsf{STkn}_w, \mathsf{st}_w)\}_{w \in [n_w]})$

WLOG, assume $(\mathcal{P}_2, \mathcal{P}_3)$ are honest and $\mathcal{P}_1$ is corrupt, in which it uses a mutated search index $\mathsf{EIDX}'_w = \mathsf{EIDX}_w + \varepsilon$ (compared with EIDX_w in $\mathcal{P}_2$ and $\mathcal{P}_3$). As DPF and KH-PRF are computed on EIDX'_w, there will be an error in $\mathcal{P}_1$'s computation, making the responses $O_{12}, O_{13} \neq O_{23}$.

By checking the consistency of O_{12}, O_{13}, and O_{23}, the reader can tell whether there is a rollback attack happens, and abort the protocol accordingly. Note that this strategy can only detect the rollback attack, a special case of malicious behavior on integrity, but is unable to tell which server is corrupted. Meanwhile, a malicious adversary can deviate from the protocol to not only compromise the integrity but also the privacy of the reader's query. That requires a more comprehensive investigation to completely achieve malicious security, which we leave as our future work.

Query Recovery from Easy to Hard: Jigsaw Attack against SSE

Abstract

Searchable symmetric encryption schemes often unintentionally disclose certain sensitive information, such as access, volume, and search patterns. Attackers can exploit such leakages and other available knowledge related to the user's database to recover queries. We find that the effectiveness of query recovery attacks depends on the volume/frequency distribution of keywords. Queries containing keywords with high volumes/frequencies are more susceptible to recovery, even when countermeasures are implemented. Attackers can also effectively leverage these "special" queries to recover all others.

By exploiting the above finding, we propose a Jigsaw attack that begins by accurately identifying and recovering those distinctive queries. Leveraging the volume, frequency, and co-occurrence information, our attack achieves 90% accuracy in three tested datasets, which is comparable to previous attacks (Oya et al., USENIX' 22 and Damie et al., USENIX' 21). With the same runtime, our attack demonstrates an advantage over the attack proposed by Oya et al (approximately 15% more accuracy when the keyword universe size is 15k). Furthermore, our proposed attack outperforms existing attacks against widely studied countermeasures, achieving roughly 60% and 85% accuracy against the padding and the obfuscation, respectively. In this context, with a large keyword universe ($\geq$3k), it surpasses current state-of-the-art attacks by more than 20%.

1 Introduction

Searchable Symmetric Encryption (SSE) [2, 4, 7, 8, 12, 23, 33, 38, 41, 48] enables users to securely search encrypted databases stored on remote servers. An SSE scheme typically consists of setup and search protocols. In the setup, the user sends encrypted indexes of the documents to the server. In the search, the user generates a search token and sends it to the server who then returns the matched documents. The search process does not reveal any confidential information about the documents or the user's search query, except for the volume pattern (also known as the response length) and the access pattern, which reveal the number of matched documents and their identities, respectively. Additionally, the server may also know the search pattern, which indicates whether two queries are identical by comparing their search tokens or access patterns.

Passive attacks on SSE can exploit the above leakages and some prior knowledge to recover queries. According to the prior knowledge given to the attacker, we categorize two main attacks in Table 1: 1) **known-data attacks** [1, 5, 22, 25, 30, 35, 46], which assume that the attacker has access to partial/full plain texts of the documents in the user's dataset; and 2) **similar-data attacks** [13, 26, 31, 32, 35], which enable the attacker to obtain a similar document set or estimations on the users' query distribution. Unlike known-data attacks, that require the plain texts, similar data attacks can recover queries by exploiting statistical information from a similar dataset, such as query frequency and the probability of two keywords appearing in the same document. Without relying on the "strong assumption" that the attacker must be provided plain texts of documents, similar-data attacks are relatively practical to deploy and bypass countermeasures. Existing works [31,32] have shown that similar-data attacks can bypass some defenses employing pattern randomization techniques [10, 36]. We note that SSE is also vulnerable to active attacks [1, 34, 50, 51] leveraging file injection to recover queries, which is orthogonal to this work.

Damie et al. [13] explored an intriguing phenomenon across various query distributions, indicating the correlation between accuracy and query volume (i.e., the number of documents containing a particular keyword). Oya et al. [31] demonstrated that high-frequency queries (i.e., the frequency with which the user queries a specific keyword) give a greater probability of being successfully recovered in their proposed attack. We note that a similar notice was given in [1] that the effectiveness of known-data attacks is also influenced by the volume of queries, wherein high-volume queries are easily recoverable. Building upon the aforementioned interesting

Table 1: Comparisons of existing passive attacks[1].

Attack	Leakage	Known prior knowledge		Similar prior knowledge		Accuracy	Padding[2]	Obfuscation[3]
		Document	Query	Document	Frequency			
IKK [22]	ap	●	◐	○	○	∼ 80%	-	-
Count [5]	ap, vp	●	○	○	○	∼ 90%	-	-
SubgraphID [1]	ap	◐	○	○	○	∼ 90%	-	-
LEAP [30]	ap	◐	○	○	○	∼ 100%	-	-
RSA [13]	ap	○	◐	●	○	∼ 85%	< 20%	< 20%
Freq [26]	sp	○	○	○	●	∼ 20%	∼ 20%	∼ 20%
SAP [31]	vp,sp	○	○	●	●	∼ 50%	∼ 30%	∼ 30%
GraphM [35]	ap	○	○	●	○	∼ 70%	< 20%	< 20%
IHOP [32]	sp,ap	○	○	●	●	∼ 90%	< 20%	∼ 85%
Jigsaw (Ours)[4]	vp,sp,ap	○	○	●	◐	∼ 90%	∼ 60%	∼ 85%

[1] "ap" denotes the access pattern, "vp" denotes the volume pattern, and "sp" denotes the search pattern. The "●" indicates that the attack needs nearly all known data or strongly relies on the corresponding similar data. The "◐" indicates that the attack needs partial known data or not particularly relies on similar data. The "○" means that the attack does not need any known data or similar data. The first four attacks are known-data attacks, and the last five are similar-data attacks. The RSA mainly relies on similar data but needs a few known queries to start the attack. We do not present the performance of the first four attacks against padding and obfuscation (denoting "-") since we mainly focus on similar-data attacks.

[2] The performance against the padding of CGPR [5] with $k = 1{,}000$ on Enron. We utilize an adaptation (Appendix B) for Jigsaw. Padding is claimed to mitigate the listed known-data attacks effectively [1, 30].

[3] The performance against the obfuscation of CLRZ [10] with TPR= 0.999, FPR= 0.05 on Enron. Note adaptations (Appendix B) are used for IHOP and Jigsaw.

[4] Our attack can reach 90% accuracy even if a defense hides the sp, and thus one may consider the sp an optional attack advantage.

hints, we conduct experiments that confirm the influence of volume and/or frequency on the performance of attacks. Moreover, we discover that leveraging this knowledge enables us to enhance the effectiveness of similar-data attacks. We provide two crucial observations regarding the query recovery.

Observation 1. *Queries containing keywords with a high volume/frequency are much easier to recover than others.*

In a database, the volume of keywords follows Zipf's law [52], which states that the volume of a keyword ranks nth in a sorted list (sorted by volume) is inversely proportional to n. We also observe that the frequency of keywords follows almost the same law. We confirm the above phenomenons by showing the concrete results in three datasets (See Section 4.1 and Appendix A for more details). Keywords with higher volume or frequency display larger disparities, which consequently makes it easier for attackers to recover those queries.

Observation 2. *By revealing the queries from observation 1, the attacker can gain advantage to retrieve further queries (even all queries).*

In [13], Damie et al. proposed an efficient similar-data attack (i.e. refined score attack, RSA) that achieves around 85% accuracy in recovering all queries by utilizing only 10 known queries. They also show that when utilizing known queries with a higher volume, the attack's accuracy increases and becomes more stable.

Challenges. Observation 1 does not explicitly facilitate a way to identify and recover those distinctive queries as they consistently intermingle with others. To the best of our knowledge, there is no attack that first focuses on filtering those distinctive queries, thereby allowing for the recovery of queries from easy to hard. Setting a start with immediately recovering all queries based on known or recovered queries is not trivial and could be defended against by countermeasures. For example, previous work [13] cannot work effectively at the outset without any proper known query set. This also implicitly explains why it achieves low accuracy under padding [5] and obfuscation [10].

Contributions. We propose a new effective similar-data attack called Jigsaw providing a "granular and incremental" strategy, which comprises three core modules. 1) The first module uses the keyword's volume and frequency information to locate and recover the most distinctive queries. 2) The second module further refines the recovered queries by matching the queries with the keywords according to the co-occurrence matrix. This module eliminates those incorrect query recoveries from the first module and tries to achieve near-perfect accuracy. 3) The last module is to recover the remaining queries using the outputs from the second module. We generate scores for query-keyword combinations using the co-occurrence matrix, volume, and frequency information. We optimize the score for queries to obtain matches between queries and keywords. We also provide comprehensive evaluations of Jigsaw. Concretely, our contributions are outlined as follows.

• *Localization and recovery of distinctive queries.* We measure the distinguishability of each query and use the volume and frequency to recover the most distinguishable queries (the first module of Jigsaw). For queries with a high volume and frequency (e.g., the top 10% of queries in volume and

frequency in Enron [44], Lucene [15], and Wikipedia [16]), we can obtain an accuracy $> 70\%$.

• *Precise verification of recovered queries.* We make a further refinement by filtering out those queries that do not align well with the co-occurrence information (the second module). We here obtain nearly 100% accuracy at the expense of recovering a smaller number of queries (about a dozen queries in Enron and 50 queries in Lucene and Wikipedia).

• *Accurate recovery of all queries.* We at last utilize the recovered queries to recover all queries with about 95% accuracy (the last module). Even if the frequency information is not given, we can still capture roughly 90% accuracy. We state that Jigsaw exhibits durability, as it can hold its effectiveness (dropping $< 5\%$ of accuracy) in the future period even by exploiting the auxiliary frequency information that was leaked long ago (e.g., 30 months in Wikipedia and 150 weeks in Enron and Lucene).

• *Comprehensive evaluations and comparisons.* We present empirical experiments and comparisons with the state of art similar-data attacks (including Graphm [35], SAP [31], RSA [13], and IHOP [32]) to highlight the performance of Jigsaw. Our attack provides $> 90\%$ accuracy surpassing the Graphm and SAP attacks, similar to the RSA and IHOP. Within the same runtime, Jigsaw exhibits about 15% more accuracy than IHOP when the keyword universe is 15k. Also, Jigsaw outperforms them when countering the defenses (padding [5] and obfuscation [10]). It maintains $> 60\%$ and $> 85\%$ accuracy against the padding (in most cases) and obfuscation and takes the lead in accuracy in most cases.

2 Related Work

Except for the SSE schemes [14, 17, 45] based on expensive primitives, such as ORAM and PIR, most SSE schemes leak the access pattern, search, volume, and response size pattern (i.e., the size of each document). With some prior knowledge, passive attacks abuse the above leakages to recover users' queries. These attacks can be categorized as similar-data attacks [13, 26, 31, 32, 35] and known-data attacks [1, 5, 22, 25, 30, 35, 46].

Similar-data attacks. Liu et al. [26] proposed the Freq attack that exploits the search pattern and the query frequency information to recover users' queries. Recently, Oya et al. [31] proposed the SAP attack, which utilizes the search and volume pattern to get the frequency and volume of each query. However, Freq and SAP strongly rely on the frequency information and achieve a relatively low accuracy. Attacks that abuse the access pattern have higher accuracy. Pouliot et al. [35] proposed the GraphM attack that formalizes the query recovery as a weighted graph match problem and solves it by PATH [49] or Umeyama [42] algorithm. Oya et al. [32] proposed the IHOP attack, which uses a co-occurrence matrix of queries and keywords, along with query frequency, to launch its attack. IHOP supposes that queries are correlated and follow a Markov process, allowing it even to threaten frequency-smoothing defenses such as PANCAKE [20]. Damie et al. [13] proposed the RSA, which starts with some known queries. Though providing an accuracy of about 85%, RSA still requires some known queries as a prerequisite. Without those, the attack will not work effectively.

Known-data attacks. Islam et al. [22] proposed the first known-data attack (IKK) with all documents and partial queries to recover queries. Cash et al. [5] proposed the Count attack that can recover most queries without known queries. In [1], Blackstone et al. proposed an attack that performs perfectly (accuracy approaching 100%) with fully known documents, but poorly (less than 10%) with a small portion of known documents. Ning et al. [30] proposed LEAP, which can recover half of all queries with 100% accuracy with only 1% of documents. These attacks are all dependent on known data information. However, the known data are hard to obtain, and the attacks are easy to prevent with countermeasures.

Countermeasures. To defend against leakage abuse attacks, many countermeasures [3, 5, 10, 14, 22, 43, 47] have been proposed. Among those, padding is one of the most commonly used methods. Cash et al. [5] first presented the padding strategy. The volume of each query is padded to the nearest multiple of an integer k. After that, Demertzis et al. [14] proposed SEAL, which pads the volume of each query to the nearest power of an integer x. The padded documents would add noise to the volume and access patterns, hampering attacks abusing those leakages. Several works also consider the keywords clustering [3, 43]. Each cluster contains no less than α keywords, and then each keyword is padded to the largest volume in the cluster.

Another countermeasure is obfuscation [10]. When querying for a keyword, if a document contains the keyword, the document will be returned with probability p (the true positive rate, TPR); otherwise, each document will be returned with probability q (the false positive rate, FPR). Shang et al. [36] proposed OSSE, which provides the same response effect and produces fresh obfuscation in each query.

3 SSE Scheme and Attack Model

We revisit the standard SSE [12], define the leakage function of queries, and describe the attacker's prior knowledge as the prerequisite of our attack. We put the summary of notations in the full version [29].

3.1 SSE

An SSE scheme [12] facilitates keyword searches over encrypted data, denoted as ED, while maintaining the confidentiality of the data and the keywords. The typical components of an SSE scheme encompass the setup, update, and query processes. Initially, the user possesses a dataset D, which

comprises a set of documents d identified by $id(d)$. Each document contains a list of keywords k. During the setup phase, the user can construct and encrypt an index, and then upload it along with the encrypted document set ED to the server. In the update, the user can dynamically update the index stored on the server. During the query process, to search a keyword k, the user generates a trapdoor $td(k)$ for the server. Eventually, the user retrieves the list $D(k)$, which is a list of $id(d)$ satisfying that k appears in d. We also denote the list $D(k)$ as $D(td(k))$ for convenience. We note that the user also needs to retrieve the encrypted documents according to the $id(d)$ and decrypt them to complete the search.

3.2 Leakages

An efficient SSE scheme typically leaks the volume pattern, the access pattern, and the search pattern of queries to the server and potential eavesdroppers. For a sequence of s queries $Td^s = [td(x_1), td(x_2), \ldots, td(x_s)]$, the leakages often used in attacks are summarized as follows.

• **Access pattern** is the family of functions $ap : ED \times Td^s \rightarrow AP^s$ where AP is a list $[D(x_1), D(x_2), \ldots, D(x_s)]$. For each query, the scheme leaks the identifiers of corresponding encrypted documents. This leakage happens in most SSE schemes [2, 4, 6, 9, 12, 24, 28, 39, 48] when the user retrieves the encrypted document. Some schemes use primitives such as ORAM [18] or PIR [11] to hide access pattern, but those primitives lead to expensive costs.

• **Volume pattern** is the family of functions $vp : ED \times Td^s \rightarrow VP^s$, where VP is a list $[|D(x_1)|, |D(x_2)|, \ldots, |D(x_s)|]$. For each query, the scheme leaks the number of documents returned by the server.

• **Search pattern** is the family of functions $sp : ED \times Td^s \rightarrow M^{s \times s}$, where $M^{s \times s}$ is a $s \times s$ binary matrix such that $M^{s \times s}[i, j] = 1$, if the underlying keywords of td_i and td_j are the same and otherwise $M^{s \times s}[i, j] = 0$. For any two queries $td(x_i), td(x_j) \in Td, i \neq j$, the attacker knows whether x_i equals x_j. While schemes may not directly reveal the search pattern from queries, repeated querying of the same keyword leads to the exposure of the same access pattern. Attackers can utilize this access pattern to infer whether two queries correspond to the same keyword [31].

3.3 Attackers

We respectively consider two kinds of attackers targeting the user's queries: honest but curious servers and eavesdroppers:

• An *honest but curious server* follows the SSE protocols but attempts to recover the users' queries by utilizing the leakage pattern and other prior knowledge, such as known data or similar data. The server also has access to all the encrypted documents.

• An *eavesdropper* who intercepts the traffic between the server and the user can observe the encrypted documents returned in each query and possess the same knowledge of leakages as the server, except for all the encrypted documents. With a similar dataset, the eavesdropper can also launch similar-data attacks.

Different from known-data attacks, the server could utilize outdated (obtained from the past) or leaked documents which are not necessarily included in the current user's dataset to launch similar-data attacks. Note the eavesdropper could also know some similar data in several scenarios by acting as a legal user. For instance, the eavesdropper may share the same email system (producing similar email data) with his colleagues. We state that both attackers can employ our Jigsaw attack by utilizing the following knowledge derived from leakage and similar data.

Attackers' knowledge derived from leakages. We use the leakages to derive the frequency, volume, and co-occurrence of queries. We assume the user issues s queries, denoted as Td^s, from which the attacker identifies l different queries by the search pattern. We denote the query list identified by the attacker as $Td_r = [td_1, td_2, \ldots, td_l]$, which does not contain repeated queries. The attacker can also observe the returned documents $[D(td_1), D(td_2), \ldots, D(td_l)]$. The server possesses knowledge of the total number of documents, denoted as $|D|$. While the eavesdropper, who can only observe the query traffic, does not know the total number of documents. We also use $|D|$ to represent the size of the document set observed by the eavesdropper. Then for each query td, we normalize the volume pattern of query denoted $v_{td} = |D(td)|/|D|$. For the query list Td_r, $V_r = [v_{td_1}, v_{td_2}, \ldots, v_{td_l}]$ is the vector of volume of all queries in Td_r. With the search pattern, the attacker acquires knowledge of the frequency at which a td appears in Td^s. We denote the frequency of td as $f_{td} = Count(td)/|Td^s|$, where $Count(td)$ computes the number of td in Td^s. For the query list Td_r, $F_r = [f_{td_1}, f_{td_2}, \ldots, f_{td_l}]$ is the vector of frequency of all queries in Td_r. Based on the access pattern, the attacker can construct a $l \times |D|$ matrix ID_r. $ID_r[i, j] = 1$, if the search result for td_i contains d_j, 0 otherwise. Then, the attacker can construct the $l \times l$ co-occurrence matrix $C_r = ID_r ID_r^\top / |D|$.

Attackers' knowledge derived from similar data. We assume the attacker knows a list of similar documents $D_s = [d_1, d_2, \ldots, d_k]$ and employs the same algorithm to extract keywords as the user. Actually, the attacker can easily obtain a similar keyword universe as the user's database with a small similar data [50]. We denote the keyword universe extracted by the attacker as $W_s = [w_1, w_2, \ldots, w_m]$. Then, the attacker can construct the volume $V_s = [v_{w_1}, v_{w_2}, \ldots, v_{w_m}]$, where $v_{w_i} = |D_s(w_i)|/|D_s|$ and the $D_s(w_i)$ is the documents in D_s which contain keyword w_i. The attacker also constructs ID_s from W_s and D_s in a similar manner as the construction of ID_r. Based on the ID_s, the attacker calculates the co-occurrence matrix $C_s = ID_s ID_s^\top / |D_s|$. The attacker can also obtain a similar query frequency $F_s = [f_{w_1}, f_{w_2}, \ldots, f_{w_m}]$ for W_s by public information such as Google Trend [19] or

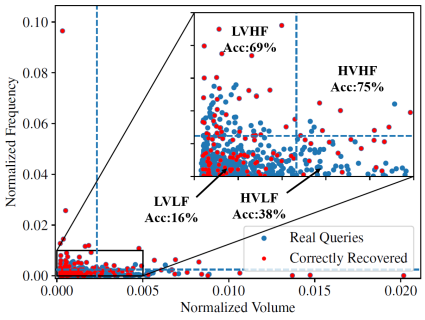

Figure 1: The distribution of queries on Enron. The horizontal dashed line divides the top 10% queries on volume from other queries; the vertical dashed line divides the top 10% queries on frequency from other queries. The blue dots denote the real queries issued by the user; the red dots denote the queries successfully recovered by the simple attack presented in Appendix A.

outdated frequency information.

4 Jigsaw Attack

We first demonstrate that Observation 1 does apply to all tested datasets although it does not directly provide an approach to recover those distinctive queries. We introduce the differential distance in the first module of Jigsaw to establish a way to distinguish these queries. We then define a distance between queries and keywords, enabling us to pair the distinctive queries with their nearest keywords. We accomplish the refinement in the second module by testing the queries' compatibility with co-occurrence relationships. Building on Observation 2, in the third module, we systematically recover all remaining queries by using those obtained in the second module. We define a specified "score" for each query-keyword pair and maximize it to get matches. The recovery process is iterative, with previously recovered queries being utilized in the recovery of subsequent queries.

4.1 Distribution of Keywords

Before proceeding to the Jigsaw attack, we present a comprehensive exposition of volume and frequency distribution (commonly found) in typical databases. We also showcase how the distribution impacts the effectiveness of attacks.

According to the Zipf's law [52], the volume of keywords in a database follows the Zipfian distribution, illustrating that *a small portion of keywords associates with a high volume.* As a result, these keywords exhibit significant disparities among each other due to their limited quantity but extensive volume range. A similar phenomenon emerges concerning query frequency, which indicates that a small subset of keywords could tend to be more frequently queried by users.

We present a simple similar-data attack to show that queries with high volume and frequency are relatively easier to recover. We employ this attack solely to demonstrate the distribution of keywords and its influence on the recovery. In this attack, the attacker generates the volume and frequency of queries and pairs them with keywords that exhibit the closest similarity w.r.t. volume and frequency. We simulate the attack on Enron [44], Lucene [15], and Wikipedia [16] and provide the results for Enron in Figure 1 (See Appendix A for details regarding the attack and its results on other datasets).

Figure 1 shows the volume and frequency correlated distribution of queries and the effectiveness of the attack (on recovery). We select the top 1, 000 keywords on volume except for the stop words as the keyword universe and categorize the corresponding queries into four quadrants: HVHF, HVLF, LVHF, and LVLF, where "L" and "H" represent "low" and "high", and the "V" and "F" denote "volume" and "frequency", respectively. High-volume queries refer to the top 10% of queries based on volume, while low-volume queries are the remaining 90%. The same classification applies to high-frequency and low-frequency queries. The lower-left corner of the figure is magnified to highlight that keywords with low volume and low frequency exhibit dense packing, which makes it difficult to differentiate these keywords. In contrast, the HVHF quadrant consists of sparser queries that are more distinguishable from each other. Using the similarity in volume and frequency, the attacker can easily recover these queries. Experimental results confirm this, with the simple attack achieving an accuracy of nearly 80% in the HVHF quadrant ($>90\%$ in Lucene and Wikipedia datasets). In the LVLF quadrant, however, the accuracy drops to 10%. We also achieve a moderately high accuracy of 62% and 34% in the LVHF and HVLF quadrants. Similar findings in [1, 13, 31] also present the correlation between frequency, volume, and accuracy.

4.2 Locating and Recovering the Most Distinctive Queries

As previously described, some queries are more distinguishable and easier to recover. Our first module aims to locate and recover these queries. We outline its details in Algorithm 1, which takes the Td_r, V_r, and F_r derived from query leakages in SSE and W_s, V_s, and F_s from similar data as input and outputs *BaseRec* predictions *Pred*. The *BaseRec* determines the number of recovered queries in this module. As we recover queries from high to low distinctiveness, a larger value of *BaseRec* can yield more predictions of queries lacking distinctiveness, consequently leading to a decline in accuracy.

Concretely, we first identify the most distinctive queries from all the queries by evaluating the *differential distance*. We define the differential distance d_{td_i} of a query td_i as follows:

$$d_{td_i} = \min_{td_j \in Td_r \wedge j \neq i} \alpha \cdot |v_{td_i} - v_{td_j}| + (1-\alpha)|f_{td_i} - f_{td_j}|. \quad (1)$$

Algorithm 1: Recover the top-*BaseRec* distinctive queries.

```
1  procedure RecoverDQ(Td_r, V_r, F_r, W_s, V_s, F_s, α, BaseRec)
2      Dis ← ∅; ▷ Dis maintains the differential distances of queries;
3      for all td_i ∈ Td_r do
4          d_{td_i} = min_{td_j ∈ Td_r ∧ j≠i} α·|v_{td_i} − v_{td_j}| + (1−α)|f_{td_i} − f_{td_j}|;
5          append (td_i, d_{td_i}) to Dis;
6      end
7      Sort Dis in descending order according to Dis.d_td;
8      Pred ← ∅; ▷ Pred stores the recoveries of distinctive queries;
9      for i ∈ [BaseRec] do
10         td_i, d_{td_i} = Dis[i];
11         w = arg min_{w_j ∈ W_s} α·|v_{td_i} − v_{w_j}| + (1−α)|f_{td_i} − f_{w_j}|;
12         append (td_i, w) to Pred;
13     end
14     return Pred;
15 end
```

Algorithm 2: Verification by co-occurrence matrices.

```
1  procedure Verify(Pred, C'_r, C'_s, BaseRec, ConfRec)
2      Temp_Pred ← Pred;
3      Td' ← Pred.td;
4      Revconf ← ∅;
5      for i ∈ [|Td'|] do
6          revconf = ||C'_r[i] − C'_s[i]||;
7          append (Td'[i], revconf) to Revconf;
8      end
9      Sort Revconf in descending order according to the
         Revconf.revconf;
10     for i ∈ [BaseRec − ConfRec] do
11         td, revconf = Revconf[i];
12         Remove the prediction of td from Temp_Pred;
13     end
14     return Temp_Pred;
15 end
```

Note that in the measurement (line 3-6), α is the weight of the volume, and $(1-\alpha)$ is the weight of the frequency. The differential distance d_{td} can assess the sparsity around the query td and thus the level of distinctiveness of the query td. Then, we sort the queries in descending order by d_{td} (line 7). We regard the top *BaseRec* queries in d_{td} as the most distinctive queries and the attack target in the first module.

Finally, we recover top *BaseRec* queries (line 9-13). Given a query td_j, we calculate the distance $s(td_i, w_j)$ between the query td_i in real data and any keyword w_j in similar data. We define the $s(td_i, w_j)$ as

$$s(td_i, w_j) = \alpha \cdot |v_{td_i} - v_{w_j}| + (1-\alpha)|f_{td_i} - f_{w_j}|. \quad (2)$$

We then recover the query td_i as

$$Pred(td_i) = \arg\min_{w_j \in W_s} s(td_i, w_j) \quad (3)$$

By properly adjusting the weight of volume and frequency information, this module can recover the distinctive queries with high accuracy (e.g., averagely 77% in Enron when $BaseRec = 100$, see Section 5.1). We use the L1 norm here. It's worth noting that we also tested other norms and found that the L1 norm yields the best performance. We note that Zipf's law could not be applicable to certain datasets, such as those containing randomly generated texts or artificially padded datasets. In this case, the module's performance could be negatively affected. Nonetheless, it is uncommon for real-world datasets to deviate significantly from Zipf's law. Furthermore, padding a dataset to the extent that the volume of keywords diverges the Zipfian distribution would result in an inflated storage cost. Though, we can still achieve relatively high accuracy as demonstrated in Section 7.

4.3 Adjustment by Query Co-occurrence

In the second module (see Algorithm 2), we utilize the co-occurrence matrix to further refine the recovered queries output by Algorithm 1. Note that the attack accuracy of all queries relies on the precise recovery of the distinctive queries. Any incorrect recovery could significantly impact the overall accuracy.

Before launching the second module, we set the following input parameters:

- The recovered queries *Pred* and its cardinality *BaseRec* from the first module.
- The co-occurrence matrix C'_r of queries and C'_s of keywords in *Pred*. We construct the two co-occurrence matrices by first extracting the columns and rows in the co-occurrence matrix C_r and C_s when the corresponding queries and keywords appear in *Pred*. Then each row of C'_r and C'_s is normalized by dividing the sum of that row.
- The parameter $ConfRec$ ($\leq BaseRec$), which reflects the number of recovered queries after refinement. Similar to the *BaseRec*, a smaller value of $ConfRec$ results in higher accuracy and a reduced number of recovered queries. In some restricted scenarios where we are only given a little prior knowledge or the leakage patterns have been "noised" by countermeasures, we should set the $ConfRec$ to a smaller value to capture high accuracy.

With the above input, the module can verify the recovered queries in *Pred* and output the predictions of $ConfRec$ queries with higher accuracy through the following process.

If most of the predictions in *Pred* are accurate, then for a correct prediction (td_i, w_i) in *Pred*, $C'_r[i]$ should be similar to $C'_s[i]$; otherwise, td_i and w_i are only similar in terms of volume and frequency and the relevant in co-occurrence matrix is not significant. Such similarity and deviation of $Pred[i]$ can be captured by calculating the Euclidean norm of $C'_r[i] - C'_s[i]$. We define $revconf$ as the reversed confidence of a prediction (td_i, w_i) as

$$revconf = ||C'_r[i] - C'_s[i]||. \quad (4)$$

If a prediction provides a smaller value of $revconf$, then it is considered more confident.

Based on the $revconf$, we calculate $Revconf$ contain-

ing $(td, revconf)$ for all $td \in Td'$ (line 4-8). Then, we sort $Revconf$ in descent order (line 9). To provide $ConfRec$ verified predictions, we remove the top $BaseRec - ConfRec$ queries from $Pred$ and return the remaining predictions (line 10-14).

At the expense of recovering a smaller number of queries, Algorithm 2 can reach almost perfect accuracy. We show in Section 5.1 that when the $BaseRec$ is set to 100, and the $ConfRec$ is 20, we obtain 96.9% and 100% accuracy in Enron and Wikipedia, respectively.

4.4 Dynamic Recovery for All Queries

The prior modules provide predictions for a subset of queries. In Algorithm 3, we present the last module of our attack that leverages the relation between the recovered distinctive queries and the remaining queries. This module recovers queries through an iterative approach, where the recovered queries by the second module serve as known queries.

The module takes the following information as input and outputs the predictions for all queries.

- The predictions $Pred$ from the second module.
- The co-occurrence matrices C_r and the query list Td_r from the leakages.
- The co-occurrence matrices C_s and the keyword universe W_s from the similar data.
- The parameter $RefSpeed$, which controls the number of recovered queries in each iteration.

We denote the $unknownTd$ as currently un-recovered queries and the $unpairedW$ as currently unpaired keywords. We denote C_r^s and C_s^s as sub-matrices of C_r and C_s, which represent the co-occurrence matrix between un-recovered and recovered queries, and between unpaired and paired keywords, respectively. We normalize each row of C_r^s and C_s^s by dividing the sum of that row at each time the set of recovered queries changes.

We use the matrix C_r^s, C_s^s, and the distance s to evaluate the score between an un-recovered query td and an unpaired keyword w. If a row of C_s^s is similar to one of C_r^s, it might indicate a correct prediction for the corresponding keyword and query. The score contains two parts, the L2-norm of $C_r^s[td] - C_s^s[w]$ and the distance $s(td, w)$ (calculated in Equation 2), which are summed with weight β and $(1-\beta)$. The score of a prediction (td_i, w_j) is defined as:

$$score(td_i, w_j) = -\ln(\beta||C_r^s[td_i] - C_s^s[w_j]|| + (1-\beta)s(td_i, w_j)). \quad (5)$$

If a prediction (td, w) is correct, the $s(td, w)$ and the $||C_r^s[td] - C_s^s[w]||$ will be small, which results in a high score.

Inspired by the RSA [13], we use a similar concept - *certainty* - to measure the level of assurance in the prediction for a query. Given a query td, the prediction (td, w_i) is considered certain if $score(td, w_i)$ is much higher than the score of any other predictions for td. The *certainty* of a prediction (td, w_i) is defined as:

$$certainty(td, w_i) = score(td, w_i) - \max_{j \neq i} score(td, w_j). \quad (6)$$

For example, if an un-recovered query has scores of 2, 3, and 7 with all three unpaired keywords, then the certainty of this query with unpaired keywords is -5, -4, and 4, respectively. In each iteration, we exclusively recover the queries with the highest certainty predictions.

This module runs through multiple iterations, each consisting of three main processes:

1. For all un-recovered queries $unknownTd$, calculate the $score$ of all predictions between $unknownTd$ and $unpairedW$. Then, based on the $score$, calculate the highest $certainty$ along with the prediction of each query, and add them to $Temp\_Pred$. (line 8-17)

2. If the number of un-recovered queries is less than $RefSpeed$, then add all the predictions in $Temp\_Pred$ to $Final\_Pred$, else add $RefSpeed$ predictions with largest $certainty$ in $Temp\_Pred$ to $Final\_Pred$ (line 18-22).

3. Update the $unknownTd$ and $unpariedW$. Update and normalize the C_r^s and C_s^s accordingly. (line 23)

Algorithm 3: Dynamically recovering all queries.

```
1  procedure RecoverAll(Pred, Td_r, W_s, C_r, C_s, RefSpeed)
2      Final_Pred ← Pred;
3      unknownTd ← Td_r − Final_Pred.td;
4      unpairedW ← W_s − Final_Pred.w;
5      Extract C_r^s and C_s^s from C_r and C_s, respectively; ▷ C_r^s and C_s^s is
         the co-occurrence matrix between unknownTd and recovered
         queries, and between unpairedW and paired keywords,
         respectively ;
6      while unknownTd ≠ ∅ do
7          Temp_Pred ← ∅;
8          for all td ∈ unknownTd do
9              Cand ← ∅; ▷ Cand stores candidate matches for td;
10             for all w ∈ unpairedW do
11                 score =
                     −ln(β||C_r^s[td] − C_s^s[w]|| + (1 − β)s(td, w));
12                 Add (w, score) to Cand;
13             end
14             Sort Cand in descending order according to the
                 Cand.score;
15             certainty = Cand[0].score − Cand[1].score;
16             Add (td, Cand[0].w, certainty) to Temp_Pred;
17         end
18         if |unknownTd| < RefSpeed then
19             Add all predictions in Temp_Pred to Final_Pred;
20         else
21             Add the RefSpeed predictions in Temp_Pred with
                 largest certainty to Final_Pred;
22         end
23         Update unknownTd, unpairedW, C_r^s and C_s^s;
24     end
25     return Final_Pred;
26 end
```

In the initial iterative process, the recovered queries have high accuracy due to their elevated level of *certainty*. As the process further operates, subsequently recovered queries are also recovered with high precision, primarily because of the augmented correlation between these queries and those that have already been recovered in previous iterations.

In this module, we use a similar method as the one introduced in RSA [13]. However, our approach provides several crucial differences. First, while the RSA algorithm exclusively utilizes the co-occurrence matrix to calculate the *score*, we incorporate both volume and frequency information in our *score* calculation. What's more, the performance of RSA is constrained to the "pre-set" known queries of high volume from the outset [13]. In Jigsaw, we use the second module to actively collect and recover the high-volume queries and further feed them into the third module. Their high volume provides Jigsaw with an advantage in query recovery. Moreover, for a query td, the RSA calculates the *score* of all keywords, potentially resulting in matching the query to a keyword that is already paired with another query. Our approach only calculates the *score* of unpaired keywords. Furthermore, we normalize the co-occurrence matrix in each iteration, which differs from the RSA algorithm. These differences collectively contribute to a more robust and accurate outcome for our algorithm, particularly when encountering defenses (for example, under the obfuscation in CLRZ [10] in Enron, our attack achieves $> 80\%$ accuracy while the RSA only captures $< 40\%$.). We provide a detailed analysis of the advantages of our approach in Section 6 and Section 7.

5 Evaluations

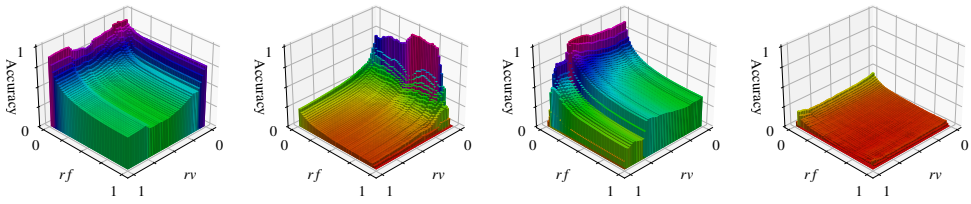
We evaluate our attack under various metrics in real-world datasets to show its effectiveness. We use Python 3.95 to simulate and run codes in Ubuntu 22.04.1 with 16 cores of an Intel(R) Xeon(R) Gold 5120 CPU (2.20GHz) and 64 GB RAM. Our code is publicly available in https://github.com/JigsawAttack/JigsawAttack.git.

5.1 Experimental Setup

Datasets. We utilize three datasets, Enron, Lucene, and Wikipedia, for our experiments. The Enron email corpus [44] was collected between 2000-2002, consisting of 30,109 emails, which is a widely used dataset in previous research. Lucene mailing list was formed between 2001-2020, with 66,491 emails from Apache Foundation [15]. For both Enron and Lucene datasets, we utilize pre-processed versions available in [31]. We use Wikipedia dataset [16] in 2020 and extract a subset of 1,000,000 documents by the algorithm in [37]. We employ the NLTK package [40] in Python to obtain all English words in datasets except the stop words for keyword extraction. In the experiments, we assume that the attacker obtains the same keyword universe as the user.

Frequency information. For the tests in Enron and Lucene datasets, we adopt the Google Trend [19], which contains 260 weeks of search trends in Google between October 2016 and October 2021, to generate query frequency for each keyword. Specifically, we calculate the sum of each query frequency in 1 to 50 weeks as the attacker's auxiliary knowledge. We normalize each keyword's frequency by dividing the frequency sum of all keywords as F_s. We also generate the user's queries according to the summed frequency in $1+\tau$ to $50+\tau$ weeks (denote as F) where τ is the time offset between the attacker's knowledge and the observation. For tests in the Wikipedia dataset, we use the Pageviews Analysis [27], which contains 75 months of page views from July 2015 to September 2021. We use the sum of each query frequency in 1 to 30 months as the attacker's auxiliary knowledge and the frequency of $1+\tau$ to $30+\tau$ months to generate queries.

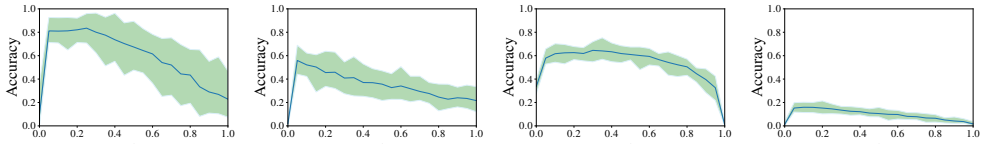
Attacker's knowledge. We randomly divide all documents into two disjoint subsets of equal size. We use one subset as the user's encrypted database (i.e., the real data D_r) and another as the similar data D_s. Then, the user generates single-keyword queries according to the frequency F. The attacker generates W_s, V_s, and C_s from similar data and observes all the user's queries to obtain Td_r, V_r, F_r, and C_r. We perform 30 independent simulations. In each simulation, we randomly select half of the documents as similar data and generate queries according to F.



Accuracy definition. We use the terms *accuracy* and *recovery rate* to evaluate the attack performance. The recovery rate refers to the proportion of recovered queries in all observed queries (i.e., $|Recovered(Td^s)|/|Td^s|$). The accuracy denotes the correctly recovered queries out of recovered queries (i.e., $|CorrectRec(Td^s)|/|Recovered(Td^s)|$).

5.2 Performance of Algorithm 1 and 2

We here provide evaluations for Algorithm 1 and 2 (the results of the entire Jigsaw are in Section 5.3 and after). We first demonstrate the results of Algorithm 1 in four quadrants (including HVHF, HVLF, LVHF, and LVLF). For our experiments, we extract the top $1,000$ keywords based on their volume and generate $100,000$ queries with $\tau = 0$.



To evaluate the recovery in different quadrants, we sort the queries in Td_r according to their volume in descending order. We treat the first $rv \cdot l$ queries as high-volume queries ($l = |Td_r|$), while the remaining are low-volume queries. Similarly, we divide the queries into high and low-frequency queries, containing $rf \cdot l$ and $(1-rf) \cdot l$ queries, respectively. Using the above division, we categorize the queries into the HVHF, HVLF, LVHF, and LVLF quadrants. We set α to 0.5 and *BaseRec* to l to recover all queries and test the accuracy in four quadrants by varying rv and rf. Figure 2 demonstrates the accuracy of Algorithm 1 on Enron. Detailed results for Lucene and Wikipedia are given in the full version [29].

Figure 2(a) depicts the results of the HVHF quadrant in

(a) HVHF (b) HVLF (c) LVHF (d) LVLF

Figure 2: The accuracy of Algorithm 1 in four quadrants with different rv and rf, where we treat keywords with top-$rv \cdot l$ highest volume as high-volume keywords and treat keywords with top-$rf \cdot l$ highest frequency as high-frequency keywords (A larger rv means more queries are considered as high-volume queries. Similarly, a larger rf yields more queries that are categorized as high-frequency queries).

(a) HVHF (b) HVLF (c) LVHF (d) LVLF

Figure 3: The accuracy of Algorithm 1 on four quadrants with different α, where α is the weight of volume and $(1-\alpha)$ is the weight of frequency in measurement.

Table 2: Results of Algorithm 1 and Algorithm 2 on Enron, Lucene, and Wikipedia. The $ConfRec$ in Algorithm 2 equals to $BaseRec \times 100\%$, $BaseRec \times 50\%$, and $BaseRec \times 20\%$ respectively.

Dataset	$BaseRec$	$ConfRec/BaseRec \times 100\%$ (accuracy/recovery rate/correctly recovered number)[1]		
		100%[2]	50%	20%
Enron	25	94.14%/23.25%/23.0	100.00%/3.46%/12.0	100.00%/0.98%/5.0
	100	77.33%/43.14%/57.6	91.53%/17.18%/39.5	96.95%/5.48%/19.0
	400	51.85%/80.10%/112.2	72.06%/46.41%/81.1	83.96%/17.37%/50.2
Lucene	25	99.36%/27.51%/24.6	99.98%/4.17%/12.0	100.00%/1.93%/5.0
	100	86.31%/48.64%/76.3	99.58%/25.55%/48.9	99.80%/5.85%/19.9
	400	63.07%/83.97%/147.7	82.85%/50.04%/103.6	96.55%/27.64%/67.1
Wikipedia	25	99.71%/11.89%/23.8	100.00%/2.58%/12.0	100.00%/0.83%/5.0
	100	91.57%/28.67%/80.9	99.61%/15.04%/47.7	100.00%/3.59%/19.9
	400	68.79%/58.17%/177.3	88.87%/34.47%/120.2	97.54%/15.94%/64.3

[1] Each result is presented as (accuracy/recovery rate/correctly recovered number). The accuracy denotes the percentage of correctly recovered queries out of recovered queries. The recovery rate is the percentage of recovered queries out of all queries. The correctly recovered number is the number of correctly recovered and distinct queries.

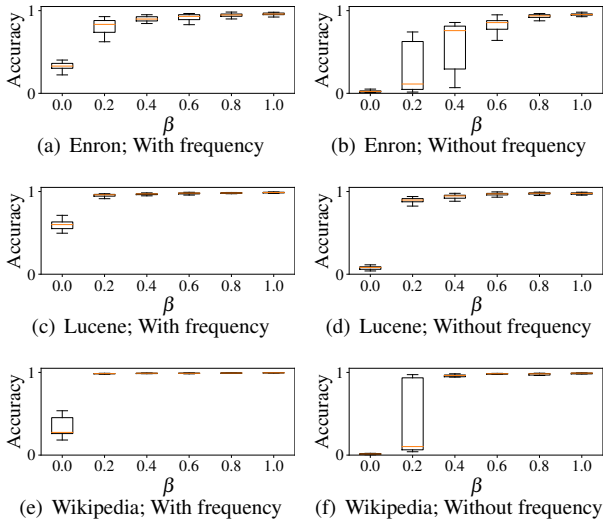
[2] This column shows the results of Algorithm 1 as Algorithm 2 does not remove any predictions.

Enron. When $rv < 0.2$ or $rf < 0.1$, the accuracy is approximately 70%. As the increase of rf or rv indicates a greater proportion of queries with lower volume and frequency within the quadrant, the accuracy falls. This indirectly proves that queries with high frequency or high volume are easier recoverable. Similar trends can be observed in the performance of Lucene and Wikipedia. In contrast, the accuracy in the LVLF quadrant is only < 0.3 (see Figure 2(d)). From Figure 1, we can see that the queries in this quadrant are much denser as compared to other quadrants. There is a lack of distinguishability based on volume and frequency, resulting in such a low accuracy. Figure 2(b) exhibits the accuracy of queries confined to the HVLF quadrant, representing the top $rv \cdot l$ and bottom $(1-rf) \cdot l$ queries w.r.t. volume and frequency, respectively. The recovery of queries mainly relies on volume, and the accuracy reaches the summit when $rv < 0.1$ and $rf < 0.8$, which implies that queries with high volume and low frequency can be recovered with high accuracy. The LVHF quadrant delivers a similar result to the HVLF quadrant, see Figure 2(c). When rf is < 0.2, the recovery provides

high accuracy, approaching 70%.

We also investigate the impact of the parameter α on the accuracy in the four quadrants. We set $rv = 0.1$, $rf = 0.1$, and $BaseRec = l$ to recover all queries, and the results are shown in Figure 3. The accuracy decreases when α is either 0 or 1, indicating that relying solely on frequency or volume for query recovery leads to poor accuracy. When α is appropriately configured, the accuracy $> 50\%$ in the HVHF, HVLF, and LVHF quadrants, while it remains relatively low in the LVLF quadrant. We also observe that the α displays a distinct impact on the accuracy in the quadrants. For example, in the HVLF quadrant, when $\alpha = 0.05$, we achieve the highest accuracy, while the LVHF quadrant's best performance is when α is about 0.3. In the HVLF quadrant, we achieve the highest accuracy when $\alpha = 0.05$, while in the LVHF quadrant, the best performance is obtained with α around 0.3. This suggests that selecting an appropriate value of α accordingly can lead to higher accuracy in different scenarios.

Table 2 presents the recovery results of Algorithm 1 and 2 when we consider $BaseRec \in \{25, 100, 400\}$ and $ConfRec/BaseRec \in \{100\%, 50\%, 20\%\}$. Overall, the accuracy achieved for various parameter combinations surpasses 50%. As $BaseRec$ and $ConfRec/BaseRec$ decrease, indicating a reduction in the number of recovered queries, the recovery rate decreases while the accuracy exhibits an increase. For instance, when we set $BaseRec = 25$ and $ConfRec/BaseRe = 20\%$, Algorithm 2 achieves around 1% recovery rate but 100% accuracy on all the datasets. We also observe that with the same parameters, the results in Wikipedia are better than those in Enron and Lucene, indicating that Wikipedia contains more distinctive queries.



Despite a decline in the recovery rate, when Algorithm 2 is employed, its accuracy remains remarkably high with a small $BaseRec$ and $ConfRec$. In comparison to RSA [13] relying on a dozen known queries and their relations (with other queries) to recover all queries accurately, the refinement on queries proposed by Algorithm 2 is sufficient to pose a significant threat to all the user's queries. We demonstrate this in detail in the experiments of the next subsection.

5.3 Results of the Jigsaw Attack

We show the results of the Jigsaw attack and demonstrate how β influences the accuracy here. We use the same setting as in Section 5.1. Besides, we set $BaseRec$ to 100, $ConfRec$ to 50, α to 0.3, and $RefSpeed$ to 15.

The experimental results when varying the values of β in Algorithm 3 are depicted in the first column of Figure 4. When $\beta = 0$, meaning the recovery only relies on the frequency and volume, the accuracy reaches around 30% in Enron and Wikipedia and 60% in Lucene. As β increases, we see the rise in accuracy, ultimately reaching the peak of over 95% accuracy for Enron and over 98% for Lucene and Wikipedia.

As demonstrated above, using similar documents and knowledge of query frequency, Jigsaw achieves $> 95\%$ accuracy. However, there are some cases where the attacker may not have access to query frequency, such as when dealing with newly established databases. To examine the effectiveness of Jigsaw under such circumstances, we perform additional evaluations without utilizing frequency information. In the absence of frequency information, the attacker should discern fewer distinctive queries, yielding a negative influence on the performance of Algorithm 1 and Algorithm 2. However, by adjusting the parameter $ConfRec$ to recover a smaller number of queries, the first two modules can still achieve high accuracy in identifying distinctive queries. We note that with this smaller yet highly accurate set of recovered queries, our attack's accuracy still remains stable and reaches $> 90\%$ when β is set to 0.8 and 1.0 (See in the second column of Figure 4).

(e) Wikipedia; With frequency (f) Wikipedia; Without frequency

Figure 4: The accuracy of Jigsaw with different β, where *beta* is the weight of co-occurrence information and $(1-\beta)$ is the weight of volume and frequency information in calculating *score*. The left and right columns display the results with and without frequency information.

5.4 Durability

Table 3: Results of recovery accuracy with outdated frequency in different τ, where τ is the time offsets between attacker's prior knowledge of the frequency and user's queries (measured in weeks for Enron and Lucene, and in months for Wikipedia).

Dataset	$\tau = 10$w	$\tau = 50$w	$\tau = 100$w	$\tau = 150$w
Enron	0.9279	0.9150	0.8881	0.8824
Lucene	0.9959	0.9963	0.9955	0.9897
Dataset	$\tau = 2$m	$\tau = 10$m	$\tau = 20$m	$\tau = 30$m
Wikipedia	0.9959	0.9919	0.9721	0.9608

In the experiment, we use an "outdated" query frequency obtained from the past as auxiliary information to enhance accuracy. We here introduce the concept of *durability* to measure the effect of the time offset between the outdated and target queries on the attack's recovery. The time offset indicates how "old" the query frequency information is. An outdated piece of frequency information might deviate significantly from the actual query frequency, possibly leading to the failure of attacks. We consider an attack to be durable if it can maintain its accuracy even as the time offset increases.

We conduct experiments to evaluate the durability of our attacks in Table 3. For Enron and Lucene, we use the frequency of the first 50 weeks in Google Trend as the attacker's auxiliary information, while the target queries are generated using the frequency during τ and $50+\tau$ weeks. For Wikipedia, we use the first 30 months' query frequency in Pageviews Analysis as the auxiliary information, and the queries are generated according to the frequency during τ and $30+\tau$ months. Note that τ is the corresponding time offset. In the time offset between 10 and 150 weeks, the drop of the attack accuracy is rough > 0.05 in Enron and Lucene. In Wikipedia, the accuracy decreases about 3.5% as the time offset increases from 2 to 30 months. These results suggest that a leaked query frequency continues to have an impact on our attack even after several years have passed.

5.5 Summary of Evaluations

The results clearly illustrate that the first module of Jigsaw successfully recovers queries with a high level of accuracy. We also confirm that the second module can obtain nearly 100% accuracy for dozens of queries, and the last module is able to recover all queries with about 95% accuracy. Even without the frequency information, the accuracy does not experience a significant decline. At last, Jigsaw demonstrates its durability by maintaining consistent accuracy, even as the time offset increases from several weeks to years.

6 Comparisons with Other Attacks

We compare the performance of our attack with Graph Match attack [35] (Graphm), Sap attack [31] (Sap), Refine Score attack [13] (RSA) and IHOP attack [32] (IHOP). We do not test the Freq attack [26] here as the Sap dominates its results.

6.1 Settings and Parameters

We extract the top $|W|$ keywords based on their volume as keyword universe. In Enron and Lucene, we evaluate the above attacks for different values of $|W|$, namely 500, 1000, and 2000. But for Graphm, we omit $|W| = 1000, 2000$ due to the extended time required for the test. For example, the running time for Graphm with $|W| = 1000$ exceeds $10,000$ seconds. We suppose the attacker knows the frequency of each keyword

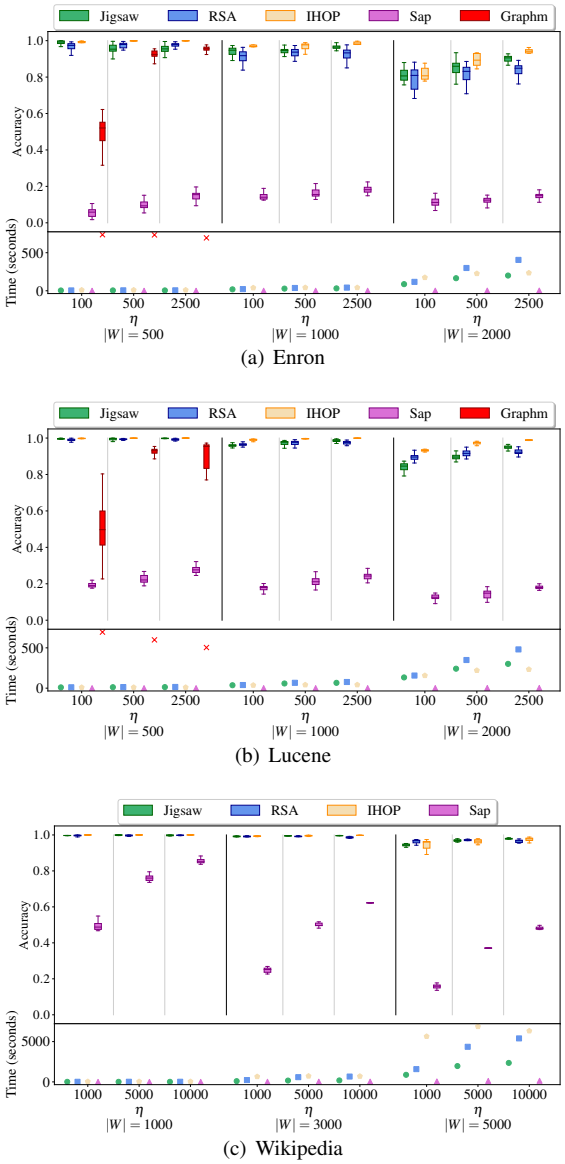

Figure 5: Accuracy & Time comparisons in Enron, Lucene, and Wikipedia.

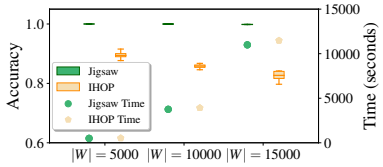

Figure 6: Accuracy comparisons with IHOP within similar runtime.

in the keyword universe in the first 50 weeks and generate η queries each week for a duration spanning from 50 to 100 weeks ($\tau = 50$) using the frequency obtained from Google

trend. We set η to 100, 500, and 2500. In Wikipedia, we test all the attacks except the Graphm, and we set the $|W|$ to 1000, 3000, and 5000. We assume the attacker knows the initial 30 months' query frequency from Pageviews Analysis, and the user generates η queries based on the frequency during the period of 10 and 40 months ($\tau = 10$). We set the η to 1000, 5000, and 10000.

Parameters for Jigsaw. Recall that the selections of α, β, *BaseRec*, and *ConfRec* can significantly influence Jigsaw's accuracy (see Section 5). We briefly introduce the reasons behind these parameters selection.

• As for α, we use it to control the weight of volume and frequency information. Based on Figure 3, it is recommended to select the parameter from 0.05 to 0.4. If the volume information is not accurate (i.e. being noised by certain countermeasures), a smaller α is recommended, and vice versa. Here, we set the α to 0.3.

• For β, one may choose β from 0.8 to 1.0 as illustrated in Figure 4. Note that as a larger β indicates assigning more weight to co-occurrence rather than volume and frequency, the co-occurrence information appears to play an important role in recovering queries. Similar to the case of α, if the co-occurrence is affected by noise, one can opt for a relatively small β. We set the β to 0.9 here.

• For *BaseRec* and *ConfRec*, we found that the *ConfRec* should be set to at least 5 for the third module to initiate, and the *BaseRec* should range from $1.2 \times ConfRec$ to $2 \times ConfRec$. In normal SSE settings, *BaseRec* and *ConfRec* should be sufficiently large to output more accurately recovered queries, whereas they are set to small when observed information is noised to ensure the accuracy of the second module. The *BaseRec* and *ConfRec* are set to 45 and 35, respectively.

• When it comes to *Refspeed*, it controls how many queries to recover in each iteration. One may use a large *RefSpeed* to optimize the runtime of Jigsaw (such as one-tenth of $|W|$), but this could harm attack accuracy. A gradually increased *RefSpeed* is recommended when dealing with countermeasures, as it can yield both practical runtime and accuracy. The *RefSpeed* is set to 10 when the keyword universe is small ($<= 2,000$) and 50 when the universe is large ($> 2,000$). As in the time-limited settings, we set the *Refspeed* to $|W|/10$.

Parameters for other attacks. We use the implementation of PATH algorithm [49] available in the package[1] to solve the graph matching problem in Graphm (aiming to produce the best performance). We set the α in Graphm to 0 because we find that Graphm can perform its best when $\alpha = 0$ in our settings. Note we conduct tests ranging from $\alpha = 0$ to $\alpha = 1$, with increments of 0.1. Recall that RSA requires some known queries in the setup. We randomly choose 10 queries and reveal the true keywords for RSA. We also include the results of RSA with varying numbers of known queries in the full version [29]. The refine speed in RSA is set to the same as Jigsaw. We set the α in Sap to 0.5. For IHOP, we set the p_{free} to 0.25 and the n_{iters} to 500.

[1] http://projects.cbio.mines-paristech.fr/graphm/

6.2 Comparison Results

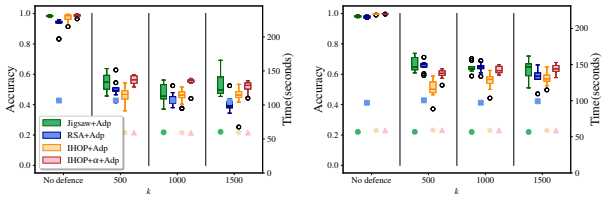
Comparisons with all tested attacks. Here, we demonstrate the results of all tested attacks in Figure 5. Our attack provides comparable accuracy to RSA and IHOP while showing a significant advantage over Sap and Graphm. Graphm's accuracy is low upon $\eta = 100$ but improves if more queries are observed. It is argued that Graphm requires observation of almost all possible queries to achieve high accuracy [31], and it also takes longer matching time between queries and keywords. On the other hand, Sap solely utilizes the frequency and volume information, resulting in relatively lower accuracy that increases as it observes more queries. We also observe that increasing $|W|$ results in a decrease in all attacks' accuracy. This is because a larger value of $|W|$ introduces a greater number of low-volume keywords.

In the context where a large number of queries are observed, our attack can outperform RSA. As the increase of this number, our attack delivers a boost in accuracy. But RSA cannot gain advantages from more queries because it does not leverage the frequency information. Our performance is similar to that of IHOP, as both of the attacks exploit the frequency and co-occurrence of queries. We observe that IHOP achieves slightly higher accuracy than our attack. This can be attributed to its random fixing and free strategy, which enhances the matching of a portion of the queries in each iteration. This strategy consumes a significant amount of time, especially when the keyword universe is large. For example, when $|W|$ is 5000 in Wikipedia, IHOP takes approximately twice as long as Jigsaw to complete the attack. We are going to show in Section 7 that the strategy used by IHOP is not robust once certain countermeasures introduce noise to the leaked information.

Comparisons with IHOP in large keyword universe under the same time limitation. We also present the performance of Jigsaw and IHOP within the same time limitation when the keyword universe is large. Before the evaluations, we adjust the parameters by setting *RefSpeed* to $|W|/10$ for Jigsaw and restricting n_{iters} for IHOP to keep both runtimes at a similar pace. Note that without any adjusting, IHOP could take approx. 24,000 seconds for 100 iterations, and nearly five times that for 500 iterations, when $|W| = 10,000$. We illustrate the results under Wikipedia in Figure 6. As the keyword universe increases, from 5,000 to 15,000, the runtime costs of both attacks jump from $< 1,000$ seconds to nearly 10,000 seconds. IHOP demonstrates a continuous fall in accuracy, from roughly 89% to 85%, while Jigsaw's accuracy stands at the same level, $10-15\%$ higher than that of IHOP.

7 Against Countermeasures

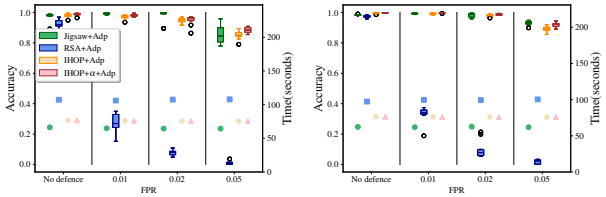
We evaluate the attacks against the padding in CGPR [5] and obfuscation [10]. We also show the results against the padding in SEAL [14] and the cluster-based padding [3,43] in Appendix C. We specifically compare the attacks against the padding strategy employed in SEAL, rather than the "entire" SEAL (i.e., padding + ORAM)[2] .



To counter obfuscation, Oya et al. [32] proposed an adaptation for IHOP, which modifies the co-occurrence matrix of keywords in similar data. We apply the same philosophy to Jigsaw and RSA. Note that we also design adaptations on the compared attacks against the padding. These adaptations can effectively minimize the difference between the user's data after the noise injection and the similar data. We highlight that the accuracy of RSA and IHOP increases significantly in most situations after applying the adaptations (such as 30% improvement against the padding in CGPR). We present a comprehensive overview of the adaptations and the performance of RSA and IHOP with/without the adaptations in Appendix B. We emphasize that there have been no systematic and proper studies for optimal adaptions in existing attacks, rendering this as an interesting open problem.

We conduct a comparative analysis of our attack, RSA [13], and IHOP [32] w.r.t. the aforementioned countermeasures, in Enron, Lucene, and Wikipedia. We do not test the SAP and Graphm in this section, as they exhibit relatively poor performance or require excessive computational time for the attacks. We also introduce an α term into the objective function of IHOP to balance the weight between the frequency and volume terms against countermeasures (noted as IHOP-α). We test the α from 0 to 1 with a step length of 0.1, and in most cases, $\alpha = 0.1$ brings the best results for IHOP-α. We fix $\alpha = 0.1$ for IHOP-α in the following presentations.

For Enron and Lucene, we set $|W|$ to 1000 and set η to 500. The attacker is allowed to observe η queries per week over a duration of 50 weeks. In Wikipedia, we set the $|W|$ to 1000, 3000 and 5000 and η to 5000, and the attacker can observe η queries per month for a total duration of 30 months. The time offset τ is set to 0. For Jigsaw, to account for the injection of noise to the volume (by the countermeasures), we set α to a relatively small value, 0.2. And we set β to 0.9. The *BaseRec* and *ConfRec* are also set to relatively small, 15 and 10, to ensure that the second module of Jigsaw can produce correct recoveries. We set the *RefSpeed* of our attack and RSA to 5 in Enron and Lucene. In Wikipedia, we use a gradually increased value to shorten the runtimes of Jigsaw and RSA. For each iteration of Jigsaw's third module and RSA, the value increases by 10%. The known query number is set to 15 in RSA. The n_{iters} and p_{free} are set to 500 and 0.25 in IHOP and IHOP-α.

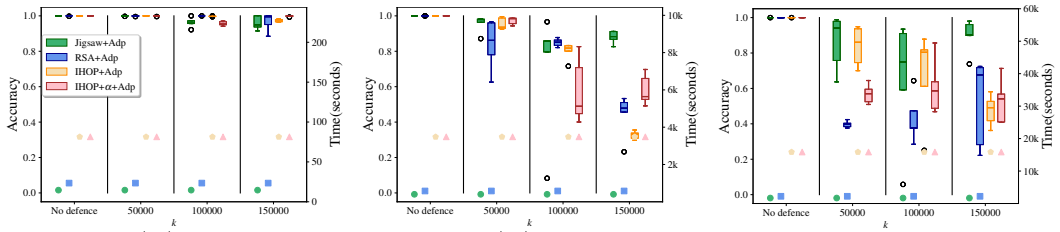


[2]We note that ORAM, another crucial component within SEAL, can be used to hide the access and search pattern, and thus could probably counter all the attacks in Table 1.

7.1 Against the Padding in CGPR

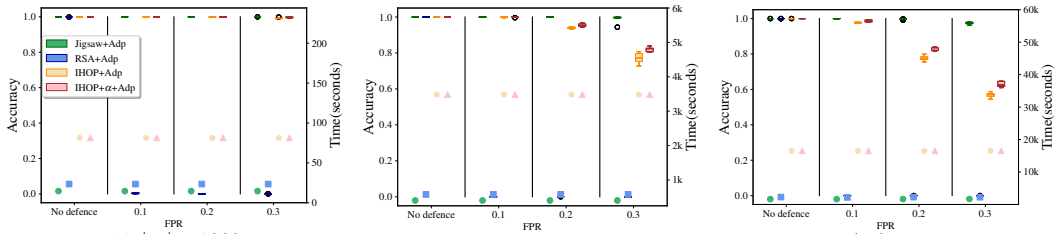
(a) Enron (b) Lucene

Figure 7: Comparisons with RSA and IHOP against the padding in CGPR [5], in Enron and Lucene.



(a) Enron (b) Lucene

Figure 8: Comparisons with RSA and IHOP against the obfuscation in CLRZ [10], in Enron and Lucene.



Padding in CGPR [5] injects fake documents to increase the query volume to the nearest multiple of k. This strategy adds noises to the volume and access pattern and at the same time increases the communication and storage costs (see the full version [29] for experimental results). For queries with low volume, the padding can substantially change the access and volume patterns, and the volume is more likely to be "expanded" to the same "length". But the high-volume queries, on the other hand, are poorly protected. This is so because, for those queries (already with a "large" volume), the (on-top) padding volume could be relatively small. In this case, the impact on the leakage patterns of high-volume queries is minimal. We state that since the first two modules of Jigsaw concentrate on recovering high-volume and high-frequency queries that are not significantly affected by the padding, they can keep producing highly accurate predictions. By leveraging these accurate recoveries, we can gain "more" pre-knowledge to pose a severe threat to low-volume queries. In Figure 7, we have $k \in \{500, 1000, 1500\}$ for Enron and Lucene; while in Figure 9, k is set much larger, $\in \{50000, 100000, 150000\}$. This is because Wikipedia contains a significantly higher number of documents than other datasets.

All the tested attacks exhibit similar accuracy, about 50% in Enron and $> 60\%$ in Lucene. In Wikipedia, the gap in accuracy is more noticeable, and Jigsaw demonstrates a significant advantage over others when $|W| \geq 3000$. For example, when $k = 150,000$ and $|W| = 3000$, Jigsaw provides nearly 90%

(a) $|W| = 1000$ (b) $|W| = 3000$ (c) $|W| = 5000$

Figure 9: Comparisons with RSA and IHOP against the padding in CGPR [5], in Wikipedia.

(a) $|W| = 1000$ (b) $|W| = 3000$ (c) $|W| = 5000$

Figure 10: Comparisons with RSA and IHOP against the obfuscation in CLRZ [10], in Wikipedia.

accuracy, whereas RSA and IHOP only obtain $< 60\%$. IHOP-α performs slightly better than IHOP, with a 60% accuracy. This above result is attributed to the fact that the padding cannot protect the distinctive queries in Wikipedia, allowing Jigsaw to recognize and further recover them, which gives it an advantage in recovery. We clearly observe that Jigsaw consumes significantly less runtime than IHOP and IHOP-α in Wikipedia due to a gradually increased $RefSpeed$.

7.2 Against the Obfuscation in CLRZ

We showcase the experimental results of attacks against the obfuscation in CLRZ [10], which works by indexing a keyword to documents that do not contain the keyword with probability FPR and removing the index of documents that do contain the keyword with probability TPR. Since the obfuscation does not involve padding, it does not affect storage costs. However, the communication costs will increase greatly due to a larger number of unrelated documents being retrieved (see the full version [29] for experimental results). In Figure 8 and 10, we set $TPR = 0.999$ and $FPR \in \{0.01, 0.02, 0.05\}$ in Enron and Lucene and $FPR \in \{0.1, 0.2, 0.3\}$ in Wikipedia.

Under the obfuscation, the accuracy of RSA drops abruptly to below 20%. Jigsaw just experiences a minor decrease as the FPR increases and, in most cases, maintains accuracy $> 85\%$ in all tested datasets. IHOP and IHOP-α perform similarly to Jigsaw in Enron and Lucene. But in Wikipedia, their accuracy drops significantly with a large $|W|$. When $FPR = 0.3$ and $|W| = 3000$, the accuracy only reaches about 80%, dropping to 60% when $|W| = 5000$. In contrast, Jigsaw remains an accuracy above 95% under the same settings.

7.3 Discussion

Under all tested countermeasures, it is evident that Jigsaw (after the adaptations) achieves the highest accuracy, $> 70\%$, in most cases. On average, RSA and IHOP could closely follow Jigsaw's performance. But they have some pitfalls. RSA is vulnerable to the obfuscation in CLRZ, resulting in $< 20\%$ accuracy. IHOP and IHOP-α also experience low accuracy against the countermeasures with a large $|W|$. Their accuracy is approx. 50% against the padding in CGPR (with $k = 150,000$) and about 60% against the obfuscation in CLRZ (with $TPR = 0.3$) on Wikipedia with $|W| = 5,000$. While one may have the option to apply the defenses to mitigate RSA and IHOP, Jigsaw proves to be a more "robust" attack that remains effective.

There are several countermeasures that might defend against Jigsaw. ORAM [45], a popular solution to SSE attacks, conceals the access pattern and the derived co-occurrence matrix, reducing the effectiveness of Jigsaw's second and third modules. But this comes with an $\Omega(\log N)$ amortized blowup of communication cost for databases of size N. Providing similar efficacy on the access pattern, PIR [21] is another potential option. However, it requires heavy server-side computation and does not support private updates by the client. Apart from completely hiding the access pattern, strong padding techniques may infuse noise into the volume pattern of the high-volume queries, making Jigsaw's first module unable to produce sufficient correct recoveries - resulting in low accu-

racy. A drawback of this solution is the necessity to pad a considerable amount of files, especially for high-volume queries. It remains an intriguing challenge to develop a padding technique that is both efficient and secure.

8 Conclusion

We propose the Jigsaw, a new similar-data attack against SSE, which works by first recovering the most distinctive queries and utilizing them to recover all queries further. We test Jigsaw in different datasets and showcase the stable accuracy of around 95% in query recovery. Moreover, our attack can provide an accuracy of about 60% and 85% against padding [5] and obfuscation [10], respectively, outperforming existing works [13, 26, 31, 32]. The proposed attack exposes the vulnerabilities of existing SSE schemes. Developing secure and practical SSE schemes that are resistant to such attacks is an open problem.

Figure 12: The distribution of queries (showing their ranks based on volume and frequency). The dot and dashed lines share the same meaning as in Figure 1. Those at further to the right indicate higher rankings in volume; those moving upwards represent elevated ranking in frequency.

A Query Distribution and Simple Attack

We present a simple attack and its evaluation to showcase the relationship between query distribution and query recovery. The attack employs knowledge of frequency and volume information to pair queries with the keywords having the most similar frequency and volume. We assume the attacker knows a similar dataset D_s and generates a keyword universe $W_s = [w_1, w_2, \ldots, w_m]$. Then, it generates the corresponding volume $V_s = [v_{w_1}, v_{w_2}, \ldots, v_{w_m}]$ of each keyword from D_s. It also knows a historical query frequency $F_s = [f_{w_1}, f_{w_2}, \ldots, f_{w_m}]$ of W_s. Also, the attacker can observe the volume and search pattern of queries the user issues and generate the frequency F_r and volume V_r of them. After normalizing the F_s, V_s, F_r, and V_r, it pairs each query td_i with keyword w_j which has the smallest value of $|v_{w_j} - v_{td_i}| + |f_{w_j} - f_{td_i}|$.

We test the attack in Enron, Lucene, and Wikipedia. The results are shown in Figure 11 and 12. In Figure 11, we normalize the volume and frequency of each query. The horizontal dashed line divides the top 10% queries on volume from other queries, and the vertical dashed line divides the top 10% queries on frequency from other queries. The two lines divide the queries into four quadrants, i.e., the HVHF, HVLF, LVHF, and LVLF. The blue dots denote the queries, and the red dots denote the queries successfully recovered by the simple attack. In all tested datasets, the queries in the HVHF quadrant are sparse, and the attack has a high accuracy there. On the other hand, in the LVLF quadrant, the queries are nearly indistinguishable and hard to be recovered. We can zoom out the left low corner to show this more clearly. We rank the queries according to their volume and frequency and show the queries according to their rank in Figure 12. As the

Figure 13: The results of RSA and IHOP with (+Adp) / without the adaptations on similar data against the padding in CGPR [5], the obfuscation [10], the cluster-based padding [3,43], and the padding in SEAL [14].

queries have a higher rank in volume or frequency, the red dot is denser, showing a higher accuracy in recovery.

In Section 4, we provide the definition of *differential distance* d_{td} of a query. The distinctiveness of a query increases as its differential distance becomes larger. Based on d_{td}, we define the number K of distinctive queries in a dataset as:

$$K = |\{i : \frac{d_{td_i}}{\sum_{td_j \in W} d_{td_j}/|W|} > \lambda\}|. \quad (7)$$

In Enron, Lucene, and Wikipedia, setting $\lambda = 5$, we have that the number is roughly 18, 20, and 33, which can concur with the results in Section 5, 6, and 7.

B Adaptations to Similar Data

It seems that the countermeasures such as padding and obfuscation do not consider the protection of the parameters. If gaining access to the parameters, the attacker will be able to make adaptations to similar data to weaken the countermeasures. For example, in the case of padding in CGPR, the attacker can utilize the parameter k to pad the similar data, thereby minimizing the disparity between the similar data and the padded data. We say that this effectively mitigates the adverse effects of padding on query recovery. Specifically, our adaptations applied to Jigsaw, RSA, and IHOP are as follows.

• *Padding in CGPR* [5]. This strategy pads the query volume to the nearest multiple of k. We here employ the same padding approach with a different parameter, k_{sim}, on similar data. We calculate k_{sim} as k multiplied by the ratio of the sizes of the similar dataset (D_s) and the original dataset (D), i.e., $k_{sim} = k \cdot |D_s|/|D|$. Accordingly, this adjustment modifies ID_s, which subsequently affects the C_s and V_s in the attacks. We also apply the same strategy for RSA and IHOP.

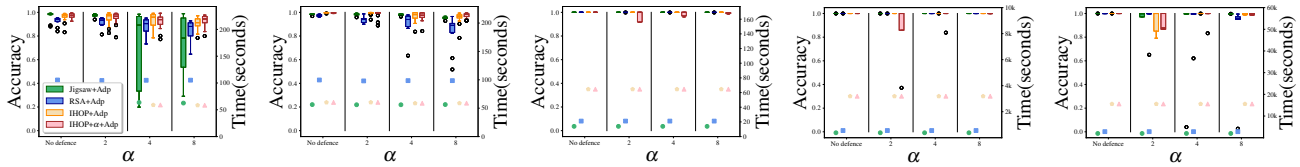
• *Padding in SEAL* [14]. In SEAL, the volume distribution of the padded queries is closely related to the size of the dataset. The varying sizes of similar data to the user's data result in different volume distributions after padding. To adapt Jigsaw against the SEAL's padding, we generate a new similar data D'_s with the size $|D|$ (aligning with the size of the user's data D) by expanding D_s with its own data "copies" to keep the volume distribution of D_s.

• *Cluster-based padding* [3,43]. We generate a new similar dataset D'_s by padding D_s with the same parameter and replace D_s with D'_s in attacks.

• *Obfuscation* [10]. We have two phases for this adaptation. Firstly, we apply the co-occurrence matrix (in Equation 8) in [32] to adapt the influence of obfuscation in similar data.

$$C_s^{obf}[i,j] = \begin{cases} TPR^2 \cdot C_s[i,j] + FPR^2 \cdot C_s^{not}[i,j] + \\ TPR \cdot FPR \cdot (1 - C_s[i,j] - C_s^{not}[i,j]),\ i \neq j; \\ TPR \cdot C_s[i,j] + FPR \cdot C_s^{not}[i,j],\ i = j. \end{cases} \quad (8)$$

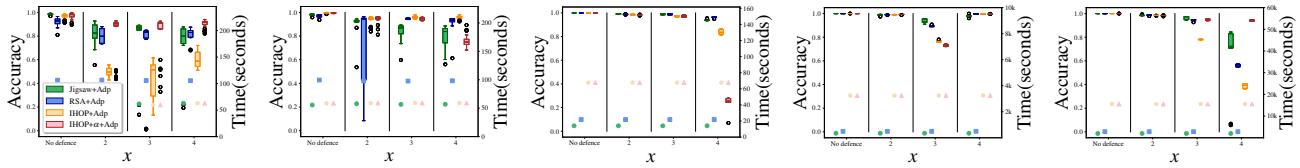
where $C_s^{not} = (1 - ID_s)(1 - ID_s)^\top / |D_s|$. Then, we revise V_s as $V_s^{obf}[i] = TPR \cdot V_s[i] + FPR \cdot (1 - V_s[i])$ for further adaptation.



We then adopt the same padding strategy on D'_s and replace the D_s with the D'_s in attacks.

We test Jigsaw, RSA [13], and IHOP [32] with/without the adaptations on Enron against the CGPR's padding [5] ($k = 1500$), the obfuscation [10] (TPR$= 0.999$, FPR$= 0.05$), the cluster-based padding [43] ($\alpha = 8$), and the SEAL's padding [14] ($x = 4$). The parameters are the same as in Section 7. The results are presented in Figure 13. For obfuscation, RSA with/without the adaption performs poorly ($< 10\%$ accuracy). On the other hand, under three padding strategies, the proposed adaptations optimize the accuracy of RSA and IHOP significantly. Noticeably our Jigsaw attack with adaptations still takes the lead in most cases, see Section 7 for comparison details.

C Results Against Other Padding Strategies



Against the cluster-based padding. Recall that the cluster-based padding [3,43] first divides all the keywords into clusters with each containing no less than α keywords. Then, this countermeasure pads each keyword to the largest volume in its cluster. To improve the padding efficiency, we sort all keywords in ascending order based on their volume and assign each continuous α keywords to the same cluster. We set α to 2, 4, and 8 and present the results in Figure 14. We set the α in Jigsaw to 0.1 (considering the cluster-based padding that injects more noise to high-volume queries) and keep other parameters the same as in Section 7.

We observe that the average accuracy of all the attacks exceeds 75%. But Enron consists of fewer distinctive queries than other datasets, leading to exceptional cases in the performance. As keywords with similar volumes are assigned to the same cluster, they become indistinguishable in terms of volume, which negatively impacts the accuracy of Jigsaw's first module. Beyond that, the cluster-based padding additionally brings instability in attacks' performance (see outliers in the figure). However, the average accuracy still remains practical.

(a) Enron (b) Lucene (c) Wikipedia, $|W| = 1000$ (d) Wikipedia, $|W| = 3000$ (e) Wikipedia, $|W| = 5000$

Figure 14: Comparisons with RSA and IHOP against the cluster-based padding [3, 43] in Enron, Lucene, and Wikipedia.

(a) Enron (b) Lucene (c) Wikipedia, $|W| = 1000$ (d) Wikipedia, $|W| = 3000$ (e) Wikipedia, $|W| = 5000$

Figure 15: Comparisons with RSA and IHOP against the padding in SEAL [14] in Enron, Lucene, and Wikipedia.

Against the Padding in SEAL. We present the results against the padding in SEAL [14], which pads the volume of keywords to the nearest power of an integer x. We note again that our attack only targets the padding strategy in SEAL. We set x to 2, 3, and 4 for the padding and demonstrate the results in Figure 15. Note that other parameters remain consistent with those previously configured. As x grows, the average accuracy of Jigsaw maintains above 70%, although there are a few outliers in the results. The padding also affects the performance of RSA and IHOP, causing an unstable and dropping trend. We summarise that though the results contain outliers when against the padding in SEAL and the cluster-based padding, the tested attacks provide fine accuracy in most cases under our settings.

GFWeb: Measuring the Great Firewall's Web Censorship at Scale

Abstract

Censorship systems such as the Great Firewall (GFW) have been continuously refined to enhance their filtering capabilities. However, most prior studies, and in particular the GFW, have been limited in scope and conducted over short time periods, leading to gaps in our understanding of the GFW's evolving Web censorship mechanisms over time. We introduce GFWeb, a novel system designed to discover domain blocklists used by the GFW for censoring Web access. GFWeb exploits GFW's bidirectional and loss-tolerant blocking behavior to enable testing hundreds of millions of domains on a monthly basis, thereby facilitating large-scale longitudinal measurement of HTTP and HTTPS blocking mechanisms.

Over the course of 20 months, GFWeb has tested a total of 1.02 billion domains, and detected 943K and 55K pay-level domains censored by the GFW's HTTP and HTTPS filters, respectively. To the best of our knowledge, our study represents the most extensive set of domains censored by the GFW ever discovered to date, many of which have never been detected by prior systems. Analyzing the longitudinal dataset collected by GFWeb, we observe that the GFW has been upgraded to mitigate several issues previously identified by the research community, including overblocking and failure in reassembling fragmented packets. More importantly, we discover that the GFW's bidirectional blocking is not symmetric as previously thought, i.e., it can only be triggered by certain domains when probed from inside the country. We discuss the implications of our work on existing censorship measurement and circumvention efforts. We hope insights gained from our study can help inform future research, especially in monitoring censorship and developing new evasion tools.

1 Introduction

The Great Firewall of China (GFW) is one of most sophisticated, well studied, yet opaque censorship apparatuses to date [39]. It has been reported to employ a complex array of filtering mechanisms, including DNS poisoning [11, 12, 32, 37, 47, 54, 71], keyword-based filtering [25, 40, 66, 83], TCP/IP blocking [25, 44, 60, 76, 79], and active probing against network relays [9, 33, 36, 78]. As the GFW continues to evolve, using increasingly advanced techniques [13, 22, 29, 31, 79], prior research efforts have not been able to fully characterize the capabilities and evolution of this dynamic censorship platform. In particular, most measurement efforts to date have been limited in scope, time period, or methodology.

To monitor censorship around the world, global measurement platforms like OONI [38], ICLab [56], and Censored Planet [64] rely on volunteers, commercial VPNs, or public servers to conduct network measurements. Each platform, however, has its own blind spots due to the trade-offs between cost, detail, and breadth of coverage (§2.2). Among prior studies focusing on Internet censorship in China, GFWatch [47] stands out as one of the largest longitudinal measurements of the GFW. However, it is singularly focused on DNS blocking, leaving the GFW's HTTP and HTTPS filtering policies largely unexplored. These two protocols, together with DNS, form the foundation of all Web communications. As a result, the collective filtering of these protocols plays a critical role in the overall operation of the GFW, and needs to be jointly studied to gain a more comprehensive understanding of the GFW's filtering capabilities. Unfortunately, no prior work has been able to conduct large-scale, longitudinal measurement of the GFW's HTTP and HTTPS filtering mechanisms.

To address these gaps, we have developed GFWeb, a large-scale system designed to uncover the GFW's different blocklists used for Web censorship (§5). GFWeb is capable of continuously testing hundreds of millions of domains on a monthly basis, profiling the censorship behavior of both HTTP and HTTPS filters. To achieve this scale, we have to overcome several challenges, that would otherwise prevent us from scaling up our measurement and obtaining a holistic view of the GFW's Web censorship. Specifically, our primary technical contributions lie in the design of a novel approach that strategically exploits the loss-tolerant and bidirectional filtering behavior of the GFW to overcome its stateful blocking, residual censorship, and asymmetric interference (§2.2).

Over a period of 20 months, from February 2022 to September 2023, GFWeb tested over one billion fully qualified domains (FQDNs), detecting 943K and 55K pay-level domains (PLDs) censored by the GFW's HTTP and HTTPS filters, respectively (§5.1). To the best of our knowledge, our findings represent the largest set of censored domains ever discovered and no prior study of the GFW matches this scale of active measurement over an extended period of time.

Our study reveals new insights into the GFW's evolving Web censorship policies. We discover that the GFW has fixed deficiencies identified by past research, including overblocking [47] and failures to reassemble out-of-order fragmented packets [20]. More significantly, we find its bidirectional blocking is not symmetric as previously thought [47, 72]. Many domains trigger blocking only when probed from within China but not externally (§5.3). We also observe localized network interference which is not caused by the GFW but individual ISPs and cloud providers (§6). These observations underscore the importance of conducting large-scale, longitudinal measurement from both sides of the GFW to better understand China's complex censorship environment.

Our findings have several implications for Internet freedom efforts (§7), and we are thus committed to keep operating GFWeb and will continue to update the community with GFW's domain blocklists and censorship behaviors. By sharing our findings, we hope to inform future research that advances the state of censorship measurement and inspires the development of novel censorship circumvention systems.

2 Background and Motivation

We first review the GFW's Web filtering techniques. We then delve into the challenges encountered by previous efforts and how they have motivated us to design GFWeb.

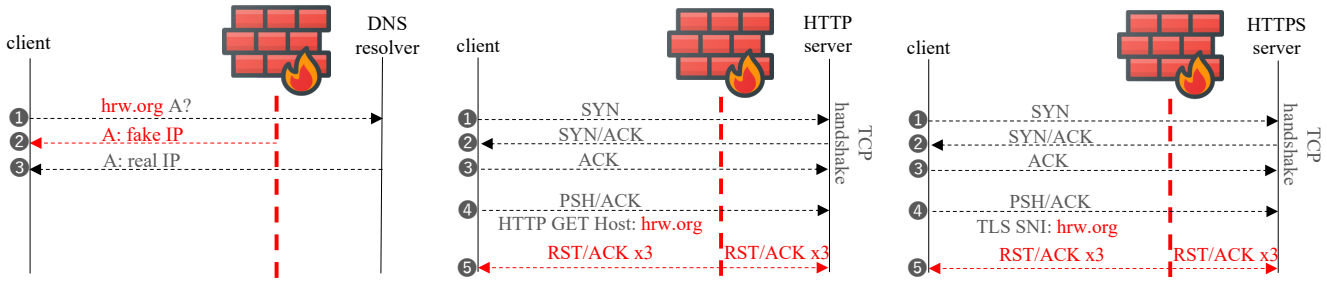
2.1 Web Filtering Mechanisms

China's Internet filtering framework, conceptualized in the late 1990s as part of the Golden Shield project [74, 82], serves as the government's tool for controlling the flow of online information. Often dubbed "the Great Firewall" (GFW) [40], this system comprises middleboxes distributed across border autonomous systems (ASes) [12, 27, 78] and managed in a centralized manner [29, 40, 83]. While the GFW employs several filtering mechanisms (§1), here we focus our discussion on DNS, HTTP, and HTTPS filtering, since these protocols play a foundational role in Web access.

2.1.1 DNS filtering

The unencrypted and unauthenticated nature of traditional DNS resolution is often targeted by censors around the world [61, 69]. The GFW operates as an on-path system and exploits the race condition of UDP-based DNS resolution by injecting false responses when it detects DNS queries for censored domains. As shown in Figure 1(a), the GFW injects a forged response towards the client upon detecting a DNS query for a restricted domain (e.g., `hrw.org`). Operating as an on-path system, the GFW does not discard the genuine response from the DNS resolver. However, since the GFW is typically closer to the client in terms of network distance, its fake responses often reach the client before the legitimate one [32, 47], effectively tampering with the DNS resolution process. Since almost every Web browsing session begins with a DNS query, this DNS blocking mechanism is the first filter of the GFW's multi-stage Web censorship operation.

2.1.2 HTTP and HTTPS filtering



When there is no DNS blocking or if a client manages to circumvent it [32, 42, 47, 50], the GFW's HTTP and HTTPS filters are the next layers of blocking. The GFW's HTTP and HTTPS filtering mechanisms involve stateful inspection of TCP connections. The GFW begins keeping track of a TCP connection's state when it sees the first SYN packet from the client sent to initiate the TCP three-way handshake. Upon detecting a censored domain in the HTTP Host header or the Server Name Indication (SNI) extension in the TLS Client Hello, the GFW then tears down the connection by injecting three RST/ACK packets to both the client and the server, as shown in Figures 1(b) and 1(c). Note that URLs explicitly prefixed with `https://` will not trigger the HTTP filter, though most users do not often type this protocol prefix.

2.1.3 Bidirectional filtering

A unique behavior of the GFW is its bidirectional blocking. Its filtering middleboxes are capable of inspecting and injecting traffic in both directions. As a result, not only clients inside the country experience censorship, but traffic sent from outside the country can also trigger censorship. This bidirectional behavior has become a common characteristic often used by the research community to measure the GFW [11, 12, 33, 35, 47, 55, 78] and other similar censorship regimes [18, 57, 58, 75]. We also leverage this behavior to design GFWeb and conduct large-scale measurement of the GFW's Web censorship against both HTTP and HTTPS connections (§4).

2.2 Existing Efforts and Challenges

Due to its reputation as being one of the most sophisticated censorship systems, impacting not just hundreds of millions of Internet users inside China but also the normal operation of the global Internet [47, 55, 71], the GFW has been the subject of numerous studies over the past two decades. Unfortunately, many of them have been limited in scope or conducted in a one-off manner, leaving gaps in our understanding of the GFW's Web filtering mechanisms over time.

(a) DNS filter over UDP (b) HTTP filter (c) HTTPS filter

Figure 1: The DNS, HTTP, and HTTPS filtering mechanisms of the Great Firewall. SYN, ACK, PSH, and RST denote TCP synchronization, acknowledgement, push, and reset flags. A packet with the RST flag set is meant to terminate a TCP connection.

GFWatch [47] is the largest active measurement system to date focusing exclusively on the GFW's DNS blocking. No study has longitudinally and systematically investigated the GFW's HTTP and HTTPS filters, which are equally important—in conjunction with DNS blocking, they form the multiple layers of the GFW's Web censorship capabilities. Understandably, probing DNS manipulation with UDP packets is much easier compared to measuring HTTP and HTTPS interference. This is because UDP-based DNS resolution is stateless and does not require a handshake process, allowing GFWatch to probe a massive amount of domains in a short period of time. On the other hand, HTTP(S) censorship, as shown in Figures 1(b) and 1(c), is stateful and necessitates several TCP packets to trigger the GFW's HTTP and HTTPS filters, making it more challenging to measure at scale.

More importantly, unlike the UDP-based DNS censorship which does not trigger residual censorship, once a TCP stream is interrupted, subsequent connections from the same client to the same server will also be blocked for a period of time, preventing continuous probing against HTTP and HTTPS filters. The GFW's TCP-based censorship has been observed to impose residual censorship on censored connections [17, 25, 66, 81]. This residual censorship is one of the main challenges that we have to tackle to conduct large-scale measurement of the GFW's HTTP and HTTPS filters.

Although the GFW might not be the main focus, there are platforms that are still actively operating to monitor global censorship, such as OONI [38], ICLab [56], and Censored Planet [64]. OONI [38] relies on volunteers to run accessibility tests. As of July 2023, however, OONI has been blocked in China, hindering regular measurement activities from within the country. More specifically, the platform has been blocked primarily by DNS injection against the main site and HTTPS filtering based on the SNI field of their data collection servers [70].

To minimize risks on volunteers, ICLab [56] uses commercial VPNs as its primary measurement vantage points. Yet, this method restricts its visibility into China, given the country's prohibitions on commercial VPNs [15, 23].

Censored Planet [64] employs remote measurement techniques to infer censorship by making use of public servers. Nonetheless, to avoid overburdening these machines the number of domains that can be frequently tested is limited, especially since these remote servers are not owned by the platform. Measuring from outside China also limits the platform's visibility into censored domains that will only trigger the GFW if tested from inside, due to asymmetric interference (§5.3).

A common design choice of these platforms is the reliance on the Citizen Lab test lists for test domains [4], limiting their measurement scope to only a few thousand domains. Collectively, these challenges and pitfalls of prior works have motivated us to design GFWeb and carry out this study to contribute to the Internet freedom community's efforts and close the gap in our understanding of the GFW's Web censorship.

3 Measurement Approach

Considering the challenges faced by prior efforts, we designed GFWeb with the following goals in mind: (1) our system should be able to conduct large-scale measurement of the GFW's HTTP and HTTPS filtering mechanisms to discover as many censored domains as possible within a reasonable amount of time to provide timely updates to the community; (2) the system should be designed to continuously monitor the GFW's Web filtering over time to gain a holistic view into its evolving Web censorship; and (3) to avoid posing any potential risks to volunteers and public servers, our system should not rely on these entities for data collection. In the following, we discuss how we overcome the challenges discussed in §2.

3.1 Reducing Cost of TCP Probing

Our first goal is to discover as many censored domains as possible and in a continuous manner. Unlike GFWatch [47],

which measures DNS censorship by simply sending UDP-based queries over port 53 from one side of the GFW to the other, TCP-based HTTP(S) probes are more expensive in terms of the required resources for several reasons, including the need for more than just one packet to establish a connection with an endpoint on the other side of the GFW.

We exploit the GFW's loss-tolerant blocking behavior to tackle this challenge. This loss-tolerant design is likely needed to cope with (1) the potential high packet loss rate due to the sheer amount of egress and ingress traffic from/to China the filtering middleboxes need to inspect, and (2) asymmetric routing that can cause packets to be routed through different network paths, i.e., packets ❷ and ❸ may not be routed through the same path as ❶ in Figures 1(b) and 1(c). Consequently, as long as the GFW can observe the initial SYN of a TCP connection (packet ❶), it will consider that connection as established and will inject three RST/ACK (packets ❺) upon detecting a censored domain in the HTTP Host header or the SNI extension of the TLS Client Hello (packet ❹).

Taking advantage of this loss-tolerant behavior, the cost of probing HTTP(S) middleboxes can be significantly reduced, as we can send a SYN packet (❶) followed by a PSH/ACK packet (❹) encapsulating the HTTP GET request or the TLS Client Hello for a domain of interest. Crucially, the PSH/ACK packet's sequence number *must be* equal to the SYN packet's sequence number plus one, to properly mimic the behavior of a real completed TCP connection. Without satisfying this condition, the GFW will not consider the connection as established, and will not inject RST/ACK packets even if the request payload contains a censored domain. This approach allows us to efficiently probe many domains by continuously sending SYN and PSH/ACK packet pairs to the other side of the GFW to trigger its HTTP(S) filters without having to wait for the three-way handshake to complete.

3.2 Bypassing Residual Censorship

Despite the above optimization, we still need to tackle another challenge, namely the GFW's residual censorship, a phenomenon that has not been fully characterized by the research community (we provide more details in §5.4). Previous reports show that once an HTTP connection is interrupted, subsequent packets with the same three-tuple will also be tampered with for a period of 90 seconds [17, 25, 66, 76, 81]. Any SYN packets sent during this period will trigger a forged SYN/ACK while other packets will be responded with RST or RST/ACK [76]. Consequently, this behavior can cause false positives in our measurement because subsequent benign probes would still trigger the filtering middleboxes.

A key mechanism of the GFW's residual censorship is that it is based on the three-tuple of the banned TCP connection, i.e., the source IP address, the destination IP address, and the destination port number. This means that if we can change any of these three fields, the residual censorship can be bypassed.

Different from the DNS filter, which only inspects packets sent to the default DNS port 53, the HTTP(S) filters are flexible and inspect packets destined to any TCP port number, instead of just the standard HTTP(S) ports 80 and 443. From a censor's perspective, this policy is necessary for coping with websites hosted on non-standard ports or censored users deliberately changing the destination port to bypass censorship. However, this flexibility also opens up the possibility for us to bypass the residual censorship by changing the destination port number of the TCP connection. In particular, we can send new HTTP(S) probes with a different destination port number than those previously used, while ensuring that GFWeb does not reuse the same port number if 90 seconds have not elapsed. Using this approach, we can bypass the residual censorship and continuously probe the GFW's HTTP(S) filters.

3.3 Accounting for the Impact of Ephemeral Ports on Censorship Behavior

Bhashkar et al. [14] find that ephemeral source ports can affect the packet routing, which in turn can affect the GFW's injection behavior. Together with the utilization of different destination port numbers to sidestep residual censorship, we also rotate the ephemeral source port of each probe to account for this potential impact. Naturally, this also becomes a tagging mechanism for us to keep track and later identify which domains trigger the GFW's HTTP(S) filters. In particular, every probe is uniquely tagged using a different combination of source and destination port numbers, virtually creating a one-to-one mapping between a tested domain and each pair of source and destination ports. We can then easily identify which exact domains are censored by checking the source and destination ports of the respective RST/ACK packets.

3.4 Avoiding Risks Posed on Volunteers and Public Servers

For our study, we opt to use a set of dedicated servers we control, located at both sides of the GFW, to avoid posing any potential risks to end users. Our machines outside China are located in an educational network where we have confirmed that there is no censorship. For machines inside China, we use servers located in two different ASes and at two distant geographical locations, allowing us to probe the GFW via different network paths. These machines are in the data centers of two major cloud providers: Aliyun and QCloud.

Although previous studies have shown the centralized blocking policy of the GFW [29, 40, 83], we still decided to use multiple servers to ensure that our findings are not limited and biased to a specific location. In fact, this decision has been proven to be beneficial, as we show later in §6, as GFWeb was also able to capture some localized network interference events that were not thoroughly investigated by prior works, but can still be of interest to the community.

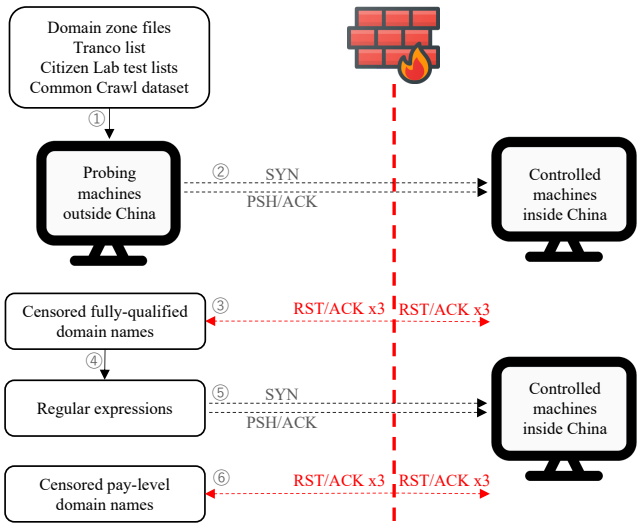


Figure 2: The design of GFWeb's probing approach, which does not rely on the completion of the three-way handshake for triggering the GFW's HTTP(S) filters.

Table 1: The number of test domains from each source.

Source	# Domains
ICANN's TLD Zone Files [2]	389.5M SLDs
Common Crawl's Web Crawl Data [1]	903.4M FQDNs
Tranco List [62]	33.4M FQDNs
The Citizen Lab Test Lists [4]	25.9K FQDNs

4 GFWeb Measurement Pipeline

We next describe the measurement pipeline of GFWeb, the test lists used, and the rationale behind our design choice.

4.1 Domain Test Lists

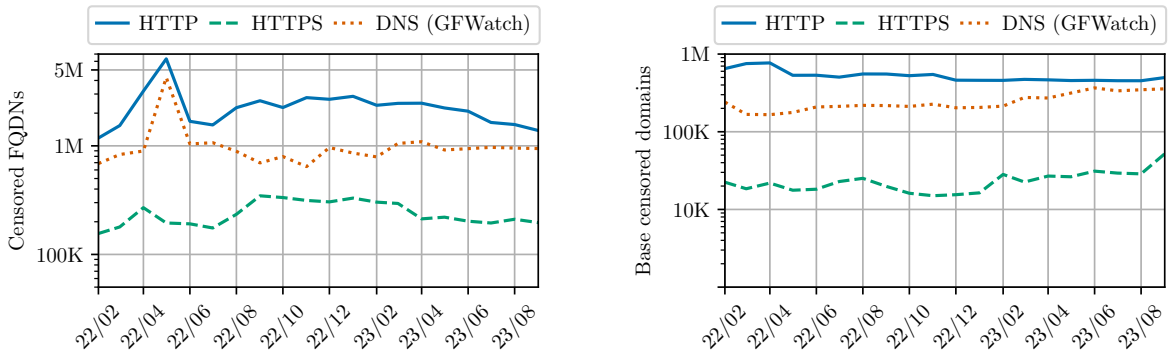
Similar to GFWatch [47], we use the same domain test lists used by this prior work to conduct our measurement, which also makes our results more comparable. These domain test lists are collected from various sources, including top-level domains (TLD) zone files [2], the Citizen Lab test lists [4], the Tranco list [62], and the Common Crawl project [1]. For every new probing batch, we download the latest version of each list to make sure that GFWeb tests up-to-date domains.

The rationale behind this choice of domain lists is their direct impact on the set of censored domains that will be discovered, as well as on subsequent analyses. Different domain test lists have different characteristics, and the censored domains discovered will be a subset of the domains tested. To avoid any potential bias introduced by individual test lists, we use multiple domain sources in our study to ensure that (1) we can cover as many domains as possible, and (2) our findings are holistic and not limited to a specific set of domains.

From February 2022 to September 2023, GFWeb has tested an average of 600M FQDNs/month, totaling 1.02 billion FQDNs over the course of 20 months considered in this paper. These domains span 1.5K TLDs[1] and 694M PLDs.[2] Table 1 summarizes the number of domains from each source.

4.2 Overall Architecture

Figure 2 illustrates the overall architecture of GFWeb and our measurement pipeline. We start with the curation of the test lists (step ①). Then, our probing machines located outside China send SYN and PSH/ACK packet pairs to the other side of the GFW (step ②), with each probe uniquely tagged by a different pair of source and destination port numbers. The payload of the PSH/ACK packet contains the HTTP GET request or the TLS Client Hello for the domain being tested.



Our machines inside China are configured to not respond to any packet sent from the probing machines. This ensures that the observed injected packets are indeed from middleboxes, allowing us to infer which domains are censored (step ③). This configuration is essential for avoiding false positives, because a typical server will respond with a RST or RST/ACK packet to any non-RST TCP packet sent to an open port that does not have a listening service. This is another benefit of using our own servers to conduct the measurement, as we can easily configure them to suit the purpose of our study, eliminating risks posed on volunteers and public servers, while also preventing false positives from tainting our results.

In our previous work [47], we showed evidence of the GFW's DNS blocking based on regular expressions. Inspired by this finding, for every censored domain discovered in step ③, we also attempt to reverse engineer its blocking pattern by creating eight different permutations by splitting the domain into different substrings and concatenating them with a random string (step ④). This set of permutations is then also probed against the GFW (step ⑤). Finally, by analyzing injections from the GFW's HTTP(S) filters (step ⑤), we can infer the blocking pattern of the censored domains (step ⑥).

This overall measurement approach is repeated in the other direction from our machines inside China, while discovered censored domains are also re-tested every day to keep track of their blocking status over time. To account for uncontrollable factors, such as packet loss or temporary failures of the GFW when it is overloaded [11, 36], each domain is probed at three different times during the day using different source and destination port number pairs.

[1]This number is larger than the number of TLDs currently reported by ICANN [2] because some TLDs that used to be active at the time of our measurement are no longer in use as of this writing.

[2]We determine pay-level domains (PLDs) using the public suffix list [3].

(a) Censored fully qualified domains

(b) Base censored domains

Figure 3: Number of HTTP(S) censored domains (in log scale) detected over time by GFWeb compared to GFWatch [47].

5 Measurement Results

In this section, we present the results of our measurements and discuss in detail the differences between the observed censorship behaviors of the GFW across the three considered protocols (DNS, HTTP, and HTTPS).

5.1 Censored Domains Over Time

As shown in Figure 3(a), on a monthly basis, GFWeb detects an average of 2.4M and 243K FQDNs censored by the GFW's HTTP and HTTPS filters, respectively, whereas GFWatch [47] detects about 1.06M FQDNs censored by the DNS filter.[3]

There is a spike in the number of FQDNs censored by the HTTP filter in May 2022, peaking at more than 6M censored FQDNs. Investigating the cause of this spike, we found that it is due to the addition of many new subdomains of domains that are already censored by the GFW (e.g., `*.blog.jp`). Our decision to include domains from the Common Crawl dataset [1] is the primary reason behind this spike, as the dataset is regularly updated with crawls containing many new subdomains of PLDs that are already censored. The same spike can also be seen in the GFWatch dataset.

To more accurately quantify the GFW's censored domains while making our results comparable to GFWatch's, we analyze the blocking rules of the censored FQDNs by reverse-engineering the regular expressions used by the GFW to identify the base censored domains. A base censored domain is the shortest domain name that matches the blocking rules of the GFW. For example, the base censored domain of `en.wikipedia.org` and `zh.wikipedia.org` is `wikipedia.org`. As shown in Figure 3(b), the number of base censored domains is indeed much smaller than the number of censored FQDNs. In particular, we find an average of 528K and 24K base censored domains per month for HTTP and HTTPS filters, respectively. GFWatch discovers an average of 247K base censored domains per month.

[3]We obtained the set of censored domains due to DNS filtering for the same time period from GFWatch's public dashboard [43].

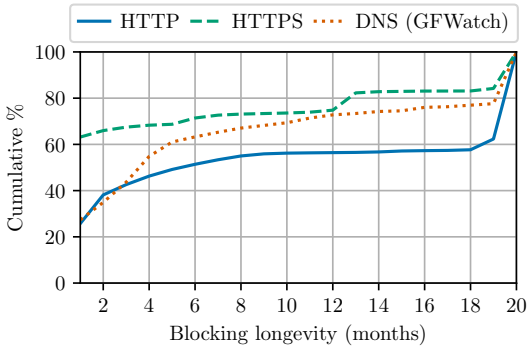


Figure 4: CDF of the longevity of domains censored by the GFW's DNS, HTTP, and HTTPS filters.

While the number of base domains censored by the HTTP filter is relatively stable, with a slight decrease in 2023, the patterns of the number of base domains blocked by the DNS and HTTPS filters are similar over time, with a slight increase in 2023. As more Web traffic gets centralized and encrypted [34, 45, 46, 48, 49] and major browsers are deprecating HTTP in favor of HTTPS (e.g., Chromium announced in August 2023 that it will automatically upgrade all HTTP connections to HTTPS [24] even if a user types in an HTTP URL), we anticipate that the HTTPS filter will block a constantly increasing number of domains in the near future.

Furthermore, our analysis of blocking longevity reveals a distinct persistence in censorship across protocols. Different from the HTTPS filter, both HTTP and DNS filters demonstrate a propensity to maintain blocks over extended periods, with over 50% of their censored domains experiencing restrictions for at least three months, as shown in Figure 4. This endurance in blocking strategies signifies a nuanced approach to Web censorship, emphasizing the need for continuous monitoring systems like GFWeb.

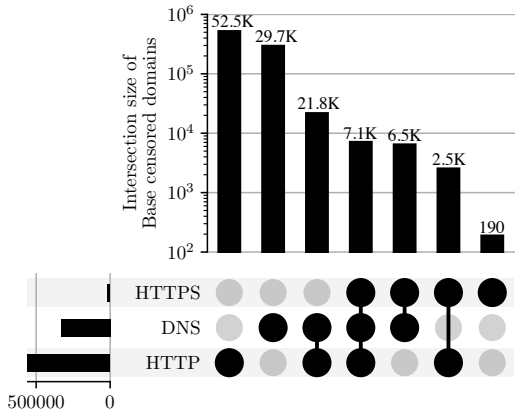

Figure 5: Intersections between the blocklists of the GFW's DNS, HTTP, and HTTPS filters, with *y*-axis in log scale.

Overblocking In our previous work [47] we observed that the GFW's DNS filter overblocks many domains that are totally unrelated to the base censored domains, causing collateral damage to tens of thousands of innocuous websites that happen to be blocked in China. For instance, the Tor Project's website (`torproject.org`) is blocked by the GFW's DNS filter using the regular expression `*torproject.org`, which also matches domains like `mentorproject.org` or `ventilatorproject.org`.

We observe that this overblocking behavior is now less prevalent across all three protocols. In particular, we find that the GFW has fixed the overblocking issue of the DNS filter. Nine out of the ten most overblocked rules reported in [47] are now correctly implemented with an additional dot (`\.`) character at the beginning of the regular expressions. Measurement results from GFWeb also indicate that the vast majority of regular expressions used by the GFW's HTTP and HTTPS filters are also more specific and properly implemented to block only subdomains and country code top-level domains (ccTLDs) of the base censored domains. While a few domains are still being overblocked by the HTTP filter due to overly broad regular expressions (e.g., `*archive.today`), overall our measurement shows that the previous issue with overblocking has been largely mitigated, significantly reducing the collateral damage caused to unrelated domain names.

5.2 Cross-Protocol Comparison

Comparing base censored domains across all three protocols, we find that the HTTP filter has the largest blocklist, followed by the DNS and HTTPS filters. We illustrate the intersections between the blocklists of base censored domains across the three protocols in the UpSet diagram [53] of Figure 5. To prevent short-lived censorship events in which a domain is blocked for only a couple of days from skewing our results, for this analysis we consider a domain to be blocked by a given filter if it is blocked by that filter for at least three months.

Figure 5 shows that there are around 7.1K base censored domains blocked across all three protocols. There are more than 21.8K domains that are blocked by the HTTP and DNS filters but not by the HTTPS filter, while 2.5K domains are blocked by the HTTP and HTTPS filters but not by the DNS filter. Less than a couple of hundred domains are blocked solely by the HTTPS filter. This result shows that the three filters operate on different blocklists that are not mutually exclusive and complement each other to form the core of the GFW's Web censorship. A regular Web browsing session of a user from inside China visiting a foreign website, without any usage of circumvention tools, will be inspected and interfered with by either one or a combination of these filters if the visited domain is censored.

While an official report of the GFW's design has never been published, the differences in the DNS, HTTP, and HTTPS blocklists can be attributed to the technical nature of each protocol, implementation cost, and strategic implications.

HTTP traffic is unencrypted, allowing for granular content-based filtering using Deep Packet Inspection (DPI). The GFW can inspect the entire content of HTTP requests and responses, allowing it to block individual pages even based on specific keywords from the URL [66]. This fine-grained control means that there could be many specific rules and block criteria, leading to a larger blocklist. Another potential explanation is that the HTTP filter has been around for a longer time, when HTTPS was not as prevalent as it is today [8]. The HTTP filter, thus, has had more time to accumulate a larger blocklist.

The DNS filter operates at the forefront of the GFW, allowing it to tamper with a browsing session even before any traffic could be sent to the actual web server if the visited domain is blocked. From an operational perspective, DNS blocking, although easily bypassed [32, 47, 50], is the cheapest to implement, as it only requires an on-path filtering middlebox to inspect DNS queries and forge DNS responses.

Among the three protocols, HTTPS blocking is arguably the most expensive to implement. Due to the encrypted nature of HTTPS, DPI becomes less effective because only the unencrypted portion of the TLS handshake can be inspected. This means that the GFW cannot inspect the content of HTTPS requests and responses, and instead has to rely on the Server Name Indication (SNI) field in the TLS handshake to identify the domain of the visited website. Moreover, a TLS Client Hello packet generally has more fields compared to an HTTP request header or a DNS query, making HTTPS blocking more operationally expensive than the other two protocols.

Collectively, the blocklist sizes reflect a balance between the technical constraints of each protocol, the cost of implementation, and the strategic goals of the GFW. As GFWeb continues to monitor the GFW's Web censorship, we anticipate that it will continue to ramp up its blocking capabilities against secure protocols like HTTPS in the future. The finding

of different blocklists across the three protocols also has several implications for existing measurement and circumvention efforts, which we discuss in more detail in §7.

5.3 Asymmetric Interference

The GFW has been long believed to be a bidirectional filtering system that symmetrically interferes with both egress and ingress network connections. Our measurements from both sides of the GFW, however, reveal that this is not always the case. Specifically, there are certain domains that will trigger the filtering middleboxes to take injection actions only when the probing direction is from inside China, but not from outside. We refer to this behavior as *asymmetric interference*.

Comparing the sets of domains that trigger the GFW from both sides, we found about 1K domains that only trigger the HTTPS filter to inject RST packets when probed from inside the country. The domains mostly belong to Google (e.g., `google.com.hk`) or are related to circumvention tools (e.g., `torproject.org`, `go-vpn.com`, `dr-wall.com`, `aihuiguo.com`, and `wallvpn.com`). Probing these domains from outside China will not trigger any interference from the GFW's HTTPS filter. This is also evident by the very low number of network anomalies detected by Censored Planet for these domains. As shown on the platform's dashboard [7], most `Unexpected Rates` for these domains are below 20%, as opposed to ∼100% for domains that are symmetrically interfered with by the GFW's HTTPS filtering middleboxes.

This finding has very important implications on censorship monitoring systems that perform their measurements under the assumption that a censoring system is always bidirectional. The GFW's HTTPS filter will not interfere with the probes for these domains that are sent from outside the country, potentially resulting in false negatives, i.e., inferring that they are not filtered while in reality they are.

5.4 Traffic Dropping as Residual Censorship

In addition to the asymmetric interference above, this group of domains also exhibit another interesting behavior: prolonged traffic dropping. In particular, probing these domains will trigger the GFW to *drop* subsequent packets that share the same three-tuple for an extended period of time. This behavior is different from the GFW's penalty box observed by previous studies, where the GFW will continue to interfere with subsequent connections by injecting RST packets. Instead, the GFW will *keep dropping* any subsequent TCP packets that share the same three-tuple.

Unlike previous reports of the 90-second penalty box [17, 25, 66, 76, 81], which keeps injecting RST packets, we discover that this traffic dropping behavior will continue happening for up to 350 seconds for TCP packets that share the same three-tuple. Although this residual censorship is only imposed on a few domains, it can impact the straightforward use of probing-based evasion tools (§7).

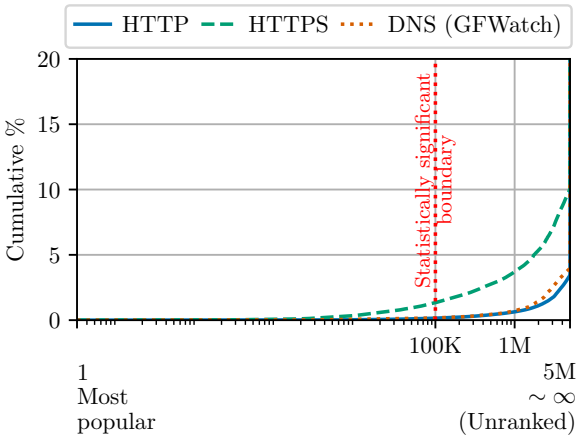

Figure 6: CDF of the popularity ranking of base censored domains (*x*-axis is in log scale).

5.5 Popularity Ranking of Censored Domains

Aggregating the ranking information provided by the Tranco list [62] and the Common Crawl dataset [1], we analyze the popularity of the base censored domains discovered by GFWeb for HTTP(S) filters in comparison to the GFWatch (DNS filter) dataset. As shown in Figure 6, the vast majority of the censored domains are not popular, with more than 98% of them having a popularity ranking higher than 100K across all DNS, HTTP, and HTTPS block lists. Less than 0.2% of the censored domains are among the top 100K for both the DNS and HTTPS block lists, and 1.3% for the HTTPS block list. Note the 100K-th position is the statistically significant boundary for website popularity ranking [68].

This result shows how different test lists (or subsets of a single list) can lead to different conclusions about which domains are censored and their popularity, especially when prior studies have often relied on relatively small test lists or just a few thousand domains from website top lists [38, 56, 64]. In contrast, to gain a more holistic view of the GFW's Web censorship, we have tested as many domains as possible, curated from diverse sources (§4.1).

5.6 A Taxonomy of Censored Domains: Web Categories and Hosting Origins

For categorizing domains, we use VirusTotal's classification service [5]. Of more than 1M based censored domains discovered, we could only categorize 79.5K domains because many domains no longer exist or do not currently host any content. Figure 7 shows the top ten categories of the base censored domain and their distribution. The categories with the most censored domains include `File sharing/storage`, `adult`

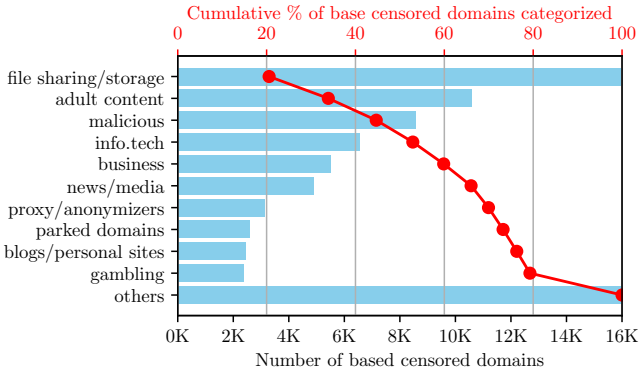

Figure 7: Top ten categories of the base censored domains discovered by GFWeb.

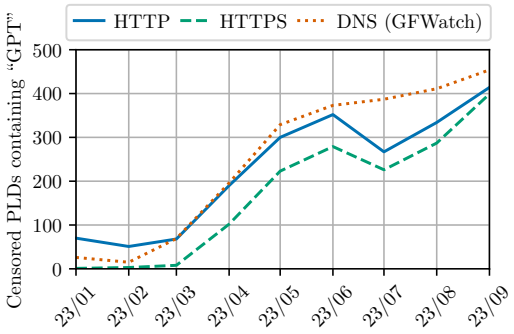

Figure 8: Number of censored PLDs containing "GPT" in their domain names detected by GFWeb and GFWatch [47] since the beginning of 2023.

`content`, `malicious`, `info.tech`, and `business`, comprising 60% of all domains classified.

Ramping Up Censorship against AI-related Domains. As Artificial Intelligence (AI) is gaining traction in recent years, China has been taking substantial steps in regulating the AI sector. On April 11, 2023, the Cyberspace Administration of China released draft measures for regulating generative AI services [28]. As a result, several popular AI tools and platforms used globally are restricted in China. We observed numerous prominent AI-related domains becoming censored during this time, including `chat.openai.com`, `deepai.org`, and `huggingface.co`. In addition, GFWeb also discovered a new wave of blocking against PLDs containing "GPT" as part of their name. Figure 8 shows the number of censored PLDs containing "GPT" in their domain names that GFWeb and GFWatch [47] detected since the beginning of 2023.

Shortly after the release of the regulations, many new AI services by domestic companies entered China's market [77]. These events reflect China's broader strategy to exercise state control over the development of AI technologies, and how monitoring the GFW can provide deeper insights into the country's policy-making process. This case also highlights the role of China's Internet censorship in economic protectionism, promoting domestic companies over foreign competitors.

Hosting Origin. We also attempt to identify the origins of the censored domains by looking up their hosting IP address(es) and mapping them to respective Autonomous System Numbers (ASNs) and organizations. The majority of the censored domains are hosted by cloud service providers from Western countries. Table 2 shows the top ten ASes responsible for hosting over 13K base censored domains each. An intriguing aspect of this analysis reveals disparities in the number of base censored domains among various cloud providers, contingent upon the type of censorship applied. More specifically, domains hosted on Google, Cloudflare, BGPNET Global, and Microsoft are more targeted by the DNS filter, whereas those on CyberNet Servers, Amazon, and Trellian Pty. Limited experience more blocking by the HTTP filter. This discrepancy underscores the nuanced approach of the GFW towards censorship across different protocols and highlights the critical need for comprehensive measurement tools such as GFWeb to fully understand and document these censorship patterns.

Table 2: Top ten ASes that host the most base censored domains that are blocked by the GFW's DNS, HTTP, and HTTPS filters. Note that the numbers are not mutually exclusive as a domain may be censored by more than one filter as discussed earlier in §5.2.

ASN	Organization	Total	DNS	HTTP	HTTPS
15169	Google	92069	81247	12767	2827

5.7 Detail Comparison with Prior Work

To better illustrate (1) the differences between GFWeb and prior censorship measurement platforms and (2) how our work complements existing efforts, we compare the number of tested and censored PLDs discovered by GFWeb with OONI [38] and Censored Planet [64], two measurement platforms that are actively measuring global Internet censorship, including China's HTTP and HTTPS filtering.

For the OONI dataset, we obtain Web connectivity tests conducted in China during the same period of time as our measurement from OONI Explorer [59]. For Censored Planet, we obtain the test results from the project's dashboard [6].

Table 3: The number of tested and censored pay-level domains (PLDs) GFWeb has discovered in comparison to current censorship measurement platforms that are still actively measuring China's HTTP and HTTPS filtering. GFWatch is not included in this table as it only measures DNS filtering and has been compared in more detail earlier in this section.

Platform	Direction	Duration	Tested PLDs		Censored PLDs		Common censored PLDs	
		Testing Protocol	HTTP	HTTPS	HTTP	HTTPS	HTTP	HTTPS
OONI [38]	inside	2022/02 - 2023/09	13K	85K	275	211	212 (77%)	151 (71.5%)
Censored Planet [64]	outside	2023/03 - 2023/09	2K		1K	220	512 (50%)	220 (100%)
GFWeb	both sides	2022/02 - 2023/09	694M		943K	55K	N/A	

Note that we could only obtain data from March 2023 to September 2023 from the project's dashboard at the time of conducting this comparison. As shown in Table 3, GFWeb has tested far more domains and also discovered a much larger number of censored PLDs than the other two platforms.

Unlike GFWeb, OONI [38] does not design dedicated tests to probe the GFW's HTTP and HTTPS filters separately. Instead, OONI's Web connectivity tests are designed to replicate the normal browsing session of a user by sequentially (1) conducting DNS lookup, (2) connecting to the web server using the IP(s) returned, and (3) sending an HTTP(S) request to the web server depending on whatever the protocol of the URL provided by the Citizen Lab's test lists [4]. Thus, to determine the number of domains tested against the GFW's HTTP and HTTPS filters, we utilize the protocol prefix (i.e., `http://` or `https://`) of the URLs tested to count the number of HTTP and HTTPS domains. Over the same period of time, OONI has tested 13K and 85K HTTP and HTTPS PLDs, respectively.

Like GFWeb, Censored Planet [64] conducts independent tests for HTTP and HTTPS. From March to September 2023, Censored Planet has tested about 2K PLDs for both protocols. The discrepancy between the number of domains tested by Censored Planet and OONI despite both platforms relying on the Citizen Lab's test lists [4] is due to Censored Planet's design choice of focusing more on testing the China-specific list while OONI's volunteers are free to choose which domains they would like to test.

Overall, GFWeb largely agrees with the other two platforms in terms of the number of censored domains that are commonly detected. As shown in Table 3, GFWeb and OONI agree on more than 70% of the censored domains detected by both platforms. GFWeb also agrees with Censored Planet on 100% of the domains censored by the HTTPS filter. Analyzing the remaining discrepancies, we find that the majority of them are due to localized network interference events but not the GFW's HTTP and HTTPS filters, as we will show in §6.

6 Other Cases of Network Interference

While the ultimate goal of our study is to investigate the GFW's Web censorship, we encounter some interesting cases where localized network interference events could also be observed from major cloud providers and ISPs in China.

6.1 Hosting Providers' Redirection

Our measurement machines in China are located in the data centers of two major cloud providers: Aliyun and QCloud. While analyzing network traffic collected by GFWeb, we found that both providers have deployed DPI middleboxes to interfere with HTTP connections and attempt to redirect users to warning pages when certain domains are requested despite the location of the request client (i.e., inside or outside China). Specifically, Aliyun injects a redirection to `batit.aliyun.com/alww.html` and QCloud injects a redirection to `dnspod.qcloud.com/static/webblock.html` as shown in Figure 9. These pages warn that the domain being requested is not registered with the Chinese government. For a domain to be hosted from within China, it needs to be registered with the Chinese Ministry of Industry and Information Technology (MIIT) and obtain an Internet Content Provider (ICP) license.

Both providers' DPI middleboxes are deployed as on-path devices and intercept packets in a stateless manner. In other words, these redirection injections can be triggered without initiating a complete TCP handshake (i.e., packets ❶-❸ in Figure 1(b)). An HTTP PSH/ACK packet (❹) with the payload of a trigger domain is sufficient to prompt the middleboxes to inject a redirection towards the side of the connection that sends the PSH/ACK packet. Bock et al. [16] has recently found that this behavior could be weaponized for TCP-based amplification attacks since the injected warning pages are much larger compared to the original HTTP request.

Over the course of our study, Aliyun and QCloud middleboxes have interfered with 36.5M and 39.1M FQDNs, respectively. Clustering these domains by their PLDs, we find a total of 7.8M and 6.8M PLDs whose HTTP requests were redirected to Aliyun and QCloud ICP warning pages. It's worth noting that this interference is not caused by the GFW and should not be considered as nation-state censorship. Instead, they are caused by the hosting providers to enforce the ICP license requirements since a benign domain like `example.com` also triggers the redirection of QCloud's middleboxes.

(a) Aliyun redirection to `batit.aliyun.com/alww.html`

(b) QCloud redirection to `dnspod.qcloud.com/static/webblock.html`

Figure 9: Redirection injected by Aliyun and QCloud to warn about ICP license requirements.

Figure 10: China's "Anti-Fraud" redirection.

6.2 China's "Anti-Fraud" Redirection

In late 2021, there were some reports of new network interference events across major state-owned ISPs [26, 73], including three largest operators: China Telecom, China Unicom, and China Mobile [51]. Many users reported that their browsing sessions were redirected to a warning page showing an "Anti-Fraud" message. As indicated in Figure 10, the warning page advises users that the site they are trying to access is suspected of fraud and asks them to install an app developed by the State Anti-Fraud Center from the Android or the Apple app stores.

GFWeb has also observed this network interference. Applying the limited time-to-live (TTL) probing approach used in prior works [11, 65], we confirm that it is indeed caused by the ISPs. While we did not have direct access to vantage points within these ISPs, one of our measurement machines in China is located in a data center whose upstream provider is China Telecom, allowing us to observe the redirection injected by this ISP's middleboxes. Similarly to the GFW, they can inspect and inject packets bidirectionally. They are also deployed as on-path devices and have a loss-tolerant design (i.e., can be triggered without a complete TCP handshake).

GFWeb observed a total of 2.3M redirection attempts caused by China Telecom's middleboxes. In addition to two URLs reported on the Tor Project's GitLab [73] (i.e., URLs 1 and 2 in Table 4), we have also observed six other URLs that share the same pattern but were injected with lower frequency. Our data also indicates that URLs ending with `parameter1` and `parameter2` were not deployed until February 2023.

Table 4 also lists some injected URLs that we deem as "buggy" because they contain either an invalid or non-routable IP address (i.e., `0.0.0.*`). We believe that these URLs are a result of misconfiguration because the injection of these URLs will not lead to any redirection, and thus they are not effective for the ISP's intended purpose.

GFWeb observed 478K unique FQDNs that trigger these injections. Still, we could not find any patterns that could explain why these domains were targeted, since they only triggered the redirection for a short period of time. Looking up the IP addresses of these domains, we find that less than half of them are associated with an IP address, while the remaining are either not associated with any IP address or not existing (i.e., NXDOMAIN [21]). Instead of targeting specific domains that are truly associated with fraud, this observation suggests that the redirection could have been randomly triggered in an opportunistic manner to redirect users to the warning page, persuading them to install the government's "anti-fraud" app. This is evident by the fact that one of the trigger domains was `baidu.com` [73], which is obviously not fraudulent.

The original anecdote [73] also reported that OONI [38] and Censored Planet [64] observed this network interference happened via DNS injection as well. However, we could not reproduce redirection cases caused by DNS injection of `182.43.124.6` anymore. This strengthens our hypothesis that the redirection is performed in an opportunistic manner and does not target any particular domains for a long period of time. At the time of writing, we are still observing this network interference from China Telecom and will continue monitoring for any change in the future.

Table 4: Redirection URLs injected by China Telecom's middleboxes.

Index	# Triggered	Redirection URLs
1	1.7M (75.2%)	182.43.124.6
2	182K (7.9%)	182.43.124.6/fzyujing?parameter
3	123K (5.3%)	0.0.0.0/fzyujing?parameter1
4	86K (3.7%)	0.0.0.0/fzyujing?parameter
5	74K (3.2%)	182.43.124.6/fzyujing?parameter1
6	67K (2.9%)	182.43.124.6/fzyujing?parameter2
7	26K (1.1%)	0.0.0.0
8	6K (0.3%)	0.0.0.0124.6/fzyujing?parameter

7 Implications

This section discusses the implications of our findings for censorship measurement and evasion, especially in the context of monitoring and circumventing the GFW's Web censorship.

7.1 External Measurement Based on Bidirectional Filtering

The asymmetric filtering policy discovered in §5.3 impacts platforms that rely on bidirectional censorship. Within the research community, there have been two main hypotheses on why the GFW's Web censorship is designed to be bidirectional. One is that the GFW is designed to also geo-block some domestic websites hosted inside China, preventing their access from outside the country. The other is that maintaining the direction information of every connection can be operationally expensive for the GFW, given the massive amount of traffic that leaves and enters the country at any given time.

In our previous work [47] we found evidence to support the former by showing that the GFW's DNS filter indeed injects forged responses to DNS queries for some websites hosted inside China. Our finding of asymmetric interference, however, shows that the GFW can maintain the direction information of network connections, and only takes interference actions when the direction of a triggering probe is from inside China.

While this asymmetric interference is only applied to a small group of domains, this filtering policy can affect systems like Hyperquack [72] which rely on bidirectional censorship to conduct remote measurement as the GFW's HTTPS filter will not interfere with certain probes from outside China. Indeed, HTTPS analysis from the project's dashboard shows relatively low `Unexpected Rates` for these domains [7].

7.2 Measurement Based on a Single Protocol

Different blocklists across DNS, HTTP, and HTTPS filters discussed in §5.2 could lead to incomplete visibility into the GFW's Web censorship of measurement systems that rely on a single protocol to detect censorship. OONI [38], for instance, is designed to capture censorship in multiple protocols for Web connectivity, but its results can be biased towards the first protocol being interfered with due to the sequential nature of its testing. For example, `hrw.org` is blocked across all three protocols, but many OONI's test results will indicate only DNS blocking because DNS is the first layer of censorship triggered. Subsequent connections may not be indicative and conclusive of HTTP(S) filtering since the resolved IPs have already been falsified by the DNS filter. Unless the testing client could evade the DNS filter [32, 42], or the GFW sometimes fails the race condition [47], OONI may not be able to observe interference caused by the HTTP(S) filters. Moreover, OONI will also not observe interference by the HTTP filter if the input URL from the Citizen Lab test list [4] is already prefixed with `https://`.

Similarly, DNS-based systems like GFWatch [47] will miss domain names that are only blocked by the HTTP(S) filters. On the other hand, TCP-based measurement systems like Cloudflare Radar [63] will miss domains that are blocked by the DNS filter. Cloudflare Radar relies on passive TCP connections observed at their CDN edge servers to detect connection tampering. However, since many censored domains may have already been blocked by the GFW's DNS filter even before the TCP connection could be established, Cloudflare will never see the TCP connections initiated for such domains. As a result, what Cloudflare Radar sees is a subset of the GFW's Web censorship imposed on domains that the DNS filter does not or fails to block.

Even outside the context of censorship measurement, Xie et al. [80] recently proposed Secrank, a China-specific domain top list built from passive DNS traffic collected by the largest public DNS resolver in China. Checking the censored domains detected by GFWeb against Secrank top SLDs, we find more than 73K common SLDs that are censored by the GFW's HTTP(S) filters, including many popular known censored domains (e.g., `google.com`, `facebook.com`, and `hrw.org`). This observation suggests that DNS queries alone may not be sufficient to reflect the actual situation of Web access in China as the GFW's HTTP(S) filters can still block a significant number of domains after the DNS resolution process.

7.3 Probing-based Evasion Strategy

The discovery of the GFW's traffic dropping as a form of residual censorship against certain domains (§5.4) also has an important implication for evasion tools that rely on probing the GFW to automate strategy searching.

Geneva [19], for example, is the state-of-the-art evasion strategy generator that functions based on genetic algorithms to automate the generation of evasion strategies. The process involves continuously probing a target censor to search for evasion strategies, and requires prior knowledge of the censor's blocking behavior to guide the search process. In particular, a consistent censoring signal (i.e., injected packets

or traffic dropping) has to be known in advance to determine whether an evasion strategy is effective or not.

Thus, the coexistence of both injected packets and traffic dropping in the GFW's blocking behavior against the same protocol as shown in §5.4 can be problematic for Geneva-like tools for two reasons. First, the GFW's traffic dropping behavior can be a significant obstacle for the automation process because once activated it can stay effective for at least 350 seconds, preventing continuous probing. Second, the absence of packets injected by the GFW may trick Geneva-like tools into concluding that an effective evasion strategy has been found if the initial assumption is that the GFW will inject packets if a strategy is unsuccessful, and vice versa.

With the increasing popularity of automated evasion tools [19, 42], Amich et al. [10] recently examined the possibility of censors using machine learning to detect probing traffic and impose traffic dropping, to prevent the discovery of straightforward automated probing-based strategies. To the best of our knowledge, this is the first time prolonged traffic dropping triggered by probing censored domains against the GFW has been observed in the wild. All traffic dropping cases observed by prior studies are in the context of blocking fully encrypted connections of network relays [9, 33, 36, 78, 79] or Encrypted SNI [52], but not Web censorship.

This newly discovered prolonged traffic dropping behavior is, perhaps, the GFW's response to recent developments in automated evasion discovery to hinder the straightforward use of such tools. In fact, we have also noticed that the GFW's HTTPS filter already fixed an issue that prevented it from reassembling out-of-order fragmented TLS Client Hello packets [20]. At the time of this writing, it is now capable of correctly reassembling these fragmented packets and takes interference actions based on the reassembled domain name detected in the SNI extension.

8 Discussion

We next discuss the ethical considerations and limitations of our work, and make suggestions for future censorship monitoring and circumvention efforts.

8.1 Ethical Considerations

Internet censorship, particularly when implemented by nation-states, is often driven by political motives [30, 41, 67], making it a delicate subject of study. Consequently, assessing network interference resulting from nation-state censorship demands careful execution that does not impose risk on any end users. In designing GFWeb (§4), we send probes between machines under our control for data collection, thus eliminating the need for participation from end users. This core strategy enables GFWeb to fully operate in an autonomous manner and allows for straightforward system redeployment from different vantage points if needed. To further reduce potential impact on the hosting providers where our measurement machines are deployed in China, we will apply the limited TTL-based probing strategy so that our external probing packets will reach the GFW but not the hosting providers' network.

We have also considered the broader implications of our research on different communities including academics, policymakers, and the general public. Our goal through this empirical measurement study is to furnish a factual, holistic, and unbiased analysis that contributes to the understanding of the GFW's Web censorship and its impact on Internet freedom of hundreds of millions of users in China. We thus design GFWeb in a scalable and longitudinal fashion such that the system can continuously test an extensive range of domain names from multiple sources instead of relying on any single test list of domain names (§4.1), which could potentially introduce bias into our measurement results.

By adhering to these considerations, our study contributes valuable knowledge to the field of Internet censorship research while upholding our commitment to responsible and ethical research practices.

8.2 Limitations

Localized Censorship. Each measurement system is designed with specific goals and limitations, and our system, GFWeb, is no different. In order to measure a wide array of domains, we are faced with the necessity of balancing the depth and breadth of our coverage. This means that certain localized censorship events, which might occur in specific residential network areas, could go undetected by our system but may be observable by others with more extensive vantage points, such as OONI [38] or Censored Planet [64]. For example, our system was able to identify network interference linked to China Telecom's "Anti-fraud" campaign, yet there have been reports of additional interference events at various network locations outside our coverage [73].

Detectability and Blockability. Similar to the blocking case of OONI [70], our measurement infrastructure is also susceptible to being identified and blocked by the GFW. Throughout our study, we did not observe any targeted blocking against our machines. However, the blocking of OONI's main site and its data collection servers significantly impeded their data collection efforts within China [70]. This incident highlights that host-based traffic analysis poses a considerable risk to the functionality of our system, particularly because GFWeb is designed to send a substantial volume of probes to elicit responses from the GFW's censoring middleboxes.

In an effort to achieve comprehensive measurement coverage while minimizing risk to end users, we accept the trade-off that GFWeb's probing traffic may be detectable by the GFW. Consequently, there exists a possibility that our machines could be blocked in the future. Crucially, however, GFWeb's operations are not confined to any particular machine and can

be readily migrated to alternative machines as necessary. Furthermore, other strategies such as splitting the probing traffic across multiple machines and/or imposing delays and rate limits on the probing traffic could be employed to mitigate the risk of detection and blocking [10]. We are actively exploring these strategies to ensure the continuous operation of GFWeb.

Moreover, our measurement strategy could become ineffective if the GFW decides to become truly stateful. While this is a valid concern, such a change is unlikely to happen since the loss-tolerant nature of the GFW, rather than a bug, is a design choice to handle common situations when packets are lost or routed through different network paths [14]. Should such a change occur, it may only slow us down but will not prevent us from running our measurement, as we can just configure our machines at the other side of the GFW to actually complete the TCP handshake, satisfying the statefulness requirement.

8.3 Suggestions

8.3.1 Censorship Measurement

The discovery of asymmetric interference (§5.3) underscores the importance of conducting measurements from both sides of the GFW, since filtering policies can be different depending on the probing direction and the domain being tested.

Furthermore, measurement systems that function based on continuous probing against remote servers using the same destination ports will need to be aware of the two different types of residual censorship and take appropriate actions to avoid incorrect inferences. More specifically, the residual censorship that "keeps injecting" packets may cause false positives as subsequent benign probes would still trigger the GFW to emit forged packets, whereas the residual censorship that "keeps dropping" subsequent traffic may cause false negatives due to the absence of forged packets that are usually anticipated. The co-existence of these two types of residual censorship in HTTPS filtering also suggests that it is non-trivial to determine whether a domain is blocked or not based solely on the presence or absence of forged packets if residual censorship is not taken into account. To that end, it is important to design measurement approaches that can sidestep the residual censorship to avoid both false positives and false negatives.

8.3.2 Censorship Circumvention

The GFW's Web censorship is composed of multiple layers of filtering based on different blocklists and protocols. While various efforts have attempted to circumvent the GFW's Web censorship at different layers [20, 25, 32, 42, 47, 76], an effective circumvention solution will need to tackle the GFW's multi-layered filtering architecture. Otherwise, circumvention solutions that only target a single filtering layer may not be sufficient to achieve the desired result.

Similarly to the suggestion for censorship measurement, probing-based evasion techniques like Geneva [19] also need to be aware of the two different types of residual censorship to avoid being tricked into thinking that the censorship has been successfully evaded when it is actually not, especially when the residual censorship is of the "keeps dropping" type [10].

8.3.3 Using Measurement Data

Internet censorship measurement is a challenging task. Each measurement system is designed with different resources and constraints. Consumers of censorship measurement data (e.g., journalists, researchers, and policy makers) should be aware of the strengths and drawbacks of each system, and consider multiple measurement results from different protocols and data sources to obtain a more complete picture of the censorship landscape. When it comes to determining the censorship status of a domain, it is important to gather results from multiple systems and protocols to obtain a more conclusive result.

9 Conclusion

DNS, HTTP, and HTTPS filtering middleboxes together form the primary pillars of the GFW's Web censorship. In this work, we present GFWeb, a longitudinal measurement system designed to discover domain blocklists used by the GFW for censoring Web access. Over the course of 20 months, GFWeb has tested over a billion fully qualified domains, and detected 943K and 55K pay-level domains censored by the GFW's HTTP and HTTPS filtering middleboxes, respectively. Our study not only complements prior efforts by providing a more comprehensive view into the GFW's Web censorship over time, but also reveals several new findings, including the GFW's asymmetric blocking behavior, and patches of overblocking and failure in reassembling fragmented packets.

The implications of our investigation extend far beyond academic circles, touching on the fabric of global Internet governance and the ongoing struggle for digital freedom. The adaptive nature of the GFW signals a future where Internet censorship will become more nuanced and technically complex, posing significant challenges for circumvention technologies and international policy efforts.

In light of these insights, our work underscores the need for a reinvigorated approach to understanding and combating Internet censorship. The dynamic between censorship and circumvention is not static; it evolves as part of a larger geopolitical and technological landscape, with implications for global Internet freedom, the free flow of information, and the resistance against digital authoritarianism.

As we keep operating GFWeb, we hope that our data (publicly available at `https://gfweb.ca`) will not only provide fresh insights into technical observations, but also promptly update the public regarding changes in the GFW's blocking policies and support other initiatives, especially those focusing on censorship detection and circumvention.

Acknowledgments

We would like to thank the anonymous reviewers and shepherd for their thorough feedback on this paper. We also thank the team at GreatFire.org and others who preferred to remain anonymous for helpful discussions and suggestions.

Snowflake, a censorship circumvention system using temporary WebRTC proxies

Cecylia Bocovich Arlo Breault David Fifield Serene Xiaokang Wang

Authors are listed alphabetically.

Abstract

Snowflake is a system for circumventing Internet censorship. Its blocking resistance comes from the use of numerous, ultralight, temporary proxies ("snowflakes"), which accept traffic from censored clients using peer-to-peer WebRTC protocols and forward it to a centralized bridge. The temporary proxies are simple enough to be implemented in JavaScript, in a web page or browser extension, making them much cheaper to run than a traditional proxy or VPN server. The large and changing pool of proxy addresses resists enumeration and blocking by a censor. The system is designed with the assumption that proxies may appear or disappear at any time. Clients discover proxies dynamically using a secure rendezvous protocol. When an in-use proxy goes offline, its client switches to another on the fly, invisibly to upper network layers.

Snowflake has been deployed with success in Tor Browser and Orbot for several years. It has been a significant circumvention tool during high-profile network disruptions, including in Russia in 2021 and Iran in 2022. In this paper, we explain the composition of Snowflake's many parts, give a history of deployment and blocking attempts, and reflect on implications for circumvention generally.

1 Introduction

Snowflake is a censorship circumvention system, a system to enable network communication despite interference by a censor. Its blocking resistance comes from a large pool of low-cost, temporary proxies that varies over time and offers a censor no fixed target for blocking. The core research purpose of this paper is to investigate experimentally to what extent a circumvention system that makes the tradeoffs Snowflake does can be effective against contemporary censors. We will present the design of the system, listing the many challenges of circumvention and showing how Snowflake addresses them. We will explain how Snowflake solves the technical challenge of providing a good user experience when proxies are individually unreliable. We will document the reactions of national censors through case studies in Russia, Iran, China, and Turkmenistan over more than three years of deployment. On the way, we will provide quantitative evaluations of various facets of the system, including the number of clients served, and the size and composition of the proxy pool.

Censorship circumvention systems may be characterized on multiple axes. Some systems imitate a common network protocol; others try not to look like any protocol in particular. Some distribute connections over numerous proxy servers; others concentrate on a single proxy that is, for one reason or another, difficult for a censor to block. What all circumvention systems have in common is that they strive to increase the *cost* to the censor of blocking them—whether that cost be in research and development, human resources, and hardware; or in the inevitable overblocking that results when a censor tries to selectively block some connections but not others. On the spectrum of imitation to randomization, Snowflake falls on the side of imitation; on the scale of diffuse to concentrated, it is diffuse. Snowflake's defining quality is that it pushes the idea of distributed, disposable proxies to an extreme.

WebRTC is a suite of protocols intended for real-time communication applications on the web [1]. Video and voice chat are typical applications. Snowflake exchanges WebRTC data formats in the course of establishing a connection, and uses WebRTC protocols to traverse of NAT (network address translation) and to connect clients and proxies. Crucially for Snowflake, WebRTC APIs are available to JavaScript code in web browsers, meaning it is possible to implement a proxy in a web page or browser extension. WebRTC is also usable outside a browser, which is how we implement the Snowflake client program and alternative, command line–based proxies.

As is usual in circumvention research, we assume a threat model in which *clients* reside in a network controlled by a *censor*. The censor has the power to inspect and interfere with traffic that crosses the border of its network; typical real-world censor behaviors include inspecting IP addresses and hostnames, checking packet contents for keywords, blocking IP addresses, and injecting false DNS responses and TCP RST packets. The client wants to communicate with some *destination* outside the censor's network, possibly with the aid of third-party *proxies*. The censor is motivated to block

the contents of the client's communication, or the destination itself. The censor knows of the possibility of circumvention, and therefore seeks to block not only direct communication with the destination, but also indirect communication by way of a proxy or circumvention system. Circumvention is accomplished when the client can reliably reach any proxy, because a proxy, being outside the censor's control, can then forward the client's communication to any destination. (In Snowflake, we separate the roles of temporary *proxies* and a stable long-term *bridge*, but the idea is the same.) The censor derives benefit from permitting some forms of network access: it cannot trivially "win" by shutting down all communication, but must be selective in its blocking decisions, in order to optimize some objective of its own. The art of censorship circumvention is forcing the censor into a dilemma of overblocking or underblocking, by making circumvention traffic difficult to distinguish from traffic that the censor prefers not to block.

Snowflake originates in two earlier projects: flash proxy and uProxy. Flash proxy [10], like Snowflake, used untrusted temporary JavaScript proxies in web browsers forwarding to a central bridge, but the link between client and proxy was WebSocket rather than WebRTC, which was then an emerging technology. Flash proxy was deployed from 2013 to 2016, but never saw much use, probably because WebSocket, which lacks the built-in NAT traversal of WebRTC, required clients to do complicated port forwarding. uProxy [38], in one of its early incarnations, pioneered the use of WebRTC proxies for circumvention. uProxy's proxies were browser-based, but its trust and deployment model was different from flash proxy's and Snowflake's. Censored clients would arrange, out of band, for an acquaintance outside the censor's network to run a proxy in their browser [39]. A personal trust relationship was necessary to prevent misuse, since browser proxies fetched destination content directly—meaning client activity would be attributed to the proxy, and the proxy might inspect the client's traffic. Clients did not change proxies on the fly. uProxy supported protocol obfuscation: its packets could be transformed to resemble something other than WebRTC. This was possible because of uProxy's implementation as a privileged browser extension with access to real sockets. Because Snowflake uses ordinary unprivileged APIs, its WebRTC can only look like WebRTC; on the other hand, for the same reason, Snowflake proxies are easier to deploy. Like flash proxy, uProxy was active in the years 2013–2016.

Among existing circumvention systems, the one that is most similar to Snowflake is MassBrowser [24], which offers proxying though volunteer proxies, called buddies. MassBrowser's architecture is similar to Snowflake's: there is a central component that coordinates connections between clients and buddies, which corresponds to a piece in Snowflake called the broker; buddies are like our proxies. Its trust model is intermediate between Snowflake's and uProxy's. Buddies preferentially operate as one-hop proxies, as in uProxy, but are not limited to proxying only for trusted friends. To deter misuse, buddies specify a policy of what categories of content they are willing to proxy. The buddy software is not constrained by a web browser environment, and can, like uProxy, use protocol obfuscation on the client–buddy link.

Other circumvention systems have used WebRTC, though without Snowflake's focus on numerous proxies. Protozoa [2] and Stegozoa [12] demonstrate point-to-point covert tunnels over WebRTC, the former by directly replacing encoded media with its own ciphertexts, the latter using video steganography. Significantly, where Snowflake now uses WebRTC data channels, Protozoa and Stegozoa use WebRTC media streams, which may have advantages for blocking resistance. We will say more on this point in Section 3. TorKameleon [40] is a WebRTC-based system with the dual goals of resisting blocking and complicating traffic correlation attacks. It uses a recent draft programming interface called WebRTC Encoded Transforms to support Protozoa-like embedding of data within media streams, without invasive browser modifications.

Our goal in this paper is to provide a realistic assessment of Snowflake, and neither to exaggerate its advantages, nor disproportionately emphasize the limitations of other systems. Circumvention research is a cooperative enterprise, and we recognize and support our colleagues who design and maintain systems of their own. With Snowflake, we have tried to explore a different point in the design space, and by this exploration widen the scope of effective circumvention techniques. We acknowledge that Snowflake will be a better choice in some censorship environments and worse in others; indeed, one of the ideas we hope to convey is that blocking resistance can be meaningfully understood only in relation to a censor and its particular resources, costs, and motivations.

As of March 2024, Snowflake supports an estimated 35,000 average concurrent users at an average total transfer rate of 2.7 Gbit/s, which works out to around 29 TB of circumvention traffic per day.

2 How it works

A Snowflake proxy connection proceeds in three phases. First, there is rendezvous, in which a client indicates its need for circumvention service and is matched with a temporary proxy. Rendezvous is facilitated by a central server called the broker. Then, there is connection establishment, where the client and its proxy connect to each other with WebRTC, using information exchanged during rendezvous. Finally, there is data transfer, where the proxy transports data between the client and the bridge. The bridge is responsible for directing the client's traffic to its eventual destination (in our case, by feeding it into the Tor network). Figure 1 illustrates the process.

These phases repeat as needed, as temporary proxies come and go. Proxy failure is not an abnormal condition—it happens, for example, when a browser running a proxy is closed. A client builds a circumvention session over a sequence of proxies, switching to a new proxy whenever the current one

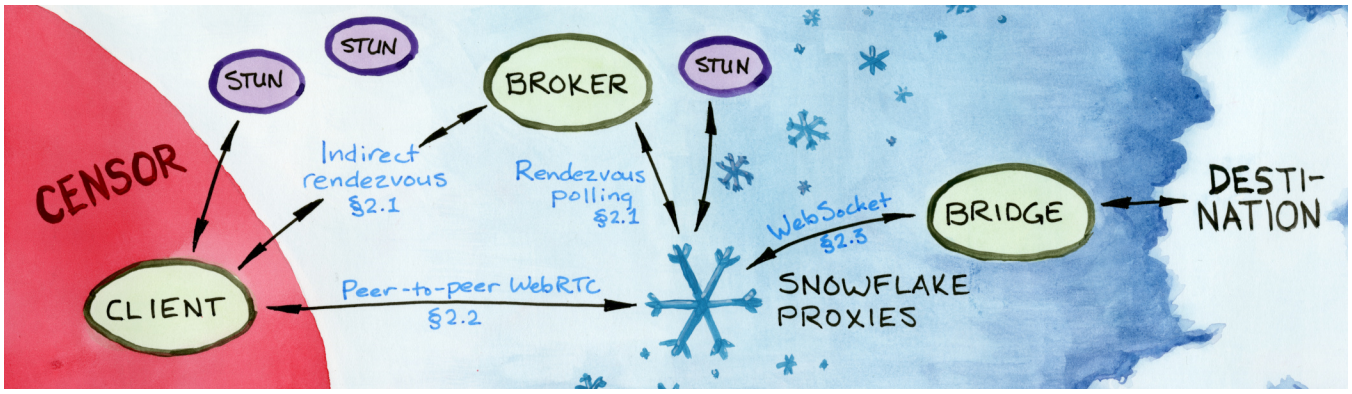

Figure 1: Architecture of Snowflake. The client contacts the broker through an indirect rendezvous channel with high blocking resistance. The broker matches the client with one of the proxies that are currently polling. The client and proxy connect to one another using WebRTC. The proxy connects to the bridge, then begins copying traffic in both directions. If the proxy disappears, the client does another rendezvous and resumes its session with a new proxy.

stops working. State variables stored at the client and the bridge let the session pick up where it left off. The change of proxies is invisible to applications using Snowflake (except for a brief delay for re-rendezvous). The Snowflake software presents an abstraction of one uninterrupted connection.

It does not avail a censor to block the broker or bridge, because Snowflake clients never contact either directly. Clients reach the broker over an indirect rendezvous channel. Access to the bridge is always mediated by a temporary proxy.

2.1 Rendezvous

A session begins with the client sending a rendezvous message to the broker. An ambient population of proxies constantly polls the broker to check for clients in need of service. The broker matches the client with an available proxy, taking into account factors like NAT compatibility.

The client's rendezvous message is a bundle of data that the broker will need in order to match the client with a proxy, and that the proxy will need in order to connect to the client. The most important part of the rendezvous message is a Session Description Protocol (SDP) *offer* [27], which contains the information needed for a WebRTC connection, such as the client's external IP addresses and cryptographic data to secure a later key exchange. The broker gives the client's offer to a currently polling proxy, which sends back an SDP *answer* with its share of connection details. The broker forwards the proxy's answer to the client, and client and proxy then connect to one other directly. In WebRTC terms, this offer/answer exchange is called "signaling" [1 §2.2], and here the broker acts as a signaling server. To gather the information for an SDP offer or answer, clients and proxies communicate with third-party servers, called STUN servers, before contacting the broker. We will say more about how STUN is used in Section 2.2. Connecting to STUN servers is a normal part of WebRTC, though there are fingerprinting considerations that we cover in Section 3.

Interaction with the broker uses a "long-polling" model, shown abstractly in Figure 2. Proxies poll the broker periodically, using ordinary HTTPS requests. The broker holds proxy polling requests open for a few seconds, waiting for a client rendezvous message. If none arrives, the broker sends a response that says "no clients" and the proxy goes to sleep until its next poll. When a client does arrive, the broker responds to the proxy's poll request with the client's SDP offer. The proxy re-connects to the broker to send back its SDP answer. The broker sends the SDP answer to the client and an acknowledgement to the proxy. At this point rendezvous is finished: client and proxy have what they need to connect.

Proxies may contact the broker directly, because they are assumed to be uncensored. But clients must use an indirect, blocking-resistant channel, because any direct connection to the broker would be easily blocked by a censor. What is needed, essentially, is a miniature circumvention system to bootstrap the full system. If clients have access to a bootstrap rendezvous method that is good enough to reach the broker, why is a more extensive circumvention system needed at all? The answer is that the restricted scope of rendezvous admits a wider range of solutions than general circumvention. Techniques that would be too slow or expensive for high-volume or interactive circumvention may yet be suited to rendezvous, because rendezvous happens infrequently and transmits only small amounts of data.

The nice thing about rendezvous that it is modular and separable. More than one method may be used, and the methods need not have anything in common with the main system. Anything that can be persuaded to convey a message of about 1,500 bytes indirectly to the broker, and return a response of about the same size, may work as a Snowflake rendezvous module. Snowflake now supports three rendezvous methods:

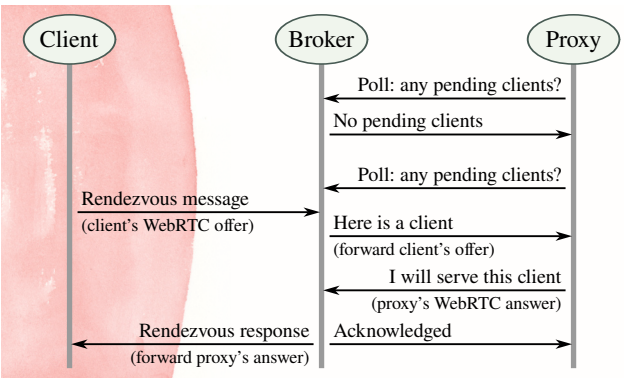

Figure 2: Information exchange in Snowflake rendezvous. When the broker makes a match, the proxy receives the client's SDP offer, then re-connects to send back its SDP answer. It all happens during one round trip from the client's point of view. Not shown is the indirect channel the client uses to access the broker.

Domain fronting In this method, the client does an HTTPS exchange with the broker through an intermediary web service such as a content delivery network (CDN), setting the externally visible hostname (the TLS Server Name Indication, or SNI [6 §3]) to a "front domain" different from the broker's. The CDN routes the HTTPS request to the broker according to the the HTTP Host header, which, under TLS encryption, reflects the actual hostname of the broker [11]. A censor cannot easily block domain-fronted rendezvous without also blocking unrelated connections to the front domain, which should be selected to have high value to the censor. The well-known drawback of domain fronting is the high cost of CDN bandwidth, but this is not a big problem when it is used only for rendezvous.

AMP cache AMP is a framework for web pages written in a restricted dialect of HTML. Part of the framework is a free-to-use cache server [26]. The cache fetches AMP-conformant pages on demand, making it effectively a restricted sort of HTTP proxy. We have a module that encodes rendezvous messages to conform to AMP requirements, allowing them to be exchanged with the broker via the AMP cache.[1] This rendezvous method is not easily blocked without blocking the cache server as a whole. It still technically requires domain fronting, because the AMP cache protocol normally exposes the broker's hostname in the TLS SNI, but it enlarges the set of usable intermediaries and front domains.

SQS (Simple Queue Service) Amazon SQS is a message queuing service designed for communication between microservices. Snowflake has the ability (new at the time of this writing) to use a message queue as a one-way communication channel.[2] Clients write into a public queue, which the broker reads from. Responses are sent back through dynamically created, single-use queues. All communication is indirect, via SQS servers.

Rendezvous is not unique to Snowflake. Other examples of rendezvous are the DEFIANCE Rendezvous Protocol [20 §3], the facilitator interaction in flash proxy [10 §3], and the registration proxy in Conjure [13 §4.1]. A key property of Snowflake and the mentioned systems is that their blocking resistance does not rely on preshared secret information. Whatever information is needed to establish a circumvention session is obtained dynamically at runtime. This is in contrast to other systems in which, before making a connection, the client must acquire some secret, such as an IP address or password, through an out-of-band channel—and blocking resistance depends on keeping that information secret. A corollary of the no-secret-information property is that an adversary is at no special disadvantage in attacking the system. There is no out-of-band channel which real clients have access to but the censor does not. The censor may pose as a client, download the software, study its network connections—and the system must maintain its blocking resistance despite this. The disadvantage of a separate rendezvous step is that it is one more thing to get right. Both the main circumvention channel and the rendezvous must resist blocking: the combination is only as strong as the weaker of the two.

2.2 Peer-to-peer connection establishment

After rendezvous, the client and its assigned proxy connect to one another directly. Even in the absence of censorship, making a connection between two Internet peers is not trivial, because of possible interference by NAT (network address translation) and firewalls. Snowflake clients and proxies run in diverse networks with varying NATs and ingress policies. Fortunately for us, WebRTC is designed with this use case in mind. It has built-in support for NAT traversal in the form of ICE (Interactive Connectivity Establishment) [19], a procedure for testing combinations of peer addresses until finding one that works. ICE uses third-party STUN (Session Traversal Utilities for NAT) servers [28] that, among other services, let a host discover its own external IP addresses. The first part of ICE happened at the beginning of rendezvous, when the client and proxy contacted STUN servers to gather external address candidates and included them in their respective SDP offer and answer. After rendezvous, the peers try pairs of candidate addresses until they are able to establish a connection.

There is no guarantee that two hosts will be able to connect using the facilities of STUN alone. Some combinations of address mapping and filtering are simply incompatible. In such a

[2] https://gitlab.torproject.org/tpo/anti-censorship/pluggable-transports/snowflake/-/merge_requests/214

	No NAT	(EI, EI)	(EI, AO)	(EI, AP)	(ED, ED)	
No NAT	✓	✓	✓	✓	✓	Unrestricted proxy
(EI, EI)	✓	✓	✓	✓	✓	
(EI, AO)	✓	✓	✓	✓	✓	
(EI, AP)	✓	✓	✓	✓	–	Restricted proxy
(ED, ED)	✓	✓	✓	–	–	
	Unrestricted client				Restricted client	

Table 1: Compatibility of NAT variations, assuming the use of STUN only (no fallback to TURN). Variations are represented by (*mapping*, *filtering*) behavior pairs. The table uses codes to indicate behaviors: EI (endpoint-independent), AO (address-dependent), AP (address- and port-dependent), and ED (either AO or AP). The incompatible cases are when one peer has ED mapping and the other has ED mapping or AP filtering. Note the asymmetry in what NAT variations are considered "restricted" in client and proxy.

case, ICE would normally fall back to relaying traffic through a TURN (Traversal Using Relays around NAT) server [30], a kind of UDP proxy. A fallback to TURN would be problematic for Snowflake, because the TURN servers themselves would become targets of blocking. But Snowflake has an advantage other WebRTC applications do not: most applications want to connect *a particular* pair of peers, whereas we are happy to connect a client to *any* proxy. Snowflake clients and proxies self-assess their NAT type and report it to the broker, which then avoids making matches that would require TURN.

Table 1 shows the compatibility of NAT variations. A NAT variation is defined by a combination of address mapping and filtering behaviors [21 §3]. Endpoint-dependent mapping means that the address a local endpoint is translated to depends on the remote endpoint's IP address (and possibly port). Endpoint-dependent filtering means that incoming packets from a remote endpoint are allowed only if outgoing packets have already been sent to that endpoint. As the incompatible cases always involve endpoint-dependent address mapping (sometimes called symmetric NAT), we further categorize the variations into the two types *unrestricted* (works with most other NATs) and *restricted* (works only with more permissive NATs). Unrestricted proxies may be matched with any client; restricted proxies may be matched only with unrestricted clients. The broker prefers to match unrestricted clients with restricted proxies, in order to conserve unrestricted proxies for the clients that need them. Endpoint-dependent mapping is always considered restricted, but the type of NATs with address- and port-dependent filtering differs depending on the peer: for proxies it is restricted, but for clients it is unrestricted. This is a heuristic to conserve unrestricted proxies for clients with endpoint-dependent NAT mapping. Though

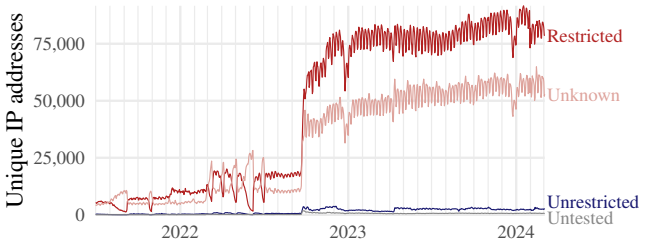

Figure 3: Proxy NAT types, in unique IP addresses per day. The places in 2021 and 2022 where "unknown" displaced other types were caused by operational problems with the NAT type testing peer.

it creates the potential for an incompatible match between a client with an address- and port-dependent filter and a proxy with endpoint-dependent mapping, this case is rare in practice, and if it happens, a client can re-rendezvous and try again.

Clients use the NAT behavior discovery feature [21] of STUN to self-assess their NAT type. Proxies cannot use the same technique, because the necessary STUN features are not exposed to JavaScript. For proxies, we adapt a technique from MassBrowser [24 §V-A] and run a centralized, always-on WebRTC testing peer behind a simulated NAT with endpoint-dependent mapping.[3] If a proxy can connect to the testing peer, its type is unrestricted; otherwise it is restricted. If a client or proxy is unable to determine its NAT type, it reports the type "unknown," which the broker conservatively treats as restricted.

Unrestricted proxies are a relatively small fraction of the proxy population, as Figure 3 shows. In absolute number, though, there are enough for restricted clients at current levels of use. The broker counts the number of unmatched (U) and matched (M) client rendezvous requests per day. If we assume that clients attempt rendezvous repeatedly until getting a match, then the number of attempts per success is $(U+M)/M$. Under this assumption, as of March 2024, the average client needs 1.01 rendezvous attempts to find a compatible proxy.

As the proxy negotiates the WebRTC connection with its client, it also connects to the bridge using WebSocket [23]. Unlike the client connection, the bridge connection presents no challenges: it's just HTTPS to an open port on a server. The choice of WebSocket for this link is arbitrary, and another protocol might be substituted in its place. It does not need to be blocking-resistant (because we are already outside the censor's zone of control), it only needs to be available to JavaScript code in web browsers.

2.3 Data transfer

No complicated processing occurs at the proxy. The main value of a Snowflake proxy is its IP address: it gives the

[3] https://bugs.torproject.org/tpo/anti-censorship/pluggable-transports/snowflake/40013

client a peer to connect to that is not on the censor's address blocklist. Having provided that, the proxy assumes a role of data transfer, copying data upstream from client to bridge and downstream from bridge to client.

Snowflake uses a stack of nested protocol layers. Figure 4 shows the stack for the link between the client and the proxy. This is the link that uses WebRTC, the one that is exposed to the censor. The stack for the proxy–bridge link is the same, but with WebSocket replacing WebRTC in the outermost layer. Layers at the top of the diagram are "outer," closer to the network; ones at the bottom are "inner," closer to the user.

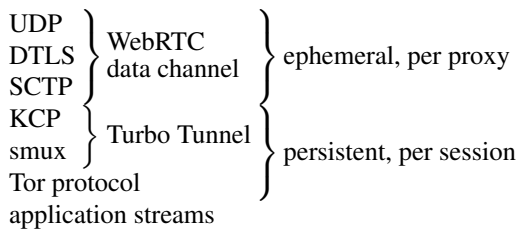

Figure 4: The protocol stack for the client–proxy link.

Each layer serves a different purpose. The layers marked "ephemeral" are replaced at every proxy switchover. These outer layers form the "carrier" over which the more stateful inner layers are transported. The layers marked "persistent" are instantiated just once per circumvention session and outlive any single proxy. They maintain end-to-end state and present an abstraction of a single long-lived tunnel. This virtual tunnel then transports user application traffic such as web browsing and messaging.

The point-to-point link between a client and its proxy is a WebRTC data channel [18]. Data channels let two WebRTC peers exchange arbitrary binary messages. A data channel is itself a composition of three protocol layers: UDP for network transport, DTLS (Datagram TLS) for confidentiality and integrity, and SCTP (Stream Control Transmission Protocol) for delimiting message boundaries and other features like congestion control. The peers authenticate each other at the DTLS layer using certificate fingerprints that were exchanged during rendezvous [17 §5.1].

Data channels are well-suited to the circumvention use case. But data channels are not the only option in WebRTC: there are also *media streams*, meant for real-time audio and video. Which of these options is used is an externally observable feature, and may therefore become a fingerprinting vector. We will consider this topic further in Section 3.

A proxy maintains two connections for each client it is currently serving: a WebRTC connection to the client and a WebSocket connection to the bridge. Data received from the client over WebRTC is copied to the bridge over WebSocket, and vice versa. Although this pair of connections effectively connects the client to the bridge, it alone is not enough for usable circumvention, because Snowflake proxies do not last forever. When a proxy goes away, its WebRTC and WebSocket connections go with it. Without additional consideration, the loss of a proxy would mean the end of a client's circumvention session. What is needed is a separate notion of session state, independent of the current proxy and its data channel.

We adopt the Turbo Tunnel design pattern [8] and insert a userspace session and reliability protocol between the ephemeral "carrier" protocols and the client's application streams.[4] This inner protocol attaches sequence and acknowledgement numbers to the pieces of data that pass through the tunnel. After a temporary break in proxy connectivity, the client and bridge first retransmit whatever data has not been acknowledged by the other side, then carry on as normal with new data, with no duplication or gaps. How this works, concretely, is the client chooses a random session identifier string at the beginning of its session, and sends it as a preamble every time it connects through a new proxy. When the bridge accepts a WebSocket connection, it inspects the preamble to find the client's session identifier string, which it uses to index a table of session state information. If the session does not yet exist, the bridge creates one; otherwise it resumes an existing session (starting by retransmitting any unacknowledged data). If a client's proxy disappears in the middle of a long download, for example, there may be a pause while Snowflake does another rendezvous to acquire a fresh proxy, but after that, the download continues uninterrupted.

For the inner session layer we use a combination of KCP [33] and smux [43]. KCP provides reliability and retransmission, and smux detects and terminates timed-out streams. Other userspace protocols, for example QUIC or TCP, could be used more or less equivalently for this purpose. We prototyped successfully with both QUIC and KCP/smux before settling on the latter. The main considerations that influenced our decision were familiarity and ease of maintenance.

One more protocol layer is needed before sending user application data through the tunnel: an end-to-end secure channel between the client and the bridge, using keys unknown to the proxy. The inner session layer does not itself provide security, and the DTLS of the data channel is only hop-by-hop, not end-to-end. The purpose of this additional secure channel is to prevent proxies from inspecting or tampering with the traffic they carry. Nothing special is needed here; for example, TLS, or any VPN protocol, would work fine. Our deployment uses the Tor protocol as this secure channel. After removing the WebSocket and Turbo Tunnel layers, the bridge feeds the data it receives into a local Tor bridge, which routes the stream into the Tor network and eventually to its destination. Tor, of course, has privacy advantages that are not, strictly speaking, necessary for circumvention, but are nevertheless nice to have, such as that not even the Snowflake bridge is trusted to know the contents or destinations of client streams. But Tor also has drawbacks, which we will comment on in Section 4.4 and Section 6.

[4] https://lists.torproject.org/pipermail/anti-censorship-team/2020-February/000059.html

Snowflake may be seen as an instance of the "untrusted messengers" model of Feamster et al. [7 §3]. Their *messengers* correspond to our *proxies*; their *portal* is our *bridge*. Proxies are trusted to deliver the client's traffic to the bridge, but do not themselves connect to the destination, or even know what it is. An inner layer of cryptography protects the client's traffic from observation and manipulation by malicious proxies. The protection goes in the other direction as well: because proxies are programmed to connect only to a Snowflake bridge, and they never process anything but ciphertext, a malicious client cannot cause a proxy to misbehave or have its actions attributed to the proxy. Without this mutual guarantee of safety, it would be too risky to associate a client and proxy who have no preexisting trust relationship.

3 Protocol fingerprinting

Snowflake's main focus is the "address blocking" side of circumvention, but the "content blocking" side matters too. The goal, as always, is to make circumvention traffic hard to distinguish from traffic the censor cares not to block. Design decisions in Snowflake—the use of WebRTC, and the requirement to run proxies in browsers—mean that Snowflake can, at best, only blend in with other WebRTC traffic. But even within that scope, there are variations in *how* WebRTC is implemented and used, which, if not carefully considered, might enable a censor to selectively block only Snowflake, leaving other uses of WebRTC undisturbed. Unfortunately for the circumvention developer, the richness of WebRTC protocols creates a large attack surface for fingerprinting. And then, there are fingerprinting considerations beyond WebRTC.

The most prevalent implementations of WebRTC are in web browsers. Snowflake originally used a WebRTC library extracted from Chromium[5], but that proved to be difficult to maintain and build for multiple platforms. Since 2019, Snowflake uses the Pion [29] implementation of WebRTC.[6] Pion is not tied to any browser, which is both good and bad. The good is less development friction, better memory safety (Pion is written in Go, Chromium WebRTC in C++), and a working relationship with upstream developers to have fingerprinting changes made when needed. The bad is that Pion's protocol fingerprints do not automatically match those of the mostly browser-originated WebRTC that Snowflake aims to blend in with.

The following is a list of the main fingerprinting concerns in Snowflake and what we have done to address them. A fingerprinting vulnerability does not automatically disqualify a circumvention system: it depends on whether the vulnerability can be fixed without changing the basic nature of the system. The important thing is to have solid fundamentals: minor flaws may be patched up as needed.

[5] https://github.com/keroserene/go-webrtc

[6] https://bugs.torproject.org/tpo/anti-censorship/pluggable-transports/snowflake/28942

Selection of STUN servers The use of STUN with WebRTC is common, but the choice of what STUN servers to use is up to the application. Running dedicated STUN servers for Snowflake would not work, because a censor would experience no collateral harm in blocking them. Our deployment uses a pool of public STUN servers that are used for purposes other than circumvention. The client chooses a random subset for each new session.

Format of STUN messages STUN is most often deployed over plaintext UDP, which leaves the contents of messages open to inspection. STUN messages consist of a fixed header followed by a list of attributes [28 §5]. What attributes appear, and their order, depends on the STUN implementation and how the application uses it.

We have not done anything particular to disguise STUN messages. Though UDP is the most common, STUN specifies other transports, including encrypted ones like DTLS. The alternative transports may be options for Snowflake in the future—of course, only if they are commonly used enough not to stick out in themselves.

Rendezvous Because the rendezvous methods of Section 2.1 are modular, each one needs a separate justification as to why it should be difficult to block. Each method must also be implemented in a way that does not expose accidental distinguishers. For example, the domain fronting, AMP cache, and SQS rendezvous methods use HTTPS, which means TLS fingerprinting is a concern [11 §5.1].

Snowflake, like many circumvention systems, uses the uTLS package [14 §VII] to get a client TLS fingerprint that is randomized or that imitates common browsers. Section 5.2 has an account of when domain fronting rendezvous was briefly blocked in Iran, because we were slow in activating uTLS.

DTLS The outermost layer of a WebRTC data connection, directly exposed to a censor, is DTLS over UDP. DTLS is an adaptation of TLS [32 §1] to the datagram setting, and therefore shares the fingerprinting concerns of TLS [14].

Owing to practical considerations, Snowflake's defenses to DTLS fingerprinting are not very robust, and are reactive rather than proactive. In the realm of TLS one may use uTLS, but there is as yet no equivalent for DTLS. The present way of altering DTLS fingerprints in Snowflake is to submit a patch to Pion when a feature used for fingerprinting is identified. Section 5.1 documents how this has happened twice, in response to blocking in Russia.

Data channel or media stream Along with data channels, WebRTC offers *media streams*, which transmit encoded audio and video. Though both data channels and media streams are encrypted, they are externally distinguishable because they use different encryption containers. Data channels use DTLS, while media streams use

DTLS-SRTP; that is, the Secure Real-Time Transport Protocol with a DTLS key exchange [31 §4.3].

Data channels are a closer match to Snowflake's communication model: media streams are meant for audio and video, not arbitrary binary messages. But the use of data channels could become a fingerprinting feature if other WebRTC applications mainly use media streams. Should it become necessary, it would likely be possible to adapt Snowflake to use media streams rather than data channels, either by modulating data into an audio or video signal in the manner of, say, Stegozoa [12 §3.3], or by replacing the encoded data inside SRTP packets, as in Protozoa [2 §4.4] or TorKameleon [40 §III-D].

Most research on detecting Snowflake to date has focused on protocol fingerprinting. Fifield and Gil Epner [9] studied the network traffic of WebRTC applications, with the goal of finding pitfalls that could affect Snowflake. Frolov et al. [14 §V-C] observed that the undisguised TLS fingerprint of Snowflake's domain fronting rendezvous was distinctive, and introduced the uTLS package now used to protect it.

MacMillan et al. [22] focused on the DTLS handshake, comparing Snowflake to three other WebRTC applications. They correctly anticipated features of the Pion DTLS handshake that would later be used to block Snowflake in Russia; see details in Section 5.1. Holland et al. [16 §5.3], using the bits of UDP datagrams directly as features, demonstrated approximately equal performance on the same DTLS handshake data set. Their automatically derived classifier assigned high feature importance to packet length fields, in fact doing well even without DTLS payload features.

Chen et al. [4] combined features of rendezvous and DTLS in order to reduce false positives. Their classifier begins by looking for DNS queries for STUN servers and front domains commonly used by Snowflake clients. They then apply a machine learning classifier to features of a subsequent DTLS handshake. The authors acknowledge that DTLS fingerprinting is fragile, as the DTLS features are, in principle, controllable by the application. The DNS prefilter may perhaps be mitigated by alternative rendezvous methods (Section 2.1), or by smarter selection of STUN servers.

Xie et al. [42] trained a decision tree to distinguish domain fronting rendezvous from certain other HTTPS exchanges, using packet size, direction, latency, and bandwidth features. Wails et al. [41] criticize past research on detecting circumvention systems, saying that accuracy claims do not hold up in light of the low base rates of circumvention traffic in practice. They developed classifiers for Snowflake and other circumvention protocols that improved on the state of the art, but found them still to be prohibitively imprecise at realistic base rates. They propose reducing false positives by combining multiple observations per IP address—classifying hosts, not flows—and suggest that Snowflake's lack of fixed proxies mitigates against this enhancement.

Related to protocol fingerprinting is *traffic analysis*: classifying connections based on features like packet lengths and transmission times, which may differ, in a circumvention system, from other uses of the cover protocol. The best classifiers of Xie et al. and Wails et al. were of this type. While traffic analysis attacks are worth thinking about, we caution that academic audiences have historically overestimated their importance. Tschantz et al. [36 §VII] observed that censors are sensitive to costs and—particularly—false positives. They claim (and our experience bears it out) that censors prefer traffic classification rules that are simple, precise, and deterministic, and avoid ones that require managing state, are computationally expensive, or have non-negligible false positive rates, like those based on traffic analysis. Nevertheless, we have tried to future-proof Snowflake in this respect: the protocol inside the WebRTC data channel supports shaping of transmission sizes and timing, which ought to be sufficient to imitate the traffic fingerprint of other WebRTC applications. But the feature is currently unused.

4 Experience

Snowflake has now been in operation for a few years. In lieu of a forward-looking evaluation, here we take a look back at the history of its deployment and reflect on the experience. Fielding a new circumvention system offers an opportunity to study experimentally its uptake and performance. In this section we discuss the number of clients over time and the bandwidth they use, the size and composition of the proxy pool, the variability of proxy IP addresses, and engineering considerations related to scaling. We take up the topic of reactions by censors in Section 5.

4.1 Client counts and bandwidth

As a consequence of our use of a Tor bridge as the backend for the Snowflake bridge, we can estimate client counts and bandwidth using the privacy-preserving techniques of Tor Metrics [35]. Tor bridges publish daily summaries of statistics, including client counts and bandwidth, as well as an aggregate distribution of client countries inferred from a local geolocation database. Figure 5 shows the number of clients and amount of bandwidth consumed since 2021. The upper graph depicts not a count of unique clients, but rather the *average number of concurrent clients* per day. For example, when the graph passes through 10,000 on 2022-02-04, it means there were, on average, 10,000 clients using Snowflake at a given time on that day. The number of users is estimated by counting the "directory requests" that Tor clients make periodically. The contribution of a client session depends on its duration, not on how many temporary proxies it uses; a client connected for two hours counts half as much as one connected for four hours. Bandwidth is computed as the average of incoming and outgoing bytes (which are approximately equal anyway),

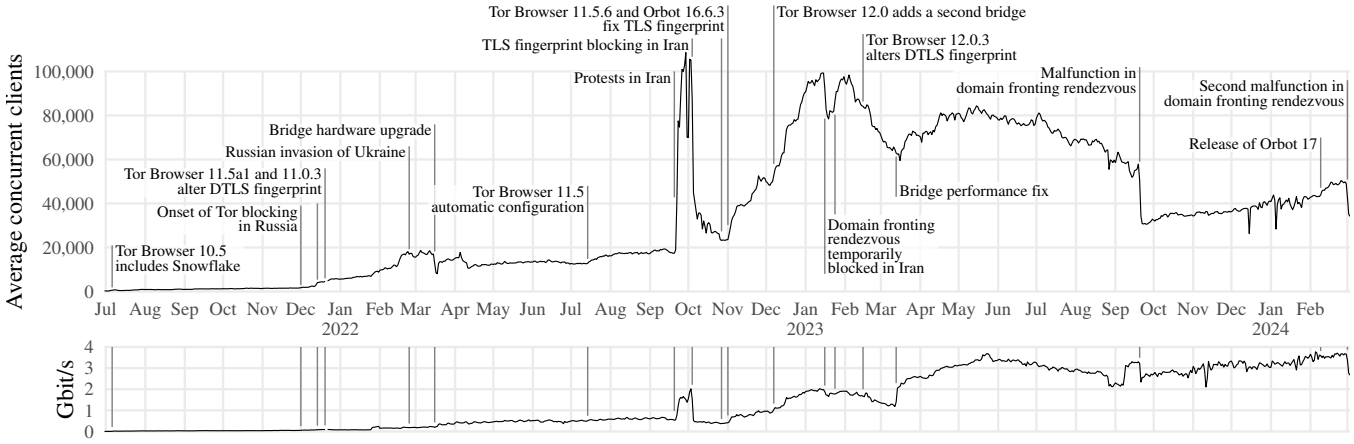

Figure 5: Estimated average concurrent Snowflake clients and consumed bandwidth by day. The values at the far left end of the graph, in early July 2021, are about 200 users and 2.7 Mbit/s.

after subtracting bytes spent processing directory requests (which are less than 1% of total bandwidth).

Snowflake shipped in the alpha release series of Tor Browser for years before entering the stable series. The first releases were for GNU/Linux in Tor Browser 7.0a1 on 2017-01-24 [7] and for macOS in Tor Browser 7.5a4 on 2017-08-08 [8]. Here we encountered difficulties with the Chromium-derived WebRTC library we had used up to that point that prevented us from making releases for other platforms. We were able to resume making progress after switching to Pion WebRTC [29] in 2019. Snowflake for Windows was released in Tor Browser 9.0a7 on 2019-10-01 [9], and for Android in Tor Browser 10.0a1 on 2020-06-02 [10].

Snowflake was then available on every platform supported by Tor Browser, but was not yet comfortably usable. Two important parts were missing: a lack of NAT type matching (Section 2.2) meant that a client could not always connect to its assigned proxy; and no persistent session state (Section 2.3) meant that even if a proxy connection were successful, the client's session would end once its first proxy disappeared. For these reasons, by early 2020, the number of concurrent users had not risen above 40. The Turbo Tunnel session persistence feature became available to users in Tor Browser 9.5a13 on 2020-05-22.[11] The client part of NAT behavior detection was released with Tor Browser 10.0a5 on 2020-08-19 [12], and proxy support was added on 2020-11-17 [13]. With these changes, Snowflake became practical to use for daily browsing, and the number of clients began to grow into 2021.

Snowflake's growth began in earnest when it became part of default installations. Orbot, a mobile app that provides a VPN-like Tor proxy, added a Snowflake client in version 16.4.0 on 2021-01-12.[14] Snowflake graduated to Tor Browser's stable series in Tor Browser 10.5 on 2021-07-06 [15], becoming a third built-in circumvention option alongside meek and obfs4. This is the first event marked in Figure 5. Being in the stable release series meant Snowflake was easily available to all Tor users, not only a self-selected group of alpha testers. The number of concurrent clients increased steadily over the next five months, reaching almost 2,000 by December 2021.

Censorship events may have the apparently contrary effects of either decreasing or increasing usage of a circumvention system. Usage decreases when the system itself succumbs to blocking; but increases when other, less robust systems are blocked, and users become concentrated onto the reduced number of systems that remain working. Two censorship events, one in Russia and one in Iran, resulted in large increases in the number of Snowflake users.

On 2021-12-01, some ISPs in Russia instituted measures to block most ways of accessing Tor, including Snowflake [44]. The measures varied in effectiveness; in the case of Snowflake, blocking was triggered by a feature of the DTLS handshake, which we were able to mitigate in new releases within a few weeks.[16] Over the next two months, the number of clients quadrupled; by May 2022, about 70% of Snowflake users were in Russia. The client count in Russia got an additional small boost starting on 2022-07-14, when Tor Browser 11.5 added a feature to automatically enable circumvention options when needed.[17] We will look at Russia in more detail in Section 5.1.

In reaction to protests that began on 2022-09-16 after the death of Mahsa Amini, the government of Iran imposed net-

work shutdowns and additional blocking, severe even by the standards of a country already notorious for censorship [3]. Users turned to the circumvention systems that continued working despite the new restrictions, Snowflake among them. Adoption was rapid: on 2022-09-20, Iran accounted for 1% of Snowflake users; by 2022-09-24 it was 67%. The sudden influx of users had us scrambling for a few days to implement performance improvements. Two weeks later, on 2022-10-04, usage dropped almost as quickly as it had risen—the cause was the blocking, in Iran, of a TLS fingerprint used by the Snowflake client.[18] After we released fixes for the TLS fingerprinting issue, the client count began to recover. But in our haste to deploy performance optimizations in September, we inadvertently introduced a bug that actually harmed performance, becoming more severe at higher client counts.[19] This dragged the count down again, until we fixed the bug in mid-March 2023. (Umayya et al. happened to be doing performance tests of Snowflake and other circumvention systems at this time [37 §4.6]—their results independently confirm the reduced reliability of Snowflake before the performance bug was fixed.[20]) We will say more about Iran in Section 5.2.

For most of this history, the Snowflake bridge was a single server, which we upgraded and optimized as needed. As the bridge reached its hardware capacity, and performance improvements got harder to achieve, we deployed a second bridge to share the load. The challenges and design considerations of doing so are discussed in Section 4.4. The new bridge was made available in Tor Browser 12.0 on 2022-12-07 and Orbot 17 on 2024-02-09. In early 2024, the second bridge handled about 15% of users and 25% of bandwidth.

The drop in users on 2023-09-20 was not caused by any censor action; rather, it was an unexpected change in the cloud infrastructure we used for domain fronting rendezvous. The front domain we had been using changed its hosting to a different CDN, which caused client rendezvous messages to fail to reach the broker.[21] We made releases with alternative front domains[22], but it took time for users to adjust. Something similar happened on 2024-03-01, when the CDN we had been using in the default configuration of domain fronting rendezvous stopped supporting domain fronting.[23] It happened just before the deadline for this paper, so we cannot yet comment on any long-term effects, but Figure 5 shows an immediate decline in users and bandwidth of about 30%.

As of 2024-03-01, Snowflake had transferred a lifetime total of 15 PB of circumvention data. Here we mean goodput: Tor TLS traffic inside the tunnel, ignoring WebRTC, WebSocket, and KCP/smux overhead. At that time, around 1.2% of Tor users (25% of bridge users) were using Snowflake.

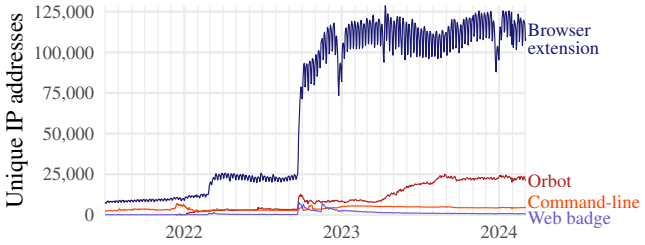

Figure 6: Unique proxy IP addresses per day, by proxy type. The two steps in the graph correspond to the invasion of Ukraine by Russia in February 2022, and network restrictions in Iran beginning September 2022, at which times there were campaigns to encourage running Snowflake proxies. Unknown proxy types (fewer than 50 instances) are not shown.

4.2 Number and type of proxies

Snowflake's effectiveness depends on its pool of proxies, of which there are several types. The primary type is the web browser extension, which runs in the background in volunteers' browsers and quietly serves clients. There is a "web badge" version of the proxy that does not require installation. It uses the same JavaScript code as the extension, but runs in an ordinary web page. Some people leave a browser tab idling on the web badge, rather than installing a browser extension. There is also a command-line implementation of the proxy that does not require a browser. This version is convenient to install on a rented VPS, for example. Long-term proxies running at fixed IP addresses are somewhat at odds with Snowflake's goal of proxy address diversity, but these standalone, command-line proxies are valuable because they tend to have less restrictive NATs, which makes them compatible with more clients. Finally, Orbot, as well as being able to *use* Snowflake for circumvention, can also *provide* Snowflake proxy service to others, a feature called "kindness mode."

We worked with the Tor Project's network health team to collect privacy-preserving metrics of client and proxy rendezvous interactions at the broker, and publish them in the same way as the bridge metrics of Section 4.1.[24] The metrics represent counts of proxy types, unique proxy IP addresses and geolocated country codes, NAT types (Section 2.2), and success rates of matching clients with proxies. Aggregate metrics are published at 24-hour intervals.[25] The broker does not record nor publish the IP addresses of clients or proxies. Metrics concerning client polls are rounded to multiples of 8, in accordance with established Tor Metrics practice.

Figure 6 shows the number of proxies by type. Web browser extension proxies predominate, representing about 80% of 140,000 daily IP addresses. For comparison, there were about 1,900 of the more traditional style of Tor bridge at this time. The difference in number is attributable to the relative ease of

[24] https://bugs.torproject.org/tpo/network-health/metrics/collector/29461
[25] https://metrics.torproject.org/collector.html#snowflake-stats

running a Snowflake proxy versus a Tor bridge—though the comparison is not quite direct, because Tor bridges have better defenses against enumeration than do Snowflake proxies.

It was not clear, at the outset, that it would even be possible to attract enough proxies to support a reasonable number of users with meaningful blocking resistance. Lowering the technical barriers to running a proxy was only part of it; it also took intentional advocacy and outreach. In the early days, circa 2017, the only consistent proxy support was a few command-line proxies, run by us for the benefit of alpha testers. The browser extension became available in mid-2019.[26, 27] Later in 2019, additional proxy capacity came when Cupcake, a browser extension for flash proxy with an existing user base, was repurposed for Snowflake.[28] Orbot's proxy feature was added in version 16.4.1 in February 2021.[29] (In Figure 6, Orbot is counted with command-line proxies until January 2022, when it got its own proxy type designation.)

It is worth reflecting on the popularity of the browser extension as compared to the web badge. A web badge had been envisioned as the main source of proxies in flash proxy, the idea being that people's browsers would automatically become proxies while on sites that had the flash proxy badge installed, unless they checked an option to prevent it. We decided, early on, that flash proxy's opt-out permission had been a mistake, and that Snowflake would be opt-in. To run a proxy, a person must take a positive action, such as installing a browser extension or activating a toggle on a web page. Our initial worry that this policy would limit the number of proxies turned out to be unfounded. People find an informative, interactive proxy control panel more appealing than a nondescript badge graphic, and install the browser extension in greater numbers than ever used the web badge in flash proxy.

4.3 Proxy churn

The size of the proxy pool is not the only measure of its quality. Also important is its "churn," the rate at which it is replenished with fresh proxy IP addresses. Churn determines how hard a censor would have to work to keep a blocklist of proxy IP addresses up to date; or alternatively, how quickly a momentarily complete blocklist would lose effectiveness.

We ran an experiment to measure churn.[30] Our technique was to record the set of proxy IP addresses seen by the broker over an interval of time, then compute the size of the intersection with other sets in nearby intervals, up to 40 hours later. Every hour, the broker recorded a snapshot of proxy IP addresses it had seen in the past hour. To avoid the risk of storing real proxy IP addresses, each snapshot was not a transparent list, but a HyperLogLog++ sketch [15], a probabilistic

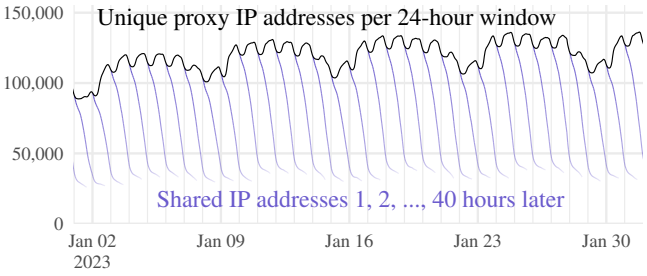

Figure 7: Proxy churn in January 2023. The dark upper line shows the number of unique proxy IP addresses in overlapping 24-hour windows. The lighter, descending lines indicate how many of the same IP addresses were in later 24-hour windows, at 1-hour increments up to 40 hours later. It takes about 20 hours for 50% of the proxy pool to turn over.

data structure for estimating the number of distinct elements in a multiset. Proxy IP addresses were hashed with a secret string (discarded at the end of the experiment) before being added to a sketch, to prevent their being recovered from our published data. A sketch supports two basic operations: count and merge. Given a sketch X, we may compute an approximate count $|X|$ of its unique elements, and given two sketches X and Y, we may merge them into a new sketch representing the union $X \cup Y$. The quantity we are interested in, namely the size of the intersection of two sketches, is computed using the formula $|X| + |Y| - |X \cup Y|$. This computation estimates how many proxy IP addresses are shared between two samples.

The broker recorded churn logs between 2022-07-22 and 2023-10-16. Figure 7 shows results from January 2023, which are representative. Proxy activity has a daily cycle, so we merged consecutive sketches into 24-hour windows. Starting from a reference window, we computed the size of its intersection with other 24-hour windows, offset by $+1, +2, \ldots, +40$ hours relative to the reference. After 1 hour, the shifted window had, on average, 97.3% of addresses in common with the reference; after 12 hours, the fraction had fallen to 68.8%; after 24 hours, 38.2%; and after 40 hours, 27.6%.

4.4 Multiple bridges

In the conceptual model of Figure 1, the bridge is a single, centralized entity. It *can* be centralized because it is never accessed directly, but only via temporary proxies. Unlike more traditional static proxy systems, Snowflake does not benefit, in terms of blocking resistance, from having multiple bridges. For reasons of scaling and performance, though, it can be useful for "the" bridge to be realized as multiple servers. Even with hardware upgrades and software optimizations, our single bridge began to hit performance limits in late 2022 (particularly after the events in Iran of Section 4.1), and we had to find ways of distributing bridge capacity to permit continued scaling. Our deployment now uses two bridges.

[30] https://bugs.torproject.org/tpo/anti-censorship/pluggable-transports/snowflake/34075

A multi-bridge system might be designed in many ways. In ours, the client tells the broker what bridge it wants to use in its rendezvous message. The broker conveys the choice to the proxy, and the proxy connects to the client's chosen bridge.[31] This may be compared to alternative designs in which the decision of what bridge to use is made by the broker or the proxy. Our design was largely dictated by technical constraints related to interfacing with Tor. Different designs may make sense with other deployments.

One minor consideration is the Turbo Tunnel layer. Recall from Section 2.3 that Snowflake maintains a virtual end-to-end session between the client and the bridge, independent of the temporary proxies. This is made possible by state stored at the bridge: a table of clients, reassembly buffers, transmission queues, timers, and so on. The state variables are not synchronized between bridges, which means a client session begun on one bridge must remain with that bridge, because no other has the context to make the packets of the session meaningful. When it is the client that chooses the bridge, this is easy to deal with: the client keeps its choice consistent in all rendezvous messages throughout a session. If the choice were instead made by the broker or proxy, it might be dealt with by hashing the client's session identifier string to an index, as long as the set of bridges does not change too frequently.

Another difficulty, harder to work around, has to do with Tor bridge authentication. A Tor bridge is identified by a long-term identity public key. If, on connecting to a bridge, the client finds that the bridge's identity is not the expected one, the client terminates the connection [5]. The Tor client can configure at most one identity per bridge; there is nothing like a certificate, for example, to indicate that multiple identities should be considered equivalent. This constraint leaves two options: either all Snowflake bridges must share the same cryptographic identity; or else it must be the client that chooses the bridge (and therefore knows what bridge identity to expect). While it would be possible to synchronize Tor identity keys across bridges, we preferred to keep keys independent, so that the effect of a security compromise at a bridge would be limited to that bridge only.

A client-chooses design risks misuse, if not handled carefully. Clients must not be able to cause proxies to connect to arbitrary destinations—otherwise proxies might be used in denial-of-service attacks, for example. To enforce this restriction, the client indicates its choice of bridge not by an IP address or hostname, but by an identity public key. The broker maps the identity to a WebSocket URL using its own database of known bridges, and rejects rendezvous messages that ask for an unknown bridge. After the broker tells the proxy what WebSocket URL to connect to, the proxy does its own check, verifying that the hostname in the URL has a known suffix reserved for Snowflake bridges. So there are two independent safeguards against misuse.

[31] https://bugs.torproject.org/tpo/anti-censorship/pluggable-transports/snowflake/28651#note_2786323

5 Notable blocking attempts

In Section 4.1 we saw how Snowflake's user counts have at times been affected by the blocking actions of censors. Now we take a closer look at selected censorship events. The effect of censorship has usually been to increase, rather than decrease, the number of Snowflake users. This is no paradox: as censorship intensifies, users are displaced from less resilient to more resilient systems. Snowflake's blocking resistance has not always been a success, though, and here we also reflect on missteps and persistent challenges. The examples are taken from Russia, Iran, China, and Turkmenistan, and are selected for being significant and instructive. Common lessons are that communication with affected users is invaluable in quickly understanding and reacting to blocking; and that blocking resistance needs to be understood relative to a censor, because every censor's cost calculus is different.

Client count estimates come from the Tor Metrics descriptors described in Section 4.1. Country code assignments are drawn from the same IP geolocation database used by ordinary Tor relays and bridges—and the caveats of IP geolocation apply to the per-country estimates in this section. In particular, we have noticed that a fraction of clients that geolocate to the United States are likely actually to be in Iran, based on correlations of their dynamics with those of other clients that geolocate to Iran, and the timing of known political events.[32] The graphs of this section use raw geolocation results, with no attempt to adjust for errors.

Snowflake is blockable by any censor that is willing to block WebRTC. We would not try to argue otherwise. Indeed, we believe that the way to present a circumvention system is not to argue for its absolute unblockability, but to lay out what actions by a censor would be necessary to block it—or more to the point, *what sacrifices a censor would have to make* in order to block it. Advancing the state of the art of censorship circumvention consists in pushing blocking out of reach of more and more censors.

5.1 Blocking in Russia

Snowflake, along with other common ways of accessing Tor, was blocked in a subset of ISPs in Russia on 2021-12-01 [44]. The event was evidently coordinated and targeted, as it happened suddenly and affected many Tor-related protocols at once. Besides Snowflake, a portion of Tor relays and bridges, as well as some servers of the circumvention transports meek and obfs4, were blocked, at least temporarily. The blocking campaign was less than totally successful—one of its effects was to substantially increase the number of users accessing Tor via circumvention transports, Snowflake among them.

We benefited from established relationships with developers and users in Russia, one of whom, through manual testing,

[32] https://bugs.torproject.org/tpo/anti-censorship/pluggable-transports/snowflake/40207#note_2844116

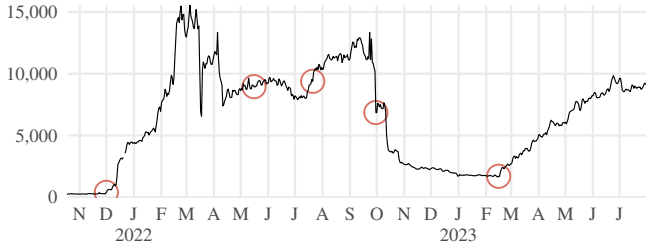

Figure 8: Snowflake users in Russia (average concurrent). Events discussed in the text are marked. The attempted blocking of Tor-related transports in December 2021 led to Snowflake's first surge in usage. The decrease in September–October 2022 coincided with an even larger influx from Iran.

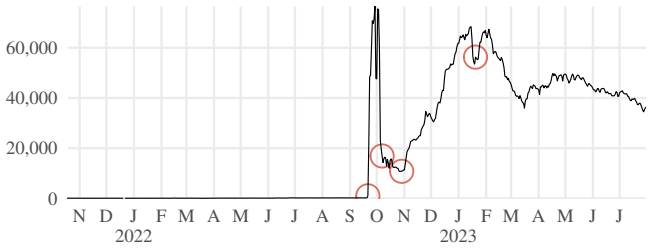

Figure 9: Snowflake users in Iran. Heightened censorship beginning in September 2022 caused Iran to become the single biggest source of Snowflake users. The drop in October 2022 was the result of TLS fingerprint blocking, which interfered with rendezvous and took some time to mitigate.

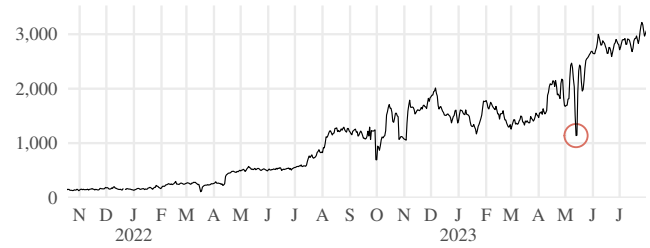

Figure 10: Snowflake users in China. Though no sustained blocking is evident, disruption of domain fronting rendezvous for three days in May 2023 briefly depressed user numbers.

Figure 11: Snowflake users in Turkmenistan. This graph shows an earlier range of dates than the other three. Though there have never been many Snowflake users in Turkmenistan, blocking events are evident on 2021-10-24 and 2022-08-03.

found the traffic feature that was being used to distinguish Snowflake. It was DTLS fingerprinting[33], of the kind cautioned about in Section 3. Specifically, it was the presence of a supported_groups extension in the DTLS Server Hello message produced by Pion. The extension's presence in Server Hello was in fact a bug[34]—but in any case, it afforded the censor a feature to distinguish DTLS connections with a Pion implementation in the server role from other forms of DTLS. The process of finding the flaw, fixing it, and shipping new releases of Tor Browser took a few weeks[35], after which the user count rose rapidly. From the beginning to the end of December 2021, the number of users in Russia grew from about 400 to over 4,000 (Figure 8). Snowflake was to become a significant tool amid the general intensification of censorship in Russia following the invasion of Ukraine in February 2022.

The Server Hello supported_groups distinguisher had been discovered and documented by MacMillan et al. [22 §3] already in 2020. We might have avoided this blocking event by proactively fixing the known distinguisher—but it was not necessarily the wrong call not to have done so. In a project like Snowflake, there is always more to do than time to do it, and one must consider the opportunity cost of preempting specific blocking that may not come to pass. In this case, a reactive approach by us was enough: the loss was minor, and we were able to patch the problem quickly. Even in ISPs where the blocking rule was present, it did not block 100% of Snowflake connections, because of the way it targeted a quirk in Pion, and only in Server Hello. When the DTLS server role in the WebRTC data channel was played by a non-Pion peer, such as a web browser proxy, the feature was not present.

In May 2022 we got a report of a new detection rule, this time keying on not just the presence, but the *contents* of the supported_groups extension, at a byte offset suggesting that it now targeted the Client Hello message, not Server Hello.[36] The presence of a supported_groups extension in Client Hello is not unusual, but the specific groups offered by Pion's implementation differed from those of common browsers. Though we confirmed the existence of the blocking rule, testers reported that Snowflake continued to work—which may have something to do with the fact that the Snowflake client does not always play the client role in DTLS. If the Snowflake client is the DTLS server, and the DTLS client is a browser proxy, then the byte pattern looked for by the blocking rule does not appear. We developed a mitigation, but by the time we prepared a testing release in July 2022, the new rule had apparently been removed and replaced by another. We can only speculate as to why, but it may be that the old rule had too many false positives, or simply was not effective enough.

The detection rule that replaced supported_groups in Client Hello looked for the server sending a Hello Verify Request

[36] https://bugs.torproject.org/tpo/anti-censorship/censorship-analysis/40030

message.[37] Hello Verify Request is an anti-denial-of-service feature in DTLS, in which the server sends a random cookie to the client, and the client sends a second Client Hello message, this time containing a copy of the cookie [32 §5.1]. It is not an error to send Hello Verify Request (it is a "MAY" in the RFC), but because the Pion implementation in Snowflake sent it, and major browsers did not, it was a reliable indicator of Snowflake connections. (At least, those in which a Snowflake client or command-line proxy took the DTLS server role.) This distinguisher, too, had been anticipated by MacMillan et al. in 2020 [22 §3]. The first reports of this blocking rule arrived in July 2022; but as you can see in Figure 8, it had no apparent immediate effect. It is hard to say whether the drastic decline in October 2022 was a consequence of this rule, or some other, unidentified one. That decline coincided with an enormous increase of users from Iran, which temporarily affected the usability of the whole system. We deployed a mitigation to remove the Hello Verify Request message from Snowflake, regrettably, only in February 2023 [38], after which the number of users in Russia began to recover.

The case of Snowflake in Russia illustrates some of the complexity of censorship measurement. The answer to a question like "Does Snowflake work in Russia?" is not always a simple yes or no. It may depend on the date, the ISP, and even details such as which endpoint plays the DTLS server role.

5.2 Blocking in Iran

In late September 2022, users from Iran became the majority of Snowflake users almost overnight, only to fall just as quickly two weeks later. See Figure 9. The cause of the rise was extraordinary new network restrictions amid mass protests [3]; the cause of the decline was TLS fingerprint blocking, which stopped Snowflake rendezvous from working. The crypto/tls package of the Go programming language (in which the Snowflake client is written) may produce several slightly different TLS fingerprints, depending on hardware capabilities and how it is compiled.[39] It was one of these fingerprints that was blocked. Because the blocking rule was specific to one fingerprint, only some users were affected. Why would a censor block only one (even if the most common) of several TLS fingerprints? It may have been a simple oversight. On the other hand, it is not certain that this instance of TLS fingerprinting in Iran was meant for Snowflake specifically. Go is a popular language for implementing circumvention systems; Snowflake may have been caught up in blocking that was intended for another system.

The fact that simple TLS fingerprinting worked to block Snowflake rendezvous was carelessness on our part. Having been aware of the possibility, we previously implemented TLS camouflage in the Snowflake client using uTLS—but failed to turn it on by default. Activating the feature required only a small configuration change[40], but we had to wait for new releases of Tor Browser and Orbot to get it into the hands of users: see the September–November 2022 interval in Figure 9.

After we repaired the TLS fingerprinting flaw, the number of users from Iran gradually recovered to near its former peak. We are aware of only minor disruptions after this time. The default rendezvous front domain was blocked (by TLS SNI) in some ISPs between 2023-01-16 and 2023-01-24 [41], which we confirmed using data from the censorship measurement platform OONI. A reduction in users is visible at this time. AMP cache rendezvous continued to work. OONI measurements in the weeks after the block was lifted showed additional sporadic failures to connect to the front domain. If these were further attempts at blocking, they did not have much of an effect.

5.3 Blocking in China

The graph of users from China, Figure 10, does not show any drastic changes like those we have seen so far. There is a modest but respectable number of Snowflake users in China. Though there has been no sustained interference, we have seen some evidence of short-term or tentative blocking attempts.

In May 2019, when Snowflake was still in alpha release, a user in China reported a failure to connect. Investigation revealed that the cause was blocking of the IP address of the few proxies that existed at the time.[42] The STUN exchange worked, and rendezvous completed successfully, but the client and proxy could not establish a connection. We experimented with running a proxy at a previously unused IP address: clients in China could connect when they were assigned that proxy by the broker. This was before the web browser extension proxy existed, when the only consistent proxy support was a few standalone proxies running at a static IP address. It stopped being a problem as the proxy pool grew in size.

That same month, we noticed blocking of the default STUN server, of which there was only one at the time.[43] The solution was to add more STUN servers[44], and select a subset of them on each rendezvous attempt[45]. Curiously, it seems that when the STUN server was blocked, the standalone proxies that had been blocked earlier in the month became unblocked.[46]

The next incidents we are aware of did not occur until 2023. On May 12, 13, and 14, a few users reported problems with domain fronting rendezvous.[47] We could not get systematic

measurements, but it appeared that censorship was triggered by observing multiple (two or three) HTTPS connections with the same TLS SNI to certain IP addresses within a short time. It is possible that Snowflake was not the target of this blocking behavior, and was affected only as a side effect. If it indeed had to do with Snowflake, our best guess is that it was aimed at rendezvous with multiple bridges (Section 4.4), though such a policy would certainly also affect a large number of non-Snowflake connections. The user count from China was about halved during those three days, an effect that is visible in Figure 10. On 2023-05-15, the blocking went away and the user count returned to what it had been.

Also in May 2023, one user reported apparent throttling (artificial reduction in speed by packet dropping) of TLS-in-DTLS connections, based on packet size and timing features.[48] Such a policy would affect Snowflake, because of the fact that it transports Tor TLS inside DTLS data channels. Reportedly, padding the first few packets would prevent throttling (a possible counterexample to our claims about traffic analysis in Section 3). Our own speed tests run at the time did not show evidence of throttling, with or without added padding.[49] There was no obvious reduction in the number of users. It may have been a localized, ISP-specific phenomenon.

5.4 Blocking in Turkmenistan

There have never been more than a few tens of Snowflake users in Turkmenistan. Even so, it has happened at least twice that the number of users dropped suddenly to zero, as shown in Figure 11. We found a variety of causes: domain name blocking by DNS and TCP RST injection, and blocking of certain UDP port numbers commonly used for STUN.

Turkmenistan is a particularly challenging environment for circumvention. Though relatively unsophisticated, the censorship there is more severe and indiscriminate than in the other places we have discussed. Only a small fraction of the population has access to the Internet at all, which makes it hard to communicate with volunteer testers and lengthens testing cycles. We have been able to mitigate Snowflake blocking in Turkmenistan, but only partially, and after protracted effort.

The drop on 2021-10-24 was caused by blocking of the default broker front domain.[50] We determined this by taking advantage of the bidirectionality of the Turkmenistan firewall. Nourin et al. [25 §2] provide more details; here we will state just the essentials. Among the censorship techniques used in Turkmenistan are DNS response injection and TCP RST injection. DNS queries for filtered hostnames receive an injected response containing a false IP address; TLS handshakes with a filtered SNI receive an injected TCP RST packet that tears down the connection. Conveniently for analysis, it works in both directions: packets that *enter* the country are subject to injection just as those that exit it are. By sending probes into the country from outside, we found that the default broker front domain was blocked at both the DNS and TLS layers. It was some time—not until August 2022—before we got confirmation from testers that an alternative front domain worked to get around the block of the broker.

The increase in the number of users from May to August 2022 was caused by a partial unblocking of the broker front domain on 2023-05-03. We realized this only in retrospect, after examining data from Censored Planet [34], a censorship measurement platform that, at that time, had continuous measurements of the domain from one autonomous system in Turkmenistan. On that date, there was a shift from RST responses to successful TLS connections. DNS measurements were not available at the moment of the shift, but they, too, showed no signs of blocking after that date. Evidently, some users were able to reach the broker, in those days. But the unblocking must not have been everywhere, because as late as 2022-08-18, users reported that RST injection was still in place for them (though DNS injection had stopped).

There was yet another layer to the blocking. Even if they could contact the broker (at the default or an alternative front domain), clients could not then establish a connection with a proxy. Testing revealed blocking of the default STUN port, UDP 3478. A client that cannot communicate with a STUN server cannot find its ICE candidate addresses (Section 2.2), without which most WebRTC proxy connections will fail. (The exceptions are proxies without NAT or ingress filtering. While there are some such proxies, censorship in Turkmenistan also blocks large parts of IP address space, including the data center address ranges where those kinds of proxies tend to run.) As chance would have it, the NAT behavior discovery feature we rely on for testing client NATs requires STUN servers to open a second, functionally equivalent listening socket on a different port [21 §6], commonly 3479. Changing to those alternative port numbers enabled some users to connect to Snowflake again. Specifically, STUN servers on port 3479 worked in AGTS, one of two major affected ISPs. The workaround did not work in Turkmentelecom, the other ISP, where port 3479 was blocked. Though we do not have continuous measurements to be sure, we suspect that the STUN port blocking began on 2022-08-03 and is what precipitated the drop seen on that date in Figure 11.

The blocking techniques described in this section are crude, surely resulting in significant overblocking—but they nevertheless offer greater challenges to circumvention than the more considered blocking of, say, Russia and Iran. We remark on this to make the point that blocking resistance cannot be defined in absolute terms, but only relative to a particular censor. Censors differ not only in resources (time, money, equipment, personnel), but also in their tolerance for the social and economic harms of overblocking. Circumvention can only respond to and act within these constraints. The government of Turkmenistan has evidently chosen to priori-

[50] https://bugs.torproject.org/tpo/anti-censorship/censorship-analysis/40024

tize political control over a functional network, to an extreme degree. To paraphrase one of our collaborators: "What they have in Turkmenistan can hardly be called an Internet."[51] In a network already damaged by oppressive policy, the additional harm caused by the clumsy blocking of this or that circumvention system is comparatively small. This shows the sense in which a resource-poor censor can "afford" certain blocking actions that a richer, more capable censor cannot.

6 Future work

We designed Snowflake to be useful today, as well as resilient to anticipated future censorship attacks. Here we list some research questions that affect Snowflake and circumvention more broadly. The uniqueness and scale of Snowflake's deployment provide a platform to help explore these questions.

What could alternative Snowflake deployments look like? A natural extension of Snowflake would be to base it on a system other than Tor, such as an ordinary VPN. Tor has attractive privacy benefits and a convenient framework for developing circumvention modules, but it also has relatively low speed and lacks support for non-TCP applications. The prospect of multiple Snowflake deployments raises the question of how the proxy pool should be managed. Building Snowflake's population of proxies has been an undertaking in itself—it would be a regrettable duplication of effort if every project had to repeat the process from scratch. Rather than retrofit our existing Tor-based proxies, a next-generation proxy pool might be designed from the ground up with multiple cooperating projects in mind. There is also the question of incentives: while some proxy operators may be happy to donate bandwidth to a free-to-use project like Tor, they may need more motivation to help a commercial VPN, for example.

How might proxy enumeration attacks be inhibited? The size (Section 4.2) and churn (Section 4.3) of the Snowflake proxy pool are obstacles to comprehensive blocking. However, it is worth considering the maximum impact of enumeration attacks, and ways to mitigate them while preserving usability.

What is a good (family of) traffic shapes? Snowflake does not yet attempt to shape its traffic analysis features (Section 3); but if it were to, what shape should it use? This consideration goes beyond just Snowflake. Frameworks for proposing and evaluating traffic shaping techniques are under-explored.

Can traffic splitting benefit performance or resistance to blocking? The Turbo Tunnel reliability layer of Section 2.3 lets us join a sequence of proxies into a session. In principle, it also makes it possible to split traffic over many proxies, not just sequentially, but simultaneously—something like multipath TCP. Sequence numbers, retransmissions, and reassembly would ensure a reliable stream, even when proxies have different lifetimes and performance characteristics. Traffic splitting could reduce the performance impact of a slow proxy, and eliminate the brief pause for re-rendezvous that now occurs between consecutive proxies. Our initial experiments did not show enough benefit to justify the change, though it may be a matter of tuning.[52] And of course, even if there are performance and usability benefits, analysis would be required to determine whether simultaneous WebRTC connections form a distinctive network fingerprint.

Abstract

Censorship circumvention is often fueled by supporters out of goodwill. However, hosting circumvention proxies can be costly, especially when they are placed in the cloud. We argue for re-examining cloud features and leveraging them to achieve novel circumvention benefits, even though these features are not explicitly engineered for censorship circumvention. SpotProxy is inspired by Spot VMs—cloud instances backed with excess resources, sold at a fraction of the cost of regular instances, that can be taken away at a moment's notice if higher-paying requests arrive. We observe that for circumvention proxies, Spot VMs not only translate to cost savings, but also create a high churn rate since proxies are constantly re-spawned at different IP addresses—making them more difficult for a censor to enumerate and block. SpotProxy pushes this observation to the extreme and designs a circumvention infrastructure that constantly searches for cheaper VMs and refreshes the fleet for anti-blocking, for spot and regular VMs alike. We adapt Wireguard and Snowflake for use with SpotProxy, and demonstrate that our active migration mechanism allows clients to seamlessly move between proxies without degrading their performance or disrupting existing connections. We show that SpotProxy leads to significant cost savings, and that SpotProxy's rejuvenation mechanism enables proxies to be replenished frequently with new addresses.

1 Introduction

Censorship circumvention is often fueled by supporters out of goodwill [93]. Whether they set up proxying infrastructure at their own cost [47, 56, 69, 74, 94, 110, 111] or rely on donations [26, 60], their available budget is eclipsed by the resources of nation-state censors. To sustain the circumvention ecosystem, therefore, censorship evasion apparatuses must be able to operate on constrained budgets and make effective use of every dollar contributed towards circumvention.

Today, proxying infrastructure is hosted in an array of network locations, including content distribution networks [54, 107], Internet service providers [103], residential homes [42], edge networks [76], and, perhaps unsurprisingly, *the cloud*. Despite the transformative impact of cloud computing on many workloads, we argue that *circumvention proxies* must use the cloud in a very different way to reap benefits. Our goal in this paper is to re-examine and fully realize the power of the cloud for hosting circumvention proxies in virtual machines (VMs), maximizing cost savings and censorship resistance.

On the one hand, many circumvention proxies already hail from the cloud. This includes many Tor relay nodes [30, 31], standalone Snowflake proxies [27], and VPNs (e.g., Psiphon [25] and Lantern [20]). The conveniences of cloud computing, including its pay-per-use model and stable performance, apply to circumvention systems as well as traditional cloud workloads (e.g., key/value stores, web services). To host circumvention proxies, a user can rely on VMs in the cloud, without provisioning physical nodes in a dedicated place.

However, cloud VMs represent a substantially different computing environment, with many intriguing features not found elsewhere. Simply "lifting-and-shifting" a workload—any workload—into cloud VMs often falls short; one must bear in mind which cloud features are uniquely suited for that workload, in order to maximize benefits [100]. This is especially true for circumvention proxies, a non-conventional workload for which the cloud is not explicitly engineered.

The inspiration for this project came from a well-known cloud feature, *Spot VMs* [39,45,61], which at first glance seem unrelated to our goal, but a deeper look reveals two interesting properties under the lens of censorship circumvention. Spot VMs are a special class of cloud instances, spawned by cloud providers just-in-time out of excess resources to maximize profit, and then taken back at a moment's notice when higher-paying tenant requests arrive. Compared to regular VMs, spot instances are sold at a much cheaper price, even when they encapsulate the same amount of compute, memory, and network resources. This aligns with the goal of *lowering the cost of hosting circumvention proxies* as much as possible. On the flip side, cloud providers may preempt Spot VMs any time and repackage the underlying resources as regular VMs for a higher price. This instability of spot instances is commonly viewed as a nuisance, since it incurs an undesirable burden for

most workloads. The tenant needs to acquire a replacement VM, slot it into their fleet with a new random IP address, and resurrect any interrupted workloads. For censorship evasion, however, we observe that this high churn is in fact *a powerful antidote against censor blocking*. Proxy instances are constantly reborn at different IP addresses, even though their previous IPs may have been blocked.

Motivated by these observations, SpotProxy is a censorship resistance infrastructure that maximizes *circumvention utility* as the first-order objective using cloud-native features. Despite its name, SpotProxy is not restricted to using spot instances. Rather, it may use any available VMs found in the current cloud catalogue, spot or regular, as long as they are among the cheapest. Moreover, SpotProxy intentionally creates a high churn in its fleet. The Spot VMs on its fleet already naturally come and go, but in addition, SpotProxy also releases VMs as they age and spawn replacement VMs at new IP addresses to increase unblockability.

We envision that one way of using SpotProxy will be for a censorship circumvention sponsor (e.g., an organization like Tor, a VPN provider, or even a regular user) to deploy it in a public cloud (e.g., Amazon). They either take donations or pay out-of-pocket to create a fleet of SpotProxy instances, which in turn proxy communication from censored regions for whoever is in need. With SpotProxy, sponsors and contributors know that their resources are put to the most effective use, explicitly optimized for advancing the circumvention endeavor. Censored clients obtain entry to the SpotProxy fleet using conventional methods (e.g., email, moat [101]), but once they are connected, their proxy instances are constantly shifted from one VM to another to defend against IP-based blocking and enumeration attacks [33, 50, 109]. In a similar spirit, the complex and often-changing cloud price structure also leads to periodic cost arbitrage and proxy migration to cheaper VMs—dovetailing efforts to reduce the cost of the infrastructure and increase its churn. Importantly, client connections remain stable, and their communication seamless, as SpotProxy takes special care to preserve ongoing flows even when proxies are migrated across VMs. At any given point in time, the SpotProxy sponsor only pays for a (potentially small) number of proxies; but in the aggregate, these proxies comprise an increasingly larger IP footprint as they hop across VMs, creating an untenable collateral damage if the censor blocks all of the enumerated/observed addresses.

At its core, SpotProxy has two key mechanisms: *infrastructure rejuvenation*, which keeps around a cheap and fresh VM fleet as its workforce, and *client migration*, which ensures seamless client connectivity despite constant movement.

The first component of SpotProxy, the *rejuvenator*, constructs the underlying VM infrastructure and keeps it cheap (for cost savings) and fresh (for anti-blocking). To reduce cost, SpotProxy dynamically assesses the costs and benefits involved in acquiring variously-configured VM instances. This involves navigating the pricing variabilities of Spot VMs in relation to regular VMs, across cloud zones and regions, with a particular attention to circumvention-specific features, such as multi-NIC instances (which can host multiple proxies thus reducing per-proxy cost), ingress/egress preferences (for serving different censored regions and destinations), and sometimes, the ability to swap in a new IP address without any other change to the VM. This real-time arbitrage leads to the decommissioning of existing VMs in preference of cheaper ones. This churn is further amplified by keeping the VMs fresh, so that their IP addresses only host proxies briefly before being reallocated to unrelated cloud services, increasing collateral damage for a blocking adversary. Each VM is attached with a rejuvenation timer, and upon firing, the rejuvenator works to find a replacement with similar or cheaper cost. Complete with the natural dynamism of Spot VMs in our fleet, the underlying infrastructure is kept in constant flux.

The second component of SpotProxy is the *relocator*, which migrates active clients from one proxy instance to another as instructed by the rejuvenator. Whether a relocation event is due to cost arbitrage, Spot VM reclamation, or rejuvenation, the relocator can actualize frequent changes to client-to-proxy assignments. This enables SpotProxy to proactively and quickly hand over clients while keeping their connections alive, thus allowing SpotProxy to exert arbitrary control over both fleet composition and updated assignments. This further involves maintaining the state of available proxy instances, client-to-proxy assignments, session states across proxies (e.g., per Turbo Tunnel [53]), and seamless session resumption upon client-to-proxy reassignment. Furthermore, the relocator mechanism is proxy-independent—the same design pattern applies to different proxy implementations in re-engineering them slightly to be relocatable.

Our current prototype is compatible with the deployment of two prominent proxying protocols over SpotProxy-operated cloud instances: Wireguard [48] and Snowflake [42]. A live deployment and evaluation of SpotProxy's performance revealed that the system is able to support active migration at scale (migrating thousands of clients and hundreds of proxies simultaneously) while meeting the reclamation deadlines of cloud providers by a wide margin. In addition, we experimentally verified that SpotProxy preserves the continuity of client connections across migration events, imposing a negligible throughput degradation. We also evaluated SpotProxy' long-term cost savings by resorting to historical AWS EC2 pricing data, and experimental deployments. Our results show that SpotProxy would have been able to achieve ∼90% instance cost savings (and ∼74% total cost savings when considering network costs[1]) across several months in operation, assuming a move from ad-hoc proxy deployments in on-demand cloud instances to deployments on multi-NIC Spot VMs acquired via SpotProxy's cost arbitrage mechanism. Finally, we evaluated the circumvention efficacy of SpotProxy against multi-

[1] Network egress costs can be significant too. We analyze this in §11.1.

ple censor behaviors based on Nasr et al.'s game-theoretical simulation framework [80]. By adopting the proxy assignment algorithm from the same framework, we found that SpotProxy can provide access to ∼60% of legitimate clients even when censors control half of the connected clients (i.e., sybils); though we note that these are results obtained from a generic censor model not specialized to SpotProxy. These results support our belief that SpotProxy will drastically fuel circumvention as a next generation, cloud-based technique.

2 Why Rediscover the Cloud?

Cloud computing is hardly a new concept—more than 94% of enterprises already use the cloud [1]. In public cloud providers, compute, memory, and network resources are packaged as "virtual machines" (VMs), sold at varying prices in a pay-as-you-go model. Many vendors are vying for the market, ranging from large-scale service providers such as Amazon, Google, Azure, Digital Ocean, and Oracle, to smaller players such as OVH [85]. The cloud has in turn transformed how modern workloads are hosted, optimized, and served [79].

Owing to the success of cloud computing, it is not uncommon to host circumvention proxies in cloud VMs today [25, 27, 30, 31]. Some proxies even provide cloud configuration scripts [30, 31] for automated deployment. However, today's proxies use the cloud in a "lift-and-shift" manner, from residential homes/enterprises to virtual machines, with little customization for the circumvention endeavor. While this is sufficient for leveraging the more common features (e.g., payment model, ease of use, robust performance), it leaves vast opportunities largely untapped. The non-profit nature of censorship circumvention also means that the rising cloud costs that led to myriad business repatriation [16] will eventually impact proxy sustainability as well.

2.1 Benefits of the cloud

The **benefits** of cloud VMs can be felt by many workloads, circumvention proxies included.

First, cloud providers strive to make virtual machines easy to deploy and use, and proxy developers often supply cloud configuration scripts for automation. This makes cloud-based proxies far easier to deploy [75] than alternative circumvention solutions that reside in core networks [69, 74, 111] or at the edge [42, 47, 76]. Second, high availability is characteristic of the cloud, and providers dedicate substantial resources to support "five or more nines" [3]. VM-backed proxies, therefore, stand in contrast to user- or web browser-based counterparts (e.g., Snowflake [42] and MassBrowser [81]), which run on less reliable residential broadband networks and get shut down without notice. Third, the cloud provides higher performance, with VM resources customizable over a range of product classes (e.g., dedicated, shared, or fractional). Thus, VM-backed proxies can handle much more traffic and connections [89], whereas proxies on user laptops compete for resources with other applications. To sum it up, the cloud offers a commercial grade solution to circumvention proxies as it does for other workloads.

2.2 Downsides of the cloud

The commercial nature of the cloud, however, is at odds with the non-profit nature of circumvention endeavors, leading to important **disadvantages** surrounding cloud expenses.

Cloud VMs are expensive, and they are charged even when the underlying resources are idle. For instance, if a proxy fleet uses ten VMs with 2 vCPUs and 8GB memory[2], it costs about $600 per month even if some proxies are underutilized or blocked. To provision VMs with more CPU, memory, disk, and network resources, or even public IP addresses, leads to additional cost. Cloud costs are also steadily increasing, and this has given rise to the ongoing trend of cloud repatriation [16], where tenants move their workloads out of the cloud back to on-prem infrastructures due to the steep expenses.

This is particularly problematic for circumvention proxies, both for proxy sponsors/contributors and censored clients. For the former, financial strain is not uncommon especially when dealing with usage surges [60]. For instance, Lantern recently resorted to accepting donations and utilizing credit cards to sustain its operations and maintain stable access while scaling up its services in response to surging user demand [2]. One could instead ask proxy users to pay, but this increases the barrier for censored clients to access the free Internet. Censored clients could be financially constrained and need donations from governments and NGO entities for circumvention [23, 26, 90]. Payment channels for proxies could be restricted [32]. The act of paying for VPN services could be criminalized [40]. Free VPNs are thus in frequent demand, as evidenced by the increased usage during free access campaigns by IVPN [90] and the predominance of free VPN services in Russia [32], despite concerns that these services have opaque ownership and have been known to harvest user data and sell personally identifiable information to data brokers [52]. Thus, for sustainable operation of VM-backed proxies, we must minimize the necessary expenditures. For proxy sponsors and contributors, we must ensure that funds maximally contribute to circumventing censorship. For censored clients, we must extend free service to the broadest user base possible to increase its overall impact and accessibility.

2.3 Unleashing the cloud's full potential

We believe that a promising path forward is to re-examine the specific requirements of circumvention proxies, and support these goals with an infrastructure that leverages unique features of the cloud. Spot VMs [38, 39, 45, 61] are poised to offer a steep cost reduction, ranging from a guaranteed 60% (GCP) up to 90% (AWS/Azure), a price competitive to even niche providers (e.g., OVH [85])[3]. Spot VMs are also conducive

[2] `m6a.large` AWS EC2 instance and `b2-7` OVH instance

[3] OVH's roadmap hints at a future Spot VM offering [84], highlighting their emerging importance among cloud features providers aim to implement.

to autoscaling, unlike reserved instances [36] which require upfront lump sum payments. Although Spot VMs can be reclaimed at a moment's notice [38], this naturally refreshes the fleet with new random IP addresses [86, 87]. SpotProxy pushes these ideas to the limit by embracing these properties.

SpotProxy also leverages a few other cloud-native features. Cloud VMs can be deployed in chosen compute regions, so that services can reach their clients in closer proximity. In our case, this works nicely for supporting different censored regions and censored content. Some VMs can be assigned with multiple virtual NIC with public IP addresses [6, 17, 21, 46]. While this feature is originally designed for multi-homing scenarios [9], under the lens of circumvention, it can potentially provide further cost saving. Censors enumerate proxies by their IP addresses, so we can host a different proxy on each virtual NIC. Elastic IP addresses are another feature, allowing a VM to disassociate from its IP address on-the-fly and acquire a new one. Last but not least, the cloud hosts a variety of services that may be critical for high-profile businesses operating within censored regions. Censors are faced with significant collateral damage should they blindly block communications towards public cloud IP addresses [119]. In sum, our central principle is to reconsider cloud features and translate them into novel, anti-censorship benefits, thereby unleashing the cloud's full potential as a robust and cost-effective circumvention infrastructure. We emphasize that SpotProxy is an initial step in this direction, with further exploration detailed in §11.

3 SpotProxy

SpotProxy aims to satisfy the following **design goals**:

(1) **Minimal cost.** Proxies deployed on cloud instances are expensive. SpotProxy aims to provide maximum cost savings, a prerogative for effective circumvention.

(2) **Cloud-native unblockability.** The cloud, collectively, offers near-limitless resources (e.g., instances, or public IP addresses). SpotProxy should take advantage of this to make blocking more challenging for censors.

(3) **Seamless client connectivity.** Pursuing our two aforementioned goals requires frequent reassignments of clients to proxy instances. Client connectivity and network performance should not be impacted as a result.

3.1 Threat model

We assume that SpotProxy clients are located within regions under the influence of a state-level adversary who can monitor and manipulate clients' traffic flowing within its jurisdiction. Our assumption centers around a rational adversary who is mindful of the potential collateral damage stemming from the use of indiscriminate, coarse-grained blocking policies. For instance, the adversary refrains from outright blocking large swaths of IP address spaces pertaining to cloud providers due to potential collateral damage, an assumption adopted by existing cloud circumvention tools (§10). In addition, the adversary operates within computational bounds, lacking the capabilities to compromise standard cryptographic assumptions (e.g., to decrypt clients' traffic or forge signatures).

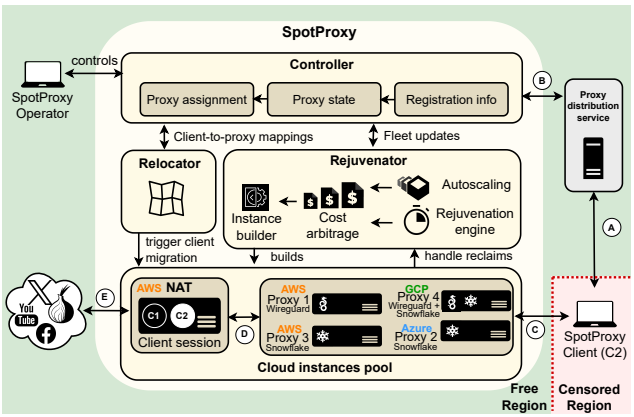

Figure 1: High-level view of SpotProxy's architecture.

However, the adversary has the power to deploy seemingly-legitimate SpotProxy clients to acquire proxy identifiers and engage in active probing. Given extensive research related to traffic analysis and active probing attacks [41, 57–59], we also assume that the proxying protocols that are deployed on top of SpotProxy's circumvention substrate already deploy adequate countermeasures, such as dedicated traffic obfuscation layers [112], probe-resistant proxy implementations [57, 59], or proxy-assignment algorithms [49, 80, 102].

3.2 Architectural overview

As shown in Fig. 1, the rejuvenator and the relocator components are our main innovation, but SpotProxy also features a central controller for orchestrating the relocation of proxy instances. Below, we describe clients' typical workflow when using SpotProxy, and then describe the operation of SpotProxy's backend components.

Client workflow. To use SpotProxy, clients leverage a modified client-side proxy binary to Ⓐ register through some existing proxy distribution service (e.g., a domain-fronted [54] broker, moat [101]), which forwards such requests to the Ⓑ *central SpotProxy controller*. Upon registration, the client is assigned a proxy (via some existing proxy-assignment algorithm) whose address is communicated back to the client by the broker, and the client can then Ⓒ initiate a connection to the proxy. Clients' requests transit through a NAT which preserves client session state Ⓓ while data is exchanged with the Internet services the client wishes to access Ⓔ.

SpotProxy backend. The fleet of proxies handled by SpotProxy is in constant flux, requiring frequent client-to-proxy re-assignments. These fleet changes are handled by the controller and do not require clients to go through re-registration. To this end, the controller continuously collects information about client registrations from the distribution service, and proxy state from periodic heartbeat signals sent by the proxies

themselves (e.g., containing CPU utilization, network transfer volumes, or the number of connected clients) to inform the remaining SpotProxy's components that we describe below.

The *rejuvenator* (details in §4) acquires cheap VM instances for cost savings, and keeps them fresh to increase unblockability. This satisfies our design goals (1) and (2). The *relocator* actuates re-assignment decisions made by the controller by migrating clients to different proxy instances for seamless connectivity (details in §5). The *proxy instances* can be of any type, as long as they can be re-engineered to become relocatable (see §6). This procedure incorporates active migration support, alongside our NAT device implementing TurboTunnel [53] (this device can be deployed on regular VMs and horizontally/vertically scaled according to client demand). This satisfies design goal (3) by providing a stable endpoint from the perspective of the destination—that is, the destination (e.g., YouTube) is unaware of the client's changing proxies because its TCP endpoint remains the (static) NAT host and its TCP connection is unaffected by client migration. Our migration technique is designed to be integrated into existing proxy implementations (as later showcased in §6).

4 The Rejuvenator

The rejuvenator minimizes cost by acquiring spot VMs or other VMs of the cheapest type, and it creates churn by refreshing its fleet periodically.

4.1 Cost arbitrage

SpotProxy opportunistically and continuously searches for the cheapest VM instances through cost arbitrage, as Spot VM pricing resembles a marketplace with variable prices [95] (across hundreds of instance types, availability zones, dozens of regions, and even potentially across clouds). This differs from existing works that (1) have a static assignment upon initialization and do not change until reclamation occurs [4, 114], (2) are focused on a single region and thus lose out on price competitiveness [4], or (3) choose a mixture of instances (e.g., more expensive regular instances) to reduce reclamation risk [28]. The ability to opportunistically select inexpensive instances is enabled by our active migration mechanism (§5) that allows for arbitrarily frequent reassignments of clients to the current cheapest proxy instances, effectively turning circumvention into a fault-tolerant application. It periodically constructs a preference catalog for autoscaling and cost arbitrage purposes. The catalog provides an up-to-date cost-ranked instance list (akin to SkyPilot [114] and OpenCost [24]) based on the number of proxies required, common filter attributes (vCPUs, RAM, bandwidth), and two circumvention-specific filter attributes:

(a) *Multi-NIC enabled.* This attribute leverages the principle that public IP addresses are the core units in circumvention, each serving as a unique proxy endpoint. Thus, it exposes another dimension for cost arbitrage, since larger but more expensive instances tend to be equipped with more virtual NICs (vNICs) as well, lowering the overall per-proxy cost. For instance, the AWS `c6in.large` instance has three vNICs, effectively reducing the cost of hosting a single proxy by two-thirds.

(b) *Egress region preferences.* This attribute is useful for proxy services (e.g., VPNs) that cater to clients with specific requirements (e.g., accessing geo-filtered services, or network performance needs).

The SpotProxy controller then relies on the catalog to select instances, and invokes cloud-level APIs to provision the underlying VM resources, forming a proxy fleet.

4.2 Infrastructure rejuvenation

Given the high cost of cloud VMs, SpotProxy seeks to ensure that cloud expenses are efficiently steered towards enabling censorship resistance. This requires solving the principal challenge of "disappearing" infrastructure in the circumvention context, which has two main root causes: (a) circumvention proxies have to contend with an adversarial censor that can block access to proxies; and (b) Spot VMs are prone to reclamation by cloud providers. Both causes are unpredictable in severity and frequency.

To address these challenges, SpotProxy introduces the concept of infrastructure rejuvenation, which harnesses the cloud's capability of on-demand provisioning of resources to continuously replenish disappearing infrastructure to maintain a stable supply of proxies. In doing so, SpotProxy can maintain a small (and thus inexpensive) proxy fleet footprint at any given moment, but their hosting VMs are constantly in flux, resulting in an infrastructure whose aggregate footprint is so large that the blocking cost is untenable. Rejuvenation employs a strategy of periodic proxy swapping based on the age of the proxies. This operates under the assumption that they will eventually be blocked or enumerated, and sometimes, the blocking events may not even be detectable by SpotProxy. This strategy is dynamic and can be as frequent as necessary (depending on the availability goals of the circumvention sponsor), thanks to the capabilities of active migration (§5) which guarantees seamless connectivity despite rejuvenation. SpotProxy provides two forms of rejuvenation: IP-based (§4.2.1) and instance-based (§4.2.2).

4.2.1 Live IP rejuvenation

Live IP rejuvenation is simple and fast, allowing for near-instantaneous rejuvenation. Conceptually, live IP rejuvenation relies on the principle that the public IP address of a cloud VM (i.e., the proxy) is the only resource that needs to be refreshed in order to counter IP-based blocking. The IP address refresh is performed on a "live" VM instance that does not need to be shutdown/restarted.

Live IP rejuvenation workflow. The workflow proceeds as follows. First, a rejuvenation period is associated with each VM within the fleet. These VMs will be assigned statically allocated public IPv4 addresses (known as elastic IPs in

AWS [6] or static IPs in Azure and GCP [17, 21]), instead of using their dynamic ephemeral IP addresses (which can only be refreshed via §4.2.2) that are allocated by default. Once the rejuvenation period (Tx) for a VM instance is reached, a new elastic IP address is allocated by the SpotProxy controller. Via the relocator (§5), the censored client receives this new address along with an associated shared secret and resumes proxying over this new address seamlessly. Prior to migration, IP remapping is triggered: the current attached elastic IP is disassociated from the existing VM and immediately deallocated; in this way, we do not have idle IP addresses which would incur additional charges [7, 10, 18]. The newly allocated IP is then associated with this VM, concluding the remapping. Finally, the associated proxy process on the VM is restarted before it resumes handling new user requests.

The cost of live IP rejuvenation. The primary advantage of utilizing live IP rejuvenation lies in its capacity to rejuvenate multiple IPs linked to multiple virtual NICs on a single VM, where each can host a proxy. This approach can significantly lower costs—for example, a single AWS `c6in.large` VM equipped with three vNICs can support three proxies, effectively reducing the hosting cost per proxy by two-thirds—in addition to the cost-saving measures previously discussed. The only additional cost incurred is the cost of acquiring additional public IPs (priced at $\$0.005/hour$ in AWS and GCP)[4], which can be billed at per-second granularities [7], just like VMs themselves [5, 19, 22]. Unfortunately, live IP rejuvenation can be cost-ineffective on Azure if Tx is low, as Azure charges IP address allocations at per-hour granularities [10] (i.e., partial hours are billed as full hours).

4.2.2 Instance rejuvenation

SpotProxy's second form of rejuvenation works by replacing the VM instances themselves. This is the most general form of rejuvenation, since every cloud provider will enable autoscaling of their VMs. Conceptually, instance rejuvenation mitigates blocking by regularly creating new VM instances that possess distinct IP addresses.

Instance rejuvenation workflow. The workflow proceeds as follows. First, a rejuvenation period is associated with each VM instance within the fleet. Note that these VMs will be using their dynamic ephemeral IP addresses that are allocated by default; the implication is that we do not support multi-NICs on a VM (since these can only be rejuvenated via §4.2.1). Once the rejuvenation period (Tx) for a VM is reached, it is substituted with a replacement instance. To allocate this instance, a request is sent to our opportunistic instance builder. Since spot VM fulfilment is not guaranteed by cloud providers (fulfilment can take minutes to hours [77, 88, 115]), this request also contains an expiration timer (Ex) that instructs the preference generator to timeout if an instance type takes more than Ex to be fulfilled, and try acquiring the next preferred instance type instead. Once the instance is activated, active migration ensures clients resume proxying seamlessly.

Embracing reclamation. In §2, we discussed the unreliability of spot VMs, noting their lack of guaranteed availability and thus the potential for spontaneous reclamation by cloud providers, usually with a short notice period (e.g., 30 seconds in GCP [62] and 2 minutes in AWS [38]). Traditional approaches to handling these reclamations view them negatively due to their disruptive impact on workloads, such as necessitating restarts from scratch or frequent, resource-intensive checkpoints [114]. In contrast, in our censorship circumvention setting, SpotProxy embraces reclamation by treating it as a special case of instance rejuvenation: SpotProxy performs instance rejuvenation spontaneously once a reclamation notice arrives rather than waiting for the next Tx. This approach involves re-provisioning a new VM instance to which impacted clients are then migrated, while ensuring seamless network continuity and minimal performance impact, as detailed in §5 and §7.1. Since reclamation occurs unpredictably and instance rejuvenation may not complete during the reclamation's short notification period, SpotProxy ensures disruption-free communication by either using a lower Ex or migrating clients temporarily to other instances.

5 The Relocator

The relocator actualizes client-to-proxy reassignment decisions made by the controller (Fig. 1) by moving clients to new proxies as the proxy fleet composition shifts, or as dictated by the assignment algorithm [49, 80, 102] used by the controller. We refer to this process as *active migration*. Reassigning clients to proxies is especially crucial because fleet composition will continuously fluctuate as SpotProxy strives to (1) maximize cost savings via runtime cost arbitrage and autoscaling, and (2) counter blocking and cloud-provider-induced reclamation through infrastructure rejuvenation (§4). Active migration needs to fulfill two design goals:

- **Seamless.** Migration should not cause client connectivity to be disrupted.
- **Automatic.** Reassignments should not require decision-making from external parties (e.g., the controller should not need to passively wait for clients to indicate that they would like to receive a proxy identifier).

Active migration mechanism. Active migration involves the following components: (1) the SpotProxy *controller* that maintains up-to-date databases regarding both the proxy instances available and current client-to-proxy assignments, performs assignment decisions based on an assignment algorithm, and initiates assignment decisions by coordinating with the relocator to construct relocation messages and; (2) *clients* running the client-side proxy binary that are connected to their assigned proxies; (3) *proxies* serving such connections that are managed by the controller; and one or more (4) *NAT* (network

[4] IP remappings are monetized on AWS ($0.10 per remap), but our experimental validation in §7.3 show that this does not apply to live IP rejuvenation, as IPs are never reassigned to another VM.

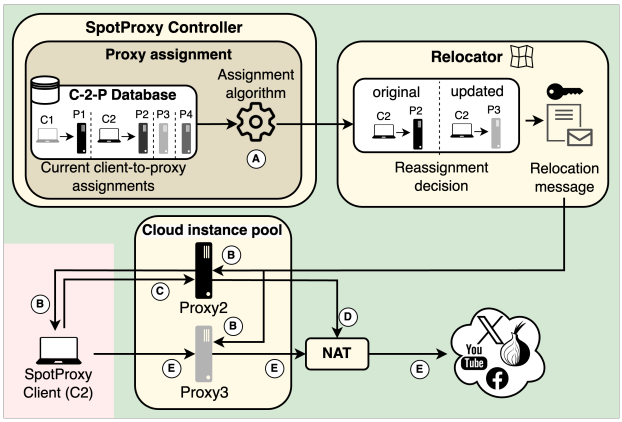

Figure 2: Active migration workflow. Re-assignment decisions made by the controller are actualized by the active migration mechanism, which allows the relocator to proactively communicate with both its managed proxy fleet (e.g., ACL) and clients (e.g., identifier and secrets) about its re-assignment decisions, and allows clients to instantly migrate to its newly assigned proxies while maintaining seamless connectivity.

address translation) devices that help maintain session state and constitute static endpoints to clients' destinations.

The workflow proceeds in phases, as illustrated in Fig. 2. We discuss these from the viewpoint of a single client, but in practice, migration would involve all clients assigned to the given proxy that needs to be migrated.

Active migration begins with the Ⓐ *planning phase* where the controller formulates a reassignment decision in response to a trigger (e.g., rejuvenation, reclamation). The controller consults up-to-date state such as the available proxy instances and current client-to-proxy assignments when forming reassignment decisions. Next, during the Ⓑ *notification phase*, the relocator informs the client of its impending reassignment via a relocation message that includes the identity and network address of the new proxy and any required secrets needed to establish connectivity with the new proxy. This message is securely relayed using the already-established channel between the client and the proxy. The controller's reassignment decision is also delivered to the new proxy, which inserts the client into its access control list (ACL).

Then, in the Ⓒ *confirmation phase*, the client parses the relocation request, and performs a three-way termination handshake with its current proxy. Next, in the Ⓓ *update phase*, the current proxy removes the client from its ACL, and informs the NAT to update its existing routes for the client. Finally, in the Ⓔ *resume phase*, the client authenticates and reconnects with the new proxy. Subsequent data packets are forwarded to the NAT (the egress point of SpotProxy traffic), which uses a Turbo Tunnel [53] design to identify the client's existing session to guarantee network continuity (e.g., without disconnecting existing TCP sessions to the client's previously-connected destinations).

Integrating relocation capabilities requires small modifications (see §6) to both the client- and proxy-side proxy software (e.g., Wireguard). The active migration process requires a client to have an ongoing connection with its current proxy to learn of its new assignment. If the client's proxy is suddenly blocked or otherwise becomes unavailable, then active migration is not possible and the client must re-register with SpotProxy as described in §3.2.

6 Implementation

We implemented a functional prototype of SpotProxy in approximately 5200 lines of code. We have open-sourced our code at https://github.com/spotproxy-project/spotproxy. SpotProxy currently supports operations on AWS (through `boto3` [37]), although its design applies to other clouds that offer programmable APIs for resource provisioning (e.g., GCP, Linode) [35, 63]. SpotProxy collects the fleet state (e.g., cost incurred by each VM in-use) by querying the appropriate cloud interfaces, and provisions/de-provisions VM instances based on various conditions that include cost arbitrage, autoscaling, and custom rejuvenation actions. The appropriate proxy implementations are then loaded/started within the VM.

The most significant modification that SpotProxy requires of existing proxies is that they need to be re-engineered to be relocatable. In what follows, we describe our implementations for two popular proxies, Wireguard and Snowflake.

6.1 Relocatable Wireguard

Wireguard is a popular network tunnel operating at layer 3, implemented as a kernel virtual network interface for Linux. The SpotProxy controller (Fig. 1) for Wireguard is written in Python using the Django [14] web framework, and the databases it maintains are managed with Django's internal ORM. It interacts with the instance manager sub-component through GET/POST HTTP endpoints.

We then implemented a management layer around the Wireguard [48] tunneling protocol, to be installed on both the proxy instances and the client. It is designed to handle multiple clients, creating individual Wireguard threads for each. Within these threads, a bidirectional connection is established linking the client, our management system, and the external NAT server. Upon instance initialization, our system, equipped with an Apache HTTPS server, starts monitoring for migration directives from the controller. Additionally, it incorporates a network traffic controller that manages data flow through the Wireguard tunnel. This controller reroutes outgoing data from the tunnel to the external NAT, and incoming data is similarly processed before entering the tunnel.

Upon a migration event, the management system receives Wireguard key configurations of clients (containing the client's public IP and Wireguard key) involved in the migration, and the traffic controller appends the migration header

(containing the replacement proxy's public IP and Wireguard key) to an arriving packet destined to the associated clients, which is encrypted by Wireguard, and delivered to the client. On the client side, the management system parses this migration header, updates the Wireguard configuration file, and restarts its Wireguard tunnel process, before reconnecting to the new proxy and resuming the network session with its last acknowledged sent packet.

6.2 Relocatable Snowflake

We made targeted modifications to Snowflake's codebase, particularly in the client, broker, and proxy components. We did not have to create a controller or NAT from scratch as with Wireguard since Snowflake's broker and server (that runs Turbo Tunnel) already provide these functions. We highlight the more prominent changes, starting with the planning phase:

When performing client-to-proxy assignments, the existing broker's knowledge of available proxies is restricted to proxies that are currently advertising their willingness to proxy client traffic (via an HTTP session opened with POST requests to the broker). This is sufficient for Snowflake browser-based proxies as they typically exist in large quantities, yielding a high probability that there is always at least one proxy advertising itself to the broker at any given time. However, this may not necessarily be the case for SpotProxy. To ensure we always have complete knowledge of available proxies, on the broker, we enhanced the `SnowflakeHeap` data structure to maintain an updated listing of proxy identifiers (e.g., IPs). Additionally, we introduced a `Client` struct that keeps a historical record of current assignments.

For the notification phase, we modified the broker's `/client` handler to issue periodic relocations. On the proxy, we set up an HTTP server with a `/transfer` handler capable of receiving relocation messages, which are then parsed and forwarded to the appropriate clients. On the client side, we added a `DecodeMessage` function to process the relocation messages and obtain details about the new proxy.

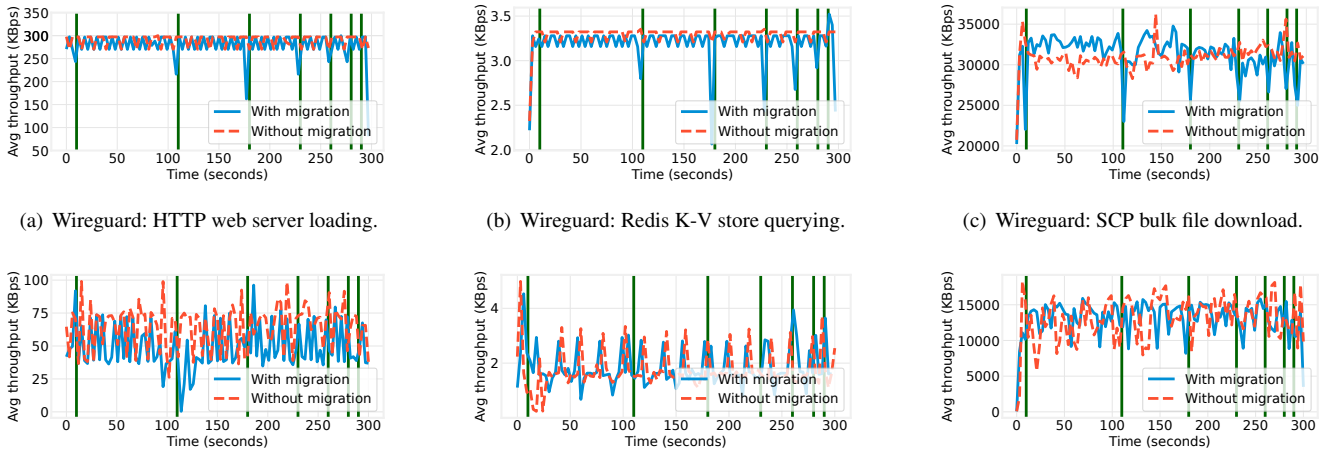
For the resume phase, on the client side, we implemented a `DirectConnect` function, enabling reconnection to a new proxy without broker involvement for seamless client handover. We also added a `/add` handler to the proxy's HTTP server to enable direct reception of SDP offers from clients, using the existing `makePeerConnectionFromOffer` function for client connection.

7 Performance and Cost Evaluation

We now evaluate SpotProxy in three dimensions: (1) how much load can SpotProxy active migration support, for varying client and proxy fleet sizes (§7.1)?, (2) how much cost savings can SpotProxy provide (§7.2)?, and (3) how fast can SpotProxy rejuvenate its infrastructure (§7.3)?. The efficacy of SpotProxy to evade censorship is evaluated later in §8.

Experimental setup. To evaluate SpotProxy performance and costs, we mostly rely on a *live network testbed*, built entirely on public AWS EC2 cloud VMs. Our controller (colocated with the rejuvenator and relocator) and NAT are both deployed on lightweight `m7a.large` EC2 instances (2vCPU and 8GB RAM), while our clients and network services acting as "free Internet destinations" are deployed on regular `c5.large` EC2 VMs (2vCPU and 4GB RAM) in various regions. For experiments whose results do not depend on SpotProxy's cost arbitrage (i.e., stress-testing the controller for active migration performance tests in §7.1), we also deploy proxies on regular `c5.large` EC2 VMs.

7.1 Active migration performance



Active migration occurs when the controller decides that clients should be reassigned to different proxies due to cost arbitrage, autoscaling, rejuvenation, or reclamation. The main constituent costs of active migration are (1) the time required for the controller to perform reassignment decisions and notify all relevant parties, and (2) the time needed for clients to successfully reconnect to their newly assigned proxies. Next, we conduct stress tests to measure these overheads.

Migration efficiency. We assess the overhead of active migration by determining the degree to which it degrades the throughput of client connections. From the viewpoint of a single client, we evaluate our active migration proxy implementations across representative workloads, including (1) long-lived connections that outlive multiple migration events (i.e., an SCP bulk file download), and (2) short-lived connections that usually complete within a few seconds (i.e., accessing a web server, or a Redis K-V store).

As shown in Fig. 3, active migration incurs negligible throughput degradation (sub-second) from the viewpoint of our client, compared to a baseline in which no migration occurs. This holds for all our workloads, even as we gradually reduced the migration period (shown as green vertical lines) down to 5 seconds. Additionally, SpotProxy preserves connection continuity; for example, clients' SCP transfers were uninterrupted even across multiple migration events.

Migration scalability. We conduct scalability tests to ascertain SpotProxy's capacity to handle a large number of concurrent active migrations. Fig. 4 shows the average migration time for various configurations of clients and fleet sizes, for both SpotProxy-equipped Snowflake and Wireguard. A client's migration time is defined as the duration between the controller initiating the active migration event until the client connects to its newly assigned proxy. For each configuration, we perform three trials and plot the average. The variance across trials is small and the range of migration times is depicted by the (barely visible) error bars.

Our aim in the first two configurations (10 clients with 1 proxy vs. 100 clients with 1 proxy) is to stress a single proxy by increasing its load (i.e., the number of assigned clients) tenfold. Even with a heavy load, migration time is still minimal, requiring only 1.47s at worst.

(a) Wireguard: HTTP web server loading. (b) Wireguard: Redis K-V store querying. (c) Wireguard: SCP bulk file download.

(d) Snowflake: HTTP web server loading. (e) Snowflake: Redis K-V store querying. (f) Snowflake: SCP bulk file download.

Figure 3: Active migration incurs negligible client-side throughput degradation across diverse workloads and proxy implementations, even as migration frequency increases (green vertical lines), from a single client's viewpoint.

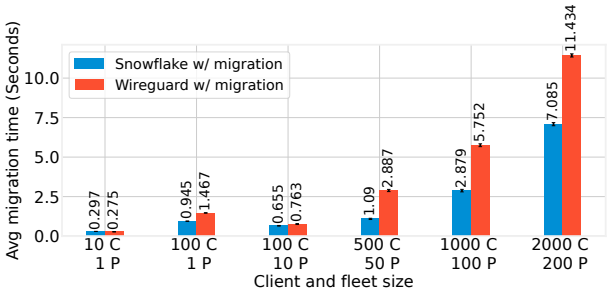


Figure 4: SpotProxy can handle a large number of concurrent active migrations. `100 C 10 P` represents a setup consisting of 100 clients and 10 proxies, where each proxy is assigned 10 clients (evenly-distributed). Error bars (barely visible) represent the range of values across all trials.

For the remaining four configurations, we focus on the *controller's* scalability by fixing a modest 10:1 client-to-proxy ratio while increasing the total number of proxies and clients (from 100 proxies and 10 clients, to 2000 clients and 200 proxies) that need to be migrated in parallel by the controller. Here, we notice a marked increase in average migration times, up to a maximum of 11.43 seconds for Wireguard. The higher times are largely due to communication overheads and our lack of parallelization—our current controller sends notification messages serially to proxies, which in turn also notify clients in a serial manner. While performance can clearly be improved by parallelizing such messaging, we note that the (unoptimized) migration times still support transparent (to the client) migration: they are well below the Spot VM reclamation notice of all cloud providers (the lowest is 30 seconds in GCP [62]), so we can be assured that all clients would have been migrated before reclamation takes effect. And, second, client throughput degradation is not noticeably worsened because the connection with the old proxy is terminated only after the new proxy becomes available.

7.2 Cost savings via cost arbitrage

To assess the potential cost savings SpotProxy can achieve through cost arbitrage, we analyzed historical spot VM pricing data, leveraging a comprehensive dataset [15] that encompasses AWS spot VM pricing histories over the last two years (Jun. 2022–Jan. 2024). Additionally, we cross-referenced this data with the AWS pricing history API (containing data for the past 90 days) to further validate it, and performed actual deployments (to confirm these cost-effective instances can be acquired). While our analysis focuses exclusively on AWS, due to the absence of comparable datasets for other providers, our findings remain relevant, since AWS's Spot VM pricing is competitive, even when compared to other major and specialized providers (e.g., Azure, GCP, OVH).

Fig. 5 depicts the analysis results for a few selected months of interest (a more comprehensive analysis over the last two years is shown in App. A.1). Our analysis covers regions within North America and targets non-burstable instances with at least 2 vCPUs and 4GB RAM. Using the historic pricing data, we derive the cost of operating a single proxy when using different strategies:

Static SpotVM denotes using the month's initially cheapest spot VM throughout, without applying cost arbitrage to adapt to price changes; while *Static on-demand VM* refers to the on-demand equivalent of the chosen static SpotVM instance. *Optimal single-NIC* refers to selecting an instance through cost arbitrage that exclusively employs its default NIC, whereas *Optimal multi-NIC* uses all the available NICs

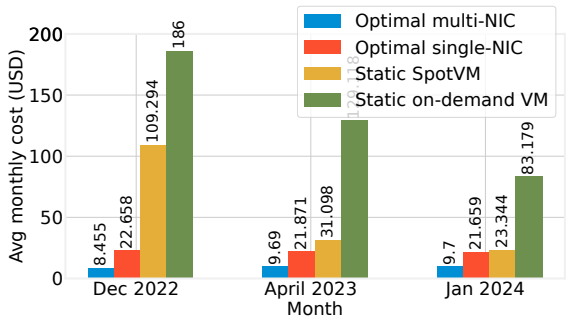

Figure 5: Average monthly cost of a single proxy. Cost arbitrage realizes significant cost savings that are stable and consistent (hovering at ∼$20 for single-NIC and ∼$9 for multi-NIC) by tempering the volatile costs of static Spot VMs.

(all with attached public IPs) on the same instances to potentially achieve further savings.

Fig. 5 shows that cost savings through arbitrage are stable and consistent, hovering around $20 for single-NIC and $9 for multi-NIC. Starting our analysis with Jan. 2024, transitioning from on-demand to Spot VMs yielded a 71% cost reduction. Implementing cost arbitrage added an extra ∼7.2% in savings, and adopting multi-NIC configurations further reduced costs by ∼55%. Initially, the most affordable spot VM, an `m7gd.large`, was priced at $0.0242 per hour, climbing to $0.0279 by month's end. Through cost arbitrage, which prompted 24 migrations within the month with intervals as brief as around 31 minutes and a median of about 10 hours, we shifted to more economical options such as the `m7g.large`, priced at $0.0241. Altogether, the shift from on-demand VMs to multi-NIC Spot VMs resulted in total savings of 88.3%.

Our analysis of the Apr. 2023 data saw even more significant savings from moving Static SpotVMs to those optimized via cost arbitrage, achieving savings of about 29.6% (single-NIC) and 68.8% (multi-NIC), respectively. This period saw cost arbitrage executed 98 times, with the quickest interval being roughly 30 minutes and a median time of 6 hours. Dec. 2022 showcased the most substantial savings with cost arbitrage activated only three times, but achieved savings of roughly 79.2% (Static SpotVM to Optimal single-NIC) and 92.2% (Static SpotVM to Optimal multi-NIC). Overall, moving from on-demand VMs to cost-arbitraged multi-NIC spot VMs yielded a maximum saving of 95.4%.

SpotProxy achieves these cost savings by facilitating arbitrarily frequent reassignments with minimal disruption (§7.1), enabling effective cost arbitrage, and the potential for further cost savings through autoscaling. This capability sets SpotProxy apart from existing systems (e.g., SkyPilot [114]) that offer cost arbitrage or autoscaling independently but lack seamless client reassignment.

7.3 Infrastructure rejuvenation stress tests

We next examine two questions: (1) how fast can we feasibly perform infrastructure rejuvenation? and (2) is rejuvenation cost sustainable? Our evaluation is motivated by two factors: Since Spot VM availability can be unpredictable, frequent rejuvenation might result in the acquisition of suboptimal (i.e., not the cheapest) VM types at a given point in time. Second, most cloud providers charge for IP address remaps [7], but the definition of remaps can be opaque (e.g., it is unclear whether AWS charges for associations/disassociations on a single VM). We therefore need to empirically validate if live IP rejuvenation results in additional remapping costs.

To answer these questions, we performed a series of experiments on AWS where we tested rejuvenation periods ranging from 2 hours to 2 minutes, with proxy fleet sizes ranging from 50 to 300. We performed three trials for each configuration, using non-burstable instances with at least 2 vCPUs and 4GB RAM within North American regions. Cost arbitrage did not occur during our experiments, and the cheapest instance was a `m6g.large` (with a maximum of three vNICs) at an hourly spot VM price of $0.0341 (excluding IP address costs). We stopped our trials at two minutes, as we observed it takes ∼10 seconds to associate/disassociate IPs (required by live IP rejuvenation), and ∼1.5 minutes to provision new instances[5].

Fig. 6 plots the cost of operating SpotProxy over a two-hour period, for various fleet sizes and proxy rejuvenation periods. As expected, operating more proxies incurs higher costs, and leveraging live IP rejuvenation and multi-NIC VMs can significantly reduce costs. Our results show that remapping costs do not apply to live IP rejuvenation (allowing us to freely associate IPs to all the available vNICs of an instance), while instance rejuvenation is generally able to acquire the cheapest (or within the top 5 cheapest) instance type even at large fleet sizes, making infrastructure rejuvenation cost sustainable.

Finally, during our evaluation, we acquired approximately 18,000 IPs which were all unique, over a period spanning multiple days. This finding is consistent with recent studies on large-scale allocations/deallocations [86, 87] that show the randomness of cloud IP assignments. SpotProxy could still reprovision another IP in edge cases where an IP is reassigned.

8 Circumvention efficacy

In this section, we evaluate the effectiveness of SpotProxy rejuvenation and relocation strategies in facilitating circumvention efforts against two main types of censor attacks.

First, we examine censors that aim to enumerate proxies and perform *IP-based blocking* (e.g., drawing comparisons with scenarios documented in previous studies [109] which

[5] A 90s provisioning time is under the current 120s warning-to-reclamation time practiced by AWS [38]. However, provisioning times which are longer than cloud providers' warning-to-reclamation times (e.g., 90s provisioning vs. 30s notification in GCP [62]) could mean that SpotProxy may have to very briefly resort to surplus capacity in the existing fleet to proxy the traffic of clients whose spot VMs will be reclaimed.

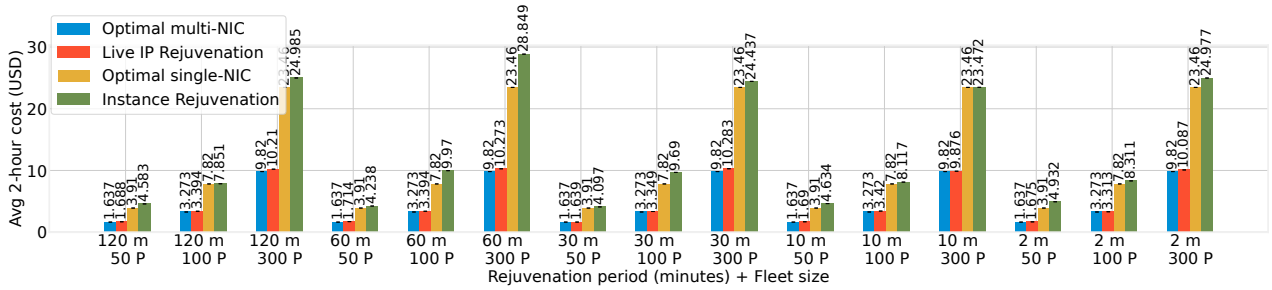

Figure 6: Both instance and live IP rejuvenation incur minimal cost overhead across rejuvenation periods and fleet sizes in AWS.

observed IP blocking in intervals as brief as 10 minutes, or only after a week [29]). We recall that SpotProxy does not consider traffic analysis and fingerprinting attacks within its threat model. Such attacks are deemed to be the responsibility of the underlying proxy technology.

Second, our analysis includes the threat posed by censors deploying *Sybil attacks*, where the adversary injects fake clients into the network to continuously acquire new SpotProxy proxy addresses to disrupt the system. This aspect of our evaluation aims to assess the resilience of SpotProxy's rejuvenation and relocation mechanisms against concerted efforts to undermine the system's circumvention efficacy.

Censor simulation platform. To test our system under a variety of scenarios, we employed the state-of-the-art game-theoretical framework introduced by Nasr et al. [80] (which we denote by *ENEM19*), also utilized by MassBrowser [81]; though we note that this is a generic framework not yet specialized to consider potential strategies by censors aware of SpotProxy. ENEM19 offers a comprehensive simulation environment, featuring over a dozen adjustable parameters. It provides a full-stack solution that includes a proposed *proxy assignment algorithm* designed to defend against Sybil attacks, alongside a detailed *censor model* that operates various strategies with different levels of blocking aggressiveness.

The ENEM19 simulator works as follows. First, its proxy assignment algorithm assigns a utility value to each client and proxy, where a high value represents a desirable proxy (e.g., alive for a long time) or trustworthy client (e.g., associated with few past blocked proxies). It then performs a greedy assignment by handing out the best proxies to the least suspicious clients. In turn, clients associated with blocked proxies have their client utility reduced, aiding in the differentiation between genuine users and those acting as censoring agents, with the latter eventually being excluded from the system.

Second, the censor controls a fleet of censoring agents (Sybils) posing as clients with the goal of acquiring proxies and blocking them via different strategies. We elaborate on two of the strategies introduced by ENEM19: (1) `ENEM19-aggressive` is a censor that commands its agents to block proxies as soon as they find them, and (2) the `ENEM19-optimal` censor behaves in a reactive manner to maximize its blocking power, by varying its waiting and blocking frequency/intensity, in an attempt to increase the number of proxies discovered and the total number of clients blocked. Censors will only gain partial knowledge of the proxy fleet, assuming some clients are benign. This is because ENEM19's assignment algorithm distributes proxies gradually rather than all at once, proxies are regularly rejuvenated, and Sybils associated with blocked proxies are systematically removed.

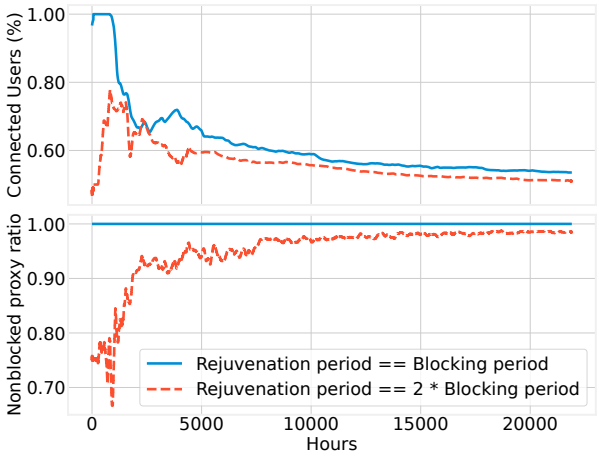

Figure 7: Results for `ENEM19-aggressive`. SpotProxy is capable of maintaining roughly 60% connectivity, despite censoring agents making up 50% of our client composition.

Simulator parameters. We largely adhered to the original choice of parameters used by ENEM19, except for its timescale: while ENEM19 assumes that operations occur at a day-level granularity, we instead increase the frequency of operations to a 2-hour granularity. This means that blocking/proxy assignment decisions occur every 2 hours. We also added a rejuvenation period to account for SpotProxy operations. We used two values of rejuvenation throughout our evaluation: 2 hours, matching the censor's blocking period; and 4 hours, two times slower than the censor's blocking period. The former ensures that SpotProxy infrastructure is rejuvenated as soon as the proxies have been blocked, while

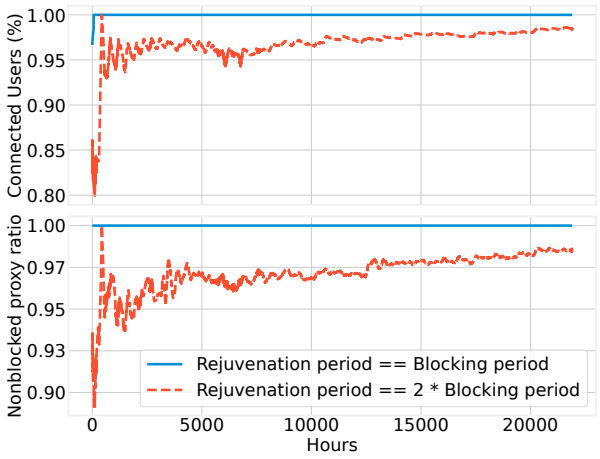

Figure 8: Results for `ENEM19-optimal`. SpotProxy is capable of maintaining over 90% connectivity, despite censoring agents making up 50% of our client composition.

the latter period only rejuvenates the infrastructure after some proxies have been blocked for 2 hours.

Simulation results. Although we tested multiple censor configurations, we highlight the more stringent censorship scenarios we handled in Fig. 7 (`ENEM-aggressive`) and Fig. 8 (`ENEM-optimal`), where censoring agents made up to 50% of our client composition. In our figures, *connected users* refer to the number of benign clients that remain connected, and *nonblocked proxy ratio* refers to the number of proxies that have not been blocked by censors. In App. A.2, we provide more details on less stringent scenarios.

First, we observe that censor blocking is largely ineffective in causing benign clients to be disconnected, for both models, since SpotProxy benefits from relocation; what actually causes clients to be disconnected is the fact that they end up being blamed by the ENEM19 assignment algorithm, which associates clients with too many blocked proxies over time. This also explains why out of all the models we tested, `ENEM-aggressive` was the most effective censorship model: since it performs blocking more frequently, it allows for this "implication-style" blocking to occur more successfully. This contrasts with the `ENEM-optimal` model, which prefers to wait longer before issuing client blocking decisions. However, when subject to the worst possible scenario, connectivity still hovers at around 60%, even though our setup was 12x more aggressive than `ENEM19`, with blocking occurring every 2 hours compared to their day-level granularity of blocking.

Second, we have a high nonblocked proxy ratio that hovers at around 90%. This highlights a caveat of `ENEM19`, in that it assumes clients blocked by implication will be removed from the system and never be able to acquire new instances; but this is a pessimistic assumption that may not be necessarily true in practice: SpotProxy could run a registration service to re-filter clients so that they can get back into the system despite having been blocked in the past, thereby increasing the connected ratio. We believe this to be a feasible effort since SpotProxy exhibits a high unblocked proxy ratio, meaning that SpotProxy maintains a large pool of available proxies to which re-filtered clients could get access.

9 Security discussion

This section discusses potential attacks to SpotProxy as well as attacks affecting proxy-based systems in general.

Financial DDoS. A censor could launch a large number of sybil clients to connect to SpotProxy, exploiting the system's autoscaling functionality to arbitrarily increase the costs of a SpotProxy deployment. However, standard sybil mitigations [49, 80, 102] apply. As another mitigation to this attack, SpotProxy's cost arbitrage module can ensure that cloud instance costs do not surpass a certain threshold, thus explicitly limiting the system's autoscaling capacity. While this does not prevent a potential DDoS to a SpotProxy deployment, it can actively avoid financial harm to SpotProxy operators.

Blanket ban of cloud services. A censor could block connections to all cloud VMs controlled by a given set of cloud providers, e.g., by applying strict IP blocking policies to the address space of such providers. While it is difficult to quantify the collateral damage experienced by censors willing to fully block connections towards cloud services, existing reports suggest that such actions cause severe economic repercussions to censoring states [11–13]. We note that other censorship circumvention systems making use of cloud storage services [43], content-delivery networks [54, 68, 120], and edge networks [76] operate under similar assumptions.

Blocking via strict allowlists. An adversary could attempt to list the IPs associated with popular cloud services, and block clients' connections aimed at IPs that are not on the list. However, since maintaining up-to-date allowlists as new Internet services are constantly added or updated is a complex task [76], censors have been known to be averse to such strategies due to potential collateral damage of overblocking [76, 99]. This is true even in today's cloud circumvention landscape where proxies are identified through static IPs. SpotProxy's dynamic rejuvenation improves the status quo by leveraging the built-in randomness of cloud IP assignments.

Proxy enumeration and blocking. A censor could launch a vast number of Sybil clients that would attempt to register in SpotProxy and enumerate proxy addresses for subsequent blocking. By design, SpotProxy makes this kind of attack impractical, as cloud instances will be continuously rejuvenated within short time intervals and alter proxies' IP addresses. Our evaluation earlier in §8 confirms this.

Proxy-to-client connectivity check. Censors may attempt to enumerate proxies and take action over users located within the censored region and which are found to be currently connected to IP addresses known to serve SpotProxy proxies.

We note that such an attack is not specific to SpotProxy, but inherent to most proxy-based circumvention systems.

10 Related work

Cloud-based censorship circumvention. Prior work has advocated for deploying anonymizing relays on cloud hosting providers [73,98], while exit bridges [119], deployed on cloud VMs, help bypass server-side censorship in Tor. While designed to be ephemeral like SpotProxy proxies, they do not allow clients to bypass state-level censorship policies. CloudTransport [43] uses public cloud storage for covert data transfer, while Camouflage [116] leverages personal cloud storage services like Dropbox. However, their performance lags behind traditional proxy services. Lastly, CDN-based techniques include those that let clients access blocked domains while appearing to access innocuous ones [54, 107], and those that allow access to censored content cached on CDNs [68, 120]. Of these, only domain shadowing [107] is able to provide access to any publicly available content, like SpotProxy.

Moving target defenses. SpotProxy can be understood as a moving target defense [71,92], dynamically shifting its attack surface by renewing the IP addresses of proxies, making it harder for adversaries to block them. Previous solutions have also drawn from moving target defenses to combat censorship. For instance, Heydari et al. [67] leverage mobile IPv6 to shuffle the IP addresses of public web servers, while Kon et al. [76] make use of programmable switches to periodically shuffle the domain-to-IP mappings of public services hosted within edge networks. Another related concept for SpotProxy involves a mobile target adversary [83], which can target and corrupt different fractions of parties in a protocol, but not all simultaneously. In SpotProxy, this corresponds to a censor that can enumerate a fraction of the proxies at any given time. To counter such threats, previous work has proposed proactively secure protocols for creating mobile target defenses [44, 51], e.g., using proactive secret sharing to distribute data among multiple storage servers and periodically refreshing cryptographic shares. Similarly, SpotProxy rejuvenates its fleet of proxy instances proactively.

Enhancing privacy through connection migration. Several encrypted protocols (e.g., QUIC [55], and Mosh [108]) allow clients to maintain session continuity despite IP address changes. SpotProxy however, enhances existing proxy implementations with active migration that allows for the seamless remote notification of updated peer addresses to connect to, while retaining session continuity through Turbo Tunnel [53].

Existing work has used connection migration for privacy-preserving communication. CoMPS [105] splits client traffic across network paths and protocols that support connection migration, making it harder for network adversaries to observe and analyze all traffic. MIMIQ [64] and RAVEN [78] use QUIC's connection migration to rotate client IP addresses and obscure the source of network flows. In contrast, SpotProxy uses connection migration to move clients across constantly changing proxies, not to prevent traffic analysis.

Cost reductions on the cloud. Before SpotProxy, researchers have already explored cost savings in the cloud (e.g., by profiling workloads and finding cost-effective VM-to-workload assignments [113]). Other works have used Spot VMs (either exclusively [65, 104] or mixed with on-demand VMs [66, 72, 117]) to lower cloud costs while increasing operational effectiveness. Further solutions for optimizing Spot VMs' cost, based on cost arbitrage and cost indexes such as HotSpot [96] and the work of Shastri et al. [97], respectively, migrate workloads to cheaper spot VMs while being optimized towards lowering reclamations and favouring applications that cannot tolerate frequent migration. In turn, SpotProxy is designed not only to embrace, but to aggressively trigger reclamations which are handled through the relocator. Skyplane [70] proposed network cost arbitrage, a strategy compatible with SpotProxy and which we aim to explore in future work, alongside other compelling directions (see §11 for more details).

11 Future work

SpotProxy offers many avenues for expansion, including:

11.1 Support for network cost savings

While we acknowledge the significance of network costs, our focus initially centers on the costs associated with instances, leaving network-related expenses for future exploration. This prioritization stems from the considerable weight that instance costs hold in cloud environments. For illustrative purposes, consider transitioning the entire Snowflake browser-based proxy ecosystem that is deployed on end-user devices (e.g., laptops), to AWS EC2 instances instead. Snowflake's network, as detailed in a recent report [42] by its creators, comprises approximately 130,000 proxies, and transfers around 30 TB of circumvention traffic per day. Rather than mirroring the one-to-one client-proxy ratio of the native Snowflake setup with 130,000 AWS instances, we make a conservative estimate that each EC2 instance could support 30 clients, given that cloud instances are more performant. Consequently, we assume that we only require provisioning 4,333 instances.

In our cost analysis, we standardize all calculations on a monthly basis to simplify comparisons. Regarding network costs [7], egress fees dominate, since (1) we can ensure minimal inter-VM costs between the proxy and NAT by situating them within the same region or zone, and (2) ingress costs are not a concern, as they are not charged. Applying AWS's tiered pricing model for egress traffic gives us a monthly network cost of $(0.09 \times 10 + 0.085 \times 40 + 0.07 \times 100 + (900 - 100 - 10 - 40) \times 0.05) \times 1000 = \$48,800$, for handling 900 TB of data transmission (30 TB per day).

For the instance cost analysis, we calculate expenses based on provisioning standard `m7g.large` instances with 2 vCPUs and 8 GB RAM. With an on-demand pricing rate of $0.077 per hour for the instance alone, the monthly cost for

operating 4,333 instances equates to $(0.077) \times 24 \times 30 \times 4333 = \$240,221.52$. Here, SpotProxy's use of multi-NIC `m7g.large` Spot VMs would instead cost $(0.0241) \times 24 \times 30 \times 4333 \div 3 = \$25,062.07$. Though we do not currently support network cost savings, this would still yield a ∼74% total savings of $240,221.52 - 25,062.07 = \$215,159.45$. This underscores the significance of both instance and network costs in our overall expense framework.

The figures presented serve merely as an example. To effectively manage network costs, one must recognize that the full integration of the Snowflake ecosystem into the cloud may not be essential or beneficial, especially since the value of existing browser-based proxies should not be overlooked, as they can continue to play a crucial role. Further, we can reserve cloud-based proxies for clients with lower bandwidth demands, and defer clients requiring substantial bandwidth allocations to proxy ecosystems where network cost are less of a concern (e.g., edge locations or user-hosted devices). Additionally, leveraging free tiers offered by cloud providers—e.g., AWS's 100 GB per month per account, and Oracle's 10 TB [82], among other offerings—can further mitigate costs.

11.2 Other directions

Integration with other clouds and proxies. We plan to support multi-cloud (e.g., GCP) and additional proxies (e.g., Tor native bridges, in addition to existing Snowflake support).

Cost calculation for burstable instances. This applies particularly to micro instances (e.g., EC2 `T4g` VMs), which operate on burstable performance models [8]. These models offer fixed or unlimited burst capabilities, potentially leading to unexpected costs when the allocated burst capacity is exceeded.

Performance variability among similar instances. We have assumed that instances with identical parameters (e.g., vCPU count) deliver equivalent performance. However, this may not always be the case, and different instances could exhibit varying performance levels (e.g., AWS instances, such as the `M7g`, that make use of the newer AWS `Graviton3` processors).

Integrating autoscaling with assignment. We incorporated basic autoscaling, such as scaling down when CPU utilization falls below 20%. However, integrating autoscaling more closely with the chosen assignment algorithm [102], currently not practiced, could improve cost efficiency or connectivity.

Cost savings via resource harvesting. Recent proposals in the cloud advocate for the harvesting of idle resources (e.g., CPU, storage) from VMs that have already been allocated to customers [34, 91, 106, 118]. While not yet made available by cloud providers, we expect that SpotProxy will also be able to utilize these to further reduce costs.

12 Conclusion

We have presented SpotProxy, a censorship circumvention infrastructure that hosts proxy instances in the public cloud while minimizing costs and improving unblockability. SpotProxy is in constant search for the cheapest virtual machines (VMs) available, reducing the cost of running circumvention proxies; at the same time, it also swaps older VMs out and spawns new ones at different IP addresses to increase unblockability. We adopted Wireguard and Snowflake for use with SpotProxy, and demonstrated the drastic cost benefits of SpotProxy, its resistance to blocking adversaries, and its ability to tolerate quick rejuvenations and relocations.

A Extended evaluation

A.1 Cost analysis

We extend our cost analysis with the remaining historical data mentioned in §7.2, executed over regions within North America and targetting non-burstable instances with at least 2 vCPUs and 4GB RAM. As seen in Fig. 9 and Fig. 10, our analysis extends from June 2022 to January 2024. Next, we provide general statistics on our overall analysis across this entire period. Transitioning from static on-demand VMs to static Spot VMs yielded a median cost reduction of 71.6%, a mean of 71.3%, a min of 41.2%, and a max of 88.2%. Transitioning from static Spot VMs to optimal single-NIC VMs yielded additional savings with a median of 9.2%, a mean of 20.9%, a min of 0.03%, and a max of 79.2%. Transitioning from optimal single-NIC to optimal multi-NIC provided extra savings with a median of 57.1%, a mean of 58.5%, a min of 55.2%, and a max of 62.6%. Transitioning directly from static on-demand VMs to optimal single-NIC yielded savings with a median of 80.8%, a mean of 78.8%, a min of 62.6%, and a max of 88.3%. Overall, transitioning directly from static on-demand VMs to optimal multi-NIC yielded savings with a median of 91.6%, a mean of 91%, a min of 83.8%, and a max of 95.5%. Finally, for cost arbitrage intervals, we have a median interval of 7.5 hours, a mean of 17 hours, a min of 16 minutes, and a max of 24 days.

A.2 Circumvention efficacy extensions

In §8, we tested `ENEM-aggressive` and `ENEM-optimal` with censoring agents making up 50% of our client composition. Here, we include the remaining configurations that we tested against, namely: 10% of censoring agents and 5% of censoring agents, for `ENEM-aggressive` (Fig. 11 and Fig. 12) and `ENEM-optimal` (Fig. 13 and Fig. 14) respectively.

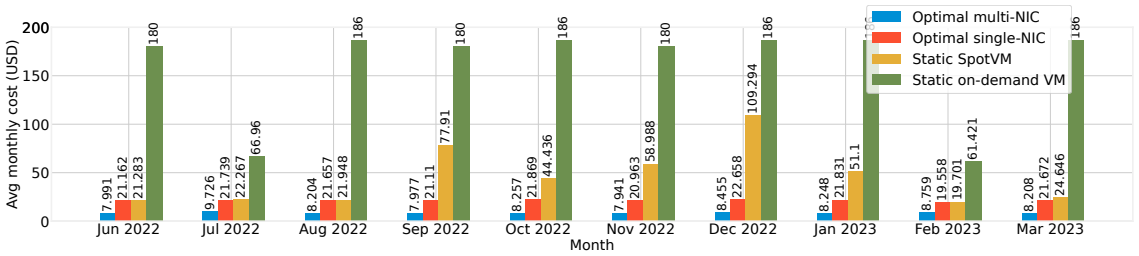

Figure 9: Average monthly cost of operating a single proxy, for months between June 2022 and March 2023.

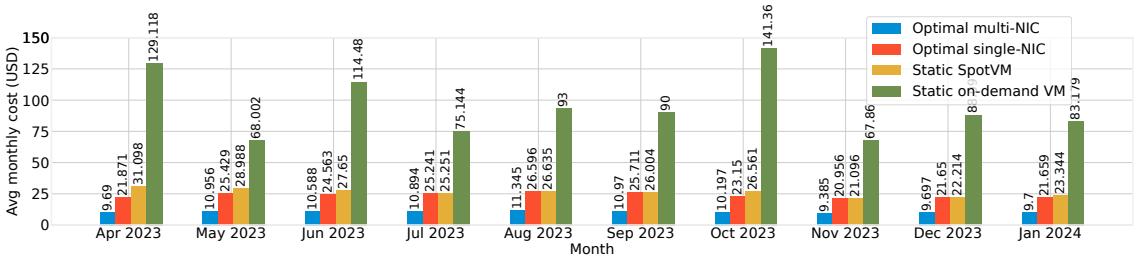

Figure 10: Average monthly cost of operating a single proxy, for months between April 2023 and January 2024.

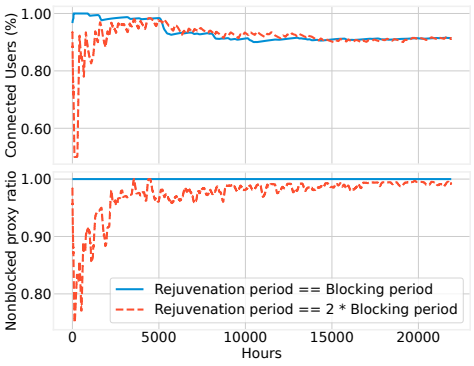

Figure 11: Results for `ENEM19-aggressive`. SpotProxy is capable of maintaining roughly 80% connectivity, with censoring agents made up 10% of our client composition.

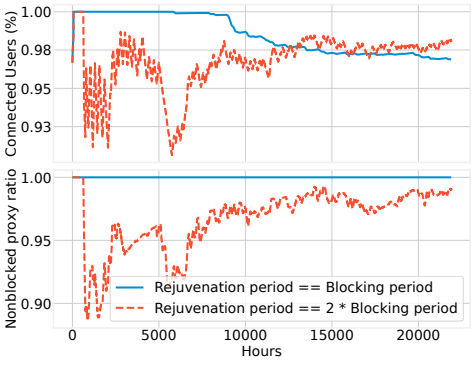

Figure 12: Results for `ENEM19-aggressive`. SpotProxy is generally capable of maintaining above 90% connectivity, when censoring agents made up 5% of our client composition.

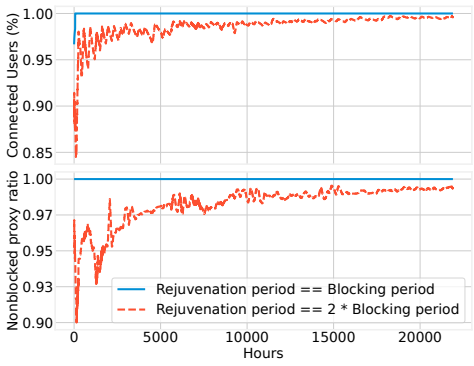

Figure 13: Results for `ENEM19-optimal`. SpotProxy is capable of maintaining generally above 90% connectivity, despite censoring agents made up 10% of our client composition.

Figure 14: Results for `ENEM19-optimal`. SpotProxy is capable of maintaining generally above 90% connectivity, when censoring agents made up 5% of our client composition.

Bridging Barriers: A Survey of Challenges and Priorities in the Censorship Circumvention Landscape

Diwen Xue*† Anna Ablove*† Reethika Ramesh† Grace Kwak Danciu‡ Roya Ensafi†

Abstract

The ecosystem of censorship circumvention tools (CTs) remains one of the most opaque and least understood, overshadowed by the precarious legal status around their usage and operation, and the risks facing those directly involved. Used by hundreds of millions of users across the most restricted networks, these tools circulate not through advertisements but word-of-mouth, distributed not through appstores but underground networks, and adopted not out of trust but from the sheer necessity for information access.

This paper aims to elucidate the dynamics and challenges of the CT ecosystem, and the needs and priorities of its stakeholders. We perform the first multi-perspective study, surveying 12 leading CT providers that service upwards of 100 million users, combined with experiences from CT users in Russia and China. Beyond the commonly cited technical challenges and disruptions from censors, our study also highlights funding constraints, usability issues, misconceptions, and misbehaving players, all of which similarly plague the CT ecosystem. Having the unique opportunity to survey these at-risk CT stakeholders, we outline key future priorities for those involved. We hope our work encourages further research to advance our understanding of this complex and uniquely challenged ecosystem.

1 Introduction

Recent decades have seen a significant escalation of censorship efforts by nation-state actors around the world. In the first half of 2023 alone, Access Now reported over 80 instances of Internet access disruptions across 21 countries [13]. Notorious among these is China's Great Firewall (GFW), which has been filtering access to foreign websites for over two decades [5, 34, 54]. Similarly in Iran, the national censor routinely targets social media platforms, particularly during times of political unrest [4, 15, 16]. In Russia, the implementation of the "Sovereign Internet" law has further restricted access to international news and media during the Ukraine war [55, 56, 77], effectively creating information bubbles that have isolated the country from the global Internet.

In response to escalating censorship measures, users in affected regions have been actively seeking methods to circumvent censorship. Starting with plain HTTP proxies, VPNs, and website mirrors, the ecosystem of circumvention tools (CT) has evolved along with the advancements in censors' detection and filtering techniques, leading to an ongoing arms race [27, 66]. Over the past decade, on-the-ground developers and academic researchers have developed various dedicated CTs (e.g. [7, 11, 12]) that are specifically designed to facilitate access in censored networks.

Despite these past efforts, challenges remain within the CT ecosystem. While much of the previous research has focused on designing circumvention protocols with evolving obfuscation strategies [2, 19, 24, 35, 36, 45, 70, 76, 79], simply having a technically sound obfuscated protocol does not automatically resolve the difficulties faced by users in censored regions. A gap exists in translating academic state-of-the-art CT research into practical, operational deployments that are available to on-the-ground users and address their actual needs. Even for those tools that are deployed, questions remain unanswered: How do users find about CTs in a sociopolitical environment determined to prevent firewall circumvention? How do CT providers sustain their service? How do factors like risk, trust, and cultural or regional specifics affect the operation and usage of CTs? Gathering feedback from those directly involved in circumvention could help with the relevance of academic research and assist those on-the-ground in creating more efficient and resilient circumvention solutions.

The CT ecosystem differs fundamentally from those of other privacy and security-focused tools. For one, the area of censorship circumvention is inherently adversarial, with CTs often operating in environments where censors actively disrupt their access. Moreover, unlike typical software engineering with iterative development-feedback loops, the development of CTs is often an ad-hoc process, hindered by limited communication between providers and their users. Due to legal and personal safety concerns, providers cannot openly promote their services and techniques, nor can users freely seek, discuss, or give feedback on these tools. These challenges, unique to the CT ecosystem, are often more heightened in the very regions where these tools are most needed.

In this paper, we present the first multi-perspective study to elucidate the challenges and needs of those directly involved

*Joint first authors.

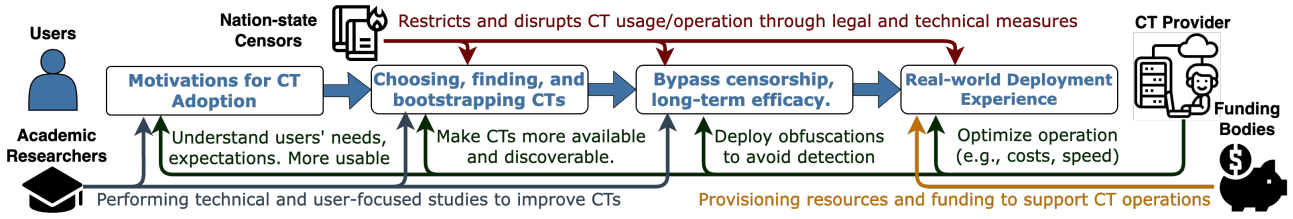

Figure 1: **CT Ecosystems and its Stakeholders**

in censorship circumvention and to identify future priorities as perceived by stakeholders. We interviewed 19 individuals from 12 organizations operating in the CT industry, referred to as "providers" throughout the paper. These organizations, including well-known CT providers such as Psiphon, GreatFire, Jigsaw Outline, ProtonVPN, and OKNO Digital [33, 48, 50, 52, 53], along with others who opted for anonymity, collectively serve upwards of 100 million monthly active users. Through semi-structured interviews, we gathered insights from providers on the technical, operational, and usability issues that drive or impede CT growth, and with inductive thematic analysis, we identified recurring themes that emerged across different phases of CT operation/usage, including:

Discovery & Bootstrapping: How do providers connect with potential users in censored regions, particularly those without existing circumvention methods? What strategies assist the initial CT setup in restricted networks?

Usage & Sustainability: What are the operational challenges for CTs? What is the role of agility and responsiveness in dealing with active adversaries? How do providers sustain their operations and restore services after being blocked?

Risks & Trust: How do participants manage risks in circumvention? In this context, what significance does *trust* hold, and how do providers establish trust with users?

Future Priorities: What do participants identify as the most pressing issues requiring attention, and what priorities should stakeholders, funding bodies, and academia focus on?

Following our interviews with providers, we expanded our study to incorporate perspectives from CT users. We surveyed 24 individuals who live or have lived in Russia or China within the last two and half years, during which they used CTs to bypass the nation-state censorship in these countries. Both provider and user studies involve significant ethical complexities, particularly regarding the sensitivity of establishing connection with on-the-ground individuals with heightened threat models. We are aware of and humbled by the risks our participants took in connecting with us, and we took procedural and technical measures to minimize potential risks, as detailed in § 3.

Our findings reveal multi-dimensional challenges that stakeholders in the CT ecosystem must navigate. Beyond the commonly cited issue of service disruption by censors, our study also highlights funding constraints, usability issues, misconceptions, and misbehaving players, all of which also plague the CT ecosystem. We identified bootstrapping as a critical yet often overlooked issue, which not only complicates CT adoption but also introduces security risks. We found that the limited funding opportunities lead to unintended competition among CT providers, impeding collaboration and sharing of knowledge. We observed a pervasive mistrust within the CT ecosystem, yet users often knowingly expose themselves to potential threats, driven by the sheer need for information access. Based on insights from our participants, we outline several future priorities for stakeholders and suggest actionable recommendations, such as prioritizing user education, coordinated efforts to establish local and regional presence, and facilitating accessible, short-term funding options that support rapid response in times of need.

For the past two decades, the censorship community has been locked in an ongoing arms race with nation-state censors, but progressing beyond this cat-and-mouse game requires a deeper understanding of not only the technical, but also the operational and human-centric aspects of circumvention. Our work identifies a range of issues that, though often less highlighted than technical circumvention research, represent critical points of failure that equally threaten the efficacy and reach of CTs. We hope this exploratory study encourages further research into this space, facilitating the development of more available, usable, and resilient circumvention systems that better address the needs of providers and users on the ground.

2 Background & Related Work

Internet Censorship News, anecdotes, and academic measurement studies collectively suggest a rise in Internet censorship by governments around the world [13, 42, 59]. Censorship researchers have studied government censorship policies, and in particular, how these policies are enforced through technical means. Inspired from the seminal work on censorship in the 2000s [22, 80], researchers have examined how nation-state firewalls disrupt users' Internet traffic [34, 51, 54], their inferred technical capabilities [41, 69], and their architecture and geographical distribution [26, 74, 77]. Other research has focused on region-specific censorship events during periods of political or social unrest, such as the increased censorship activities in Iran and India near protests or elections [3, 15, 17], and the restrictions on social media and news websites in Russia in the lead-up and course of the Ukraine war [56, 78].

Internet censorship often operates differently across various nation-states. China has consistently enforced a nation-wide web filtering policy for over two decades, using techniques like DNS, SNI, and HTTP keyword filtering [34,54,75]. More recently, in response to the increased use of CTs, the GFW has also been experimenting with new blocking techniques that specifically target these tools, such as blocking fully encrypted CTs based on payload entropy [73]. On the other hand, Russia's approach to Internet censorship has historically been more "decentralized" [55], with the federal communication agency maintaining a blocklist but leaving enforcement and blocking methods to the discretion of individual ISPs. However, since the enactment of the "RuNet" law in 2019, Russia has been moving towards a more centralized censorship model, known as "TSPU" [8, 77]. By 2021, this model allowed Russia to enforce uniform censorship policies across the nation and experiment with new techniques targeting CTs, similar to China's approach [56, 78].

Circumvention Arms Race As censorship measures escalate, users in affected regions are increasingly seeking ways to circumvent these restrictions, leading to an ongoing arms race between censors and circumvention tools (Figure 1). This dynamic is best illustrated in the conflict between GFW and various CTs: censors started by direct blocking of CT websites and public relays, for which CTs deployed website mirrors and unpublished bridges [9]. As censors began exploiting traffic signatures, CTs countered with dedicated obfuscators mimicking mainstream browsers or popular protocols [1, 28, 31]. Censors then used active probing to identify CT servers, leading to the development of probe-resistant defenses [25, 30, 72]. These iterations exemplify the current landscape of the circumvention arms race, where both sides constantly balance between efficacy and expenditure, with new detection and/or obfuscation techniques shifting the costs of various approaches [66].

Prior Qualitative Studies Prior work examined the impact of censorship on information access and users' perception and attitudes towards it. Roberts et al. model censorship as practiced in China not as a ban but as a "tax" on information, positing that if accessing certain information becomes too costly in terms of time and inconvenience, individuals are less likely to seek it out [58]. Their survey among urban Chinese Internet users found that awareness of censorship is low, and the motivation to circumvent it is even lower, largely due to the associated inconvenience. Wang et al. and Kou et al. also explored perceptions of censorship within China [39, 67]. Both studies identified mixed attitudes even among those aware of censorship, with the majority refusing to denounce censorship as purely evil or repressive. They found that attitudes are influenced by demographic background, cultural values, and political inclinations, with a tendency to normalize censorship over time. Shen et al. looked at censorship perceptions across 11 countries outside China, noting significant variations in attitudes towards different types of censored content (e.g. religious vs. political) [64]. More recently, Chen et al. investigated the relationship between censorship and self-censorship [21] and found that perceived necessity of self-censorship amplifies its impact on users' expression desires, which in turn affects their attitudes towards censorship.

On the circumvention side, Kou et al. examined how Chinese Internet users adapt their strategies based on their understanding of the censorship apparatus, such as switching between public and private communication channels based on perceived content sensitivity or communicating in ways believed to be less susceptible to censorship scrutiny [38]. Gebhart et al. surveyed Thai users and found that the way they use CTs can be exposed to potential risks of malware and surveillance, highlighting the need for more informed CT selection [32]. Dai et al. focused on Iranian users, investigating psychological factors influencing CT adoption [23]. They found that attitudes towards media freedom and compatibility with regime ideology significantly impact individuals' decision to use CTs. Contrasting these findings, Mou et al. observed that in China, the usage of CTs is driven not by personal stances or political motivations but by more practical needs, which they attributed to political apathy among Chinese Internet users [46]. More recently, Kwak-Danciu et al. surveyed CT providers to examine their motivations for helping people overcome censorship [40]. They found that the providers were often motivated by a deep-seated belief in the right to access information and a moral imperative to fight back against what they perceived as repression. During the course of our study, Okthanks independently documented insights from eight VPN providers using the Outline tool developed by Jigsaw, revealing the social, technological, and operational challenges they face in circumventing censorship [71].

To the best of our knowledge, we are the first to conduct a study of CT providers augmented by experiences from CT users. Given the CT ecosystem's opaque nature and the heightened risks faced by its stakeholders, our multi-perspective study aims to help security researchers, technologists, funding agencies, and advocates of information freedom better understand the challenges of the current CT ecosystem and highlight areas of priority for concerted efforts.

3 Ethics

Research on censorship and circumvention is inherently sensitive, especially when it involves on-the-ground individuals directly engaged in circumvention efforts. Thus, we followed best practices to mitigate any direct or indirect harm to the participants involved in the study. First, we outlined our survey protocols and sought consultation with senior members of the anti-censorship community. Based on their feedback we finalized our approach. We also cleared our research plan with our university's Institutional Review Board (IRB), who approved our study under Exemption 2.

Our team has a background in performing peer-reviewed censorship measurements in collaboration with in-situ activists for both Russia and China. For our survey's initial recruitment, we leveraged the secure channels established from these previous collaborations. Subsequent recruitment was accomplished with the involvement of Internet freedom NGOs, which facilitated vetted regional meetups to connect us with potential participants. Once the participants were finalized, we provided them an IRB-approved consent form (appended in A.3), which detailed our privacy policy and allowed them complete freedom to abstain from answering any particular question. We opted for asynchronous, text-based interviews for the participants that still reside in censored countries, while offering live and/or in-person options to all other participants (see § 4.3). All live and/or in-person interviews were transcribed in real-time by a team member and the transcriptions were accessible only to select members of the team, following the principle of least-privilege. We additionally emphasize that at no point during the project's duration were audio or video recordings made. Moreover, we ensured to not collect any personally identifiable information during the entire recruitment or interview processes.

4 Methods

We set out to study the perspectives of both providers and users of CTs to understand challenges and dynamics within the ecosystem. To this end, we conducted qualitative interviews with stakeholders from both groups.

4.1 Participant Recruitment

Most of the provider recruitment efforts leveraged our existing connections within the censorship circumvention community, established through either previous collaborations or participation in invite-only events hosted by NGOs or regional meet-ups. To reach additional participants, we used relevant online mailing lists, message boards, and censorship forums. In our recruitment message, we explicitly sought participation from individuals actively involved in the CT industry as developers, distributors, or operators – whom we collectively refer to as "*providers*". We also solicited CT user participants who live/have lived in Russia or China within the last two and half years. We focused on these two countries due to their domestic censorship practices, substantial CT user base, and their sizable diaspora populations. We did not offer any compensation to participants, other than the potential to make an impact assisting academic research on censorship circumvention.

In total, we interviewed 19 individual providers from 12 organizations, among which three focus their operations on Russia, four on China, and the remainder have a global outreach. In addition, we interviewed 24 CT users, including 16 from Russia and 8 from China.

4.2 Interview Protocol

The escalation of censorship practices has significantly driven the demand for effective circumvention tools, yet research on the factors influencing CT adoption and usage lags behind. We designed our interview questions based on our combined experience in censorship research over the past nine years, including both the measurement and analysis of censorship practices and the development of circumvention approaches. These questions cover both the technical and operational aspects of CTs, as well as modes of discovery, usability, and considerations related to risk and trust.

Participants began by answering background questions to describe their involvement in censorship circumvention. For user participants, we asked for their awareness of and reactions to censorship, and motivations driving their circumvention efforts. We then guided both provider and user participants through the journey of discovering and using a CT, followed by a discussion on CTs' operation and sustainability in adversarial settings (e.g., how providers restore services after blocking, and how users react to CTs becoming unavailable). We then explored the perceived risks associated with circumvention efforts and the role of trust in the decision-making processes of both groups. Lastly, we concluded the interviews with open-ended dialogue about future priorities within the CT ecosystem, as identified by the participants. The interview questions can be found in Appendix A.1 and A.2.

Our interviews followed a semi-structured protocol: while we started with a planned script of questions, we also allowed for deviation from the script to clarify statements and explore areas introduced by interviewees. Such an approach balances between maintaining consistency across interviews and allowing novel and unexpected insights to surface [20].

4.3 Interview Procedure

Considering the sensitive nature of research on censorship circumvention, we offered our interview process over multiple modalities: in-person, online via video conference, and asynchronously through text. We extended these options to accommodate any requests for anonymity from our interviewees and to mitigate language and communication barriers, along with the mental loads associated with them.

Each live interview was led by 2-3 researchers from our team, with the lead interviewer following the interview questionnaire and maintaining discussions, while the other(s) actively transcribed in real time. These interviews were not recorded due to privacy and anonymity concerns. All interviews began with the researchers presenting and requesting verbal consent from the interviewee using the IRB-approved consent form. Interviews took between 30 minutes and two hours.

Our text-based interviews included the same set of questions as our synchronous audio/video interviews. For discussion beyond participants' initial responses, we sometimes sent

follow-up text-based questionnaires, but the scope of these follow-up discussions was limited due to the asynchronous nature of these interviews.

4.4 Qualitative Coding and Analysis

Each interview was transcribed by 1-2 researchers in real time. For our analysis, we adopted an inductive, open-coding approach to reflexive thematic analysis [18]. We chose to use reflexive thematic analysis as it aligns closely with our research objectives, which set out to "describe the 'lived experiences' of particular social groups" [65].

To generate initial codes, three researchers randomly selected two interview transcripts each from CT providers and users and collaboratively coded them to develop separate sets of codes for each group. Then, all remaining transcripts were first coded by one primary coder, followed by two secondary coders who independently reviewed the initial coding to identify any missed codes or propose changes where needed. After every three to four interviews, the researchers held meetings to reconcile disagreements until consensus was reached. The iterative process continued until all transcripts had been independently reviewed by at least three researchers.

Following the coding process, we held meetings to collaboratively collate codes into candidate themes and identify emerging themes. As part of our reflexive thematic analysis approach, we then collectively reviewed the candidate themes against the collated codes as well as the original interview responses, refining and collating themes as necessary. Since the researchers reviewed every independently-coded transcript together, we do not present inter-rater reliability [43, 44].

4.5 Limitations

Our provider participants represent some of the most popular CT providers across various regions, yet our user sample may not be fully representative of the global demographic of CT users. For one, many of our user participants were recruited from university mailing lists, which resulted in a demographic that skewed younger and more educated. Moreover, our exploration of user perspectives was limited to Russia and China, as we were not able to safely reach enough respondents from other censored regions, such as Iran or Turkmenistan. However, our study offers concrete insights into the experiences and challenges faced by those directly engaged in censorship circumvention, a group that operates under significant risks yet remains largely understudied in previous work.

5 Results

Based on interviews with both CT providers and users, we present in this section an analysis of the dynamics and challenges in the circumvention ecosystem. The interview questions posed to both groups share many parallels and examining their responses side-by-side can reveal potential (mis)alignments. For this, we structure our results not by separating providers and users, but rather around key themes that surfaced recurrently from our inductive thematic analysis, as shown in Figure 2. Then, for each specific response or quote, we indicate whether it originates from a (**P**)rovider or (**U**)ser.

5.1 Motivations for CT Adoption

The decision to adopt CTs is preceded by the awareness of censorship. While this might seem intuitive, the often subtle and covert practice of censorship can make this recognition less obvious. We ask participants for their perceptions of censorship and to identify the factors that motivated circumvention.

Perception of Censorship Participants associated censorship with emotional distress, such as sadness, frustration, and a sense of being restricted. "*It feels really sad that we have to go through all this, and the isolation worries me.*" (U5) Some users displayed a sense of resignation, accepting censorship and the need for circumvention as "*a daily reality we have to deal with.*" (U14) Other participants expressed anger:

> "Censorship gets you feel irritated! There's no way to actually disable access to anything, everyone mastered proxy use. But it makes hassle, makes your life a bit less comfortable, force you to make small but irritating actions all the time..." (U4)

Regarding motivations for adopting CTs, most participants (n=14) identified practical and entertainment needs that are denied by censorship as primary drivers for seeking circumvention. They emphasized the tangible impacts of censorship on their daily lives, such as being unable to access work-related resources like Github for developers, educational materials like Wikipedia and foreign college applications, and entertainment like gaming or adult websites. Other users (n=7) cited political motivations or personal stances on information freedom. These users turned to CTs to access news or articles censored for political reasons or to advocate for free access to information, and to explore alternative viewpoints that were otherwise unavailable through censored media channels.

Local Alternatives While both Russian and Chinese participants mentioned local websites impacted their CT usage, Chinese participants (n=11) further highlighted the how the existence of local alternatives to blocked services have the potential to make circumvention less urgent or appealing. Especially for services with a social dimension, local alternatives might even be favored as they are more popular among the residents of the censored region:

> "I tried to persuade my parents to use [a CT] but it was not as appealing to them. We set up a family chat on Signal, but it was hard to switch just for three of us while everything else is happening on WeChat. My mom thinks censorship is not good, but she simply doesn't have motivation to circumvent." (U12)

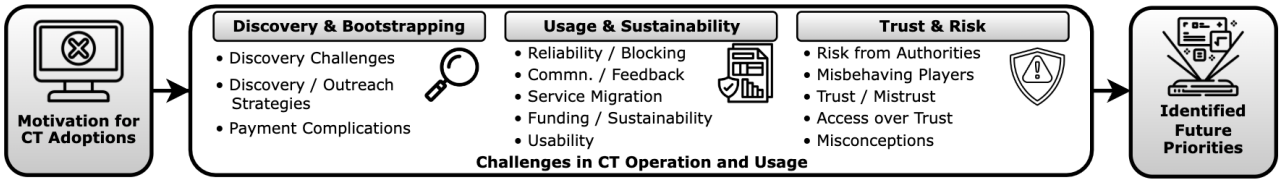

Figure 2: **Structure of the Results Section.** We begin with the motivations behind circumvention efforts, followed by the identified challenges in CT operation and usage, grouped into recurring themes from the interviews. Finally, we highlight future priorities for stakeholders.

More generally, providers also observed that the existence of local alternatives might mitigate the need for circumvention:

> "There is a massive population who are blissfully unaware that outside Internet exists...there's a complete domestic ecosystem that people almost never accidentally stumble upon a website that's censored. How can we make getting past the firewall more appealing? Because no one ever regrets using a CT, it's just that people don't know what they are missing out." (P10)

Perception of Circumvention Several participants pointed out that certain perceptions of CTs, particularly among the non-technical population, can deter their adoption. These perceptions are often fueled by targeted propaganda from the authorities, associating CT usage (VPNs * in particular) with stigmas such as "*VPNs are for people who have things to hide*" (U14), CTs are tools from "*the evil west*" to promote certain narratives, or even that CTs are "*scary, used by terrorists*" (U13). These perceptions can create psychological barriers that demotivate people from adopting CTs.

5.2 CT Discovery and Bootstrapping

In regions where censorship is prevalent, the way potential users discover and connect with CT providers differs significantly from how they might find typical Internet services. As the legal status of CTs often ranges from ambiguous to outright illegal, traditional advertising and outreach channels are often not viable options. In this part of our survey, we discussed with both providers and users how they manage to find each other and bootstrap a circumvention connection.

Censorship Challenges CT Discovery The primary challenge in CT discovery lies in the practice of censorship itself, which often limits access to information about these tools. Surveyed users noted mainstream search engines, a go-to resource in other less adversarial contexts (e.g., western-focused commercial VPNs), are "*outdated as a source for finding CTs*" (U12) due to being blocked themselves. Users from China mentioned that download links for CTs are often not useful for bootstrapping, as these links are regularly censored either by the GFW or by local browsers with built-in URL filters. Additionally, participants mentioned that online forums where CT information might be shared are heavily monitored and censored, with posts frequently being deleted and posters risking consequences (more on risks in § 5.4). U22 on how users discuss CTs by using creative homonyms to stay under the radar, in a continual game of cat-and-mouse with the censors:

> "We refer to providers as 'airports' to evade detection, or 'ladder' (to climb Wall) or 'scientific browsing'. But censors develop extensive lists of such terms, updated mostly manually. [For this,] people have to continuously come up with new words [for CTs]." (U22)

Discovery & Outreach Strategy Censorship against CTs forces both providers and users to adopt a more covert approach to connect with each other. A predominant method, as noted by surveyed users (n=19), is through word-of-mouth – sharing CTs within close-knit circles of friends and family. Recommendations for effective and reliable CTs are passed along in these underground networks. Providers echoed:

> "In China and Iran, there's a massive underground market for circumvention services. Entire Telegram groups dedicated to things like sharing proxy details and selling this information for money." (P10)

U16 shared their experience of obtaining access to CTs through a referral on social media:

> "I paid this anonymous person on WeChat and they provided me with their tools and account info. I don't know if the service has a name. It is not an app I can find in mobile or PC app stores. " (U16)

Participants also mentioned acquiring their CTs through exposure to outside, less censored environments. For example, traveling abroad often allows access to information about CTs that is otherwise censored. Students attending international schools mentioned learning about CTs from their foreign instructors or peers. Maintaining connections with friends and relatives living overseas also creates cross-border information flows for learning about and obtaining CTs.

Another common (n=11) yet somewhat counter-intuitive practice among users is to use one CT as a means to find/bootstrap another CT. In these cases, the initial CT is often a temporary solution, such as a less trusted free VPN or a temporary VPS from a friend. This approach serves mainly

*We note that VPN and CT are not identical: not all VPNs serve as CTs (e.g., enterprise VPN) and not all CTs provide layer 2/3 tunneling (e.g., app-layer proxy). Yet, surveyed users often used the two terms interchangeably.

two purposes: First, users need access to the uncensored Internet to find other, more reliable CTs. Some users mentioned Google as a trusted gateway to finding CTs, and the initial CT is used to unblock such a gateway:

> "I use a free shady VPN from the Chinese app store to then find more reliable tools."(U17) "I can search [CTs] from Google, but first I'll need to have access to Google." (U16)

Moreover, many CTs require a bootstrapping stage before they can provide access. This stage involves authentication or configuration setup, which often cannot be completed under censored network conditions. As such, users may need a secondary CT to complete the bootstrapping process for their primary CT:

> "[Redacted] has a browser extension, which occasionally requires re-authentication. However, the login page itself is blocked. In that case, I need to turn on a third-party VPN to access the login page and authenticate the tool." (U19)

The practice of using CTs to find/bootstrap CTs is also noted by providers:

> "We always wonder how do we reach people without any CTs? Many of our users switched from some other worse CTs. How can these users find us directly [when] obviously our website is blocked?" (P10)

Providers shared their alternative outreach strategies in the absence of traditional advertising channels. Six providers mentioned collaborating with local partners, such as grassroots networks, media organizations, and CT resellers (who bulk purchase access from providers and then sell to individuals). These collaborations allow providers to indirectly reach potential users by leveraging the existing trust and reach of these partners. For example, P2 noted a major influx of new users referred by Russian news websites, which, after being blocked following the start of the Ukraine war, directed their audience to CT services to maintain access.

Payment Complications Users also reported facing difficulties in making payments for their CT services, which is often related more to the challenge of cross-border transactions than to the technical aspects of CTs themselves. For example, some providers only accept payments in USD, which may not be readily accessible to users dealing in local currencies. Additionally, some Russia participants (n=4) discuss how the payment process can be further complicated by economic sanctions, where conventional payment methods like credit cards are restricted. As U8 shared:

> "I often help friends and family pay [for CTs], as Russian banks and cards are blocked under sanction. I think users should be able to pay in some ways... right now they have to circumvent sanctions to actually circumvent censorship." (U8)

5.3 CT Usage and Sustainability

We next discuss the experiences of providers and users in operating and using CTs. Unsurprisingly, a recurrent theme is the issue of CT reliability due to disruption from censors. In regions where censorship is prevalent, authorities often impose restrictions on circumvention methods, through either legal [60–62] or technical measures [14, 25, 72, 73]. Additionally, factors such as usability and funding also affect the adoption and sustainability of the CT ecosystem.

CT Reliability and Blocking The issue of CT services being unreliable is unanimously noted by both providers and users as a primary concern. All surveyed providers recounted instances of their service being blocked in the past. P4 noted on this matter, *"Tools get disrupted all the time in our market. We try to make our tool more available. However, there are cases where authorities still effectively crack down on our service."* Providers servicing Chinese users even postulate that the reliability of their service is often not a matter of the technical capabilities of censors but is rather a choice made by censors, based on non-technical factors such as the CT's popularity or public sentiment.

> "The Chinese censor is a different animal; they are highly organized, well-funded, and work very hard. We manage to remain operational because I sense they intentionally leave a crack...I truly believe that if they decide to shut everyone down, they have the [technical] capability to do so." (P8)

The majority of surveyed users (n=20) also identified CT reliability as the primary issue they faced. Interestingly, their descriptions of CT availability were not in binary terms, i.e., "the CT works" or "the CT does not work". Instead, they described availability as highly contingent on the specific network they were connected to and the time of their connections. Participants noted that their CTs' availability varied greatly as they moved between different networks, e.g., smaller local ISPs that are equipped with less sophisticated Deep Packet Inspection (DPI) or licensed academic or corporate networks. A majority of users (n=12) reported instances of their CTs becoming unavailable during major events, such as election or war.

> "Anytime there's a major conference or significant change in the government, or some negative news that gains public attention, VPN services tend to go down. Circumvention tool users usually expect the tools to fail during these time periods." (U15)

Providers and users agree that censors adopt a strategic, targeted approach to suppress the most popular CT services. "*The problem with CT in China*", as noted by U12, "*is that once the service scales up to a level where it becomes widely known, it attracts the censor's attention for blocking*". Providers additionally shared that the scope of being targeted

by censors extends beyond just the disruption of CT traffic, affecting other operational aspects of their organizations, such as website, email, and API access.

Beyond popularity, a CT's perceived political stance can also make it a higher priority target for censors. P10 alluded to this when discussing what they thought other CTs might be doing:

> "If you seem to be less anti-government than the VPN next door, like by blocking politically controversial websites for your users, maybe they'll crack down on that other VPN first." (P10)

CT providers proactively address the reliability challenge by researching new circumvention techniques or by enhancing the resilience of their existing tools, often through increased redundancy. Four providers specifically mentioned their multi-protocol architecture. This approach involves deploying a variety of transport protocols, enabling their CTs to switch to an alternative protocol in the event of blocking. Moreover, as a more straightforward strategy, providers often resort to rotating IP addresses and servers, particularly when censors are able to fingerprint a CT's traffic.

> "We have a server farm with over 3,000 server instances, rotating IPs faster than the censors block their addresses, with different [rotation] frequency in different targeted countries...still, there have been instances where the censors detected our servers too fast, and [as a result] we lost many users during that period [the shadowsocks blocking incident in 2021 [73]]." (P8)

Following a blocking incident, providers actively work to restore their services. Six providers detailed this process where their R&D teams detect the blocking, reverse-engineer the blocking mechanism, and then develop and deploy countermeasures. For example, P6 shared a specific case [73]: "*Recently, both Iran and China have blocked our tools...we discovered that they were blocking seemingly random traffic. Our countermeasure was to change the output of encryption [to show less entropy].*"

A common thread among providers is the necessity of maintaining communication channels with their users as they recover services from blocking.

> "We need visibility about what happens on the other side...a network of skilled individuals who can test things we are developing. [Without that] we are operating somewhat like shooting in the dark." (P9)

Such communication can range from soliciting help from in-situ users to triangulate the censorship mechanism, to distributing updates once a patch is developed, or simply informing users that a solution is underway. However, maintaining such communication has proven to be one of the most challenging aspects in CT operation.

Communication and Feedback Both providers and users noted the challenge of maintaining a communication and feedback loop, a challenge that is exacerbated during periods of heightened censorship aggression, such as politically sensitive times. These are precisely the moments when effective communication between the provider and the user is most crucial. "*Dictated by the very nature of our work, obtaining feedback is always hard. But it becomes even harder to receive in real time during a blocking [incident], which is crucial for enabling rapid response*" (P8). Seven providers emphasized how the absence of feedback loops complicates their efforts to restore blocked services. P6 and P9 shared that "*knowing how [censorship] is working is hard, as we don't collect metrics on client-side network activities*", and even when they do receive *some* feedback, it's often "*very sparse compared to changes of censorship behaviors*" both geographically and temporally. P11, on how inadequate feedback blocks iterative development:

> "I observe many outages but have little means to diagnose the cause. The available user reports are vague, confused, non-technical, and irreproducible. I try to come up with some general obfuscation, but again, have no way to validate their effectiveness." (P11)

Another challenge highlighted is the difficulties of distributing software patches or updating client-side configurations when the usual communication channels to users are severed due to blocking.

Five providers discussed their existing channels for gathering limited user feedback, such as conducting user surveys, displaying messages on the landing page, addressing support tickets, and communicating through social media posts or press releases. Still, the challenge remains as these channels are either constrained in their bandwidth or limited to uni-directional or asynchronous communications.

Surveyed users (n=4) echoed the communication challenges and expressed the desire for more effective channels to both receive messages from providers and to provide feedback. U7 said "*[I want] More feedback on connection problems. Now, it's hard to understand why the tool is not working - whether the server is down or connection is blocked.*" Participants also asked for a way to share files and logs with providers, which would assist in diagnosing their connection problems.

Providers shared that the disruption from censors is only partially to blame for the lack of communication and feedback. Another significant factor cited is concerns related to privacy.

> "Our philosophy is: by not collecting data, we ensure it cannot be accessed by others. For this we do not collect traffic data." (P8)

Security is often another concern. Providers noted that running services catering to users with heightened threat models can deter outreach or user studies.

> "We had a lot of pushbacks when it comes to talking to users. The more you talk to them, the more they are highlighted. In Turkmenistan there have been stories where police show up to the user's door and ask them to stop using [redacted]" (P5)

Similarly, concerns for their own safety may also deter CT developers located outside censored regions from engaging and conducting tests with in-situ users.

> "We are somewhat limited by concern for anonymity. None of us want any exposure. So when users proposed using their machines in China as vantage points for testing, we didn't dare to do it." (P12)

One surveyed provider highlighted security concerns not in terms of personal risk, but regarding the potential for making their service vulnerable to censors' detection. In response to users requesting more explicit error messages for diagnosing connection problems, the provider explained that providing any feedback at all could inadvertently aid censors with active probing capability to gain information about the server.

> "Our [connection] feedback is not very clear. Users are not able to tell between a revoked access key and network problem. [This way,] we don't leak to a censor anything if they try probing. We always time out instead, which is not ideal for debugging as [a timeout] could also occur due to blocking." (P6)

Service Migration When asked about their strategies in response to their CTs being blocked by censors, user participants mentioned that they would attempt to resolve the issue either by searching online in censorship forums, by reaching out to more tech-savvy friends, or simply by re-attempting connection to a different endpoint if the CT offered multiple options. Two participants expressed a sense of resignation, accepting CT blocking as inevitable during certain time periods, and choosing to just wait "*for the blocking to pass*" (U15,21). Only one participant mentioned directly contacting their CT provider for assistance. The majority of other surveyed users (n=11), however, found themselves in a continual cycle of service migration in order to maintain access to the free Internet.

> "I maintain a lot of back-ups. If one stops working, perhaps the operator gets in trouble or run away, I just switch to another service. (U22) These [CT] services might get shut down [as soon as] next month, so I don't commit to long subscriptions. (U12)"

Participants provided a perspective on why they switch services, believing once a CT is blocked, it is unlikely to recover.

> "They keep becoming unusable, but there's nothing to fix. It just means that the state's filtering system found how to disable them. You just go download a new [CT] because this tool is done. (U4)"

Interestingly, users' frustration over the need to constantly switch to new services is echoed by providers, but from a different perspective: providers find that users often migrate too quickly, leaving little time for providers to implement countermeasures or communicate potential solutions.

> "Once blocked, eventually people believe [redacted] doesn't work anymore. It took us a month to develop [a countermeasure], but the users are not willing to come back because they think it won't work."(P9)

Funding and Sustainability A common (n=5) theme that emerged from our interviews with CT providers is the financial burden associated with running a CT service. Expenses such as renting servers, buying upstream bandwidth, and constantly rotating IP addresses pose a challenge to the sustainability of CT operation. Providers who only offer self-setup CT solutions face this challenge to a lesser extent compared to those who directly operate such services, especially those who offer services free of charge.

> "We have a problem with too many users... It's a free tool. People use it and we don't know how to pay the bills. We always try to support short-term user surges no matter the cost. But once these users start to be active for more than a month, we have to actively try to figure out how to fund it." (P5)

P9, operating a free CT service, shared their frustration on the difficulties in securing funding to support their operation.

> "The bigger problem we face is the lack of resources. Currently, there is no such a thing as a unified entity that recognizes or supports those doing this kind of work. At the end of the day, this operation doesn't pay one cent, and our resources are limited." (P9)

This difficulty in securing funding is a common issue among CT providers. They recognize that operating CTs often means serving users who are unable to pay; as such, they often seek funding from government agencies or organizations. This responsibility of obtaining funding places a burden on providers, who, as P2 mentioned, "*expend a great deal of effort in trying to secure funding*". This process can be complicated by several factors. First, the application for funding can be a lengthy process, which contrasts with the need for rapid response to the changing censorship landscape. P5 shared, "*Censorship is volatile. You can have a user surge of thousands to millions in a single day, while funding agencies are often slow to react.*"

Additionally, providers need to evolve their CT capabilities to stay matched in the ongoing arms race against censors, yet they often struggle to explain their specific needs to justify funding, such as the costs involved in researching and developing new circumvention solutions. The funding can also be insufficient to cover long-term operational costs. One participant shared their experience of having to "*constantly create*

new projects just to get funding" (P4). The funding can also come with restrictive conditions, such as region-specific funds that limit their use to support users only from a certain area.

Providers raised a concern about the limited funding opportunities creating an unintended competition among CT providers, which can have negative effects on the ecosystem.

> "There's a competition mentality, particularly in competing for the same funding dollars. I wish we look at censorship more collaboratively...We are now at a stage where we no longer have to scramble for funding, but unfortunately I don't think as a community we have that 'we are in this together' mindset." (P4)

Some providers highlighted that due to limited resources, they have had to degrade their services when user demand exceeded their capacity. P6 and P8, for example, shared situations where they had to throttle their traffic during recent surges in users, so that a larger number of users received some level of connectivity, albeit degraded.

The possibility of monetizing CT services through user payments or advertising has been considered by providers as a potential way to sustain their operations. Providers have considered accepting cryptocurrency as an alternative payment method or subsidizing free CT services with revenue from other sources (e.g., paid, western-focused VPNs). However, these efforts face complexities due to privacy and security concerns, given the elevated threat models of both providers and users, as well as the regions where these tools are most used.

> "It's difficult to monetize the service in a way that doesn't expose developers and providers to additional risk. With KYC (Kow Your Customer) and anti-money laundering / terrorism financing laws, it's hard to monetize without revealing our identities while also allowing common payment methods." (P7)

Usability U18 characterized the censorship in China as "*The Wall serves as a filter - anyone with enough technical knowledge can circumvent it.*" This observation aligned with the efforts of five providers, who highlighted being usable by people with varying technical skills as a key aspect of their tools. P4 explained their approach: "*as simple as possible, as our target users are not tech-savvy.*" P9 similarly remarked: "*We don't expect users to tweak it. We have to figure out how to make it work without telling users how they have to change things.*" Common usability efforts from providers include straightforward "one-click" UI designs and localized versions that offer various languages.

Most (n=13) surveyed users reported little to no usability issues, mainly with commercial VPNs or browser add-ons that require only "*average computer literacy*"(U7). This observation is consistent with prior studies [39]. The users appreciated the shift from complex interfaces to simpler, one-button connection options.

However, those who have used/attempted self-setup CTs (n=7) noted significant technical barriers. These solutions often require users to manage their own servers – a task that is already too complex for non-technical users. Additionally, most self-setup CTs are highly customizable, supporting various protocols and use cases, but this flexibility often demands deeper technical understanding and more manual configurations than "one-click plug-and-play".

> "All of them are total crap from the UI perspective. Nothing is explained. You choose between options gibberish1 and gibberish2 all the time. They made us all experienced users, even the ones who weren't tech savvy before." (U4)

A provider offering self-setup protocols echoed the confusion non-technical users face, particularly with the requirement of managing their own servers.

> "The fact that [our protocol] needs a server is a challenge. We try to make it easier by simplifying access keys and so on, but many users still just download the client app and are not sure what to do." (P6)

Finally, CT users also reported usability issues stemming from server-side security policies that discriminate against CT/VPN traffic. Common problems include applications detecting and blocking VPNs, increased encounters of CAPTCHAs, and local websites geoblocking foreign proxy IP addresses. These negative experiences align with findings from research on VPN adoption [57].

5.4 Trust and Risk Considerations

Next, we asked both providers and users about their perceptions of the risks involved in operating and using CTs, and the role of trust in this context. Both groups identified two primary types of risks – one related to the use of proxy or tunneling tools in general, and the dangers posed by authorities given that CT operation and usage is often illegal. These risks are interconnected and may exacerbate each other. For example, the potential consequences from CT usage heightens the threat model for users, which makes the security implications from proxy operator's possible misconduct even more critical.

Risk from Authorities Several participants highlighted an increased risk associated with operating, distributing, or sharing CTs, compared to simply using them. U18 commented "*The police don't care if it's just you. But if you're spreading it, then there's more likely to be legal issues*". For this reason, users mentioned that they only share access to their CT with close, trusted individuals. Providers echoed this observation, expressing their concerns for their in-situ distributors.

> "[CT] Distributors living in China or similar regions are under the jurisdiction of governments that apply censorship... There have been cases where they get felony for running anti-censorship services." (P7)

On the other hand, there's less clarity and agreement among participants regarding the consequences of just being a CT user. Participants from Russia indicated they don't perceive any legal issues with using CTs, provided that the tool is able to bypass the blocking; though, some highlighted the fragility of this status. "*I'm very afraid that a political decision to ban all and any VPNs can be taken.*" (U6). In China, while the use of CTs is technically illegal, participants noted that they never heard of anyone facing legal consequences merely for using circumventing solutions. "*I was using VPNs like everyone else*" (U14). Yet, participants also acknowledged the existence of an ambiguous "red line". For example, discussing CTs is perceived to be riskier than using them, and using CTs for political purposes, as opposed to leisure or entertainment, similarly carries its own set of risks.

Risk from Misbehaving Providers CT users, like users of other tunneling tools such as VPNs, are essentially transferring trust from their local network providers onto the CT providers, who are in a privileged position to collect and potentially profit off users' data. Participants voiced concerns about privacy risks from operators who might mishandle users' traffic. U13 shared a previous incident where "*some user data was leaked by one of the developers who was paid by [redacted]. I stopped using the service. They still were not transparent about what happened.*"

An even greater concern is the potential for misbehaving CT providers to collude with the authorities. Five surveyed users feared that CTs could be government-backed honeypots, or at least obligated by law to cooperate with the government's demands, such as sharing logs or filtering contents.

Trust and Mistrust These risks escalate the threat model for users, also emphasizing the importance of trust between CT users and providers. Providers we surveyed shared their various efforts to earn and maintain this trust, such as being more reliable in this volatile ecosystem:

> "Initially we assume there is no inherent trust. We gain trust primarily by working well."(P5) "...that the tool works reliably is the single most important factor to build trust."(P8)

In addition to providing reliable services, some providers aim to build trust through transparency about their operations. P10, for example, mentioned associating their service with their real names, offering a level of personal accountability:

> "I grew up in China and have friends there, so it's a decision I didn't take lightly. But I decided to not be anonymous precisely because people can look up where I got my education and what I do for work, and know I'm not a honeypot... Plus, if anything ever happens to me, someone would notice." (P10)

P9 elaborated on efforts to increase transparency such as having a clean background on the CT's ownership and building open-source software that allows independent audits:

> "In this space everything is trust. We are fully open-source and conduct 'no logs' audits every year. We say where we are based, and that we are a public organization with a clear and established background in this field... When we are blocked we also transparently communicate what is happening." (P9)

Providers also aim to build trust by exercising particular caution in their collection and handling of user data. For example, to minimize data collection, P5 claimed they "*don't see incoming IPs, only do a MaxMind lookup and then toss away. Don't gather any user info. Don't ask anything non-generic.*" For providers that accept payments, they implement mechanisms to separate CT usage records from payment records, as the latter often contains more identifiable information. These protective measures often exceed the typical safety protocols noted in studies of commercial VPNs [57].

Despite these efforts, there remains a widespread sense of mistrust between providers and users, a sentiment acknowledged by both sides (n=15U, n=8P). Many participants attributed this mistrust to the covert nature of censorship and the potential legal and personal risks involved. U14 shared the challenges in fostering a sense of community and trust:

> "It's good to have a community, but it doesn't exist because [CTs] are technically illegal in China, and there's so much distrust and snitching going on that unfortunately I just can't trust anyone." (U14)

Several providers noted that the frequent disruptions to CTs caused by censorship also impede the building of trust over time. P9 pointed out that the general lack of understanding among users about the technical aspects of CTs often leads to misattributing blocking-induced connectivity issues:

> "Users don't understand what a VPN, a protocol, or an IP is. Understanding connection errors and correctly attributing them is even harder. Often, users don't know what's happening and tend to blame you [CT providers] rather than government censors." (P9)

P7 and P10 mentioned that the trust relationship between users and providers, while initially founded on mutual goals of bypassing censorship, can be fragile under duress of legal and governmental pressure. For example, when confronted by the authorities, providers might shift their priority from providing access to self-preservation, a possibility that fuels users' cautious approach to trust.

> "I ask [other providers] why they require users to submit their IDs. They are not honeypots, but rather they keep this information so that if the government comes knocking, they have something to bribe - like saying 'Don't put me in jail, put these people in jail'." (P10)

The precarious legal standing of CTs, in contrast to other online services operating within regulated frameworks and

industry standards, leads to some dubious practices among providers. Examples include providers marketing their services with security claims that are impossible to verify, such as "no log policy" or "impossible to block", or operators profiting from spamming and advertising. One provider also discussed the differing notions of OSS among developers and raised doubts about the actual security assurances these open-source claims offer. These practices in the CT market also contribute to the overall lack of trust.

Access over Trust Despite the mistrust and significant risks associated with CT usage, these considerations surprisingly have limited influence on users' decisions to start using a CT. Many users adopt a pragmatic approach to using CTs, motivated not by trust in the CT's security or the operator's integrity, but by the sheer need to access censored resources.

For some users, this perspective reflects a resigned acceptance of the limited options available in a heavily censored environment, where the need to access information justifies using any available CT regardless of its trustworthiness:

> "I use whatever VPN that gets me connected. I don't know how it works, but since I had to use it, I had to trust it." (U16)

For others, indifference towards trust comes from a calculated assessment of risks; trust is considered irrelevant as long as their use of CTs does not involve high-stakes activities:

> "I don't trust the tool at all. For any activities beyond reading the prohibited sources I wouldn't use it. I would post something sensitive only outside the border. So for me it's enough if the tool just works." (U4)

Providers also recognize that users in the CT market often face the choice between using a potentially insecure tool or lacking access to censored contents:

> "Users tend to use any software that connects, even if it triggers antivirus alerts. They often face a choice between using this shady software to access the [uncensored] Internet or hardly having it at all. I can't say for everyone, but I'll sum up as: trust matters but not to a great extent." (P1)

Misconceptions When discussing the risks of CTs and the threat they can mitigate, there exists a disconnect between providers' priorities and users' expectations. CT providers, focusing on enabling access to content restricted by censorship, typically prioritize access above all other features.

> "I believe it is important to separate anonymity, privacy, and censorship circumvention, as they are quite different. Average users don't know the difference and just use the term 'VPN"'(P1) "We emphasize access over privacy-enhancing" (P4)

Yet, some users attribute additional security properties to CTs, such as online anonymity, privacy from local Internet providers, or security on unsecured networks. These expectations are more aligned with dedicated tools (e.g. Tor, default-gateway VPNs), rather than the objectives of standard CTs.

> "I look for anonymity...in the sense that I can easily disconnect myself. I don't want to be tracked down."(U22) "People use CT not just to unblock sources but to hide from their own Internet providers and police that they are reading [redacted]." (U4)

This gap in understanding can potentially put users at risk, since it may foster a false sense of security from tools primarily engineered for access.

6 Identified Future Priorities & Discussion

Our findings highlight multi-dimensional challenges that stakeholders in the CT ecosystem must navigate. These challenges are not limited to the technical aspect of circumvention (e.g., protocol obfuscation), but also cover areas such as service discovery, funding support, usability issues, and trust and risk considerations, each critically affecting the sustainability of the CT ecosystem. In the concluding part of our interviews with both providers and users, we shifted from the semi-structured interview protocols to more open-ended discussions, where we explicitly asked participants to identify the most pressing issues of the CT ecosystem and their views on future priorities for stakeholders. These dialogues were intentionally unstructured and often extended beyond the allocated time. In this section, we outline several themes that repeatedly surfaced throughout these discussions.

Bootstrapping Challenges The initial bootstrapping stage is a significant yet often overlooked challenge for users in censored regions. This stage involves making the first contact with a provider, acquiring client software and configurations, user authentication, *etc.* Most of these actions require a connection to the CT provider, which censors often obstruct. Yet, the CT itself cannot facilitate such connections until the bootstrapping steps are completed. For this, many systems, both in deployment and academic proposals, presuppose the existence of an "out-of-band" channel (e.g. [12, 19, 29, 36, 37, 47, 63, 68, 79]). This assumption not only complicates usability and wider adoption but also introduces potential security risks. As shown in this work, users might knowingly use less secure VPNs temporarily in order to bootstrap CTs, or they could have to install software from unverified sources if CTs are restricted on mainstream distribution channels like appstores.

Complicating the issue further, many bootstrapping steps need to be repeated following a server or key rotation (e.g. after blocking). One provider noted that requiring users to fetch updated IPs and keys, and then knowing how to apply the updates to their clients, is their main usability issue, as "*the more steps you have, the fewer people can do*" (P3). Developing secure and reliable methods for distributing CT software and

streamlining the bootstrapping and server rotation process remain a critical area for future research.

Outreach & Feedback Channels Establishing and maintaining resilient outreach and feedback channels is highlighted by both sides as a priority. Users acknowledge that service disruptions are often inevitable in the adversarial environment in which CTs operate. However, they stress the need for a reliable channel that remains accessible even during blocking incidents, allowing them to receive support and updates on the CT's status. For providers, maintaining a feedback loop with in-situ users is critical, especially during efforts to restore service after a blocking event, when immediate user feedback is essential for testing the effectiveness of any fixes. The absence of such feedback loops with in-situ users blocks iterative improvement and complicates the development cycles of CTs.

Providers highlight the importance of adapting outreach strategies to local norms and the value of establishing a local presence or partnering with local entities within censored regions to connect with users. These local partners, who are more familiar with the cultural and regulatory norms, can facilitate communication while also ensuring sensitivity to the users' environments and the ethical implications involved in engaging with users in these areas.

Flexible Funding CT providers often operate in a market characterized by volatile and unpredictable demands, particularly in the wake of major political or social events that trigger sudden surges in user numbers. For this, providers emphasize the need for two types of funding: long-term funding for sustainable development, research, and maintenance of their services; and short-term, emergency funding to quickly scale services in response to event-induced demand spikes. For the latter, initiatives like the OTF's Surge and Sustain Fund [6] aim to address these needs by helping to offset the marginal costs related to demand surges. Providers are calling for more accessible rapid-response funding opportunities with shorter application cycles and faster turnaround times to allow them to accommodate sudden influxes of users and maintain uninterrupted service during critical periods.

The fact that most funding comes from entities associated with government bodies restricts funding opportunities for grassroots CT providers operating within countries like Iran or Russia, where funding agencies like OTF cannot provide financial support due to trade restriction or export sanctions. Moreover, in regions like China, receiving funds from foreign governments, particularly the U.S., is often perceived as risky or unlawful, compelling local providers to distance themselves from such funding sources. Private grants or donations could serve as viable alternative funding avenues.

Academic Priorities vs. On-the-ground Needs The circumvention arms race demands continuous research and development efforts by CTs to keep up with evolving censorship techniques. However, providers noted a disconnect between the priorities of academic researchers and RFC/Internet standard designers, and the needs of CT users and developers in censored regions. Existing general-purpose protocol suites (e.g., OpenVPN), for example, were rarely designed with the censorship threat model in mind, and their architects often show little interest in engaging in the cat-and-mouse game [49]. Moreover, the localized nature of censorship practices places researchers based outside the censored regions at a disadvantage. As one provider puts it, it's "*like trying to solve a problem you don't experience or understand.*" (P4)

Academic research often values novelty over incremental improvements, prioritizing developing new concepts over improving the usability of existing tools. For example, recent studies on re-purposing voice chat or online games as circumvention transports, while academically appreciated, often fall short of translating into tangible, deployable solutions that address the simpler, practical needs of users facing censorship.

User Education Both providers and users identified inadequate user education as a significant barrier to CT adoption. This issue goes beyond basic usability or learning to use the tool; it's about understanding of what a CT is, how it works, the associated risks, and the specific threat models they address or fall short against. Multiple users shared their struggle in understanding how exactly CTs bypass censorship, which complicates their ability to make informed trust and risk assessments. Inadequate education also contributes to their stigmatization, often fueled by government propaganda linking CT use to cybercrime. Appropriate user education could help demystify CTs and encourage broader adoption. Moreover, providers highlighted a related concern of users prioritizing access and speed above security and privacy, which likely stems from the same gap in education. Better informing users about the exposure involved in using CTs and the risks from malpracticing providers could enable them to make educated decisions on whether to use CTs and which CT to choose. Yet, the question of *how* to safely and effectively engage users given the associated risks remains a challenge.

The importance of user education has been similarly noted by studies on the commercial VPN sector [57] and is echoed by similar initiatives from privacy-enhancing technologies (in more "open" countries). For example, Tor, which has long sought to dispel misconceptions and stigma around its use, provides educational resources that explain how it works and showcases its diverse variety of use cases by military, journalists, and "normal people" [10].

Collaboration & Community There are no simple solutions to many of the issues surfaced from our interviews. While generic recommendations such as increasing funding, communication, or expanding user education might appear as straightforward, the highly localized nature of censorship practices (and corresponding circumvention strategies) demands solutions tailored to specific regions. For example, our findings (§ 5) reveal that due to the different censorship land-

scapes in Russia and China, users in these two countries have different needs and priorities when it comes to circumvention.

A key aspect underlying many identified priorities is the need for providers and researchers to engage with local grassroots groups in censored regions for a better understanding of the specific censorship practices and user needs. Establishing effective communication with these groups, however, presents both technical and ethical complexities, especially in the presence of active adversaries. Some participants suggest that, where safe, in-person meetings could offer a more trusted space for stakeholders to share knowledge and experiences. Similarly, there's also a growing recognition among providers themselves of the need to foster collaboration and a sense of community, encouraging providers to view each other as allies rather than rivals competing for limited funding. A "we are in this together" mindset could lead to more efficient resource pooling, timely sharing of data and insights, and collective actions in response to censorship incidents, which would not only address immediate priorities but also facilitate the passing of knowledge and "lessons learned" across current and future generations of stakeholders in the CT ecosystem.

7 Conclusion

The escalation of censorship efforts by nation-state actors has fueled a surge in demand for circumvention tools across the world's most restricted networks. Yet, the ecosystem surrounding CTs remains largely opaque to researchers and regulators, due to its adversarial nature and the inherent risks faced by those directly involved. This exploratory study represents the first multi-perspective survey to shed light on the needs and challenges of both CT providers and users on the ground. We hope our study raises awareness and encourages further research, advocacy, and concerted efforts among stakeholders, academia, and funding bodies to improve the efficacy and sustainability of the CT ecosystem.

8 Acknowledgement

The authors would like to express their deepest gratitude to Jed Crandall and Armin Huremagic for their feedback, insightful discussions, and thorough review of this work. Their contributions have greatly improved the quality of this research. We also extend our thanks to Kyle Astroth for her assistance in conducting the study. Finally, the authors appreciate the constructive feedback provided by the anonymous reviewers.
