Abstract

Root-Cause Analysis (RCA) is crucial for discovering security vulnerabilities from fuzzing outcomes. Automating this process through triaging the crashes observed during the fuzzing process, however, is considered to be challenging. Particularly, today's statistical RCA approaches are known to be exceedingly slow, often taking tens of hours or even a week to analyze a crash. This problem comes from the biased sampling such approaches perform. More specifically, given an input inducing a crash in a program, these approaches sample around the input by mutating it to generate new test cases; these cases are used to fuzz the program, in a hope that a set of program elements (blocks, instructions or predicates) on the execution path of the original input can be adequately sampled so their correlations with the crash can be determined. This process, however, tends to generate the input samples more likely causing the crash, with their execution paths involving a similar set of elements, which become less distinguishable until a large number of samples have been made. We found that this problem can be effectively addressed by sampling around "counterexamples", the inputs causing a significant change to the current estimates of correlations. These inputs though still involving the elements often do not lead to the crash. They are found to be effective in differentiating program elements, thereby accelerating the RCA process. Based upon the understanding, we designed and implemented a reinforcement learning (RL) technique that rewards the operations involving counterexamples. By balancing random sampling with the exploitation on the counterexamples, our new approach, called RACING, is shown to substantially elevate the scalability and the accuracy of today's statistical RCA, outperforming the state-of-the-art by more than an order of magnitude.

1 Introduction

With the pervasiveness of software systems, their security quality needs to be ensured in a scalable way. For this purpose, *automated vulnerability discovery* has been intensively studied in past decades [30, 42, 48, 51]. Among all techniques being proposed, fuzzing is no doubt the most successful one, which has been credited with discovery of the most consequential security flaws, such as CVE-2017-5380 [2], CVE-2018-4145 [3] and CVE-2022-36320 [4]. A problem here, however, is that fuzzing alone does not find a vulnerability: it just induces crashes of the target program with test cases it produces, while leaving triage of the crashes, a critical step to identify the *root cause* – the vulnerability behind the crashes, to the human analyst. Manual *root-cause analysis* (RCA) is a slow and pains-taking process, particularly for today's complicated software system involving subtle connections across different components, so the program locations where the crashes occur may not have explicit data dependencies upon the true cause of the crashes. As a result, vulnerability discovery tends to be significantly delayed even after the flaws have been reached by test cases, raising a strong demand for the techniques that enable automated, highly scalable RCA.

Challenges in automated RCA. Today, most RCAs have been done manually with the help of some analysis tools. These tools bucket different crash inputs for identifying the underlying vulnerability [27], or perform reverse execution and backward taint analysis [16, 17, 45] to trace back to the program location where the vulnerability is introduced, from the location where the crash is observed. These approaches rely on a set of manually drafted rules to identify some specific types of vulnerabilities and become less effective in the absence of explicit data flows between a vulnerability and observed crashes, such as the case of type-confusion flaws [21].

A more generic alternative capable of handling different types of vulnerabilities, including those without explicit data dependency on the crash they induce, is *Spectrum-based Fault Localization* (*SFL*), a set of statistical, ruleless, fully automated RCA techniques known to outperform other automated

RCA supports [18]. These techniques aim at capturing the fundamental causal relations between a crash and its root cause (a vulnerable program entity like blocks, statements or the predicate of a statement) based upon their statistical correlation. More specifically, for each crash observed from a program, an SFL technique generates a set of test cases to fuzz the target program, and uses the fuzzing outcome (either leading to the crash or not) to estimate the statistical correlation between each program entity encountered during the fuzzing process and the crash; the entities found to be highly correlated are then ranked and output as suspicious root causes [12, 39, 52]. With its generality and effectiveness, the approach is known to be heavyweight, incurring a massive overhead, due to the requirement to fuzz the program on a large number of test cases for establishing the correlation for each entity and also differentiating their contributions to the crash. Indeed, prior research reports that analysis on each crash through SFL could take 12 hours [12] or even a week [52], rendering these techniques hard to scale in the presence of a large number of crashes induced by fuzzing.

RCA with counterexample based RL. To move SFL closer to practical use, its performance needs to be elevated. In our research, we found that a fundamental weakness of existing SFL approaches is their sole reliance on the guidance of known inputs leading to the crash: by mutating these crash inputs for new test cases, program entities potentially related to the crash can be repeatedly sampled; however, these new test cases tend to be biased toward the crash and cannot effectively differentiate these entities in terms of their contributions to the crash. As a result, a large number of random inputs need to be produced and tested before enough distinguishing outcomes (particularly those covering repeatedly sampled program entities related to the crash but leading to non-crashing results) are observed so the root-cause entity can stand out of the crowd. This weakness can be addressed by sampling around the differentiating test cases discovered, which we call *counterexamples* – the test cases that cause a significant change to an entity's putative correlation with the crash or the putative order of the entities (based upon their contributions) estimated on the outcomes of previous fuzzing rounds. These counterexamples balance the sampling strategy of the existing approaches (e.g., Aurora [12]), which is biased toward crash inputs, and therefore facilitate identification of the root cause.

Based upon the understanding, we designed and implemented a high-performance, scalable SFL-based RCA technique, using *reinforcement-learning* (*RL*) to dynamically adjust the sampling (fuzzing) strategy based upon the estimates of program predicates' relations with a given crash. Our approach, called RACING (Root-cAuse-analysis on Counterexamples based reinforcement-learnING), utilizes the outcome of each fuzzing round, including its impacts on each predicate's estimated contribution to the crash and the estimated rankings of these predicates based upon their contributions, to guide the next round of fuzzing. More specifically, given the test cases known to cause a crash, our approach first performs random mutations on them (as done in the prior work [51]) and fuzzes the target program using these mutations to generate a baseline estimate for each predicate's correlation with the crash and their relative order of correlation strengths. Then, our approach runs RL on the follow-up fuzzing process, rewarding the selection of the seeds (that are the inputs mutated by the fuzzer to generate new inputs) and the mutations that could lead to significant changes to the current estimates (the correlation of each predicate and their order). By balancing the exploitation of the selection strategy with a high expected reward and exploration of a random strategy, this learning process guides RACING toward a ranked list of the predicates, with the root cause being top on the list.

Evaluation and findings. We implemented RACING and evaluated it on 30 vulnerabilities found in 21 popular applications or libraries, including 19 also used in the prior research (Aurora [12]). Our study shows that RACING significantly outperforms the state-of-the-art, speeding up the RCA process by 13.22 times on average, compared with Aurora: typically an analysis that needs hours to complete by the prior approach can be done within minutes, with more than 2/3 of the delay being reduced even in the worst case. This performance gain does not come at any quality cost. Comparing with Aurora, RACING produces a high-quality ranked list of predicates, with the root cause keeping its rank in Aurora's report in 20.00% of the cases, slipping slightly below 33.33% of the time, while going above in 46.67% of all the results. Our findings provide strong evidence that indeed RACING enhances both the scalability and the effectiveness of SFL.

Contributions. We outline our contributions below:

• *New understanding*. We analyzed how counterexamples impact the discovery of the rank for a given crash's root cause, which has never been done before. Our analysis shows that by sampling these counterexamples, an enhanced SFL approach can quickly identify the program entities most related to the crash. This enables significant acceleration of the RCA process through statistical SFL.

• *New techniques*. Based upon the new understanding, we developed a novel RL-enhanced SFL technique that automatically learns from the outcome of each fuzzing round to adjust the seed selection and mutation strategy. This new technique is shown to improve the performance of the state-of-the-art SFL approach by over an order of magnitude and also elevate its effectiveness in finding the root-cause vulnerability. We have published the code of our approach online [5].

Roadmap. The rest of the paper is organized as follows: Section 2 provides the background of our research; Section 3 presents our analysis on the impact of counterexamples; Section 4 describes the design and implementation of RACING; Section 5 reports our experimental results; Section 6 discusses the limitations and potential future research; Section 7 surveys related prior work and Section 8 concludes the paper.

2 Background

Statistical RCA framework. As mentioned earlier, SFL is a statistical RCA, which is known to be the state-of-the-art in triaging the crashes of a program and identifying underlying vulnerabilities [12, 39, 52]. This approach is based upon the belief that the program entity fundamentally responsible for crashes (the root cause) should be encountered when the program is running on the inputs causing the crash (*crash inputs*), rather than those leading to a normal exit (*non-crash inputs*). Therefore, it requires a testing set with both crash inputs and non-crash inputs, and estimates the statistical correlation between the program entity and the crash on both crash and non-crash inputs. A higher estimated correlation indicates that the program entity is more likely to be the root cause. A prominent example of the estimation is *mutual information*, which is represented by a matrix for measuring the contributions of different program entities to the crashes [52]. Specifically, the mutual information I between X (program entity) and Y (crash or non-crash inputs) can be calculated as follows:

$$\begin{aligned} &\mathbf{I}(X;Y) = H(Y) - H(Y|X) \\ &H(Y|X) = -\textstyle\sum_{x\in\{0,1\}} Pr(x) \sum_{y\in\{0,1\}} Pr(y|x) \log_2 Pr(y|x) \end{aligned} \quad (1)$$

where $H(Y)$ is the marginal entropy and $H(Y|X)$ is the conditional entropy. Mutual information is also used in RACING, to measure the correlation of a program entity to the crash.

Predicate. A root cause is a program entity serving as a *necessary condition* for the crash, which depending on the granularity of RCA, could be a predicate, statement, or block. Following Aurora [12], our research focuses on the predicate-level root causes including three types: (1) register and memory predicates, (2) flag predicates, and (3) control-flow predicates. Specifically, predicates (1) and (2) are assertions on an instruction, predicting the occurrence of the crash when some conditions on the instruction's destination operand and the flag register are satisfied. For example, a predicate could be `eax<=z` for the destination operand `eax` of an instruction `mov eax, ebx`, indicating that an execution will crash *when* `eax<=z` *and exit normally otherwise*. And, `flag.ZF>0` is a flag predicate that predicts a crash *only when the zero flag is set to 1*. Predicate (3) evaluates the difference between executions on the control-flow graph (CFG), including the execution of certain edges and the number of successors for nodes. For example, the predicate $\texttt{count}_{\texttt{x->y}}\texttt{>0}$ is used to predict a crash *when the edge* `x->y` *has been executed for at least once*, while the predicate $\texttt{successor}_{\texttt{x}}\texttt{>2}$ predicts a crash *when the number of executed successor nodes for x is more than 2*. All three types of predicates are expressed in a union format `Var op Thr`, where `Var` represents the variable of interest, `op` denotes an operator (<= or >), and `Thr` denotes a threshold calculated during the fuzzing process. We follow Aurora's method to construct the predicates (see details at Appendix A.1). In particular, we use mutual information (Eq 1) to estimate the correlation of the predicates with the crash.

Note that a predicate might change during a fuzz test, when new observations have been made to affect the estimate of the condition that leads to the crash. However, at any fuzz round, a variable of interest is always associated with a predicate based upon the best estimate so far. Therefore, throughout the paper, we consider any execution of the instruction as a sample on its predicate, which both affects the estimate of the predicate's correlation with the crash and could lead to the adjustment of the predicate itself, and use the term "sample value" to refer to the value assigned to the variable of a predicate during an execution.

AFL in RCA. American Fuzzy Lop (AFL) [51] is a code-coverage-based brute-force fuzzer, which is among the most popular fuzzing tools. Given a set of seed inputs, AFL repeatedly selects and mutates seeds to generate new inputs to test a target program and detect its exceptions (e.g., crashes). Any mutation improving code coverage is added to a queue as a new seed candidate. During this fuzzing process, AFL tends to generate an enormous number of inputs, including both crash and non-crash inputs. Existing statistical RCA techniques run AFL for a predetermined period of time to produce a large number of fuzzing outcomes on a test set, which serve as samples for estimating the correlations between program elements and observed crashes [12, 52]. However, we found that this testing set generation process is optimized for code coverage, as AFL is supposed to do, rather than for efficient identification of the root causes. Also it is biased towards crashes, since all these RCA approaches enable the AFL's *crash exploration mode*, only selecting seeds from crash inputs (see Section 3). Therefore, in our research, we modified AFL's seed selection and mutation strategies to incorporate our counterexample-based RL, so as to make the fuzzing process more suitable for efficient discovery of program vulnerabilities (Section 4).

Reinforcement learning. In this paper, we will utilize the algorithm for a reinforcement learning problem, the Adversarial Multi Armed Bandits (AMAB) problem. This problem describes a game of T rounds between a player and an adversary. In each round $t = 1, \ldots, T$, the player selects a distribution d_t over the k-arms and the adversary selects a reward vector $g_t \in \mathbb{R}^k$. An action a_t is sampled from d_t and the player observes the reward $g_t(a_t)$. The player's expected regret is

$$G_T = \mathbb{E}[\max_{i\in[k]} \sum_{i=1}^{T} g_t(i) - \sum_{i=1}^{T} g_t(a_t)]. \quad (2)$$

We assume that the reward vector g_t depends only on the player's actions. So, the expectation above is calculated on the distribution of the player's actions. The goal of the player is to select the distributions $d_1, \ldots, d_T$ such that the regret G_T across the T rounds is minimized.

During RL, the player typically employs two important strategies, *exploitation* and *exploration*. Exploitation refers to the player using the knowledge it has already gained to make the best decision in a given state. Exploration refers to the

player trying new actions that may have not been experienced before (often via random sampling) to gather more information and potentially uncover better strategies. In RACING, for RL's exploration mode, we adopt a random strategy.

3 Counterexamples for Root Cause Analysis

At the center of a statistical RCA is the estimate of accurate predicate rankings according to these predicates' contributions to a given crash. For this purpose, existing approaches, such as Aurora [12], assess each predicate's correlation with the crash using a sampling strategy biased toward the crash, which as mentioned earlier, is less differentiating and therefore requires a lot of samples (outcomes of fuzz tests). We believe that by balancing the sampling around known crash inputs (as the prior approaches do) and the sampling around the test cases with the most differentiating power, the root cause for the crash can be discovered much more efficiently, on a small set of samples. In our research, we refer to such testing cases, which are characterized by their outcomes' disagreement with the current estimates, as *counterexamples*.

In our research, we consider two kinds of counterexamples: those correcting the current estimates of rankings (counterexamples for rankings, or CoRs) and those correcting the estimate of each predicate's correlation (counterexamples for predicates, CoPs). Our research shows that CoRs alone can help determine accurate rankings of predicates on a small number of inputs, while CoRs and CoPs together can further cut down the required sample size for accurately estimating the ranking of the root cause. Following we present our analysis on the efficacy of these two types of counterexamples.

3.1 Counterexample for Ranking

To understand the impacts of CoRs on learning of predicate rankings, we first formalize the ranking problem, whose solution depends upon effectively distinguishing predicates from each other based upon their contributions to a given crash. Then, we show that CoRs are exactly such differentiating inputs and a sampling strategy leveraging them can speed up the process to move the root-cause predicate up on the list, due to the small sample size it requires.

Problem modeling. We model RCA as a ranking problem, ranking predicates according to their associated statistics that measure how likely each of them causes a given crash, based upon its correlation with the crash. Formally, consider N predicates $\{p_1, p_2, ..., p_N\}$ to be ranked and their associated statistics $\{s_1, s_2, ..., s_N\}$. We use s_i^* to denote the true value of the statistic s_i for the predicate p_i and $\tilde{s}_i$ an estimate of s_i^*. An order of these N predicates is denoted by r, which is a permutation of the first N positive integers, i.e., $r \in \Pi([N])$. We denote the i-th element in r as r_i, and the ranking of predicate p_i as $r(i)$. Our purpose is to determine the true order (rankings) r^* of these N predicates according to the true values of their statistics (in a descending order, i.e., $s^*_{r_1^*} > ... > s^*_{r_N^*}$). In practice, however, we only know the estimates of these statistics $\{\tilde{s}_i\}$, which are calculated on n_i samples $e_i = \{e_{i1}, e_{i2}, ..., e_{in_i}\}$ for the predicate p_i. To highlight the importance of the sample size, we use $\tilde{s}_{i,n_i}$ to describe the estimate made on n_i samples. Note that each sample e_{ij} is produced by running the program under the RCA analysis on an input sample – a testing case and each execution of the program can generate multiple samples for different predicates. Since this fuzz process is time-consuming, our objective is to minimize the number of testing cases for determining the true order r^*.

Sampling strategies for ranking estimates. A direct way to estimate the order r is to generate unbiased random inputs so each predicate is adequately sampled, leading to the convergence of their statistics ($\tilde{s}_i \to s_i^*$), according to the Law of Large Numbers [36]; in this case, the estimated order r will converge to r^*. This simple solution, however, is less practical since it is hard to ensure that randomly generated inputs can reach the predicates, so a large number of the input samples need to be produced and tested, particularly for a complicated program, to provide each predicate with adequate coverage.

To address this problem, prior SFL approaches, such as Aurora [12], take advantage of a known input leading to the crash, called *Proof of Concept* (PoC), to guide the generation of other input samples. By mutating the PoC input and other crash inputs mutated from the PoC, these approaches create random samples around such an input, which are likely to go through a similar instruction set as the crash input, to sample the predicates on these instructions. This strategy enables the generation of the test inputs that more effectively cover the predicates than the unbiased random samples. However, these input samples are biased toward the crash and their related execution paths are less effective in distinguishing different predicates' contributions to the crash. Oftentimes, a subset of the predicates tends to appear *together* on the execution paths of the inputs leading to the crash, and are also less likely to show up on a non-crash path. As a result, these predicates become less distinguishable, rendering the root cause hard to stand out. Only after a large number of random trials around the crash inputs, would enough non-crash inputs be identified, which carry some of these predicates (so their contributions to the crash are sufficiently undermined), and to a lesser extent, new crash inputs discovered involving a small subset of the predicates (so their contributions to the crash become sufficiently prominent). These input samples could eventually move the root cause up the ladder, towards its true rank. We consider some of these inputs CoRs when they cause a significant change to the estimated order.

To speed up the convergence of the root-cause predicate's rank, we need to more efficiently differentiate different predicates' contributions to the crash. This purpose can be served by sampling around the discovered CoRs. Specifically, these inputs generated by mutating the CoR are likely to be differentiating, since a CoR is characterized by its capability to distin-

guish among predicates, mostly through causing a normal-exit result that is less observable under the PoC-guided approaches like Aurora. By incorporating this approach, our sampling strategy becomes more balanced between using the inputs that likely go through predicate-related instructions and leveraging those that differentiate the predicates' impacts on the crash, potentially leading to quick discovery of a root cause.

Counterexamples and convergence. As mentioned earlier, we consider a CoR to be an input sample that causes a big change to the estimated order. Specifically, a program's execution on a given input sample can hit multiple predicates to generate either a crashing or a normal-exit sample for each predicate, thereby inducing changes in ranks for some of them. To measure the impact of such input, we simply sum up the rank changes across all predicates encountered on its execution path in their absolute values, compared with the estimated order before the execution: that is, $\sum_{i=1}^{N} |r_t(i) - r_{t-1}(i)|$, where r_t is the estimated order after t fuzzing rounds. This measurement is found to work well in our experiments (Section 5), which is essentially twice of the Kendall Tau distance [19] (KTD) between two orders.

By balancing between the sampling around crash inputs and the sampling around CoRs, the estimate of the predicate order will converge and tends to converge quickly (Section 5). To avoid fuzzing the program even after the order estimate is stabilized, we can monitor the variation of the rank change measured between two consecutive fuzzing rounds, until the measurement approaches zero (below a threshold used in our research), indicating the convergence of the ranking list, according to the Cauchy's convergence theorem [13].

3.2 Counterexample for Predicate

As described earlier, the root-cause predicates can be more efficiently identified with the help of CoRs. This process can actually be further accelerated by seeking the counterexamples for estimating individual predicates' correlations with a given crash, as discovered in our research. These CoPs serve to amplify the distances between different predicates' estimated statistics through their oversized impact on each predicate's *error rate* (for predicting the crash). As a result, the number of samples required for ranking these predicates (based on their contributions to the crash) can also be reduced.

Distance amplification. For a predicate, CoPs are testing cases on which the execution disagrees with the predicate (e.g., the normal-exit execution, however, makes the condition associated with the predicate satisfied). Hence, if we increase the sampling rate of CoPs for a predicate, the error rate of the predicate should increase. We developed a method that increases the sampling rate of CoPs for each predicate (see Section 4.2) and, at the meantime, does not promote those non-root-cause predicates be ahead of root-cause predicates.

Formally, for the predicate p_i, $\tilde{s}_i$ could be seen as an estimate of how accurate this predicate can predict the exit status (crash or exit normally) of an execution of the program, and thus the error rate of this predicate is $1-\tilde{s}_i$. If the error rates of all predicates are amplified by a factor $\alpha > 1$, the distance between the estimated error rate of any two predicates increases accordingly: for two predicates p_1 and p_2, if $\tilde{s}_1$ and $\tilde{s}_2$ are both amplified by α, their distance increases from $(\tilde{s}_1 - \tilde{s}_2)$ to $\alpha(\tilde{s}_1 - \tilde{s}_2)$.

Sample size reduction. Consider a simple task where we want to rank two statistics according to their estimates. Intuitively, the larger the distance between true values of them, the fewer samples are required to rank them. Formally, we assume that there are two predicates p_1 and p_2 with the estimates $\tilde{s}_{1,n_1}$ and $\tilde{s}_{2,n_2}$ respectively. The true value of $\tilde{s}_{i,n_i}$ is s_i^* that represents how often the predicate p_i correctly predicts whether an execution triggers the given crash or not (i.e., the error rate of the predicate is $1-s_i^*$). Thus, among the n_i samples, the number of correct prediction based on the predicate p_i, referring as $c_{i,ct}$, follows a binomial distribution with the parameters n_i and s_i^*, a.k.a, $c_{i,ct} \sim \mathbf{B}(n_i, s_i^*)$, and an unbiased estimate of s_i^* on n_i samples is $\tilde{s}_i = \frac{c_{i,ct}}{n_i}$. According to the Wald method [7], we obtain that $\tilde{s}_i$ approximately follows a normal distribution with the mean of s_i^* and the variance of $\frac{s_i^*(1-s_i^*)}{n_i}$, a.k.a., $\tilde{s}_i \approx \mathbf{N}(s_i^*, \frac{s_i^*(1-s_i^*)}{n_i})$. If we further assume that the predicate p_1 and p_2 were sampled the same number of times, and their true values are ranked as $s_1^* > s_2^*$, then we can get $\tilde{s}_1 - \tilde{s}_2 \approx \mathbf{N}(s_1^* - s_2^*, \frac{1}{n_1}[s_1^*(1-s_1^*) + s_2^*(1-s_2^*)])$. Therefore, for a fixed distance between the two true values $(s_1^* - s_2^*)$, the greater number of samples (n_i) are used, the less likely we estimate $\tilde{s}_1 - \tilde{s}_2 < 0$. Equivalently, at a given confidence level, when the distance becomes larger, fewer number of samples are required to confidently rank them.

The same argument applies to the scenario of more than two predicates. If we increase the distance among true values of statistics (without changing the rank), the number of samples required to confidently rank the predicates decreases, and thus the number of testing cases required for producing these samples will also decrease. As shown in the beginning of this section, using more CoPs in fuzzing will effectively increase the distances of error rates between every pair of predicates. Therefore, in general, oversampling CoPs can accelerate the process of finding the correct rank r^*.

4 RACING: Design and Implementation

Our study (Section 3) shows that by leveraging counterexamples (CoRs and CoPs), statistical RCA can effectively determine an accurate ranking list just based on a small set of testing cases. This finding has been incorporated into RACING, which runs a reinforcement learning algorithm to guide a fuzzer to generate the testing cases highly likely to be counterexamples, which are more useful for identifying the root cause of a given crash than the others, thereby accelerating the RCA process. More specifically, RACING learns information

from prior fuzzing rounds, particularly the impacts of the test cases on the order of predicates and their statistics, to iteratively approximate an optimal seed-selection and mutation strategy, following the rewards for the strategies that make a big difference to the rankings and the statistics estimated so far (which are mostly counterexamples); these selected strategies are then applied to the next fuzzing round.

4.1 RL on Counterexamples

Our solution to the RCA problem is based upon a reinforcement learning technique designed to address the Adversarial Multi Armed Bandits (AMAB) problem. AMAB is a T-round game where the player intends to maximize her expected reward. In each round, the player selects an action to perform: in the context of RCA, such an action includes the selection of a seed or a method to mutate the seed to produce input samples. After running the target program on these inputs, we use the outcomes of the execution to determine the reward for the current round, and further estimate an expectation for the action based upon all the rewards it has received so far. In the rest of the section, we report our design of the reward mechanism and actions for selecting seeds and mutation methods.

Reward. The classical AMAB game (Eq 2) generates a reward for each round in the form of regret increment, for the purpose of minimizing the accumulated regret. For RACING, the reward is designed to guide the selection of the action that maximizes the differentiating power on predetermined predicates: that is, the seed selection or the mutation method that maximizes the difference among these predicates' estimated contributions to the crash. To this end, our RL technique rewards the action that maximizes the combined effect of CoR that changes the estimated order of the predicates, and CoP that causes the violation of the predicates on the instructions encountered, based upon our analysis in Section 3. Specifically, our reward G_t for the round t is defined as follows:

$$g_t = g_t^{order} + g_t^{count} \tag{3}$$

where g_t^{order} is the order change measured by the normalized KTD [28] between the estimated order before and after the round t, and g_t^{count} is the ratio of the predicates being violated during the program's executions in that round.

Action for seed selection. An action of our RL technique is selection of a seed for fuzzing the target program. The seed here is an input to the program, which is used to produce other input samples through mutating the input. To choose the input that stands the best chance to help maximize the reward for the next fuzzing round, we first organize all the input samples that have been evaluated so far into groups, according to the predicate-carrying instructions the execution on each input has encountered: each group corresponds to one such instruction, including all the inputs whose executions go through the instruction; every input tends to be affiliated with multiple such groups. Each group is associated with a *value* that is the average of all the rewards generated by its members. To select a seed, our approach first chooses the group with the highest value, and then picks from the group an input most likely to produce a CoP violating the predicate of the instruction associated with the group (see Section 4.2). This input is then used as the seed for generating other input samples.

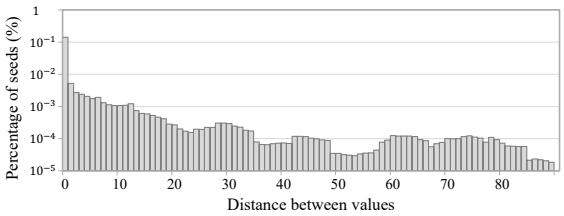

Figure 1: Distribution of distance.

Action for mutation selection. After selecting a seed, our approach takes further actions to choose a location (which byte on the input) and an operator for mutation, which are then applied to the seed to generate other input samples. Again, both the location and the operator are selected based upon their values – the average reward they have generated so far. For locations, we only gather rewards gained by mutating the top 2,000 bytes of an input and use RL to determine the probability of choosing them. For the bytes after the first 2,000, they might be selected only when the RL is in the exploration mode (random sampling). Here, 2,000 is selected experimentally (see details in Appendix A.2). For operators, RACING utilizes 16 different operators in 3 categories: insertion, modification, and deletion of some bytes on the seed. For instance, we may flip one bit on the seed, insert bytes with pre-defined tokens into the seed, etc. The full list of these operators can be found in Table 6 (see Appendix A.3).

4.2 Optimizing CoP Generation

Based on our analysis in Section 3.2, RCA could be accelerated by increasing the probability of generating CoPs that amplify the distance between the true values of the statistic for a root-cause predicate and that for a non-root-cause predicate. For a predicate `eax<=z`, CoPs are testing inputs on which non-crashing executions would assign `eax` values no more than z while crashing executions would assign `eax` values larger than z. Thus, to find CoPs, we need to generate the input sample whose execution causes the value of `eax` to fall within or beyond a boundary. To study how to generate such inputs with a high probability, we look into the relationship between a seed and the inputs generated from it.

The nearer the better. Comparing the value generated by the execution on a seed for a predicate and that produced on the input mutated from the seed, we found that they tend to be similar. Figure 1 shows the distribution of the distance

Table 1: Transferabilities between crash and non-crash inputs.

	Crash (to)	Non-Crash (to)
Crash (from)	54.73%	45.27%
Non-Crash (from)	0.01%	99.99%

between such sample values (defined in Section 2) of predicate, across all predicates within all programs (Table 2) we analyzed. As we can see, such a distance is very likely to be small: actually the probability becomes higher when the values become more similar. As a result, to generate the test cases more likely to produce the target value for a predicate, we should use the seed that leads to the predicate value as close to the target as possible. Based on the analysis, we can obtain the CoPs effectively from those "in-range" seeds: taking the predicate `eax<=z` as the example, those non-crash inputs but making `eax<=z` satisfied are more likely to generate CoPs of this predicate.

Transferability between crash and non-crash input. Besides the distance, we also look into the relationship between crash inputs and non-crash inputs. Table 1 illustrates the transferabilities between these two kinds, which are averaged among values gained from all programs we studied. From the table, we can see that, compared with crash inputs, the non-crash inputs, once used as seeds, are more likely to generate non-crash inputs with almost negligible probability to produce crash inputs. Besides from non-crash inputs, there are about half-to-half probabilities to produce crash and non-crash inputs respectively from crash inputs.

Optimizing seed selection. Considering both the distance and transferability, to generate CoPs for the predicate `eax<=z`, a good choice of seeds is the non-crash inputs making `eax<=z` satisfied. If no such non-crash inputs, a crash input making `eax<=z` satisfied would be also a good choice. In practice, to generate CoPs of a "`<=z`" predicate, we utilized the above strategy to set the seed as an available (not being chosen before) non-crash input, or a crash input if no such non-crash inputs, on which the execution will assign the smallest value to the operand of this predicate. Similar strategy is used to choose the seed for generating `>z` predicates' CoPs.

Root cause towards end. Our strategy increases the probability of generating CoPs for predicates. However, it is unclear whether our strategy would promote those non-root-cause predicates wrongly be ahead of root-cause predicates. To understand that, we investigate the relationship between thresholds of root-cause predicates and that of non-root-cause predicates. Respectively for `<=z` and `>z` predicates (see definitions in Section 2), we draw their thresholds' distributions on Figure 2a and Figure 2b. Figure 2a demonstrates that the thresholds of those `<=z` predicates crowd on small values, and the smaller the value, the greater the likelihood that it is the threshold of `<=z` predicates, regardless of root-cause or non-root-cause. Specially, the thresholds of root-cause predicates are more likely to be small values compared with that of non-root-cause predicates. Figure 2b demonstrates that there are two crowds (peaks) of threshold's values: one nears 2^{32} and another is bigger than 2^{50}, in the distribution of `>z` predicates' thresholds. We attribute the present of the first crowd (nears 2^{32}) to 32-bit operands used in a part of predicates, and similarly attribute the present of the second crowd ($> 2^{50}$) to 64-bit operands used in the rest predicates. In both two crowds, root-cause predicates exhibit a greater preference for using a large value as their threshold than non-root-cause predicates (where the red solid line is above the blue dash line). Based on the above results, we conclude that the thresholds of root-cause predicates are more likely extreme values (the smallest or the largest values) compared with that of non-root-cause predicates. Therefore, for `<=z` predicates, the thresholds of the root-cause predicates are, with high probability, smaller than that of non-root-cause predicates, and the probability of generating a CoP, on which executions would assign the operand with values smaller than the threshold, for the root-cause predicate is smaller than the probability of generating such CoPs for non-root-cause predicates, even though these probabilities all has been amplified by our strategy. And a consistent conclusion could be drawn for `>z` predicates.

(a) $<= z$ predicates. (b) $> z$ predicates.

Figure 2: Distribution of predicates' threshold.

4.3 RACING Algorithm

Algorithm 1 illustrates RACING, which takes a program *Prog* and a *PoC* leading to a crash as inputs to generate top-50 predicates mostly related to the crash and the order of their contributions r^*. Here we describe each RACING function:

Select_Action. This function returns a distribution d_t over all possible actions. Since there are two types of actions, selection of seed and selection of mutation, as mentioned earlier, this function outputs a pair of distributions $d_t = (d_{t,seed}, d_{t,mutate})$ over $N_a = (N_{a,seed}, N_{a,mutate})$ number of actions. Specifically, the distribution for seed selection $d_{t,seed}$ is built upon the average rewards for all $N_{a,seed}$ groups:

$$d_{t,seed}(i) = \frac{\exp(avg(i))}{\sum_{j=1}^{N_{a,seed}} \exp(avg(j))}, \tag{4}$$

where $d_{t,seed}(i)$ is the probability of choosing the group i, and $avg(j)$ is the average reward for the group j. This distribution

Algorithm 1: RACING algorithm

Input: Program *Prog*, and a Proof of Concept *PoC*.
Result: Top-50 predicates and their true order r^*.

```
begin
    S_0 = [], γ_0 = 0.5, t = 1
    do
        d_t ← Select_Action(S_{t-1})
        a_t ← Sample_Action(d_t, γ_t)
        {input} ← Generate_Input(a_t)
        {(e_i, p_i)} ← Run(Prog, {input})
        r_t ← Rank({(e_i, p_i)})
        g_t ← Compute_Reward({(e_i, p_i)}, S_{t-1})
        S_t ← Update_State(S_{t-1}, r_t, g_t, {(e_i, p_i)})
        γ_t ← Update_Gamma({g_i}, {d_i}, {a_i})
    while (! Converge(S_t))
    {p_i}_50, r* ← select top-50 p_i according to r_t
    return {p_i}_50, r*
end
```

is biased toward the groups with high average rewards. The distributions for mutation selection $d_{t,mutate}$ are constructed in a similar way, based upon the average rewards of the mutation locations and 16 mutation operations.

Sample_Action. This function randomly draws an action a_t from the distribution d_t, according to an exploration probability γ_t. The γ_t is used to balance exploitation and exploration, with a probability of 1-γ_t for exploitation and γ_t for exploration. Similar to d_t, $\gamma_t = (\gamma_{t,seed}, \gamma_{t,mutate})$. Specifically, for selecting a seed in each round, the probability of choosing the i-th input group as the seed is $d'_{t,seed}$(i), formally, it is:

$$d'_{t,seed}(i) = (1-\gamma_{t,seed})d_{t,seed}(i) + \frac{\gamma_{t,seed}}{N_{a,seed}}, \tag{5}$$

and the probability of choosing the mutation i is $d'_{t,mutate}(i)$, which is adjusted under the exploration probability $\gamma_{t,mutate}$ using the similar equation to Eq 5. Within the chosen input group (seed), we further identify the input sample most likely to produce a CoP, as mentioned earlier (Section 4.2). In this way, RACING identifies for the round t the joint action $a_t = (a_{t,seed}, \{a_{t,mutate}\})$, where $a_{t,seed}$ is the seed and $\{a_{t,mutate}\}$ is a set of the mutations sampled according to $d'_{t,mutate}$.

Generate_Input. This function returns a set of input samples $\{input\}$ by applying sampled mutations $\{a_{t,mutate}\}$ on the seed $a_{t,seed}$.

Run. This function executes the program on the selected test-case inputs and updates the statistics for each predicate encountered by the execution. Also based upon the statistics, our approach further adjusts the predicate as Aurora does [12] (also see Algorithm 2 in Appendix A.1). This update process has a time complexity $O(n_i)$ if there are n_i samples in total for the predicate p_i. In general, this function updates each predicate p_i and gathers all samples on p_i throughout all fuzzing rounds to form the set e_i.

Rank. This function returns the order r_t of all current estimates $\{\tilde{s}_i\}$. Each $\tilde{s}_i$ is updated concurrently with the predicate p_i based on the sample set e_i obtained in the round t.

Compute_Reward. This function generates the reward for this round according to Eq 3. Particularly, our approach utilizes the normalized KTD to calculate g_t^{order}, which is also normalized to a value in $[0,1]$ (simply dividing it by 2).

Update_State. This function updates the information for action selection, particularly the average reward $avg(i)$ for each seed group and the average award for each mutation, based upon the new award received.

Update_Gamma. This function adjusts $\gamma_t = (\gamma_{t,seed}, \gamma_{t,mutate})$ to balance exploration and exploitation efforts. Specifically, we update $\gamma_{t,seed}$ as follows ($\gamma_{t,mutate}$ is updated similarly):

$$\gamma_{t,seed} = \frac{N_{a,seed}}{2N_{a,seed} + \sum_{i=1}^{t} \Gamma_i(\gamma_{i-1,seed})}, \quad \text{where} \quad \Gamma_i(\gamma) = \frac{\gamma * g_i}{(1-\gamma) * d_{i,seed}(a_i) + \gamma / N_{a,seed}}. \tag{6}$$

Here Γ_i function computes the contribution of the current exploration strategy to the reward received in the round i. In our research, we utilized a monotonously decreasing function to let γ_t decline with the growth of the information gathered from prior rounds: the higher the rewards in the prior rounds can be attributed to exploitation, the faster the γ_t decreases.

Converge. This function checks whether the ranking list $[r_i]$ estimated in each round converges. Specifically, our approach calculates the KTD between the orders in two consecutive rounds to get a distance list $[KTD(r_1,r_2), ..., KTD(r_{t-1},r_t)]$. Then, we measure the variance of the last several $(\min(10,t))$ distances on the list. If this variance is smaller than a threshold (0.01), we conclude that the order list has converged and exit the loop. Here, 10 is a value found in our experiments that can improve analysis performance. Additionally, we only calculate the distance for the top-k ($k = 100$) predicates in the list. As Table 3 column T_{top100} shows, all root causes we studied have been elevated to the top-100, and the vast majority of them are moved up within a short period of time (in 3 minutes for 26 out 30 root causes).

4.4 Implementation

To implement RACING, we combine our reinforcement learning algorithm with AFL [51] algorithm that is customized accordingly, as well as cooperate with the code instrumentation techniques to record values (samples) produced for each instruction (predicate) during fuzzing the given program.

AFL customization. In RACING, the fuzzer is modified from AFL through replacing its strategies for seed selection and mutation with our own (Section 4.3).

Code instrumentation. Since the root cause of a vulnerability is inherently linked to the instructions executed by the Proof of Concept (PoC), to reduce the unnecessary cost, we only instrumented a code fragment following each instruction in the PoC's execution trace to record the assigned values and the control-flow transitions during the execution of test cases.

Table 2: Vulnerability information for evaluating RACING.

Existing binary instrumentation tools have limited capabilities, such as instrumenting limited lines of code or taking a considerable amount of time. Hence, we instrumented code using the following way: we execute the PoC with the help of IntelPIN [24] to obtain the binary code addresses of the PoC's execution trace at first; then, we use add2line [1] to locate source code corresponding to those addresses; finally, we create a custom LLVM Pass, an LLVM plugin, to insert a logging handler (triggering the recording of the assigned values to the target operand in an instruction as well as control-flow transitions) after each LLVM instruction in the Intermediate Representation of those located source code. In this way, the instrumented binary code has been included in the executable program compiled by the LLVM.

5 Evaluation

5.1 Setting

Environment. All experiments were conducted on a 64-bit Ubuntu 20.04 server with 32 Intel Xeon(R) Silver 4110@2.10 GHz CPU cores, 128 GB memory, and a 22 TB hard drive.

Vulnerability. We use 30 vulnerabilities to evaluate RACING, as illustrated in Table 2, including 19[1] from Aurora [12] (V_1-V_{19}) and 11 more collected ourselves in the real world (V_{20}-V_{30}). The 30 vulnerabilities were found in 21 programs varying in volumes, ranging from 857 to 980,019 lines of source code. These vulnerabilities cover 9 distinct types of common software vulnerabilities, including integer overflow, heap buffer overflow, stack buffer overflow, use after free, double free, divided-by-zero, nullptr dereference, type confusion, and uninitialized variable. Moreover, the level of complexity for each vulnerability is also diverse, which can be approximated by its number of distinct instructions of each PoC's execution trace, as illustrated in Table 2. The simplest vulnerability V_{21} in an XML parsing library, named ezXML, contains 453 distinct instructions in its PoC's execution trace, while the most complex one V_{17} of Python contains 49,689. Notably, when a program cannot be directly crashed by the PoC, we leverage the Address Sanitizer (ASAN) [38] or Memory Sanitizer (MSAN) [40] to compile the program and capture the exceptions to trigger a crash.

[1]The remaining 6 vulnerabilities in Aurora data set cannot be reproduced, so we only consider the 19.

Table 3: Evaluation result of RACING

Note: The time duration is given in the format `hours:minutes:seconds`.
blue: better result, red: worse result, green: equal result.

Ground truth. In order to obtain the ground truth, we found it from the vulnerability's patch. Specifically, we manually studied the 30 vulnerabilities' patches. The vast majority of patches (76.67%) consist of no more than ten lines of modified code, and even 11 patches are within three lines of modified code, making it easy to determine the root cause. For the remaining complex patches, which may be related to multiple files and contain a large number of modified lines, we referred to the vulnerability report, if any, and manually inspected the vulnerability with a debugger to determine a reasonable ground truth. Table 2 illustrates the file name and the number of line in which the root cause is located. Additionally, we provide an example in the appendix to illustrate how the ground truth is determined (see details at Appendix A.5).

5.2 Results

RACING is designed based on the classic statistics-based RCA framework, but uses counterexamples for RCA acceleration. In the evaluation, we answer the following research questions:

- **RQ1:** How does the effectiveness of RACING compare to current works for locating root causes?
- **RQ2:** How much does RACING improve efficiency?

To answer these questions, we compared our result to Aurora [12], the state-of-the-art work for identifying predicate-level root causes. Table 3 presents the evaluation result. As illustrated in Table 3, all 30 root causes were identified within top-50 by RACING, including 73.33% (22) in the top 10, 33.33% (10) in the top 3, and 4 even at the top spot. Comparatively to Aurora, we have 6 root causes of vulnerabilities (colored in green in the *Ranking* column of Table 3) receiving the same rankings as Aurora, yet, 14 (46.67%) root causes are ranked even higher by RACING than Aurora (colored in blue in Table 3). For instance, V_9 was identified by RACING with a ranking of 20, whereas Aurora gave it a ranking of 58, which is not only significantly lower but also outside the top 50, meaning an expert has to put in much more effort to check the actual root cause. On average, the rankings obtained by RACING for these vulnerabilities' root causes are 3.80 positions higher than those obtained by Aurora. This result is reasonable. Even though Aurora spends a large amount of time (e.g., 12 hours) to generate testing set, nobody knows whether the randomly generated data set is statistically adequate. Our approach, RACING, not only attempts to generate counterexamples to aid in the accurate ranking of predicates, but also uses a termination strategy to determine whether the testing set is sufficient to identify the root cause. Therefore, we have better rankings than Aurora for some vulnerabilities' root causes. Of course, due to the random nature of fuzzing in practice, 10 root causes are ranked lower than Aurora by

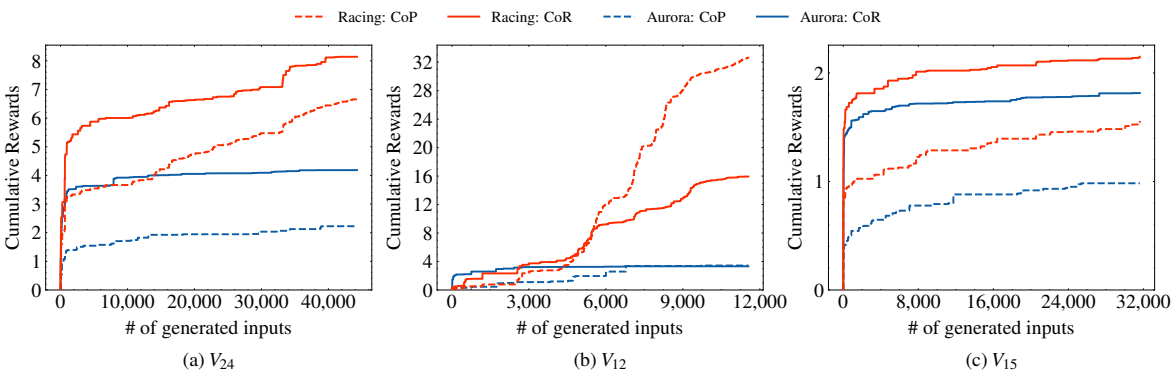

Figure 3: Comparison between RACING and Aurora on CoP and CoR generation.

RACING (colored in red in Table 3). However, the maximum ranking difference for the same root cause is 9 positions, with an average difference of 5.80 positions. Considering, except V_3 with a ranking of 28 and V_{17} with a ranking of 33, all of them are in the top 20, we deem these lower rankings acceptable. Overall, RACING possesses the same efficacy as existing works for locating root causes, which concludes **RQ1**.

To evaluate the efficiency improvement of RACING, we first compare the total time cost (T_{all}) by RACING and Aurora to perform RCA. Notably, Aurora includes two separate steps to analyze root causes. It uses AFL to generate the testing set with $T_{fuzzing}$ time and then $T_{analysis}$ time to determine each predicate's ranking. Particularly, when Aurora generates less than 100 test cases in 2 hours, it will take an additional 10 hours to collect a larger testing set. Unlike Aurora, in RACING, the test case generation and the ranking computation are performed successively in each round (see Algorithm 1). As shown in the *Speedup* column in Table 3, RACING identified each root cause significantly faster than Aurora, with a minimum increase of 1.15x for V_{18} and a maximum increase of 602.42x for V_{21}. Specifically, RACING identified 86.67% (26) root causes in 1 hour, 80.00% (24) in 30 minutes, 56.67% (17) in 10 minutes, and 13.33% (4) even in 1 minute (e.g., 15 seconds for V_{20} and 12 seconds for V_{21}). On average, RACING required approximately 27 minutes to identify the root cause, whereas Aurora required approximately 6 hours, a 13.22x reduction. Figure 4 illustrates the detailed distribution of RACING over Aurora based on speed multiples. One may question whether Aurora wastes time in the later period generating test cases. To figure it out, we examined the earliest time the root cause received the same ranking as its final ranking (denoted by $T_{ranking}$) during the test case generation in Aurora. The results indicate that Aurora did waste a great deal of time generating more test cases even though the root causes could be identified with a relatively high ranking. For instance, V_2 ranked first in the data set generated in 15 minutes by Aurora, but Aurora used 12 hours to collect more test cases to analyze it. Nevertheless, RACING performs better. It takes only 51 seconds to rank the root cause of V_2 number one. On average, the root causes obtained the same ranking as their final rankings in about 2 hours in the Aurora-generated testing set, whereas RACING could allow the root causes to receive the same ranking as their final rankings in around 14 minutes. This comparative study demonstrates that RACING can expedite the process of predicates obtaining their final rankings. Moreover, we checked the rankings of root causes in Aurora at the end time of RACING (see *Ranking** in Table 3). 83.33% (25) root causes are ranked lower than those computed by RACING, which once again demonstrates the efficiency of RACING. Therefore, we conclude **RQ2** that RACING has significantly improved efficiency compared with existing works on root cause analysis.

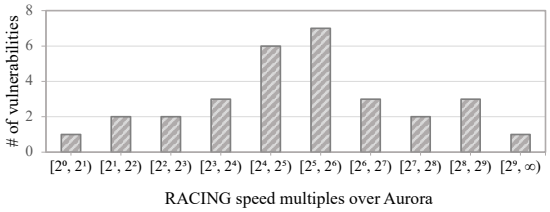

Figure 4: RACING speed multiples' distribution over Aurora.

In addition, to evaluate whether RACING actually generates counterexamples, i.e., whether a counterexample affects more predicates and whether an input results in a larger change in order, we compare RACING to Aurora using three selected vulnerabilities whose root cause was identified within 10 minutes (V_{24} in 2 minutes and 20 seconds), 30 minutes (V_{12} in 23 minutes and 17 seconds), and more than 30 minutes (V_{15} in 46 minutes and 52 seconds). Specifically, for each generated input, we counted what is the percentage of predicates this input is the counterexample (CoP) for and how much KTD (see Section 4) this input causes, which indicates the change in the order (CoR). As shown in Figure 3, the lines for CoPs and CoRs in the Aurora testing set rise very slowly, except at the beginning, demonstrating that fewer CoPs and CoRs have been generated by Aurora due to their blind test case generation method as we analyzed in Section 3. How-

Table 4: Result of ablation studies.

Note: The time duration is given in the format `hours:minutes:seconds`

	V_{24}		V_{12}		V_{15}	
	Time	**Ranking**	**Time**	**Ranking**	**Time**	**Ranking**
RACING (reward: CoR + CoP)	00:02:20	3	00:23:17	4	00:46:52	39
RACING (reward: CoR)	00:14:14	3	00:33:43	4	01:51:03	39
Aurora	02:07:27	10	02:12:15	6	14:00:14	47
RL + top 100	00:09:02	3	00:40:35	4	01:10:21	39
RL + optimizing + top 100	00:02:20	3	00:23:17	4	00:46:52	39
RL + optimizing + top 300	00:45:47	3	01:07:48	4	01:23:25	39
RL + optimizing + top 500	01:57:15	4	02:07:39	5	04:57:22	39

ever, the lines for CoPs and CoRs in the testing set generated by RACING rise rapidly and continuously, indicating that the inputs are successfully generated by RACING, resulting in more predicates affected and greater order changes than Aurora. Especially, for V_{15}, RACING generates significantly more CoPs and CoRs from the beginning to the end. Combining the *Ranking** of V_{24}, V_{12}, and V_{15} in Table 3, which are all lower than the rankings computed by RACING at the end of RACING's analysis time, this result again demonstrates the effectiveness of counterexamples (CoPs and CoRs) for estimating the accurate rankings of predicates.

5.3 Ablation Study

As stated in Section 4.1, the reward is comprised of the combined effect of CoRs and CoPs. To evaluate their utilities in the reward, we conducted an ablation study by removing the CoP from the reward and setting $g_t = g_t^{order}$ in RL, based on three selected vulnerabilities in the evaluation (V_{24}, V_{12}, V_{15}). As shown in Table 4, the result demonstrates that CoRs alone can assist in identifying the root cause with a higher ranking in a shorter time, increasing 8.95x for V_{24}, 3.92x for V_{12}, and 7.57x for V_{15} in comparison to Aurora. Furthermore, CoRs and CoPs together can further cut down the analysis time.

Besides using reinforcement learning to guide the fuzzer, RACING also includes an optimizing method to generate CoPs (Section 4.2), and always focuses on top 100 predicates to avoid wasting time on those ranked below 100. Therefore, we conducted additional ablation studies to evaluate their utilities in RACING, again based on V_{24}, V_{12}, V_{15}. The result is presented in Table 4. The 5th row labeled "RL+optimizing+top 100" indicates the result of RACING.

To evaluate the optimizing method, we replace it with a random method selecting an input on which execution goes through a given instruction at random. The result demonstrates that the optimizing method enables the order to be converged more rapidly to locate the root cause. Specifically, the optimizing method is around 17 and 23 minutes faster than the random selection when analyzing V_{12} and V_{15}, respectively. And for analyzing V_{24}, the optimizing method takes only 2 minutes and 20 seconds, whereas the random selection takes 9 minutes and 2 seconds, which is nearly 4 times longer. Moreover, to figure out whether the optimizing method generates the CoPs as anticipated, with a higher probability of generating counterexamples for a given predicate than random selection, we compared the average percentage of successfully generated CoPs for both methods. We found that with the help of the optimizing method, we generated CoPs with an average probability of 0.35% (=158/44,266) on V_{24}, 3.99% (=461/11,554) on V_{12}, and 0.18% (=58/31,614) on V_{15} while generating inputs, whereas using the random selection, the probability reduces to 0.09% (=227/253,062) on V_{24}, 1.37% (=388/28,364) on V_{12}, and 0.09% (=84/89,837) on V_{15}. This result indicates that our optimizing method is more likely to produce counterexamples for given predicates.

To evaluate how well the k is configured, we set two more values 300 and 500 to k. As illustrated in Table 4, as the value of k increases, the ranking of the root cause almost does not change, but the termination time increases significantly. Taking V_{24} as an example, RACING ($k = 100$) has spent 2 minutes and 20 seconds locating the root cause, whereas the time cost multiplies 20fold (45 minutes and 47 seconds) when $k = 300$ and even 50fold (1 hour and 57 minutes) when $k = 500$. This result is reasonable, because a larger k indicates that more time is needed to generate counterexamples for more predicates. Also, this result demonstrates that setting $k = 100$ is sufficient, since RACING can locate the root cause with the same ranking as when k is set with a larger value.

6 Discussion

Limitation. Below, we illustrate the limitations of RACING that managed to rank the root cause of vulnerabilities, as demonstrated in our experiments, at the very top in a short time. There are still some root causes failed to be ranked at the first by our RACING due to two reasons: 1) RACING failed to generate counterexamples that can lower the ranks of those predicates falsely ranked at the top. 2) some executions (coincidentally correctness) making the root-cause predicate satisfied however exit normally. These two reasons reveal the limitations of RACING in discovering a comprehensive set of counterexamples and dealing with coincidentally correctness.

Also, our current implementation of RACING relies on the program's source code for code instrumentation, limiting the application of our tool on those programs without the source code. However, this implementation (our code) is readily expandable if a more comprehensive and potent binary code instrumentation tool becomes available in the future.

Additionally, predicates could be classified into atomic predicates (e.g., `x<=10`) and compound predicates (e.g., `x<10 AND y>=8`). Currently, RACING only takes the first step to deal with atomic predicates. It lacks the support for compound predicates, which account for *less than half* of the vulnerabilities[2]. However, the idea of RACING can be straightforwardly extended to handle compound predicates because they still have counterexamples like `x>=10 OR y<8` for `x<10 AND y>=8`, and RL can be used to generate such counterexamples. Specifically, the design of RACING's reward mechanism (Eq 3) as well as the actions for seed and mutation selection (Eqs 4,5,6) can be directly used, with non-trivial adjustments to the construction of (compound) predicates and customization on the optimization strategy for CoP generation. To estimate the likely cost of RACING to support compound predicates, we developed a prototype called RACING$^+$ to support a simple type of compound predicate by combining two atomic predicates using the logical operator "AND" (`A AND B`) and tested it on two vulnerabilities (see details at Appendix A.4). In order to understand RACING$^+$'s ability, we additionally modified the computational component of Aurora (called Aurora$^+$) to handle the same type of compound predicate. As shown in Table 7 in Appendix A.4, RACING$^+$ accelerates over Aurora$^+$ by an average of 6.58x, while still identifying the compound root causes within its top-50, surpassing Aurora$^+$ in terms of ranking. These preliminary results indicate the potential of RACING for effectively supporting compound predicates in future endeavors.

Future work. We attribute the sluggishness of current RCA techniques to their employed biased sampling method raised from the crash centered fuzzing. Our research steps forward to overcoming this bias through incorporating with counterexamples. Along this path, further efficient RCA methods working with balanced sampling methods are anticipated in the future. Especially, working with an unbiased fuzzer is promisingly effective for RCA.

7 Related Work

Spectrum-based fault localization. Spectrum-based fault localization (SFL) technique is a statistically-based automated cause analysis method. Based on a testing set containing both crash and non-crash inputs, the SFL technique estimates the statistical correlation between each program entity (such as a statement, block, or predicate) and crash, and outputs the highly correlated entities in rank order as potential root causes. The majority of SFL research focused on designing statistical quantities, including ranking metrics [6, 15, 25, 34, 37, 43] and distribution statistics [8, 10, 31, 32]. Different from them, our work is not focused on the improvement of statistics metrics. We are concentrating on the generation of the testing set. The metric we used in RACING is mutual information, which is proposed by DeFault [52], one of the most recent SFL studies. There are some SFLs that have provided strategies to improve the testing suite [6, 11, 22, 49]. To evaluate a test case, Baudry *et al.* proposed a testing criterion called Dynamic Basic Block [11]. Hao *et al.* proposed three strategies for reducing the number of test cases based on their capability [22]. Abreu *et al.* contend, based on an experimental study, that a greater number of crash inputs results in greater effectiveness [6]. Yu *et al.* eliminates the test cases that have no impact on the ranking performance [49]. All of them, however, improve the testing suite on an existing data set. In contrast to them, we generate test cases dynamically based on our strategies to construct the testing set, and our evaluation demonstrates the efficacy and efficiency of the test generation method.

Non-statistical RCA. Non-statistical RCA strives to identify the root cause of certain vulnerability types through detailed and precisely formulated rules. Typical non-statistical RCA solutions [14, 23, 46, 47] employ program analysis techniques (e.g., data flow analysis, symbolic execution) to verify the program entities against manually crafted rules and uncover potential root causes. However, such analysis rules are often specific to certain vulnerability types, limiting their broader use. Among these solutions, FreeWill [23] can diagnose only 1 vulnerability type (use after free), while Bunkerbuster [46] supports the most with 6 vulnerability types, but it still cannot handle types such as uninitialized variables, type confusion and nullptr dereference in our dataset. Moreover, most non-statistical RCA faces inherent limitations associated with program analysis techniques, such as the high computational overhead of data flow analysis and program slicing [14], as well as scalability issues in symbolic execution [46,47]. Given that Bunkerbuster [46] supports the most vulnerability types, we ran it on 21 vulnerabilities it covers in our dataset. We found that 20 out of 21 aborted early due to problems like memory exhaustion, with only 1 successful case taking nearly 13 hours, which is almost 300 times longer than the execution time of RACING or 6 times longer than that of Aurora. Overall, compared to non-statistical RCA methods, statistical RCA methods have broader applicability and better efficiency.

Fuzzing. Fuzzing techniques have led to a tsunami of security vulnerability discovery and elimination through automatically and quickly funding abundant crashes. In the early days of fuzzing, random selection and mutation of seed were used to generate new inputs for testing programs [20, 35]. In order

[2]Since no previous studies have investigated this specific proportion, we randomly selected 20 vulnerabilities from Defects4J [26], a real-world fault dataset widely used for benchmarking fault localization, and found that 45% of the root causes were compound predicates.

to conduct more exhaustive testing, modern fuzzing typically employs heuristic strategies to guide exploration [29, 33, 51]. The coverage-guided fuzzing is one of the most popular techniques, such as AFL [51], which increases the likelihood of discovering more vulnerabilities by increasing code coverage. Current statistics-based RCA works, such as Aurora [12], DeFault [52], directly employed AFL to generate a testing set. However, as we analyzed in Section 3, such a generation process is time-consuming. Our approach, RACING, modified AFL's seed selection and mutation strategies to make the fuzzing process more suitable for efficient root cause analysis. In addition, recently, many researchers use reinforcement learning to enhance the fuzzing process. For example, Woo et al. [44] use the number of crashes as a reward function to find the greatest number of unique bugs in a fuzzing campaign. Yue et al. [50] proposed EcoFuzz, which uses the adversarial MAB algorithm to solve the seed energy allocation problem. AFL-HIER [41] chooses UCB1 [9], one of the MAB algorithms, to solve the seed scheduling problem under fine-grained coverage metrics. These works have demonstrated the effectiveness of reinforcement learning applied in fuzzing. However, the purpose of these works is to find more vulnerabilities, whereas the reinforcement learning in RACING is to learn how to generate more CoPs and CoRs for efficient root cause analysis.

8 Conclusion

In this paper, we introduced our reinforcement learning (RL) based approach, RACING, to elevate the scalability and accuracy of today's statistical RCA. Compared to previous works that generate the input samples more likely causing the crash, RACING harnesses our new observation that by sampling around "counterexamples" causing significant changes to the current estimates of correlations, suspicious program elements can be more effectively differentiated, thereby accelerating the RCA performance. Our evaluation on 30 real-world vulnerabilities demonstrates the efficiency and effectiveness of RACING: it successfully elevated all 30 root causes to the top (within the top-50) within half an hour in average, which is significantly faster than the state-of-the-art method of SFL that could take more than twelve hours for RCA, thereby speeding up the RCA process by more than an order of magnitude and elevating its effectiveness in locating the root-cause of vulnerabilities.

A APPENDIX

A.1 Predicate Construction

Following Aurora [12], our research focuses on three types of predicates. Below we elaborate on the details of their union form transformation and threshold selection.

Union form transformation. All three predicate types follow a union form `Var op Thr`. For register and memory predicates, `Var` is the destination operand of an instruction, `op` could be <= or > and `Thr` is an integer chosen dynamically (see below). For flag predicates, `Var` is the flag bit of interest, `op` is > and `Thr` is 0. For control-flow predicates, there are two primary types: the execution of an edge and the number of executed successors for nodes. For each edge `x->y` connecting the node `x` and `y` in the CFG, an additional variable $\texttt{count}_{\texttt{x->y}}$ is maintained to track the number of times the edge has been executed during one execution of the program. In this scenario, `Var` is the variable $\texttt{count}_{\texttt{x->y}}$, `op` is > and `Thr` is 0. Similarly, for each node `x`, an additional variable $\texttt{successor}_{\texttt{x}}$ is created to store the number of its successors that have been executed during one execution of the program. In this scenario, `Var` is the variable $\texttt{successor}_{\texttt{x}}$, `op` is > and `Thr` is either 0, 1 or 2.

Threshold selection algorithm. Both flag predicates and control-flow predicates have a limited number of predefined thresholds. Conversely, the threshold of register and memory predicate can encompass tens of thousands of possible values. Evaluating each potential value is computationally impractical in real-world scenarios. To address this challenge, Algorithm 2 is employed to dynamically update the threshold, ensuring it is linked to the best estimate of the mutual information so far.

Algorithm 2: Threshold selection

Input: m_i sample values $\{v_1, v_2, \ldots, v_{m_i}\}$ in ascending order for a predicate p_i on n_i inputs $\{e_{i1}, e_{i2} \ldots, e_{in_i}\}$.
Result: The updated predicate p_i' and its statistic $\tilde{s}_i$.

```
1  begin
2      s̃_i = 0, C_t = 0, N_f = 0
3      for j ← 1 to m_i do
4          C_t = C_t + CrashSamples(v_j)
5          N_f = N_f + NonCrashSamples(v_j)
6          s̃_i' = Compute_MutInf(C_t, N_f, C_a, N_a)
7          if s̃_i' > s̃_i then
8              s̃_i = s̃_i'
9              if C_t > C_a − C_t then
10                 p_i' ← Var<=v_j
11             else
12                 p_i' ← Var>v_j
13     return (p_i', s̃_i)
```

Concretely, given m_i sample values $\{v_1, v_2, \ldots, v_{m_i}\}$ for a predicate, it tries to use each v_j in ascending order (line 3-12) as the threshold, computes its mutual information with the crash (line 6), and updates the predicate's threshold `Thr` if a new value v_j yields higher statistic than previous ones (line 7-12). To evaluate the predicate's mutual information on the fly, we maintain two counters, C_t and N_f, which represent the number of crash inputs that satisfy the current predicate at v_j, and the number of non-crash inputs that violate the predicate at v_j, respectively. In each step, we increment C_t with the number of crash samples for v_j, and N_f with the number of non-crash samples for v_j (lines 4-5). With C_t, N_f, C_a (the total number of crash inputs), and N_a (the total number of non-crash inputs), we can obtain the number of crash inputs that violate the predicate via $C_f = C_a - C_t$, and the number of non-crash inputs that satisfy the predicate via $N_t = N_a - N_f$. We then evaluate the mutual information I (Eq 7) between X (predicates) and Y (crash or non-crash) using Eq 8.

$$\begin{aligned} I(X;Y) =& H(Y) - H(Y|X) \\ =& -\sum_{y\in\{0,1\}} Pr(y)\log_2 Pr(y) \\ &+ \sum_{x\in\{0,1\}} Pr(x) \sum_{y\in\{0,1\}} Pr(y|x)\log_2 Pr(y|x) \end{aligned} \tag{7}$$

$$\begin{aligned} Pr(x=1) &= \frac{C_t+N_f}{C_a+N_a},\ Pr(x=0) = \frac{C_f+N_t}{C_a+N_a} \\ Pr(y=1) &= \frac{C_a}{C_a+N_a},\ Pr(y=0) = \frac{N_a}{C_a+N_a} \\ Pr(y=0|x=0) &= \frac{N_t}{C_f+N_t},\ Pr(y=1|x=0) = \frac{C_f}{C_f+N_t} \\ Pr(y=0|x=1) &= \frac{N_f}{C_t+N_f},\ Pr(y=1|x=1) = \frac{C_t}{C_t+N_f} \end{aligned} \tag{8}$$

Ultimately, the value v_j with the highest statistic is chosen as the predicate's threshold `Thr` (line 13). Note that when <= covers more crash inputs than >, the predicate's `op` is <= (line 9-12). Otherwise, it is >.

A.2 Determination of exploitation set of location for mutation

In our dataset, the inputs of several vulnerabilities are extremely long. Such inputs require a more extensive payoff table for determining the optimal locations in RL, thereby increasing computational costs. To minimize the cost to obtain higher rankings for the root causes, we only exploit a certain number of head bytes of an input with RL with the remaining bytes randomly selected. Testing values from 500 to 3,000 on three vulnerabilities with long inputs (V_{22} with 2,036 bytes, V_{25} with 4,170 bytes, V_{29} with 31,248 bytes), we found that 2,000 bytes allow RACING to achieve the highest rankings with the lowest time costs, as shown in Table 5. Therefore, we only gather rewards for the top 2,000 bytes of an input (see Section 4.1).

Table 5: Evaluation of varying byte numbers.

Note: The time duration is given in the format `hours:minutes:seconds`

#Bytes	V_{22}		V_{25}		V_{29}	
	Ranking	**Time**	**Ranking**	**Time**	**Ranking**	**Time**
500	3	00:00:30	1	00:03:54	9	01:08:18
1,000	2	00:00:33	1	00:03:16	8	00:43:36
2,000	1	00:00:40	1	00:02:32	7	00:25:58
3,000	1	00:00:45	1	00:02:59	7	00:36:36

A.3 Mutation operators

RACING uses the mutation operators defined by AFL, as shown in Table 6.

A.4 RACING's extension for compound predicates

Below we detail our adjustments to RACING+ to support compound predicate of type `A AND B` (Section 6). Concretely, we make the following adjustments:

The construction of compound predicates: We constructed `A AND B` by joining two atomic predicates like `x<10` and `y>=8`, each of them associated with a variable of interest (e.g., `x`, `y`). To achieve this, we modified our implementation to enumerate all combinations of any two variables associated with atomic predicates. Meanwhile, based on the same threshold adjustment method, we slightly modified the implementation to iterate over all possible combinations of sample values for the two variables and select the pair that maximizes the mutual information between the compound predicate and the crash as the thresholds.

Table 6: Mutation operators defined by AFL.

ID	Operators Name	Meaning
1	bitflip 1/1	Randomly flip 1 bit.
2	interest 8/8	Randomly replace byte to hard-coded interesting values.
3	interest 16/8	Randomly replace word to hard-coded interesting value.
4	interest 32/8	Randomly replace dword to hard-coded interesting value.
5	arith-sub 8/8	Randomly subtract from byte.
6	arith-add 8/8	Randomly add to byte.
7	arith-sub 16/8	Randomly subtract from word.
8	arith-add 16/8	Randomly add to word.
9	arith-sub 32/8	Randomly subtract from dword, random endian.
10	arith-add 32/8	Randomly add to dword, random endian.
11	random bytes	Randomly select one byte and set the byte to a random value.
12	delete bytes	Randomly select several consecutive bytes and delete them.
13	insert bytes	Randomly copy some bytes from a test case and insert them to another location in this test case.
14	overwrite bytes	Randomly overwrite several consecutive bytes.
15	user extras (over)	Randomly overwrite bytes with user-provided tokens.
16	user extras (insert)	Randomly insert bytes with user-provided tokens.

Table 7: Evaluation on RACING+ for compound predicates.

Note: The time duration is given in the format `hours:minutes:seconds`

Vulnerability	RACING+		Aurora+	
	Ranking	Time	Ranking	Time
CVE-2017-7962	40	00:11:50	116	02:04:29
CVE-2018-19209	47	01:07:55	261	02:58:47

Optimization strategy for CoP generation: We also customized the optimization strategy for CoP generation to choose the inputs most likely to generate new inputs that violate the compound predicate. For example, for a predicate `x<10 AND y>=8`, we prioritize the selection of non-crash inputs that satisfy `x<10 AND y>=8`.

A.5 Ground truth analysis

We use V_1 as an example to illustrate how to determine the ground truth for a vulnerability. Listing 1 displays the patched code of V_1, where the developer adds a check at lines 16,177–16,181 to fix a heap buffer overflow vulnerability at line 16,204. This patch explicitly reveals that the vulnerability is related to the relative sizes of `sect->sh_size` and `sizeof(*eopt)`. To further investigate the root cause, we dynamically analyze the unpatched code (line 16,182–16,384) with a Proof of Concept (PoC) and find that during execution, the value of `sect->sh_size` is 1, and the value of `sizeof(eopt)` is 8, which results in the value of `sect->sh_size / sizeof(eopt)` being 0. In this case, the code attempts to request a buffer of size 0 through `cmalloc` (line 16,187). However, the allocator actually returns a buffer of size one, which is stored in `iopt`, and later assigned to `option` (line 16,195). Since `offset` is 0, `sizeof(*eopt)` is 8, and `sect->sh_size - sizeof(*eopt)` equals `0xfffffffffffffff9`, the program satisfies the loop condition (the unsigned comparison at line 16,197) and enters the loop, attempting to write to `option` (line 16,203–16,204). Here a buffer overflow occurs because the program tries to write to `option->size` (line 16,204), which is the second byte of `option`, exceeding the boundary of the buffer. Therefore, the fundamental reason behind V_1 is the entering of the loop when `sect->sh_size < sizeof(*eopt)`. Since the result of `sizeof(*eopt)` is fixed at 8, we identify the root cause as `sect->sh_size < 8` at line 16,197.

```
16177 + if (sect->sh_size < sizeof (* eopt))
16178 + {
16179 +  error ("The MIPS options section is too small.\n");
16180 +  return FALSE;
16181 + }
16182 eopt = get_data (NULL, filedata, options_offset, 1,
16183                  sect->sh_size, _("options"));
16184 if (eopt)
16185 {
16186   iopt = (Elf_Internal_Options *)
16187         cmalloc ((sect->sh_size / sizeof (eopt)),
       sizeof (* iopt));
16188
      ...
16194   offset = 0;
16195   option = iopt;
16196
16197   while (offset <= sect->sh_size - sizeof (* eopt))
16198   {
16199     Elf_External_Options * option;
16200
16201     eoption = (Elf_External_Options *)((char *) eopt +
        offset);
16202
16203     option->kind = BYTE_GET (eoption->kind);
16204     option->size = BYTE_GET (eoption->size);
16205
      ...
16216     offset += option->size;
16217     ++option;
16218   }
16219
      ...
16384 }
```

Listing 1: Patched code snippet of V_1

To map the root cause from the source code to the instruction level, we further analyze the assembly code of line 16,197 and find that the subtraction expression `sect->sh_size - sizeof(*eopt)` corresponds to two instructions, (1) `mov rax, qword ptr [rax + 0x20]` and (2) `sub rax, 8`. The first instruction loads the variable `sect->sh_size` (stored at address `rax+0x20`) into the register `rax`, while the second instruction subtracts `rax` by 8. Since we have identified the root cause as `sect->sh_size < 8`, we use the predicate `rax<=7` on the destination operand of the first instruction `mov rax, qword ptr [rax + 0x20]` as the ground truth of V_1.

Uncovering the Limits of Machine Learning for Automatic Vulnerability Detection

Niklas Risse
MPI-SP, Germany

Marcel Böhme
MPI-SP, Germany

Abstract

Recent results of machine learning for automatic vulnerability detection (ML4VD) have been very promising. Given only the source code of a function f, ML4VD techniques can decide if f contains a security flaw with up to 70% accuracy. However, as evident in our own experiments, the same top-performing models are unable to distinguish between functions that contain a vulnerability and functions where the vulnerability is patched. So, how can we explain this contradiction and how can we improve the way we evaluate ML4VD techniques to get a better picture of their actual capabilities?

In this paper, we identify overfitting to unrelated features and out-of-distribution generalization as two problems, which are not captured by the traditional approach of evaluating ML4VD techniques. As a remedy, we propose a novel benchmarking methodology to help researchers better evaluate the true capabilities and limits of ML4VD techniques. Specifically, we propose (i) to augment the training and validation dataset according to our cross-validation algorithm, where a semantic preserving transformation is applied during the augmentation of either the training set or the testing set, and (ii) to augment the testing set with code snippets where the vulnerabilities are patched.

Using six ML4VD techniques and two datasets, we find (a) that state-of-the-art models severely overfit to unrelated features for predicting the vulnerabilities in the testing data, (b) that the performance gained by data augmentation does not generalize beyond the specific augmentations applied during training, and (c) that state-of-the-art ML4VD techniques are unable to distinguish vulnerable functions from their patches.

1 Introduction

Recently several different publications have reported high scores on vulnerability detection benchmarks using machine learning (ML) techniques [1,12–15,28]. The resulting models seem to outperform traditional program analysis methods, e.g. static analysis, even without requiring any hard-coded knowledge of program semantics or computational models. So, does this mean that the problem of detecting security vulnerabilities in software is solved? Are these models actually able to detect security vulnerabilities, or do the reported scores provide a false sense of security?

Even though ML4VD techniques achieve high scores on vulnerability detection benchmark datasets, there are still situations in which they fail to meet expectations when presented with new data. For example, it is possible to apply small semantic preserving changes to augment the testing dataset of a state-of-the-art model and then measure whether the model changes its predictions. If it does, it would indicate a dependence of the prediction on unrelated features. Examples of such transformations are identifier renaming [18,38,39,41,42], insertion of unexecuted statements [18, 35, 39, 41] or replacement of code elements with equivalent elements [2, 21]. The impact of augmenting testing data using these transformations has been explored for many different software-related tasks and the results seem to be clear: Learning-based models fail to perform well when testing data gets augmented using semantic preserving transformations of code [2, 5, 18, 30, 35, 38, 39, 41, 42].

In our own experiments, we were able to reproduce the findings of the literature and made additional observations: ML4VD techniques that were trained on typical training data for vulnerability detection are also unable to distinguish between vulnerable functions and their patched counterparts. If a patched function is also predicted as vulnerable, this indicates that the prediction critically depends on features unrelated to the presence of a security vulnerability.

It has previously been proposed to reduce the dependence on unrelated features by augmenting not just the testing data but also the training data [5, 18, 35, 38, 39, 41, 42]. Indeed, this seems to restore the lost performance back to previous levels, but does it really reduce the dependence on unrelated features, or are the models just overfitting to different unrelated features of the data?

In this paper, we propose a novel benchmarking methodology that can be used to evaluate the capabilities of ML4VD techniques by using data augmentation. First, we propose

Algorithm 1, in which a selected semantic preserving transformation is applied to the training dataset of a model, and a *different* transformation is applied to the testing dataset. When repeated for all possible pairs out of a set of transformations, the resulting scores provide a better measure of overfitting to the unrelated features that are introduced by the semantic preserving transformations during training data augmentation. Second, we propose Algorithm 2, in which a trained model is evaluated on a testing dataset that contains both vulnerable programs and their respective patches. The results provide a measure of the model's ability to generalize to a modified vulnerability detection setting.

In order to validate Algorithm 1 and Algorithm 2 empirically, we selected six state-of-the-art ML4VD techniques. All evaluated ML4VD techniques happen to be token-based large language models (LLMs). As our selection criterion, we defined the top-performing ML4VD techniques on the most widely known ML vulnerability detection benchmark CodeXGLUE [24, 25] that are available as open source. This gave us ranks 1, 2, 6, 10, and 12 of the leaderboard, all of which are token-based LLMs. In fact, 9 of the Top-10 solutions on the leaderboard are token-based LLMs. By applying Algorithm 1 and Algorithm 2 in our empirical study of six state-of-the-art ML4VD techniques and three datasets, we confirmed that ML4VD techniques continue to leverage unrelated features when deciding whether a function contains a vulnerability.

For Algorithm 1, we implemented 11 different semantic preserving transformations for data augmentation and evaluated the trained models using two popular vulnerability detection datasets. As expected, we find a strong benefit of training data augmentation (69.0% and 66.2% average restoration of accuracy/f1-score for the two datasets) when the transformations applied to training and testing datasets are the same. However, we find no improvement in performance when the transformations applied to training and testing datasets are different. In fact, we even find an additional 30.2% and 77.5% average *decrease* in accuracy/f1-score for the two datasets. In other words, ML4VD techniques still severely overfit to the specific label-unrelated features introduced by training data augmentation. The improvement in performance gained by data augmentation only applies to the specific type of transformations used during training.

For Algorithm 2, we introduce a new dataset, VulnPatchPairs, which contains 26.2k C functions and is derived from the CodeXGLUE/Devign vulnerability detection dataset [43]. Exactly half of the functions in VulnPatchPairs contain security vulnerabilities. The other half are patched versions of the first half.[1] We investigated six ML4VD techniques using VulnPatchPairs and evaluated their ability to generalize from their typical training data to VulnPatchPairs, and vice versa. To our surprise, all six ML4VD techniques that were trained on a typical training dataset were unable to distinguish between the vulnerable functions and their patched counterparts in VulnPatchPairs. On average, the accuracy turned out to be worse than random guessing. The trained models are unable to generalize from a standard vulnerability detection dataset to the modified setting.

In summary, this paper contributes two novel algorithms that can be used to uncover major problems of ML4VD techniques that are not detected using the standard evaluation setup: Overfitting to semantic preserving code changes and the inability to generalize between related vulnerability detection settings. Additionally, we provide an empirical evaluation of six state-of-the-art ML4VD techniques using the proposed methodology.

- ⋆ We present a general methodology consisting of two algorithms, that can be used to evaluate ML4VD techniques.
- ⋆ We show empirically, that state-of-the-art ML4VD techniques overfit to the unrelated features introduced by semantic preserving transformations during data augmentation.
- ⋆ We introduce *VulnPatchPairs*, a new dataset that contains vulnerable C function and the corresponding patched versions of the same functions. It is available at `https://github.com/niklasrisse/VPP`.
- ⋆ We demonstrate, that six state-of-the-art ML4VD techniques are not able to distinguish between the vulnerable and patched functions in VulnPatchPairs.
- ⋆ We publish all of our code and results for reproducibility. They are available at `https://github.com/niklasrisse/USENIX_2024`.

2 Related Work

One of the main tools to study the limits of ML4VD techniques are semantic preserving transformations of code. Previous work [2, 5, 18, 21, 22, 30, 35, 38, 39, 41, 42] proposed methods to generate semantic preserving transformations for source code datasets and investigated their impact when used to augment testing data of learned models.

Many of the works that reported the failures of learned models when testing data was augmented also investigated training data augmentation using their respective methods [5,18,35,38,39,41,42]. A common finding in all of these publications is that training data augmentation using a specific type of semantic preserving transformation leads to improved performance on testing sets that have been augmented the same way. But does the performance gained by data augmentation generalize beyond the specific augmentations applied during training?

Some of the publications that propose methods for data augmentation [5, 18, 35, 38, 41] take it a step further; they

9         coeff = 666;
10    return coeff;
11 }
```

(b) Transformed Code Snippet

Figure 1: Example of a simple semantic preserving transformation. The change (orange) has no effect on the vulnerability label. Both code snippets contain a security vulnerability (integer overflow in line 4). The code was taken from the Ffmpeg GitHub repository (URL: `https://github.com/FFmpeg/FFmpeg/commit/92da2309`) and is part of the CodeXGLUE/Devign dataset.

augment the training data using a slightly different but related type of transformation than for the testing data. For example, Henkel et al. [18] apply their gradient-based approach for identifier renaming to the training data and a random renaming strategy to the testing data. Similarly, Yang et al. [38] apply their method for variable renaming to a training dataset and the method proposed by Zhang et al. [42] to a testing dataset. All of these works find an improved performance when the training dataset is augmented in a similar way than the testing dataset. However, the transformations used for augmenting the training and testing data in these publications are all similar in type, e.g. they both rename identifiers. But does the performance also improve when training data is augmented in a different way than the testing data? Our work aims to fill this gap in the literature by carrying out a thorough empirical study that considers a diverse set of 11 different transformations, six state-of-the-art ML4VD techniques, and two high-quality datasets.

Similar to other related publications listed above [18, 35, 38], Rahman et al. [31] investigate overfitting of ML4VD techniques to variable and API names by transforming them in the testing data. Additionally, they propose a new method to address the overfitting based on causal learning, which aims to disable models from using superficial features (e.g. variable names) entirely. While their approach seems to be effective to avoid overfitting for concrete and simple transformations (e.g. changing variable names), the authors do not investigate how their method performs when faced with unseen semantic preserving transformations, that were not specifically trained for. Our proposed methodology can be used as a tool to do this, which allows to draw conclusions about overfitting to unrelated features fundamentally, irrespective of the type of transformation applied to training- and testing data.

In order to evaluate the general capabilities of ML4VD techniques, we collected a new dataset (VulnPatchPairs), which contains both vulnerable functions and their respective patches. The collection of a pairwise vulnerability-patch dataset has been proposed by previous work [4, 8, 29], e.g. for the research field of automated fixing. However, to the best of our knowledge, we are the first to utilize such a dataset to evaluate the general capabilities of ML4VD techniques.

Two recently published papers [10, 36] report poor generalization capabilities of different ML-based techniques (e.g. LLMs and GNNs) when evaluated on functions from unseen git projects. Our Algorithm 2 also investigates the generalization capabilities of ML4VD techniques, but using a different setup, in which functions in the evaluation data belong to a modified vulnerability detection setting (e.g. vulnerable functions and their patches), but can be from the same projects.

3 Methodology

We propose a novel benchmarking methodology to help researchers better evaluate advances in ML4VD techniques. The methodology consists of two parts, Algorithm 1 (A1) and Algorithm 2 (A2).

3.1 Data Augmentation

A central component of our methodology is data augmentation, and the expectations for vulnerability detection models that emerge from using code transformations for data augmentation.

We define data augmentation as the application of one or multiple code transformations onto all code snippets of a given code snippet dataset $CD \subset \mathcal{C}$, where $\mathcal{C}$ is a space that represents all possible code snippets $c \in \mathcal{C}$ in a given programming language.

A code transformation $t : \mathcal{C} \to \mathcal{C}$ is a function that maps from and to $\mathcal{C}$. Let's assume we have an oracle function $g : \mathcal{C} \to \{0, 1\}$, which maps from the space of code snippets $\mathcal{C}$ to either 0 or 1. The oracle function g represents the ground truth, i.e. it shows whether a code snippet c does (1) or does not (0) contain a security vulnerability. For a given code snippet dataset $CD \subset \mathcal{C}$, a code transformation t can be characterized by its effect on $g(t(c)) \; \forall \; c \in CD$:

Semantic Preserving Transformation. We call a transformation t_p semantic preserving w.r.t. CD, if the changes

  $score[MLM[Tr], Te_k] = evaluate\_model(MLM[Tr], Te_k, M)$
  $effect[Tr, Te_k] = score[MLM[Tr], Te_k] - score[MLM[Tr], Te]$
  $Tr_k = t_k(Tr)$ *// training data augmentation*
  $MLM[Tr_k] = train\_model(Tr_k)$
  $score[MLM[Tr_k], Te_k] = evaluate\_model(MLM[Tr_k], Te_k, M)$
  $MLM[Tr_k, Te_k] = score[MLM[Tr_k], Te_k] - score[MLM[Tr], Te]$
  for each $t_{j \neq k} \in T$ **do**
    $Te_j = t_j(Te)$ *// testing data augmentation*
    $score[MLM[Tr_k], Te_j] = evaluate\_model(MLM[Tr_k], Te_j, M)$
    $effect[Tr_k, Te_j] = score[MLM[Tr_k], Te_j] - score[MLM[Tr], Te]$
  end for
end for

Output: $output_{A1.1} = (\sum_k effect[Tr, Te_k])/N$
$output_{A1.2} = (\sum_k effect[Tr_k, Te_k])/N$
$output_{A1.3} = (\sum_k \sum_{j \neq k} effect[Tr_k, Te_j])/(N(N-1))$

introduced by applying it do not affect the ground truth vulnerability label, $g(c) = g(t_p(c)) \; \forall \; c \in CD$. Figure 1 shows an example of a simple semantic preserving transformation applied to a real-world code snippet.

Label Inverting Transformation. We call a transformation t_d label inverting w.r.t. CD, if the changes introduced by applying it change the ground truth vulnerability label, $g(c) \neq g(t_d(c)) \; \forall \; c \in CD$. In other words, a label inverting transformation either adds or removes a vulnerability from a code snippet.

In general, we expect a vulnerability detection model to correctly predict, whether a given code snippet contains a security vulnerability, independent of any semantic preserving or label inverting transformations that have been previously applied to the code snippet. Specifically, we can formulate the following expectations:

1. If we change a code snippet without affecting the vulnerability label (semantic preserving transformation), we expect a vulnerability detection tool to compute the same correct prediction as before applying the change.

2. If we add or remove a vulnerability from a code snippet (label inverting transformation), we expect a vulnerability detection tool to still deliver a correct prediction, or i.e. we expect it to change its prediction with the ground truth label of the code snippet.

In the following sections, we present two algorithms, which allow to evaluate ML4VD techniques using the two formulated expectations.

3.2 A1: Detecting Overfitting to Code Changes

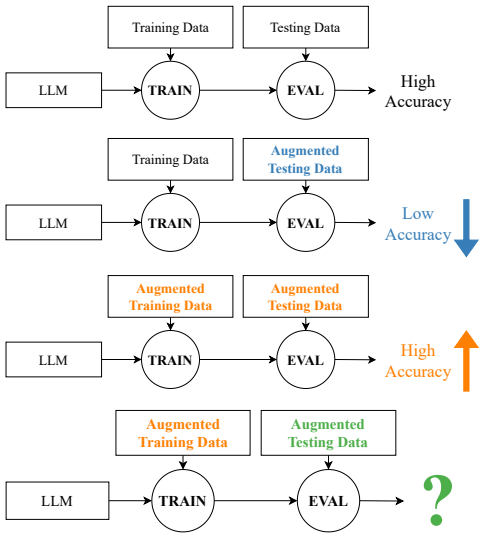

Figure 2: Visualization of Algorithm 1, which we created to detect overfitting of ML4VD techniques to unrelated features introduced by data augmentation. Colors represent that either only testing data is augmented (blue), training- and testing data are augmented using the same (orange), or different augmentation methods (green).

The goal of Algorithm 1 is to measure, whether ML4VD techniques overfit to augmentations of their training data that are unrelated to the respective vulnerability labels and whether the performance gained by data augmentation generalizes beyond the specific augmentations applied during training. We provide a simple visualization of the idea behind the algorithm in Figure 2, the algorithm itself in Algorithm 1, and a description of the most important parts in the following paragraphs. We use the colors blue, orange, and green, to connect the basic ideas of the algorithm with the experimental results across the paper[2].

What are the inputs? The inputs of Algorithm 1 are a set of different semantic preserving transformations $T := \{t_1, ..., t_N\}$, a training dataset Tr, a testing dataset Te, a ML training method *train_model*, a ML evaluation method *evaluate_model*, and a performance metric M. The training and testing datasets Tr and Te consist of code-label pairs (c_i, v_i), with $c_i \in \mathcal{C}$ representing code snippets and $v_i \in \{0, 1\}$ representing labels that indicate the absence (0) or presence (1) of security vulnerabilities in the respective code snippets. The method *train_model* can utilize the training dataset Tr to train a machine learning model $MLM : \mathcal{C} \rightarrow \{0, 1\}$, which maps from the space of code snippets $\mathcal{C}$ to either 1 (vulnerability) or 0 (no vulnerability). The method *evaluate_model* can use the performance metric M to quantify and aggregate the performance of a trained model MLM on a testing dataset Te into a single number between 0 (bad) and 1 (perfect).

[2] See Figure 2, Algorithm 1, Figure 5, Figure 7, Figure 7c and Table 2.

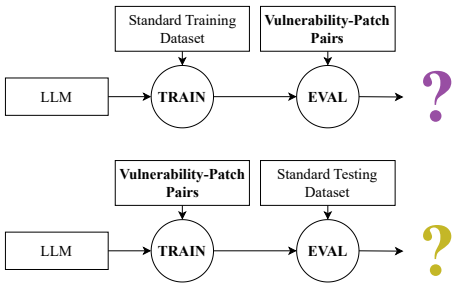

Figure 3: Visualization of Algorithm 2, which we created to test whether ML4VD techniques are able to generalize to a modified setting, which requires to distinguish between vulnerabilities and patches.

What is computed? Algorithm 1 computes the average effects of (a) augmenting the testing data of the selected ML technique using transformations $t_k \in T$ ($out\,put_{A1.1}$), (b) using the same transformations to also augment the training data ($out\,put_{A1.2}$), and (c) using different transformations to also augment the training data ($out\,put_{A1.3}$).

In lines 4-6, Algorithm 1 computes the effect of augmenting the testing dataset Te with the transformation t_k on the performance of the trained model $MLM[Tr]$. The result is $effect[Tr, Te_k]$, the absolute difference between the scores of $MLM[Tr]$ on the clean testing dataset Te and the augmented testing dataset Te_k. In other words, $effect[Tr, Te_k]$ quantifies how many points in score are lost if we augment the testing dataset with transformation t_k. $out\,put_{A1.1}$ aggregates this intermediate result over all transformations $t_k \in T$.

In lines 7-10, Algorithm 1 goes a step further and computes the effect of both augmenting the training dataset Tr and the testing dataset Te using the same transformation t_k. The result is $effect[Tr_k, Te_k]$, the absolute difference between scores of $MLM[Tr_k]$ on the augmented testing dataset Te_k and $MLM[Tr]$ on the testing dataset Te. In other words, $effect[Tr_k, Te_k]$ quantifies how many points in score are lost if we augment both the training and the testing dataset with transformation t_k. $out\,put_{A1.2}$ aggregates this intermediate result over all transformations $t_k \in T$.

In lines 12-14, the algorithm computes the effect of augmenting the testing dataset using a *different* transformation t_j than for the training dataset. The result is $effect[Tr_k, Te_j]$, the absolute difference between scores of $MLM[Tr]$ on the testing dataset Te and $MLM[Tr_k]$ on the augmented testing Te_j. In other words, $effect[Tr_k, Te_j]$ quantifies how many points in score are lost if we augment the training and the testing dataset with different transformations t_k and t_j. $out\,put_{A1.3}$ aggregates this intermediate result over all transformations $t_k \in T, t_{j \neq k} \in T$.

How can the results be used? Using this algorithm, researchers can effectively evaluate new ML4VD techniques. Specifically, for a selected technique researchers can answer

Algorithm 2 Distinguish between Vulnerability and Patch

Input: Standard Training Dataset Tr
Standard Testing Dataset Te
Vulnerability-Patch Training Dataset VPTr
Vulnerability-Patch Testing Dataset VPTe
ML Training Method *train_model*
ML Evaluation Method *evaluate_model*
Performance Metric M

1: $MLM[Tr] = train\_model(Tr)$
2: $MLM[VPTr] = train\_model(VPTr)$
3: $score[MLM[Tr], Te] = evaluate\_model(MLM[Tr], Te, M)$
4: $score[MLM[Tr], VPTe] = evaluate\_model(MLM[Tr], VPTe, M)$
5: $score[MLM[VPTr], VPTe] = evaluate\_model(MLM[VPTr], VPTe, M)$
6: $score[MLM[VPTr], Te] = evaluate\_model(MLM[VPTr], Te, M)$

Output: $out\,put_{A2.1} = score[MLM[Tr], Te]$
$out\,put_{A2.2} = score[MLM[Tr], VPTe]$
$out\,put_{A2.3} = score[MLM[VPTr], VPTe]$
$out\,put_{A2.4} = score[MLM[VPTr], Te]$

the following questions:

1. How much does the performance of the selected ML technique decrease if we augment the code snippets for testing without affecting the vulnerability labels? Answer: On average, the performance does change by $out\,put_{A1.1}$ points.

2. How much performance of the selected ML technique can be restored, if we augment the training code snippets in a similar way than the testing code snippets? Answer: On average, $out\,put_{A1.2} - out\,put_{A1.1}$ of the initial decrease can be restored.

3. How much performance of the selected ML technique can be restored, if we augment the training code snippets in a different way than the testing code snippets? Answer: On average, $out\,put_{A1.3} - out\,put_{A1.1}$ of the initial decrease can be restored.

4. Does the selected ML technique overfit to specific augmentations of the training data that are unrelated to the respective vulnerability labels? Answer: If $out\,put_{A1.2} >> out\,put_{A1.3}$: Yes, otherwise No.

3.3 A2: Distinguish between Vulnerability and Patch

The main goal of Algorithm 2 is to evaluate, whether ML4VD techniques are able to generalize from their typical training data to a modified setting, which requires to distinguish security vulnerabilities from their patches. Additionally, the algorithm also aims to evaluate the reverse, or i.e. whether ML4VD techniques that were trained to distinguish between vulnerabilities and their patches are able to perform well on standard testing data. We provide a simple visualization of the idea behind the algorithm in Figure 3, the algorithm itself in Algorithm 2, and a description of the most important parts in the following paragraphs. We use the colors purple and

yellow to connect the basic ideas of the algorithm with the experimental results across the paper [3].

What are the inputs? In addition to the inputs of Algorithm 1, Algorithm 2 requires a special vulnerability-patch testing dataset $VPTe$ and a vulnerability-patch training dataset $VPTr$. $VPTe$ and $VPTr$ also consist of code snippets $c_i \in \mathcal{C}$ and vulnerability labels $v_i \in \{0,1\}$, but for every code snippet c_j with label $v_j = 0$, they also contain a snippet $c_{l \neq j}$ with $v_l = 1$ which represents the patched version of c_j. The relationship between a code snippet and its patched version can be characterized as a label inverting transformation $t_{PATCH} : \mathcal{C} \rightarrow \mathcal{C}$, which maps code snippets c_j to their patched versions c_l.

What is computed? The purpose of Algorithm 2 is to quantify the ability of the selected ML technique to generalize between two related vulnerability detection settings. The first setting, represented by the standard training and testing datasets Tr and Te, consists of code snippets, which either contain or do not contain a vulnerability. This setting is most frequently used in the related literature [1, 12–15, 28]. The second setting, represented by the vulnerability-patch training and testing datasets $VPTr$ and $VPTe$, consists of vulnerable code snippets and their respective patches. As formulated in Section 3.1, a perfect vulnerability detection model should be able to perform well in both settings, irrespective of the setting on which it was trained. In other words, a vulnerability detection model should be able to generalize between the settings.

In total, Algorithm 2 computes four scores. In line 3, Algorithm 2 computes the score of a model $MLM[Tr]$, which was trained on the standard training dataset Tr, on the standard testing dataset Te. This score represents the standard evaluation and serves as a baseline for the other scores.

In line 4, Algorithm 2 computes the score of a model $MLM[Tr]$, which was trained on the standard training dataset Tr, on the vulnerability-patch testing dataset $VPTe$. When compared to the first score, this result serves as a measure of $MLM[Tr]$s ability to generalize to the modified setting, which requires to distinguish vulnerabilities from their patches.

In line 5, Algorithm 2 computes the score of a model $MLM[VPTr]$, which was trained on the vulnerability-patch training dataset $VPTr$, on the vulnerability-patch testing dataset $VPTe$. Again, this score serves as a baseline for the other scores.

In line 6, Algorithm 2 computes the score of a model $MLM[VPTr]$, which was trained on the vulnerability-patch training dataset $VPTr$, on the standard testing dataset Te. When compared to the third score, this result serves as a measure of $MLM[VPTr]$s ability to generalize back to the standard vulnerability detection setting.

The four computed scores are returned as the outputs of the algorithm ($output_{A2.1}$, $output_{A2.2}$, $output_{A2.3}$ and $output_{A2.4}$).

[3] See Figure 3, Algorithm 2, and Table 3.

How can the results be used? Using Algorithm 2, researchers can effectively evaluate whether the high scores of ML4VD techniques are specific to the testing datasets on which they were computed. Specifically, for a selected technique researchers can answer the following questions:

1. Does the performance of the selected ML technique generalize from a standard vulnerability detection dataset to a modified setting, which requires to distinguish vulnerabilities from their patches? Answer: The selected ML technique can distinguish between vulnerabilities and their patches with performance $output_{A2.2}$, compared to a score of $output_{A2.1}$ on the standard testing dataset.

2. Does the performance of the selected ML technique generalize back to the standard vulnerability detection setting when it is explicitly trained to distinguish vulnerabilities from their patches? Answer: The selected ML technique achieves a score of $output_{A2.4}$ on the standard testing dataset, compared to a score of $output_{A2.3}$ in the modified setting.

4 Experimental Setup

4.1 Research Questions

Our objective is to validate empirically, whether the two proposed algorithms can be used to evaluate state-of-the-art ML4VD techniques. Specifically, we aim to answer the following research questions.

RQ.1 How is the performance of ML4VD techniques affected, if we augment the input code snippets without affecting the vulnerability labels? (a) Can we measure a decrease in performance, if we augment the testing data of ML4VD techniques using semantic preserving transformations? (b) Does training data augmentation using the same transformations restore the initial performance? (c) Are there differences between the individual transformations?

RQ.2 Do ML4VD techniques overfit to specific augmentations of their training data that do not affect the respective vulnerability labels? Can we still restore the performance, if we augment the training dataset with a different semantic preserving transformation than the testing dataset?

RQ.3 Are the high scores of ML4VD techniques specific to benchmark datasets or do they generalize to a modified vulnerability detection setting? (a) Are state-of-the-art ML4VD techniques able to distinguish between vulnerable functions and their patches? (b) Does training to distinguish between vulnerable functions and their patches improve the performance on standard testing data?

Table 1: The semantic preserving transformations that we used in our experiments.

Identifier	Type	Description
t_1	Identifier Renaming	Rename all function parameters to a random token.
t_2	Statement Reordering	Reorder all function parameters.
t_3	Identifier Renaming	Rename the function.
t_4	Statement Insertion	Insert unexecuted code.
t_5	Statement Insertion	Insert comment.
t_6	Statement Reordering	Move the code of the function into a separate function.
t_7	Statement Insertion	Insert white space.
t_8	Statement Insertion	Define additional void function and call it from the function.
t_9	Statement Removal	Remove all comments.
t_{10}	Statement Insertion	Add code from training set as comment.
t_{11}	Random Transformation	One transformation sampled from $\{t_1,\ldots,t_{10}\}$ is applied to each function.

4.2 Semantic Preserving Transformations

One of the central components of algorithms 1 and 2 are semantic preserving transformations of code. The most common semantic preserving transformations that are used in the literature to investigate the limits of learned models for source code related tasks are identifier renaming [18, 35, 38, 39, 41, 42], insertion of unexecuted statements [18, 35, 39, 41], replacement of statements with equivalent statements [21], reordering of unrelated statements [27], deletion of unexecuted statements (e.g. comments) [21], or combinations of the before mentioned [18, 35, 41].

Table 1 shows the 11 semantic preserving transformations that we implemented for the experiments presented in this paper. We tried to cover all types of transformations commonly used in the literature. The table lists all transformations, categorizes them by type, and provides short descriptions for each of them.

Since ML4VD techniques are ultimately aimed at detecting security vulnerabilities in real-world code, augmenting code using our semantic preserving transformations should also result in code that looks natural, or i.e. looks like it could occur in real-world software. To address this, we experimentally confirmed that our semantic preserving transformations do not decrease the naturalness (measured by cross entropy) of the code. We provide more information on this as supplementary material in Appendix A.

4.3 Vulnerability Detection Datasets

We use two publicly available vulnerability detection datasets for our experiments.

CodeXGLUE/Devign. CodeXGLUE is a machine learning benchmark for code understanding and generation [24]. It consists of several datasets for different source code related tasks. In our experiments, we only use the dataset for vulnerability detection, which is based on the Devign dataset [43]. Throughout this paper, we refer to this dataset as the *CodeXGLUE/Devign dataset* or just as the CodeXGLUE dataset. The CodeXGLUE dataset contains 26.4k C functions, from which 45.6% contain vulnerabilities, i.e. the dataset is fairly balanced. The types of vulnerabilities were not formally classified, but based on the collection process the authors found most vulnerabilities in the dataset to be memory-related, e.g. memory leaks, buffer overflows, memory corruption, or crashes. The authors of the CodeXGLUE benchmark also maintain a leaderboard [25], which tracks the performance of popular learning-based techniques on the different datasets of the benchmark.

VulDeePecker. The other vulnerability detection dataset that we use in this paper is the Code Gadget Database, which was introduced with the VulDeePecker bug detector [23]. We refer to this dataset as the *VulDeePecker dataset*. The original dataset contains 61.6k C/C++ code samples derived from the NVD [7] and the SARD [6], from which 17.7k contain vulnerabilities, mainly buffer (CWE-119) and resource management errors (CWE-399).

4.4 New Dataset: VulnPatchPairs

In order to investigate the ability of ML4VD techniques to distinguish between vulnerabilities and their patches (RQ3), we collected a new dataset, which we call *VulnPatchPairs*. We provide a simple visualization of the collection process for VulnPatchPairs in Figure 4.

VulnPatchPairs is an extension of the CodeXGLUE/Devign vulnerability detection dataset [43], which consists of C functions from two popular open source repositories, FFmpeg[4] and Qemu[5]. The creators of the dataset describe the collection process in their original publication [43]. As a first step, they filtered the selected repositories for security-related commits using a list of keywords. Then, they invested 600 work hours of a four-person team of security researchers to classify the security-related commits into vulnerability-fix commits (VFCs) and non vulnerability-fix commits (non-VFCs) and extracted the respective functions before the commits were applied as vulnerable (before VFCs) and non-vulnerable (before non VFCs) functions. The actual patched versions of the functions (after the VFCs were applied) are not part of their original dataset. However, for each function of their dataset, the authors released the respective commit ID from the two open-source repositories as additional information. We used this information to extract the actual patched versions of the vulnerable functions in the CodeXGLUE dataset from the FFmpeg and Qemu repositories and created a new dataset: VulnPatchPairs.

We manually verified 100 randomly chosen functions from the CodeXGLUE dataset that were labelled as vulnerable. We found 68 out of these 100 functions to actually contain a security vulnerability, 23 to contain no security vulnerability, and 9

[4] FFmpeg repository: `https://github.com/FFmpeg/FFmpeg`
[5] Qemu repository: `https://github.com/qemu/qemu`

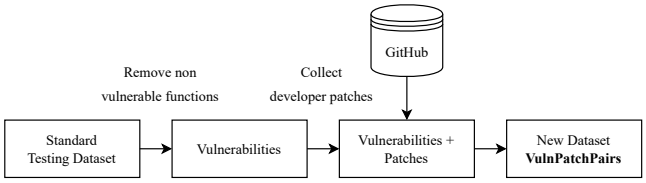

Figure 4: Visualization of the collection process for our new dataset VulnPatchPairs.

with no decision after 10 minutes of manual effort. The results are available at `https://github.com/niklasrisse/VPP_label_accuracy`. Even though these results show that there are inaccurate labels in the CodeXGLUE dataset, we do not expect any changes to our main findings. While the absolute performance might change if we used perfectly labeled data, we expect the relative performance (e.g., augmented vs non-augmented) to remain comparable for all of our individual evaluations.

In total, VulnPatchPairs consists of 26.2k C functions from the two open source repositories FFmpeg and Qemu. Exactly half (13.1k) of the 26.2k functions contain security vulnerabilities and were copied from the CodeXGLUE/Devign vulnerability detection dataset. The other 13.1k are the respective patches of the vulnerable functions, which we extracted from the open-source repositories. We published VulnPatchPairs as supplementary material in an open GitHub repository[6].

4.5 Machine Learning Techniques

We selected six state-of-the-art ML4VD techniques for our experiments.

Selection Criteria. In order to select techniques that represent the state-of-the-art of ML4VD, we chose the top techniques from the CodeXGLUE leaderboard [25] for which the authors provide open-source implementations. Measured by citations[7] (496) and GitHub Stars[8] (1.2k), CodeXGLUE is the most well-known benchmark for source code related machine learning techniques. The vulnerability detection dataset of the benchmark [43] is also highly cited (407 citations[9]) and widely used to evaluate ML4VD techniques for automatic vulnerability detection.

Selected Techniques. Based on the described criteria, we selected UniXcoder [13], CoTexT [28], VulBERTa [15], PLBart [1], and CodeBERT [12] for our experiments. At submission time of this paper, the six techniques hold rank 1 (UniXcoder), rank 2 (CoTexT), rank 6 (VulBERTa), rank 10 (PLBart), and rank 12 (CodeBERT) on the CodeXGLUE leaderboard for vulnerability detection [25]. In addition to the five techniques from the CodeXGLUE leaderboard, we selected GraphCodeBERT (abbreviated as *GraphCB* in Table 3) [14], a technique related to CodeBERT, which utilizes graph representations of source code during the training process.

Model Details. Since the selected techniques belong to the same family of techniques, they also share the same basic architecture:

1. Tokenization: A given code function is split into tokens (small sequence of characters that forms a semantic entity), based on a given strategy.

2. Embedding: Tokens are transformed into numbers, usually by indexing via a learned vocabulary and the addition of positional information.

3. Transformer Network: Several steps of parametrized computation are applied, resulting in a final embedding.

4. Prediction Layer: The final layer of the model is a parametrized prediction layer, which computes an output number between 0 and 1 based on the final embedding of the previous step. The output number represents the predicted probability that the input function contains a security vulnerability.

During model training, the parametrized computational layers of steps 3. and 4. are optimized to compute the correct predictions for given training data. The six selected techniques mainly differ in tokenization strategy, training data, optimization objective, and the specific transformer network architecture used. We provide additional information on the specific models in Appendix C.

The authors of all six techniques provide publicly available implementations of their techniques [1, 12–15, 28].

4.6 Model Training Pipeline

We used a similar training setup for all model instances that we trained for our experiments.

Pre-training. All models that we train in our experiments have been pre-trained by the authors of the respective publications using various source code datasets. The size of the pre-training datasets spans from 2.3 million (VulBERTa) to 680 million code snippets (PLBart). The original publications provide more information on the pre-training datasets [1, 13, 15, 28]. We use the pre-trained models released by the authors of the respective techniques as starting points for our pipeline and finetune the models on our selected datasets.

Data split. For the CodeXGLUE/Devign dataset, we used the train-/validation-/testing dataset split provided by the authors of the benchmark [24], which resulted in a training dataset with 21k functions, a validation dataset with 2.7k functions, and a testing dataset with 2.7k functions. For the VulDeePecker dataset, we used the split provided by Hanif et

[6] VulnPatchPairs: `https://github.com/niklasrisse/VPP`
[7] `https://api.semanticscholar.org/CorpusID:231855531`
[8] `https://github.com/microsoft/CodeXGLUE`
[9] `https://api.semanticscholar.org/CorpusID:202539112`

al. [15], which resulted in a training dataset with 128.1k functions, a validation dataset with 16k functions, and a testing dataset with 16k functions. The split for VulnPatchPairs is derived from the split of CodeXGLUE, such that *all and only* vulnerable functions in training, validation, and testing sets, respectively, of CodeXGLUE were taken as training, validation, and testing sets of VulnPatchPairs, augmented by their corresponding patches.

Pre-processing. For the VulDeePecker dataset, we removed all duplicate functions and also replaced all label-revealing tokens (e.g. comment with token "bad" above a vulnerable function) that we found by manual inspection of the dataset with randomly selected tokens. For the CodeXGLUE and VulnPatchPairs datasets, we applied no additional preprocessing steps.

Hyperparameters. For all six ML4VD techniques, we used the pre-trained models and tokenizers provided by the respective authors as starting points for our experiments. Similar to Hanif et al. [15], we noticed a relatively quick convergence of our performance metrics in our initial experiments on the validation dataset (after 2-7 epochs), which is why we trained each model instance for 10 epochs. For all model-specific hyperparameters, we used the values that were reported in the original papers [1, 12–15, 28]. Consult our published training scripts[10] for the complete list of hyperparameter values that we used.

Performance metrics. We tracked and quantified the performance of our trained models on the selected testing datasets using several commonly used performance metrics. We report six metrics in this paper: Accuracy, f1-score, precision, recall, false positive rate (FPR), and false negative rate (FNR).

For CodeXGLUE/Devign as a balanced dataset (45.6% vulnerable functions), we use accuracy as the main performance metric, since it is also used exclusively in the CodeXGLUE benchmark [24] and on the leaderboard [25].

For VulDeePecker as a relatively imbalanced dataset (28.7% vulnerable functions) we use the f1-score as the main performance metric. The f1-score is defined as the harmonic mean of precision and recall and is most suitable when the positive class (in our case vulnerable functions) is the minority class in an imbalanced dataset.

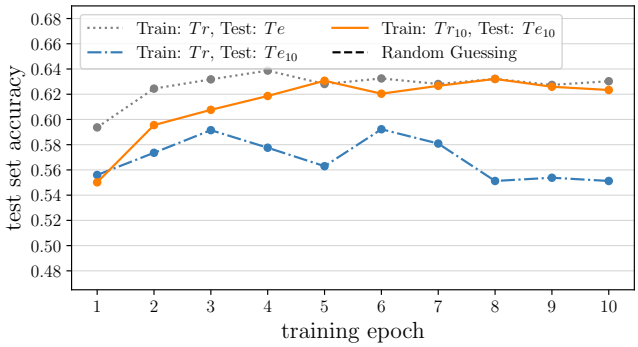
Hardware. We used a setup of five Nvidia A100 GPUs, each equipped with 40 GB RAM. One run of all our experiments takes approximately 60 days on a single A100 GPU.

5 Experimental Results

RQ.1 Testing- and Training Data Augmentation

We investigate, whether (a) testing data augmentation using semantic preserving transformation decreases the performance of state-of-the-art ML4VD techniques, whether (b) training data augmentation using the same transformations restores the performance towards previous levels, and whether (c) there are differences between the individual transformations.

Methodology. We used Algorithm 1 to investigate all three questions. We ran the algorithm for each ML technique and dataset separately and measured the outcomes using the respective preferred performance metrics (see Section 4.6). We did not only record the outcomes after completing the full training of the respective models but also after each training epoch in order to observe the progression of the learning process.



Results. Figure 5a shows the test set accuracy of different VulBERTa models measured after each of the ten training epochs. We can observe, that augmenting the testing dataset Te with transformation t_{10} leads to a substantial drop in accuracy, represented by the gap between the dotted gray and blue graphs in the figure. We can also observe, that augmenting the training dataset Tr with the same transformation t_{10} as the testing dataset, restores the accuracy back to previous levels (orange graph).

Figure 5b extends the results of Figure 5a to all semantic preserving transformations $t_k \in T$, and to all six ML4VD techniques. Instead of showing the accuracy for each training epoch, we only use the maximum accuracy across the full training. Across all six ML4VD techniques, we can observe, that augmenting the testing dataset Te with transformations $t_k \in T$ (represented by the blue boxplots), on average, leads to a drop in accuracy compared to evaluations on the standard testing dataset Te (represented by the horizontal lines with stars). In parallel to Figure 5a we can also observe that, on average, training data augmentation using the same transformation as for testing data augmentation leads to a restoration of the observed drops in accuracy (represented by the orange boxplots).

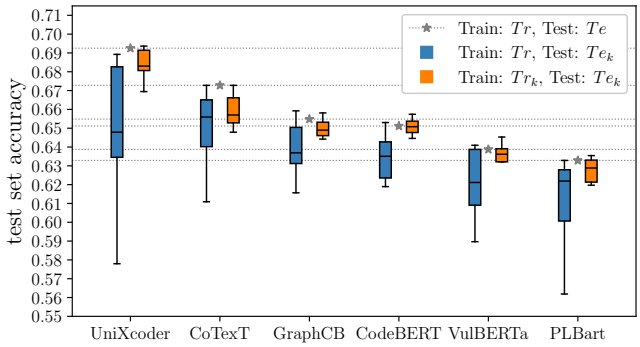


Table 2 summarizes the outputs of Algorithm 1 for all six ML4VD techniques and both datasets. Specifically, it shows the average recorded changes in the respective metrics, when only the testing dataset was augmented (blue columns, $output_{A1.1}$), when the training and testing datasets were augmented using the same transformation (orange columns, $output_{A1.2}$), and when the training and testing datasets were augmented using a different transformation (green columns, $output_{A1.3}$). We observe that, on average, augmenting the testing dataset leads to a drop in accuracy/f1-score (-0.025 for CodeXGLUE, -0.043 for VulDeePecker), and augmenting the training dataset using the same transformation restores that decrease towards previous levels. On average, approximately 69.0% (CodeXGLUE) and 66.2% (VulDeePecker) of the lost accuracy/f1-score is restored.

Figure 6 shows the impact on accuracy caused by augmenting only the testing data using the individual transformations $t_k \in T$ ($impact(t_k) := accuracy[MLM[Tr], Te_k] - accuracy[MLM[Tr], Te]$) for all six ML4VD techniques. In other words, Figure 6 displays the severity of the performance

[10] GitHub: https://github.com/niklasrisse/USENIX_2024

(a) Test set accuracy over ten training epochs of different models trained with VulBERTa on the CodeXGLUE/Devign dataset. Augmenting the testing set Te with transformation t_{10} (blue) decreases the accuracy, but applying the same transformation also to the training dataset Tr (orange) restores the accuracy back to previous levels.

(b) Extension of the results in Figure 5a, for all transformations $t_k \in T$, and for all six ML4VD techniques. The boxplots represent distributions of the resulting accuracies. Augmenting the testing set Te with transformations $t_k \in T$ (blue boxplots) decreases the accuracy, but applying the same transformation also to the training dataset Tr (orange boxplots) partially restores the accuracy, although not always to its previous levels.

Figure 5: Effects of augmenting the testing data and the training data using the same semantic preserving transformations.

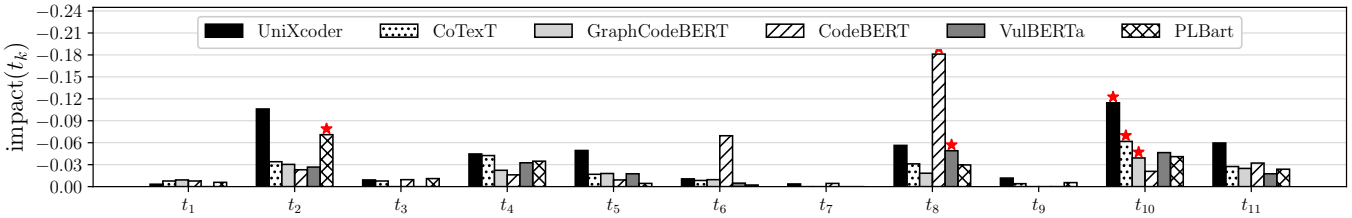

Figure 6: Impact on accuracy caused by augmenting the testing data using the individual transformations $t_k \in T$ ($impact(t_k) := accuracy[MLM[Tr], Te_k] - accuracy[MLM[Tr], Te]$). The most impactful transformations for each ML technique are marked by red stars.

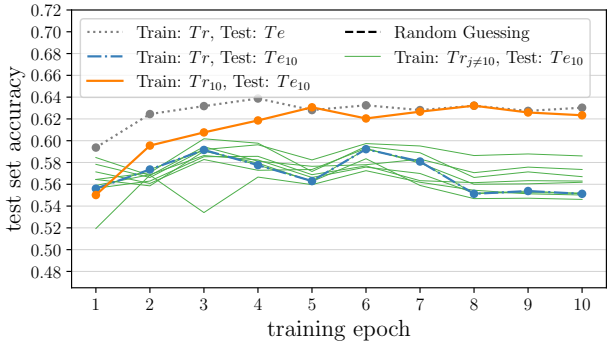
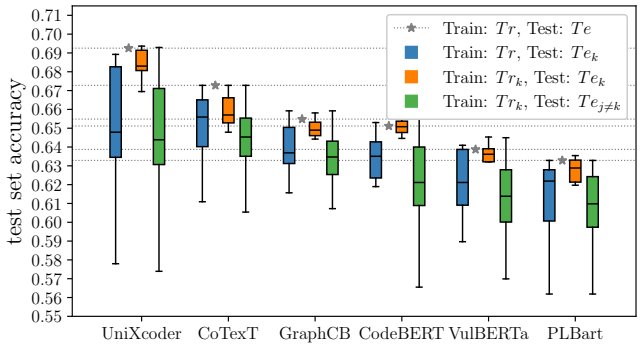


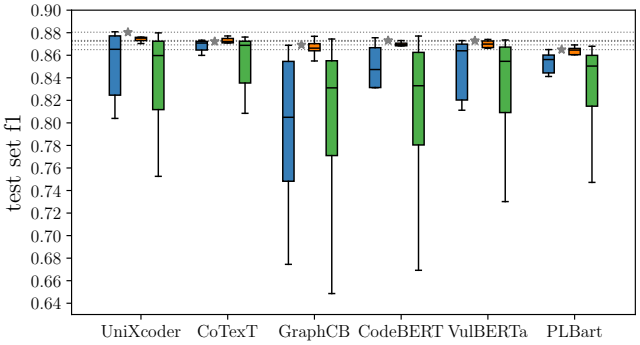
decline of the techniques when only applying semantic preserving transformations on the testing set. The most impactful transformations for each ML technique are marked by red stars.

If a specific semantic preserving transformation has a high negative impact on the accuracy of an ML technique, we can assume that either (a) the ML technique partly relied on unrelated features that were removed or modified by the transformation (e.g. removal of comments) to achieve its original high accuracy, or (b) that the ML technique relied on unrelated features introduced by the transformation (e.g. addition of comments) to achieve the decreased accuracy after applying the transformation.

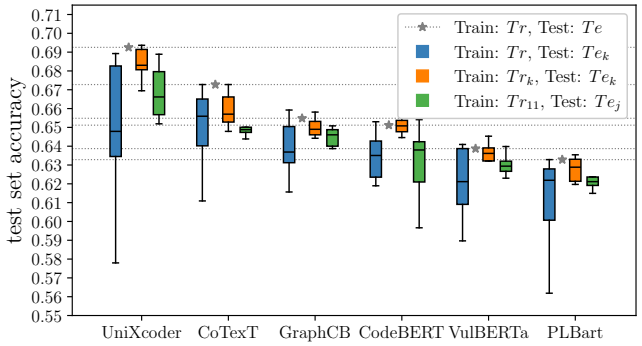


From the results presented in Figure 6 we can observe, that there are clear differences both between transformations and ML4VD techniques. As one might expect, a trivial transformation such as adding whitespace (t_7) has little to no impact on the accuracy of all six ML4VD techniques. The severity of this impact is, on average, below 1% accuracy, which means that below 1% of predictions are changed from correct to incorrect by applying this transformation. The ML4VD techniques also seem to be robust against identifier renaming (t_1 and t_3) and removal of comments (t_9), for which the severity of impact is also below or close to 1%. The most impactful transformations are changing the order of the function parameters (t_2), defining an additional void function (t_8), and adding code snippets from the training set as comments (t_{10}). For these transformations, a substantial part of the predictions is changed from correct to incorrect: Between 2.3% and 10.6% for t_2, between 1.8% and 18.1% for t_8, and between 2.1% and 11.5% for t_{10}. Overall, transformations that insert statements (e.g. t_4, t_5, t_8, and t_{10}) or reorder statements (e.g. t_2 and t_6) seem to have a higher impact than the other types.

Additionally, there are also differences between the six ML4VD techniques. For example, moving the code into a separate function (t_6) only seems to have a high impact on CodeBERT, and inserting a simple comment (t_5) seems to have a much higher impact on UniXcoder than on the other ML4VD techniques. Future work is required to determine why the ML4VD techniques are more or less robust against specific transformations.



We also investigated the impact of each individual transformation when not only the testing data but also the training data is augmented using a different transformation than for



(a) Test set accuracy over ten training epochs of different models trained with VulBERTa on the CodeXGLUE/Devign dataset. Augmenting the training set Tr with different transformations $t_{j\neq 10}$ than the testing dataset (green lines) does not restore the accuracy back to previous levels.

(b) Extension of the results in Figure 7a, for all transformations $t_k \in T$ and for all six ML4VD techniques. The boxplots represent distributions of the resulting accuracies. Augmenting the training set Tr with different transformations $t_{k\neq j}$ than the testing dataset (green boxplots) does not restore the accuracy back to previous levels. Instead of restoring, the accuracy sometimes even drops further compared to using standard training data (green below blue).

(c) Same setup as for Figure 7b, but using the VulDeePecker dataset. The boxplots represent distributions of the resulting f1-scores. Augmenting the training set Tr with different transformations $t_{k\neq j}$ than the testing dataset (green boxplots) does not restore the f1-score back to previous levels.

(d) Same setup as for Figure 7b, but the green boxplots represent the accuracies achieved by augmenting the training data using the meta transformation t_{11}, in this case sampled from $\{t_1,\ldots,t_{10}\}\setminus\{t_j\}$, and the testing data using a single left-out transformation t_j. Augmenting the training dataset Tr with t_{11} partially restores the accuracy, although not to its previous levels.

Figure 7: Effects of augmenting the training data with different semantic preserving transformations than the testing data.

the testing data. However, due to the results being very similar to Figure 6, we decided to omit this from the paper and provide it as supplementary material in Appendix B.

Across two datasets, six ML4VD techniques, and 11 transformations, on average, (a) testing data augmentation using semantic preserving transformations leads to a drop in accuracy/f1-score (CodeXGLUE: −0.025, VulDeePecker: −0.043), (b) training data augmentation using the same transformations restores 69.0% (CodeXGLUE) and 66.2% (VulDeePecker) of the lost accuracy/f1-score, and (c) transformations that insert or reorder statements seem to be more impactful than other types of transformations.

RQ.1 has already been studied in the literature, for many different techniques, datasets, and tasks [5, 18, 22, 35, 38, 39, 41, 42]. Based on our evidence, we can approve the findings of the literature.

RQ.2 Overfitting to Specific Transformations

We investigate, whether the performance of ML4VD techniques can still be restored if we augment the training dataset with a different semantic preserving transformation than the testing dataset. We use Algorithm 1 to investigate RQ.2, with the same setup as for RQ.1.

Results. Figure 7a is similar to Figure 5a, it also shows the test set accuracies of different VulBERTa models measured after each of the ten training epochs. In addition to the results displayed in Figure 5a, Figure 7a shows the accuracies (green lines) of VulBERTa models trained on data that was augmented using all transformations except t_{10}, which was used to augment the testing dataset. We observe, that augmenting the training dataset Tr with different transformations $t_{j\neq 10}$ as the testing dataset does not restore the accuracy back to previous levels.

Figure 7b visualizes the same extended results for all semantic preserving transformations $t_k \in T$ and for all six

Table 2: Algorithm 1: Average changes when augmenting only the testing data ($out\,put_{A1.1}$), training and testing data using the same ($out\,put_{A1.2}$), or a different transformation ($out\,put_{A1.3}$).

ML4VD techniques. Again, the blue and the orange boxplots represent the distributions of accuracies, when either only the testing dataset (blue) or training and testing datasets were augmented using the same transformation (orange). The green boxplots represent the distribution of accuracies achieved by models that were trained on data, which was augmented using a different transformation than for the testing data. Across all six ML4VD techniques, we observe that, on average, augmenting the training dataset Tr with a different transformation $t_{k\neq j}$ than the testing dataset does not restore the accuracy back to previous levels.

Figure 7c visualizes the same results as Figure 7b, but using the VulDeePecker dataset. In this figure, the y-axis measures the f1-score, since it is the preferred evaluation metric for the VulDeePecker dataset. Again, we observe that, on average, augmenting the training dataset Tr with a different transformation $t_{k\neq j}$ as the testing dataset does not restore the accuracy back to previous levels.

In Figure 7d the green boxplots represent the distribution of accuracies achieved by augmenting the training data using our *meta transformation* t_{11}. Slightly different to the definition of t_{11} in Table 1, each function in the training set is transformed using a random transformation t_k with $k \in [1,10] \setminus j$, with one left-out transformation t_j which is applied to the testing data. Since our set of implemented transformations contains groups of similar transformations (e.g. adding different types of comments), we would expect the accuracies to be higher compared to applying only a single different transformation to the training set (green boxplots of Figure 7d), but lower compared to applying exactly the same transformation to the training set (orange boxplots). Based on Figure 7d, we observe that is the case across all six ML4VD techniques. Augmenting the training dataset Tr with the meta transformation t_{11} does not fully restore the accuracy, but moves it closer towards the accuracy on unaugmented data compared to applying only a single different transformation to the training set.

In addition to the results for RQ.1, Table 2 also shows the average recorded changes in the respective metrics, when the training and testing datasets were augmented using different transformations (green columns, $out\,put_{A1.3}$). We observe that, on average, the score drops by 0.032 accuracy (CodeXGLUE) and 0.059 f1-score (VulDeePecker). Across the six techniques, the decrease is on average 30.2% (CodeXGLUE) and 77.5% (VulDeePecker) stronger than for training on unaugmented data. In other words, augmenting the training dataset using a different transformation than for the testing dataset did not restore the score towards previous levels, but instead decreased it even further.

For the other metrics (recall, precision, FPR and FNR), we generally observe similar patterns than for accuracy and f1-score. However, there are also slight deviations, e.g. for CodeXGLUE recall improves on average by 0.023 when training data is augmented using a different transformation than the testing data instead of decreasing as expected. These deviations can be explained by innate tradeoffs between recall/-precision and FPR/FNR, and can only be intepreted in context of the other metrics. Accuracy and f1-score provide a better summary of the performance, which is why they are used as the preferred metrics for the two datasets.

Across two datasets, six ML4VD techniques, and 11 transformations, augmenting the training dataset using a different transformation than for the testing dataset does not restore the performance back to previous levels. In other words, the ML4VD techniques overfit to the label-unrelated features introduced by semantic preserving transformations during training data augmentation.

In summary, we can observe that across the tested ML4VD

Table 3: Algorithm 2: Performance of six ML4VD techniques evaluated on the standard CodeXGLUE/Devign testing dataset Te or the vulnerability-patch testing dataset $VPTe$.

techniques, transformations, and datasets, training data augmentation only restores the performance to previous levels when the testing dataset is augmented in a similar way than the training dataset.

The performance gained by data augmentation only applies to the specific transformations used during the training of the model. ML4VD techniques continue to leverage unrelated features when deciding whether a function contains a security vulnerability.

RQ.3 Generalization to VulnPatchPairs

We investigate, whether (a) ML4VD techniques are able to generalize from typical vulnerability detection training datasets to a modified setting, in which they are required to distinguish between vulnerabilities and their patches, and (b) whether training to distinguish between vulnerabilities and patches improves the performance on standard testing data.

Methodology. We used Algorithm 2 to investigate both questions. As inputs to the algorithm, we selected the training and testing subsets of the CodeXGLUE/Devign dataset as the standard training and testing datasets Tr and Te, and the training and testing subsets of VulnPatchPairs as the vulnerability-patch training and testing datasets $VPTr$ and $VPTe$. We ran the algorithm for all six ML4VD techniques separately.

Results. Table 3 shows the results of running Algorithm 2. Specifically, it shows the performance of different models evaluated on the standard CodeXGLUE/Devign testing dataset Te or the vulnerability-patch testing dataset $VPTe$. We focus our analysis on the results measured in accuracy since it is the preferred performance metric for balanced datasets such as CodeXGLUE and VulnPatchPairs.

We observe, that the accuracy of all six ML4VD techniques is highest (between 0.633 and 0.693) when trained and evaluated on standard training and testing data (second column, $out\,put_{A2.1}$). This is expected and consistent with the findings in the literature [1, 12–15, 28]. When trained and evaluated on VulnPatchPairs (fourth column, $out\,put_{A2.3}$) the accuracy is consistently lower than in the standard setting (between 0.558 and 0.617), but still significantly higher than the expected accuracy of a random guesser[11]. However, when trained on standard training data and evaluated on the VulnPatchPairs testing dataset (third column, $out\,put_{A2.2}$), the accuracy drops dramatically (between 0.294 and 0.527). Even the best model (VulBERTa) is only 0.027 points better than a random guesser. On average, the accuracy is worse than random guessing. In other words, all six ML4VD techniques that we evaluated are unable to distinguish between vulnerabilities and their patches when trained on a typical vulnerability detection dataset.

When trained on VulnPatchPairs and evaluated on standard testing data (fifth column, $out\,put_{A2.4}$), we get a similar picture. The performance is significantly worse (between 0.546 and 0.575) compared to models trained on standard training data (second column). However, the performance in this case is notably better than random guessing.

(a) All six ML4VD techniques are not able to distinguish between vulnerabilities and their patches when trained on standard training data. On average, the accuracy is lower than the expected accuracy of a random guesser. (b) When trained to distinguish between vulnerabilities and their patches, the ML4VD techniques are able to predict standard testing data better than a random guesser, but still significantly worse than when trained on standard training data. In other words, the ML4VD techniques are unable to generalize from their training data to a slightly modified vulnerability detection setting.

[11] Since $VPTe$ is perfectly class balanced (50% vulnerable, 50% clean), a random guesser (coin flip) would be expected to achieve an accuracy of 0.5.

6 Threats to Validity

As for any empirical study, there are various threats to the validity of our results and conclusions.

Internal validity. A common source of systematic error in empirical studies on ML4VD techniques is hyperparameter selection. Given a particular desired outcome, hyperparameters can be optimized to move the result in the desired direction. We tried to minimize this risk by taking the values for hyperparameters provided by the authors of the chosen ML4VD techniques.

Another potential source of systematic error is the training-/testing dataset split. Similar to hyperparameter selection, dataset split can also be varied to change a result in a desired direction. We tried to avoid this risk by taking the provided splits of the CodeXGLUE benchmark [24] and by Hanif et al. [26].

External validity. The degree to which our results generalize to other learning-based techniques, datasets, semantic preserving transformations, and performance metrics, are concerns of external validity. We tried to minimize the risk attached to these concerns by evaluating a wide set of six state-of-the-art techniques, two datasets, six performance metrics, and 11 semantic preserving transformations. For RQ.3, we only investigate the generalization between CodeXGLUE/Devign and VulnPatchPairs. To maximize generality, we tried to keep both Algorithm 1 and Algorithm 2 as general as possible, so that they can easily be adapted to other techniques, datasets, transformations, and metrics.

Simplicity of Transformations. Some of the semantic preserving transformations that we used (see Table 1) could be easily addressed by adding additional data pre-processing (e.g. mapping identifiers to standardized names). However, the specific transformations that we implemented are merely a tool to demonstrate, that the performance gained by training data augmentation only applies to the specific transformations used for training and that the techniques that we investigated overfit to the label-unrelated features introduced by these transformations. For a new technique, they could be replaced by a different set of transformations.

Class balance. Multiple works have shown that learning-based vulnerability detection techniques trained on fairly balanced datasets (such as CodeXGLUE) often fail to generalize to real-world code repositories [3,9,16], which usually contain a much smaller ratio of security vulnerabilities [20]. However, measured by citations, class-balanced datasets are still by far the most popular datasets to evaluate learning-based techniques for vulnerability detection. To our current knowledge, there is no vulnerability detection dataset with sufficient size (more than 10k code snippets), high-quality labels (manually provided by security experts), and a realistic distribution of vulnerable to non-vulnerable code snippets that is widely used in the research community (at least 50 citations). This is why we decided to focus our experiments on the CodeXGLUE and VulDeePecker datasets, even though they do not reflect a realistic class distribution.

7 Discussion and Future Work

Overfitting of learned models is a well-known problem in the machine learning research field [11, 40]. However, as shown in our experiments, the traditional approach to evaluating ML4VD techniques often fails to detect overfitting to label-unrelated features in the training data. Our proposed Algorithm 1 is a novel way to measure overfitting of ML4VD techniques, that goes beyond the traditional approach, and can even detect overfitting if there is no gap in the standard setup at all. There are several common strategies to reduce overfitting in the standard evaluation setup, e.g. early-stopping, dropout, or large pre-training datasets [40], which are already integrated in the ML4VD techniques that we used in our experiments. However, our experiments demonstrate that the techniques are still severely overfitting to label-unrelated features introduced by semantic preserving transformations during training data augmentation. Finding ways to robustify ML4VD techniques without or with minimal overfitting will be a central challenge of the ML4VD research area.

Generalization. The results for RQ.3 (see Section 5) reveal, that state-of-the-art ML4VD techniques lack the ability to generalize from their training data to a modified setting, which requires to distinguish between vulnerabilities and their patches. Since we can not assume that real-world software systems would be similar to the training data of these techniques, the ability to generalize to modified settings would be required for these techniques to be safely integrated into real software engineering environments.

The ability of a ML technique to generalize to testing data that is differently distributed than the training data is also called *out-of-distribution generalization*, and the lack of it for learning-based techniques has been recently identified (e.g. in the computer vision domain [17, 34]). Our proposed Algorithm 2 can be seen as a tool to measure out-of-distribution generalization for the domain of automatic vulnerability detection. It would be interesting to try approaches that have been used to address out-of-distribution generalization in other domains (e.g. causal representation learning [32]) on the task of automatic vulnerability detection and measure the success using our Algorithm 2.

A Naturalness

Since vulnerability detection techniques are ultimately designed to be applied to real-world code, we also need to ensure that our transformations lead to code snippets that could occur in the real world, or i.e., lead to *natural* code. We measured the naturalness of our transformations using the method introduced by Hindle et al. [19] (implemented as a 2-gram markov model) and present the results in Figure 8. Using the method introduced by Hindle et al., we can compute the *cross entropy* of a given code snippet, which represents how surprising or *unnatural* the code snippet is relative to the code snippets observed in the training dataset (for a detailed explanation consult the work of Hindle et al. [19]). Using this approach, we computed the cross entropy for all code snippets in the CodeXGLUE testing dataset (dark gray boxplot), and for transformed versions of the CodeXGLUE testing dataset (light gray boxplots). The horizontal black line represents the average cross entropy for all code snippets in the untransformed CodeXGLUE testing dataset. We can observe, that for all transformations except t_1 (identifier renaming), the cross entropy is similar or lower than for the untransformed dataset. In other words, all transformations except t_1 (identifier renaming) lead to code snippets that are similar in naturalness compared to the real-world code of the CodeXGLUE testing dataset.

B Impact of Individual Transformations

Figure 9 shows the impact on accuracy caused by augmenting the testing data with a different transformation than the training data ($impact(t_k) := \frac{1}{(N-1)} \sum_{t_j \in T} accuracy[MLM[Tr_j], Te] - accuracy[LLM[Tr_j], Te_k]$). The most impactful transformations for each LLM are marked by red stars. The results are very similar to Figure 6, which is why we chose to omit Figure 9 from the main paper and provide it as supplementary material.

C Model Architecture Details

All selected ML4VD techniques happen to be token-based large language models (LLMs), specialized for the task of vulnerability detection. LLMs are based on the transformer architecture, which is a neural network model architecture for sequence-to-sequence tasks based on the attention mechanism [37]. The attention mechanism is essentially a weighted dot product that allows models to focus on specific parts of the input data that are most relevant to the task at hand, improving their ability to capture dependencies and context. In a transformer model, the attention mechanism is combined with parametrized feed-forward layers and repeated multiple times, resulting in a complex multi-layer network. A detailed

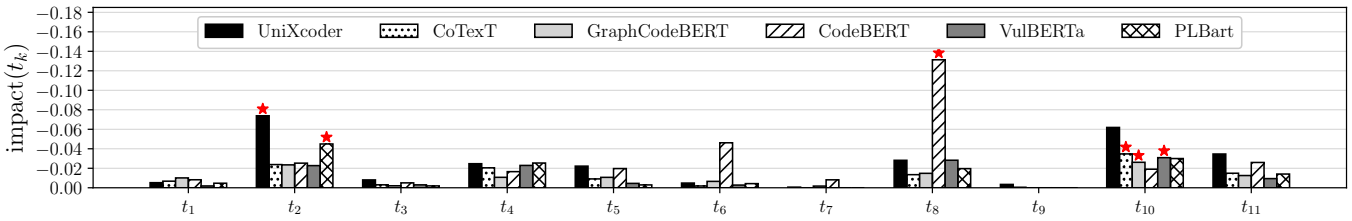

Figure 9: Impact on accuracy caused by augmenting the testing data with a different transformation than the training data ($impact(t_k) := \frac{1}{(N-1)} \sum_{t_j \in T} accuracy[MLM[Tr_j], Te] - accuracy[MLM[Tr_j], Te_k]$). The most impactful transformations for each ML technique are marked by red stars.

Figure 11: Additional metrics for RQ.2 using the VulDeePecker dataset. The results support the conclusions that we generated based on the main metric (f1-score).

description of the transformer architecture can be found in the original paper [37]. While the base architecture is the same for all of the six techniques, there are some notable differences in the pre-training setup, size, or specific parts of the model training:

VulBERTa. VulBERTa leverages a custom tokenization strategy, which is based on the *byte pair encoding* algorithm [33] combined with a set of pre-defined code tokens (standard C/C++ keywords, punctuation, and library API calls) to achieve better code encodings through maintaining the syntactical structure of source code.

CoTexT. CoTexT uses multi-task learning for pre-training, which means that the model is trained to perform multiple code-related tasks (e.g. vulnerability detection, code summarization, and code generation) in parallel. The model architecture also contains significantly more trainable parameters than the other techniques (222M parameters), because it contains more more multi-head attention layers. CoTexT also uses a different tokenizer than the other techniques.

UniXcoder. UniXcoder introduces a new pre-training setup, which includes tokenization of the abstract syntax trees (ASTs) of the code, and three different 'training modes' that leverage different self-attention masks.

PLBart. PLBart uses a special pre-training procedure called 'denoising autoencoding', which is a combination of token masking, token deletion, and token infilling, that has to be reversed by the model.

CodeBERT. CodeBERT uses a pre-training setup in which natural language (e.g. documentation) and code are combined to produce a more semantically stable representation of the input.

GraphCodeBERT. GraphCodeBERT uses a pre-training task, where in addition to natural language and the code, a graph-based representation of the data flow of the function is provided.

D Additional Metrics for RQ.2

Figure 10 and Figure 11 show additional results for RQ.2 using all of our available metrics (accuracy, f1-score, precision, recall, FPR, and FNR). Generally, the results support the conclusions that we generated based on the respective preferred metrics on the two datasets (accuracy for CodeXGLUE/Devign and f1-score for VulDeePecker). While the observed patterns deviate for some of the metrics (e.g. precision, recall, FPR, or FNR), these deviations can be explained by the relationships between them. For example, a model can have a really high precision, but low recall. Similarly, a model can have really low false-negative-rate, but the corresponding false-positive-rate is really high. Accuracy and f1-score provide a better summary of the performance, which is why they are used as the preferred metrics for the two datasets.

Improving ML-based Binary Function Similarity Detection by Assessing and Deprioritizing Control Flow Graph Features

Abstract

Machine learning-based binary function similarity detection (ML-BFSD) has witnessed significant progress recently. They often choose control flow graph (CFG) as an important feature to learn out of functions, as CFGs characterize the control dependencies between basic code blocks. However, the exact role of CFGs in model decisions is not explored, and the extent to which CFGs might lead to model errors is unknown. This work takes a first step towards assessing the role of CFGs in ML-BFSD solutions both theoretically and practically, and promotes their performance accordingly. First, we adapt existing explanation methods to interpreting ML-BFSD solutions, and theoretically reveal that *existing models heavily rely on CFG features*. Then, we design a solution $\delta_{\texttt{CFG}}$ to manipulate CFGs and practically demonstrate the lack of robustness of existing models. We have extensively evaluated $\delta_{\texttt{CFG}}$ on 11 state-of-the-art (SOTA) ML-BFSD solutions, and find that the models' results would flip if we manipulate the query functions' CFGs but keep semantics, showing that *most models have bias on CFG features*. Our theoretic and practical assessment solutions can also serve as a robustness validator for the development of future ML-BFSD solutions. Lastly, we present a solution to utilize $\delta_{\texttt{CFG}}$ to augment training data, which helps deprioritize CFG features and enhance the performance of existing ML-BFSD solutions. Evaluation results show that, MRR, Recall@1, AUC and F1 score of existing models are improved by up to 10.1%, 12.7%, 5.1%, and 27.2% respectively, proving that *reducing the models' bias on CFG features could improve their performance*.

1 Introduction

Binary function similarity detection (BFSD) takes a pair of functions (usually in assembly or intermediate form) as input, and computes a similarity score between them [10,38]. BFSD has proven effective in a broad spectrum of applications, such as known vulnerability discovery [12,21,29], malware lineage [2,3,30,52], software plagiarism detection [43,44,58], patch analysis [27,32,68], and software supply chain analysis [25]. Given recent advances in machine learning (ML), SOTA BFSD are mostly ML-based [21,37,38,46,62–64,67,72], and we call them ML-BFSD solutions for brevity. Instead of heavily relying on manually specified features, such solutions design ML models to embed target binary functions into a latent vector space, where geometric metrics are adopted to compute function similarity.

We notice many ML-BFSD solutions [21,38,46,67,72] develop their models over CFGs, which characterize control dependencies within functions and help ML-BFSD solutions interpret function semantics. However, reliance on CFGs could impact the learning of semantics. For instance, solutions [38,72] that use GNNs distribute instructions among different graph nodes based on control dependencies depicted by CFGs. While GNNs effectively perceive relationships between instructions within directly connected basic blocks, they struggle to learn relationships between instructions located in distantly separated blocks. This limitation indicates that CFG-based learning could restrict models' ability to learn function semantics. Since model decisions are influenced by both semantic and CFG features, the impact on learning semantics could lead to models' over-reliance on CFG features.

We also note several works [28,39] raise the concern that some approaches heavily rely on CFG features, thereby underestimating the significance of semantics. Unfortunately, these works mention the over-reliance on CFGs issue based purely on experience or intuition, and the problematic approaches they point out are typically non-machine learning methods. Few studies explore the exact role of CFG features on decisions of ML-BFSD solutions. Furthermore, it is unknown to what extent the side effects introduced by CFGs could lead to model errors. Modern developers are still unaware of this issue. For instance, recent works [23,33,45,66] still heavily rely on CFGs and are prone to errors. Given this, it is imperative to quantify the exact role of CFG features and systematically evaluate the severity of the over-reliance issue, serving as a

§ Corresponding authors.

robustness validator for future work. More importantly, we should also provide a solution to mitigate the over-reliance problem and improve model performance.

We take the first step towards assessing the role of CFG features in ML-BFSD solutions. First, we theoretically interpret the importance of CFG features in ML-BFSD models, and show that *existing models heavily rely on CFG features*. Then, through practical experiments, we evaluate the robustness of existing models on CFGs. Specifically, we design a solution δCFG to manipulate CFGs, while keep function semantics intact. After manipulation, we evaluate existing models' performance on the modified functions. Results show existing models tend to make mistakes once the CFGs change, suggesting that *existing models have bias on CFG features*. Containing theoretical interpretation and practical experiments, our work serves as *a robustness validator* for developers. For example, they can use our work to determine whether a model exhibits over-reliance on CFG features, thereby guiding further improvements. Without a validator, even if developers recognize the over-reliance issue and make adjustments, it remains challenging to verify that the adjustment is effective. Further, we analyze why existing models are prone to such bias, and show δCFG can be used to augment training data and *improve models through deprioritizing CFG features*.

First, we analyze the importance of CFG features, by adapting existing explanation methods to ML-BFSD solutions. This is not a trivial task. In traditional scenarios, *e.g.*, computer vision, a single pixel can be treated as a feature, and explanation methods can be employed to calculate the importance of each pixel. Thus the importance of different features on model decisions is intuitive. However, in BFSD scenarios, it is inappropriate to model each byte as a feature, as binary code has higher level of semantics (*e.g.*, opcode, operands, CFGs, call graphs). Given this challenge, we design function features that are human-readable, which can represent both CFGs and function semantics. Based on this, explanation methods can intuitively reflect the importance of different features. We adapt approximation-based explanation methods to 11 representative ML-BFSD solutions, and reveal that CFG features are significantly more important than other features on most of these solutions. In other words, most of the existing ML-BFSD solutions heavily rely on CFG features.

In addition to the theoretical analysis on CFG importance, we further evaluate the robustness of existing models on CFG features with quantitative experiments. Particularly, in real-world software development, function CFGs can undergo changes due to various factors such as code refactoring. Such natural CFG transformations present unique challenges to ML-BFSD solutions. To simulate and assess these real-world, natural changes in CFGs, we design a solution δCFG, which can manipulate CFGs while maintaining function semantics. Given a pair of dissimilar (or similar) functions, δCFG can make them have similar (or dissimilar) CFGs. As a result, we have constructed hard-to-detect samples, including (1) different functions with identical CFGs and (2) same function with different CFGs, and evaluated 11 representative solutions on them. Evaluation results show that most existing models make mistakes on these samples. In other words, CFG features are not reliable and may cause bias to ML-BFSD solutions.

Further, we analyze why these solutions heavily rely on CFG features, with two potential reasons identified. (1) We identify design flaws in these ML-BFSD solutions that impede the learning of semantics. (2) We reveal that there is a bias when constructing training datasets. Existing ML-BFSD solutions construct training sets without considering function pairs with identical CFGs but different semantics, inducing the over-reliance on CFG features. Thus, we leverage δCFG to augment training data and enhance the performance of ML-BFSD solutions. Empirical results show δCFG can considerably enhance model performance, improving MRR, Recall@1, AUC and F1 score by up to 10.1%, 12.7%, 5.1%, and 27.2% respectively. We further explain the enhanced models, revealing that the over-reliance on CFG features has been deprioritized.

In summary, this work makes the following contributions.

- We take the first step towards assessing the role of CFG features in ML-BFSD solutions, with theoretic explanation and quantitative evaluation, and provide a robustness validator for developers to identify whether their models suffer from the over-reliance issue.
- We are the first to adapt explanation methods to the BFSD scenario for theoretic analysis, revealing that existing models heavily rely on CFG features.
- We present a CFG manipulation solution δCFG and conduct practical experiments, which shows that most models have bias on CFG features.
- We also present a data augmentation solution based on δCFG, which helps deprioritizes CFG features and promote existing models' performance.

2 Background and Related Work

2.1 ML-BFSD Solutions

Definition. ML-BFSD solutions aim to compute the similarity of two binary functions (raw bytes), measured with a similarity score from 0 (no similarity) to 1 (identical). Two functions compiled from two source code functions that are the same or similar to some extent (*e.g.*, one is a patched version of the other) should acquire high similarity scores [45,64]. Compared with Non-ML-BFSD solutions [14, 15, 29, 49, 53], ML-BFSD solutions [9, 21, 36, 39, 55, 61, 69, 72, 74] generally offer higher accuracy, require less human involvement, and have generalizes better. We present an intuitive example describing the workflow of ML-BFSD solutions in Figure 1.

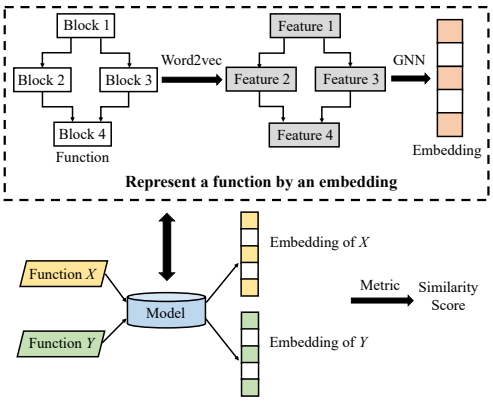

Figure 1: The general workflow of ML-BFSD solutions.

ML-BFSD solutions represent binary functions as embeddings through adopting ML models, and then apply specific metrics to compute the similarity score between functions. In practical applications, a given function is compared with all the functions in a function pool. Similarity scores are then used to rank functions in the pool, identifying the closest matches to the given function.

ML-BFSD solutions studied by us. CFGs encode function structures, depicting control dependencies between basic blocks. We note numerous ML-BFSD solutions treat CFGs [6, 45, 64] as critical components. However, the exact role of CFGs and the side effects of over-reliance on CFGs are not investigated. In this work, we conduct studies on 11 representative ML-BFSD solutions, which are proven to be top-performing, open-sourced and widely adopted [64]. Our work is model-agnostic, suitable for evaluating solutions regardless of whether they employ CFGs. To validate this point, beyond assessing solutions that use CFGs (the first eight [8, 16, 33, 38, 46, 50, 67, 72]), we also selected three solutions that don't use CFGs for evaluation (the last three, namely Safe [47], Trex [52] and jTrans [64]).

2.2 Explanation Methods

Explanation methods [41, 57, 70, 71] have been widely used in interpreting model behaviors. We aim to utilize explanation methods to study the role of CFGs. We hope that explanation methods can explicitly determine the importance of CFG features in model decisions. In this regard, we refer to approximation-based explanation methods [7, 22, 54, 56, 73].

Approximation-based approaches. We focus on local explanation approaches [7, 22, 54, 56, 73] which are the most prevailing form in the explanation domain [24, 40]. Such local approximation-based approaches concentrate on explaining the decision of target models for a given input instance. These approaches use interpretable models to locally approximate decision boundaries of target models in the vicinity of the input model. According to the interpretable models, these approaches can provide the importance score of each feature. Specifically, given an instance $\mathbf{x}$ with d features, *i.e.*, $\mathbf{x} = [x_1, x_2, ..., x_d]$, they perturb feature values of $\mathbf{x}$ under specific strategy to generate numerous variants (*i.e.*, local instances in the vicinity of $\mathbf{x}$) as training data. With training data, they adopt interpretable models f (e.g., linear models) to locally approximate decision boundaries of target models. When the approximation finishes, they utilize f to form a vector $\mathbf{a} = [a_1, a_2, ..., a_d]$, where a_i is treated as the contribution (importance score) of x_i to the decision of target models at $\mathbf{x}$.

Why choose approximation-based approaches? We choose approximation-based approaches for three reasons. First, such methods approximate target models with interpretable models, which can explicitly measure feature importance, helping understand the role of CFGs. Second, such approaches are model-agnostic. ML-BFSD solutions to be explained contain different types of models, such as GNNs and Transformers. We need a model-agnostic method that can be applied to explain all these models. Third, such methods are popular in explaining models deployed in function-related scenarios [13, 22, 40], which are closely related to our tasks.

There are other types of explanation approaches, such as backpropagation-based [11, 59, 60], perturbation-based [4, 17, 18], and GNN-based [41, 42, 42, 65, 71] approaches. We neglect these approaches since many of them are tailored for the image domain. Additionally, some of them focus on specific network architectures, *e.g.*, GNNs, and are not model-agnostic. For example, CFGExplainer [26] specifically supports GNN-based classifiers. In contrast, our task targets a broader range of models such as RNNs and Transformers. More importantly, we focus on exploring the role of CFG features. It is essential to separate CFG features from semantic features to ascertain the role of CFGs. CFGExplainer can only identify significant function sub-parts encompassing many instructions, which merge CFG features with semantic features, obscuring the role of CFG features.

2.3 Divergence from Related Work

Related work on model evaluation. A recent study [45] evaluates a batch of BFSD solutions, aiming at fair and meaningful comparison among them. It fails to consider the role of CFGs, and is considerably different from our work. They argue many solutions are tailored to slightly different objectives, depending on the context or specific scenarios, and as such, a direct comparison of BFSD solutions is infeasible. Thus, they focus on establishing a uniform dataset, and re-implement many BFSD solutions to conduct comparison with uniform metrics, such as recall and area under curve (AUC). Even though the study tries to observe the performance of BFSD solutions under different settings, for instance, by using different GNN variants and diverse feature engineering methods, they do not consider exploring the role of CFGs. In contrast, we focus on exploring the role of CFGs, model enhancement,

and mitigation on the over-reliance on CFG features.

Limited understanding on CFG over-reliance. Although several studies [28, 39] came across over-reliance on CFGs, the approaches they identify are non-ML models, which are rather different from ML-based models. For example, Liu *et al.* [39] comment that some non-machine learning approaches [20, 48] based on graph isomorphism heavily rely on CFGs. Furthermore, these studies often briefly acknowledge over-reliance based on experience or intuition, without a systematic evaluation of CFG's exact role. This makes it hard to effectively caution subsequent developers about the over-reliance. In line with this observation, later studies [38, 46, 72] tested by us still suffer from this issue. Our work fills this gap. It serves as a model-agnostic robustness validator, poised to be applied to future models, aiding in discerning their potential over-reliance on CFG features. Otherwise, even if developers refine their models, efficacy of such refinement is elusive.

Table 1: Human-readable features.

Type	Feature Name
Semantic Features	Call Instructions (Call)
	Jump Instructions (Jump)
	Arithmetic Instructions (Arith)
	Data Transfer Instructions (Data-Tran)
	Other Instructions (Other)
CFG Features	No. of Nodes (Nodes)
	No. of Edges (Edges)
	Graph Similarity (Graph-Sim)

3 Explainer: Explaining ML-BFSD Solutions

To understand the role of CFGs in ML-BFSD solutions, we implement an explanation module `Explainer`, which refers to prior art [7, 22, 54, 56, 73] and adapts them to the BFSD domain. The basic idea is to locally approximate a target model with an interpretable ML model, then present the importance of different features. Given a model F adopted by the target ML-BFSD solution, an instance (a function) $\mathbf{x}$, we aim to acquire the importance score of each feature in $\mathbf{x}$ to the decision of F at $\mathbf{x}$. (1) we first specify features to represent functions, supporting `Explainer` to score the importance of each feature. (2) Then, we generate local instances in the vicinity of $\mathbf{x}$, to locally approximate F with an interpretable model M. M explicitly represents the importance score of each feature, and the role of CFGs becomes intuitive. We introduce the above two points in Sections 3.1 and 3.2, respectively, and present the explanation results in Section 3.3.

3.1 Feature Specification

We are the first to apply explanation approaches to the BFSD domain, and existing explanation approaches lack feature specifications, particularly regarding the features depicting CFGs. This hinders `Explainer` from scoring the importance of each feature. We note some explanation methods [22] directly score function bytes, which is pointless in our task, since CFGs are hard to directly characterize using bytes, and the importance of CFGs is lacking in these explanation methods. To overcome this challenge, we specify human-readable features to represent functions. Each feature represents a component affecting decisions of ML-BFSD solutions, and can be scored by `Explainer` to intuitively reflect its importance. We specify eight features in Table 1, the first five are used to depict function semantics, namely *semantic features*, and the last three to characterize CFGs, namely *CFG features*.

Semantic features. We design semantic features to depict function semantics in two stages. *Stage I*: Instead of employing function bytes directly, we disassemble them into instructions, each viewed as an individual semantic feature. The motivation is two-fold: (1) Instructions, in contrast to bytes, are more human-readable, enhancing direct understanding of feature importance. (2) Instructions capture the entirety of a function's semantics without loss. However, acquiring global explanation results typically requires analyzing many functions consisting of a variety of instructions. Given the expansive nature of the instruction space and the myriad combinations of opcodes and operands, directly enumerating the importance scores of instructions becomes impractical.

Stage II: To address the above challenge, we categorize instructions into five common types: call, jump, arithmetic, data transfer, and others, collectively denoted as $T = \{T_1, T_2, T_3, T_4, T_5\}$. We first aggregate the importance scores of each type's instructions. A challenge arises from the potential variation in the number of instructions among these types, which could lead to biased perceptions of importance. We normalize these aggregated scores by dividing them by the total number of instructions within the respective type, thereby ensuring an equitable depiction of importance. Formally, if I_k is the set of instructions of type T_k and $s(i)$ indicates the importance score for instruction i, then the score for type T_k is $S_{T_k} = \frac{\sum_{i \in I_k} s(i)}{|I_k|}$. Using this approach, we compute scores for these five instruction types, presenting them as semantic feature scores to users.

CFG features. We then specify CFG features to depict characteristics of CFGs. We first consider the number of nodes and edges to represent the basic attributes of CFGs. Depicting CFGs is equivalent to depicting graphs, and these two features cannot distinguish graphs with the same number of nodes and edges. We further specify graph similarity, which reflects the difference between two graphs, and could distinguish graphs with the same size. We choose the widely-adopted Weisfeiler-Lehman optimal assignment kernel [34] to compute CFG similarity. For each local instance $\mathbf{x}'$ in the vicinity of $\mathbf{x}$, we compute the graph similarity between the CFGs of $\mathbf{x}'$ and $\mathbf{x}$, and treat it as a feature.

After feature specification, we represent $\mathbf{x}$ by d-dimension features, i.e., $\mathbf{x} = [x_1, x_2, ..., x_d]$. Here, $\mathbf{x}[1 : d-3]$ represents

all the instructions (stage I) within $\mathbf{x}$, while $\mathbf{x}[d-2:d]$ denotes CFG features. Explanation methods can then assign importance scores to each feature. Note that when presenting scores of semantic features to users, we compute scores for the five instruction types (stage II) based on the scores of each individual instruction and then present these scores to users.

3.2 Local Approximation

We then locally approximate decision boundaries of target models. (1) we first generate local instances in the vicinity of $\mathbf{x}$. (2) Then, we label these instances, constructing the training set. (3) We train interpretable models to locally approximate decision boundaries.

Local instance generation. The basic idea for the generation is to perturb $\mathbf{x}$ to generate local instances in the vicinity of $\mathbf{x}$ [22, 56]. Perturbations target both semantic and CFG features. To this end, we randomly delete instructions in $\mathbf{x}$ for the generation. From a semantic perspective, any instruction deletion naturally results in perturbation of semantic features. On the CFG side, if a jump instruction is deleted, it affects the number of CFG edges. Furthermore, if all instructions within a basic block are coincidentally deleted, it leads to the removal of that particular basic block, which then alters the number of CFG nodes. Both scenarios influence graph similarity. During the generation of local instance $\mathbf{x}'$, `Explainer` randomly deletes q of instructions, where q is uniformly sampled from $(0,\tau]$. Here we set the threshold τ to restrict the perturbations, to ensure $\mathbf{x}'$ is in the vicinity of $\mathbf{x}$. Each local instance is generated by applying a direct perturbation to the original $\mathbf{x}$, not iteratively on previously perturbed versions. Under this strategy, `Explainer` generates $\mathcal{N}$ unique local instances, which are utilized as training data.

Labeling training data. Then, we label the generated local instances for approximating decision boundaries. Given a local instance $\mathbf{x}'$, existing approximation-based methods label it with $F(\mathbf{x}')$, which is unsuitable in our scenarios. The main reason is that similarity detection models are trained in a contrastive learning manner, dramatically different from a supervised learning manner. Here, $F(\mathbf{x}')$ is a multi-dimension feature vector, which cannot be directly treated as a label.

Similarity detection models make decisions by computing the similarity between function feature vectors. Inspired by this, we propose labeling $\mathbf{x}'$ by computing the similarity between $\mathbf{x}'$ and $\mathbf{x}$. Specifically, we label $\mathbf{x}'$ with $D(F(\mathbf{x}'),F(\mathbf{x}))$, where D represents the cosine similarity function. Such labels reflect the impacts of feature perturbations on model decisions. Intuitively, a high $D(F(\mathbf{x}'),F(\mathbf{x}))$ implies $\mathbf{x}'$ and $\mathbf{x}$ are similar, and the corresponding perturbations on features do not significantly affect model decisions, and vice versa.

Model development. After labeling training data, we train interpretable models to locally approximate decision boundaries. Previous approximation-based methods assume local decision boundaries to be either linear [56], or non-linear [22]. This work applies both types of methods to interpret ML-BFSD solutions, since local boundaries vary in different solutions. Specifically, (1) for the linear hypothesis, we train a linear regression model f to locally approximate decision boundaries [56]. Recall we represent $\mathbf{x}$ as $[x_1,x_2,...,x_d]$. After approximation, $f(\mathbf{x}) = \sum_{i=1}^{d}(w_i * x_i)$, where w_i is the coefficient of f that corresponds to the feature x_i, and the coefficient presents the importance of x_i. (2) For the non-linear hypothesis, we construct a mixture regression model to locally approximate F [22], and score feature importance.

3.3 Explanation Results

Experiment setup. To assess the role of CFGs, we adopt `Explainer` to explain 11 representative ML-BFSD solutions. Eight of them leverage CFGs: Genius [16], Asm2Vec [8], Gemini [67], GMN [38], GraphEmb [46], OrderMatters [72], XBA [33], and DEXTER [50]. The remaining three, Safe [47], Trex [52], and jTrans [64], do not. We randomly select 5,000 functions from open-source projects. For each function $\mathbf{x}$, we generate 1,000 local instances around it, and set the threshold $\tau = 0.5$. Then we apply both linear and non-linear models to the local approximation, as mentioned in Section 3.2. (1) Linear model. For each x and its local instances, we follow LIME [56] to train a Ridge regression model for the approximation. (2) Non-linear model. Similarly, we follow LEMNA [22] to train a Gaussian mixture model.

Metrics. As mentioned in Section 3.2, given a function $\mathbf{x}$, `Explainer` computes the importance scores of each feature. Rather than showing explanation results for each function in sequence, we evaluate overall results based on two metrics. First, we compute the **average importance score** of each feature. The average score of feature i is defined as $\frac{sum(x_i)}{num(\mathbf{x})}$, where $sum(x_i)$ is the sum score of feature i across all functions, and $num(\mathbf{x})$ is the number of functions. Second, we compute the **top-1 rate** of semantic features and CFG features, which are considered as the most important features. The top-1 rate of semantic features is defined as: $\frac{num(semantics)}{num(\mathbf{x})}$, where $num(semantics)$ is the number of functions whose highest scores are acquired by one of the semantic features. The top-1 rate of CFG features is defined as: $1 - \frac{num(semantics)}{num(\mathbf{x})}$.

Results. Overall, the results of average importance score and top-1 rate indicate CFG features are much more important than semantic features on most solutions. Thus, we conclude most of them heavily rely on CFG features. In detail, Table 2 shows average importance score. On most ML-BFSD solutions, both LIME and LEMNA yield the highest scores for CFG features. For example, in DEXTER, according to LIME, Graph-Sim acquires the highest score 0.163, while the importance scores of Call, Jump, Arith, Data-Tran, and Other are just 0.117, 0.126, 0.109, 0.108, and 0.116. Figure 2 and 3 present the results of top-1 rate for LIME and LEMNA, and we find that on most ML-BFSD solutions, CFG features

Table 2: Evaluation results of average importance scores on each similarity detection solution.

Explanation Method	BFSD Solutions	Average Score								CFG features score the highest?
		Semantic Features					CFG Features			
		Call	Jump	Arith	Data-Tran	Other	Nodes	Edges	Graph-Sim

	Trex	0.118	0.121	0.131	0.126	**0.133**	0.127	0.121	0.123	No
	jTrans	0.132	**0.162**	0.112	0.127	0.136	0.110	0.103	0.118	No

achieve a significantly higher top-1 rate than semantic features. This indicates CFG features have the greatest influence on most solutions, confirming the importance of CFGs in model decisions. Taking DEXTER as an example, according to LIME, the top-1 rate of CFG features is 2.9× higher than that of semantic features. We analyze the reason behind such over-reliance in Section 5.3. SAFE, Trex, and jTrans don't show a strong dependence on CFGs, which aligns with their non-utilization of CFGs. This alignment underscores `Explainer`'s capability to effectively assess the importance of CFG features.

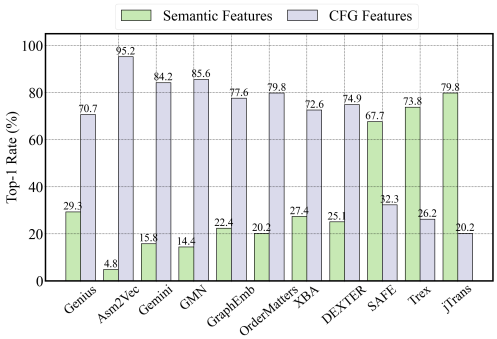

Figure 2: LIME shows the top-1 rate of semantic and CFG features. On most ML-BFSD solutions, CFG features outperform semantic features.

4 δCFG: Assessing the Impact of CFGs

After `Explainer` reveals the importance of CFG features, we aim to explore the impacts of CFGs on decisions of ML-BFSD

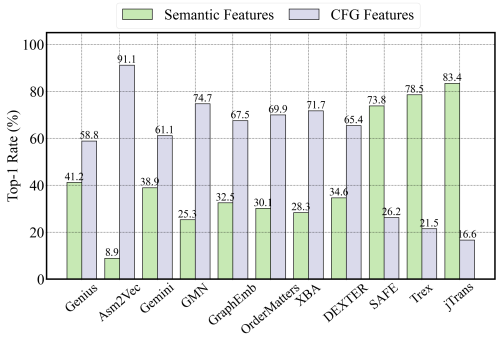

Figure 3: LEMNA shows the top-1 rate of semantic and CFG features. On most ML-BFSD solutions, the top-1 rate of CFG features is higher than that of semantic features.

solutions. We note that CFGs have a dynamic nature. Activities such as code refactoring [19] introduce changes in CFGs, mirroring the fluidity and evolution of software codebase. For instance, common refactoring techniques like method extraction, loop simplification, and dead code removal can substantially alter a CFG without changing function semantics. These changes are organic and are part of the life cycle of software development, aiming at improving code readability, maintainability, and performance. However, since ML-BFSD solutions heavily rely on CFG features, such changes might considerably affect model decisions.

We hope to explore the impact of CFG changes by manipulating CFGs of a given pair of functions to make them identical or different, without changing function semantics. In detail, (1) given an ML-BFSD solution model F, a pair of randomly selected functions **<x, y>** with different CFGs, we manipulate

their CFGs to make them identical. The modified functions are denoted as <$\mathbf{x}'$, $\mathbf{y}'$>, and they have identical CFGs. We then investigate the impact of the modification on their similarity score, by comparing $D(F(\mathbf{x}'),F(\mathbf{y}'))$ and $D(F(\mathbf{x}),F(\mathbf{y}))$. (2) Conversely, given a randomly selected function $\mathbf{x_2}$, which has identical CFG as $\mathbf{x}$, $\mathbf{x}'$ has different CFG from $\mathbf{x_2}$. We compare $D(F(\mathbf{x}'),F(\mathbf{x_2}))$ and $D(F(\mathbf{x}),F(\mathbf{x_2}))$ to assess the impact when CFGs become different.

Furthermore, based on the manipulated functions, we can explore errors caused by the over-reliance on CFG features, which indicates that CFG changes in real-world software development can threaten ML-BFSD solutions. For example, we compare the similarity scores of the function pairs that have the same CFGs but different semantics against those with different CFGs but the same semantics. More specifically, we re-sample function pair <$\mathbf{x}$, $\mathbf{y}$> that has different semantics, and function pair <$\mathbf{x}$, $\mathbf{x_2}$> that has identical semantics (e.g., $\mathbf{x_2}$ is a compilation variant of $\mathbf{x}$). Then, after manipulation, if the similarity score $D(F(\mathbf{x}'),F(\mathbf{y}'))$ is higher than $D(F(\mathbf{x}'),F(\mathbf{x_2}))$, it indicates an error in the model, since the former with different semantics is claimed more similar than the latter with identical semantics. Such errors can jeopardize downstream tasks that use ML-BFSD solutions. Taking malware clustering as an example, the analysts adopt ML-BFSD solutions to identify common functions across different malware samples according to their similarity [1,30]. In this case, the wrong behaviors of ML-BFSD solutions could introduce irrelevant functions, compromising the accuracy of clustering.

4.1 Methodology

We propose δCFG to manipulate function CFGs to be identical or different. The main challenge lies in automating the manipulation while preserving function semantics: (1) the manipulation should be automated, since comprehensive evaluation and exploring model errors requires manipulating abundant function pairs. The cost of human intervention is unacceptable. (2) As δCFG needs to verify the importance of CFGs, the manipulation should preserve the original semantics, which avoids introducing altered semantics that affect model decisions. Once the manipulation of CFGs is made, any change in model decisions can be attributed to CFGs.

We note that obfuscation techniques [5,31] can also modify CFGs without altering semantics. However, these techniques are not appropriate in our scenario. Firstly, they introduce drastic code changes that are not common in software evolution. Secondly, they typically make CFGs different, and it is challenging to make CFGs identical.

To address the above challenge, we propose a solution δCFG. We show the basic idea in Figure 4, and the detailed workflow in Algorithm 1. δCFG contains two algorithms: the *basic block match algorithm*, and the *edge match algorithm*. Using these two algorithms enables δCFG to automatically manipulate CFGs of function pairs, and make them identical, without disturbing the semantics. Moreover, these algorithms can also manipulate CFGs to be different. Consider a pair <$\mathbf{x}$, $\mathbf{x_2}$> that has identical CFGs. If we select another function $\mathbf{y}$ with a distinct CFG and apply our algorithms, we obtain a pair <$\mathbf{x}'$, $\mathbf{y}'$> with identical CFGs. This inherently makes CFGs of $\mathbf{x}'$ and $\mathbf{x_2}$ different. To this end, we primarily introduce how to make the CFGs of function pairs identical, with the divergence of CFGs emerging as an inherent consequence.

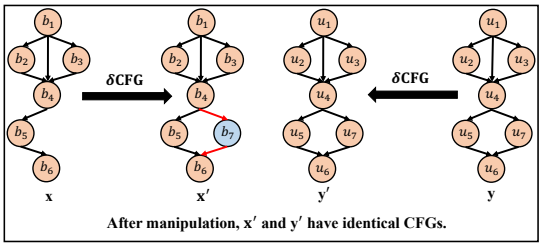

Figure 4: Basic idea of δCFG. Red edges and blue basic blocks are introduced by δCFG.

In this context, V represents the set of basic blocks, and E denotes the set of edges. To generate identical CFGs for $\mathbf{x}$ and $\mathbf{y}$, we essentially establish two mappings between their modified counterparts, $\mathbf{x}'$ and $\mathbf{y}'$. The first is a basic block mapping, $f_v : V_{\mathbf{x}'} \rightarrow V_{\mathbf{y}'}$. That is, there is a one-to-one correspondence between each basic block in $V_{\mathbf{x}'}$ and each basic block in $V_{\mathbf{y}'}$. We use the basic block match algorithm to establish this mapping. The second is an edge mapping, $f_e : E_{\mathbf{x}'} \rightarrow E_{\mathbf{y}'}$. We establish the one-to-one correspondence between each edge in $E_{\mathbf{x}'}$ and each edge in $E_{\mathbf{y}'}$, by using the edge match algorithm.

Basic block match algorithm. To establish the basic block mapping, we match each basic block of $\mathbf{x}$ with that of $\mathbf{y}$, resulting in a one-to-one correspondence. Overall, we first match the entry block of $\mathbf{x}$ with that of $\mathbf{y}$. Then, using these two entry blocks as starting points, we use a breadth-first search (BFS) strategy to match the remaining blocks across both functions.

Given that CFGs are directed graphs, when matching basic blocks, it is logical to match blocks at similar depths within the two CFGs. Thus, we employ BFS, which enables match progress from earlier depths to later depths within the CFGs. Our BFS-driven algorithm begins by matching the entry blocks b_{entry} and u_{entry} ($b \in \mathbf{x}$ and $u \in \mathbf{y}$). As BFS unfolds, we match the direct successors of each previously matched pair, aiming to match blocks at similar depths in their respective CFGs.

In detail, for each pair (b_i, u_i) that has been matched during BFS traversal, we identify their direct successor sets as S_{b_i} and S_{u_i}. We remove basic blocks from S_{b_i} and S_{u_i} that are already matched, resulting in refined sets M_{b_i} and M_{u_i}. The question left is how to match basic blocks within these two sets. We leverage the principle that basic blocks with similar connectivity patterns within CFGs should match. That is, blocks with a larger number of direct successors should be matched with each other, and vice versa. To this end, the basic blocks in M_{b_i}

and M_{u_i} are sorted in descending order based on their number of direct successors and matched accordingly. When blocks have identical direct successor counts, we count their paths toward the final block in CFGs and prioritize matching blocks with more paths. If the number of paths is equal, we randomly match blocks. We also recognize size disparities between M_{b_i} and M_{u_i} can occur. That is $|M_{b_i}| \neq |M_{u_i}|$. To solve this problem, we introduce $k = |M_{b_i}| - |M_{u_i}|$ empty basic blocks to $\mathbf{y}$ if $k > 0$, or infuse $-k$ empty blocks to $\mathbf{x}$ if $k < 0$. This strategy ensures that each block from $\mathbf{x}$ and $\mathbf{y}$ is matched with a corresponding counterpart, whether it is a genuine basic block or an introduced empty one. This iterative process proceeds until all blocks within both $\mathbf{x}$ and $\mathbf{y}$ find their counterpart.

Upon completing block mapping, the algorithm introduces empty basic blocks, transitioning the block sets for functions $\mathbf{x}$ and $\mathbf{y}$ from $V_\mathbf{x}$ and $V_\mathbf{y}$ to $V_{\mathbf{x}'}$ and $V_{\mathbf{y}'}$ respectively. Now, both $V_{\mathbf{x}'}$ and $V_{\mathbf{y}'}$ contain an identical number of blocks. Assuming each now consists of m blocks, we can represent them as $V_{\mathbf{x}'} = \{b_1, b_2, \ldots, b_m\}$ and $V_{\mathbf{y}'} = \{u_1, u_2, \ldots, u_m\}$. Here, b_i in $V_{\mathbf{x}'}$ corresponds directly to u_i in $V_{\mathbf{y}'}$. The block mapping will be used when establishing the following edge mapping.

Edge match algorithm. We design this algorithm to establish the edge mapping. The basic idea is to conduct a bijection between edges of $\mathbf{x}$ and $\mathbf{y}$. We iterate through each edge in $\mathbf{x}$, and if its corresponding edge is absent in $\mathbf{y}$, we add the required edge to $\mathbf{y}$. This process is then reciprocated for $\mathbf{y}$.

To traverse each edge in $\mathbf{x}$, we iterate through each basic block in $V_{\mathbf{x}'} = \{b_1, b_2, \ldots, b_m\}$, and record the direct successors of each basic block with a corpus $S_{\mathbf{x}'} = \{S_{b_1}, S_{b_2}, ..., S_{b_m}\}$. Each $S_{b_i} \in S_{\mathbf{x}'}$ denotes direct successors of b_i, indicating there are directed edges from b_i to each basic block in S_{b_i}. These directed edges should all have corresponding edges in $\mathbf{y}$. Recalling the basic block mapping, we note that b_i matches u_i, and all basic blocks in S_{b_i} also match the basic blocks in $V_{\mathbf{y}'}$, denoted as S_{u_i}. To this end, for each $u_i \in V_{\mathbf{y}'}$, we check if there are directed edges from u_i to each basic block in S_{u_i} one by one. If certain edges are missing, they are appended to $\mathbf{y}$. After traversing each edge in $\mathbf{x}$, we reciprocate the process for $V_{\mathbf{y}'}$. After performing the bidirectional matching on both $\mathbf{x}$ and $\mathbf{y}$, the edge match algorithm completes a comprehensive mapping for all edges between the two functions.

After adopting the two match algorithms, δCFG results in $\mathbf{x}'$ and $\mathbf{y}'$. The CFGs of them become identical, as shown in Figure 4. We note that δCFG introduces empty basic blocks, which do not compromise the semantics. However, the introduced edges might perturb original control flows and compromise original semantics. To solve this problem, we manipulate branch conditions, such as setting corresponding conditions to be always true. This guarantees functions maintain their original control flows, steering clear of the newly added branches, and thus preserving original semantics. We introduce details in Section 4.2. Additionally, observing the characteristics of the two algorithms, we can discern the CFG change on $\mathbf{x}$ (or $\mathbf{y}$) depends on the CFG of $\mathbf{y}$ (or $\mathbf{x}$). As long as we select target functions with diverse CFGs, we can achieve diverse CFG changes. This implies that our δCFG can simulate a wide variety of CFG changes that occur during software development.

Algorithm 1: The workflow of δCFG

```
Input: x = (V_x, E_x), y = (V_y, E_y);
Output: the manipulated functions x' = (V_x', E_x'), y' = (V_y', E_y');
Function δCFG:
    V_x' = V_x, V_y' = V_y, E_x' = E_x, E_y' = E_y;

```

4.2 Implementation

δCFG requires source code of functions, which is easily available. δCFG manipulates CFGs on LLVM intermediate representation (IR) [35]. After δCFG changes CFGs on IR, we use clang to compile the IR to binary. Here, we introduce key implementation details. For the basic block match and edge match algorithms, they need to create basic blocks, determine successors of basic blocks, and add edges. LLVM offers functions to implement all these operations. More specifically, we apply `Create` to create empty basic blocks, and `getSuccessor` to determine successors of basic blocks. The crux is how to add edges.

Edge addition. Given a basic block $b_i \in V_{\mathbf{x}'}$ with $|S_{b_i}|$ direct successors before edge addition, we suppose the number of direct successors increases to M after the addition ($|S_{b_i}| < M$). (1) When $M = 1$, it is an indication of a situation that requires the addition of a single edge. To facilitate this, we directly employ the `CreateBr` function to create this edge. (2) When $M = 2$, it signifies a conditional jump situation, *i.e.*, two edges need to be added. This scenario requires the use of the `CreateCondBr` function to introduce the two edges. (3) When $M > 2$, this implies a switch case scenario (our analysis reveals that at the IR level, a switch case would uniquely result in more than two branches). For adding multiple edges in such a scenario, we utilize function `SwitchInst::Create` to introduce a switch-case construct.

Semantics preservation amid edge addition. When a basic block already has direct successors, *i.e.*, $|S_{b_i}| \geq 1$, the addition of edges implies replacing the previous branch instruction with a new one, and introducing new branches, which may compromise function semantics.

For $|S_{b_i}| = 1$, it indicates b_i originally has a direct successor, and the existing branch instruction is a direct jump instruction. Given the fact that $M > |S_{b_i}|$, when $M = 2$, we need to substitute the existing branch instruction with a conditional jump. To maintain semantics, we ensure the path from b_i to b_j is consistently executed by setting the corresponding condition to be always true. When $M > 2$, we substitute the existing branch instruction with a switch-case construct. Then, we designate the preferred path (b_i to b_j) as the default. By manipulating the corresponding switch condition, we ensure that the default branch is invariably taken.

For $|S_{b_i}| = 2$, it indicates b_i originally has two direct successors, and the existing branch instruction is a conditional jump instruction. Given that $M > |S_{b_i}| = 2$, we substitute the branch instruction with a switch-case construct. Recognizing that the condition of the original branch evaluates to boolean values true or false, we employ the `CreateZExt` to map true to 1 and false to 0. These mapped values then serve as switch variables for the switch-case construct. Specifically, the original path taken when the condition is true is now associated with case 1 in the switch-case construct. Similarly, the original path taken when the condition is false is associated with case 0. Any other branches in the switch-case construct are designed not to be taken, thus preserving the original semantics.

For $|S_{b_i}| > 2$, it implies b_i has multiple direct successors, and the existing branch instruction is a switch-case construct. Accordingly, we add $M - |S_{b_i}|$ branches by introducing new cases to a switch-case construct. We employ the `addCase` for this purpose. By carefully setting case values, we ensure that these new branches remain untaken, thereby maintaining the original semantics. Here, how to set case values is the crux. More specifically, assuming S_{b_i} contains n basic blocks ($|S_{b_i}| = n$), given a switch variable *var*, there are n case values, represented as $C = \{C_0, C_1, ..., C_{n-1}\}$. Each case value C_j corresponds to a basic block b'_j in $S_{b_i} = \{b'_0, b'_1, ..., b'_{n-1}\}$. During each execution, the switch variable *var* will take on one of the case values, subsequently executing the corresponding basic block. To maintain the original semantics, when adding $M - n$ new cases, it's essential to ascertain that these new case values do not overlap with the existing ones in C. Thus, these new case values will never equal *var* and the newly added branches will never be executed. This approach maintains the original semantics.

The question left is how to ensure that the newly added case values do not overlap with C. The main challenge lies in ensuring that the newly added case values do not overlap with C. It's noteworthy that each function may have a unique set of C. To automate the addition of non-overlapping case values, we replace all existing case values in C with a continuous sequence $\widetilde{C}$ ranging from 0 to $n-1$, i.e., $\widetilde{C} = \{0, 1, ..., n-1\}$. That is, now each case value $\widetilde{C}_j$ corresponds to basic block b'_j. Concurrently, we adjust the switch variable *var* to match this new sequence, yielding var_{new}. The adjustment is realized through the operation: $var_{new} = \bigvee_{1 \leq j \leq n-1} \texttt{CreateSExt}(var == C_j) \wedge j$, where LLVM function `CreateSExt` extends a signed value to 32 bits. To this end, when $var = C_j$, var_{new} equals to $\widetilde{C}_j$, and b'_j will be executed. Thus, the case value replacement will not compromise the original semantics. With this replacement in place, when new case values arise, we can straightforwardly set their values greater than $n-1$, automating the addition of case values. As the new case values exceed $n-1$, they do not overlap with $\widetilde{C}$, without compromising the original semantics.

5 Evaluation on δCFG

We adopt δCFG to answer four research questions (RQs):

- **RQ1:** What is the impact on model decisions when a pair of functions with identical CFGs are modified to have different CFGs? (Section 5.1)
- **RQ2:** What is the impact on model decisions when a pair of functions with different CFGs are modified to have identical CFGs? (Section 5.2)

- **RQ3:** How come these ML-BFSD solutions rely heavily on CFGs? (Section 5.3)

- **RQ4:** Can our $\delta_{\texttt{CFG}}$ be utilized to mitigate the over-reliance and enhance the performance of ML-BFSD solutions? (Section 5.4)

5.1 Change Identical CFGs to Be Different

Overall, results reveal that for the majority of the ML-BFSD solutions, the similarity scores for function pairs with identical CFGs experience a substantial decrease when their CFGs become different. More importantly, these changes in CFGs could result in model errors. That is, functions that are semantically identical might be incorrectly identified as dissimilar.

Experimental setup. For each ML-BFSD solution **F**, we randomly select 5,000 function pairs with identical CFGs and semantics to investigate the impact of modifying CFGs. During the selection of each function **x**, we traverse all possible combinations of compilation variants, such as (O0, O1) and (O0, O2), until we identify a pair of variants whose CFGs are identical. If no such pair is found, the function is not selected. Ultimately, we collect 5,000 function pairs with identical CFGs and semantics, each denoted by <**x**, $\mathbf{x_2}$>.

Evaluation metrics. We use decrease ratio and error rate (ER) to evaluate the impact when CFGs become different. (1) Similarity scores will decrease when CFGs of pairs change from being identical to different. We evaluate the decrease in their similarity score by *decrease ratio*: $\frac{\mathbf{F}(\mathbf{x},\mathbf{x_2})-\mathbf{F}(\mathbf{x}',\mathbf{x_2})}{\mathbf{F}(\mathbf{x},\mathbf{x_2})}$. (2) We further measure *ER* caused by CFG changes. Recalling scenarios where ML-BFSD solutions are used, given a **x**, the task is to identify the closest counterpart $\mathbf{x_2}$ from a pool of candidate functions. We mimic real-world scenarios where **x** has been changed to $\mathbf{x}'$ due to CFG changes such as code refactoring, and test whether **F** can still identify $\mathbf{x_2}$ as the most similar function despite the CFG changes.

For each function **x**, we create four function pools with sizes of 16, 32, 64 and 128, respectively, with functions randomly selected from open-source projects. We guarantee that, within each pool, the similarity score between **x** and $\mathbf{x_2}$ ranks at the top. Subsequently, upon computing similarity scores between $\mathbf{x}'$ and all functions in the pool (including $\mathbf{x_2}$) using **F**, we rank all functions based on these scores. We evaluate whether the pair <$\mathbf{x}'$, $\mathbf{x_2}$> maintains its top rank despite the CFG changes. Any deviation from the top rank is deemed an error. Thus, $ER = \frac{num(error)}{num(all)}$, where $num(error)$ is the number of errors, and $num(all)$ is the total number of function pairs, *i.e.*, 5,000, declared in our setup.

Results. Figure 5 shows the decrease ratios observed. ML-BFSD solutions that rely on CFGs are sensitive to CFG changes, reflecting high decrease ratios with many function pairs experiencing a decline in similarity scores by 40% $\sim$ 60% or more than 60%. Taking OrderMatters as an example,

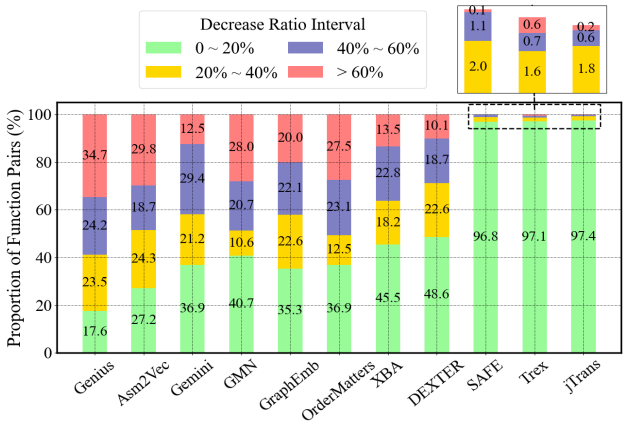

Figure 5: Evaluation results of decrease ratios. In non-CFG dependent solutions, most function pairs exhibit decrease ratios within the 0 $\sim$ 20% interval (represented by the green bars).

23.1% function pairs witness a decrease of 40% $\sim$ 60%, and 27.5% experience a decrease exceeding 60%.

In contrast, in non-CFG dependent solutions, namely SAFE, Trex, and jTrans, a significant majority of function pairs exhibit decrease ratios within the 0 $\sim$ 20% interval, while only a minor fraction of function pairs show higher decrease ratios. Such results indicate these solutions are insensitive to CFG changes. For instance, in jTrans, 97.4% of function pairs show decrease ratios within 20%, while only 2.6% of function pairs exceed 20%.

The ER results in Table 3 highlight that a majority of solutions demonstrate a substantial ER, even at the smallest pool size of 16. This suggests that when CFGs of function pairs differ, many models often misjudge them as dissimilar, despite their identical semantics. To elaborate, with a pool size of 16, most solutions' ER is still above 40%. As we increase the pool size from 16 to 128, the ER for the majority further escalates significantly.

Summary. Most solutions exhibit high decrease ratios and ER due to the over-reliance on CFGs, revealing a notable model limitation. In contrast, SAFE, Trex, and jTrans diverge in performance compared to others, displaying much lower ratios and ER. This aligns with our explanation results that these three do not heavily rely on CFGs.

5.2 Change Different CFGs to Be Identical

We further consider scenarios where function pairs with different CFGs are changed to have identical CFGs. On most ML-BFSD solutions, we observe that such changes induce a significant similarity score increase, despite different function semantics. Furthermore, a considerable number of function pairs are misjudged as similar, with similarity scores rising to the top position.

Table 3: Evaluation of ER when CFGs become different.

BFSD Solutions	ER (%)			
	pool size = 16	pool size = 32	pool size = 64	pool size = 128
Genius	62.7	67.9	73.3	75.1

GraphEmb	38.7	45.6	52.1	60.2
OrderMatters	57.8	65.1	70.7	75.2
XBA	52.0	62.5	70.6	76.0
DEXTER	46.5	56.3	63.7	70.6
SAFE	1.4	1.8	2.0	2.5
Trex	1.3	1.5	2.2	4.1
jTrans	1.1	1.5	2.4	3.0

Experimental setup. For each solution **F**, we randomly select 5,000 function pairs with different semantics from open-source projects. Each function pair <**x**, **y**> is chosen such that $\mathbf{F}(\mathbf{x},\mathbf{y})$, their similarity score, is lower than the score between **x** and its compilation variants, ensuring that the semantics of <**x**, **y**> are different and can be correctly distinguished by **F**. Then, $\delta_{\texttt{CFG}}$ manipulates each pair <**x**, **y**> into <$\mathbf{x}'$, $\mathbf{y}'$>. Here, $\mathbf{x}'$ and $\mathbf{y}'$ have identical CFGs but different semantics.

Evaluation metrics for RQ2. We use increase ratio, error rate (ER), and top-1 rate to evaluate for the evaluation. When function pair CFGs are changed to be identical, (1) we assess the improvement of their similarity scores by measuring *increase ratio*: $\frac{\mathbf{F}(\mathbf{x}',\mathbf{y}')-\mathbf{F}(\mathbf{x},\mathbf{y})}{\mathbf{F}(\mathbf{x},\mathbf{y})}$. (2) Following the ER metric defined in Section 5.1, we construct four function pools of sizes 16, 32, 64, and 128 in a similar way. Each pool encompasses a randomly selected compilation variant of **x**, denoted as $\widetilde{\mathbf{x}}$. Additionally, each pool includes $\mathbf{y}'$ to emulate a scenario in which the CFG of **x** is modified to be identical to a function (i.e., $\mathbf{y}'$) in pools. We ensure that, prior to the modification, the similarity score between **x** and its compilation variant $\widetilde{\mathbf{x}}$ is the highest within the pool. After the CFG modification, we compute similarity scores between $\mathbf{x}'$ and all functions in the pool (including $\widetilde{\mathbf{x}}$), and rank all functions based on these scores. If the similarity score between $\mathbf{x}'$ and $\widetilde{\mathbf{x}}$ no longer holds the top rank, we regard it as an error. Then, we calculate the ER in the same manner as described in Section 5.1. (3) We further underscore the extent to which identical CFGs can contribute to misjudging functions as similar. We measure the proportion of pairs that, when modified to possess identical CFGs, achieve the top-1 position in terms of similarity scores within their respective pools. To this end, we introduce the metric *top-1 rate*: $\frac{num(top\text{-}1)}{num(all)}$. Here, $num(top\text{-}1)$ represents the count of pairs for which the similarity score of $\mathbf{x}'$ and $\mathbf{y}'$ ranks first within the pool. Meanwhile, $num(all)$ signifies the total number of function pairs investigated.

Results. Figure 6 presents the results of increase ratios. For the majority of solutions, manipulating CFGs to be identical leads to significant increases in similarity scores for function pairs with different semantics. Specifically, over 56.9% of function pairs (100% – 43.1% on OrderMatters) register increase ratios above 40%, with at least 42.4% surpassing 60%. Table 4 further underscores a major shortcoming in ML-BFSD solutions when evaluating function pairs with identical CFGs. These models frequently misidentify them as similar, a clear discrepancy from their true different semantics. Remarkably, the ER for a bulk of solutions breaches the 50% mark at a modest pool size of 16, and this exceeds 70% when the pool size extends to 128. Moreover, Table 5 shows that considerable function pairs, upon becoming identical CFGs, achieve the top-1 similarity scores within their respective function pools. On most solutions, the top-1 rate remains above 20% even as the pool size increases to 128.

Summary. Except for SAFE, Trex and jTrans that do not rely on CFGs, other solutions show pronounced increase ratios, ER, and top-1 rate. Such results illuminate the stark challenges these models grapple with when tasked with recognizing semantic dissimilarities amidst identical CFGs, validating the pitfalls of over-reliance on CFGs.

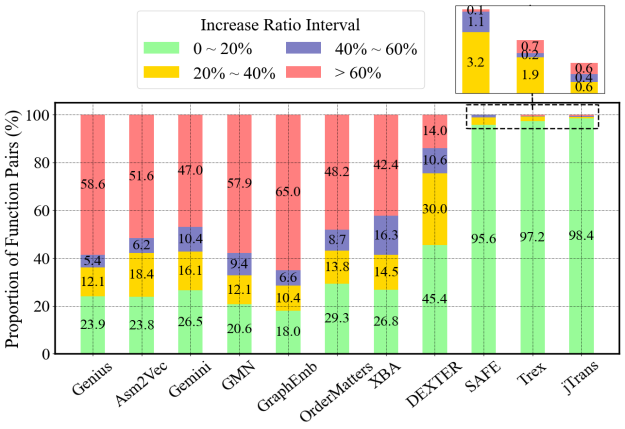

Figure 6: Evaluation results of increase ratios.

5.3 Interpreting CFG Over-reliance

After validating ML-BFSD solutions heavily relying on CFG features, we conclude two potential reasons that cause the

Table 5: Evaluation results of top-1 rate.

BFSD Solutions	Top-1 rate (%)			
	pool size = 16	pool size = 32	pool size = 64	pool size = 128
Genius	39.1	35.8	30.5	25.6

Trex	4.6	2.3	1.9	1.7
jTrans	2.0	1.9	1.6	1.5

over-reliance: (1) Many ML-BFSD solutions suffer from design flaws that compromise the learning of semantics. (2) The training set has a bias. Based on the above analysis, we clarify the reasoning between semantics and CFG features.

Design flaw analysis. We find that these ML-BFSD solutions have design flaws that undermine the learning of semantics, resulting in the over-reliance on CFG features.

First, some methods [16, 50, 67] manually specify features, potentially resulting in information loss. For instance, both Gemini and DEXTER neglect the order of instructions when defining manual features, which leads to information loss. Second, instruction relationships are not well captured by many ML-BFSD solutions. Genius learns intra-block semantics but not inter-block relations. Asm2Vec only partially learns relationships through a random walk, which covers a small number of basic blocks. In ML-BFSD solutions utilizing GNNs [33, 38, 46, 67, 72] , GNNs assign instructions to various graph nodes based on control dependencies depicted by CFGs, where each node corresponds to a basic block. However, GNNs typically excel at learning relationships between instructions within basic blocks that are directly connected. For instructions located in distant blocks that are not directly connected, it is generally less effective for GNNs to capture relationships between them. This implies that learning based on CFGs could limit models' understanding of instruction context. We note that Pei et al. [51] explore the potential of utilizing large language models (LLMs) for representation. Given their exceptional representation capabilities, using LLMs for representation may become a future trend.

Bias of training set. We note many solutions use a biased training set, resulting in over-reliance on CFGs. These solutions aim to train models to identify function pairs with identical semantics as similar (denoted as $\langle \mathbf{x}, \widetilde{\mathbf{x}} \rangle$) and function pairs with different semantics as dissimilar (denoted as $\langle \mathbf{x}, \mathbf{y} \rangle$). Here $\mathbf{x}$ and $\mathbf{y}$ are semantically distinct functions taken from the function set constructed by the ML-BFSD solutions, and $\widetilde{\mathbf{x}}$ is a compilation variant of $\mathbf{x}$. However, the distribution of function pairs has a bias, and thus causes models to heavily rely on CFGs. Specifically, function pairs can be generally categorized into four types. (1) Type 1: different CFGs and different semantics. (2) Type 2: different CFGs but same semantics. (3) Type 3: same CFGs and same semantics. (4) Type 4: same CFGs but different semantics. We find that numerous pairs belong to types 1-3, while only a small amount of them belong to type 4. Note that, only function pairs in types 3 and 4 have the same CFGs. However, type 3 is much more common than type 4, which can cause models to tend to identify functions with the same CFGs as similar, namely, over-reliance on CFG features.

Table 6: The proportion of four types of function pairs.

Repetition Count	Proportion (%)			
	Type 1	Type 2	Type 3	Type 4
Repetition #1	49.71	40.49	9.51	0.29
Repetition #2	49.73	42.46	7.54	0.27
Repetition #3	49.75	39.39	10.61	0.25
Repetition #4	49.72	40.31	9.69	0.28
Repetition #5	49.68	39.33	10.67	0.32

Specifically, these solutions use the BinaryCorp-3M training set from jTrans [64], which compiles tens of thousands of open-source projects and establishes this uniform and large-scale dataset containing approximately 3,000,000 functions. We randomly select 400,000 function pairs from the training set, and observe the proportion of the four types of function pairs. We repeat each experiment five times. Table 6 presents the proportion of the four types of function pairs, and the proportion of type 4 is much lower than that of others. Only function pairs in types 3 and 4 have identical CFGs, but type 3 is $27.9 \sim 42.4\times$ more than type 4, which leads to overfitting and over-reliance on CFGs. That is, models are prone to identify function pairs with the same CFGs as semantically equivalent.

Reasoning between semantics and CFG features. Semantics are determined by both instructions themselves and their contexts, i.e., relationships between instructions. Thus, ML-BFSD solutions need to learn not only the instructions but also their contexts. However, CFGs can only aid models in learning a portion of (not all) the context of instructions and may even limit the model's learning of instruction context. On the other hand, modeling the full context, i.e., an instruction sequence, may yield different embeddings by different ML-BFSD solutions. But this is not an issue. Their embeddings differ because they reside in different latent spaces. These differing latent spaces can be aligned through projection.

5.4 Model Performance Improvement

After analyzing the reasons behind the over-reliance on CFGs, we find δCFG can be used to mitigate this issue by alleviating training set bias. Consequently, δCFG helps ML-BFSD solutions better learn function semantics, improving model performance. We use δCFG to manipulate function CFGs, thus increasing the number of function pairs with identical CFGs but different semantics. Subsequently, we use the manipulated functions generated by δCFG, as well as the original training

set to fine-tune ML-BFSD solutions, enhancing ML-BFSD solutions.

We use the training set from BinaryCorp-3M, and randomly select 50,000 function pairs exhibiting differing semantics and employ δCFG to generate manipulated pairs. Then, we curate a fine-tuning dataset by integrating these manipulated pairs (50,000) into the training set. Using this enhanced set, we fine-tune the top six performing solutions with 5 epochs: Gemini, GMN, GraphEmb, OrderMatters, XBA and DEXTER. Finally, we evaluate model performance on the test set (no augmented data) from BinaryCorp-3M, with pool size of 32.

Performance and semantics enhancement with δCFG.

Table 11: Change in importance scores: increase for semantic features and decrease for CFG features in enhanced models.

We assess model performance using four metrics commonly employed in previous literature [45, 46, 64]: MRR, Recall@1, AUC, and F1 score. Table 7, 8, 9 and 10 highlight performance enhancements across all models upon applying δCFG, with the highest observed boosts of 10.1% in MRR, 12.7% in Recall@1, 5.1% in AUC and 27.2% in F1 score. On average, MRR, Recall@1, AUC and F1 score experience an uplift of 0.5% $\sim$ 5.7%, 0.8% $\sim$ 7.7%, 0.2% $\sim$ 3.3%, and 0.2% $\sim$ 13.5% respectively. Conversely, models fine-tuned solely with the BinaryCorp-3M training set (denoted as **clean**) often stagnate and even regress in performance. Further, we use our `Explainer` to explain the enhanced models, revealing that the importance of semantic features is improved. According to Table 11, the enhanced models exhibit increased importance scores for semantic features and reduced scores for CFG features, signifying a better understanding of function semantics and reduced over-reliance on CFG features.

Robustness evaluation. The above results validate the enhancement of models through the application of δCFG. Such enhancement enables models to generate new function representations. To evaluate the robustness of new representations, we increase instruction separation by augmenting the number of basic blocks between instructions. This methodology allows us to assess models' robustness to such changes and validate their improved capability in learning relationships between instructions in distinct basic blocks.

We employ the same set of function pairs as declared in Section 5.1, each consisting of semantically equivalent functions with identical CFGs, denoted as <**x**, $\mathbf{x_2}$>. For each pair, we randomly select k basic blocks within **x** to split using LLVM's function `splitBasicBlock`, with k randomly chosen from the set {1,2}. We then reconnect the divided basic blocks with direct jump instructions to maintain the original control flow. After the split, we introduce a stochastic element by randomly determining whether to incorporate additional branches between the newly formed basic blocks. For example, if a basic block b is split into b_1 and b_2, with a direct transition from b_1 to b_2, we randomly decide whether to introduce a new successor node b_3 to b_1 and switch the direct jump to a conditional jump. These modifications effectively increase instruction separation.

We compare the performance of models enhanced by δCFG against the original models without enhancements (denoted as **baseline**). For comparisons, we use the decrease ratio and ER metrics as defined in Section 5.1. Lower values in both metrics indicate greater robustness, affirming models' superior ability to learn relationships between instructions.

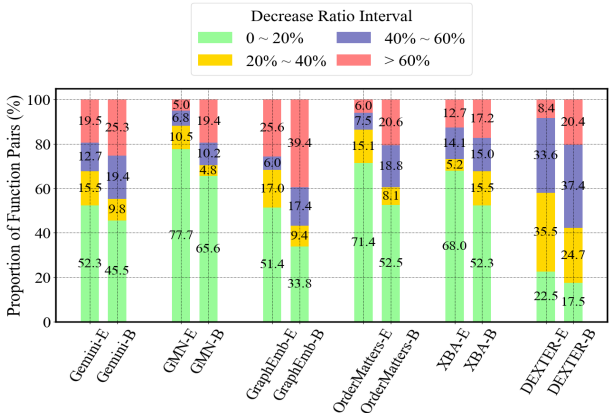

Figure 7: Comparison of decrease ratios between enhanced (-E) and baseline (-B) models.

Figure 7 and Table 12 show that function pairs analyzed using enhanced models exhibit lower decrease ratios and ER compared to those analyzed with baseline models. Such results validate the improved robustness of enhanced models. In Figure 7, a greater proportion of function pairs evaluated using enhanced models maintain decrease ratios within the 0 $\sim$ 20% interval. In contrast, function pairs analyzed with baseline models more frequently fall into higher decrease ratio intervals, namely 40% $\sim$ 60% and above 60%. For instance, in GMN-E (enhanced GMN), only 11.8% function pairs show

Table 12: Comparison of ER between enhanced and baseline models.

BFSD Solutions	ER (%)							
	pool size = 16		pool size = 32		pool size = 64		pool size = 128	
	δCFG	baseline	δCFG	baseline	δCFG	baseline	δCFG	baseline
Gemini	**30.6**	36.0	**36.8**	42.8	**40.9**	47.4	**46.1**	51.6
GMN	**23.0**	33.5	**26.4**	37.3	**29.2**	41.7	**32.8**	46.1
GraphEmb	**23.2**	47.1	**28.3**	51.4	**33.7**	54.6	**38.7**	57.3
OrderMatters	**13.5**	29.6	**18.6**	35.5	**24.2**	43.3	**28.8**	50.5
XBA	**47.6**	51.5	**53.9**	57.4	**58.8**	61.5	**62.0**	65.2
DEXTER	**40.4**	49.3	**43.2**	55.5	**47.9**	60.1	**53.1**	62.8

decrease ratios exceeding 40%. In comparison, GMN-B (the baseline) results in 29.6% function pairs experiencing decrease ratios above 40%. This indicates greater variability in similarity scores when computed using the baseline model. In Table 12, across all function pool sizes , enhanced models consistently achieve lower ER. Overall, the above results indicate that enhanced models are less affected by increased instruction separation, thereby affirming their better robustness and improved ability to discern instruction relationships.

6 Conclusion

This work is the first to investigate the role of CFG features in ML-based BFSD, serving as a robustness validator for model developers. We first designed `Explainer` to explain 11 representative ML-BFSD solutions and reveal that CFG features are overly relied on. Then, we designed δCFG to explore the impact of CFG features on model decisions, and discovered numerous errors in ML-BFSD solutions by manipulating function CFGs. We further analyzed the reasons behind such over-reliance on CFG features, and discovered design flaws in solutions, as well as a serious bias in training data. In addition, we found that ML-BFSD solutions could also be used to enhance model performance. We conducted fine-tuning with δCFG on all ML-BFSD solutions studied by us, significantly improving model performance as well as de-prioritizing the over-reliance issue.

Abstract

Binary type inference is a core research challenge in binary program analysis and reverse engineering. It concerns identifying the data types of registers and memory values in a stripped executable (or object file), whose type information is discarded during compilation. Current methods rely on either manually crafted inference rules, which are brittle and demand significant effort to update, or machine learning-based approaches that suffer from low accuracy.

In this paper we propose TYGR, a graph neural network based solution that encodes data-flow information for inferring both basic and struct variable types in stripped binary programs. To support different architectures and compiler optimizations, TYGR was implemented on top of the ANGR binary analysis platform and uses an architecture-agnostic data-flow analysis to extract a graph-based intra-procedural representation of data-flow information.

We noticed a severe lack of diversity in existing binary executables datasets and created TYDA, a large dataset of diverse binary executables. The sole publicly available dataset, provided by STATEFORMER, contains only 1% of the total number of functions in TYDA. TYGR is trained and evaluated on a subset of TYDA and generalizes to the rest of the dataset. TYGR demonstrates an overall accuracy of 76.6% and a struct type accuracy of 45.2% on the x64 dataset across four optimization levels (O0-O3). TYGR outperforms existing works by a minimum of 26.1% in overall accuracy and 10.2% in struct accuracy.

1 Introduction

Decompilation, the process of transforming a compiled program to a higher-level language such as C, plays a crucial role in the analysis of computer security threats, as it provides a deep understanding of the behavior of compiled programs. However, decompiled code tends to offer less information compared to the original source code. Many abstractions and constructs such as variable types, comments, and control-flow structures are discarded during compilation, posing a challenge for reverse engineers engaged in program analysis.

Type inference is a major opportunity to significantly improve the output of decompilation [20]. The precise inference of types in binary code has many applications, including binary reverse engineering, malware analysis, vulnerability discovery on binary code [11], software patching, binary rehosting, and other security-critical applications [8, 19, 47]. However, automated and precise binary type inference is challenging [31, 68] due to the lack of high-level abstractions and the rich variety and sophistication of compiler optimizations and hardware architectures [55].

Existing binary type inference solutions can be broadly classified into three categories: (1) Rule- and heuristic-based solutions (e.g., type inference in IDA and Ghidra). (2) constraint-solving-based solutions (e.g., TIE [35], RETYPD [42], and OSPREY [70]). (3) machine-learning-based solutions (e.g., DEBIN [32], STATEFORMER [45], TYPEMINER [38], and DIRTY [10]). Our work is motivated by three key challenges that the state-of-the-art techniques face: (1) *Low accuracy in inferred types on stripped binaries*: Even the best solution only achieves an accuracy of 55.7% during evaluation. (2) *Composite struct type prediction*: Most of the existing solutions either do not predict struct member types or partially support member prediction. (3) *Limited architectural and optimization level support*: Many solutions, especially heuristic-based and constraint-based ones, only support binaries on one or a limited number of architectures and compiler optimization levels. This is because generalizing rules, heuristics, and constraint-solving methods to a diverse set of binaries is difficult.

In this paper, we present TYGR, a machine-learning-based binary type inference technique that assists binary reverse engineers by inferring types for registers and memory locations with a high accuracy. TYGR lifts binary code into VEX IR [41], an intermediate representation (IR) with a wide architecture support, runs a light-weight data-flow analysis on each function to collect information about how each variable

* The first two authors contributed equally to this paper.

is accessed, generates a graph-based representation of data-flow information, and finally trains a model based on Graph Neural Networks (GNN) [50] for type inference.

To strike a balance between scalability and accuracy, TYGR employs a novel graph-based intra-procedural representation of the data-flow information. Because the representation is constructed on a per-function basis, TYGR scales to large, real-world binaries. This representation is acceptable to GNNs, a deep neural network model that is well-suited for predicting rich properties of graph-structured data [61]. To the best of our knowledge, TYGR is the first to demonstrate the effective application of GNNs to the problem of binary type inference. Particularly, we demonstrate that they can adequately tolerate missing inter-procedural information, thereby allowing data-flow analysis to scale.

Our evaluation revealed that existing datasets contain many duplicates. Prior works [44, 56] also made this observation. For instance, recent work by Pal *et al.,* [44] found that 52% of functions in the DIRT dataset are duplicates. Similarly, we found that STATEFORMER dataset has an average of 90% duplicate functions. Such high percentages of duplicates make these datasets unsuitable for properly evaluating learning techniques. To handle this, we created TYDA, a deduplicated binaries dataset built from Gentoo and Debian packages for five architectures (x64, x86, AArch64, Arm32, and Mips) across four optimization levels (O0, O1, O2, and O3).

We implement TYGR on top of the ANGR binary analysis framework [55]. Our evaluation on TYDA dataset shows that TYGR has an overall type prediction accuracy of 76.6% and struct type prediction accuracy of 45.2%—outperforming existing state-of-the-art techniques by 10.2% to 26.1%.

Contributions. This paper makes the following contributions:

- We propose a novel graph-based representation of data-flow information that allows a synergistic combination of a data-flow analysis and a graph neural network model to balance scalability and accuracy.
- We employed innovative techniques to construct a new dataset, incorporating binaries from x64, x86, AArch64, Arm32 and Mips architectures. This dataset is notably larger and more expansive compared to existing datasets.
- We implement TYGR, a system that uses the GNN model that is trained on a large dataset of binary functions to infer types of program variables in unseen functions from stripped binaries.
- We demonstrate the effectiveness of TYGR by extensively evaluating it on a subset of TYDA. TYGR demonstrates an overall accuracy of 76.6 % and a struct type accuracy of 45.2% on the x64 dataset across four optimization levels (O0-O3). TYGR outperforms existing works by a minimum of 26.1% in overall accuracy and 10.2% in struct accuracy.

In the spirit of open science, we release our research artifacts at https://github.com/sefcom/TYGR.

2 Background

Before diving into the technical details of TYGR, we will first present necessary background knowledge for readers on binary reverse engineering, binary type inference, and GNNs.

2.1 Binary Reverse Engineering

Binary reverse engineering is the process of understanding a program without access to, or only having limited access to its source code. Reverse engineers analyze binaries to understand the behaviors or provenance of malware [21, 65], discover vulnerabilities in binaries [39], and mitigate defects in legacy software [53]. In most cases, debug symbols are not available to reverse engineers; They are forced to manually recover lost semantic information, such as variable locations, names, and types, during reverse engineering.

2.2 Type Inference on Binaries

Binary type inference is the automated process of reconstructing source-level type information, e.g., types of local variables and function arguments, from untyped byte-addressed memory locations and registers. It is challenging because most information is discarded during compilation unless debug symbols are preserved. As shown in Table 1, existing binary type inference solutions can be broadly classified into three categories based on their core techniques: (1) Rule- and heuristic-based type inference solutions, (2) constraint-solving-based solutions, (3) machine-learning-based solutions.

A key difference between these solutions is if they support type inference of structs and struct members (or struct layouts). Inferring struct members and their types requires complex and accurate reasoning and fine-grained flow information [8], which is hard to gain during static analysis. Most non-constraint-based inference techniques (i.e., top and bottom row groups) do not predict struct member types. REWARDS [37] and HOWARD [57], which do predict struct member types, use dynamic traces to get precise offset information. However, as with any dynamic techniques, they suffer from low completeness: they only support assembly code that is reachable during execution. Therefore, we make a design decision for TYGR to not use dynamic traces and not infer struct members.

2.3 Graph Neural Networks

Graph Neural Network (GNN) is a deep neural network architecture that is well-suited for predicting rich properties of

Table 1: A qualitative comparison among existing binary type inference techniques. All techniques support inferencing primitive types, which are omitted in this table. "Struct," "Struct Ptrs," and "Struct Members" refer to whether each technique can *automatically* infer such information. IDA and Ghidra only support manually specifying struct types to variables and perform extremely limited automated type inference of structs. TypeMiner does not attempt to recover the complete struct layout or types of all struct members. DIRTY only predicts types in its vocabulary and does not support predicting structs that did not appear in its training set.

graph-structured data [61], through a procedure called *message passing*. GNNs have been used for many program understanding and analysis tasks, such as identifying variable misuses in C# programs [4], localizing and repairing bugs in JavaScript code [18], predicting types in Python programs [3], and detecting code clones [62]. To the best of our knowledge, TYGR is the first to demonstrate the effective application of GNNs to the problem of binary type inference.

3 Overview

In this section, we first define the binary type inference problem. We then provide an overview of TYGR's architecture, highlighting key design choices that enable it to achieve precise and scalable type inference on binary code.

3.1 Binary Type Inference

We consider the problem of mapping binary-level variables to source-level types. Specifically, we focus on function parameters and local variables, which are crucial for understanding the behavior and intent of the function—and are thus of interest to reverse engineering. We illustrate our objective with an example in Figure 1, which shows a C function and its assembly code extracted from an x64 binary compiled with GCC using optimization level O0. In practice, only the binary is available, but inferring types for data that directly correspond to source-level variables is helpful for understanding the intent of the function, and perhaps even extracting a faithful decompilation. At the binary level, local variables are typically stored at stack offsets. For instance, the stack offset `-0x30(%rbp)` corresponds to `name_len` and `-0x38(%rbp)` corresponds to `ext_len`.

Our goal is to predict fine-grained type information in the form of C types, such as `int32`, `uint64`, and `struct*`. These types are familiar to reverse engineers with experience in popular reverse engineering tools (e.g., IDA). We treat type inference as a classification problem and use a fixed subset of primitive types. While C types may be arbitrarily complex, our finite subset is expressive enough to cover over 97.1% types that arise in our large dataset.

It is worth noting that existing machine learning-based type inference techniques are all type *prediction* techniques. The crucial difference between type inference and type prediction is that type prediction techniques only predict types that are in the vocabulary while type inference may output new types that are not in the vocabulary. This difference matters most in inferring struct types, where existing machine learning-based solutions fail to predict struct shapes or types for struct members (DEBIN and STATEFORMER), or can only predict known struct types (DIRTY), which severely limits their use in revese engineering tasks. TYGR supports predicting struct shapes and member types, which essentially makes TYGR a type inference technique.

3.2 TYGR Architecture

Figure 2 shows an overview of TYGR. A key goal of TYGR is architecture independence over the input binary. Therefore, TYGR uses VEX IR [41], an architecture-agnostic IR for binary code in many different architectures.

Importance of Data-flow Information. Data-flow information is highly relevant for type inference. This is evident in traditional constraint-based type inference techniques wherein the typing constraints encode such information [8, 35, 42]. However, these methods are often limited by the constraint-solving step, which prevents them from effectively scaling to

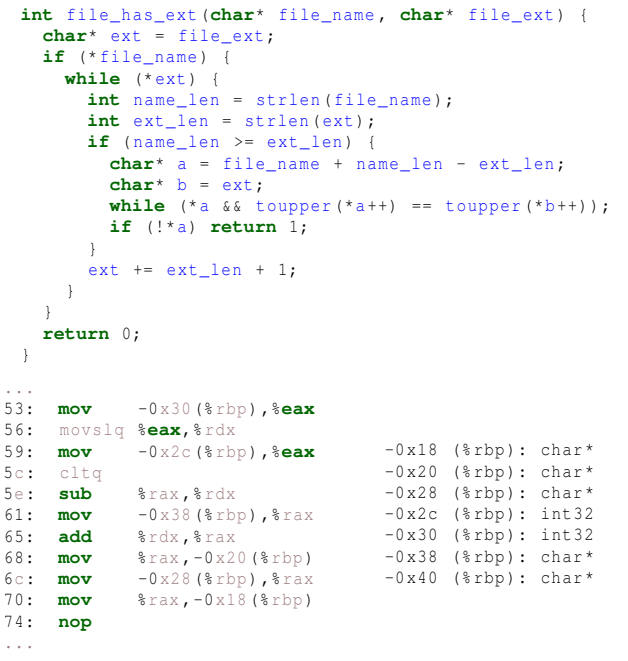

Figure 1: Top: A C function that checks file extensions. Bottom left: The disassembly abstract of the function in compiled x64 binary. Bottom right: Type predictions for variables at their corresponding stack offsets.

large binary applications. An attractive work-around is to employ machine learning. TYGR thereby uses a model to learn the data-flow patterns in binaries and outputs predicted types. To integrate classic data-flow analysis and modern machine learning, we must design a representation for typing information that is both easy to extract and suitable for machine learning.

Representing Data-flow Information. Our key insight is to design a graph-based intra-procedural representation of data-flow information. First, constraint-encoded data-flow information is also naturally modeled through graphs, and in fact light-weight data-flow graphs are easy and efficient to acquire using ANGR. Moreover, modern graph neural networks (GNNs) are remarkably well-suited to learning and approximating the latent semantics of graph-structured data. This motivates the central data structure of TYGR, which is an efficiently constructed and information-rich graph that explicitly marks the derivation, usage, and location of data-flow throughout program execution. In short, we use ANGR to generate function-level data-flow graphs that are fed to a graph neural network. The graph neural network then generates a continuous embedding of the data-flow graphs that approximate the underlying typing semantics.

Inference as Classification. We model type inference as a classification problem [48], in which we classify an entity as one of the finite C-level types. Although the possible types are, in principle, arbitrarily many, we observe that selecting a much smaller range of commonly seen types already encompasses a large portion of those that exist in the wild. Therefore, rather than incorporating the full complexity of structured prediction, the formulation of type inference as a classification problem suffices for binaries.

TYGR's output is a mapping of binary-level variables to their respective C-level types. It is easily interpretable as this closely matches the type systems of popular tools like IDA and GHIDRA, and is therefore also in a format that is easy to integrate with existing analysis loops.

4 Methodology

In this section we present TYGR's approach to binary type inference as a machine learning problem.

4.1 The VEX IR

TYGR first lifts the input binary function into VEX IR using the ANGR binary analysis framework [55]. Figure 3 shows how TYGR converts a few lines of x64 binary assembly into their corresponding VEX statements. The core semantics of VEX IR center around accesses (reads and writes) to registers, memory locations, and temporary variables (e.g., `t2` and `t6`). Temporary variables are a VEX-specific convention to enforce static-single assignment form [15].

4.2 Data-Flow Analysis

We next discuss how TYGR uses data-flow analysis to generate graphs that capture the relevant information for type inference. Figure 4 shows the function `foo` and its control-flow graph (CFG). Depending on the parameter `a`, either path P_1 or P_2 will be taken, which will appropriately modify the values of the two local stack variables `b` and `p`.

Our goal is to infer the types of `a`, `b`, `p`. To do this we aim to generate information-rich data-flow graphs as shown in Figure 5. These graphs convey how variables derive and use data during execution, and capture information for a GNN to infer types. As a high-level overview, our strategy for data-flow analysis comprises two steps:

Step 1. Perform program execution along different non-cyclic paths in the CFG of a function to generate a data-flow graph for each variable along each path. Each path is then associated with a collection of variable-level data-flow graphs (Figure 5, left).

Step 2. Aggregate the variable-level data-flow graphs of both paths into a function-level data-flow graph (Figure 5, right). This in turn is passed to the training stage of TYGR's pipeline.

4.2.1 Exploring the Control-Flow Graph

TYGR explores all nodes and edges in the CFG of a function and inspects the read-from and written-to locations in each IR

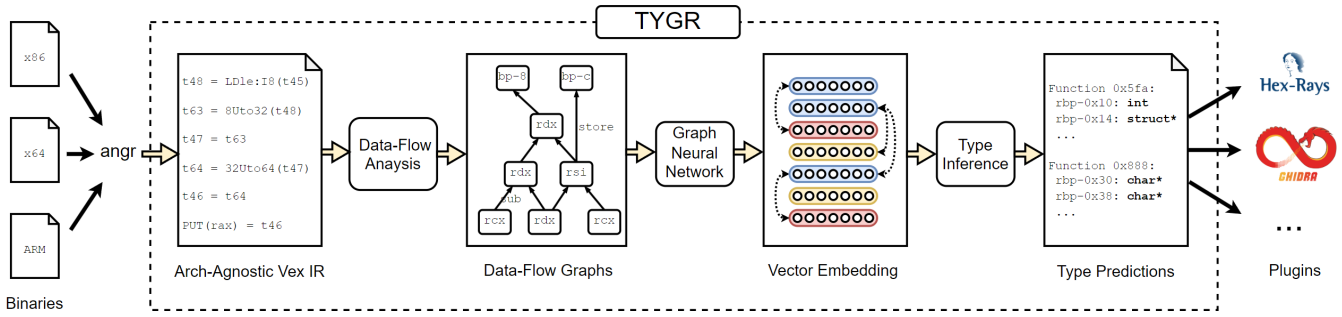

Figure 2: The pipeline of TYGR. Binaries are first converted to VEX IR followed by data-flow analysis to yield a data-flow graph for each function. Each such graph is then passed to a graph neural network which yields a continuous representation that aims to capture the semantic information of the function. This representation is then used to predict a type for each variable present.

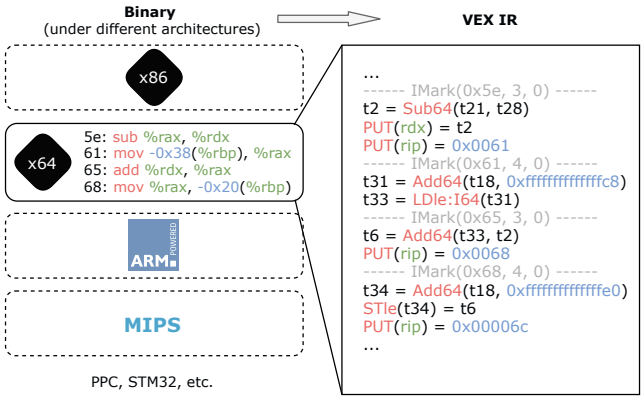

Figure 3: Binary to VEX IR conversion for offset 0x5e–0x68 of the function in Figure 1. Note that all architecture-specific side effects (e.g., changing `rip` in x64) are explicitly encoded in VEX IR.

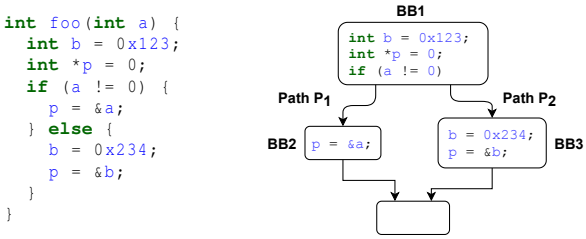

Figure 4: An example illustrating the data-flow analysis in TYGR. (Left) A simple function with two possible paths. (Right) The control-flow graph of the function.

statement. During the exploration, TYGR extracts *variable-level data-flow graphs* that captures the value at each location.

Our key insight is that it suffices to evaluate each path *once*. This is because how the binary code in a block uses data does not change when it runs for more than once. Another insight is that we can completely disregard the feasibility of each branch and forcibly explore both branches of each branch condition. We are only interested in *how* the binary code uses data at each location and not under what condition each block is reached. Infeasible paths still contain value information regarding how binary code accesses data locations.

Using our insights, we design a function exploration algorithm for TYGR that executes the blocks in a function following a topological order starting from the entry point. The sequence of nodes that TYGR visits induces a set of simple paths. TYGR collects how each data location is accessed along each simple path.

4.2.2 Data-Flow Graphs

We derive data-flow graphs from the information that TYGR collects during function CFG exploration. By examining the read-from or written-to locations along each simple path, we obtain a set of symbolic expressions. Then TYGR uses these expressions to derive the variable-level data-flow graphs as shown in Figure 5 (left). The nodes in these data-flow graphs are constant values (constant bitvector expressions). They correspond to either *immediate operands* (e.g., constants and register offsets) in VEX expressions (e.g., arguments to some VEX operations) or *computed values* (e.g., to-be-written values) that result from some VEX operation. VEX operations include arithmetic operations (e.g., addition and multiplication) and data-access operations (e.g., register-reads and memory-writes). TYGR uses *edge labels* to mark how each node is used: `Addr` means a node is used as the address of a data-access operation; `Value` means a node is used as the value of a data-access operation; `Op1` and `Op2` mean a node is used as the first and second operand of an arithmetic operation, respectively; and `RegID` means a node is used as the "register offset" (which corresponds to a register name) of a register-access operation.

Variable-level data-flow graphs describe how a particular expression at a particular location along a particular path is derived. They do not convey how the value of a variable

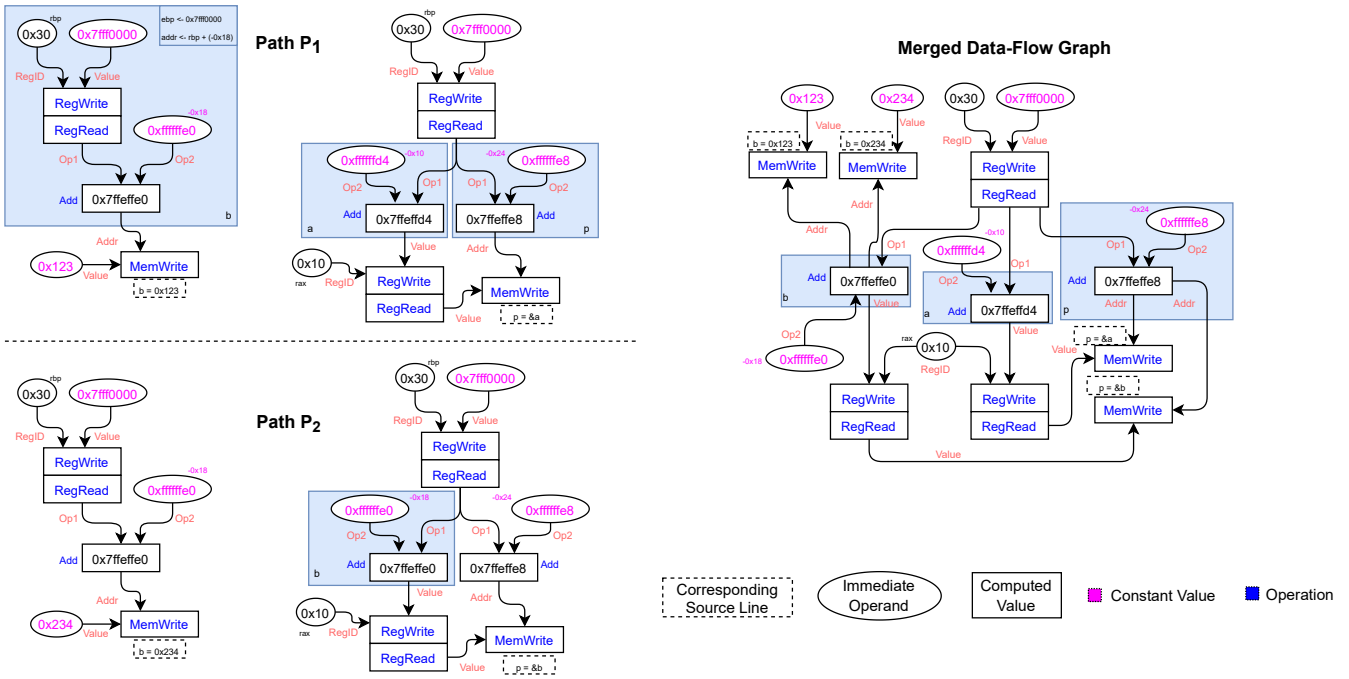

Figure 5: Data-flow graphs for the function `foo` in Figure 4. (Left-Top) variable-level data-flow graphs for `b` and `p` along P_1. (Left-Bottom) variable-level data-flow graphs for `b` and `p` along P_2. Note that because `b` was over-written, it has the value `0x234` rather than `0x123`. (Right) aggregation of all data-flow graphs. Above is a simplified view; data-flow graphs track the operands, operators, bitsizes, and locations of data derivation and usage.

is used by other variables throughout the function. Indeed, different variable-level data-flow graphs may share identical sub-graphs, and inter-variable data-flows give additional information about the type of an expression. Therefore, TYGR aggregates all variable-level data-flow graphs into a single function-level data-flow graph using a graph-union operator, as shown in Figure 5 (right).

4.3 Type Inference with GNNs

We deliberately chose to use a GNN to infer variable types because a GNN explicitly captures the access patterns of variables through edges representing operations and nodes representing variable locations. Such access patterns are only implicitly captured in textual NN structures that other ML-based solutions employ.

Given a graph $G = (V, E)$ that contains a set of nodes V and edges E, a GNN f would embed the graph into a set of vectors (or embeddings), i.e., $f(G) : \mathcal{G} \mapsto \mathbb{R}^{|V| \times d}$. Here $\mathcal{G}$ represents the space of the graphs, while d specifies the dimensionality of the embedding per each node. As shown in Figure 6, the GNN encodes the graph in an iterative fashion, where each iteration or layer of GNN propagates the information from nodes to their direct neighbors. We next elaborate the specific design choices of f.

Node embedding initialization. The first layer of the GNN starts with the initial embedding representation of each node $h_v^{(0)}, \forall v \in V$. In our setting, we represent the node with the following simple features (Figure 6):

- Bitvector expression sizes: one-hot encoding of the size of the node value, from the set of possible sizes $\{1, 8, 16, 32, 64, 128, \text{others}\}$.
- Five register related features, including *is_register*, *is_arg_register*, and *is_ret_register*.
- 11 value features related to the concrete node value, e.g., *is_bool*, *is_float*, *close_to_stack_pointer*, *is_zero*, *is_negative*, and *is_one*.

We denote the above features as $x_v \in \mathbb{R}^D$ where D is the dimension of the features. Then, the initial embedding is $h_v^{(0)} = W_0 x_v + b_0$ where $W_0 \in \mathbb{R}^{d \times D}$ and $b_0 \in \mathbb{R}^d$ are learnable parameters.

Edge type. In our setting, each edge $e \in E$ is a triplet $e = (u, r, v)$ that represents a directional edge of type r from node u to v. An edge type represents the data-flow, control-flow, and other operational meanings in pre-defined types $\mathcal{R}$. For a GNN to function properly, one would need to create a backward edge for any forward edge in the original data-flow graph. The backward edge type must be different from the forward edge type. Therefore for any edge type r, we have an

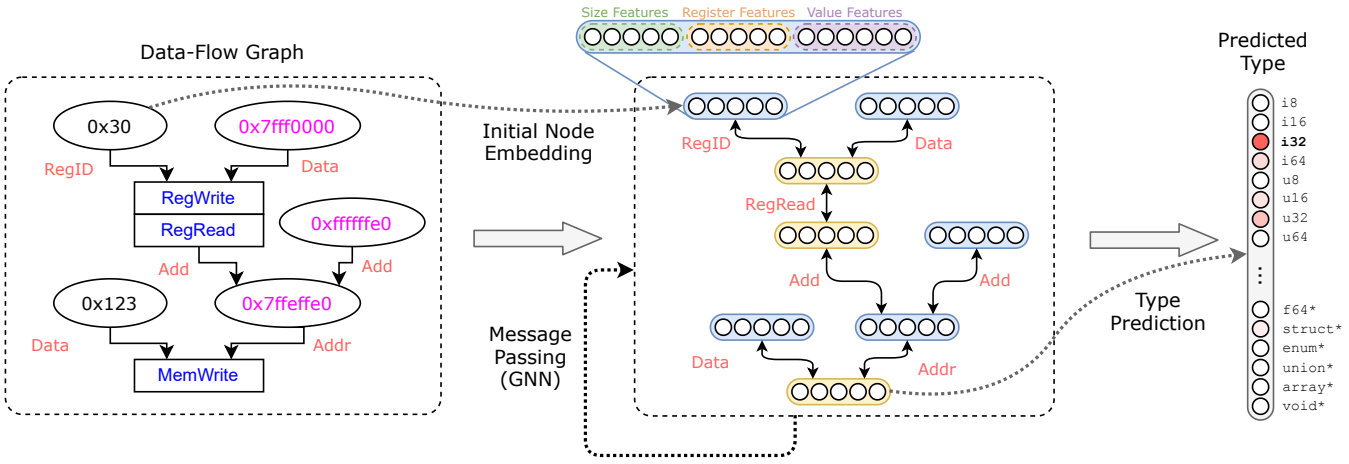

Figure 6: The architecture of the graph neural network in TYGR. The data-flow graph (left) is converted into the vector representation (middle). The nodes in the data-flow graph is transformed into node embedding using Node Embedding Initialization. The directed edges are augmented to allow message passing on both forward and backward directions. After message passing, the node embedding is passed to the type prediction layer to produce the type vector (right).

edge type $\text{rev}(r) \in \mathcal{R}$ representing its backward edge type. As the total number of possible types $|\mathcal{R}|$ is known beforehand, we can design the message passing operator based on the edge types, as described next.

Message passing layer. Each layer of GNN f performs a "message passing" operation that propagates the information from the nodes to their direct neighbors. We denote the embedding of node v at layer l as $h_v^{(l)}$, with the boundary case of $h_v^{(0)}$ defined above, and the update formula defined recursively as follows:

$$h_v^{(l)} = \sigma\Big(\text{AGGREGATE}(\{g(h_u^{(l-1)}, r, h_v^{(l-1)})\}_{e=(u,r,v)\in\mathcal{N}_v})\Big) \tag{1}$$

Here σ is an activation function such as ReLU or Sigmoid. AGGREGATE is a pooling function that aggregates the set of embeddings into a single vector. $\mathcal{N}_v$ denotes all incoming edges to node v, while the function $g(u,r,v)$ is the message function that produces an embedding. We adopt the design choice from RGCN [51], and realize Equation 1 as follows:

$$h_v^{(l)} = \text{ReLU}\Big(\sum_{r\in\mathcal{R}} \text{MEAN}(\{W_r^{(l)} h_u^{(l-1)} + W_0^{(l)} h_v^{(l-1)}\}_{e\in\mathcal{N}_v^r})\Big) \tag{2}$$

where $W_r^{(l)} \in \mathbb{R}^{d\times d}$ are weights that depend on layer index l and edge type r, and $W_0^{(l)} \in \mathbb{R}^{d\times d}$. $\mathcal{N}_v^r \subseteq \mathcal{N}_v$ denotes the incoming edges to node v with edge type r.

After L layers, we use the output of the last layer as the vector representation for each node, $h_v = h_v^L$, and this vector is used for label prediction, as described next.

Type prediction. After obtaining the embedding h_v for a particular node v, we use a multi-layer perceptron (MLP) to classify h_v into the node label, which is the type corresponding to the node. Given a set of types T, our type prediction layer produces a vector $t_v \in \mathbb{R}^{|T|}$ for the node v, as shown as the right most vector in Figure 6. During training, our predicted type vector t_v is then compared with the ground truth type vector $\hat{t}_v \in \mathbb{R}^{|T|}$, the one-hot encoding of the ground truth type under the set of types T. In this work, we apply cross entropy loss function

$$\mathcal{L}(y,\hat{y}) = -\sum_i \hat{y}_i \log(y_i) + (1-\hat{y}_i)\log(1-y_i)$$

to compute the loss $l = \mathcal{L}(t_v, \hat{t}_v)$. The loss l is then back-propagated to update the learnable parameters. During testing and prediction phases, we apply argmax on t_v to obtain the type that is predicted to have the highest probability. While we predict types for all nodes in the graph, during both training and testing, because we know the mapping from source-level variables to graph nodes, we only compare to ground truth the predicted types of the nodes that correspond to source-level variables.

4.4 Type Inference for Structs

Inferring the shape and member types for structs is challenging. Existing approaches, such as OSPREY and DIRTY, either fail to infer types for struct members or use a common type (`struct`) for all struct members. Figure 7 shows a simple C function that involves several operations for one struct variable. OSPREY infers the type of `quoting_options` as `struct<4, 1, 8>` but does not predict struct member types (inferring member sizes only). DIRTY cannot predict types that are not part of the training set. For this function, DIRTY predicts the same incor-

```c
struct options{
    int flag;
    char buffer_type;
    char* name;
};

int set_buffer(struct options default_options, int
     s_flag, char s_type)
{
    struct options quoting_options;
    quoting_options = default_option;
    quoting_options.flag = s_flag;
    quoting_options.buffer_type = s_type;

    int qsize = buffer_restyled(quoting_options);
    return qsize;
}
```

Figure 7: A simple C function that sets a buffer.

rect type `struct{int, char, char*}` for all members of `quoting_options`.

The unique GNN design allows TYGR to tackle the aforementioned limitations. We divide the approach of inferring struct types into two steps. First, we infer struct shapes: For each location, TYGR predicts whether it stores a struct. Second, we infer types for members inside each struct: After knowing a location belongs to a struct type in the first step, TYGR further predicts its type.

During training, suppose TYGR takes the function in Figure 7 as input, every location related to `quoting_options` (e.g., `quoting_options.flag` and `quoting_options.buffer_type`) are first marked as `struct` along with all other basic types for training to obtain $\text{MODEL}_{\text{Base}}$. Then for the second step, we train a new model $\text{MODEL}_{\text{Struct}}$ for predicting struct member types, where we mask all variables of primitive types (base types and pointer types in Figure 9) and only keep struct members in training data. Ideally, this new model will predict `quoting_options.flag` as `int`.

During type inference, for each location $\text{MODEL}_{\text{Base}}$ inferred as `struct`, we further use $\text{MODEL}_{\text{Struct}}$ to infer their struct-member-specific types. If correctly inferred, the model output for `quoting_options.flag` will be `int_S` suggesting it is an `int` type and also a struct member. We derive the final struct accuracy by multiplying the struct accuracy of $\text{MODEL}_{\text{Base}}$ with the overall accuracy of $\text{MODEL}_{\text{Struct}}$.

5 Building the Dataset

When training TYGR on existing datasets that the state-of-the-art solution uses, we found issues that would impact the reliability of type inference. In this section, we first briefly discuss these issues, and then detail how we build our dataset, TYDA, for training and evaluating TYGR.

5.1 Shortcomings with Prior Datasets

An essential component for training and evaluating any machine learning model is a high-quality dataset that is both diverse and accurately reflects the task at hand. Unfortunately, the binary datasets from previous studies are plagued by various significant limitations. They are either inaccessible to the public or contain excessive duplicates. The sole publicly available dataset, provided by STATEFORMER, unfortunately contains a substantial amount of duplicated functions and only 1% of the total number of functions in TYDA. Table 2 shows detailed statistics of duplicates on the STATEFORMER x64 dataset. Figure 8 shows the number of occurrences for each unique functions on a logarithmic scale. On taking a closer look at STATEFORMER binaries, we found that many are built from different versions of the same source package, *e.g.,* `coreutils1.0` and `coreutils2.0`. Furthermore, several source packages produce multiple binaries with only a minor difference. For instance, `binutils` produces 25 `addr2line` binaries. Each of these binaries is slightly customized to handle ELF files from different architectures. These contribute to a high duplication rate in the training set, which may skew the model's learning and bias the outcome [2]. Additionally, significant duplicates may result in substantial overlap in the training and testing sets; while it may appear that the model is generalizing, it might actually be memorizing [36].

To determine the function duplication rate, we hashed the disassembly of every function in the dataset after unifying instruction pointer-relative offsets and immediates that fell within the boundary of each binary's addres space. This is an over-approximation as some non-address referencing immediates will be sanitized as well as instruction pointer relative offsets that point to differing locations. On average 89.9% of functions consist of duplicates, potentially biasing a model's training by overemphasizing these repeated functions. Even after deduplicating these functions, the remaining unique functions may be insufficient to adequately represent real-world binaries. Recent work [44] also shows that the dataset used by DIRTY (another state-of-the-art) inference work has 56.9% duplicate functions and 65.5% overlap in their training and test sets. Such high rates of duplicate functions will lead to inflated prediction accuracy. We argue that there is an imperative necessity for the construction of a more extensive, thorough dataset to facilitate a faithful evaluation of type inference techniques.

5.2 Building The Dataset

We collected C packages from Gentoo and Debian repositories. For compiling Gentoo packages, we utilized the tool used in VarBERT [44] and extended the tool for multi-arch support. We compiled packages from Gentoo for x86 and x64 for four compiler optimization levels, *i.e.,* O0 (no optimization), O1,

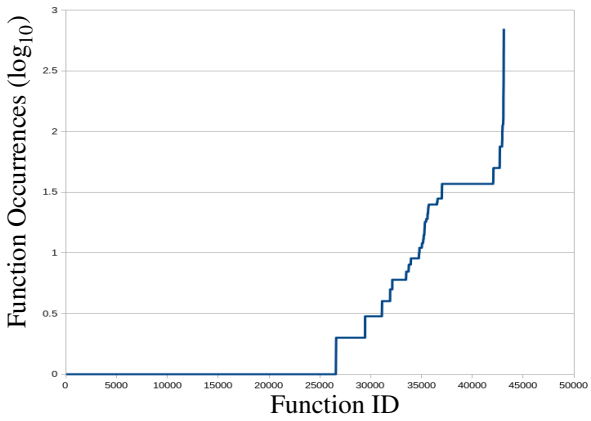

Figure 8: A logarithmic graph of the number of occurrences for each unique function in the StateFormer x64 O0 dataset.

Arch.	Opt. Level	# Unique Functions	# Functions	#Dup Rate(%)
x64	O0	43,116	337,608	88.7
	O1	37,507	330,926	89.8
	O2	35,987	335,056	90.3
	O3	34,009	333,076	90.7

Table 2: Statistics of unique functions in the StateFormer dataset.

O2, and O3, with debug symbols (-g) preserved. Similarly, we compiled C Debian packages for AArch64, Arm32, Mips for four optimizations using QEMU. In total, we built 163,643 binaries, with 83,020 x86, 47,106 x64, 14,885 AArch64, 14,524 Arm32, and 4,107 Mips binaries. We randomly selected approximately 8% binaries from the TyDa dataset to train, develop, and evaluate TyGr due to constraints in the available computing resources that we use for this research project. For ease of reference, we refer to this subset of TyDa as TyDa_{MIN}. Due to the smaller size of the Mips dataset, we use all Mips binaries. Note that TyDa_{MIN} still contains significantly more binaries and unique functions than the dataset that StateFormer uses. Table 3 shows the statistics of TyDa_{MIN} and TyDa. We provide function sizes, in terms of instruction counts, in Appendix A.1.

We deduplicated all the functions in TyDa_{MIN} before creating train, test, and validation splits. We disassemble all function bodies, unify all instruction pointer-relevant offsets and intermediates that fall within the address space of the corresponding binary, and get sanitized function body disassembly. We then hashed the disassembly using SHA256 and removed functions with duplicate hashes. Lastly, we introduce these deduplicated functions in TyDa_{MIN} binaries into the TyGr pipeline.

Arch.	Opt. Level	# Functions		Dup. Rate
		TyDa_{MIN}	TyDa	
x64	O0	543,101	12,639,052	53.6%
	O1	534,181	14,876,300	54.9%
	O2	540,132	13,865,615	54.3%
	O3	524,611	19,601,677	52.0%
x86	O0	332,644	11,079,340	13.8%
	O1	379,106	9,834,631	22.4%
	O2	392,195	11,291,892	22.9%
	O3	371,174	11,627,507	25.0%
AArch64	O0	131,984	958,931	23.6%
	O1	133,100	1,936,300	22.1%
	O2	140,214	2,041,829	24.3%
	O3	127,610	526,949	22.6%
Arm32	O0	112,714	711,992	42.6%
	O1	116,506	9,008,051	43.9%
	O2	103,791	3,534,106	45.3%
	O3	106,085	5,594,100	41.8%
Mips	O0	-	158,897	28.3%
	O1	-	178,279	32.0%
	O2	-	184,929	30.7%
	O3	-	164,777	32.2%

$$

Figure 9: All types that TyGr can predict.

6 Implementation

TyGr comprises 7k lines of Python code. The data-flow analysis module is based on the angr framework [55]. The learning module is written using PyTorch Geometric library of PyTorch 1.8.1. Figure 9 shows all output types that TyGr supports, which covers 97.1% of all observed types in the dataset. We convert types that TyGr does not support to the closest type. For example, `struct***` is cast to `void*`.

7 Evaluation

Our evaluation aims to answer the following questions:

RQ1 *(Effectiveness)* How accurate is TyGr's type inference on real-world binaries?

RQ2 *(Comparative Evaluation)* How does TyGr compare to existing binary type inference techniques?

RQ3 *(Efficiency)* How efficient is TyGr's type inference engine?

Arch	Opt. Level	Overall Acc.	Struct Acc.
x64	O0	81.8	46.7
	O1	76.0	42.9
	O2	75.7	50.4
	O3	72.8	41.0

Table 4: Overall accuracy and struct accuracy of TYGR on the x64 TYDA_{MIN} dataset.

Arch	Opt. Level	Precision %	Recall %	F1

	O3	45.0	44.2	44.6

Table 5: The precision, recall and F1 scores of TYGR on different architectures and optimization levels.

Training Setup. We use the Adam optimizer with an initial learning rate of 10^{-3} and a batch size of 32. We train our model end-to-end using 35 epochs and pick the model with the lowest validation loss. The expected training time is about 50 hours on average for each architecture. We use ReLU as the activation function during message passing and the type prediction. Finally, our GNN is configured to have eight ($L = 8$) message passing layers, with latent dimension $d = 64$. For every architecture-optimization combination, we adhere to common practices by employing an 8:1:1 split ratio for training, validation, and testing.

Machine Setup. All the experiments are run on a Linux server with Ubuntu 20.04, Intel Xeon Gold 5218 at 2.30GHz with 64 cores, 251GB of RAM, and two NVIDIA GeForce RTX 3090-Ti GPUs.

7.1 RQ1: Type Inference Performance

We first evaluate the performance of TYGR on TYDA_{MIN}. We train and test TYGR for each combination of architecture and optimization level (e.g. x64-O0).

Overall performance. Existing work uses different performance metrics. For example, DIRTY and OSPREY use accuracy while STATEFORMER uses precision, recall, and F1 scores. Therefore, we show the performance of TYGR using both metrics.

Table 4 shows the accuracy of TYGR on x64. TYGR achieves an average overall accuracy of 76.6% and an average overall struct accuracy of 45.2%. Table 5 shows the precision, recall, and F1 scores. TYGR achieves an average F1 score of 65.5%. Compared to other optimization levels, TYGR performs best on O0. We believe that as optimization levels increase, more variables are eliminated during compilation, leading to reduced information that can be encoded into data flow graphs. For example, in the O0 dataset, the average number of edges and nodes per graph nearly triples that of the O2 dataset, resulting in comparatively inferior type inference performance.

However, it seems that increasing optimization levels does not always led to less performance. Upon closer examination of the O2 and O3 datasets, we discovered that the average number of edges and nodes generated per graph for O3 *increased* compared to O2. We believe that this is because functions are inlined (and thus optimized away) when compiling in O3, and this is what improves performance (for O3 compared to O2). We observed the same trend for STATEFORMER on TYDA_{MIN} (and their datasets). To contextualize this, we provide the average number of edges and nodes generated per graph in Appendix A.3.

Inference accuracy per type. Table 6 illustrates how inference accuracy varies across different types. In general, the inference accuracy of each type is relatively high (between 74.7% to 91.1%) until the very bottom of the table, where the inference accuracy for `i16` is only 55.0%. This shows (a) with a sufficient number of samples of a specific type, TYGR can easily achieve a high accuracy in inferring that type, and (b) TYGR needs more samples to make precise inference for types that do not appear frequently enough in the dataset.

Types of return variables. Although TYGR does not infer function prototypes, knowing the types of variables that a function returns can act as a secondary source of information when recovering function prototypes. We take a deeper look into the prediction performance of TYGR on return variables of all functions in the x64-O0 split of TYDA_{MIN}. TYGR achieves a prediction accuracy of 81.3%, which conforms with the overall accuracy of x64-O0 in Table 4.

Generalizability. To evaluate the generalizability of TYGR, we test TYGR on randomly selected functions that are in TYDA but not in TYDA_{MIN}. For each optimization level, we randomly select 40k functions for x64 and x86 and 13k functions for AArch64 and Arm32 to test. There is no test on Mips as we are using all binaries from TYDA Mips. Table 7 shows the results. TYGR demonstrates consistent performance for unseen data.

Type	Percentage (%)	Accuracy (%)
`Pointer Types`	52.8	80.0
`struct*`	25.6	91.1
`i32`	23.1	90.9
`char*`	16.3	74.7
`u64`	7.0	84.7
`u32`	5.9	80.0
`bool`	1.7	83.9
`char`	1.4	92.0
Omitted	...	...
`f64*`	0.3	48.5
`i16`	0.1	55.0

Table 6: Distribution and inference precision for variables whose types present more than 0.1% of the x64-O0 TYDA$_{MIN}$ dataset. "Pointer Types" refers to the collection of all pointer types.

Arch	Opt. Level	Precision	Recall	F1
x64	O0	81.1	80.2	80.6
	O1	77.6	76.0	76.8
	O2	77.4	76.0	76.7
	O3	74.7	73.1	73.9
x86	O0	77.4	75.7	76.5
	O1	59.1	60.4	61.0
	O2	58.3	57.1	57.7
	O3	61.0	60.0	60.5
AArch64	O0	81.2	80.6	80.9
	O1	74.2	73.6	73.9
	O2	63.5	62.8	63.1
	O3	73.7	72.6	73.1
Arm32	O0	75.4	74.7	75.1
	O1	59.2	57.9	58.5
	O2	58.1	57.6	57.9
	O3	58.5	57.9	58.2

Table 7: Test of TYGR on the functions that are not from TYDA$_{MIN}$.

7.2 RQ2: Comparison Against Baselines

We compare TYGR against state-of-the-art binary type inference techniques that are publicly available: DIRTY [10], OSPREY [70], and STATEFORMER [45]. We omit comparisons against commercial tools (Ghidra and IDA Pro) because OSPREY outperforms both.

7.2.1 Comparison against DIRTY and OSPREY

To ensure a fair evaluation, we only compare against the configurations for which each tool was originally designed and evaluated (e.g., DIRTY and OSPREY only support x64 binaries).

While OSPREY is not publicly available, its authors provide results of OSPREY on x64-O0 binaries of GNU Coreutils. For a fair comparison, we remove the Coreutils functions that

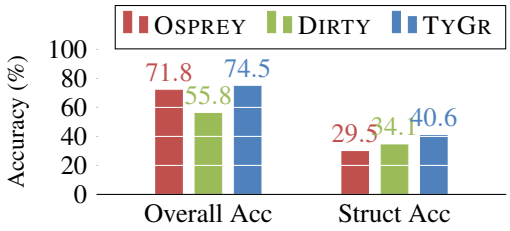

Figure 10: Accuracy results on GNU coreutils O0 executables.

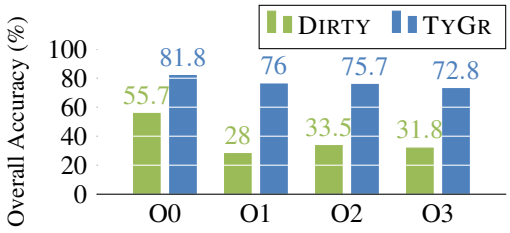

Figure 11: Overall accuracy of TYGR and DIRTY on the TYDA$_{MIN}$ x64 dataset.

are within TYGR's training set. Because the authors compared OSPREY against DIRTY in their paper, we also evaluate DIRTY on the same set of binaries. OSPREY predicts only a few primitive and complex types (e.g., `Primitive_1`, which represents a primitive type that takes one byte in memory), so we post-process the prediction results of DIRTY and TYGR into the types that OSPREY supports. For example, we convert both `bool` and `char` to `Primitive_1`, and `const char *` and `char *` to `Pointer`.

Figure 10 shows the prediction accuracy of both overall types and only struct types for DIRTY, OSPREY, and TYGR. TYGR outperforms the other tools. Specifically, TYGR is 2.7% more accurate than OSPREY in terms of overall type prediction, and more than 11.1% more accurate when predicting struct types.

DIRTY was trained and evaluated only on x64 O0, but should support predicting types on x64 O1-O3 binaries (as stated in their paper). Therefore, we also train and test DIRTY on x64 O1-O3 binaries. Because the authors of DIRTY only report prediction accuracy, we compare the accuracy of DIRTY against the accuracy of TYGR.

Figure 11 shows the overall type prediction accuracy of DIRTY and TYGR, where TYGR outperforms DIRTY by at least 26.1%. Figure 12 shows prediction accuracy for struct types. TYGR outperforms DIRTY by at least 10%. Both struct accuracy and overall accuracy for DIRTY on O1 are low due to the aforementioned shortcoming that is related to unseen variables. A further analysis was performed for the O1 dataset and we found 20.8% of variable types do not existing in the ground truth of DIRTY. DIRTY is unable to infer the types for them, causing the low accuracy.

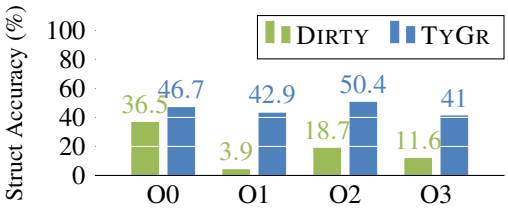

Figure 12: Accuracy of predicting `struct` types for TYGR and DIRTY on TYDA_{MIN} x64 dataset.

7.2.2 Comparison against STATEFORMER

STATEFORMER does not support AArch64, so we only train and test it on x64, x86, Arm32, and Mips. STATEFORMER does not support struct member prediction; It only predicts every struct member variable as `struct`. Therefore, we post-process the prediction results of TYGR and unify struct member types that TYGR predicts into `struct` for a fair comparison.

As Table 8 shows, STATEFORMER achieves an average F1 score of 22.5% on x64, x86, Arm32, and Mips datasets. Whereas TYGR achieves an average F1 score of 63.3% and outperforms STATEFORMER by 40.8%. We believe that this difference is because STATEFORMER is evaluated on TYDA_{MIN} (Table 3) which contains significantly more unique functions compared to their dataset (Table 2). In addition to a lower F1 score, STATEFORMER's method of identifying variables (*i.e.,* type inference candidates) results in significant redundancy [45, Table 1], further raising concerns about its effectiveness. Specifically, STATEFORMER considers *every* token in a stream of assembly as a candidate for type inference. This results in a lot of entities, such as `nop`, having the sentinel type of *no-access*. This inflates the successful predictions count, where most predictions are made on entities that are not directly usable by the end-user or any downstream analysis task, *e.g.,* decompiler.

We have also evaluated on the obfuscation binaries provided by STATEFORMER. Shown in Table 9, STATEFORMER achieves an average F1 score of 72.1% while TYGR achieves an average F1 of 79.9% and outperforms STATEFORMER by 7.8%.

Our results show that TYGR outperforms the state-of-the-art machine learning-based type inference techniques by a considerable margin.

7.3 RQ3: Efficiency of TYGR

In this section, we measure the inference performance of TYGR. Specifically, we measure each function's inference time and memory consumption, and the average numbers for each architecture.

Arch.	Opt.	TYGR	STATEFORMER
x64	O0	82.5	52.6
	O1	78.2	38.7
	O2	77.7	40.8
	O3	74.8	22.8
x86	O0	76.2	38.9
	O1	61.0	39.7
	O2	58.1	20.7
	O3	60.8	25.4
Arm32	O0	76.3	12.8
	O1	59.7	11.6
	O2	56.8	4.1
	O3	58.6	7.7
Mips	O0	56.8	12.1
	O1	46.5	5.7
	O2	43.6	15.5
	O3	44.6	10.3

Table 8: Comparison on F1 scores between STATEFORMER and TYGR.

Arch.	Opt.	TYGR	STATEFORMER
x64	bcf	80.2	72.0
	cff	81.0	72.1
	sub	78.5	72.2

Table 9: Comparison on F1 scores between STATEFORMER and TYGR for obfuscation binaries.

7.3.1 Inference Time

The per function inference time for TYGR ranges from 1.5 to 4.5 seconds, which is reasonable. The inference time per function for TYGR is slightly higher for O0 binaries across all architectures, ranging from 1.8 to 4.5 seconds. The inference time per function for other optimization levels range from 1.7 to 3.1 seconds This is because O0 binaries (without compiler optimizations) have more variables and more instructions (thus more VEX expressions and statements) than binaries that are compiled under higher compiler optimization levels.

7.3.2 Memory Consumption during Type Inference

The average memory consumption of TYGR ranges from 0.7 to 2.3 MB per function. As expected, TYGR uses more RAM during type inference for functions in O0 binaries. Interestingly, the memory consumption is higher for RISC architectures. On average, TYGR uses 2.1 MB for AArch64. In comparison, TYGR uses an average of 0.8 MB of RAM for x86 and 0.9 MB of RAM for x64. This is because RISC architectures have higher numbers of load and store instructions than on x86 and x64, leading to more nodes in the data-flow graph and, consequently, higher memory consumption.

We present the inference time in the same environment for four software projects in comparison with STATE-

Project	# Variables	Runtime (CPU)			
		TYGR	Stateformer	Debin	Ghidra
ImageMagic	23,727	208	148	N/A*	597
PuTTY	22,429	143	124	3,042	359
Findutils	6,534	43	18	675	80
zlib	730	6	3	41	9

*Debin terminated abruptly after running on one of the binaries for 138 minutes.

Table 10: Prediction time on CPU (in seconds) of TYGR, STATEFORMER, DEBIN, and GHIDRA on four software projects with varying number of variables.

FORMER, DEBIN and GHIDRA in Table 10. We chose these projects as they were used to measure the inference time in STATEFORMER. TYGR performs on par with STATEFORMER with slight difference. This shows that TYGR achieves higher precision with the same inference time.

7.3.3 Graph Building (or Training) Performance

We also measure the time it takes to build data flow graphs necessary for training on x64 Coreutils O0 binaries. It takes less than ten seconds for 80.42% of functions and 93.37% of functions complete within 30 seconds, and 97.35% of functions complete the process within 60 seconds.

For most cases, as expected, the graph build time is proportional to the number of variables. However, there are some cases where this is not the case. For instance, it took 400 seconds to build the data flow graph for a complex function with few variables. This is because the graph-building time also depends on the complexity of the data flows (e.g., nested loops and conditionals).

7.4 Feature Analysis

Table 6 provides inference results for certain types. An intriguing observation is that although bool type occupies a very small portion of the dataset, 1.7% in this case, it achieves comparative high accuracy. To understand what features contribute to this unique high precision, we conducted a case study on bool type. Bool type is typically used as a flag for branches and determines the following program path, and thereby the same bool variable may occur multiple times for different program paths when performing dynamic analysis. While other variables like i32 can also be utilized for branching purposes, bool variables are predominantly used for this task. This feature for bool variables exhibit a distinct characteristic. Specifically, bool nodes display a structure pattern that involves more than twice the number of location nodes and edges, such as `RegRead` node and `Value` edge in Figure 5, with respect to other variable nodes. Furthermore, these bool nodes are found to be connected to a greater number of edges with labels related to comparison operations such as `__eq__`.

8 Discussion

Our experiments demonstrate that using graph neural networks to learn and apply data-flow patterns for type inference is competitive with other machine learning approaches as well as industry-standard tools such as IDA. We now discuss the main limitations of TYGR and how to overcome or mitigate them.

Choice of program variables. The memory space is partitioned to three distinct regions: global, stack, and heap. TYGR focuses on predicting the types of stack and heap variables . It is possible to extend our implementation to handle global variables in a similar manner. In particular, it necessitates combining data-flow graphs from different functions that use the global variable.

Training set sizes and model performance. We varied the size of training set and retrained our models, and we observed that the prediction accuracy peaks at around 80%. We believe that the main reasons are (a) Certain variable types (e.g., `enum*` and `union*`) are too rare in the training set for training, and (b) Some variable types cannot be effectively differentiated by only observing how the variables are used. Interested readers can refer to Appendix A.2 for an in-depth analysis of these reasons. A critical improvement for TYGR will be incorporating callee- and caller-access patterns when building the data-flow graphs, which we leave as future work.

Predicting boundaries between two adjacent struct. For all struct variables, TYGR infer their types as `struct` before further inferring types for their members. However, if there are two adjacent struct variables on the stack, TYGR will predict them as a large consecutive struct variable and cannot infer the boundaries between them. Luckily, this scenario is rare in TYDA: Out of all functions with struct variables on their stack frames, only 0.1% of these functions have two or more struct variables, and even fewer of these struct variables are adjacent on the stack. We leave it as future work.

Scope of data-Flow analysis. Our data-flow analysis only examines intra-procedural data-flow. We expect that an inter-procedural analysis will yield richer input data for the learning model, and thus better performance. However, inter-procedural analysis is potentially expensive, and excessive analysis might offset the scalability benefit of using a machine learning approach. Nevertheless, we believe this to be a fruitful direction of investigation.

Indirect jump target resolution. Our analysis relies on ANGR to construct control-flow graphs. While ANGR can accurately compute the targets of direct jumps, estimating the targets of jumps that involve dynamic computation is much harder. As a result, we may end up never exploring certain

Because heap variables must be indirectly accessed by dereferencing pointers, TYGR predicts the type of a heap variable by predicting the shape of pointers that point to the variable.

parts of a function. Fortunately, the learning model can cope with such missing information.

9 Related Work

This work primarily focuses on type inference applied to binaries. Specifically, we focus on data type inference, i.e., recovering simple types for the identified variables.

Static analysis, specifically constraint solving, is one of the commonly used approaches. These techniques work by first introducing types based on specific rules and then propagate this seed information to different entities (variables/registers or memory objects) based on the program's data-flow [40]. One one hand, some prior works focus on inferring a limited set of types such as signed/unsigned integers [66], strings [12], `struct` types [58]. On the other hand, works such as TIE [35] and Retypd [42] attempt to infer a more comprehensive set of types specified using a type-lattice. These techniques seed their algorithms by assigning types based on certain base rules. For instance, an operand for `load` or `store` instruction should be of pointer type. They then use propagation techniques either based on Value Set Analysis [5] or constraint solving to propagate these seed types to all other entities.

Best-effort techniques [22, 29] that are based on heuristics suffer from precision. Furthermore, most of these techniques are specific to each architecture, such as x64, x86, etc. Although TIE [35] and Retypd [42] try to be architecture-agnostic by using an IR such as BIL [7], not all architectures (e.g., MIPS) are supported by BIL. Finally, none of these techniques are available as open-source [8], which makes it hard to evaluate or extend them. There are other techniques specific to C++ [26], where the main goal is to determine the classes and layout of objects. These techniques are not directly applicable as they mainly focus on recovering object-oriented features [67] such as class hierarchy [27, 52] and virtual table layout [17].

Some techniques use dynamic analysis [14, 30, 34, 69], wherein type propagation is usually done by taint tracking, and finally combine results from different executions to determine the type of a variable. However, the effectiveness of these techniques depends on the feasibility of executing the program and the availability of high coverage test cases, which is not easy, especially for libraries, embedded programs, and network-based programs.

Machine learning (ML) techniques have been explored in the context of binary analysis, popular applications being vulnerability detection [24, 24, 43, 60], function identification [6,49,54,59], and code clone detection [16,23,25,46,62–64]. Most of these use traditional ML models such as SVMs. However, recent work [54, 62] have started using Neural networks, especially Recurrent Neural Networks (RNNs). ML techniques are also used for semantic problems such as type inference. CATI [9] uses word2vec to predict types based on usage contexts. Similarly, EKLAVYA [13] uses RNNs to predict function signatures, including types of the arguments. DEBIN [32] uses probabilistic models to predict debug information (types and names of variables) in stripped binaries. They use a dependency graph to encode uses of identified variables and then convert them into feature vectors and then train a model based on Extremely Randomized Trees [28]. STATEFORMER [45] sidesteps the problem of feature selection by using transformers on micro execution traces to learn the instruction semantics as pre-trained models. These pre-trained models are further used to perform type prediction. Similarly, DIRTY [10] also uses a transformer model for type prediction. The most recent technique, OSPREY [70] tries to combine both constraints solving and machine learning. Unfortunately, as shown in Table 1, none of these techniques have multi-architecture support and require considerable effort to extend to a new architecture. Finally, our comparative evaluation in Section 7.2 shows that TYGR outperforms all these techniques.

In contrast, TYGR uses data-flow analysis to precisely capture intra-procedural data-flow graphs and encodes them using graph neural networks, which in turn perform type inference via classification.

10 Conclusion

We present TYGR, a new technique for binary type inference. TYGR uses data-flow analysis to precisely track data flows for variables in an architecture-agnostic manner. The data-flow information is encoded using GNN, which then performs type inference as a classification task. We evaluate TYGR on TYDA_{MIN}, and demonstrate that it predicts types for variables with a high accuracy.

A Appendix

A.1 Function Sizes

Detailed function size data, based on instruction counts, are shown in Table 11. We only show x64 here because the other architecture results are very similar.

Arch.	Opt. Level	MIN	AVG	MAX
x64	O0	4	1,787	254,465
	O1	4	1,302	467,033
	O2	4	1,323	517,754
	O3	4	1,273	1,155,116

Table 11: Function sizes in terms of instruction counts on x64 TyDa_{MIN}

A.2 Impact of Data on Prediction Accuracy

To analyze the effect of data volumes on the prediction performance of TyGr, we varied the size of the training data for x64 O0 and measured the change in the performance of our models. Training data was subsampled from TyDa_{MIN} at rates of 30%, 40%, 60%, and increased by 20% for the rest. We also oversampled from TyDa to show the effect on training beyond TyDa_{MIN} (this is represented as the size of training data between 100% and 140%). Figure 13 shows the results of our experiments, where the prediction performance of TyGr remains stable at around 80% beyond using 100% of TyDa_{MIN}.

What may cause the plateau of TyGr's prediction performance? We believe there are two main reasons: **(1) Some variable types are too rare.** Certain variable types are too rare in the training set. For example, `union*` is only 0.14% of the dataset while `enum*` is 0.08%. The prediction accuracy

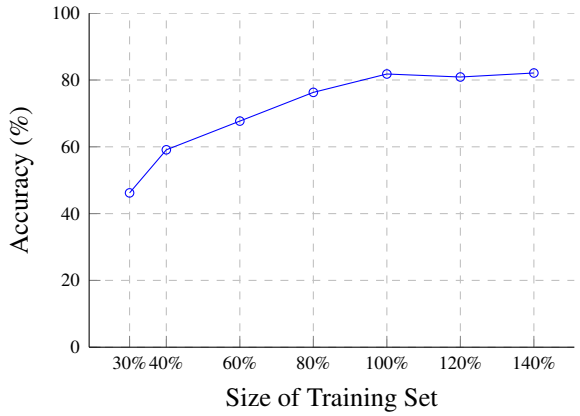

Figure 13: The accuracy of TyGr on x64-O0. 100% usage represents TyDa_{MIN}. The extra 20% and 40% are randomly selected from TyDa.

of these two types are 65% and 31%, respectively. We measured a total of 4.4% variables whose types occupy less than 1% of the training set, and the prediction accuracy for them are all around 50%, which are significantly lower than the overall accuracy of 80%. **(2) Similar access patterns for different variable types.** We also noticed that some variable types cannot always be effectively differentiated only by their access patterns, such as `char*` versus `struct*` (consider a struct with only one-byte member fields), and `i32` versus `u32`.

We took a deeper look into `i32` variables. Out of all mis-prediction cases for `i32`, 36.35% are mis-predicted as `u32`, which is the most mis-predicted type. We randomly selected from our test set 40 C functions (15% out of 269) where `i32` variables are mis-predicted as `u32`. Then we compiled two versions of such functions: original (without change the type of the mis-predicted variable) and type-updated (where we update the type of the mis-predicted variable from `i32` to `u32`). Finally we compare the assembly after compiling both versions of functions. Not surprisingly, the assembly of type-updated function is the same as the assembly of the original function in all 40 pairs, which means that their access patterns will be the same, making it impossible for TyGr (or any other type inference tools that only rely on variable access patterns) to differentiate. We also manually inspected these 40 functions to understand how they use the mis-predicted `i32` variables. In most cases, these variables are used as flags, file descriptors, and other variables that only hold small integers; Updating their types to `u32` does not change their access patterns.

We observed a similar situation for `enum`, which is the second most mis-prediction cases (33.04% for `i32` mis-predictions). In most cases, `enum` variables are used like `i32` variables (e.g., both `int SANE_STATUS_GOOD = 0;` and `typedef enum{SANE_STATUS_GOOD = 0, ... }` used in the same code: `if (SANE_STATUS_GOOD) {...}`), resulting in the exact same assembly code after compiling.

A.3 Graph Statistics

Detailed statistics about the generated graphs (average number of nodes and edges) are shown in Table 12. O0 binaries contain the most variables and contribute to the highest average number of nodes and edges. The increase for the average numbers from O1 to O3 could be caused by the decrease of functions that contain variables.

Arch.	Opt. Level	Avg #Nodes	Avg #Edges
x64	O0	181	288
	O1	24	29
	O2	27	33
	O3	26	33
x86	O0	65	99
	O1	27	37
	O2	37	53
	O3	39	56
AArch64	O0	196	309
	O1	99	147
	O2	95	138
	O3	118	175
ARM	O0	180	295
	O1	67	101
	O2	81	122
	O3	89	137
MIPS	O0	142	238
	O1	55	83
	O2	64	98
	O3	67	102

MFKDF: Multiple Factors Knocked Down Flat

Matteo Scarlata

Matilda Backendal
ETH Zurich

Miro Haller
UC San Diego

Abstract

Nair and Song (USENIX 2023) introduce the concept of a Multi-Factor Key Derivation Function (MFKDF), along with constructions and a security analysis. MFKDF integrates dynamic authentication factors, such as HOTP and hardware tokens, into password-based key derivation. The aim is to improve the security of password-derived keys, which can then be used for encryption or as an alternative to multi-factor authentication. The authors claim an exponential security improvement compared to traditional password-based key derivation functions (PBKDF).

We show that the MFKDF constructions proposed by Nair and Song fall short of the stated security goals. Underspecified cryptographic primitives and the lack of integrity of the MFKDF state lead to several attacks, ranging from full key recovery when an HOTP factor is compromised, to bypassing factors entirely or severely reducing their entropy. We reflect on the different threat models of key-derivation and authentication, and conclude that MFKDF is always weaker than plain PBKDF and multi-factor authentication in each setting.

1 Introduction

With more and more data stored online or distributed across multiple devices, an increasing number of security-sensitive applications face the challenge of combining data availability with user-friendly key management. The traditional solution is passwords, for both authentication and key derivation. Password-based systems are relieved from some of the difficulties of key management, since users do not have to handle cryptographic keys. In return, allowing (and even encouraging) human-memorable secrets means that passwords often have low entropy, come from a small and predictable "dictionary" and may be highly correlated.

In response to a wide variety of attacks stemming from these issues, password-only authentication to web services is being phased out. Instead, users are offered a two step verification process, where they need to provide a second "factor" in addition to their password. This is known as Two-Factor Authentication (2FA), or more generally, Multi-Factor Authentication (MFA). Examples of such second factors include Time-Based and HMAC-Based One-Time-Passwords (T/HOTP), Out-Of-Band (OOB) authentication and codes generated by hardware tokens such as YubiKeys. Surveys show a sharp increase in the adoption of MFA among users [14], and cybersecurity advisory bodies such as CISA now advise the use of MFA in their recommended best practices [15].

In contrast, passwords are still commonly used as the sole source of entropy for key derivation, as input to Password-Based Key Derivation Functions (PBKDFs), in systems performing client-side encryption. Examples of this include full disk encryption, end-to-end encrypted cloud storage, password managers and cryptocurrency wallets. In all of these settings, keys derived from passwords remain as (in)secure as the passwords from which they stem.

MFKDF. In an attempt to remedy this, Nair and Song propose the concept of a "Multi-Factor Key Derivation Function" (MFKDF) as a way to integrate the advantages of multi-factor authentication into password-based key derivation [37]. MFKDF extracts entropy from existing authentication factors, such as T/HOTP, and combines them with the password before applying a PBKDF to derive a key. The goal is to derive a key that has the entropy of all the factors and password combined, and to retain security even against partial compromise of the source key material (i.e., the password and the authentication factors). The security guarantees claimed for MFKDF state that attackers should not be able to separately guess individual MFKDF factors, and that the difficulty of correctly guessing all factors simultaneously gives an "exponential security improvement over password-based key derivation" [37].

Nair and Song (NS) propose to use MFKDF-derived keys directly in other applications requiring a symmetric key, such as database encryption in a password manager. We will refer to this setting as the *key derivation* setting. Additionally, the authors state that MFKDF-derived keys can be used to authenticate users, as a replacement for MFA, since an MFKDF

key implicitly verifies the user's authentication factors. We will refer to this setting as the *authentication* setting.

The concept of MFKDF was presented at USENIX 2023 [37], and is accompanied by a Javascript reference implementation [34].

1.1 Our Contributions

We analyzed MFKDF and discovered several issues, ranging from a fundamental problem with the idea of using authentication factors for key derivation (Attack 3.1), to vulnerabilities in the proposed constructions (Attacks in 3.2–3.3). We briefly outline the attacks below.

1. The **Dynamic Factor Attack** (3.1) surfaces a critical mismatch between the goals of key derivation and authentication, and shows that the use of the most common authentication factors is unsuitable for key derivation. By construction, key derivation functions are deterministic; they need to always re-derive the same key on the same input. Hence, MFKDF extracts *static* key material from so called *dynamic* authentication factors, such as T/HOTP. This attack shows that an adversary can recompute this static key material from a single one-time code from the authentication factor, thereby permanently degrading the security of MFKDF. This is in sharp conflict with the original security models of TOTP and HOTP.

The threat models for authentication and key derivation allow for different kinds of leakage of secret values. In particular, "one-timeness" of authentication codes is not reflected in the confidentiality requirement of KDF inputs. So while the idea of using authentication factors to strengthen password-derived keys is praiseworthy, our first attack shows that—because of these disparate threat models—the use of existing authentication factors for key derivation is problematic.

We present many other attacks, showcasing vulnerabilities in the MFKDF construction that undermine the claimed security guarantees. These attacks fall into two main categories:

2. The **State Integrity Attacks** (3.2) leverage the fact that a malicious server can modify the MFKDF state: this allows the adversary to control the output of the key derivation, to bypass factors, and even to recover derived keys when users interact with the MFKDF construction.

3. The **Specification Attacks** (3.3) exploit incorrect or missing assumptions in the specification of MFKDF. In particular, we show that MFKDF as currently built from H/TOTP is insecure. Additionally, MFKDF relies on properties of symmetric cryptography that do not follow from traditional security notions such as IND-CPA, and incorrectly assume information theoretical security of the many-time pad. These mistakes, and others, invalidate the security theorems presented by NS.

Most of the above attacks impact not only the formal specification of MFKDF, but also the reference implementation. This highlights how mistakes at the specification level transform into practically exploitable vulnerabilities in code.

After presenting the attacks, we propose countermeasures for the issues which can be mitigated, and draw wider conclusions from the remaining fundamental problems. We argue that the proposed combination of MFA and PBKDF fails to recognize the distinct threat models for authentication and key derivation, and is therefore irrecoverably flawed.

In the authentication setting, we show that MFKDF is always weaker than corresponding traditional MFA choices. Additionally, we believe that the statement that MFKDF can be implemented with "no noticeable change to the user experience" may lead to careless handling of one-time codes, which are much more security critical when used for MFKDF than for traditional MFA. We hence caution against the use of MFKDF in this setting.

In the key derivation setting, our attacks show that the usage of MFKDF can annul the security of a strong password. We propose mitigations to these issues, but show that even after patching the vulnerabilities, MFKDF does not provide a significant advantage over a naïve PBKDF construction which derives the key from the concatenation of multiple static secrets.

1.2 Related Work

MFA and Key Derivation. The state of the art in multi-factor authentication includes WebAuthn [21], a part of the FIDO2 Project [3]. WebAuthn enables completely passwordless authentication, thus side-stepping the problem of user passwords. WebAuthn credentials, also known as Passkeys [13], leverage public-key cryptography for authentication, and can either be bound to a hardware authenticator (such as a YubiKey [19]), or synchronized across user devices.

For local authentication and key derivation, modern approaches include relying on secure hardware to achieve higher security guarantees. Examples include the use of Trusted Platform Modules (TPMs) [22, 31] for disk encryption and smartphones leveraging secure chips [22,50] to defend against bruteforce attacks on PINs and passcodes.

In the online setting, Oblivious Pseudo-Random Functions (OPRFs) [17, 24, 39] let a client derive a key as a function of its password and a server secret, without the server learning the password or the derived key. Combining the entropy of the password with the server secret increases the cost of offline dictionary attacks on the password for external adversaries, making OPRFs a promising alternative to PBKDFs.

KeeChallenge and OtpKeyProv. KeePass [43] is a password manager that supports authentication factors, such as HOTP and HMAC challenge-response authentication [52], in addition to a password to encrypt the application

database. This integration is implemented through two plugins, KeeChallenge [45] and OtpKeyProv [44], which both predate MFKDF [28]. While an in-depth analysis of the security of these plugins is outside of the scope of this paper, we note that these plugins also suffer from some of the same problems of MFKDF; namely, the lack of ephemerality of one-time codes and the HOTP bias.

MF*. MFKDF also appears in other works by NS. The custodial wallet design [35] and is based on MFKDF and inherits its vulnerabilities, as does their follow-up implementation of an MFKDF-based Ethereum wallet [48]. The MFCHF credential hashing function [36] is vulnerable to our attacks on factor constructions.

Attacks. There is a flourishing variety of attacks on cryptosystems in the wild. Key-overwriting attacks in the style of our OOB attack began with Klima and Rosa [26], and have seen a recent resurgence in modern cryptanalysis [1, 6, 12]. Lack of integrity in metadata has been exploited in practice in recent attacks in messaging applications [2, 40], but its perils have been long known by the community [41].

Non-uniform distributions were exploited in the contexts of biased ECDSA nonces [11], randomness failures in RSA key generation [20], and RC4 [29]. While RFC 4226 [32, A.4] discusses why HOTP biases are negligible in the authentication setting, to the best of our knowledge we are the first to construct and evaluate an attack that exploits the bias when HOTPs are used for encryption.

PBKDF constructions have been analyzed before [4, 51], but MFKDF aspires to be an entirely novel primitive, warranting its own analysis.

1.3 Ethical Considerations

We disclosed our findings to Nair and Song (NS) on 01/17/2024 and they acknowledged receiving them on 01/22/2024. While NS argue that the underspecification exploited by some of our attacks is intentional for "flexibility and future-proofness" of MFKDF, they confirmed the vulnerabilities in their implementation, as well as that Attack 3.1 is unavoidable. We discussed the mitigations from Section 4 with NS. They intend to modify the MFKDF specifications to highlight the importance of protecting the integrity of the MFKDF state and the use of secure encryption primitives. They clarified that the MFKDF implementation is intended as a proof of concept; they are unaware of any deployment of their code, and they would implement any necessary changes prior to use in production applications.

1.4 Paper Structure

We start by defining a formal syntax for the MFKDF constructions and primitives in Section 2, adapting it slightly from the syntax presented in [37] for the sake of clarity.[1] Section 3 presents our attacks against the MFKDF construction and reference implementation. Section 4 follows with the possible mitigations. Finally, Section 5 discusses the inherent flaws in MFA-based key derivation functions, and the different threat models of key derivation and multi-factor authentication. We conclude and propose future directions in Section 6.

2 Background

Notation and Conventions. We denote assigning value x to variable a by $a \leftarrow x$, where x might be the output of an algorithm. Similarly, $a \leftarrow\!\!\$\, \mathcal{X}$ denotes sampling uniformly at random from the set $\mathcal{X}$ and assigning the result to a. We write $[0, 10^6)$ for the right-open interval of all integers from 0 (inclusive) to 10^6 (exclusive). The symbol $\|$ denotes string concatenation and $\oplus$ denotes XOR. For an encryption scheme $(\mathsf{Enc}, \mathsf{Dec})$, $\mathsf{Enc}(k, m)$ denotes the encryption of message m under key k and $\mathsf{Dec}(k, c)$ the decryption of ciphertext c.

2.1 Authentication Factors

Following [37], we define a *factor*, F, to be a two-valued probability distribution (σ, α) generated by an efficient probabilistic algorithm, which we also refer to as F. The *factor material* σ represents the secret part of the factor (for example, a password, or a key for the HOTP algorithm) whereas the *factor parameters* α represent the public knowledge about σ.

An authentication factor additionally specifies a protocol between a prover and a verifier, consisting of a *witness generation* algorithm and a *verification* algorithm. The witness generation algorithm, run by the prover, takes the factor material σ and some optional additional input *inp* to produce a witness W. Depending on the protocol, the optional input *inp* may be generated by the verifier and sent to the prover (e.g., in challenge-response protocols), or be part of the state kept by both parties (e.g., a counter). The verification algorithm takes as input σ, *inp* (if present) and W, and checks if W is a valid witness.

As an example, in the case of passwords the witness W is often the password σ itself. For T/HOTP, W is a one-time password, and *inp* the current timestamp or counter value used to generate it. The secret factor material σ is assumed to be shared (for example, during a setup phase) between the prover and the verifier, such that at the time of authentication, only the witness must be communicated. We say that an authentication factor is *dynamic* if the witness changes with every use of the factor, and learning W does not allow an adversary to compute σ.

Below, we review the dynamic factors used in MFKDF.

[1] Note that none of our attacks are affected by this change in syntax; we deviate from the original MFKDF description only in the interest of clearness and internal consistency.

HOTP and TOTP. The HOTP algorithm, defined in RFC4226 [32] and shown in Algorithm 1, takes as input a static symmetric key k_h (the secret factor material σ) and a counter ctr (as the witness input inp). It first generates a 20-byte digest hs by computing HMAC on the key and counter, then truncates the digest to 31 bits using a dynamic truncation algorithm that we call DynTrunc.[2] Finally the truncated digest is transformed to an integer using the function BitsToInt, which on input a bitstring $b_n b_{n-1} \ldots b_0$ returns the integer $s_{int} = \sum_{i=0}^{n} b_i \cdot 2^i$. The reduction of s_{int} to d digits is the resulting one-time password $\mathsf{HOTP}(k_h, ctr)$, which constitutes the witness W.

Algorithm 1 HMAC-based One-Time Password

```
1: procedure HOTP(k_h, ctr)                    ▷ Witness generation
2:     hs ← HMAC-SHA-1(k_h, ctr)
3:     s_bits ← DynTrunc(hs)                   ▷ |s_bits| = 31 bits
4:     s_int ← BitsToInt(s_bits)
5:     return s_int mod 10^d                   ▷ Witness W
```

The verification algorithm simply recomputes the one-time password and checks that $\mathsf{HOTP}(k_h, ctr) = W$.

TOTP [33] is defined as $\mathsf{TOTP} := \mathsf{HOTP}(k_h, T)$[3] where the counter ctr is replaced with T, a coarse-grained integer representation of the current time. Note that for both HOTP and TOTP, the PRF security of HMAC [7, 8] implies that access to old one-time codes does not allow an attacker to produce new ones or recover k_h, making these factors dynamic.

Out-Of-Band Codes. A popular non-cryptographic way to implement a dynamic factor is to send one-time codes over an "out of band" channel (e.g., SMS or email). In this case, there is no shared secret material, i.e., σ is empty. Instead, the server generates a random one-time code as the witness input inp, and sends it to the user over the OOB channel. The user then sends this value back to the server over the main channel. Hence, the witness is directly the input inp. The server verifies that $inp = W$, i.e., that the user sent back the same code that the server generated. This kind of factor lacks cryptographic guarantees, and assumes the OOB channel to be confidential and exclusive to the user.

HMAC Hardware Tokens. Some hardware tokens such as YubiKeys use HMAC-SHA-1 evaluation for authentication: this is equivalent to HOTP, except that the input to the witness generation algorithm is an arbitrary challenge rather than a counter, and the output is the full-length HMAC tag.

2.2 MFKDF

The core idea of MFKDF is to combine MFA with PBKDF. That is, the goal is to use some combination of authentication factors to derive a static symmetric key. The MFKDF paradigm consists of two parts: (1) a factor construction part, which takes the factor material from an authentication factor and turns it into *source key material*, and (2) the KDF part, in which the source key material from multiple authentication factors is turned into a key. See Figure 1 for an illustration.

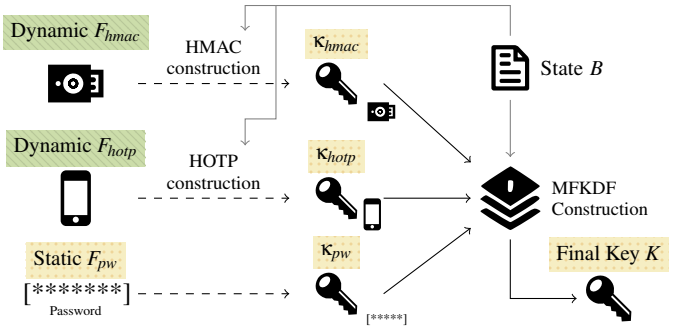

Figure 1: MFKDF combining authentication factors (F_{hotp} and F_{hmac}) with a password to derive a key. Dynamic factors are colored green and striped, static ones yellow and dotted.

In the following, we briefly describe the syntax of a factor construction, and the constructions proposed by NS for some dynamic factors. Next, in Section 2.2.2, we review the syntax of a key derivation function and describe how factor constructions are combined to build MFKDF.

2.2.1 Factor Constructions

A factor construction for a factor F consists of algorithms Setup and Derive. Via $(\kappa_F, \beta_0) \leftarrow \mathsf{Setup}(\sigma)$, the randomized setup algorithm on input the factor material σ "constructs" the static source key material κ_F and initial state β_0.[4] Then, the randomized and stateful algorithm Derive, on input a witness W_i for F and (public) state β_i, enables continued evaluation by reconstructing the key material κ_F and producing an updated state β_{i+1}. That is, $(\kappa_F, \beta_{i+1}) \leftarrow \mathsf{Derive}(W_i, \beta_i)$.

For dynamic factors, the witnesses change over time, making it non-trivial to derive the same static κ_F from every witness. NS solve this by storing the secret factor material σ in β, thereby allowing future witnesses to be computed within algorithm Derive and the changes offset by updates to the state. To protect σ, it is encrypted under the MFKDF-derived key K. This establishes a "feedback mechanism" where K is first derived from all factors, and then used to encrypt the factor materials. In order for the feedback mechanism to work, the setup and derive algorithms must be run in parallel for all factors used in MFKDF, and intermediate outputs from

[2] This algorithm is defined on page 7 of RFC4226 [32], but the details do not matter for our purposes.

[3] Additionally, TOTP may use a different hash function than HOTP.

[4] Note that in [37], NS refer to the source key material κ_F as "factor material" and the public parameters β as "factor parameters" (and denote them σ and α, respectively). However, not all factor constructions use the factor material σ as the source key material κ_F, (for example, the HOTP construction uses a fresh static secret as κ_F, not the HMAC key $\sigma = k_h$). Hence, we choose to separate the notation to avoid confusion.

each factor construction influence the computations of others. To model this, we deviate from the syntax presented in [37] and split algorithms Setup and Derive into two stages each: Setup_1, Setup_2, Derive_1, and Derive_2. Stage one reconstructs κ_F, which is combined with other factors' key material to derive K. Stage two uses K and κ_F to create β_{i+1} for the next iteration. We thus define a factor construction as follows.

Definition 1 (Factor Construction)**.** A factor construction for factor F with factor material σ is a tuple of algorithms

$$\begin{aligned}\kappa_F &\leftarrow \mathsf{Setup}_1(\sigma),\\ \beta_0 &\leftarrow \mathsf{Setup}_2(K,\sigma,\kappa_F),\\ \kappa_F &\leftarrow \mathsf{Derive}_1(W_i,\beta_i), \text{ and}\\ \beta_{i+1} &\leftarrow \mathsf{Derive}_2(K,\kappa_F,\beta_i),\end{aligned}$$

where K is the final key output by MFKDF (see Section 2.2.2).

For factors that do not employ the feedback mechanism, we will simply refer to the combined algorithms $(\kappa_F,\beta_0) \leftarrow \mathsf{Setup}(\sigma)$ and $(\kappa_F,\beta_{i+1}) \leftarrow \mathsf{Derive}(W_i,\beta_i)$.

In the following paragraphs, we review the factor constructions proposed by NS in [37] relevant to our attacks.

HOTP Factor Construction. Recall that for an HOTP factor F_{hotp}, the private factor material σ is the HMAC key k_h, and the witness is a one-time password $W_i = \mathsf{HOTP}(k_h,i)$, where i is a counter. In the factor construction for MFKDF, shown in Algorithm 2, the source key material κ_{hotp} consists of a d-digit integer (called the "target" in [37]), which is sampled uniformly at random from $[0,10^d)$.[5] The source key material κ_{hotp} is encrypted in a stream-cipher fashion by subtracting modulo 10^d the next one-time password W_{i+1}, generating a ciphertext $c_{\kappa,i+1}$ which is stored in the factor state β_{i+1}. This allows κ_{hotp} to be (re-)derived by adding the witness back to $c_{\kappa,i+1}$.

To access the next witness W_{i+1} used to encrypt κ_{hotp}, NS use the feedback mechanism described above: the HMAC key k_h is stored encrypted in the state using the final MFKDF key K. NS do not further specify the encryption scheme used in their HOTP (and TOTP) factor construction. In particular, they do not demand that the scheme should be randomized, nor do they define the expected security properties. As we will see later, this under-specification makes the HOTP (and TOTP) factor construction of MFKDF vulnerable to attacks.

This feedback mechanism adds an element of circular security to the factor construction: the source key material κ_{hotp} is encrypted with the witnesses derived from k_h, and k_h itself is encrypted under the key K derived from the source key material. This is true for all factor constructions proposed by NS that make use of the feedback mechanism. A formal proof of security of MFKDF would hence be limited to what can be achieved in this setting of key-dependent messages [10].

[5] In practice, $d = 6$ is commonly used for HOTP tokens.

Algorithm 2 HOTP Factor Construction for HOTP key k_h

1: **procedure** $\mathsf{Setup}_1(k_h)$
2: $\quad\kappa_{hotp} \leftarrow\!\!\$\ [0,10^d)$
3: $\quad$**return** κ_{hotp}
4: **procedure** $\mathsf{Setup}_2(K,k_h,\kappa_{hotp})$
5: $\quad W_0 \leftarrow \mathsf{HOTP}(k_h,0)$
6: $\quad c_{\kappa,0} \leftarrow (\kappa_{hotp} - W_0) \bmod 10^d$
7: $\quad c_\sigma \leftarrow \mathsf{SK.Enc}(K,k_h)$
8: $\quad$**return** $(0,c_{\kappa,0},c_\sigma)$
9: **procedure** $\mathsf{Derive}_1(W_i,\beta_i)$
10: $\quad(i,c_{\kappa,i},c_\sigma) \leftarrow \beta_i$
11: $\quad\kappa_{hotp} \leftarrow (c_{\kappa,i} + W_i) \bmod 10^d$
12: $\quad$**return** κ_{hotp}
13: **procedure** $\mathsf{Derive}_2(K,\kappa_{hotp},\beta_i)$
14: $\quad(i,c_{\kappa,i},c_\sigma) \leftarrow \beta_i$
15: $\quad k_h \leftarrow \mathsf{SK.Dec}(K,c_\sigma)$
16: $\quad W_{i+1} \leftarrow \mathsf{HOTP}(k_h,i+1)$
17: $\quad c_{\kappa,i+1} \leftarrow (\kappa_{hotp} - W_{i+1}) \bmod 10^d$
18: $\quad$**return** $(i+1,c_{\kappa,i+1},c_\sigma)$

TOTP Factor Construction. The TOTP factor construction is analogous to the HOTP construction, except that the ciphertext $c_{\kappa,i}$ is replaced by a vector $\overline{c_{\kappa,i}}$ which contains the encryption of κ_{hotp} under all OTP witnesses for a window of future times, such that decryption is possible using any witness generated during a time in the window. For details, see [37, Appendix A].

HMAC Factor Construction. This is similar in spirit to the HOTP construction, but this time the HMAC key k_h is directly used as the source key material κ_{hmac}. Challenges are random 160-bit values, and the witnesses W_i from the authenticator are used as one-time pads to encrypt κ_{hmac}. Refer to Appendix A for a full pseudocode description.

OOB Factor Construction. Recall that OOB authentication factors rely on a secure channel between the verifier and the prover, such that the verifier can send a one-time password (OTP) to the prover when they want to authenticate. For MFKDF, NS assume a particular instantiation of this channel, based on S/MIME: the users owns a key pair (sk,pk) for an associated public-key encryption scheme $(\mathsf{PK.Enc},\mathsf{PK.Dec})$. The key material κ_{oob} is sampled uniformly at random in $[0,10^6)$, and encrypted in a stream-cipher fashion (like in the HOTP construction) with a random OTP $\in [0,10^6)$ generated by the user. Finally, the user encrypts the OTP to themselves and sends it to the server for storage. At factor derivation time, the user can fetch the OTP and decrypt it. Refer to Appendix A for the pseudocode.

2.2.2 Combining Factors

Here we review how MFKDF uses the source key material from the factor constructions to derive a key. NS present two variants of MFKDF: a plain one, where all the factors are necessary to derive the final MFKDF key K, and a threshold variant, where K can be derived using only t-out-of-n factors. We focus here on the threshold construction in order to provide the necessary background for Attacks 3.2.2 and 3.3.4. The details of the plain construction are given in Appendix B.

The threshold MFKDF presented in [37, App. A] is built from a PBKDF and a Shamir secret sharing scheme [47]. We review the syntax of both as used in MFKDF.

Definition 2 (Password-Based Key Derivation Function)**.** A key derivation function $\mathsf{PBKDF}(\kappa, salt, \ell) \mapsto K$ takes as input source key material κ, a salt $salt \in \{0,1\}^*$ and a length $\ell \in \mathbb{N}$ to produce a key $K \in \{0,1\}^\ell$.

Definition 3 (Shamir Secret Sharing)**.** A Shamir secret sharing scheme consists of algorithms

$$\begin{aligned}(s_1,\ldots,s_n) &\leftarrow \mathsf{Share}(\kappa,t,n),\\ \kappa &\leftarrow \mathsf{Comb}((s_{u_1},\ldots,s_{u_t}),t,n), \text{ and}\\ s_j &\leftarrow \mathsf{Rec}(\kappa,t,n,j).\end{aligned}$$

Share splits secret κ into n shares, out of which t suffice to reconstruct the secret through algorithm Comb. We refer to [47] for the correctness and security properties. Algorithm Rec is introduced by Nair and Song, who do not describe its properties explicitly. From its use, we deduce that given the secret κ and the sharing parameters, it recovers the j^{th} share.

Similarly to factor constructions, both the plain and threshold MFKDF schemes define algorithms Setup and Derive. Threshold MFKDF additionally defines an algorithm Recover, which is used in case a factor is lost or needs to be replaced.

Definition 4 (Threshold MFKDF Construction)**.** Let $F_1, F_2, \ldots, F_n$ be authentication factors and let $\overline{\sigma} = (\sigma_{F_1}, \sigma_{F_2}, \ldots, \sigma_{F_n})$ be a vector with the corresponding factor materials. The t-out-of-n threshold MFKDF construction for factors $F_1, F_2, \ldots, F_n$ consists of algorithms

$$\begin{aligned}(K, B_0) &\leftarrow \mathsf{Setup}(\overline{\sigma},t,\ell),\\ (K, B_{i+1}) &\leftarrow \mathsf{Derive}(\overline{W}_i, B_i), \text{ and}\\ B_{i+1} &\leftarrow \mathsf{Recover}(\overline{W}_i, B_i, x, \sigma_{F'_x}).\end{aligned}$$

Algorithm Setup takes as input $\overline{\sigma}$, the threshold parameter t and $\ell \in \mathbb{N}$. It returns the derived key $K \in \{0,1\}^\ell$ and the initial public state B_0. Derive takes as input a vector of witnesses for a subset of t factors $\overline{W}_i = (W_{i,u_1}, \ldots, W_{i,u_t})$ and the i^{th} public state B_i (containing the state of all n factors). It returns the key K and the updated state. Algorithm Recover takes as input $\overline{W}_i$, the public state B_i, the index x of the factor F_x to be replaced, and the new factor material $\sigma_{F'_x}$ of factor F'_x replacing it.

Appendix B contains the full specification of the algorithms. Here, we recall a high-level overview from [37].

$\mathsf{Setup}((\sigma_{F_1}, \ldots, \sigma_{F_n}), t, \ell)$

1. Sample κ and $salt$ randomly from $\{0,1\}^\ell$.
2. Split κ into n shares using $(s_1, \ldots, s_n) \leftarrow \mathsf{Share}(\kappa, t, n)$.
3. For each factor F_j, compute the key material κ_j using algorithm F_j.Setup associated to the factor construction.
4. Expand each κ_j to pad_j of length ℓ using HKDF-Expand.
5. Encrypt each share s_j with the pad derived from the expanded factor via $c_{s_j} \leftarrow s_j \oplus \mathrm{pad}_j$.
6. Run $K \leftarrow \mathsf{PBKDF}(\kappa, salt, \ell)$ to derive $K \in \{0,1\}^\ell$.
7. Compute $\beta_{0,j}$ for each factor (using K for the factors that use the feedback mechanism).
8. Let $B_0 \leftarrow (t, \ell, salt, (c_{s_1}, \ldots, c_{s_n}), (\beta_{0,1}, \ldots, \beta_{0,n}))$.
9. Return K and the public state B_0.

$\mathsf{Derive}((W_{i,u_1}, \ldots, W_{i,u_t}), B_i)$

1. For each of the t witnesses, derive the source key material κ_{u_j} from witness W_{i,u_j} using algorithm F_{u_j}.Derive.
2. Expand each κ_{u_j} to pad_{u_j} of length ℓ using HKDF-Expand.
3. Decrypt share s_{u_j} via $s_{u_j} \leftarrow c_{s_{u_j}} \oplus \mathrm{pad}_{u_j}$.
4. Combine the shares into κ using $\mathsf{Comb}((s_{u_1}, \ldots, s_{u_t}), t, n)$.
5. Use PBKDF on κ to produce K.
6. Compute β_{i+1,u_j} for each factor (using K for the factors that use the feedback mechanism) and update B_{i+1}.
7. Return K and the updated public state B_{i+1}.

$\mathsf{Recover}(\overline{W}_i, B_i, x, \sigma_{F'_x})$

1. Compute κ as in steps 1–4 of Derive.
2. Set up the new factor F'_x, computing κ'_x and pad'_x as in steps 3 and 4 of Setup.
3. Recover the share of the lost factor via $s_x \leftarrow \mathsf{Rec}(\kappa, t, n, x)$.
4. Update c_{s_x} to $c'_{s_x} \leftarrow s_x \oplus \mathrm{pad}'_x$.
5. Compute the inital state for F'_x and update the state of each of the t factors used in the recovery.
6. Update B_{i+1} with the new states and c_{s_x} and return it.

3 Attacks

In this section, we present our attacks against the MFKDF construction and its reference implementation (release v1.4.7) [34]. Table 1 provides an overview of our attacks, categorized by fundamental (Section 3.1), attacking unauthenticated state (Section 3.2) and exploiting underspecifications and bad assumptions (Section 3.3). It also shows prerequisites, impact, and whether the attack can be mitigated.

Under impact, we highlight the security goals of MFKDF contradicted by our attacks. In particular, all attacks break the "Entropy" goal [37, §3]: *"Attacking the derived key should be as hard as attacking the weakest set of allowed factors."* Some attacks additionally contradict "Safety": *"Providing an invalid set of factors should be highly unlikely to derive the*

Table 1: Summary of the attacks, listing the type of attack (**fund**amental, state **int**egrity, **impl**ementation-related, or caused by bad assumptions or insufficient detail the **spec**ification), and for each attack its prerequisites (*read/write* access to the MFKDF state B; *leak* of a witness W_i or the factor material σ; *user actions* such as key derivation and replacing a factor), and its impact (recover the final key K, the source key material κ_F, or violate security theorems) and whether it can be mitigated (from 'no mitigations possible' ○, to 'mitigations unclear' ◑, and 'mitigations provided' ●).

correct key." [37, §3]: Together, they invalidate the MFKDF security theorem [38, App. B, Thm 4].

We also falsify the claim of "exponential security" by showing attacks that recover the final key or the source key material of factor constructions: *"[A]ttackers cannot separately guess individual MFKDF factors, and must simultaneously correctly guess all factors to derive a key. [...] Therefore, given n available factors with a mean factor entropy of* 2^{-m} *bits, the crack time t will be* $t \propto 2^m$ *for PBKDFs and* $t \propto 2^{mn}$ *for MFKDF. We thus claim that n-factor MFKDF provides an exponential security improvement over PBKDFs."* [37, § 6]. Many of our attacks additionally lead to practically exploitable vulnerabilities in the reference implementation of MFKDF.

3.1 Dynamic Factor Attack

The H/TOTP, HMAC and OOB factor constructions convert dynamic authentication factors into static source key material. We show that these constructions inherently degrade the security compared to what is expected of a dynamic factor: namely, that access to an old witness does not compromise the security of the factor. When used for MFKDF, leakage of a single witness to an adversary with access to the public factor state instead compromises the factor permanently. As we discuss in Section 5, this represents a fundamental issue with MFKDF, that cannot be mitigated.

Setting. The attack assumes an adversary with access to an authentication witness for the dynamic factor. The witness does not have to be "fresh", in the sense that it would be valid if the factor was used for authentication. For example, an already used or outdated H/TOTP or OOB code suffices.

This threat model matches the standard expectation that "one-time" codes are ephemeral, in the sense that leakage of an old code does not compromise the security of the factor. It is also formally supported by the threat model for HOTP described in RFC 4226 [32]. As a real-world example, an adversary that captures a one-time code as it is being used (e.g., by looking over the shoulder of the victim as they type it in, or through a key-logger on a public computer) can mount this attack, even after the code has been used or expired.

Additionally, the attack assumes read access to the MFKDF state. Recall that the MFKDF state contains all factor construction states (see Line 8 of the Setup algorithm of Definition 4). As described in [37], this state does not have to be kept confidential, and could even "be stored on a public blockchain" [37, p. 4]. This threat model is further supported by the proposed deployments of MFKDF as an online password manager [37, §10.1] or a decentralized cryptocurrency wallet [37, §10.2], where the state is outsourced by the client and available to the adversary.

Attack Overview. Recall from Figure 1 that the source key material κ_F associated to a factor construction F is derived from the i-th witness W_i, and the public factor state β_i via

$$\kappa_F \leftarrow \mathsf{Derive}_1(W_i, \beta_i) \ .$$

This means that an adversary with access to the public state β_i can recover κ_F as soon as a witness is observed, thereby reducing the entropy of the final MFKDF key by the amount provided by factor F. Furthermore, since the adversary can record all past public states $\beta_0, \ldots, \beta_i$, κ_F can be compromised as soon as any previous witness is leaked. As stated above, this removes the security guarantee of dynamic factors which is normally provided by the ephemerality of the witnesses.

Impact. The consequence of this attack is that dynamic factors are no more secure than static factors with the same entropy. For instance, a 6 digit HOTP code from a software authenticator is no stronger than a six digit PIN which the user could store in a password manager or memorize. More troublesome, the gap between the expected security of one-time codes (that is, that exposure of old codes is harmless) likely leads to a false sense of security in users, who, unaware of the implications for MFKDF, might not protect their old one-time codes as they would a PIN or a password, thereby inadvertently risking the security of the source key material. In conclusion: in MFKDF, one-time codes are not one-time.

3.2 State Integrity Attacks

Beside the inherent issues with using dynamic authentication factors, the public state B of MFKDF provides a large attack surface. This state is accessed and updated in both the plain and threshold constructions (see algorithm Derive in Definition 4 and 5). In [37], NS do not consider whether the state needs to be authenticated or protected in any way. We show that the lack of integrity of the state leads to practical attacks against MFKDF. In Section 4, we argue that mitigations to this problem are non-trivial, because of its circularity: the integrity of the state should be verified prior to its usage, but before using the state, an MFKDF user has no key that can be used for this verification.

The attacks presented here assume an adversary with read and write access to the MFKDF construction state. This is the standard threat model for end-to-end encrypted systems where users outsource the public state to the server. For instance, if MFKDF is used in an online password manager with an untrusted server, as proposed by NS, the service provider or an adversary controlling the server could perform these attacks.

3.2.1 OOB Overwriting Attack

This attack exploits that users fetch their S/MIME public key from the unauthenticated MFKDF state. Due to the lack of integrity of the outsourced key, an attacker with access to the public state can overwrite the user's public key pk with a malicious key, such that the user encrypts their next OOB witness to the adversary. This allows the attacker to recover the source key material κ_{oob}, since it is stored in the public state "encrypted" under the OOB witness.

Attack Overview. Let $\beta_i = (pk, c_{\kappa,i}, c_{W,i})$ be the (honest) OOB factor state after the i-th use of the OOB factor, consisting of the user's public key pk, the encrypted key material $c_{\kappa,i}$ and the encryption of the current one-time code $c_{W,i}$.

The attacker overwrites the state with $\beta_i^* = (pk^*, c_{\kappa,i}, c_{W,i})$, where pk^* is the public key of an S/MIME key pair for which the adversary knows the corresponding private key sk^*. Upon the next use of the OOB factor, the user fetches β_i^* from the state and runs:

$\underline{\mathsf{Derive}(W_i, \beta_i^*)}$
$(pk^*, c_{\kappa,i}, c_{W,i}) \leftarrow \beta_i^*$
$\kappa_{oob} \leftarrow (c_{\kappa,i} + W_i) \bmod 10^6$
$W_{i+1} \leftarrow\!\!\$\ [0, 10^6)$
$c_{\kappa,i+1} \leftarrow (\kappa_{oob} - W_{i+1}) \bmod 10^6$
$c^*_{W,i+1} \leftarrow \mathsf{PK.Enc}(pk^*, W_{i+1})$
Return $(\kappa_{oob}, (pk^*, c_{\kappa,i+1}, c^*_{W,i+1}))$

In particular, the key pk^* of the adversary is used to encrypt the next OOB code W_{i+1}. Since the attacker has access to the updated public state $\beta_{i+1} = (pk^*, c_{\kappa,i+1}, c^*_{W,i+1})$, it can recover the code as $W_{i+1} \leftarrow \mathsf{PK.Dec}(sk^*, c^*_{W,i+1})$. After this, it is trivial to recover the source key material as $\kappa_{oob} \leftarrow (c_{\kappa,i+1} + W_{i+1}) \bmod 10^6$.

Impact. A malicious server can use this attack to compromise the OOB source key material as soon as the OOB factor is used, removing the entropy from this factor from the MFKDF key. This compromise is invisible to the user: after obtaining the source key material, the adversary can overwrite β^*_{i+1}, either with the previous honest state β_i, or by replacing $c^*_{W,i+1}$ with $c_{W,i+1} \leftarrow \mathsf{PK.Enc}(pk, W_{i+1})$, ensuring that the user can successfully decrypt the witness ciphertext with their S/MIME private key the next time the OOB factor is used.

3.2.2 Parameter Tampering Attacks

The public MFKDF state B includes information on the key derivation function and its parameters, such as the number of iterations for PBKDF and the length of the derived key. Tampering with this information will, in most cases, result in deriving a bogus key. Nonetheless, the resulting key could be used to infer information about the factors, or can be easy to guess. The attacks we present illustrate the danger of storing this "KDF metadata" unauthenticated in the MFKDF state, rather than having the MFKDF client use a fixed KDF.

For this attack, we additionally assume that the MFKDF key is used to, for example, encrypt data with an AEAD, or to authenticate to a service, and that the adversary can see the resulting ciphertexts or authentication messages. If MFKDF is used to derive a key for a password manager or outsourced file storage, an attacker in the malicious or compromised service provider threat model can perform this attack. Similarly, if MFKDF is used for authentication with the ISO/IEC 9798-2 Unilateral Authentication protocol, as proposed by NS [38, §7], the verifier can perform this attack.

1: Short Key Attack. Consider MFKDF with key length ℓ chosen by the user. (The default length is 32 bytes.) The adversary can overwrite ℓ, picking a new arbitrary length: let's assume 4 bytes. If this key is used to encrypt user data or to produce authentication messages, the adversary can easily guess the 4-bytes key by brute-force.

This trivially violates the confidentiality of the encrypted data, but also has further consequences. Note that some of the

PBKDFs proposed for use in MFKDF (such as PBKDF2) are actually Extendable Output Functions (XOFs), meaning that the 4-bytes derived key will be a prefix of the original key K. The adversary would thus learn the first four bytes of K. The attack can then continue iteratively: the adversary sets the key length to 8 bytes, and guesses the remaining unknown 4 bytes. This process can be iterated until the full key is recovered.

2: Weak PBKDF Attack. The recommended choice of PBKDF for MFKDF is Argon2, a memory-hard PBKDF. The use of Argon2 slows down a brute-force attack on the MFKDF factors, by limiting the effectiveness of parallelization [9, 42].

However, since the choice of PBKDF is stored in the public state B, an adversary can overwrite B, replacing Argon2 with a weak KDF such as, e.g., PBKDF2 with a single iteration of HMAC. When MFKDF is evaluated, a different key $K' \neq K$ will be derived from the same factors. If the adversary observes cryptographic operations where K' is used, like encryption or authentication, it can mount a brute-force attack to guess the source key material of the factors used to derive K', with a high degree of parallelism and fast computation for each guess. A successful attack would expose the source key material, enabling the adversary to recover the original key K. Hence, the benefits of using a memory-hard PBKDF are void against an attacker with write access to the state.

Impact. The attacks significantly reduce the computation cost of brute-force attacks on MFKDF. For the weak PBKDF attack, an analysis by Percival [42] estimates the cost of guessing a password with 56 bits entropy to $10M for PBKDF2, compared to $210B for a memory-hard KDF. For the short key attack, a full key search for a 32 byte key requires 2^{256} guesses, compared to only $8 \cdot 2^{32}$ guesses when iterating the attack to recover 4 bytes at a time.

3.2.3 Share Dilution Attack

The t-out-of-n threshold MFKDF construction (Section 2.2.2) uses Shamir secret sharing to allow the MFKDF key to be derived from any subset of at least t out of the n factors. Like for the parameter tampering attacks, the threshold value t is stored in the unauthenticated MFKDF state. This attack effectively removes factors from MFKDF, exploiting the lack of integrity of the state, together with the fact that the concrete implementation of algorithm Recover [34] in the reference implementation deviates from what NS describe in [37].

Attack Overview. Instead of recovering the share of the lost factor with Rec, as specified in [37], the implementation of algorithm Recover runs $\mathsf{Share}(\kappa, t, n)$ to generate fresh shares for all factors, where t is fetched from the MFKDF state B.[6] This is equivalent to running the share setup algorithm again with the same secret. Since B is not integrity-protected, an adversary can overwrite t with an arbitrary value $t' < t$. This change has no effect until the user runs algorithm Recover (e.g., to change their password). At that point, the adversary-chosen threshold t' is used instead of t as input to Share, with the result that t' of the new shares suffice to derive the MFKDF key.

Impact. This attack impacts the security of the t-out-of-n threshold MFKDF construction by reducing the threshold needed to compute the final key, hence "diluting" the entropy provided by multiple factors. As an example, a 3-out-of-4 construction with HOTP, HMAC, password and OOB as factors becomes trivially broken when t' is set to 2: an extensive key search for the ~40 bits of entropy provided by the OOB and HOTP factors would take seconds on a laptop.

Limitations. The MFKDF reference implementation is only vulnerable to our attack if the attacker sets $t' > 1$, as Shamir secret sharing is not used for thresholds of 1.

3.3 Specification Attacks

Underspecification in cryptographic systems can lead to attacks, as showcased by for example JWT [49]. We now turn to attacks on MFKDF which fall into this category. They either stem from a lack of rigor in the specification of cryptographic primitives, or from incorrect assumptions on the security of these primitives. Most of these attacks are also reflected in the reference implementation of MFKDF itself. The attacks in this section all assume read-only access to the public MFKDF state.

3.3.1 HOTP Compromise Attack

This attack allows an adversary who already compromised the H/TOTP factor material (i.e. the HMAC key)[7] to recover the MFKDF key if H/TOTP factor constructions are used, bypassing other factors entirely. For both HOTP and TOTP, the HMAC key is stored in encrypted form in the public factor state. This encryption is performed using a "symmetric encryption scheme", but no security requirements of the scheme are specified. In their concrete implementation of the H/TOTP factor constructions, Nair and Song use the one-time pad (i.e. XOR) as the symmetric encryption scheme.

Attack Overview. In the reference implementation of MFKDF, the feedback encryption mechanism using the final MFKDF key K creates the factor material ciphertext on line 7 of Algorithm 2 as $c_\sigma \leftarrow \mathsf{SK.Enc}(K, k_h)$, where

$$\mathsf{SK.Enc}(K, k_h) := K \oplus k_h \,.$$

The ciphertext c_σ is part of β_i, contained in the public MFKDF state. Hence, an attacker that compromises the factor material k_h of a *single* HOTP or TOTP factor can recover the final MFKDF key as $K \leftarrow c_\sigma \oplus k_h$.

[6] See src/classes/MFKDFDerivedKey/reconstitution.js, line 365

[7] This HMAC key can be commonly extracted from authenticator apps for smartphones by using the backup functionality [5, 16, 18].

Impact. This attack violates the MFKDF security guarantee that the derived key can only be recovered after *all* factors have been compromised. While the leakage of the HMAC key is a strong prerequisite, the consequence is that this attack completely voids the security of MFKDF in the presence of a *single* compromised factor.

3.3.2 HOTP Bias Attack

This attack exploits a small bias in HOTP witnesses to recover the source key material κ_{hotp} from sufficient observations of the public state in the HOTP factor construction.

The reduction of the 31-bit integer s_{int} modulo 10^d on Line 5 of HOTP in Algorithm 1 adds a small bias to the output, favoring values closer to zero. While this bias is too small to be an issue for authentication [32, A.4.1], it can be exploited for MFKDF because NS use the HOTP witnesses to protect the confidentiality of a static secret. This connects different samples (despite independent witnesses) and allows an adversary to exploit the small bias in each observation to accumulate information about the hidden secret.

Attack Overview. The HOTP factor construction uses a d-digits long witness to hide the static source key material $\kappa_{hotp} \in [0, 10^d)$: it predicts the next witness W_{i+1} and encrypts κ_{hotp} via $c_{\kappa,i+1} = \kappa_{hotp} - W_{i+1} \bmod 10^d$ (line 17 of Algorithm 2). The resulting ciphertext $c_{\kappa,i+1}$ is called the "offset" in [37]. The adversary may observe many such offsets, since they are part of the public state.

Contrary to the assumption of NS, the HOTP values specified in RFC 4226 [32] are not uniformly random in $[0, 10^d)$: they have a slight bias towards smaller values. Algorithm 1 shows that HOTP produces the witness by generating 31 random bits, interpreting them as an integer, and taking the result modulo 10^d to get a d-digit witness. This results in a bias, since the largest number, $2^{31}-1$, is not divisible by 10^d. Hence, for $\gamma = (2^{31}-1) \bmod 10^d$, values in $[0, \gamma]$ are slightly more likely to be output than values in $(\gamma, 10^d)$. While the HOTP factor construction would be provably secure with truly uniformly random witnesses (as alleged by NS in the security theorem for the H/TOTP factor construction [37, §5.2.2]), the actual, biased, witnesses can be exploited to recover κ_{hotp}.

As above, let γ denote the largest witness which occurs more frequently than average. Figure 2 illustrates the bias for a simplified example with 1-digit ($d = 1$) HOTP values.[8] Since the offsets $c_{\kappa,i} = \kappa_{hotp} - W_i \bmod 10$ are generated by subtracting the biased factor witnesses W_i from the secret, offsets in the interval $[\kappa_{hotp} - \gamma, \kappa_{hotp}]$ (modulo 10^d) will appear more frequently than the rest. Hence, κ_{hotp} can be recovered by finding the upper endpoint of this interval.

Figure 3 shows a possible distribution of the biased offset for the static secret $\kappa_{hotp} = 2$. By I_h we denote the interval of more frequent offsets, and I_l the less frequent. In the previous example, we have $I_l = [3,6]$ and $I_h = [0,2] \cup [7,9]$.

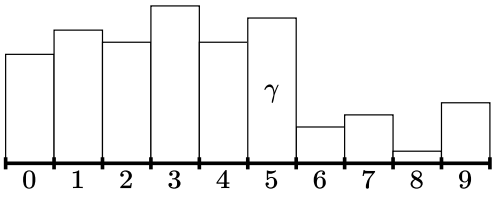

Figure 2: Bias of 1-digit HOTP witnesses for $n = 10$ bins.

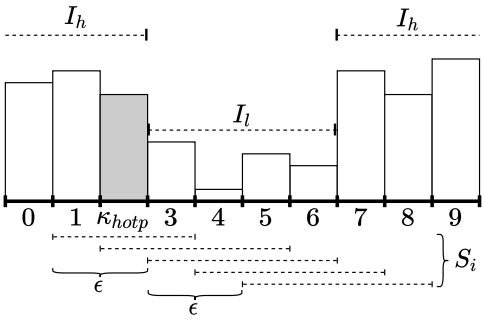

Figure 3: Bias of offsets, shifting the HOTP witness bias depending on the hidden secret κ_{hotp}.

Given m offsets $c_{\kappa,i}$, the optimal attack strategy to locate interval I_h uses the maximum likelihood estimator. Hence, we identify the consecutive interval (with wraparound at 10^d) that has the maximal sum of offsets. We generalize the problem of finding the exact end point of I_h to finding a value that is at most ε values away from the correct secret κ_{hotp}, as the adversary may have external means to test multiple guesses for κ_{hotp}. For instance, it may be feasible to try some number of HOTP values for every password guess, and perform trial decryption with the resulting MFKDF key to verify the correctness of the guess.

It is instructive to model MFKDF offsets as a "balls into bins" problem with biased probabilities, where samples correspond to balls and integers in $[0, 10^d)$ to bins, to gain a more rigorous understanding of our attack. As discussed in the full version of this paper [46], we can express the number of balls in an interval of bins as the sum of Bernoulli random variables and use Chernoff bounds to estimate the worst case number of samples needed to get within ε distance of κ_{hotp}.

Attack Cost. TOTP factor constructions of MFKDF, which build on HOTP, require the user to precompute many offsets to allow keys to be re-derived in the future. As TOTP witnesses change every 30 seconds, NS suggest storing 86400 offsets, such that users can be inactive for 30 days without losing access to their key material. This is an unusually high number of HOTP codes that are available to the adversary "for free" in the public MFKDF state. To understand the practicality of

[8] Our attack targets full-sized HOTP codes of at least 6 digits, as specified in RFC 4226 [32]. Figure 2 is only an illustrative example.

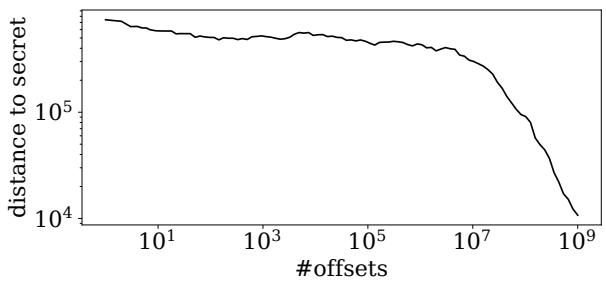

Figure 4: Simulated attack on HOTP factor constructions with up to 10^9 samples, averaged over 100 random targets κ_{hotp}.

our attack, we simulate it by generating samples of the bias using 6-digit HOTP codes (conforming to RFC 4226 [32]) to hide different targets κ_{hotp}.[9] Figure 4 shows a log-log plot of the attack success, averaged over 100 targets and up to 10^9 samples. We measure the attack success as the position of target κ_{hotp} in the list of possible values i that is sorted in decreasing order by the overall sum of offsets observed in the interval $[i-\gamma, i] \pmod{10^d}$.[10] This distance decreases from around 300,000 for 10^7 samples to 10700 for 10^9 samples.

Impact. This attack recovers the source key material κ_{hotp} from the bias in HOTP witnesses, given enough observations of the offsets stored in the MFKDF state. While our simulation indicates that this HOTP bias attack is not practical[11], it directly invalidates the security theorem for the H/TOTP factor constructions in [37, §5.2.2]. In particular, the claims that the offsets "reveal no further information" about the source key material are clearly false.

Unfortunately, this attack also means MFKDF cannot use T/HOTP codes and would require witnesses that are actually uniformly random. This significanly weakens the contribution of MFKDF, as one of its major advantages is the *"compatibility with existing systems using PBKDFs; systems should not need to be entirely rearchitected to use MFKDF, and the user experience should not be impacted whatsoever."* [37, § 4]. However, T/HOTP codes are widely used for authentication, and we are not aware of any authentication factors with uniform witnesses that are similarly popular.

3.3.3 Share Recovery Attack

This attack impacts the security of the t-out-of-n threshold MFKDF construction (Section 2.2.2).

Let F_x be a "lost" factor and let F'_x be the new factor that will replace it. Before the recovery process, the public MFKDF state contains $c_{s_x} = s_x \oplus \text{pad}_x$, the encryption of s_x under a pad derived from the source key material of F_x. If the algorithm Recover works as described by NS in the paper[12], then step 3 uses algorithm Rec to recover s_x with help of the other factors. The recovered share is then re-encrypted with the pad corresponding to the new source key material pad'_x, and the ciphertext in the public state is updated to $c'_{s_x} = s_x \oplus \text{pad}'_x$. However, the share itself is not updated.

Attack Overview. The share not being updated when Recover is run has two consequences. First, an adversary who compromises the source key material of the *lost factor* can use it to decrypt c'_{s_x} and recover s_x. Hence key material of a lost factor is as critical for security as that of any still valid factor. Second, the same share s_x is encrypted twice using different pads pad_x and pad'_x, a "two-time pad". This is completely insecure when the pads have small entropy. If the adversary observes the public state before and after the update, it obtains c_{s_x} and c'_{s_x}. It can therefore compute

$$c_{s_x} \oplus c'_{s_x} = \text{pad}_x \oplus \text{pad}'_x$$

and start guessing values for pad_x and pad'_x. For factors of entropy m, pad can only take $M = 2^m$ possible values. We can efficiently recover the values of the pads in $O(M)$ guesses: first we precompute all the M possible values of $\text{pad}_x \oplus c_{s_x} \oplus c'_{s_x}$, storing them in a hashtable. Then we iterate over the M possible values of pad'_x, checking the hashtable for matches. This attack succeeds with overwhelming probability if $2^m \ll 2^\ell$, where ℓ is the bit length of the share. We analyse this in more detail in the full version of this paper [46].

Impact. Our first observation means that the recovery algorithm should not be used as a means of *replacing* a compromised factor (e.g., in the event of a password breach), as witnesses for the lost factor can still be used to compute the share, therefore bypassing the new factor. By our second observation, the recovery process allows an adversary to efficiently recover the share corresponding to low-entropy factors when they are replaced, violating the security claim that individual MFKDF factors cannot be guessed in isolation.

3.3.4 Share Format Attack

Recall that in threshold MFKDF, the public MFKDF state B contains a one-time pad encrypted share c_s and factor construction state β_i for each factor F. NS note that the one-time pad can "be replaced by symmetric-key encryption as long as no checksums or integrity mechanisms are included in the scheme" [37, A.4]. The following attack shows that this esoteric requirement is vital for the security of MFKDF, but that

[9] Running the simulations took 14.5 hours on an Intel® Xeon® CPU E5-2699A v4 @ 2.40GHz with 44 physical cores and 512 GB of memory.

[10] We conservatively measure attack success and count values that have the same overall sum as the target κ_{hotp} to the values in front of κ_{hotp} to get the worst-case distance of the correct answer from the top of the sorted list.

[11] However, it could be dangerous for an application to allow users to be inactive for many years, which leads to it publishing many more samples in the MFKDF state.

[12] The reference implementation diverges from this description, and is therefore vulnerable to the share dilution attack described in Section 3.2.3.

even using the one-time pad, threshold MFKDF is vulnerable to a theoretical guessing attack against individual factors, leveraging the byte representation of Shamir shares.

Attack Overview. The attack assumes that the byte representation of the shares produced by Shamir secret sharing is non-uniform. Note that in Shamir's original description [47], shares are elements of a prime field; for an l-byte prime $p < 256^l$, each share is a value in $[0, p)$, and hence cannot be represented as an l-byte string uniform in $[0, 256^l)$. Since the distribution of shares is non-uniform, we can construct a distinguisher algorithm $\mathcal{D}$ that, given as input either a share or a random byte string of the same length, outputs 1 if the input was a share and 0 otherwise. We refer to the success probability of this algorithm as:

$$p = |\Pr[\mathcal{D}(\mathrm{s}) = 1 | \mathrm{s} \text{ is a share}] - \Pr[\mathcal{D}(\mathrm{s}) = 1 | \mathrm{s} \text{ is random}]|$$

An attacker can use this distinguisher to guess witnesses for each factor independently of the other factors, as follows. The adversary can check a witness guess W_i^* for F by computing:

$$\kappa_F^* \leftarrow \mathsf{Derive}_1(W_i^*, \beta_i)$$
$$\mathrm{pad}^* \leftarrow \mathsf{HKDF.Exp}(\kappa_F^*, \varepsilon, \ell)$$

It can now use the distinguisher to check if guess was correct by evaluating if $\mathcal{D}(c_\mathrm{s} \oplus \mathrm{pad}^*) = 1$. This confirms a correct guess with probability p.

Note that if the encryption scheme included any "integrity mechanisms", the distinguisher could be replaced by the decryption algorithm. The attack would then succeed with overwhelming probability even if the shares were uniform.

Impact. This attack undermines the claims of exponential security of MFKDF, allowing an adversary to attack each factor separately if shares have a biased representation. For example, in case the distinguisher fails with probability 2^{-20}, i.e. $p = 1 - 2^{-20}$, HOTP and TOTP factors are trivial to brute-force since they individually provide only ~20 bits of entropy.

Limitations. In the reference implementation, the share representation used is such that the bias is always contained in the first byte of each share. Additionally, because of an implementation bug, the first 16 bytes of shares are actually not encrypted. Therefore, the reference implementation inadvertently avoids being vulnerable to this attack. However, the attack would work if the shares were properly encrypted.

4 Mitigations

In this section, we discuss how some of the attacks from Section 3 can be mitigated. Unfortunately, this does not apply to Attack 3.1; due to the static nature of key derivation[13] and the mismatch between the threat models of authentication and key derivation, this attack *cannot be mitigated*. The result is that dynamic authentication factors such as H/TOTP, OOB codes and HMAC hardware tokens—the most common MFA methods in practice—are unsuitable for use with MFKDF. This represents a significant drawback for MFKDF, as one of its main goals is to *"realize the full benefits of multi-factor authentication within the key-derivation process"* with *"no noticeable change to the user experience, and while supporting all of the same 2FA factors that users have already grown accustomed to"* [37, §2]. Section 5 discusses this fundamental problem of MFKDF in more detail; in the rest of this section, we focus on the problems that can be fixed.

State Integrity. It is clear at this point that MFKDF should not be used if its state has no integrity protection: the OOB Overwriting (3.2.1), Parameter Tampering (3.2.2) and Share Dilution (3.2.3) attacks all result from this lack of integrity.

A partial solution could be to give up on some of the flexibility and functionality of MFKDF, such as the support for arbitrary threshold policies and user-specified key length, and embed these parameters in the client software instead of keeping them in the state. While fixing the threshold value, key length, and PBKDF parameters prevents attacks 3.2.2 and 3.2.3, it is not possible to hard code public keys to protect against attack 3.2.1. Moreover, other attacks that rely on the lack of integrity of the remaining state may still be possible; this mitigation only helps against some of the concrete vulnerabilities that we found, but does not fundamentally solve the issue of state integrity.

Unfortunately, verifying the integrity of the state presents a "chicken-and-egg" dilemma: the purpose of MFKDF is to derive a key, so we cannot assume the existence of a key which can be used to protect the state, but without a key, the integrity of the state cannot be verified. The only option is to use the MFKDF key, derived from the unprotected state, to itself ensure the integrity of the state. But this circular approach is vulnerable to attacks where the adversary exerts control over the derived key (in the vein of Attack 3.2.2).

Therefore, as it stands, MFKDF itself cannot achieve state integrity. The two plausible alternatives to instantiate MFKDF in a secure way are to rely on a trusted third party to protect the state, or to come up with a new, stateless construction.

In their response to our disclosure, NS suggest the first option, saying that the state can be stored on a blockchain or on IPFS. This impacts the practicality of MFKDF, and leaves open the problem of updating the state: either the state is immutable, or the user would need to authenticate in order to modify it. An MFKDF construction without state might be of interest for future work, but requires considerable change to the current design.

Cryptographic Primitives. The HOTP Compromise (3.3.1) and Share Format (3.3.4) attacks result from underspecified requirements for the cryptographic primitives used in MFKDF. NS argued in their response that this underspeci-

[13] For functionality, the key must be deterministically deriveable from the factors.

fication is intentional, to ensure that MFKDF is "future proof" and can be adapted and implemented as required by applications. We believe the specification should be more stringent and clarify the security properties of the primitives on which MFKDF relies. In this vein, NS convene with us that symmetric encryption should at least be IND-CPA secure (hence in particular excluding the usage of one-time pad).

Independently from our other proposed mitigations, we advise to use AEAD encryption where appropriate to protect dynamic parts of the state from changing. A notable exception is the encryption of shares, which instead requires a non-authenticated scheme to avoid factor bruteforce attacks through trial-decryption. Avoiding this class of attack requires non-standard assumption on the encryption scheme: decryptions under incorrect keys should yield plausible-looking shares. This has been studied by Jules and Ristenpart in their work on *honey encryption* (HE) [25]: we postulate that a HE scheme could be used to encrypt the shares while withstanding brute-force attacks on low-entropy keys.

HOTP. While the HOTP Bias Attack (3.3.2) can be avoided by discontinuing the use of HOTP codes as an MFKDF factor, the fundamental issue with dynamic factors (including HOTP) remain; they should not be used for key derivation.

Share Recovery. As described in Section 3.3.3, the Share Recovery Attack can be prevented by having Recover generate fresh shares when a factor is lost. If the share threshold t were to be additionally authenticated or constant, this results in a secure factor recovery mechanism (that does not instead expose the user to the Share Dilution Attack 3.2.3).

5 Discussion

In our analysis of MFKDF, we found multiple issues with both the proposed constructions and the implementation. However, the most damaging finding is arguably the dynamic factor attack, which points to a fundamental flaw in the *concept* of MFKDF, and cannot be mitigated. This flaw stems from a gap between the two threat models of password-based systems in which MFKDF operates: key derivation and authentication.

In the following, we discuss this gap and why it arises. We compare MFKDF to the state of the art in authentication and key derivation, respectively. Our analysis shows that for authentication, MFKDF is always weaker than traditional MFA, and that for key derivation, MFKDF is no better than using PBKDF on a longer password—and the latter is arguably the safer option from a usability point-of-view.

Authentication. In the setting of (multi-factor) authentication, the goal is to prevent *outsiders* from impersonating the prover towards the verifier. For instance, consider the case of a server authenticating a user to an application such as e-banking, unencrypted email or cloud storage. In its role as a verifier, the server is trusted: it aims to prevent an external actor—which may partially compromise user secrets and observe the communication between user and server—from gaining access to the user's resources. For MFKDF, this threat model is relevant when the derived key is used for authentication; NS propose this usage, arguing that the final key implicitly verifies the authentication factors used to derive it, and can hence replace traditional MFA.

Next, we compare the security achieved by using the MFKDF key for authentication, to directly using traditional authentication factors for MFA. Note, however, that the state-of-the-art for authentication are protocols like WebAuthn [21], which leverage public-key cryptography for completely passwordless authentication. MFKDF does not try to compete with these more modern alternatives; its goal is instead to strengthen the security of password-based systems, making MFA the appropriate baseline.

MFKDF vs. MFA. In traditional MFA, dynamic authentication factors present a significant advantage over static ones: access to a dynamic factor witness is only useful to authenticate *once* (the witness is "one-time"), and sometimes only during a short time interval (cf. TOTP). This is possible thanks to the threat model, which allows the client to put some trust in the server (concretely, in the form of a shared secret such as an HMAC key, or a server-generated OOB code).

This is not the case in MFKDF. Because the final key has to be static, dynamic factors need to be turned into static ones. Consequently, the one-timeness/freshness properties of dynamic factor witnesses are lost; as shown in Attack 3.1, corrupting a single witness allows an adversary to recover the source key material for the corresponding factor.

NS do not discuss the consequences of turning dynamic factors into static ones in their paper, and—in response to our disclosure—dismissed this limitation as inherent to the properties of a key derivation function. However, dynamic factors can make a difference in practice: consider a user authenticating to their e-banking with a password and a TOTP token, on a device infected with a keylogger. The adversary learns the password and the token witness, allowing it to derive the MFKDF key. This enables the attacker to repeatedly authenticate as the user, also in the future. In contrast, if traditional MFA was used, the attacker would be unable to authenticate at all since it does not have access to the TOTP token, and the captured witness has already been used.

Hence, authenticating with traditional MFA is stronger than using MFKDF. Furthermore, the connotation that, for example, TOTP codes are "one-time" (as alluded to in the name) might convey a false sense of security to users, who should not reasonably be expected to understand that their previously dynamic authentication factors have now become static, and that their "one-time passwords" need to be treated with as much care as their normal passwords.

Key Derivation. In the setting of password-based key derivation, the goal is to extract entropy from a password to produce a cryptographic key, while making brute force and dictionary attacks hard. The resulting key can then be used for cryptographic operations, without requiring the user to memorize or store the key. Notable use-cases include encrypting files for end-to-end encrypted cloud storage (e.g. MEGA [30]), or protecting passwords stored in an online password manager (e.g. Bitwarden [23]): here, the service provider hosting the encrypted data is not trusted. This threat model differs from that of authentication in two ways.

First, if the key is used to protect outsourced data, the server storing that data is considered malicious. As we outlined under *Authentication* above, this deviates from the authentication setting, where the client may share secret key material with the server for the purpose of authentication.

Second, the attacker "trivially" wins if it compromises the device of the user where the key derivation is taking place, since it then learns the key. In the case of MFKDF, this is true even if the attacker has not compromised any of the factors used for the key derivation. In the authentication setting, in contrast, compromise of the device where authentication is taking place is insufficient to impersonate a user thanks to the dynamic factors; all factor material must be corrupted in order for the attacker to win (see the keylogger example above).

One of the explicit goals of MFKDF is to bring the security guarantees of MFA to key derivation, but this is unattainable, as the two threat models are in conflict: trust in the server cannot be leveraged in the key derivation setting, and MFKDF cannot help against compromise of the user's device (as MFA does) if the server is also malicious.

MFKDF vs. PBKDF. In light of the above considerations, we argue that MFKDF is no stronger than using PBKDF on a longer password (or, equivalently, the combination of multiple static secrets). First of all, Attack 3.1 shows that dynamic factors are unsuitable for use with MFKDF; they have to be turned into static source key material to satisfy the requirements for key derivation, and hence lose their advantage over static factors. Since MFKDF internally applies PBKDF to the concatenated source key material of all factors (see lines 5–6 of Algorithm 5), it is clear that this approach is no more secure than applying PBKDF to a longer password of the same entropy as that of the factors combined. More importantly, users are faced with the non-obvious shift in threat model which implies that one-time codes from their dynamic factors need to be treated as secrets lest they permanently degrade the security of their key.

The other claimed advantages of MFKDF, such as threshold key derivation and factor recovery, have to be traded off against their disadvantages. Indeed, our attacks show that the substantial complexity added by MFKDF can easily make it considerably less secure than just PBKDF. Among the reasons for this are the vulnerabilities that arise from having security critical values in unauthenticated state, as well as implementation pitfalls such as the use of biased Shamir shares combined with encryption, a use case for which they were not designed. Such features would require careful formal treatment.

6 Conclusions

MFKDF is promoted as a more secure alternative to PBKDF, bringing the advantages of multi-factor authentication to password-based key derivation. In our analysis, we showed that the security claims made for MFKDF are void: the proposed construction suffers from vulnerabilities that allow an adversary to compromise or bypass the factors used for key derivation, or directly recover the derived key without corrupting all of the factors. Additionally, even with the mitigable vulnerabilities patched, MFKDF is not more secure than PBKDF with longer passwords of equivalent entropy.

As a concept, MFKDF does propose a way of harvesting the entropy from authentication factors that a user might already have, and use it for key derivation. Indeed, the authors state that MFKDF provides *"a paradigm shift toward direct cryptographic protection of user data using all available authentication factors, with no noticeable change to the user experience"* [37]. However, when proposing to use authentication factors for key derivation, they fail to discuss the disparate threat models of these objects. The result is that the protection provided by dynamic factors against impersonation attacks is lost when MFA is replaced by authentication through MFKDF with the same factors. Additionally, dynamic factor witnesses such as HOTP codes are no longer one-time when used for MFKDF; they lose their advantage over static factors, and they instead represent a security risk for users who do not understand this change.

Future Work. Constructing an alternative to PBKDF which strengthens the security of derived keys by combining the password with additional inputs is a highly relevant quest. If we move away from the authentication threat model, we can design dynamic factors specifically for key derivation purposes which can achieve this goal, and provide security for the KDF even under leakage of all the inputs and outputs of the factor. Think, for instance, of placing an OPRF key on a smartphone, and using the phone as a second factor to interactively evaluate the OPRF on input a static secret such as a password. With such a design, even with access to all the messages of the OPRF flow, an adversary would need to compromise both the password and the OPRF key in order to derive the final key.

Acknowledgments

We thank Kenny Paterson and Nadia Heninger for their valuable input on the Share Recovery and HOTP attacks. We also thank the reviewers for their valuable feedback.

A MFKDF Factor Constructions

Algorithm 3 HMAC Factor Construction for HMAC key k_h

procedure Setup(k_h)
  $\kappa_{hmac} \leftarrow k_h$; $c_0 \leftarrow\$ \{0,1\}^{160}$
  $W_0 \leftarrow$ HMAC-SHA-1(κ_{hmac}, c_0)
  return $(\kappa_{hmac}, (c_0, \kappa_{hmac} \oplus W_0))$
procedure Derive(W_i, β_i)
  $(c_i, c_{\kappa,i}) \leftarrow \beta_i$
  $\kappa_{hmac} \leftarrow c_{\kappa,i} \oplus W_i$
  $c_{i+1} \leftarrow\$ \{0,1\}^{160}$
  $W_{i+1} \leftarrow$ HMAC-SHA-1(κ_{hmac}, c_{i+1})
  return $(\kappa_{hmac}, (c_{i+1}, \kappa_{hmac} \oplus W_{i+1}))$

Algorithm 3 shows the HMAC factor construction used in MFKDF to enable support for hardware authenticators, such as YubiKeys, via the HMAC-SHA-1 challenge-response mechanism. In contrast to the usual authentication protocol of an HMAC hardware token, where the authenticator is used to compute the response to a freshly sampled challenge, here the next challenge c_{i+1} is derived ahead of time and stored in the public state β_{i+1}. The state also contains the XOR of the HMAC key k_h with the next witness W_{i+1} computed as response to c_{i+1}. When the client authenticates, it uses the hardware authenticator to re-derive the witness W_{i+1} in response to the stored challenge and can hence recover κ_{hmac}.

Algorithm 4 OOB Factor Construction

Require: Let (PK.Enc, PK.Dec) be a public-key encryption scheme with associated keys (pk, sk).
procedure Setup()
  $\kappa_{oob} \leftarrow\$ [0, 10^6)$
  $W_0 \leftarrow\$ [0, 10^6)$
  $c_{\kappa,0} \leftarrow (\kappa_{oob} - W_0) \bmod 10^6$
  $c_{W,0} \leftarrow$ PK.Enc(pk, W_0)
  return $(\kappa_{oob}, (pk, c_{\kappa,0}, c_{W,0}))$
procedure Derive(W_i, β_i) ▷ The user has derived W_i using their sk by $W_i \leftarrow$ PK.Dec$(sk, c_{W,i})$.
  $(pk, c_{\kappa,i}, c_{W,i}) \leftarrow \beta_i$
  $\kappa_{oob} \leftarrow (c_{\kappa,i} + W_i) \bmod 10^6$
  $W_{i+1} \leftarrow\$ [0, 10^6)$
  $c_{\kappa,i+1} \leftarrow (\kappa_{oob} - W_{i+1}) \bmod 10^6$
  $c_{W,i+1} \leftarrow$ PK.Enc(pk, W_{i+1})
  return $(\kappa_{oob}, (pk, c_{\kappa,i+1}, c_{W,i+1}))$

Algorithm 4 shows the setup and derive procedures for the OOB factor construction proposed by Nair and Song. Here, the witness is the OTP from the OOB authentication factor, but generated by the client rather than the server. Note that the decryption of the OTP witness W_i from the outsourced ciphertext $c_{W,i}$ is part of the normal authentication protocol for the OOB authentication factor, and hence assumed to happen outside of algorithm Derive.

B MFKDF Constructions

Definition 5 (Plain MFKDF Construction)**.** Let $F_1, F_2, \ldots, F_n$ be authentication factors and let $\overline{\sigma} = (\sigma_{F_1}, \sigma_{F_2}, \ldots, \sigma_{F_n})$ be a vector with the corresponding factor materials. The MFKDF construction for factors $F_1, F_2, \ldots, F_n$ consists of algorithms

$$(K, B_0) \leftarrow \text{Setup}(\overline{\sigma}, \ell), \text{ and}$$
$$(K, B_{i+1}) \leftarrow \text{Derive}(\overline{W}_i, B_i).$$

Here ℓ is the desired length of the derived key and $\overline{W}_i = (W_{i,F_1}, \ldots, W_{i,F_n})$ is a vector consisting of the i^{th} witness for each factor in the construction. K is the final key output by MFKDF and B_i is the i^{th} public state.

For each factor F_j, let F_j.Setup and F_j.Derive be the setup and derive algorithm, respectively, associated to F_j by the factor construction. The "plain" (n-out-of-n) MFKDF construction for factors $F_1, F_2, \ldots, F_n$ is given in Algorithm 5.

Algorithm 5 Plain MFKDF Construction

Require: Let PBKDF be a memory-hard KDF.

procedure $\mathsf{Setup}((\sigma_{F_1},\ldots,\sigma_{F_n}),\ell)$
  for $j=1$ to n **do**
    $\kappa_{F_j} \leftarrow F_j.\mathsf{Setup}_1(\sigma_{F_j})$ ▷ If F_j uses feedback
    $(\kappa_{F_j},\beta_{0,F_j}) \leftarrow F_j.\mathsf{Setup}(\sigma_{F_j})$ ▷ Else
  $\kappa \leftarrow \kappa_{F_1}\|\kappa_{F_2}\|\ldots\|\kappa_{F_n}$; $salt \leftarrow\$ \{0,1\}^\ell$
  $K \leftarrow \mathsf{PBKDF}(\kappa, salt, \ell)$
  for $j=1$ to n **do** ▷ If F_j uses feedback
    $\beta_{0,F_j} \leftarrow F_j.\mathsf{Setup}_2(K,\sigma_{F_j},\kappa_{F_j})$
  $B_0 \leftarrow (\ell, salt, (\beta_{0,F_1},\ldots,\beta_{0,F_n}))$
  return (K,B_0)
procedure $\mathsf{Derive}(\overline{W}_i, B_i)$
  $(W_{i,F_1},\ldots,W_{i,F_n}) \leftarrow \overline{W}_i$
  $(\ell, salt, (\beta_{i,F_1},\ldots,\beta_{i,F_n})) \leftarrow B_i$
  for $j=1$ to n **do**
    $\kappa_{F_j} \leftarrow F_j.\mathsf{Derive}_1(W_{i,F_j},\beta_{i,F_j})$ ▷ If feedback
    $(\kappa_{F_j},\beta_{i+1,F_j}) \leftarrow F_j.\mathsf{Derive}(W_{i,F_j},\beta_{i,F_j})$ ▷ Else
  $\kappa \leftarrow \kappa_{F_1}\|\kappa_{F_2}\|\ldots\|\kappa_{F_n}$
  $K \leftarrow \mathsf{PBKDF}(\kappa, salt, \ell)$
  for $j=1$ to n **do** ▷ If F_j uses feedback
    $\beta_{i+1,F_j} \leftarrow F_j.\mathsf{Derive}_2(K,\kappa_{F_j},\beta_{i,F_j})$
  $B_{i+1} \leftarrow (\ell, salt, (\beta_{i+1,F_1},\ldots,\beta_{i+1,F_n}))$
  return (K,B_{i+1})

The syntax defining the t-out-of-n threshold MFKDF construction is given in Definition 4. We review the details of algorithms Setup and Derive in Algorithm 6, and of algorithm Recover in Algorithm 7. Algorithms $(\mathsf{Share},\mathsf{Comb},\mathsf{Rec})$ are part of a Shamir secret sharing scheme (see Definition 3).

Algorithm 6 t-out-of-n Threshold MFKDF Construction

Require: Let PBKDF be a memory-hard PBKDF, and let HKDF.Exp be HKDF-Expand per RFC 5869 [27].

procedure $\mathsf{Setup}((\sigma_{F_1},\ldots,\sigma_{F_n}),t,\ell)$
  $\kappa \leftarrow\$ \{0,1\}^\ell$; $salt \leftarrow\$ \{0,1\}^\ell$
  $K \leftarrow \mathsf{PBKDF}(\kappa, salt, \ell)$
  $(s_1,\ldots,s_n) \leftarrow \mathsf{Share}(\kappa,t,n)$
  for $j=1$ to n **do**
    $\kappa_j \leftarrow F_j.\mathsf{Setup}_1(\sigma_{F_j})$ ▷ If F_j uses feedback
    $(\beta_{0,j},\kappa_j) \leftarrow F_j.\mathsf{Setup}(\sigma_{F_j})$ ▷ Else
    $\mathrm{pad}_j \leftarrow \mathsf{HKDF.Exp}(\kappa_j,\varepsilon,\ell)$ ▷ Expand κ_j to length ℓ with empty context
    $c_{s_j} \leftarrow \mathrm{pad}_j \oplus s_j$
  for $j=1$ to n **do**
    $\beta_{0,j} \leftarrow F_j.\mathsf{Setup}_2(K,\sigma_{F_j},\kappa_j)$ ▷ If feedback
  $B_0 \leftarrow (t,\ell,salt,(c_{s_1},\ldots,c_{s_n}),(\beta_{0,1},\ldots,\beta_{0,n}))$
  return (K,B_0)

Algorithm 7 Threshold MFKDF Construction Continued

procedure $\mathsf{Derive}(\overline{W}_i, B_i)$ ▷ Using t factors $(F_{u_1},\ldots,F_{u_t})$ of the n original factors
  $(W_{i,u_1},\ldots,W_{i,u_t}) \leftarrow \overline{W}_i$
  $(t,\ell,salt,(c_{s_1},\ldots,c_{s_n}),(\beta_{i,1},\ldots,\beta_{i,n})) \leftarrow B_i$
  for $j=1$ to t **do**
    $\kappa_{u_j} \leftarrow F_{u_j}.\mathsf{Derive}_1(W_{i,u_j},\beta_{i,u_j})$ ▷ If feedback
    $(\kappa_{u_j},\beta_{i+1,u_j}) \leftarrow F_{u_j}.\mathsf{Derive}(W_{i,u_j},\beta_{i,u_j})$ ▷ Else
    $\mathrm{pad}_{u_j} \leftarrow \mathsf{HKDF.Exp}(\kappa_{u_j},\varepsilon,\ell)$

      $\beta_{i+1,j} \leftarrow F_j.\mathsf{Derive}_2(K,\kappa_j,\beta_{i,j})$ ▷ If F_j uses feedback
    else $\beta_{i+1,j} \leftarrow \beta_{i,j}$
  $B_{i+1} \leftarrow (t,\ell,salt,(c_{s_1},\ldots,c_{s_n}),(\beta_{i+1,1},\ldots,\beta_{i+1,n}))$
  return (K,B_{i+1})
procedure $\mathsf{Recover}(\overline{W}_i, B_i, x, \sigma_{F'_x})$ ▷ Recover share x using t factors $(F_{u_1},\ldots,F_{u_t})$ of the n original factors
▷ Recover the secret and update existing factors:
  $(W_{i,u_1},\ldots,W_{i,u_t}) \leftarrow \overline{W}_i$
  $(t,\ell,salt,(c_{s_1},\ldots,c_{s_n}),(\beta_{i,1},\ldots,\beta_{i,n})) \leftarrow B_i$
  for $j=1$ to t **do**
    $\kappa_{u_j} \leftarrow F_{u_j}.\mathsf{Derive}_1(W_{i,u_j},\beta_{i,u_j})$ ▷ If feedback
    $(\kappa_{u_j},\beta_{i+1,u_j}) \leftarrow F_{u_j}.\mathsf{Derive}(W_{i,u_j},\beta_{i,u_j})$ ▷ Else
    $\mathrm{pad}_{u_j} \leftarrow \mathsf{HKDF.Exp}(\kappa_{u_j},\varepsilon,\ell)$
    $s_{u_j} \leftarrow \mathrm{pad}_{u_j} \oplus c_{s_{u_j}}$
  $\kappa \leftarrow \mathsf{Comb}((s_{u_1},\ldots,s_{u_t}),t,n)$
  $K \leftarrow \mathsf{PBKDF}(\kappa, salt, \ell)$
  for $j=1$ to n **do**
    if $j \in \{u_1,\ldots,u_t\}$ **then**
      $\beta_{i+1,j} \leftarrow F_j.\mathsf{Derive}_2(K,\kappa_j,\beta_{i,j})$ ▷ If feedback
    else $\beta_{i+1,j} \leftarrow \beta_{i,j}$
▷ Replace the lost factor:
  $\kappa'_x \leftarrow F'_x.\mathsf{Setup}_1(\sigma_{F'_x})$ ▷ If F'_x uses feedback
  $\beta_{i+1,x} \leftarrow F'_x.\mathsf{Setup}_2(K,\sigma_{F'_x},\kappa'_x)$
  $(\beta_{i+1,x},\kappa'_x) \leftarrow F'_x.\mathsf{Setup}(\sigma_{F'_x})$ ▷ Else
  $\mathrm{pad}'_x \leftarrow \mathsf{HKDF.Exp}(\kappa'_x,\varepsilon,\ell)$
  $s_x \leftarrow \mathsf{Rec}(\kappa,t,n,x)$
  $c_{s_x} \leftarrow \mathrm{pad}'_x \oplus s_x$
  $B_{i+1} \leftarrow (t,\ell,salt,(c_{s_1},\ldots,c_{s_n}),(\beta_{i+1,1},\ldots,\beta_{i+1,n}))$
  return B_{i+1}

LaKey: Efficient Lattice-Based Distributed PRFs Enable Scalable Distributed Key Management*

Hart Montgomery
Linux Foundation

Abstract

Distributed key management (DKM) services are multi-party services that allow their users to outsource the generation, storage, and usage of cryptographic private keys, while guaranteeing that none of the involved service providers learn the private keys in the clear. This is typically achieved through distributed key generation (DKG) protocols, where the service providers generate the keys on behalf of the users in an interactive protocol, and each of the servers stores a share of each key as the result. However, with traditional DKM systems, the key material stored by each server grows linearly with the number of users.

An alternative approach to DKM is via *distributed key derivation* (DKD) where the user key shares are derived on-demand from a constant-size (in the number of users) secret-shared master key and the corresponding user's identity, which is achieved by employing a suitable distributed pseudorandom function (dPRF). However, existing suitable dPRFs require on the order of 100 interaction rounds between the servers and are therefore insufficient for settings with high network latency and where users demand real-time interaction.

To resolve the situation, we initiate the study of lattice-based distributed PRFs, with a particular focus on their application to DKD. Concretely, we show that the LWE-based PRF presented by Boneh et al. at CRYPTO'13 can be turned into a distributed PRF suitable for DKD that runs in only 8 online rounds, which is an improvement over the start-of-the-art by an order of magnitude. We further present optimizations of this basic construction. We show a new construction with improved communication efficiency proven secure under the same "standard" assumptions. Then, we present even more efficient constructions, running in as low as 5 online rounds, from non-standard, new lattice-based assumptions. We support our findings by implementing and evaluating our protocol using the MP-SPDZ framework (Keller, CCS '20). Finally, we give a formal definition of our DKD in the UC framework and prove a generic construction (for which our construction qualifies) secure in this model.

1 Introduction

1.1 Distributed key management

Distributed key management (DKM) systems play an important role in digital custody solutions for consumers as well as institutional customers [17, 23, 30, 40, 45, 49–51] which have an estimated market size of nearly 500 billion USD [18]. They allow a user to outsource the task of cryptographic key management to a set of servers, such that no individual server learns the key in the clear, but the key can only be accessed if sufficiently many servers cooperate. Here we are mostly concerned with m-out-of-n access structures, where there are n servers in total and to gain access to the key at least m out of the n servers need to cooperate.

At the core of a distributed key management system typically is a distributed key generation (DKG) protocol [22,31,38] that is used by the servers to generate fresh keys for onboarding users. The resulting keys are then kept in *secret-shared form* [48], which means that each server only holds some partial information about each key, and the full key can only be reconstructed by combining sufficiently many of these so-called *key shares*. The user can access its key by authenticating against the servers, downloading the key shares, and reconstructing the key locally. Alternatively, it can instruct the servers to run a secure multi-party computation (MPC) protocol [20, 29] to compute a function of the key distributedly without reconstructing the key in the clear. For example, the user may instruct the servers to run an MPC signing protocol [16, 21, 26, 36] to generate a digital signature for a given message remotely.

1.2 Scalability challenges

The security of a distributed key management system as described above relies on the assumption that a certain fraction of the servers are honest and the corresponding key shares are stored securely. To maintain security against gradual corruption, the servers must regularly run a share refresh proto-

col [37] that updates all user key shares, so that old shares can no longer be combined with new shares. A similar protocol is run if the access structure needs to be changed, e.g., for adding or removing a server. However, since key shares are stored for each user individually, the workload for all of these maintenance operations **grows linearly** with the number of users and managed keys.

1.3 Distributed key derivation

One solution to reducing the size of the key share database and the maintenance workload is to use a *distributed key derivation* (DKD) protocol instead of a standard DKG protocol for generating user keys. In contrast to a DKG, which produces a fresh and uncorrelated key on every run of the protocol, a DKD allows the servers to deterministically derive the user key on-demand from the user's identity and a constant-size secret-shared master key. Consequently, the servers no longer need to store and maintain the individual user key shares, but only need to store and maintain a single secret-shared master key. Thereby, the database size and maintenance workload are reduced from linear in the number of user keys to **constant**.

A DKD can essentially be realized by employing a distributed pseudorandom function (PRF) that satisfies a certain set of requirements. Informally speaking, a PRF is a keyed function $F_k : A \to B$ that appears indistinguishable from a randomly chosen function with the same domain and range, to any computationally-bounded observer who does not know the secret key. If the range of the PRF is equal to the key space of the targeted cryptographic scheme (e.g., an integer prime field in the case of the ECDSA signature scheme), then the PRF can be used as a key derivation function to derive a large number of user keys from a single master key and the corresponding user identities. That is, given a master PRF key k and a user identity u, the derived user key is $F_k(u)$. Note that while this user key is completely determined by k and u, yet, it appears completely random to anyone who does not know the master key k. By a *distributed PRF* we mean an interactive protocol that is run between a set of parties where the master key is secret-shared and the PRF can be evaluated without ever knowing the key in the clear.

1.4 Application requirements

For distributed key derivation, we are looking for a distributed PRF that satisfies the following properties.

User Identifiers $\subseteq$ Input(PRF). The PRF input space must contain all user identifiers, because the user keys will be derived from them.

Output(PRF) = Key Space: The PRF output distribution should be indistinguishable from the key distribution of the targeted cryptographic scheme. Specifically, in the case of ECDSA, we are looking for a uniform distribution over a prime field.

Refreshable master key shares: It should be possible to refresh the master key shares so that there is protection against gradual corruption and support for changing the access structure.

Secret-shared output: The output of the distributed PRF should be in secret-shared form so that it remains hidden from the servers and can be fed into subsequent multi-party computation protocols such as a multi-party signature generation protocol.

Robust to faulty or malicious servers: The protocol must be robust and secure against a subset of faulty or malicious servers.

Well-founded assumptions: The security of the protocol should rely on well-founded security assumptions that are reliable in real world applications.

Low round complexity: The protocol should require only a small number of interactions between the servers in order to be deployable to settings where the servers reside in different locations and network latency is high.

Why do we focus on round complexity? We focus on measuring performance in terms of round complexity because we found this to be a major bottleneck with respect to existing candidate protocols and our application. Existing distributed PRF protocols have a round complexity on the order of 100 rounds and more (cf. Table 3), where each round adds a small delay depending on the network latency, which in turn affects the user experience of the key management system.

1.5 State of the art

[34] give an overview of the state of the art of MPC-friendly PRF constructions and we mostly summarize their observations here.

Traditional PRFs (e.g., AES [28], SHA-3 [27]) are not designed for use in MPC protocols. They typically have a higher multiplicative depth than specialized constructions and work over bytes instead of prime fields.

The Naor-Reingold construction [43] yields an efficient distributed PRF protocol but has a public output and is therefore not suitable for our use case. [35] describe an efficient distributed PRF protocol based on the hardness of the Shifted Legendre Symbol Problem, which, however, is a rather unconvential and seemingly less reliable assumption [10].

LowMC [4], MiMC [1], GMiMC [3], HadesMiMC [33], and Rescue [5] are invertible block ciphers. However, invertibility is not required for our application, and a lower multiplicative complexity may be achieved by working with non-invertible functions [24]. Moreover, LowMC is defined

over binary fields and is therefore not suitable for our application where we typically work over prime fields. More specifically, there are two large issues with using LowMC: we eventually want a large uniform prime field element, and using random binary field entries to generate this is expensive. Moreover, we also use MPC that works over prime fields, so implementing LowMC in our chosen MPC framework would be very inefficient.

Farfalle [9] is an efficiently parallelizable permutation-based PRF construction with arbitrary input and output length. Ciminion [24] is a modified version of Farfalle based on a Feistel scheme. However, both require the expensive computation of a key schedule. Finally, Hydra [34] is a recent MPC-friendly PRF construction with comparable performance to Ciminion but without the need for a key schedule. Both compare favorably to the state of the art in terms of multiplicative complexity, but still require on the order of 100 online communication rounds per PRF evaluation, which incurs a significant latency overhead in our application.

Another interesting candidate for MPC-friendly PRFs is the "dark matter" PRF construction family [2,11]. However, these constructions rely on non-standard security assumptions and are therefore not ready to be used in production environments like we target with our application. In addition, the security analysis of the "dark matter" constructions focuses on outputs of vectors with small entries. Using these to generate a single large random field element is expensive, and this process might negate any efficiency advantages the construction originally had. We leave examining the security of the "dark matter" construction with larger moduli as interesting future work that could be relevant to our applications.

Another approach for distributed generation of secret shares is via Pseudo-Random Secret Sharing (PRSS) [19]. However, with this approach it is unclear how the master key can be reshared and therefore it is not suitable for a system that runs over extending periods of time (like a key management system) and protection against gradual server corruption is needed. Moreover, it only works in a setting with an honest super majority.

Other related work. [41] also addresses the problem of scalable distributed key management via on-demand distributed key derivation. In comparison to our approach, they use the lattice-based PRF construction from [12] as an almost key-homomorphic PRF, which leads to a non-interactive approximate distributed PRF protocol. Due to the PRF not being exactly key homomorphic, they have to account for a small error in the key derivation. This unfortunately makes the protocol rather complex to implement as it requires the use of particular secret sharing schemes and zero-knowledge proofs to maintain protocol efficiency, correctness, and security. In contrast, our approach does not impose any additional requirements on the used secret sharing scheme and can be directly paired with subsequent MPC protocols without the need for costly post-processing of the generated key shares.

1.6 Our contributions

We analyze the lattice-based PRF of Boneh et al. [12] and show that it can be adapted to the MPC setting to obtain a distributed PRF protocol that fulfills all our requirements (cf. Section 1.4) and runs in only $2+\log_2^2(q)+\log_2^2(q/p)$ online rounds, where q and p are lattice parameters. For concrete parameter choices derived from [13] for 128-bit security, we obtain distributed PRF protocols (REG_{12}, REG_{32}) that run in as low as 8 online rounds, which is sufficient for real-time on-demand distributed key derivation. In terms of round complexity, this is an improvement over the state-of-the-art by an order of magnitude (cf. Table 3), at the expense of increased communication. We also propose an optimized construction that leads to protocols with improved communication complexity (OPT_{12}, OPT_{32}). We support our findings by implementing and evaluating our protocols using the MP-SPDZ framework [39] in the honest majority setting with $n=3$ servers and a corruption limit of $t=1$. Finally, we model our application DKM in the UC Framework [15] and show that it can be efficiently instantiated using an MPC framework such as MP-SPDZ [39] and our distributed PRF protocol.

We envision that our DKD protocol will replace traditional key generation protocols in DKM systems that particularly target large user bases (e.g., [23,50]) as these benefit the most from an efficiency improvement per user. With our protocol, the key material of millions of users will fit within a small HSM and tasks like key share refresh can be performed by running a single instance of a share refresh protocol.

Last but not least, distributed PRFs are an important building block in MPC-based applications [34,35], and we believe that our proposed protocols may also be of interest beyond our application.

1.7 Organization

Section 2 introduces notation, basic primitives, and the lattice-based PRF construction of [12]. Section 3 describes how we adapt the construction to the MPC setting. Section 4 describes a number of enhanced constructions that further improve the efficiency. Section 5 describes the implementation of our constructions as MPC protocols and evaluates their performance. Section 6 models our application in the UC framework and shows that it can be efficiently realized using our distributed PRF protocol.

2 Preliminaries

We first introduce some basic notation. For an integer $n \in \mathbb{N}$ we denote by $[n]$ the set $\{1,\ldots,n\}$. For a random variable X we denote by $x \leftarrow X$ the process of sampling a value x according to the distribution of X. Similarly, for a finite set

S we denote by $x \leftarrow S$ the process of sampling a value x according to the uniform distribution over S. We denote by $\mathbf{x}$ a vector $(x_1, \ldots, x_{|\mathbf{x}|})$. For two bit-strings x and y we denote by $x \| y$ their concatenation. For a bit string $x \in \{0,1\}^\ell$, for every $j \in [\ell]$, let $x|_j$ denote the bit string comprising the bits j through ℓ of x. A non-negative function $f : \mathbb{N} \to \mathbb{R}$ is negligible if it vanishes faster than any inverse polynomial in some (security) parameter λ. For a group $\mathbb{G}$ of order p, element $g \in \mathbb{G}$ and a matrix $\mathbf{M} \in \mathbb{Z}_p^{n \times m}$ (for any n and m in $\mathbb{N}$), we denote the matrix in $\mathbb{G}^{n \times m}$ whose $(i,j)^{\text{th}}$ entry is $g^{m_{i,j}}$ by $g^{\mathbf{M}}$. We denote by $\mathrm{Rk}_i(\mathbb{Z}_p^{a \times b})$ the set of all $a \times b$ matrices over $\mathbb{Z}_p$ of rank i. We use $(\mathbb{Z})$ to denote computing an operation over the integers (rather than something like $\bmod q$) when it may not be clear from context.

Distributions. By $\eta_{\mathsf{Bin}(k)}$ we denote the uniform distribution on $\{0,1\}^k$. For an $\alpha \in (0,1)$ and a prime q, the random variable $\overline{\Psi}_\alpha$ over $\mathbb{Z}_q$ is defined as $\lceil qX \rfloor \pmod q$ where X is a normal random variable with mean 0 and standard deviation $\alpha/\sqrt{2\pi}$. For two probability distributions X and Y over a finite domain D, we define their statistical distance as

$$\Delta(X,Y) = \frac{1}{2} \sum_{a \in D} |\Pr[X = a] - \Pr[Y = a]| \ .$$

We denote the uniform distribution over a finite domain D by $U(D)$. The following theorem describes a bound on the statistical distance between $U(\mathbb{Z}_m)$ and $U(\mathbb{Z}_n) \bmod m$, for $m, n \in \mathbb{N}$.

Theorem 2.1. *For $m, n \in N$, $\Delta(U(\mathbb{Z}_m), U(\mathbb{Z}_n) \bmod m) \leq m/n$.*

A similar bound is also used in [35], but left without a proof. For completeness, we include a proof of the theorem in Appendix A.1.

Rounding. We use $\lfloor \cdot \rfloor$ to denote rounding a real number to the largest integer which does not exceed it. For integers q and p where $q \geq p \geq 2$, we define the function $\lfloor \cdot \rfloor_p : \mathbb{Z}_q \to \mathbb{Z}_p$ as $\lfloor x \rfloor_p = i$, where $i \cdot \lfloor q/p \rfloor$ is the largest multiple of $\lfloor q/p \rfloor$ that does not exceed x. We also overload $\lfloor \cdot \rfloor_p$ for p a power of 2 in the natural way so that it is well-defined over $\mathbb{Z}$: in this case, we define $\lfloor x \rfloor_p$ to be eliminating the lowest $\log p$ bits of x and then outputting x/p. For a vector $\mathbf{v} \in \mathbb{Z}_q^m$, we define $\lfloor \mathbf{v} \rfloor_p$ as the vector in $\mathbb{Z}_p^m$ obtained by rounding each coordinate of the vector individually. A probability distribution χ over $\mathbb{R}$ is said to be *B-bounded* if it holds that $\Pr_{x \leftarrow \chi}[|x| > B]$ is negligible in the security parameter.

2.1 Pseudorandom Functions

A *pseudorandom function* (PRF) [32] is an efficiently computable function $F : \mathcal{K} \times \mathcal{X} \to \mathcal{Y}$ such that for a uniform k in $\mathcal{K}$ and a uniform function $f : \mathcal{X} \to \mathcal{Y}$, an oracle for $F(k, \cdot)$ is computationally indistinguishable from an oracle for $f(\cdot)$. In this paper, we allow our PRFs to be further parameterized by a public parameter pp. When needed, this pp is generated by a Setup algorithm.

Security for a PRF is defined using an experiment between a challenger and an adversary $\mathcal{A}$. For $b \in \{0,1\}$ define the following experiment $\mathsf{Expt}_b^{\mathsf{PRF}}$:

1. Given security parameter λ, the challenger samples and publishes public parameters pp to the adversary. Next, if $b = 0$ the challenger chooses a random key $k \in \mathcal{K}$ and sets $f(\cdot) := F_{\mathsf{pp}}(k, \cdot)$. If $b = 1$ the challenger chooses a random function $f : \mathcal{X} \to \mathcal{Y}$.
2. The adversary (adaptively) sends input queries $x_1, \ldots, x_Q$ in $\mathcal{X}$ and receives back $f(x_1), \ldots, f(x_Q)$.
3. Eventually the adversary outputs a bit $b' \in \{0,1\}$.

Let W_b denote the probability that $\mathcal{A}$ outputs 1 in experiment $\mathsf{Expt}_b^{\mathsf{PRF}}$.

Definition 2.2 (Pseudorandom Function)**.** A PRF $F_{\mathsf{pp}} : \mathcal{K} \times \mathcal{X} \to \mathcal{Y}$ is secure if for all efficient adversaries $\mathcal{A}$ the quantity

$$\mathbf{Adv}^{\mathsf{PRF}}[F, \mathcal{A}] := |W_0 - W_1|$$

is negligible.

2.2 Lattice Preliminaries

Learning with errors. The *learning with errors* (LWE) problem was introduced by Regev [46] who showed that solving the LWE problem *on average* is as hard as (quantumly) solving several standard lattice problems *in the worst case*. Here we define LWE with the flexibility to sample the key from a non-uniform distribution.

Definition 2.3 (Learning With Errors)**.** For integers $q = q(n) \geq 2$, a noise distribution $\chi = \chi(n)$ over $\mathbb{Z}_q$, and a key distribution Ψ over $\mathbb{Z}_q^n$, the learning with errors problem $(\mathbb{Z}_q, n, \chi, \Psi)$-LWE is to distinguish between the following pairs of distributions:

$$\{\mathbf{A}, \mathbf{A}^\intercal \mathbf{s} + \chi\} \qquad \text{and} \qquad \{\mathbf{A}, \mathbf{u}\},$$

where $m = \mathrm{poly}(n)$, $\mathbf{A} \leftarrow \mathbb{Z}_q^{n \times m}$, $\mathbf{s} \leftarrow \Psi$, $\chi \leftarrow \chi^m$, and $\mathbf{u} \leftarrow \mathbb{Z}_q^m$. We refer to the m columns of the matrix $\mathbf{A}$ as the LWE sample points.

Regev [46] shows that for a certain noise distribution χ (a discrete Gaussian), for Ψ the uniform distribution over $\mathbb{Z}_q^n$, for n polynomial in λ, and a sufficiently large q, the LWE problem is as hard as the worst-case SIVP and GapSVP under a quantum reduction (see also [14, 44]). These results have been extended to show that Ψ can be sampled from a low norm distribution (in particular, from the noise distribution χ) and the resulting problem is as hard as the basic LWE problem [6, 14]. Similarly, the noise distribution χ can be a simple low-norm distribution [42] if m is small enough.

Learning with rounding. Banerjee, Peikert, and Rosen [7] consider a related problem, denoted the "learning with *rounding*" (LWR) problem (recall the notation $\lfloor \cdot \rceil_p$).

Definition 2.4 (Learning With Rounding)**.** For integers $q = q(\lambda)$ and $p = p(\lambda)$ such that $q > p \geq 2$ and a key distribution Ψ over $\mathbb{Z}_q^n$, the learning with rounding problem $(\mathbb{Z}_q, n, p, \Psi)$-LWR is to distinguish between the following pairs of distributions:

$$\{\mathbf{A}, \lfloor \mathbf{A}^T \mathbf{s} \rceil_p\} \qquad \text{and} \qquad \{\mathbf{A}, \lfloor \mathbf{u} \rceil_p\},$$

where $m = \text{poly}(n)$, $\mathbf{A} \leftarrow \mathbb{Z}_q^{n \times m}$, $\mathbf{s} \leftarrow \Psi$, and $\mathbf{u} \leftarrow \mathbb{Z}_q^m$.

Banerjee et al. show that for any B-bounded distribution χ over $\mathbb{Z}$ and $q \geq pBn^{\omega(1)}$, the $(\mathbb{Z}_q, n, p)$-LWR problem is at least as hard as solving the $(\mathbb{Z}_q, n, \chi)$-LWE problem. We note that some papers in this area (e.g. [12]) define LWE and LWR to use non-uniform *samples*, and not just keys, but we do not need non-uniform samples in our proofs, so we can simplify our definitions here.

For both LWE and LWR, we sometimes treat the parameter m as an arbitrary polynomial, meaning that we can "query" and LWE/LWR "oracle" and receive any polynomial number of samples that we like. This greatly simplifies our proofs and is standard in the literature (e.g. [12]).

2.3 Lattice-Based PRF from [12]

We restate the LWE-based PRF from [12], Section 5. It will serve as the basis for our MPC-friendly PRF construction.

Construction. Let q, p, n, and m be integers such that $m = n\lceil \log q \rceil$ and p divides q. Let $\overline{\Psi}_\alpha$ be the standard LWE discrete Gaussian noise distribution with parameter α.

Let the public parameter pp be a pair of matrices of the form $\mathbf{A}_0, \mathbf{A}_1 \in \mathbb{Z}_q^{m \times m}$ where each row of $\mathbf{A}_0$ and $\mathbf{A}_1$ is sampled from $\eta_{\text{Bin}(m)}$ such that both matrices are full rank. The secret key $\mathbf{k}$ is a vector in $\mathbb{Z}_q^m$. Define $F_{\text{LWE}} : \mathbb{Z}_q^m \times \{0,1\}^\ell \to \mathbb{Z}_p^m$ as follows:

$$F_{\text{LWE}}(\mathbf{k}, x) = \left\lfloor \prod_{i=1}^{\ell} \mathbf{A}_{x_i} \cdot \mathbf{k} \right\rceil_p .$$

Security. [12], Theorem 5.1 establishes the security of F_{LWE} under the LWE assumption. We restate the theorem here for reference.

Theorem 2.5. *The function F_{LWE} is pseudorandom under the $(\mathbb{Z}_q, n, \overline{\Psi}_\alpha)$-LWE assumption for parameter choices satisfying $\alpha \cdot m^\ell \cdot p \leq 2^{-\omega(\log n)}$.*

3 Adaptation to MPC

In the following, we describe how we adapt and optimize the lattice-based PRF construction of [12] (cf. Section 2.3) for the MPC setting, with a particular focus on the application to distributed key derivation. It turns out that highly structured, lattice-based PRFs like that of [12] compose quite efficiently with certain arithmetic MPC protocols, a fact that seemingly has not been exploited extensively in the MPC literature. The intuition is quite natural–MPC protocols designed for arithmetic circuits will quite naturally fit lattice-based schemes–but rather than explain this in detail, we will show it with performance numbers later in the paper.

We note that the PRF F_{LWE} from [12] outputs a *vector* of entries over $\mathbb{Z}_p^m$, and we need to output an integer that is uniform modulo a large prime (i.e. the ECDSA group order). At a first glance, it might be tempting to choose p to directly be this prime and output a single entry in the output vector of F_{LWE}. However, as shown in [46] (and implicitly in Theorem 2.5), the hardness of LWE (and, by corollary, LWR) is proportional to the ratio of the noise (or number of rounded bits) to the modulus. The larger p gets in our case, the worse security we have, and if we choose p to be exponentially large, there may be an efficient attack on our scheme (note that Theorem 2.5 does not hold in this case). Thus, we must compose many small LWR outputs into one larger one, which we do in our construction below.

3.1 Use a random oracle

For practical purposes, it is generally accepted to rely on the random oracle model (ROM) [8]. Relying on this model, we can replace the product $\prod_{i=1}^{\ell} \mathbf{A}_{x_i}$ by a call to a hash function $H(x)$ modeled as a random oracle. This leads to the following PRF construction.

Construction. Let q, p, l, m, and n be integers such that $m = n\lceil \log q \rceil$ and p divides q. Let $H : \{0,1\}^* \to \mathbb{Z}_q^{l \times m}$ be a cryptographic hash function that gets as input a binary string of arbitrary length and outputs a matrix in $\mathbb{Z}_q^{l \times m}$. The secret key $\mathbf{k}$ is a vector in $\mathbb{Z}_q^m$ sampled uniformly at random. Define $F_{\text{RO}} : \mathbb{Z}_q^m \times \{0,1\}^* \to \mathbb{Z}_p^l$ as follows:

$$F_{\text{RO}}(\mathbf{k}, x) = \lfloor H(x) \cdot \mathbf{k} \rceil_p .$$

Security. The following theorem establishes the security of F_{RO} under the LWE assumption in the random oracle model. We note that this follows almost immediately from the proof of hardness of learning with rounding in [7], Theorem 3.2.

Theorem 3.1. *Let n, p, and q be integers, and let χ be any B-bounded distribution over $\mathbb{Z}$ such that, for security parameter λ, $q = q(\lambda)$, $p = p(\lambda)$, $q > p \geq 2$, and $q \geq pBn^{\omega(1)}$. Any adversary that can win the PRF security game as defined in Definition 2.2 with non-negligible advantage ε can be used to solve the $(\mathbb{Z}_q, n, p)$-LWR problem with advantage ε.*

Proof. Suppose we are given access to a $(\mathbb{Z}_q, n, p)$-LWR oracle which either outputs "real" samples of the form

$\left(\mathbf{A}_i \in \mathbb{Z}_q^{l\times m}, \lfloor \mathbf{A}_i\mathbf{k}\rceil_p \in \mathbb{Z}_p^l\right)$ for a fixed (but uniformly random) key $\mathbf{k} \in \mathbb{Z}_q^m$ and "fresh" uniformly random samples $\mathbf{A}_i$ or "random" samples $\left(\mathbf{A}_i \in \mathbb{Z}_q^{l\times m}, \mathbf{r} \in \mathbb{Z}_p^l\right)$. We show how to build a PRF simulation such that any adversary that wins the PRF security game can be used to solve the associated LWR problem.

Consider the following challenger $\mathcal{C}$ in the PRF security game. $\mathcal{C}$ will keep a database consisting of entries of the form $\left(\{0,1\}^*, \mathbb{Z}_q^{l\times m}, \mathbb{Z}_p^l\right)$. Recall that $\mathcal{C}$ has access to a $(\mathbb{Z}_q, n, p)$-LWR oracle O which is either a "real" or "random" LWR oracle. $\mathcal{C}$ does the following on respective queries:

- On query $x_i \in \{0,1\}^*$ to H, $\mathcal{C}$ checks if x_i exists in the database. If so, it responds with the *second* entry in the database (some $\mathbf{A}_i \in Z_q^{l\times m}$, as we will see soon). If not, it queries the LWR oracle, getting a query of the form $\left(\mathbf{A}_i \in \mathbb{Z}_q^{l\times m}, \mathbf{t}_i \in \mathbb{Z}_p^l\right)$, where $\mathbf{t}$ could be either "real" or "random", depending on the LWR oracle. $\mathcal{C}$ then adds the tuple $(x_i, \mathbf{A}_i, \mathbf{t}_i)$ to the database.

- On query $x_i \in \{0,1\}^*$ to F, $\mathcal{C}$ checks if x_i exists in the database. If so, it responds with the *third* entry in the database (some $\mathbf{t}_i \in Z_q^l$). If not, it queries the LWR oracle, getting a query of the form $\left(\mathbf{A}_i \in \mathbb{Z}_q^{l\times m}, \mathbf{t}_i \in \mathbb{Z}_p^l\right)$, where $\mathbf{t}$ could be either "real" or "random", depending on the LWR oracle. $\mathcal{C}$ then adds the tuple $(x_i, \mathbf{A}_i, \mathbf{t}_i)$ to the database.

Note that if the LWR oracle is "real", then $\mathcal{C}$ simulates F_{RO} perfectly. On the other hand, if the LWR oracle is "random", then $\mathcal{C}$ simulates a truly random function. Thus, any adversary that can win the PRF game with advantage ε can be used to solve the LWR problem with identical advantage, completing the proof. □

3.2 Adapt lattice parameters

Our goal is to choose the PRF parameters so that the PRF can be evaluated efficiently as an MPC protocol. In particular, we focus on minimizing the online round count, which is important for achieving low latency in our distributed key derivation application.

We observe that if we choose q and p as powers of 2, then both the modulo operation $x \mod q$ and the rounding operation $\lfloor x \rceil_p$ can be expressed efficiently by bitwise operations. For an integer x with binary representation $x_1, \ldots, x_n$, we have

$$\lfloor x \mod q \rceil_p = \mathsf{int}(x_{\log_2(q/p)}, \ldots, x_{\log_2(q)}) \ ,$$

where $\mathsf{int}(x_1, \ldots, x_n) = \sum_{i=1}^n x_i \cdot 2^{i-1}$.

As we will see later, this adaptation enables us to evaluate the modulo and rounding operation efficiently in the MPC setting.

3.3 Adapt message space and compose outputs

For our application, we need the PRF to output random values in a prime field $\mathbb{Z}_{p'}$, where p' is determined by the application. However, so far the lattice PRF outputs a vector in $\mathbb{Z}_p^l$, where p is a power of 2.

Adapt message space. As we would like to obtain PRF outputs in $\mathbb{Z}_{p'}$, for some prime p', we will choose $\mathbb{Z}_{p'}$ as the native message space of computation, which is also compatible with many MPC protocols. State-of-the-art MPC protocols allow for non-interactive addition and one-round multiplication over $\mathbb{Z}_{p'}$.

Compose outputs. To convert a vector of random elements over $\mathbb{Z}_p$ into a single random value over $\mathbb{Z}_{p'}$, we use the following map M_{COMP},

$$M_{\text{COMP}} : \mathbb{Z}_p^l \to \mathbb{Z}_{p'}; \mathbf{x} \mapsto \sum_{i=1}^{l} x_i \cdot p^{i-1} \ .$$

We denote the composed PRF by

$$F_{\text{COMP}} : \mathbb{Z}_q^m \times \{0,1\}^* \to \mathbb{Z}_p'; (\mathbf{k}, x) \mapsto M_{\text{COMP}}(F_{\text{RO}}(\mathbf{k}, x)) \ .$$

Security. The security of the PRF F_{COMP} follows from the security of F_{RO} (Theorem 3.1) and a bound on the statistical distance between the distribution of M_{COMP} over uniform-random inputs and the uniform distribution over $\mathbb{Z}_{p'}$ (Theorem 2.1).

Theorem 3.2. *F_{COMP} satisfies Definition 2.2.*

Proof. By a corollary of Theorem 2.1, we have that

$$\Delta\left(M_{\text{COMP}}(U(\mathbb{Z}_p^l)), U(\mathbb{Z}_{p'})\right) \leq p'/p^l \ .$$

Moreover, by Theorem 3.1 we know that F_{RO} is computationally indistinguishable from $U(\mathbb{Z}_p^l)$. It follows from hybridizing the above statements that F_{COMP} is computationally indistinguishable from $U\left(\mathbb{Z}_{p'}\right)$, and that the advantage $\mathbf{Adv}^{\mathsf{PRF}}[F_{\text{COMP}}, \mathcal{A}]$ is negligible for all polynomially-bounded $\mathcal{A}$. □

4 Enhanced constructions

In this section, we show how to build an optimized version of our PRF. We gain (sometimes substantial) performance improvements at the cost of provable security. In particular, we conjecture new circular security assumptions around LWE/LWR, prove that assumptions that are "very close" are secure under the standard LWE assumption, and show how we gain performance. Due to space constraints, we are unfortunately unable to include all of our proofs in this section. For readability, we have included this full section in the appendix.

4.1 Overview of core ideas

The basic idea of our construction is to combine LWR outputs together to create some value that is computationally indistinguishable from uniform modulo some large prime p. Consider some number p_0. If we have LWR instances $t_1, ...t_\ell$ that give us some uniform value over $\mathbb{Z}_{p_0}$, then we compute the sum $\sum_{i=1}^{\ell} p_0^{i-1} t_i$. If $p_0^t - p$ is superpolynomially large, then we have constructed a uniformly random value $\mod p$ assuming that the LWR assumption is true.

In some sense, this seems a little bit wasteful: for instance, what happens if we do not compute the rounding operation of the higher-order terms (those that are multiplied by some p_0^i for $i > 1$ in the above exposition)? If we are rounding away k bits, we could instead not round away the low order bits when computing t_2 and multiply this version of t_2, for instance, by $\frac{p_0}{2^k}$. This way t_1 would "hide" the noise bits of t_2 that we haven't rounded away and hopefully we could still have security.

A concrete example. Consider two integers p_1 and p_2. We set $P_1 = 2^{p_1}$ and $P_2 = 2^{p_2}$ and then $q = P_1^2 P_2$. We also set $P = P_1^3 P_2^2$, ignoring for a brief moment that we would eventually like P to be prime. Suppose we let $\mathbf{a} \in \mathbb{Z}_q^n$ be sampled uniformly at random for some integer n and also let $\mathbf{s_1}, \mathbf{s_2} \in \mathbb{Z}_q^n$ be sampled such that each entry is random in $[0, ..., P_1]$. We could compute $t_1 = \left\lfloor \mathbf{a}^T \mathbf{s_1} \right\rfloor_{p_2 p_1}$ and $t_2 = \mathbf{a}^T \mathbf{s_2}$ and then set $t = t_1 + P_1 P_2 t_2$.

What is going on here? the highest order bits of t_1–P_1 of them, in fact–mask the lowest P_1 bits of t_2 that we would normally round away. It perhaps surprisingly turns out that, assuming P_1 and P_2 are large enough, we can actually prove that t is pseudorandom $\mod P$ assuming LWE holds. The proof follows from a relatively natural hybrid argument.

We can also extend this idea for higher values of ℓ: in general, setting $t_1 = \left\lfloor \mathbf{a}^T \mathbf{s_1} \right\rfloor_{P_2 P_1}$, $t_2 = \mathbf{a}^T \mathbf{s_2}$, ... , $t_\ell = \mathbf{a}^T \mathbf{s}_\ell$ and combining in the same style as before still works in the sense that we can prove security from LWE. This allows us to reduce the work needed in our MPC.

Moving to circular security. However, the above approach is a little bit unsatisfactory. No matter how we set ℓ, we still have to compute $t_1 = \left\lfloor \mathbf{a}^T \mathbf{s_1} \right\rfloor_{P_2 P_1}$, which effectively lower bounds the number of rounds needed in our MPC. Since our MPC is over arithmetic circuits, there are two expensive (because they are bitwise) operations here which must be done: computing $\mod q$, and rounding. We can try to improve things in the following ways:

- First, suppose we sample the keys $\mathbf{s}_i$ from a slightly different distribution: uniform over $[0, ..., P_1/n]$ rather than uniform over $[0, ..., P_1]$. This would give us the property that $\mathbf{a s_1} < P_1 P_2 P_1^2$, simplifying our argument.
- Then, in our computation, suppose we just compute $t_1 = \left\lfloor \mathbf{a}^T \mathbf{s_1} (\mathbb{Z}) \right\rfloor_{P_2 P_1}$: where we compute $\mathbf{a}^T \mathbf{s}_1$ over $\mathbb{Z}$. In other words, we *never* compute a mod q operation, and instead only round away the lowest-order p_1 bits.
- Furthermore, suppose we restrict $P_2 \geq P_1$.

We can now see how to argue that $t_1 + P_1 P_2 t_2$ is uniform mod P. Note that we cannot reduce to standard LWE, but must make a circular security-style of assumption:

- Normally, letting an adversary see $t_1 = \left\lfloor \mathbf{a}^T \mathbf{s_1} (\mathbb{Z}) \right\rfloor_{P_2 P_1}$ instead of $t_1 = \left\lfloor \mathbf{a}^T \mathbf{s_1} \right\rfloor_{P_2 P_1}$ where we compute mod q would break security with enough samples. However, the high-order bits in t_1 that would be "eliminated" by the mod q operation are going to correspond to the integer representation between $P_1 P_2 P_1^2$ and $P_1 P_2 P_1^2 P_2$: in other words, where the "good bits" of t_2 lie.
- The bits of t_2 that we would usually round away still lie within the "good bits" of t_1 as before.

So, in this case, the "good" bits of each LWR instance effectively mask the "sensitive" bits of the other instance. While we can't prove that this construction holds under a standard LWE assumption, we can conjecture that it stands a good chance of being secure based on the previous intuition. However, such an assumption certainly would need more study before being used in a practical system. We formalize this later in this section as the "overlapping LWR assumption".

Generalizing this intuition. As before, we can continue to chain more and more terms together for larger values of P. However, in this case we know far less about the security: it could be the case, for instance, that our assumptions hold for a constant ℓ but not if ℓ is larger. We leave a formal assessment of the security of these assumptions to future work.

We also note that, in the above, we have technically not defined what to do with the "middle" terms, i.e. t_2 through $t_{\ell-1}$: do we need to still compute the $\mod q$ operation, or is it OK if we just add them in directly, only computing the rounding operation on t_1 and the $\mod q$ operation on t_ℓ? We do not know the answer to this for sure and thus define a flexible assumption.

4.2 LWR with nonuniform key distributions

In our constructions below, we will need to use LWR with a nonuniform key distribution. We note that [6] showed that LWE with key distribution drawn from the noise distribution was (almost) exactly as hard as regular LWE for certain moduli, and [14] refined this idea further, among many other contributions. Although we cannot directly make these proofs work with rounding, we can take their core ideas and apply the standard rounding reduction of [7] to show that we can

use LWR with a nonuniform (and even non-Gaussian) key distribution. Below, we prove that LWR with an appropriate nonuniform key distribution is as hard as (relatively) standard LWE.

Theorem 4.1. *Let n, p, and $q' < q$ be integers, and let χ be any B-bounded distribution over $\mathbb{Z}$ such that, for security parameter λ, $q = q(\lambda)$, $p = p(\lambda)$, $q > p \geq 2$, and $q' \geq Bn^{\omega(1)}$ and $q \geq pBn^{\omega(1)}$. Let Ψ be the distribution over $\mathbb{Z}_q^n$ that outputs each value in the vector uniformly at random between 0 and q'. It is the case that the $(\mathbb{Z}_q, n, p, \Psi)$-LWR problem is at least as hard as solving the $(\mathbb{Z}_q, n, \chi)$-LWE problem.*

Proof intuition. We first show that LWE with the key drawn from the noise distribution is as hard as standard LWE. This is a result that has been shown numerous times in a number of different contexts [6, 14], but we found it easier to prove it directly here ourselves than to adapt these other results to our context. We then show that LWE with a key uniformly sampled over $\mathbb{Z}_{q'}$ is at least as hard as LWE with key drawn from the noise distribution, similar to a result of [14]. Finally, we apply techniques from [7] to show that our LWR assumption is at least as hard as this LWE assumption with the key sampled uniformly over $\mathbb{Z}_{q'}$. For the full proof, please see Appendix B.

A corollary for uniform noise. With a very slight tweak, we can extend our line of results above to handle uniformly sampled noise instead of rounding. We state this below in the following theorem.

Theorem 4.2. *Let n and $q' < q$ be integers, and let χ be any B-bounded distribution over $\mathbb{Z}$ such that, for security parameter λ, $q = q(\lambda)$, $p = p(\lambda)$, $q > p \geq 2$, and $q' \geq Bn^{\omega(1)}$ and $q \geq pBn^{\omega(1)}$. Let ψ be a distribution over $\mathbb{Z}_q$ that outputs a value uniformly at random between 0 and q', and let Ψ be the distribution over $\mathbb{Z}_q^n$ that outputs each value in the vector uniformly at random between 0 and q'. It is the case that the $(\mathbb{Z}_q, n, \psi, \Psi)$-LWE problem is at least as hard as solving the $(\mathbb{Z}_q, n, \chi)$-LWE problem.*

We prove this theorem in Appendix B.

4.3 Defining and proving the secure instance

We next define and prove secure the optimized instance for which we have a security proof to standard lattice assumptions. This is just a general and more formally defined version of what we discussed above.

Construction. Our construction takes as setup parameters a security parameter λ and some prime P, and then includes other integer parameters n, p_1, p_2, ℓ, n, and E. We require the following from these parameters:

- We set $P_1 = 2^{p_1}$ and $P_2 = 2^{p_2}$.
- We set $q = P_1 P_2 P_1$.
- $P_1^{\ell+1} P_2^{\ell} \geq PE$.
- P_1, P_2, and E are superpolynomially large in λ.
- We set n as a lattice dimension dependent on λ.

We assume the existence of a hash function $H : \{0,1\}^k \to \mathbb{Z}_q^n$. The secret key of our PRF F_{SEC} is a matrix $\mathbf{S} \in \mathbb{Z}_q^{n \times \ell}$ sampled so that each entry is uniform in $[0, ..., P_1]$.[1] We denote $\mathbf{S}_i$ to be the ith column of $\mathbf{S}$.

We formally define our PRF $F_{\text{SEC}} : \{0,1\}^k \times \mathbb{Z}_q^{n \times \ell} \to \mathbb{Z}_p$ as follows. On input x, we:

- Set $\mathbf{a}_x \in \mathbb{Z}_q^n = H(x)$.
- Let $c_{x,i} \in \mathbb{Z}_q = \mathbf{a}_x^T \mathbf{S}_i$.
- Output the sum $\lfloor c_{x,1} \rfloor_{P_1 P_2} + P_2 c_{x,2} + P_1 P_2^2 c_{x,3} + ... + P_1^{\ell-2} P_2^{\ell-1} c_{x,\ell} \mod P$.

Intuition of the construction. What is going on here? Each of the "LWR" instances works mod $q = P_1 P_2 P_1$ and overlaps on the top and bottom (if applicable) by P_1. So the top of each fresh instance hides the "noise bits" of the instance above it. This is the goal of the construction, and how we can gain efficiency: we only have to compute one rounding operation in entire computation of the PRF. This isn't much if we are directly computing the PRF, but may save us considerable time if we compute the PRF in an MPC.

Proof of security. As we claimed earlier, we can in fact prove the above construction secure under the standard learning with rounding assumption. We note that, as shown in [7], this follows from the LWE assumption with slightly superpolynomial (in the security parameter λ) modulus.

Our core argument is relatively straightforward: we use a hybrid argument, progressively randomizing the terms $c_{x,i}$, starting with $i = 1$ until all of the terms are random. Note that the randomness of each $c_{x,1}$ term immediately follows from the LWR assumption. Once we "switch" the $c_{x,1}$ terms to random, then they mask the lowest p_1 bits of the $c_{x,2}$ terms, meaning that we can once again apply LWR. We can then continue this argument all the way up to the $c_{x,\ell}$ terms. There are some subtleties in the proof, particularly with how we deal with "overflow" bits, but the overall idea is pretty straightforward.

We state this formally below with the following theorem:

Theorem 4.3. *Let P, n, q, p_1, P_1, p_2, P_2, ℓ, n, and E be parameters as defined above. Let Ψ denote the distribution over*

[1] We could set our keys here to be uniform over $\mathbb{Z}_q$, but we choose to set them this way for efficiency reasons (i.e., lesser bitlength leads to fewer preshared random bits consumed in MPC). As shown in [6] and myriad follow-ups, we lose little security for doing so.

$\mathbb{Z}^n$ defined by sampling each entry as an integer uniformly at random in the range $[0, P_1]$ and ψ be the distribution over Z defined by sampling an integer uniformly at random in the range $[0, P_1]$. Any adversary that can win the PRF security game as defined in Definition 2.2 with non-negligible advantage ε can be used to solve the $(\mathbb{Z}_q, n, p_1 p_2, \Psi)$-LWR problem or the $(\mathbb{Z}_q, n, \psi, \Psi)$-LWE problem with advantage polynomial in ε assuming that H is a random oracle.

We prove this theorem in Appendix B. We note that by theorems 4.1 and 4.2 (proven in Appendix B), the assumptions used in this theorem are reducible from standard LWE. So therefore the hardness of this PRF follows from standard LWE. Also, the assumptions in this proof are not substantially worse in terms of parameters than just regular LWR. So it would not be irresponsible to use this scheme in a real deployment.

4.4 Instances with only conjectured security

In this section, we discuss other PRF constructions for which we cannot prove security from standard assumptions. While the lack of security proofs is obviously big drawback of these constructions, they do offer substantial efficiency advantages compared to the provably secure PRFs, especially within the context of MPC computations.

We start with a construction that is very close to our construction with provable security.

A construction with almost a security proof. As before, our construction takes as setup parameters a security parameter λ and some prime P, and then includes other integer parameters n, p_1, p_2, ℓ, n, and E. We have the same requirements for these parameters as with F_{SEC} with the additional requirement that $p_2 \geq p_1$.

We assume the existence of a hash function $H : \{0,1\}^k \to \mathbb{Z}_q^n$. The secret key of our PRF F_{ASEC} is a matrix $\mathbf{S} \in \mathbb{Z}_q^{n \times \ell}$ sampled so that each entry is uniform in $[0, ..., P_1/n]$. We denote $\mathbf{S}_i$ to be the ith column of $\mathbf{S}$.

We formally define our PRF $F_{\text{ASEC}} : \{0,1\}^k \times \mathbb{Z}_q^{n \times \ell} \to \mathbb{Z}_p$ as follows:

- Set $\mathbf{a}_x \in \mathbb{Z}_q^n = H(x)$.
- Set $c_{x,1} = \mathbf{a}_x^T \mathbf{S}_1$ over $\mathbb{Z}$.
- For $i \geq 1$, let $c_{x,i} \in \mathbb{Z}_q = \mathbf{a}_x^T \mathbf{S}_i \mod q$.
- Output the sum $\lfloor c_{x,1} \rfloor_{P_1 P_2} + P_2 c_{x,2} + P_1 P_2^2 c_{x,3} + ... + P_1^{\ell-2} P_2^{\ell-1} c_{x,\ell} \mod P$.

Intuition of the construction. What is going on here? Changes from the secure instance are highlighted. Each of the "LWE" instances works mod $q = P_1 P_2 P_1$ and overlaps on the top and bottom (if applicable) by P_1. So the top of each fresh instance hides the "noise bits" of the instance above it. In addition, the "overlap" bits of the $c_{x,1}$ terms are hidden by the $c_{x,2}$ term. So there is some kind of circular security-like thing going on here. Unfortunately, we do not know how to prove this from standard LWE, but we can make a relatively simple and straightforward assumption from which we can prove security (in conjunction with standard LWE). As before, we could choose $\mathbf{S}$ to be from a larger space (i.e. uniform over $\mathbb{Z}_q$), and our implementation even does this, but it would be more difficult to reason about security since there would be more "overlaps".

The main advantage of this construction is it essentially lets us halve the number of rounds needed from our secure construction when we compute the PRF using MPC. For every $c_{x,i}$ term we either need to round or compute a $\mod q$ operation–but not both. Previously, we needed to do both for the $c_{x,1}$ term, which blew up the number of MPC rounds required.

A security proof with a new assumption. We can actually prove this construction secure if we are willing to use a non-standard assumption. We call this new problem the *Overlapping LWR problem.*

Definition 4.4. Overlapping LWR. Consider parameters P_1, P_2, and q, where we set $P_1 = 2^{p_1}$, $P_2 = 2^{p_2}$, and $q = P_1 P_2 P_1$. We also have a security parameter λ, a lattice dimension n based on λ, and the requirement that P_1 and P_2 are superpolynomially large in λ. Let Ψ be a distribution over $\mathbb{Z}^n$. The overlapping learning with rounding problem $(q, n, m, P_1, P_2, \Psi)$-OLWR is to distinguish between the following pairs of distributions:

$$\{\mathbf{A}, \lfloor \mathbf{A}\mathbf{s}(\mathbb{Z}) \rfloor_p + P_2 (\mathbf{A}\mathbf{s} \mod q) \mod P_1^2 P_2^2\}$$
$$\text{and} \qquad \{\mathbf{A}, \mathbf{u}\},$$

where $m = \text{poly}(n)$, $\mathbf{A} \leftarrow \mathbb{Z}_q^{n \times m}$, $\mathbf{s}_1, \mathbf{s}_2 \leftarrow \Psi$, and $\mathbf{u} \leftarrow \mathbb{Z}_{P_1^2 P_2^2}^m$. Note that we are explicitly *not* computing mod q within the rounding operation.

It turns out, if we assume the overlapping LWR problem to be true, we can prove that our above construction is secure. We state this with the theorem below:

Theorem 4.5. *Let P, n, q, p_1, P_1, p_2, P_2, ℓ, n, and E be parameters as defined above. Let Ψ denote the distribution over $\mathbb{Z}^n$ defined by sampling each entry as an integer uniformly at random in the range $[0, P_1]$ and ψ be the distribution over Z defined by sampling an integer uniformly at random in the range $[0, P_1]$. Any adversary that can win the PRF security game for F_{ASEC} as defined in Definition 2.2 with non-negligible advantage ε can be used to solve the $(q, n, m, P_1, P_2, \Psi)$-OLWR problem or the $(\mathbb{Z}_q, n, \psi, \Psi)$-LWE problem with advantage polynomial in ε assuming that H is a random oracle.*

We sketch this proof in Appendix B. We believe that this overlapping LWR assumption is quite interesting and merits further study.

A construction far from a security proof. We next outline a construction where we exploit overlapping over all of the terms, not just the first two. As before, our construction takes as setup parameters a security parameter λ and some prime P, and then includes other integer parameters n, p_1, p_2, ℓ, n, and E. We have the same parameter requirements (and needed hash function) as our previous construction. The secret key of our PRF F_{FSEC} is a matrix $\mathbf{S} \in \mathbb{Z}_q^{n\times\ell}$ sampled so that each entry is uniform in $[0,...,P_1/n]$. We denote $\mathbf{S}_i$ to be the ith column of $\mathbf{S}$, and we again note that we could sample $\mathbf{S}$ from a larger space, as before.

We formally define our PRF $F_{\text{FSEC}} : \{0,1\}^k \times \mathbb{Z}_q^{n\times\ell} \to \mathbb{Z}_p$ as follows:

- Set $\mathbf{a}_x \in \mathbb{Z}_q^n = H(x)$.
- Set $c_{x,1} = \mathbf{a}_x^T \mathbf{S}_1$ over $\mathbb{Z}$.
- For $1 < i < \ell$, let $c_{x,i} \in \mathbb{Z} = \mathbf{a}_x^T \mathbf{S}_i$ over $\mathbb{Z}$.
- Set $c_{x,\ell} \in \mathbb{Z}_q = \mathbf{a}_x^T \mathbf{S}_i \mod q$.
- Output the sum $\lfloor c_{x,1} \rfloor_{P_1P_2} + P_2 c_{x,2} + P_1 P_2^2 c_{x,3} + ... + P_1^{\ell-2} P_2^{\ell-1} c_{x,\ell} \mod P$.

Construction explanation. Once again, we highlighted changes from the previous construction. The basic idea here is that we try to take our circular security idea to the extreme. This construction is quite efficient when computed in MPC since we only need to do one mod q operation and one rounding operation.

At first glance, this construction may seem similar to "vanilla" LWR with a very high modulus to "noise" ratio, which would obviously not be good. This is because we can write the construction's outputs as something very close to $\lfloor \mathbf{a}_i (\mathbf{S}_1 + P_2\mathbf{S}_2 + ...) \rfloor_{P_1^{\ell-1}P_2^{\ell}} \mod P$. However, the fact that we are computing a mod q operation in the middle throws chaos into this representation and makes it seemingly unlikely that standard attacks on overstretched LWE will not work here. Attacks on this aggressive construction may have more in common with approaches that might be used to attack the "dark matter" PRF in [11] than LWE itself.

Switching the role of the samples and key. In our constructions in this section, we have used samples (i.e. the outputs of the hash function) that are vectors and keys that are matrices. This was done solely because we could prove security; we know of no attacks if we use samples that are matrices and keys that are vectors (i.e. switching from $\mathbf{a}_i$ and $\mathbf{S}$ to $\mathbf{A}_i$ and $\mathbf{s}$). It is also possible that this could bring about efficiency improvements since we would need to deal with fewer secret bits.

5 Implementation and evaluation

In order to better understand the practical performance of our lattice-based PRF constructions when evaluated in MPC, we implemented and evaluated them using the MP-SPDZ framework [39], which is a framework for evaluating MPC protocols that comes with its own high-level programming language and supports a variety of base MPC protocols. The source code can be found at https://github.com/torusresearch/MP-SPDZ/blob/lattice-prf/Programs/Source/ in files `lattice_prf*.mpc`.

MPC setup. We configure MP-SPDZ to use `mal-shamir` as the base MPC protocol, which is a maliciously secure MPC protocol based on Shamir secret sharing that requires an honest majority, and thereby satisfies our robustness requirement. Moreover, it supports prime field message spaces, which suits the message space of our PRF construction. We run our experiments between 3 parties and with security against 1 corrupted party, and we use a prime field $\mathbb{Z}_{p'}$ as the native message space, where p' is a 256-bit prime.

PRF parameters. We choose the lattice PRF parameters q and p as powers of 2, with varying concrete values during the experiments (e.g., $q = 2^{12}$ and $p = 2^8$). Furthermore, we set $l = \lceil (\log_2(p') + \Delta_s)/\log_2(p) \rceil$, where $\Delta_s = 40$ controls the statistical distance between F_{COMP} and F_{RO}.

Key generation. For generating the master PRF key, the parties need to sample secret shares of a uniformly random $\mathbf{k} \in \mathbb{Z}_q^m$. As there is no method for directly sampling secret-shared values modulo q over the message space $\mathbb{Z}_{p'}$, we rely on random bit sampling [47]. Concretely, for each entry of $\mathbf{k}$, we sample $\log_2 q$ shared random bits and then accumulate them to obtain a shared random integer in $\mathbb{Z}_q$.

Computation modulo q. Evaluating the PRF in MPC requires computing the matrix-vector product $H(x) \cdot \mathbf{k}$ modulo q, where $H(x)$ is a public matrix and $\mathbf{k}$ is a secret-shared vector.

We first compute the matrix-vector product $H(x) \cdot \mathbf{k}$ over the prime field $\mathbb{Z}_{p'}$. Note that p' must be large enough so that the computation does not wrap. Per row of $H(x)$, this involves m cleartext-ciphertext multiplications and $m-1$ ciphertext-ciphertext additions, which can all be done locally. Let $\mathbf{y} \in \mathbb{Z}_{p'}^l$ denote the resulting vector.

Next, we compute each entry of $\mathbf{y}$ modulo q. Since q is a power of 2, this can be done using algorithm `sint.mod2m` of MP-SPDZ, which runs in $1 + \lceil \log_2^2(q) \rceil$ online rounds and makes use of pre-shared random bits.

Rounding operation. Given the vector $\mathbf{y}' = H(x) \cdot \mathbf{k} \bmod q$, we next compute the rounding operation $\lfloor \mathbf{y}' \rceil_p$. Concretely, this means we need to map each element y'_i of $\mathbf{y}'$ to the largest integer j such that $j * q/p \leq y'_i$. Since q and p are powers of 2, this is equivalent to cutting off the $\log_2(q/p)$ lowest order bits of y'_i. In MP-SPDZ this can be done using algorithm `sint.right_shift`, which runs in $1 + \lceil \log_2^2(q/p) \rceil$ online rounds and makes use of pre-shared random bits.

Composition. Finally, we compose the entries of the rounded output vector $\lfloor \mathbf{y}' \rceil_p$ into a single uniform random value $y'' \in \mathbb{Z}_{p'}$ by evaluating M_{COMP}. This involves plaintext-ciphertext multiplications and ciphertext-ciphertext additions, which can all be done locally.

Total round count. The total round count for computing $F_{\text{COMP}}(x)$ in MPC is $2 + \log_2^2(q) + \log_2^2(q/p)$. For $q = 2^{12}$ and $p = 2^8$, this results in a MPC PRF protocol running in 8 online rounds, assuming sufficiently many shared random bits have been generated during preprocessing.

5.1 Parameter selection

In the following, we describe the lattice parameters that we use for our evaluation. As in all practical lattice-based cryptosystems, parameters are derived from what we know about best possible attacks rather than theoretical reductions, so we do not carry over parameters from our theorems here. Instead, our parameter selection is inspired by the parameters of Frodo [13] with 128 bit classical security, as this scheme relies on a similar assumption. We emphasize that Frodo was meant to be a very conservative construction as well.

As the lattice dimension we choose a fixed value of $m = 512$. We note that the lattice dimension does not affect the complexity of the multi-party computation. This is because only the size of the secret key $\mathbf{k}$ and the hash output $H(x)$ depend on m. However, as the vector product $H(x) \cdot \mathbf{k}$ collapses these vector elements onto a single element, and this is computed locally at the start of the protocol, the interactive part of the protocol does not depend on m at all.

For the modulo parameter q and the rounding parameter p, we use the two parameter sets $(q,p) = (2^{12}, 2^8)$ and $(q,p) = (2^{32}, 2^{24})$. Here, smaller values optimize for round complexity, while larger values optimize for preprocessing complexity due to the lower number of pre-shared random bits required. We also distinguish between whether we use the regular PRF construction F_{COMP} (cf. Section 3.3), the optimized secure PRF construction F_{SEC} (cf. Section 4.3), or the optimized conjectured constructions F_{ASEC} and F_{FSEC} (cf. Section 4.4). We list all considered protocol instances in Table 1.

Instance	Construction	Param q	Param p
REG_{12}	F_{COMP}	2^{12}	2^8
REG_{32}	F_{COMP}	2^{32}	2^{24}
OPT_{12}	F_{SEC}	2^{12}	2^8

$\mathsf{CON}_{12}^{\text{ASEC}}$	F_{ASEC}	2^{12}	2^8
$\mathsf{CON}_{32}^{\text{ASEC}}$	F_{ASEC}	2^{32}	2^{24}
$\mathsf{CON}_{12}^{\text{FSEC}}$	F_{FSEC}	2^{12}	2^8
$\mathsf{CON}_{32}^{\text{FSEC}}$	F_{FSEC}	2^{32}	2^{24}

Table 1: Parameterized instances of our PRF constructions used for evaluation.

5.2 Evaluation

We measure the performance of our distributed PRF protocol with respect to the different instances defined in Section 5.1 and also in comparison with other existing distributed PRF protocols. We run our experiments on a single machine with an M1 Pro CPU, 32GB RAM, and with local communication (e.g., without network latency) and mostly focus on measuring performance of the online phase without preprocessing if not stated otherwise.

Comparison between instances. We first measure and compare the performance of the different protocol instances defined in Section 5.1. The results are shown in Table 2. We observe that larger values for q and p lead to less preprocessing at the cost of a higher online round count. Furthermore, the optimized variant further reduces the preprocessing and communication cost, at the expense of more computation due to the larger secret key.

Comparison with other protocols. We compare our provably secure distributed PRF protocols with existing constructions in Table 3, relying on the implementations from [34]. Most of the other protocols are designed for producing multiple field elements per protocol evaluation. Notably, GMiMC does not support output size 1 and for Rescue reducing the output size to 1 increases the round complexity. Hence, we chose an output size of 2 for these schemes.

Overall, our protocol compares favorably in terms of running time and round complexity. However, we note that due to the large number of random bits consumed by our protocol, it requires more communication, especially during the preprocessing phase. We note that the amount of preprocessing communication is still comfortably within the realms of feasibility and does not limit the applicability of our protocol. It is an interesting open question how to produce a large number of pre-shared random bits with less communication. For many applications of DKD systems, like cryptocurrency transac-

Protocol	Time (ms)	Data (MB) Online / Total	Rounds	Bits

Table 2: Measurements for running one evaluation of each of our PRF protocol instances. *Time* is the time required to run the protocol on a single machine without network latency. *Data* is the global amount of data sent between all parties in the online phase and including preprocessing, respectively. *Rounds* is the number of online communication rounds. *Bits* is the number of pre-shared random bits consumed.

tions or other digital proof claims, requests are triggered by a user interacting with a wallet. This typically means that having low latency is extremely important, but requests are relatively infrequent and there is ample time for preprocessing.

6 Application to Distributed Key Management

In the following we propose a model for distributed key management in the Universal Composability Framework [15]. We first introduce an abstract MPC functionality $\mathcal{F}_{\mathsf{MPC}}$ that our protocols will depend on. Then, we model the ideal functionality of DKM with a key distribution $\mathcal{K}$, define a real protocol based on a PRF F, and show that the real protocol realizes the ideal functionality in the $\mathcal{F}_{\mathsf{MPC}}$-hybrid model if the key distribution $\mathcal{K}$ is indistinguishable from the output distribution of the PRF F. Finally, as an example instantiation, we show that the proposed DKM protocol instantiated with one of our distributed PRF protocols efficiently realizes distributed key management for ECDSA signing.

We work in the universal composability framework [15] and assume authenticated private channels between parties. Furthermore, we assume access to the following ideal MPC functionality, $\mathcal{F}_{\mathsf{MPC}}$, which abstractly represents an MPC protocol library such as MP-SPDZ [39]. We require that any realization of $\mathcal{F}_{\mathsf{MPC}}(P,t)$ is secure against static corruption of at most t parties of P.

Functionality 6.1 ($\mathcal{F}_{\mathsf{MPC}}(P,t)$, Multi-party computation)**.** This functionality is parametrized by the set of servers P and the corruption threshold t. The simulator $\mathcal{S}$ may statically corrupt up to t parties in P. We denote by $[x]$ the identifier of a stored secret value x.

Evaluate: On message $(\texttt{eval}, \mathsf{sid}, f, [k], x)$ from all parties in P, compute $y \leftarrow f(k,x)$, store y, and send $(\texttt{result}, \mathsf{sid}, [y])$ to all parties in P.

Open: On message $(\texttt{open}, \mathsf{sid}, [x], u)$ from all parties in P, send $(\texttt{value}, \mathsf{sid}, x)$ to party u.

6.1 Ideal functionality

In the following, we first define an ideal functionality for Distributed Key Management involving a set of servers P and a set of users U, where the servers create and manage secret keys on behalf of the users. The users can ask the servers to evaluate a fixed set of algorithms, $\mathcal{F}_{\mathsf{Eval}}$, on their secret keys, where $\mathcal{F}_{\mathsf{Eval}}$ depends on the application and may, for example, allow the users to create digital signatures using the managed secret keys as input.

Functionality 6.2 ($\mathcal{F}_{\mathsf{DKM}}(P,t,U,\mathcal{K},\mathcal{F}_{\mathsf{Eval}})$, Distributed Key Management)**.** This functionality is parametrized by the set of servers P, the corruption threshold t, the set of users U, the key distribution $\mathcal{K}$, and the set of supported key-dependent algorithms $\mathcal{F}_{\mathsf{Eval}}$. The simulator $\mathcal{S}$ may statically corrupt up to t parties in P and any subset of parties of U, which it announces at the start of the protocol.

Setup: On receiving $(\texttt{init})$ from all parties in P, store $(\texttt{ready})$, and send $(\texttt{ready})$ to all parties in P.

Eval: On receiving $(\texttt{eval}, \mathsf{sid}, f, x)$ from party $u \in U$, assert that $(\texttt{ready})$ is stored and $f \in \mathcal{F}_{\mathsf{Eval}}$. If this is the case, do the following.

1. Check if there is a storage entry $(\texttt{key}, u, k)$, for some key k. If there is no such entry, sample $k \leftarrow \mathcal{K}$, and store $(\texttt{key}, u, k)$.
2. Call $k \leftarrow \mathsf{Key}(u)$, compute $y \leftarrow f(k,x)$ and all parties in U, and send $(\texttt{result}, \mathsf{sid}, y)$ to u.

6.2 Real protocol

The real protocol is defined in the $\mathcal{F}_{\mathsf{MPC}}$-hybrid model and defines a simple interaction between the users U and the servers P where in each protocol instance a user instructs the servers to run an algorithm $f \in \mathcal{F}_{\mathsf{Eval}}$ on its derived key, and the servers use $\mathcal{F}_{\mathsf{MPC}}$ to perform this request in MPC.

Protocol 6.3 ($\pi_{\mathsf{DKM}}(P,t,U,F,\mathcal{F}_{\mathsf{Eval}})$)**.** This protocol is parametrized by the set of servers P, the corruption thresold t, the set of users U, the PRF F, and the set of supported key-dependent algorithms $\mathcal{F}_{\mathsf{Eval}}$. It makes use of functionality $\mathcal{F}_{\mathsf{MPC}}(P,t)$.

Setup:

Protocol	Computation (ms)	Communication (MB) Online / Total	Rounds	Time with network latency (in seconds, extrapolated)
Ciminion [24]	31.93	0.11 / 0.36	283	28.33
GMiMC [3]	59.04	0.26 / 0.84	670	67.06
HadesMiMC [33]	47.81	0.18 / 0.60	466	46.65
Hydra [34]	21.42	0.07 / 0.24	140	14.02
MiMC [1]	33.18	0.13 / 0.46	331	33.13
Rescue [5]	26.35	0.28 / 0.97	124	12.43
Our protocol REG_{12}	11.34	0.41 / 6.01	8	0.81
Our protocol REG_{32}	8.06	0.43 / 3.85	10	1.01
Our protocol OPT_{12}	24.79	0.33 / 3.85	8	0.82
Our protocol OPT_{32}	12.86	0.36 / 2.79	10	1.01

Table 3: Comparison of existing distributed PRF protocols with our provably-secure protocols. *Time with network latency* estimates the execution time with an assumed round trip time of 100 milliseconds.

1. On message $(\texttt{init}, \mathsf{sid})$ from the environment $\mathcal{Z}$, each party $\mathcal{P}_i \in P$ checks whether there is an entry $(\texttt{prfkey}, \cdot)$ in memory. If not, $\mathcal{P}_i$ sends $(\texttt{eval}, \mathsf{sid}, F.\mathsf{KeyGen})$ to functionality $\mathcal{F}_{\mathsf{MPC}}$.
2. On message $(\texttt{result}, \mathsf{sid}, \mathbf{k})$ from $\mathcal{F}_{\mathsf{MPC}}$, $\mathcal{P}_i$ stores $(\texttt{prfkey}, \mathbf{k})$.

Eval:

1. On message $(\texttt{eval}, \mathsf{sid}, f, x)$ from the environment $\mathcal{Z}$, a user $u \in U$ sends $(\texttt{eval}, \mathsf{sid}, f, x)$ to each party in $\mathcal{P}_i \in P$.
2. On message $(\texttt{eval}, \mathsf{sid}, f, x)$ from a user $u \in U$, each party $\mathcal{P}_i \in P$ asserts that there is an entry $(\texttt{prfkey}, \mathbf{k})$ in memory, for some $\mathbf{k}$, and that $f \in \mathcal{F}_{\mathsf{Eval}}$. It then sends $(\texttt{eval}, \mathsf{sid}, g, \mathbf{k}, u, x)$ to $\mathcal{F}_{\mathsf{MPC}}$, where $g(\mathbf{k}, u, x) = f(F.\mathsf{Eval}(\mathbf{k}, u), x)$.
3. On message $(\texttt{result}, \mathsf{sid}, y)$ from $\mathcal{F}_{\mathsf{MPC}}$, $\mathcal{P}_i$ sends $(\texttt{open}, \mathsf{sid}, y, u)$ to $\mathcal{F}_{\mathsf{MPC}}$.
4. On message $(\texttt{value}, \mathsf{sid}, y)$ from $\mathcal{F}_{\mathsf{MPC}}$, u outputs $(\texttt{result}, y)$.

6.3 Security proof

The following thereom establishes that protocol π_{DKM} with key distribution $\mathcal{K}$ realizes functionality $\mathcal{F}_{\mathsf{DKM}}$ with PRF F, for any fixed set of algorithms $\mathcal{F}_{\mathsf{Eval}}$, if the key distribution $\mathcal{K}$ is indistinguishable from the output distribution of F.

Theorem 6.4. *Let P and U be sets of parties, and t be a corruption threshold. Let F be a PRF and $\mathcal{K}$ be a key distribution such that the output distribution of F is indistiguishable from $\mathcal{K}$. Let $\mathcal{F}_{\mathsf{Eval}}$ be a set of polynomial-time algorithms. Then, protocol $\pi_{DKM}(P,t,U,F,\mathcal{F}_{\mathsf{Eval}})$ UC-realizes functionality $\mathcal{F}_{\mathsf{DKM}}(P,t,U,\mathcal{K},\mathcal{F}_{\mathsf{Eval}})$ in the $\mathcal{F}_{MPC}(P,t)$-hybrid model against a malicious adversary that statically corrupts up to t parties of P and any subset of parties of U.*

The proof follows immediately from the definition of the protocol, the security of the MPC functionality in the specified corruption setting, and the indistiguishability of the key distribution $\mathcal{K}$ and the output distribution of the PRF F. A more explicit version of the proof can be found in appendix A.2.

6.4 Example application: Scalable distributed key management for ECDSA signing using our distributed PRF protocol

In the following, we show, as an example, that our distributed PRF protocol in combination with a realization of $\mathcal{F}_{\mathsf{MPC}}$ can be used to efficiently realize a distributed key management system that supports ECDSA signing in MPC.

Ideal functionality $\mathcal{F}_{\mathsf{DKM}}^{\mathsf{ECDSA}}$. We first define the ideal functionality of a distributed key management system for ECDSA. Let ECDSA denote the ECDSA signature scheme over group $\mathcal{G}$ with generator G and prime order p. Define the following algorithms.

PubKey**:** On input (k,x), parse k as (sk,pk), and return pk.

PrivKey**:** On input (k,x), parse k as (sk,pk), and return sk.

Sign**:** On input (k,x), parse k as (sk,pk), compute $\sigma \leftarrow \mathsf{ECDSA.Sign}(sk,x)$, and return σ.

Let $\mathcal{F}_{\mathsf{ECDSA}} = \{\mathsf{PubKey}, \mathsf{PrivKey}, \mathsf{Sign}\}$. The ideal functionality of a distributed key management system for ECDSA is defined as

$$\mathcal{F}_{\mathsf{DKM}}^{\mathsf{ECDSA}}(P,t,U) = \mathcal{F}_{\mathsf{DKM}}(P,t,U,\mathsf{ECDSA.KeyGen},\mathcal{F}_{\mathsf{ECDSA}}) \ .$$

Real protocol $\pi_{\mathsf{DKM}}^{\mathsf{ECDSA}}$. Let LPRF denote our lattice-based PRF instantiated over $\mathbb{Z}_p$. Define Derive as an algorithm that

takes as input a PRF key k and a user identifier u, and outputs an ECDSA keypair (sk, pk), as follows. First, compute $sk = \mathsf{LPRF.Eval}(k,u)$. Then compute $pk = sk \cdot G$. Output (sk, pk). Define $F_{\mathsf{ECDSA}} = (\mathsf{LPRF.KeyGen}, \mathsf{Derive})$. Now, the real protocol for ECDSA DKM is defined as

$$\pi_{\mathsf{DKM}}^{\mathsf{ECDSA}}(P,t,U) = \pi_{\mathsf{DKM}}(P,t,U,F_{\mathsf{ECDSA}},\mathcal{F}_{\mathsf{ECDSA}}) \ .$$

Security. By Thereom 3.2, we know that the output distribution of LPRF is indistiguishable from a uniform random distribution over $\mathbb{Z}_p$. This, however, is exactly the secret key distribution of ECDSA over $\mathcal{G}$. It follows that the output distribution of F_{ECDSA} is indistiguishable from the distribution of ECDSA.KeyGen and, hence, by Thereom 6.4 we have that $\pi_{\mathsf{DKM}}^{\mathsf{ECDSA}}(P,t,U)$ realizes $\mathcal{F}_{\mathsf{DKM}}^{\mathsf{ECDSA}}(P,t,U)$.

Realizing $\mathcal{F}_{\mathsf{MPC}}$. To fully realize $\mathcal{F}_{\mathsf{DKM}}^{\mathsf{ECDSA}}$ one will also need to instantiate $\mathcal{F}_{\mathsf{MPC}}$ with a real world MPC framework such as MP-SPDZ [39]. Furthermore, existing optimized MPC-based ECDSA signing protocols [16, 21, 25, 26, 36] should be considered for efficient realization of ECDSA signing in MPC.

A Proof of Theorems 2.1 and 6.4

A.1 Proof of Theorem 2.1

Proof. Let $m,n \in \mathbb{N}$, $X = U(\mathbb{Z}_m)$, and $Y = U(\mathbb{Z}_n) \bmod m$. By the definition of the statistical distance, we have

$$\begin{aligned}\Delta(X,Y) &= \frac{1}{2}\sum_{a\in\mathbb{Z}_m} |\Pr[X=a] - \Pr[Y=a]| \\ &= \frac{1}{2}\sum_{a\in\mathbb{Z}_m} |1/m - \Pr[Y=a]| \ .\end{aligned} \tag{1}$$

For $a \in \mathbb{Z}_m$, define $D_a = \{x \in \mathbb{Z}_n : x \bmod m = a\}$. We have

$$\Pr[Y=a] = \sum_{b\in D_a} \Pr[U(\mathbb{Z}_n)=b] = |D_a|/n \ , \tag{2}$$

where

$$|D_a| = \begin{cases} \lceil n/m \rceil & \text{if } a < n \bmod m, \\ \lfloor n/m \rfloor & \text{else.} \end{cases} \tag{3}$$

Next, we determine an upper bound on $|1/m - \Pr[Y=a]|$ by writing out the equation using (2) and (3). For $a < n \bmod m$, we have

$$\begin{aligned}\left|\frac{1}{m} - \Pr[Y=a]\right| &= \left|\frac{1}{m} - \frac{\lceil n/m \rceil}{n}\right| \\ &= \left|\frac{1}{m} - \frac{n+m-n \bmod m}{mn}\right| \le \frac{1}{n} \ ,\end{aligned} \tag{4}$$

and for $a \geq n \bmod m$,

$$\left|\frac{1}{m} - \Pr[Y = a]\right| = \left|\frac{1}{m} - \frac{\lfloor n/m \rfloor}{n}\right| = \left|\frac{1}{m} - \frac{n - n \bmod m}{mn}\right| \leq \frac{1}{n} \ . \tag{5}$$

Finally, by combining (1), (4), and (5), we obtain an upper bound on the statistical distance of X and Y,

$$\Delta(X,Y) \leq \frac{1}{2} \sum_{a \in \mathbb{Z}_m} 1/n \leq m/n \ .$$

□

A.2 Proof of Thereom 6.4

Proof. We have to show that for every adversary $\mathcal{A}$, there exists a simulator $\mathcal{S}$, such that for every environment $\mathcal{Z}$, the environment $\mathcal{Z}$ cannot distinguish a real execution of protocol $\pi_{\mathsf{DKM}}(P,t,U,F,\mathcal{F}_{\mathsf{Eval}})$ with adversary $\mathcal{A}$ from an ideal execution of functionality $\mathcal{F}_{\mathsf{DKM}}(P,t,U,\mathcal{K},\mathcal{F}_{\mathsf{Eval}})$ with simulator $\mathcal{S}$.

Let $\mathcal{A}$ be such an adversary that controls up to t corrupted parties of P and any subset of parties of U in the real protocol execution. We define $\mathcal{S}$ as a simulator that simulates $\mathcal{A}$ in the ideal execution, as follows.

Setup: Whenever the simulator obtains an input $(\texttt{init}, \mathsf{sid})$ on behalf of a corrupted server $\mathcal{P}$, the simulator forwards this message to $\mathcal{A}$. If $\mathcal{A}$ behaves according to the protocol and sends $(\texttt{eval}, \mathsf{sid}, F.\mathsf{KeyGen})$ to functionality $\mathcal{F}_{\mathsf{MPC}}$, the simulator sends $(\texttt{init})$ to $\mathcal{F}_{\mathsf{DKM}}$ on behalf of $\mathcal{P}$. If $\mathcal{F}_{\mathsf{DKM}}$ responds with $(\texttt{ready})$, $\mathcal{S}$ sends $(\texttt{eval}, \mathsf{sid}, F.\mathsf{KeyGen})$ to functionality $\mathcal{F}_{\mathsf{MPC}}$ on behalf of all parties in P, and forwards the response $(\texttt{result}, \mathsf{sid}, \mathbf{k})$ to the adversary $\mathcal{A}$ and stores $(\texttt{prfkey}, \mathbf{k})$.

Eval: Whenever the simulator obtains an input $(\texttt{eval}, \mathsf{sid}, f, x)$ on behalf of a corrupted user u, the simulator forwards this message to $\mathcal{A}$. The simulator then emulates an execution of the Eval protocol, where it plays the role of the honest parties and the adversary $\mathcal{A}$ plays the role of the corrupted parties. Here, the simulator makes use of functionality $\mathcal{F}_{\mathsf{MPC}}$ and the stored PRF key reference $\mathbf{k}$. Since the adversary controls only up to t parties, the user u is guaranteed to receive $(\texttt{value}, \mathsf{sid}, y)$ from $\mathcal{F}_{\mathsf{MPC}}$ as a result. The simulator then sends $(\texttt{eval}, \mathsf{sid}, f, x)$ to $\mathcal{F}_{\mathsf{DKM}}$ on behalf of party u and waits for response $(\texttt{result}, \mathsf{sid}, y)$.

We observe that, by the definition of $\mathcal{F}_{\mathsf{MPC}}$, executions of the real protocol with $\mathcal{A}$ look almost identical to executions of the ideal functionality with $\mathcal{S}$ from the viewpoint of $\mathcal{E}$. The difference is that in the real execution the key $\mathbf{k}$ comes from the output distribution of F while in the ideal execution $\mathbf{k}$ comes from the key distribution $\mathcal{K}$. However, since we chose F and $\mathcal{K}$ such that their distributions are indistiguishable, the environment cannot distinguish the real execution from the ideal execution. □

Exploiting Leakage in Password Managers via Injection Attacks

Abstract

This work explores *injection attacks* against password managers. In this setting, the adversary (only) controls their own application client, which they use to "inject" chosen payloads to a victim's client via, for example, sharing credentials with them. The injections are interleaved with adversarial observations of some form of protected state (such as encrypted vault exports or the network traffic received by the application servers), from which the adversary backs out confidential information. We uncover a series of general design patterns in popular password managers that lead to vulnerabilities allowing an adversary to efficiently recover passwords, URLs, usernames, and attachments. We develop general attack templates to exploit these design patterns and experimentally showcase their practical efficacy via analysis of ten distinct password manager applications. We disclosed our findings to these vendors, many of which deployed mitigations.

1 Introduction

Password-based authentication suffers from well-know pitfalls, such as the fact that users tend to choose passwords that can be easily guessed by attackers [28]. Password managers are often cited as the default solution to this problem [32, 56], as users can offload to them the complexities of password generation, storage, and retrieval. Indeed, password managers have enjoyed a noticeable rise in popularity [28, 51], placing them among the most ubiquitous security-oriented tools.

Password managers have benefited from academic attention [8, 9, 13, 22, 24, 25, 27, 38, 43, 46, 52, 53], which has helped understand and improve their security along various dimensions. The attacks uncovered by prior work broadly fall under two general threat models. First are attacks that use a client-side resource controlled by the adversary, such as a malicious website visited by the client [38, 53], a rogue application in the victim's device [9, 22], or the client's WiFi network [52]. Second are adversaries that somehow acquire a copy of a user's encrypted vault, and exploit leakage from unencrypted vault metadata [24, 43] or by offline cracking attacks of a user's master password [8, 13, 27]. State-of-the-art password managers are therefore designed to resist both kinds of threats and, notably, use slow cryptographic hashing to prevent cracking attacks for well-chosen master passwords.

In this work, we consider a new kind of threat model in which an adversary (1) controls their own application client, through which they can send chosen payloads to the victim (for example, via the password sharing feature found in most modern password managers); and (2) can observe some form of encrypted state and associated metadata, such as the user's encrypted vault backups or network requests received by the application servers. Borrowing terminology from prior work in other domains (see Section 2), we refer to attacks in this threat model as *injection attacks*.

The core idea behind injection attacks is that the adversary can use injections to trigger subtle interactions in the application logic between their data and target victim data (e.g., other passwords used by the target), which are reflected in their observations of ciphertexts (e.g., inspecting their lengths) and metadata in a way that allows recovering sensitive information. We argue that this threat model is increasingly important as password managers become more complex and feature-rich, which provides new avenues for injection mechanisms and vulnerable cross-user interactions.

To understand whether this threat model is of practical concern or not, we performed a security analysis of ten popular password managers that support sharing—LastPass, Dashlane, Zoho Vault, 1Password, Enpass, Roboform, Keeper, NordPass, Proton Pass, and KeePassXC. Together these reportedly account for over 30% of all password manager users [51]. We uncover a series of exploitable vulnerabilities that implicate all of the password managers investigated.

Our first class of attacks exploits the fact that a common feature of password managers is for clients to periodically log outside the device various metrics about the "health" of a user's vault, such as the number of duplicate passwords. We show how an adversary can leverage these benign-looking metrics to perform an efficient binary-search-based dictio-

Attack vector	Leakage	Adversary type	Vulnerable applications
Vault-health logs	Passwords	Eavesdropper	L, D, Z, E, R, K, N
Vault-health logs	Passwords	Network	Z
URL icon fetching	URLs	Network	D, 1P, E, R, P, N
Attachment deduplication	Attachment	Eavesdropper	KX
Compression	URLs and usernames	Eavesdropper	KX

Figure 1: Summary of the vulnerabilities discovered in this work, which lead to efficient attacks that recover sensitive information from a victim's vault. These vulnerabilities were present in ten applications we studied: LastPass (L), Dashlane (D), Zoho Vault (Z), 1Password (1P), Enpass (E), Roboform (R), Keeper (K), NordPass (N), Proton Pass (P), and KeePassXC (KX).

nary attack that recovers the target user's saved passwords. Our attacks do not require the adversary to know additional information about the victim's saved credentials beforehand (for example, URLs nor usernames). Seven out of the ten applications are vulnerable to this attack. In most cases, the adversary must be a passive *eavesdropper* that observes these metrics directly (for example, by having a persistent foothold in the application servers), while for one application the attack is feasible by a passive *network adversary* that simply observes the HTTPS channels under which the E2EE data is transmitted. We note that both eavesdropping and network adversaries are within scope of the threat models under which password managers are designed, and the ubiquity of server-side breaches [37, 54, 58], combined with the difficulty of detecting such breaches [50], make it critical that password managers resist such attacks.

Our second class of attacks exploits another feature of password managers: clients often display a small identifying icon, such as a company logo, alongside each of a user's saved credentials. Importantly, such icons are only fetched once per URL, and subsequent credentials reuse the icon stored in the client. We show how this fact allows an adversary to perform an efficient dictionary attack on the URLs in a victim's vault. The attack always succeeds in our experiments, and mounting it requires no additional assumptions about the victim's saved credentials. Six of our case study applications are vulnerable to this attack, and in all cases exploitation only requires observations by a network adversary.

We then turn our attention to adversaries that have an encrypted copy of the entire vault, such as compromising a local password-protected database file or backup of it. In this case, we analyze the security of KDBX [12], which is a file format used by many password managers, notably KeePass [33] and its derivatives [12, 57]. To optimize for storage, KDBX employs a variety of storage-saving techniques, such as file deduplication and compression. We show two attacks exploiting these features to recover URLs, usernames, and attachment contents. Compression and deduplication have led to attacks against other systems before (see Section 2), but our work is the first to show that these types of vulnerabilities also arise in the context of password managers. Our attacks target features of the underlying file format itself, and thus can potentially be leveraged against any application that uses KDBX. We implement a proof-of-concept for our attacks in the case of KeePassXC, and experimentally show that its accuracy is sufficiently high to make it a practical threat.

A summary of our attacks is shown in Figure 1. They exploit common design patterns found in password managers, and as such other applications that employ these can be vulnerable to our attacks. Indeed, for each of our attacks, we describe a general template for it, which is agnostic to lower-level application details, and that can be used to target any application that follows the relevant design pattern. More broadly, our findings uncover higher-level issues in password manager design, and we discuss the future work that will be required to provide generally applicable mitigations for injection attacks.

Summary of contributions. We begin the study of a new threat model for password managers called injection attacks. We identify three design patterns that lead to attacks, and we implement practical attacks that affect a variety of applications. We stress, however, that our attack vectors are features of password managers, instead of bugs that are specific to our case study applications, and thus other password managers can potentially be vulnerable to them. Some of our vulnerabilities reveal new attack vectors, whereas others exploit known malpractices (compression and file deduplication). Thus, for the latter, our work is the first to show that these issues are also present in password managers.

Our attacks highlight broader classes of design malpractices found in password managers (and E2EE applications more generally). We close this work by identifying these higher-level issues, and outlining a series of takeaways for application designers. Our results thus pave the way for future work along various dimensions: identifying other password managers that are vulnerable to our attacks, uncovering other patterns that lead to injection attacks, and designing general tools to study and mitigate injection attacks. We expand on these ideas, and other opportunities for future work, in Section 8.

Ethics. All of our attacks were performed against isolated research accounts. We kept the scale of our proof-of-concept experiments as minimal as possible, so as to confirm the attacks' efficiency without overloading any application or cloud servers. Some of our experiments required a high volume of

network traffic, for which we implemented local simulators that we validated via smaller experiments with real clients.

We first studied four applications (LastPass, Dashlane, Zoho Vault, and KeePassXC), and disclosed our findings to these vendors, who have since all deployed mitigations for our vulnerabilities (see Section 8). We later expanded the scope of our study to include more applications, and are thus currently in a second round of disclosures with the other six vendors, who are investigating our results. We have made ourselves available to help with mitigations before public release of our findings. We will update the paper to document the results of the disclosure processes with the six remaining vendors once they are complete.

2 Related Work

Security analysis of password managers. Prior work has investigated attacks on password managers in threat models involving some combination of client-side attacks, adversarial networks, and a malicious service provider. Such examples include attacks that rely on malicious applications in the victim device [22], malicious websites that the victim is tricked into visiting [38], XSS adversaries that inject code into a website's login page [53], and a rogue WiFi network under the adversary's control [52]. The goal of the adversary is to exploit some feature of the application, such as password generation [43], autofill policies [52], and clipboard vulnerabilities [9, 22], to exfiltrate user passwords.

More relevant to our findings, some existing attacks on password managers involve an adversary that obtains the encrypted database of the victim [8, 13, 24, 27, 43]. However, most of these attacks focus on offline cracking of the master password, using the recovered vault as a decryption oracle [8, 13, 27]. Other works, such as [24] and [43], simply document unencrypted metadata in the encrypted database files or consider a much weaker adversarial goal, namely, producing a new, valid database after observing other valid ones (for example, by tweaking metadata headers). Neither attack violates the confidentiality of the password vault contents.

Our injection attack threat model is different from settings explored in prior work on password managers. We consider an adversary that, in addition to potentially compromising the platform and/or network, can spin up clients of its own that interact with the victim client using standard password manager features. The adversary uses these cross-user interactions to mix data of its choosing with sensitive victim data. Then, via a leakage channel, the adversary learns information about the combination of the victim data and its own injected data.

Injection attacks. Although we are the first to apply injection attacks to password managers, prior work has studied the injection threat model in other contexts. For example, [10, 59, 60] present attacks against searchable encryption schemes and encrypted search indexes, where the adversary is able to inject payloads that trigger a query into the encrypted store. Our attacks take inspiration from techniques used in this prior work, such as the binary search attack presented in [60]. However, our contribution lies in how we apply these techniques through the leakage channels and injection vectors we identify, specific to the password manager setting.

A setting closer to ours is that of [20], which introduces attacks against E2EE backups of messaging applications, in the presence of an adversary that can message the victim and subsequently observe their encrypted chat backups. A few of our attacks (Section 7) rely on similar attack vectors (file deduplication and compression). However, beyond targeting different types of applications, our attacks represent a different class of injection attacks: our work exploits encrypted state *synchronization*, whereas [20] exploits encrypted state *backups*. As such, our setting represents a richer attack surface, with a higher frequency and granularity of observations, and so our attacks are significantly more practical, as we explain further in this section. Furthermore, our attacks exploit features such as health metric logs and URL icon fetching, going beyond the attack vectors explored in prior work on encrypted backups.

Attacks on compression before encryption. It has long been known that compression before encryption can lead to vulnerabilities [34], which has resulted in exploits against real-world systems [20, 26, 31, 34, 44, 49, 61], such as TLS [26, 49] and the iMessage E2E encrypted messaging protocol [23]. Our work, however, is the first to exploit compression in the context of password managers (Section 7.2). Our attacks combine techniques from prior works (highlighted, as needed, in the attack descriptions) with novel insights in order to exploit this new setting.

Some works have studied compression in the broader context of encrypted databases, such as [20, 31, 44]. The attacks in both [44] and [31] rely on assumptions that are not present in our setting, such as physical access to the target's handset and the ability to unlock it [44], and little to no noise in the side channel [31, 44]. Further, their attacks are tailored to the specific systems that are being targeted. The setting in [20] is much more limited than our work, as the adversary is limited by daily backups, every injection results in much more noisy metadata that is added to the database, and the adversary cannot edit past injections. Thus, we devise new attacks that are significantly more practical: our attacks handle larger dictionary sizes (hundreds of items instead of, e.g., 10 to 20 items), have higher accuracy (for example, for a dictionary of size 20—the largest [20] experiments with—our attacks succeed with 90% probability instead of 20-30%), and have an additional confirmation step to verify if the found item is the correct one or not. Further, their compression-based attacks require the victim not to send or receive external messages for multiple days, whereas our attacks run in a matter of minutes.

File deduplication, a common form of compression before

encryption, has been exploited in other contexts, such as client-side encrypted file storage [29, 30] and E2EE messaging [20]. Our injection attacks exploiting deduplication (Section 7.1) require new techniques due to details of KDBX 4's architecture. In particular, KDBX 4 employs both deduplication *and* compression, which required mitigating noise from the latter. We also note that the attack from [20] is not applicable to the applications we consider in this work.

3 Password Managers Background

We describe the general architecture of password managers in this section.

Password manager abstraction. We denote by U and PW a user of a password manager service S and their account password, respectively. The user U owns one or more devices with an application client for S installed in each. The types of clients available vary by service, but these typically consist of mobile applications, desktop applications, web applications, and browsers extensions. Each client stores U's saved passwords and other information in the local storage of its respective device in the form of a *local vault*, which is (often) encrypted. We represent the contents of a vault by $\mathcal{V} = \{e_1, ..., e_m\}$, where each e is a vault entry storing U's credentials for a website. Each e contains various fields such as username (e_{user}), URL (e_{url}), password (e_{pw}), and a list of attachments (e_{attach}).[1]

In order to have consistent local vaults, U's devices need to synchronize their state. For most password managers, this involves clients periodically communicating with platform servers, which serve as intermediaries that facilitate synchronization. To do so, clients export an E2EE version of (only) the latest state changes (e.g., new passwords added), using an application-specific symmetric encryption scheme, and send this to S's servers using HTTPS. The server then forwards the updates to all other devices the next time they come online; the receiving clients decrypt the changes and update their local vaults accordingly.

Alternatively, if the service provider does not directly facilitate synchronization, U has to ensure that their clients are consistent, either by propagating updates manually, or by using out-of-band synchronization mechanisms such as storing the encrypted database file on an external cloud-storage provider. In this case, state updates are less granular, as these consist of a re-encryption and a re-upload of the entire database file to the cloud via HTTPS. Note that this setup is explicitly suggested by various applications that do not automatically synchronize clients [19, 55].

State synchronization is very frequent: exports generally occur after every modification to the local database, and clients automatically check for imports (from S or from modifications to their cloud-stored file) every couple of seconds; the exact periodicity varies across services.

Database file formats. Most password managers use simple data structures and file formats for their local vaults, which typically consist of encrypting each field of each $e \in \mathcal{V}$ separately, and sequentially organizing these entries using some lightweight file format like JSON or XML. Some file formats then additionally employ a variety of storage-saving mechanisms, such as attachment deduplication and compression, to minimize the size of the database file. This pattern is most often seen in applications that do not route information through S's servers, as everything is stored on the user's device and (potentially) exported to some third-party cloud service. Conversely, other applications can leverage S's servers for storage; for example, instead of storing the binary content of all attachments, local vaults can just store a pointer to a blob store managed by S, which contains the encrypted file itself.

Credential sharing. A common feature of modern password managers is *cross-user sharing*, which allows users to jointly hold entries in their vaults. For this, whenever some user wants to share a credential e from their vault with U, the former derives an ephemeral key that is used to encrypt e, and sends this ciphertext alongside the ephemeral key (itself encrypted under a public key associated with U). Next time one of U's devices comes online, its client will download the shared items and decrypt them locally to recover e.

We note that, generally, U must first accept the shared entry e before it gets added to their vault.[2] However, subsequent updates to e require no approval, and are propagated automatically to all clients. Further, many password managers allow users to share *folders* in addition to individual entries. In this case, U must once again accept the initial share of the folder, but all future updates, including adding or deleting new entries to the folder, require no approval.

For some applications, credential sharing is restricted to accounts that are part of the same "organization", e.g., where both accounts are affiliated with a corporate or family license for the application. In this case, shared credentials should still provide E2EE guarantees, such as cryptographic access control, even across all organization members. These guarantees should hold even in the presence of privileged users such as organization administrators (who may have access to organization-wide metadata).

4 Threat Model and Case Studies

While password managers have traditionally been non-interactive applications, newer features like credential sharing require us to re-think their security model: what attacks, if

[1] A common feature of password managers is for users to be able to attach arbitrary files, e.g., sensitive documents, to their vault entries.

[2] Some managers place additional trust constraints on password sharing: Zoho Vault only allows sharing with users who are part of the same "organization", which are groups that the user can belong to.

any, arise from *interaction with other malicious clients*? This question is the starting point for our threat model.

4.1 Threat Model

Our threat model, which we describe in detail in this section, assumes an adversary that (1) can inject content into the victim's vault, and (2) subsequently observe some form of protected application state.

Injections. The injection channel of our attacks will be the aforementioned *cross-user sharing* feature of password managers. That is, the adversary can share with the victim a credential e, which gets incorporated and synchronized across all victim vaults, resulting in e being "injected" into $\mathcal{V}$. We stress that, in our setting, the adversary exclusively controls an (unmodified) application client, and sends their payloads through the standard interface provided by the application. Thus, tampering with either the victim or the adversary's clients, or controlling any other parts of the environment, is explicitly out of scope.

As mentioned earlier, password managers often require the victim to first accept the shared items before they are incorporated into their vault, which is thus a necessary assumption required to establish an injection channel. We stress, however, that all of our attacks require the victim to accept a *single* shared item, as all subsequent updates to it, through which injections are performed, require no approval. As such, our threat model assumes some initial degree of trust between the user and the adversary, or that the latter can trick the former into accepting a share request. Accepting such a request, however, should not lead to disclosure of a user's vault content.

Observations. Our threat model then assumes that the adversary has *persistent access* to some function of the data that leaves the victim's device, e.g., as a result of recurring backups or state synchronization between devices. We distinguish between two variants, depending on the trust assumptions required for each attack: (1) an *eavesdropping adversary*, who has access to the E2EE data itself, e.g., ciphertexts of new passwords, as well as other plaintext metadata; and (2) a weaker *network adversary* that can only observe the HTTPS packets under which the E2EE data is transmitted. We highlight the difference between both settings in Figure 2. We discuss the periodicity of synchronization (and, hence, the frequency of adversarial observations) for all case study applications in the relevant attack sections.

Password managers promise end-to-end confidentiality [5, 7, 35], i.e., a user's data is compromised only if their master password is leaked, and so password managers are designed to protect against eavesdropping and network adversaries. A network adversary can arise from any number of traffic analysis techniques, such as ARP or DNS spoofing, BGP hijacking, router compromise, a malicious ISP, etc. An eavesdropping adversary generally corresponds to a malicious or breached

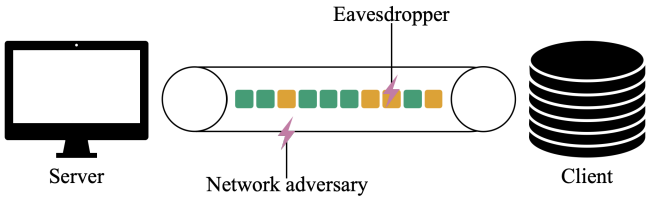

Figure 2: A network adversary can observe the HTTPS packets under which a mix of E2EE data (green squares) and plaintext metadata (orange squares) is transmitted; an eavesdropper has direct access to these.

service or cloud provider, or from a privileged user within an organization with access to metadata (e.g., an administrator). However, they may also arise from other attacks against the TLS layer of traffic, e.g., attacks on certificate authorities (CA) or malicious client-side proxies. Breaches on password managers and cloud services [37, 54, 58] suggest that such an eavesdropping adversary is a realistic threat model, and indeed *persistent* access is a practical concern: an IBM report from 2022 [50] found that the average time it takes to identify a breach is 212 days.

The process of injections and (passive) observations occurs iteratively: the adversary sends a payload to the victim (either by sharing a new credential, or modifying older ones), observes the resulting encrypted state——which is now a function of both adversarial and sensitive data—adaptatively chooses the next payload to inject, and so on. The adversary's goal is then to back out confidential information from their observations.

A priori, no sensitive user data should be leaked, since the victim's confidential information is encrypted before leaving their device. However, our attacks exploit the fact that application logic often *mixes* personal and externally-received data in subtle ways which may leak information. Thus, an adversary can use injections to trigger these *cross-user interactions*, which are then reflected in the exported application state, revealing confidential data. We stress that injections attacks assume strong cryptographic primitives, and thus low-level, cryptanalytic vulnerabilities are outside their scope; instead, the *lengths* of ciphertexts and plaintext metadata form the basis of our attacks.

In addition to the adversary's injections, the state changes between observations may additionally contain new, benign data added by the victim while the attack is running; we refer to this as the "noisy device" setting, and to the case where the only additions are the adversary's injections as the "quiet device" setting. Some attacks are robust to noise, while others require the victim's client to be quiet while the attack is running; we will specify the noise assumptions required for each attack in the relevant sections.

Out-of-scope attacks. We do not consider attacks in which a compromised service attempts to deploy client code con-

taining backdoors. All E2EE threat models implicitly or explicitly assume trusted client software. Improved assurance here can be aided via mechanisms such as public auditability of software or monitoring via binary transparency services (e.g., [42]). Without trustworthy client side software, no confidentiality is possible. More pragmatically, we note that such client subversion would require an active adversary that hijacks client code distribution, while our injection attacks would be easier to mount, requiring only a passive adversary that either compromises some platform server (e.g., a web or storage server) to enable eavesdropping or has visibility into the target's network communications.

In our threat model, we assume that the adversarially controlled client that performs injections honestly follows the protocol. One could also consider a fully malicious client that deviates from the E2EE protocol when performing injections. We are unaware of any additional attacks that this would enable.

4.2 A Corpus of Password Managers

We gathered a set of password managers to experimentally investigate the feasibility of injection attacks. To build a list of targets, our starting point was a report by Security.org [51] that includes a list of password managers ranked by popularity. We also considered informal online polls on password manager popularity [47, 48]. We investigated the advertised features of each of the resulting 16 applications, and excluded those that do not meet either of two inclusion criteria: (1) the application must support cross-user credential sharing, and (2) the application must target cryptographic access control for shared credentials. The first requirement rules out applications that are unlikely to have any way to inject adversarial content into a target, and the second requirement rules out applications for which simpler attacks would work in our threat model, due to lack of E2EE security guarantees.

All browser-integrated password managers were excluded due to the first criteria, as they do not yet support credential sharing. The second criteria ruled out one application, Bitwarden, which does support credential sharing, but not in a cryptographically secure way: Bitwarden has support for establishing separate "collections" within an organization, but surprisingly all collections use the same secret key. So, in our threat model, any organization member can already decrypt all organization credentials.[3]

Our final list of applications consisted of LastPass (v4.123), Dashlane (v6.2346), Zoho Vault (v3.8), 1Password (v2.25.0), Enpass (v6.11.0), Roboform (v9.6.2), Keeper (v116.18.0), NordPass (v.5.16), Proton Pass (v1.17.4), and KeePassXC (v2.7.6). These applications cover over 30% of all password manager users according to [51], and all follow the basic abstraction presented in Section 3. All application except for KeePassXC and Enpass rely on the application servers for stateful storage and synchronization. These tend to use simple file formats for their local vaults (see [43] for an overview), with no additional storage-saving mechanisms. Conversely, KeePassXC and Enpass do not natively handle synchronizing across clients. Instead, they suggest [19, 55] storing the database file in an external cloud provider to which all user devices have access.

KeePassXC's file format, KDBX [12] (detailed in Section 7), supports attachment deduplication and vault compression. We note that KDBX is used by other password managers, which are ports and derivatives of KeePass [33], a popular open-source password manager that introduced this file format. See [12, 57] for comprehensive lists of applications that use KDBX. Even though we implement our attacks on one such example, KeePassXC (which is a more cross-platform and feature rich version of the original KeePass), our attacks target the underlying file format itself, and thus other applications that use it may be vulnerable to our attacks.

4.3 Overview of Attacks

Our security analysis of the case study applications uncovered three main classes of attacks in the context of injection attacks. We provide an overview of these here, and discuss them in detail in the next three sections.

Attack #1: application-wide metrics (Section 5). The first attack arises from the fact that many password managers compute sensitive metrics, such as the number of duplicate passwords in the vault, across both personal *and* shared vault entries. If these metrics are logged somewhere outside the device (e.g., the application servers), an adversary can trigger fluctuations in these metrics with injections, and observe how they are updated in the external location. As such, besides injecting credentials, in this attack the adversary needs to have access to the location where the metrics are logged (e.g, a foothold in the application servers.)

Attack #2: URL icon fetching (Section 6). The second attack arises from the fact that many password managers display a graphical icon next to each credential, identifying the website for it. This icon is only fetched once from the application servers, and future entries for the same website reuse the image that is stored in the client. Thus, an adversary can use this to test whether the victim has a credential for a particular URL or not, depending on whether the victim's client re-fetches the icon of an injected URL. So, besides updating credentials, in this attack the adversary needs to be able to observe the HTTPS requests that leave the victim's client, or have a foothold in the server where the icons are fetched from.

Attack #3: storage-saving mechanisms (Section 7). The third attacks arise from storage-saving mechanisms that an

[3] We disclosed this to Bitwarden, who confirmed that privilege separation across collections is "at the authorization level, not at the encryption level". Thus, they target a weaker security model than other applications.

Attack	Pre-conditions	LastPass	Dashlane	Zoho Vault	1Password	Enpass	Roboform	Keeper	NordPass	Proton Pass	KeePassXC
App-wide metrics (Section 5)	Support for reports of duplicate password	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓
	No. of duplicates computed across all passwords	✓	✓	✓	×	✓	✓	✓	✓	✓	✓
	No. of duplicates logged outside the device	✓	✓	✓	✓	✓	✓	✓	✓	×	×
URL icon fetching (Section 6)	Support for URL icons	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓
	URL icons fetched from servers	✓	✓	×	✓	✓	✓	×	✓	✓	✓
	Fetched URL icons re-used across all vault items	×	✓	×	✓	✓	✓	×	✓	✓	×

Figure 3: Summary of the pre-conditions required for an application to be vulnerable for two of our attacks, each represented by a set of rows, and the conditions satisfied by each application we analyzed. An application that has a ✓ for all pre-conditions in a set of rows is thus vulnerable to the attack.

application may use to decrease the size of the encrypted vault. At a high-level, since these mechanisms remove redundancy in the plaintext vault, the adversary can tell whether their content matched the victim's other credentials or not by looking at fluctuations in the size of the encrypted vault. So, besides injecting credentials, in this attack the adversary would need to have persistent access to the victim's encrypted vault (for example, in a cloud provider where the victim uploads backups of their vault). In our work, we show attacks against two such mechanisms: database compression and attachment deduplication.

In Table 3, we summarize the main pre-conditions required for an application to be vulnerable to our first two attacks, as well as the pre-conditions satisfied by each application in our study. We leave implicit the fact that an application must satisfy the inclusion criteria for our threat model to begin with, e.g., support credential sharing. For our compression-based attack, the only pre-condition is that the application compresses the database file across all vault entries; for our deduplication based attack, the preconditions are (1) the application has support for attachment deduplication, and (2) deduplication occurs across attachments in all vault entries, irrespective of sender. From the applications we investigated, only KeePassXC meets the pre-conditions for these two attacks.

5 Attacks From Application-wide Metrics

Equipped with the background from the preceding sections, we proceed to describe our attacks, starting with our first class of attacks in this section.

Our close study of the network traffic of various password managers revealed that many of them periodically log outside the user's device a variety of metrics about the overall "health" of a user's vault, most notably the number of reused passwords. These logs are sent to either the application servers directly, or to some other member of the user's organization, e.g., an administrator with access to a company-wide security dashboard. These metrics, however, are computed across both personal *and* shared vault entries. As we will show, the adversary can leverage this fact to perform an efficient dictionary attack on a user's passwords.

Dictionary attacks are a standard adversarial goal in the context of password-based authentication, as it is common for users to choose weak or reused passwords [28]. Importantly, and perhaps surprisingly, this is a problem even among users of password managers [39, 45]. This arises from, for example, users that import but do not update old passwords; or users that use password managers for convenience features (e.g., autofill) rather than for security features (e.g., password generation), which is a common practice [21].

We now proceed to describe the attack. We first explain the general structure of it, which serves as an attack template that can be used against any password manager that satisfies the pre-conditions for the attack. For now, we will assume that the adversary is an eavesdropper, and has a persistent foothold to wherever the vault metrics are stored, as described in Section 4.1

Attack description. Given a dictionary of candidate passwords $P := \{p_1, ..., p_n\}$, the adversary $\mathcal{A}$ wants to determine which $p_i \in P$ is present in U's vault $\mathcal{V}$. Let $\mathsf{dup}(\mathcal{V})$ be the number of duplicate passwords across all entries in U's vault, i.e., $\mathsf{dup}(\mathcal{V}) = \frac{1}{2}\sum_{e',e'' \in \mathcal{V}}(e'_{pw} = e''_{pw})$. In this setting, we assume U's clients periodically send $\mathsf{dup}(\mathcal{V})$ to some external location (e.g., automatically every couple of seconds or as a result of a particular action). The key idea behind this vulnerability is that, since $\mathsf{dup}(\mathcal{V})$ is computed across both personal and shared passwords, an eavesdropping adversary with access to this metric can use it as an oracle to determine whether a candidate password p is in the victim's vault or not. Namely, they can compare the value of $\mathsf{dup}(\mathcal{V})$ before and after injecting an entry e such that $e_{pw} = p$; if $\mathsf{dup}(\mathcal{V})$ stays the same, it must be the case that p is not yet in $\mathcal{V}$, and thus is not one of the personal passwords of U. Conversely, $\mathsf{dup}(\mathcal{V})$ increases if and only if p matches one of U's personal passwords.

The adversary can leverage this oracle to find all passwords in P that are in U's vault. There are two injection strategies that $\mathcal{A}$ can use. If the application supports shared folders, instead of "querying" the oracle with each candidate password, one at a time, $\mathcal{A}$ can use a binary-search injection strategy to arrive at the target password more quickly, as follows:

(1) *Setup:* establish a shared folder F with U, which requires U to accept the share.

(2) *Baseline measurement:* wait for a network request from U that contains the initial $n' = \mathsf{dup}(\mathcal{V})$.

(3) *Inject:* split P into two halves P', P'' of equal size. For

each $p \in P'$, create an entry e in F such that $e_{pw} = p$.

(4) *Measure:* wait for a network request from U with an updated $n'' = \mathsf{dup}(\mathcal{V})$.

(5) *Recurse:* set $P_{found} = P'$ if $n'' > n'$, and $P_{found} = P''$ if $n'' = n'$. If $|P_{found}| = 1$, output it as the target password. Otherwise, repeat steps 3–4 with $P = P_{found}$ as the input set and n'' as the baseline measurement.

If the application instead only supports sharing individual entries, $\mathcal{A}$ must use a slower, sequential injection strategy. Let t be the number of individually-shared entries between $\mathcal{A}$ and U, where $t < \frac{n}{2}$ (otherwise, $\mathcal{A}$ can just use the binary-search strategy from above). In this case, $\mathcal{A}$ can inject t candidate passwords at a time, interleaved between observations of $\mathsf{dup}(\mathcal{V})$, by updating the password field in each of the shared entries with a new batch of t candidate items. Eventually, one of these injections will trigger an increase in $\mathsf{dup}(\mathcal{V})$. Then, to find which of the t items of the prior injection is actually the reused password, $\mathcal{A}$ can run the binary-search attack from before, using the t shared entries as a "folder".

Since $\mathsf{dup}(\mathcal{V})$ is deterministic, both variants of the attack always find the target password, if present, or confirm that no password is in the vault. The binary-search injection strategy requires $\lceil \log_2 n \rceil$ injections and observing the same number of network requests containing $\mathsf{dup}(\mathcal{V})$; the sequential injection strategy instead requires $\frac{n}{t} + \lceil \log_2 t \rceil$ injections and observations. Which strategy to use depends on the target application, and whether it supports shared folders or not. Further, as we discuss in Section 5.1, in some cases $\mathsf{dup}(\mathcal{V})$ reveals additional information, which allows $\mathcal{A}$ to speed up our generic injection strategies even further.

The exact wall-clock time of the attack depends, of course, on how often these requests are triggered, which varies across applications (we discuss some examples in Section 5.1). Note that the runtime of the attack is independent of the number of user accounts in $\mathcal{V}$. That is, since $\mathsf{dup}(\mathcal{V})$ is computed across all accounts, our attack essentially checks each password on *all* user websites at once. Further, our attack can be easily tweaked to find all matching passwords, instead of just one, by recursing into all branches that increase $\mathsf{dup}(\mathcal{V})$. In addition, our attack confirms to $\mathcal{A}$ if no password in P is in $\mathcal{V}$, which would be reflected by the fact that $\mathsf{dup}(\mathcal{V})$ does not increase after all candidate items have been injected.

5.1 Vulnerable Password Managers

In summary, the pre-conditions that an application must satisfy to be vulnerable to our generic attack are: (1) have support for vault-health metrics that contain the number of duplicate passwords; (2) the number of duplicate passwords must be computed across all vault entries; and (3) these metrics must be logged somewhere outside the victim's device (for example, in the application servers or in some organization administrator portal). We performed an analysis of all ten applications and found that LastPass, Dashlane, Zoho Vault, Enpass, Roboform, Keeper, and NordPass all satisfy these pre-conditions, and are thus vulnerable to our attack. We show in Figure 3 the breakdown of pre-conditions across all ten applications.

To experimentally validate our attack, we deployed proof-of-concept implementations of it against three of these vulnerable applications—LastPass, Dashlane, and Zoho Vault. We discuss these below, and refer readers to Appendix B for additional details of these.

In all three applications, updates to shared credentials are automatically synchronized across all clients with access to these, i.e., adversarial injections are automatically incorporated into $\mathcal{V}$. The main difference between each application is then the frequency of when clients log $\mathsf{dup}(\mathcal{V})$ to the applications servers. In LastPass, logs of $\mathsf{dup}(\mathcal{V})$ are triggered automatically after a client imports the updates to the shared credentials. In Dashlane and Zoho Vault, they are triggered once per day. A second notable difference is that LastPass supports shared folders, but Dashlane does not. Thus, $\mathcal{A}$ can use the binary-search and sequential injection strategies for the former and the latter, respectively. For Zoho Vault, the generic binary-search injection strategy is also feasible. However, in fact, application-specific details allow $\mathcal{A}$ to significantly speed up the attack, allowing them to recover *all* matching passwords with a *single* injection. Zoho Vault's vault-health logs consist of an array O of JSON objects, such that there is one such object for each entry $e \in \mathcal{V}$, containing metadata about the corresponding entry. In particular, each object contains a "`reused`" field, which maps to a boolean indicating whether e_{pw} is a duplicate or not. So, $\mathcal{A}$ can inject all candidate passwords in a single batch, scan O next time the logs are triggered, and identify whether the objects in O corresponding to the injected credentials are marked as a duplicate or not, thus revealing if that candidate password was already present in the user's vault. We discuss this optimized attack in more detail in more detail in Appendix B.

In all three applications, no interaction is required from U, and the attack only requires U to be logged into their account (for example, in their Chrome extension or web vault). Importantly, the victim need not have their vault open while the attack runs: if a user is logged in, background scripts check for updates, sync them to the vault, and trigger the requests to $\mathsf{dup}(\mathcal{V})$. As such, the attack can operate silently in the background while U is engaged in other tasks. Further, the attacks do not require the victim client to be quiet while the attack is running, and thus fall under the noisy device setting. So, $\mathcal{A}$ can just silently run an extended attack if need be, irrespective of the activity of the victim, until the passwords are found.

Attack implementation. We used an open-source list of common passwords [40] to gather our testing data, and confirmed that our attacks successfully recover the target string every time. Since our attacks are false-positive free—in particular, their correctness does not depend on the distribution nor

number of candidate passwords—we only tested our attacks on small, proof-of-concept workloads, and thus confirmed the correctness of the attack without overloading the applications' servers.

For each application, our experimental setup consisted of two test accounts on two different devices, representing the victim and the adversary, with a shared folder between them. The list of candidate passwords consisted of a subset of the aforementioned list of common passwords. We sampled uniformly at random a password from the list of candidate passwords, added it to the victim's vault from their machine, and ran the attacks from the adversary's machine. We set up a proxy server in the victim's machine to capture all outgoing network requests, and inspect the traffic from the victim to the server during the attacks. This simulates the information that would be learned by a malicious server. We explain additional details of our testing methodology in Appendix A.

Extension to a network adversary. For some applications, our attack may be able to be modified to assume a weaker network adversary instead of an eavesdropper. The key challenge is that a network adversary does not have access to the plaintext value of $\mathsf{dup}(\mathcal{V})$, as this is transmitted through encrypted channels. As such, we require an additional property from applications: that changes in the number of duplicate passwords result in changes in the size of the payload of the HTTPS requests that transmits the vault-health logs.[4]

From the applications vulnerable to an eavesdropping adversary, only Zoho Vault can be extended to a network adversary. Since there is a separate boolean string in O for each vault entry, $\mathcal{A}$ can leverage the subtle fact that the string `false` has one additional character than the string `true`, and thus the payload of the HTTPS request with O as its payload will fluctuate by 1 byte depending on whether each password is a duplicate or not. As such, our binary-search injection strategy can be used once again, by determining whether a batch of injections contains the target password or not based on this 1-byte difference.

6 Attacks from URL Icon Fetching

A feature of some password managers is to display a small identifying icon, such as a company logo, next to each vault entry. To do so, clients send a request to the server with the URL for the website, in plaintext, and receive back an image file with the icon. This clearly leaks the victim's URLs to an eavesdropping adversary (prior work [43] has pointed this out already for a few applications). However, as we show in this section, these requests can also be leveraged by a weaker *network* adversary to leak information about a victim's URLs.

This leakage arises from the fact that URL icons are fetched only *once*: any new entries for websites for which there is already a credential simply reuse the icon that is already on the client, and no new fetch request is sent to the server. These requests thus serve as oracle to determine whether a candidate URL w is in the victim's vault or not: $\mathcal{A}$ can inject an entry e such that $e_{url} = w$, wait for U's client to (automatically) synchronize this new credential, and observe if an icon fetch request is triggered or not; the latter indicates that w is already present in U's vault, since e is reusing the URL icon that is already downloaded. Importantly, note that this attack only requires the adversary to know whether a request to fetch the icon is *triggered or not*, and that, unlike our first attack, the actual (plaintext) payload of the request is not relevant. This information is also visible to a network adversary, who simply monitors whether a fetch request is triggered or not.

Analogous to our attack from Section 5, this basic oracle can be used to perform a dictionary attack on the websites stored on the victim's vault. In particular, the same sequential and binary-search injection strategies can be used, depending on whether the application supports shared folders or not.

6.1 Vulnerable Password Managers

In summary, the pre-conditions that an application must satisfy to be vulnerable to our generic attack are: (1) have support for URL icons; (2) fetch these URL icons from the application servers (instead of, e.g., storing them all in the client to begin with); and (3) re-use the stored icons across all vault entries. Our analysis of all ten applications revealed that Dashlane, 1Password, Enpass, Roboform, NordPass, and Proton Pass all satisfy these pre-conditions. We show in Figure 3 the breakdown of pre-conditions across all ten applications.

We experimentally validated our attack against Dashlane, using the Majestic ranking of top websites [4] to gather our testing data, using the same experimental setup as in Section 5, and confirmed that our attacks successfully recovers the target URL. Note that, as before, the correctness of the attack does not depend on the distribution nor number of candidate URLs, since icon fetch requests are deterministic, and as such it was sufficient to test on small workloads that did not overload their application servers.

7 Attacks from Storage-Saving Mechanisms

As discussed in Section 3, some password managers employ a variety of storage-saving techniques to reduce the size of their encrypted vault files. In this section, we show how two such mechanisms—file compression and attachment deduplication—lead to injection attacks against password managers. These have both been studied in other domains before (see Section 2), and here we show that they also lead to exploits in the context of password managers.

From the ten applications of our study, only KeePassXC supported storage-saving mechanisms. This is due to the fact

[4] We also technically require that request bodies are not compressed, but this is almost always true [41] (including for Zoho Vault).

that deduplication and compression are part of the specification of its underlying file format, KDBX 4, which is used by a variety of other password managers. Even though we implement our attacks on KeePassXC, we stress that our vulnerabilities target KDBX 4 itself, and thus any application that uses it (and that supports credential sharing) can be vulnerable to them.

Looking ahead, our attacks rely on the adversary being able to observe fluctuations in the *size* of the encrypted database file. Note that, if an application relies on third-party cloud providers to synchronize devices, a network adversary is sufficient: since each update re-uploads the entire encrypted file, the size of the payload of the HTTPS request can be used to detect fluctuations in the underlying file size. Further, since the attacks rely on very precise measurements, they operate in the quiet device setting, i.e., we assume the victim does not interact with their vault while the attack is running. However, our attacks benefit from the fact that modifications to shared entries are propagated automatically to the victim's vault, and thus our attacks can be run in a few minutes.

Background on KDBX 4. Broadly speaking, a database $\mathcal{V}$ serialized in KDBX 4 file format (the latest version of KDBX) consists of three main parts: an outer header H_{out}, an inner header H_{in}, and an XML payload I.

The file starts with H_{out}, which is unencrypted, and contains metadata about the database, such as cipher information, KDF parameters, whether the XML payload is compressed or not, etc. This is followed immediately by H_{in} and I (explained below), which are both under a single layer of encryption—using one of AES-CBC, Twofish-CBC, or ChaCha20—with a bespoke authentication mechanism; the details of the latter are unimportant for our attacks, so we omit them hereafter. Users can select their preferred encryption cipher in the database settings, with the default being ChaCha20. As usual, the encryption key K used is derived from PW, using either AES-KDF or Argon2. Then, H_{in} and I may optionally be compressed with gzip [17] before being encrypted, which is also a tunable parameter that is on by default.

The inner header H_{in} consists of two main parts: the encryption key K' used in the second encryption layer (more on this later), and an array A storing the binary content of all attachments across all entries in $\mathcal{V}$ concatenated together. Importantly, only one copy of each binary file is stored in A, even if the attachment is added multiple times to the database.

The XML payload I contains the user's data itself (excluding attachments, which are in H_{in}). For every entry $e \in \mathcal{V}$, there is a corresponding XML element in the payload, where each field of e is saved as an XLM subelement. There are two important types of subelements: (1) for every attachment in the list e_{attach}, if any, there will be a subelement with an integer denoting the index within A corresponding to the binary content of this attachment; (2) the subelement for e_{pw}, which stores an encrypted copy of e_{pw} using ChaCha20 and K'. There is no authentication on this inner encryption layer, since it is already under the authentication mechanism of the outer one. Further, the key K' is rotated after every modification to the database, and all passwords are re-encrypted. Other fields of e, such as e_{user} and e_{url}, are stored as unencrypted subelements; we denote by $\hat{e}$ all subelements of e, excluding e_{pw}, concatenated together.

Putting it all together, the serialization of $\mathcal{V} \coloneqq (e_1, ..., e_m)$ has the following structure:

$$\mathcal{B} \coloneqq H_{out} \,\|\, \mathsf{Enc}_K\Big(\mathsf{gzip}\big(H_{in} \,\|\, I\big)\Big)$$

where H_{in} and I have the following form:

$$H_{in} \,\|\, I = K' \,\|\, A \,\|\, \mathsf{Enc}_{K'}(e_{1,pw}) \,\|\, \hat{e_1} \,\|\, ... \,\|\, \mathsf{Enc}_{K'}(e_{m,pw}) \,\|\, \hat{e_m}$$

For simplicity, this notation omits low-level details such as XML tags and metadata that are not relevant to our attacks. We refer readers to documentation such as [12] for a more complete treatment.

Our attacks target the underlying file format itself, and any password manager that uses it may be vulnerable to them. Our attacks, however, require two assumptions regarding the target application and its users: that the application has support for cross-user sharing, and that compression is left on (note that official documentation from KeePass, the designers of KDBX, explicitly state that "it is not recommended to save databases without compression" [11].) Further, for clarity of presentation, we will assume that ChaCha20 is indeed the cipher used to encrypt the outer encryption layer, since it is the only stream cipher out of the three supported ones, but note that our attacks can be modified to work with the other ciphers.

The application on which we implement our attacks is KeePassXC, which is a newer, feature-rich port of the original KeePass. KeePassXC supports cross-user sharing (both for individual entries and folders) which are added as new XML elements in I, just like personal entries. Updates to these shared credentials are synchronized automatically if the victim has their vault unlocked (e.g., open in the background), and there is just a short time delay of 1-2 seconds.

7.1 Leakage from Attachment Deduplication

As discussed earlier, the KDBX 4 file format stores only one copy of the binary content of each attachment in A, even if it is received multiple times: whenever U adds a new attachment to their vault, it is compared against all attachments in A (by computing its checksum using a hash function), and added if and only if there is no match. If there is a match, the attachment pointer in the XML element for this entry simply refers back to the index of the first copy in A. Notably, deduplication occurs across both personal *and* shared attachments, which leads to a cross-user interaction that an adversary can leverage to leak information about the user's saved attachments.

Attack description. Our attack consists of a dictionary attack on attachments. That is, for a list of candidate attachments $W := \{w_1, ..., w_n\}$, the adversary wants to determine which w_i, if any, is in $\mathcal{V}$. We first note that there is a straightforward (but inefficient) attack. Assume that U and $\mathcal{A}$ have a shared entry e. Then, $\mathcal{A}$ can simply add each $w \in W$ to e_{attach}, one at a time, until some attachment does not increase the size of $\mathcal{B}$, which implies that it got deduplicated and thus is present in $\mathcal{V}$. This naive injection strategy is false-positive free, since deduplication is deterministic.[5] However, the number of injections scales linearly with $|W|$. We now describe a more complex injection strategy that an adversary can use for larger $|W|$. This second strategy leads to more false positives, and as such there is a trade-off between success rate and number of required injections.

Our refined strategy consists of a binary-search attack, which requires only $\lceil \log_2 n \rceil$ injections, analogous to that of Section 5: instead of injecting each attachment, one at a time, $\mathcal{A}$ can split W into two sets W' and W'' of equal size, and inject *all* attachments in W' in a single batch, followed by all attachments in W'' in a second one. Then, one of these injections will increase $|\mathcal{B}|$ by less than $|W^i|$, which means that some attachment in it got deduplicated. We can then recurse into this set, and repeat this attack iteratively until the target attachment is found.

A challenge with this approach is that, recall, the list of attachments is gzip-compressed with the rest of H_{in} and I, which adds noise to our measurements. In particular, it could be the case that the target file is in W', but all files in W'' are similar to each other. So, if the decrease in size from compressing all files in W'' is smaller than the target file, we would recurse into the wrong set. To address this, $\mathcal{A}$ can measure the compressibility of each injected list of files, and "penalize" the measurement according to this. Concretely, on every iteration of the attack, $\mathcal{A}$ computes $z' = \left|\text{gzip}(w_1 \,\|\, ... \,\|\, w_{n/2})\right|$ and $z'' = \left|\text{gzip}(w_{n/2+1} \,\|\, ... \,\|\, w_n)\right|$ locally, and recurses into W' if

$$\mathcal{B}_2/(\mathcal{B}_1 + z') < \mathcal{B}_3/(\mathcal{B}_1 + z'')$$

and into W'' otherwise; $\mathcal{B}_1$, $\mathcal{B}_2$, and $\mathcal{B}_3$ respectively denote the encrypted database before both injections, after the first injection, and after the second injection.

After the attack is over, $\mathcal{A}$ can confirm whether the attack was successful or not by making an additional injection with just the found attachment: if the guess is correct, $\mathcal{B}$ will have no increase in size (except, potentially, for a negligible number of bytes due to noise from the re-encryptions.)

Attack implementation. We implemented both the naive and the binary-search attacks against KeePassXC, and confirmed that the former successfully recovers the target attachment every time. For the latter, we ran a sequence of experiments to estimate its probability of success. Our experimental setup consisted of two testing environments: (1) using real KeePassXC clients (version 2.7.6), and (2) a local re-implementation of all client-side operations relevant to our attacks, to simulate the real setting.

[5] The only edge case in which this attack may fail is if the candidate files are very small, such as less than 50 bytes. This is due to the fact that minimal noise is generated by the re-encryption of passwords after every save. In this case, however, $\mathcal{A}$ can simply inject each w_i multiple times, and compute the average file size, which mitigates the noise.

	Enron	$\|w\|$**=10KB**	**500KB**	**1MB**
$\|W\| = 32$	92	74	44	47
128	81	53	34	38
512	52	29	18	8

Figure 4: Experimental success probability of our dictionary attack on attachments exploiting deduplication, for real-world files (first column), and for synthetic test files (each file is of some random size between between 1 and $|w|$, and contains sequences of repeated characters). Each row represents a number of candidate files. These probabilities can be amplified via repetition.

This dual-setup approach is a common strategy used to evaluate deployed systems [6, 20, 44]. The real environment allows us to confirm the overall correctness and implementation of our attacks, while the simulated environment allows us to compute an empirical estimate of the probability of success. For the latter, we can run a high volume of trials in a reasonable amount of time, and without overloading the cloud-service provider. In addition, we can ensure that the trials are independent, by using the same starting state across each. We discuss our experimental setup in more detail in Appendix A.2.

Equipped with this setup, we used three types of datasets to gauge the attack's success rate on different workloads. The first consisted of the Enron corpus [2], which is a public dataset of real-world emails. This dataset helped us evaluate our attack on practical targets. The other two datasets, generated locally by us, consisted purely of synthetic data for benchmarking purposes: a set of random files, all of the same size; and a set of files of varying sizes, and composed of substrings of repeated characters. The reasoning behind these datasets is that random bytes and equal file sizes minimize the effects of gzip noise (since random data is less compressible), while substrings of repeated characters and different file sizes maximize gzip noise.

For each data set, we ran 100 trials of the attack, and recorded the fraction of these in which the target attachment was successfully recovered. Each trial consisted of sampling a fresh set of candidate files of the appropriate type, choosing one file at random, adding it to the victim's vault in a personal entry, and running the attack. For the dataset consisting of files of the same size and all random bytes, our attacks succeed with 100% probability for all file sizes. The results for the other two datasets are displayed in Figure 4. As our

experiments show, our attack succeeds with high probability. Further, as explained earlier, the adversary can confirm whether the output is correct or not, and re-run the attack if needed until the correct attachment is found, which essentially gets rid of false positives.

7.2 Leakage from Compression

The second vulnerable mechanism we identified in KDBX 4 is the fact that $H_{in} \| I$ is gzip-compressed before it is encrypted. The (oversimplified) way in which gzip works is that repeated substrings are replaced with short pointers to their prior occurrences, if any, which gets rid of redundancy in the payload. The resulting sequence of pointers and (unmatched) characters is then serialized using Huffman coding to yield the compressed bytestring.

Since I (resp. H_{in}) contains both personal *and* shared entries (resp. attachments), the first step of the gzip algorithm leads to a cross-user interaction that an adversary can exploit: if fields in the injected credentials match some field in U's personal credentials, the length of the resulting encrypted database will be shorter than if they do not match, as in the former case gzip will replace the injected content with a short pointer to U's private content.

Attack description: dictionary attack. Our attack consists of a dictionary attack, i.e., for a list of candidate items $W := \{w_1, ..., w_n\}$, $\mathcal{A}$ wants to determine which w_i, if any, is in $\mathcal{V}$. The items of interest consist of login information, except for passwords (e.g., usernames or URLs), and contents of attachments. The reason why passwords are not recoverable is due to the fact that these are under an additional layer of encryption, which prevents matching passwords from being deduplicated by gzip.

One possible attack approach is to simply inject each candidate string, one at a time, and return the one that leads to the smallest increase in database size. This attack, however, suffers from low accuracy, since it compares compressibility across *different* candidate strings. Since each string contains different characters, the Huffman coding step of gzip may lead to false positives: it could be the case that an incorrect candidate string is composed of characters that appear very frequently in the database, which leads to shorter Huffman codes and the appearance of a more compressible string.

Instead, drawing inspiration from other compression-based attacks such as [26, 31, 49], we use *two* injections per candidate w—the first containing w itself and the second a *scrambled* version of w—and compare their relative compressibility. Thus, each pair of injections consist of the same characters, which reduces the effects of Huffman coding. (To our knowledge this implementation of the generic "two-tries" method is novel.) More concretely, for each w_i, $\mathcal{A}$ first injects w_i through a shared entry e (depending on the type of W, e.g., by setting either $e_{url} = w_i$ or $e_{user} = w_i$). Then, $\mathcal{A}$ records $n'_i = |\mathcal{B}|$. This is followed by a second injection, where $\mathcal{A}$ replaces w_i in the relevant field with a random permutation of its characters, and records the updated $n''_i = |\mathcal{B}|$. Finally, $\mathcal{A}$ returns whichever w_i yield the maximum value for $|n''_i - n'_i|/|w_i|$.

The intuition behind the strategy is that, in the first injection, the correct string gets compressed in its entirety, while incorrect strings only get partially compressed. Then, the second injection serves as a baseline measurement to gauge the "worst-case" compression of a string with the same characters as w_i, to control for the noise from the Huffman coding. So, it may be the case that some string leads to the smallest total increase in $\mathcal{B}$ but, in fact, this is also the case when the string is replaced by a scrambled version of it. This confirms that the decrease in size comes from the short Huffman codes and not from redundancy with the rest of the database (otherwise, the second string would "break" the effects of compression).

As in the prior attack, $\mathcal{A}$ can confirm whether the attack was successful or not by, for example, re-injecting the found string, prepended with a pad of 32K bytes (the length of zlib's search window), and confirming that output file increased by the size of the string.

We note that our dictionary attack can potentially be extended to a *byte-by-byte* recovery attack, where the list of candidate guesses is not known a priori. To do so, $\mathcal{A}$ can instead employ a CRIME-style attack [49]. In such attacks, $\mathcal{A}$ first has knowledge of a prefix p, of length at least three bytes,[6] that precedes the secret, which serves to "bootstrap" the attack. To guess the first character, the high-level idea is that $\mathcal{A}$ tries all possible values z_i for it by injecting $p \| z_1$ followed by $p \| z_2$, and so on. Then, all incorrect guesses will get compressed by only $|p|$, but the correct guess will match an *additional* character, leading to a slightly smaller ciphertext. The attacker proceeds in this fashion, one byte at a time, until eventually the entire secret is recovered. If the adversary is extracting information in attachments, the known prefix p can be part of a document's template; for example, if recovering the salary in a contract, p may be "Salary: ". Conversely, if the adversary is recovering URLs or usernames, we can take advantage of the structure of KDBX 4, and set p to be the *XML tags* of the field. For example, if recovering a username, $p =$ `<Key>UserName</Key><Value>`. Further, $\mathcal{A}$ could recover a field from a *specific* credential, by appending additional information to p. For example, to recover the username specifically for `target-site.com`, $\mathcal{A}$ can use $p =$ `<Key>URL</Key><Value>target-site.com</Value>` ... `UserName</Key><Value>`. As before, injections are performed by updating the URL, username, or attachment fields of a shared entry, this time with $p \| z_i$ as the payloads. Exploring this extension further is outside the scope of our work, as such attacks rely on lower-level details of compression algorithms.

[6] gzip does not compress matching substrings unless they are at least four bytes long.

	Websites	Usernames	$\|w\| = 5$	10	15	20
$\|W\| = 4$	99	80	89, 61	100, 74	100, 86	100, 88
10	97	66	81, 51	98, 59	100, 57	100, 63
25	92	54	64, 30	97, 33	100, 48	100, 44
50	89	46	50, 17	93, 28	100, 29	100, 38
100	84	24	39, 8	92, 13	100, 16	100, 14

Figure 5: Experimental success probability of our dictionary attack on usernames and URLs exploiting compression, for real-world files (first two columns), and for synthetic test files (last four columns); the left and right values denote, respectively, when the strings consist of random bytes and are all of length w, and when they have repeated substrings and vary in length between 1 and $|w|$. These probabilities can be amplified via repetition.

Attack implementations. We experimentally verified our dictionary attack against KeePassXC, using URLs and usernames as examples of items of interest. An additional complication about KeePassXC is that, as explained earlier, every database save rotates K', re-encrypts all passwords, and updates metadata (for example, a timestamp indicating the last modification time of the shared entry). This results in a small number of bytes of noise in the compression side-channel. Given that our target items are only a few bytes long, such as URLs and usernames, this noise is noticeable. So, we use a simple refinement from [61]: inject each candidate item t times instead of just once, compute the average value of the resulting $|\mathcal{B}|$, and use this in the measurements. Of course, the larger t is, the higher the probability of success will be. $\mathcal{A}$ can pick an appropriate value based on the context of the attack (for example, the size of W, how long the victim will be using their device, etc).

We tested our attack in the same dual-setup as in Section 7.1 and using the same three types of workloads; the datasets of real-world data consisted of a list of the Majestic ranking of top websites [4], and a corpus of common usernames compiled from various data breaches [40]. The results of our experiments on usernames are displayed in Figure 5, which correspond to the success rate across 100 independent trials of each workload, using $t = 10$ for each injection.

8 Mitigations and Responsible Disclosure

We discuss mitigations for our attacks in this section, as well as the results of our responsible disclosure with the vendors directly affected by our work. The patches adopted by these may serve as inspiration for other applications that are vulnerable to our attacks.

The most immediate mitigation to our attacks from Section 5 would be to remove shared credentials from the computation of vault-health metrics that are logged to the servers, in order to disable the injection side-channel. This, however, would result in a loss of information for users, as they would no longer be able to detect duplicate passwords present in (non-malicious) shared credentials. Other mitigation approaches would depend on the exact purpose of these metrics, which is opaque to us. For example, if the metrics are only used for client-side computation and stored on the server, clients can encrypt these locally before exporting them. Conversely, if the metrics are used to compute server-side statistics, applications could use privacy-preserving aggregate statistics frameworks such as [15].

Our attacks from Section 6 against a network adversary can be mitigated by fetching icons every time a new credential is added to the vault, even if the URL is a duplicate. Note that clients can potentially still store only one copy of each icon in the client side, and the requests can be repeated just for the sake of hiding fetch patterns. To also hide the URLs from an eavesdropping adversary, applications can use private-information retrieval (PIR) schemes [14] to retrieve icons without revealing the URL in question.

A direct mitigation to our attacks from Section 7 is for applications to, of course, disable storage-saving mechanisms. However, this could result in a prohibitive blowup in their storage footprint. By definition, disabling deduplication doubles the cost of storing repeated attachments. The cost of disabling compression depends on the file format and the underlying user data; for highly structured file formats like XML, the increase is particularly noticeable. Local tests on example KeePassXC databases resulted in 5-6x increases in size.

Another mitigation approach is to confine the storage-saving mechanisms to subsets of the application data that are within the same trust context, which would disable the injection channel. For deduplication, this translates to deduplicating files separately for every shared folder. More work is required to devise an analogous solution for compression. A different mitigation approach for compression would be to isolate sensitive fields within the database by encrypting them under a second layer of encryption, which prevents similar data from matching with these fields. This is analogous to how KeePassXC protects passwords, as described in Section 7, and indeed they could consider encrypting other fields in a similar fashion. Yet another approach could be to add padding or noise to the database before encrypting it, in order to obfuscate the real size of the database. Adversaries can use statistical techniques to adapt to such mitigations, however, as has been the case in other contexts such as network traffic fingerprinting (see, e.g., [18]).

Responsible disclosure. The first version of our study analyzed just four applications (LastPass, Dashlane, Zoho Vault, and KeePassXC), who proceeded to deploy mitigations, which we describe below. A second round of disclosures is still ongoing, since we recently expanded the scope of our study. We will update the paper once we complete these.

LastPass adopted our suggested mitigation of separating vault-health metrics between personal and shared credentials,

which disables the injection channel. They released an initial implementation of this fix in version 4.129.0, removing shared folders from the vault-health logs, as these lead to the most severe variant of our attack. Removing individually shared credentials from the logs is more technically challenging—and individual credentials lead to a less practical version of our attack—and thus has been deferred to later in their roadmap; their projection is to release this fix by the end of the year, which would complete a full mitigation to our attack.

Zoho Vault plans to adopt a similar fix, by implementing an option to separately compute vault-health metrics on personal passwords as of version 4.0. Dashlane opted for a partial mitigation instead, namely, increasing their rate limits on the sharing endpoints "as much as possible". Given the fact that their vault-health metrics are only logged once per day, their tight sharing limits significantly affect the practicality and runtime of the attack. In addition, the resource limits on their web application and extensions prevent an adversary from sharing an unlimited number of credentials with a victim, which increases the runtime of the attack even more. As part of the disclosure, they informed us that incorporating shared passwords is a core feature of their vault-health metrics, and thus removing shared passwords would represent a notable disruption to this feature.

Then, to mitigate our URL icon fetching attack, Dashlane implemented a new feature as of version 6.2415 that allows users to turn off fetching credential icons, which disables the side-channel for both an eavesdropping and network adversary, and is thus a full mitigation to our attack; details of this new feature can be found at [16]. In addition, they migrated their icon fetching tool to a new endpoint (`api.dashlane.com`), which is used by multiple parts of their application logic. As such, this would make it significantly more challenging for a network adversary to use traffic analysis techniques to identify whether an icon fetch request is included in the traffic sent to this top-level endpoint, due to the high amount of noise from the other requests sent to this endpoint.

To address our attack on attachment deduplication, KeePassXC adopted our suggested mitigation of deduplicating files separately for every shared folder, which disables the injection side channel. Then, to address our compression-based attacks, they modified their file format by, every time the database is saved, picking a random length between 64 and 512 bytes, generating a random array of this length, and including this in a "custom data" field of their file format. We note that this is only a partial mitigation, as an adversary can potentially use statistical techniques to bypass the noise; this, however, would require a significantly higher number of injections. Both fixes were promptly implemented by the KeePassXC team, and have since rolled out as part of version 2.7.

9 Conclusion

We introduce a new threat model for password managers in this work, which we exemplify via four general attacks, using ten applications as case studies. Our attacks suggest the need to rethink certain aspects of password manager design, and of E2EE applications more broadly. We highlight some takeaways in this section.

Our attacks from Section 5 are symptoms of the more general pattern of exporting application state that is a function of both personal *and* externally-received data, which can potentially open the door for injection attacks. Thus, a guiding principle for E2EE application designers is to *separate data according to the trust assumptions of their system*. Our attack from Section 6 is an example of the broader pattern of fetching content from external sources in a *state-dependent way*, which an adversary can potentially exploit by injecting payloads and seeing how this affects subsequent fetches. Thus, a guiding principle for application designers is for client-server communication to be *as resource-specific as possible, and to not depend on the results of prior operations*. Lastly, our attacks from Section 7 serve as an example of the tensions between security and performance. Since storage-saving mechanisms get rid of redundancy in application files, techniques of this form naturally pave the way for potential injection attacks. As such, more work is required to understand how to balance storage costs and security, particularly in the context of compression and file deduplication, and to devise frameworks that help explore these trade-offs in a principled way.

We disclosed our attacks to the vendors affected by our work, who deployed fixes to address these. These mitigations, however, are bespoke solutions for the attack vectors presented in this work; a central direction for future research is to design general-purpose detection and mitigation techniques against injection attacks, and to deepen our understanding of this threat model.

A Testing Methodology and Analysis

We explain the testing methodology for our attacks in this section, where we include a summary of the steps shared with vendors that allowed them to reproduce the attacks.

General setup. For each analyzed application, we first created two separate accounts for the service. The devices used were laptops running macOS Monterrey. If relevant for the application, we additionally created an organization under which both accounts were registered. Then, we established a shared folder (or individual credentials, if the application does not support folders) between both accounts.

A.1 Attacks from Sections 5 and 6

To simulate the view of both a compromised server and network adversary, we used Charles Proxy [1] to establish a proxy server on the victim's device. This allowed us to intercept both the encrypted HTTPS traffic, and enable SSL proxying to intercept the unencrypted traffic that would reach the application servers.

Our testing data consisted of an open-source list of common passwords [40] and the Majestic ranking of top websites [4], for the attacks in Section 5 and 6, respectively. We explain the main steps for our attack from Section 5 below; the steps for the attack in Section 6 are analogous, except that we inject URLs instead of passwords.

To implement the attack, we first sampled uniformly at random a password from this list, and added it to the victim's vault as the target password. We then sampled at random various subsets of passwords of increasing sizes (1 through 512, in increasing powers of 2), which represented the list of candidate passwords. Lastly, we ran the attack from the adversary's account, following the steps described in Section 5. At a high-level, this consisted of creating a batch of shared passwords in the adversary's account, waiting for the next request from the victim's account reporting the updated number of duplicates (which was intercepted by our proxy server), and repeating these steps, until completion of the attack.

To determine the network delay for each log of duplicates, as reported in Section 5, we compared (1) the timestamp from the initial request for the upload of the shared credentials, against (2) the timestamp of the request that logged the number of duplicate passwords. We computed the average delay between each injection. Then, the total time to run each attack is simply $t \cdot n$, where t is the number of iterations the attack requires, and n is the experimental delay between logs of duplicates.

Both attacks succeed with 100% probability by design: computing the number of duplicates in the vault and fetching URL icons are both deterministic, noise-free operations. Thus, there was no need for an experimental estimate of the attack's correctness. Indeed, our attack implementations succeeded every time.

A.2 Attacks from Section 7

To simulate the view of a compromised encrypted vault, it sufficed to place the encrypted database file in a local folder in the victim's device, and measure its size directly.

We verified the general correctness of the attacks by implementing them using real KeePassXC clients, and then computed an empirical estimate of their probability of success on a local simulation (described below). We used various data sources as testing data for the attacks, as described in Sections 7.1 and 7.2. For each, we first added the target item to the victim's device. Then, we ran the attack from the adversary's device as explained in the relevant sections, by iteratively adding credentials to the shared folder with injected items and measuring the updated size of the victim's encrypted vault. In this way, we were able to confirm the presence of the deduplication and compression mechanisms.

Statistical analysis. We implemented a local simulation of the core operations of the KeePassXC client that are relevant to our attacks, which allowed us to compute the statistical error rates of our attacks. Concretely, our simulation received as input an initial KDBX 4 database, and provided an interface for adding shared credentials to the database, which would update the vault in-place, in a way that is consistent with updates from real clients. This consisted of two steps: (1) Modifying the plaintext database, by adding the shared credential as a new XML element to the payload, adding new attachments to the inner header (if any), and updating metadata; and (2) Re-encrypting the new plaintext database, by rotating the secret key in the inner header, and compressing-then-encrypting the inner header and XML payload with this key.

Our implementation of this simulated environment was guided by KeePassXC's open-source codebase, in addition to manual comparison of decrypted KDBX 4 databases before and after a shared credential was added, which revealed all modifications that resulted. In particular, this is derived from files `src/format/Kdbx4Writer.cpp` and `src/format/KdbxXmlWriter.cpp` in KeePassXC's codebase [3]. We tested the consistency of this simulation by adding shared credentials via both our local implementation and real KeePassXC clients,

and verifying that the resulting database states are equivalent in both cases.

Equipped with this simulation, we ran the attacks (following the steps described in Section 7) in a single device, to be able to compute a high number of trials without overloading the application servers. We used the interface provided by our simulation to add credentials to the vault (which mocks the injected credentials), followed by local measurements of the resulting file size (which mocks the adversary's view of the compromised encrypted vault). This allowed us to empirically estimate the noise present in our attacks, by repeating each experiment many times on the same starting state, and tallying the number of successful attempts (see Section 7 for more details, and the reported error rates).

B Details of Case Studies from Section 5

We explain additional details for the case studies of our attacks from Section 5 in this section.

Case study #1: LastPass. LastPass's Chrome extension and web vault log vault security metrics via POST requests to the endpoint `lastpass.com/lmiapi/users/me/security/score`.[7] The payload of this request, among other things, maps the string "`numallduppasswords`" to the number of duplicate passwords in the vault, i.e., $\mathsf{dup}(\mathcal{V})$. Importantly, this metric only quantifies how many passwords themselves are reused, and not across how many accounts. That is, if there are already two copies of a password in a vault, adding a third copy does not increase this metric. As such, our attack on LastPass requires the additional assumption that U only has one copy of the target password in their vault at the start of the attack.[8]

The POST requests to `lastpass.com/.../score` are triggered after every modification to any entries in $\mathcal{V}$. In particular, a request is sent as soon as U's client automatically imports the updates to the shared folder F. Synchronization of changes to shared folders is very frequent. Indeed, LastPass claims that changes are "synchronized automatically and propagate to everyone with whom the folder has been shared" [36]. In practice, there is a short time delay, which represents the time the adversary has to wait between each of the $\lceil \log_2 n \rceil$ injections. We measured this to be between 3 to 5 minutes on average.

Case study #2: Dashlane. Dashlane's web vault and Chrome extension log their vault security metrics via POST requests to `styx.data.dashlane.com/v1/event/user`. The payload of this request contains the string "`passwords_reused_count`", which corresponds to $2 \cdot \mathsf{dup}(\mathcal{V})$. Unlike LastPass, this metric quantifies the number of *accounts* with reused passwords, i.e., we do *not* need to assume that U's vault only contains one copy of the target password. More generally, the attack requires no assumptions about the (lack of) activity by U,[9] and thus falls under the noisy device setting.

Case study #3: Zoho Vault. Zoho Vault's web vault logs their vault security metrics via POST requests to the endpoint `vault.zoho.com/api/rest/json/v1/dashboard/sendAssessmentDetails`. The payload of this request contains an array O of JSON objects, with the format described in Section 5.1. By counting the number of objects such that "`reused`" maps to `true`, the adversary can identify $\mathsf{dup}(\mathcal{V})$, and thus run the attack using the binary-search injection strategy. However, Zoho Vault is revealing much more granular information: $\mathcal{A}$ learns whether the password of each *specific* entry is a duplicate or not, instead of just the total number of duplicate passwords. So, the adversary can simply inject all candidate passwords in a *single* batch, and look for the `reused` field of the objects in O that correspond to the injected credentials.

The challenge with this approach is identifying which specific objects correspond to which specific injected credentials. To do so, the adversary can leverage an additional fact: upon creation, each credential is assigned a unique string identifying it, which is also stored in each credential's object in O. This ID is preserved after a credential is shared. So, the adversary can (1) locally create a credential for each candidate password, (2) note the assigned ID for each, and (3) look for these IDs in O after sharing the credentials. This allows the adversary to map every injected credential to its corresponding object in O, as desired.

Unlike the prior attack on LastPass, the correctness of this attack does not depend on U having only one copy of the target password in their vault. More broadly, our attack is robust to any kind of external noise, and thus falls under the noisy device threat model. We note that our extension of this attack to a network adversary does require that the device is free of external noise at every recursive round of the binary-search injection strategy, in order for fluctuations in $|O|$ to correspond only to changes in the `reused` flags of injected passwords. Importantly, however, the device need not be quiet for the *entire* attack: if $\mathcal{A}$ notices that external changes also took place, they can simply repeat this round of the attack. As such, the attack as a whole falls under the noisy device setting.

[7] This is only the case for users with premium accounts (any one of Families, Teams, Premium, and Enterprise plans, and the trial versions of these).

[8] Similarly, the basic attack requires a trivial refinement: if $P_{found} = P'$ in step (5), $\mathcal{A}$ needs to first delete or overwrite the entries they just injected, as otherwise there would already be a copy of the target password in the vault (from their prior injection).

[9] Unlike LastPass, when the metric increases $\mathcal{A}$ can distinguish false positives from legitimate matches by unsending the candidate, and seeing if the metric decreases again.

OPTIKS: An Optimized Key Transparency System

Julia Len[1], Melissa Chase[2], Esha Ghosh[2], Kim Laine[2], and Radames Cruz Moreno[2]

Abstract

Key Transparency (KT) refers to a public key distribution system with transparency mechanisms proving its correct operation, *i.e.*, proving that it reports consistent values for each user's public key. While prior work on KT systems have offered new designs to tackle this problem, relatively little attention has been paid on the issue of scalability. Indeed, it is not straightforward to actually build a scalable and practical KT system from existing constructions, which may be too complex, inefficient, or non-resilient against machine failures.

In this paper, we present OPTIKS, a full featured and optimized KT system that focuses on scalability. Our system is simpler and more performant than prior work, supporting smaller storage overhead while still meeting strong notions of security and privacy. Our design also incorporates a crash-tolerant and scalable server architecture, which we demonstrate by presenting extensive benchmarks. Finally, we address several real-world problems in deploying KT systems that have received limited attention in prior work, including account decommissioning and user-to-device mapping.

1 Introduction

The term *Key Transparency* (KT) refers to a key distribution system – a key directory – that provides transparency guarantees for its operation. These transparency properties are often implemented using cryptographic proof techniques, but may in some cases be implemented using trusted execution environments as well. While KT cannot prevent the system from misbehaving (for example, making an unrequested key update on a user's account), it ensures any incorrect behavior will be detected either immediately, or with a delay.

The importance of KT is particularly evident in end-to-end encrypted (E2EE) communication. If the communication service simply distributes the public keys of communication partners, nothing would prevent it from inserting itself into the conversation as a *meddler-in-the-middle* (MitM) and capturing traffic intended for the victim. Realizing this obvious problem, some communication system providers have implemented mitigations like *security codes*, which require scanning QR codes for text-based messaging or reading out long strings of numbers among participants for calls or meetings. However, using these techniques requires manual interaction. KT provides an automated way of checking that the users are getting the correct keys: as it requires no user interaction, it provides a much more usable and secure solution.

In a KT system, the server maintains the directory of user public keys. It periodically publishes a privacy-preserving[1] commitment to its current directory on a bulletin board. The server produces a cryptographic proof of consistency along with any keys it distributes: the purpose of this proof is to show that the keys distributed are both the latest and consistent with the commitment posted on the bulletin board. A KT system supports two types of queries. The user devices can monitor their own key history by asking for their key history and proof. Users can also ask for the latest key of their contacts.

KT has gained significant traction, both in industry [4, 23] and academia [5, 6, 10, 16, 17, 20, 22]. This increased interest is also evident from the developing IETF standardization effort [18]. Notably, WhatsApp [12], Apple iMessage [1], and Proton Mail [2] recently deployed KT, with WhatsApp's design based on academic systems SEEMless [5] and Parakeet [16], iMessage's design based on CONIKS [17] and Proton Mail's design combining ideas from CONIKS [17], SEEMless [5] and Parakeet [16].

While there has been a rich body of literature on KT systems, most of these prior systems lack important features like scalability, among others. To the best of our knowledge, Parakeet is the first paper tackling scalability challenges that arise

*Work partially done at Microsoft Research.

[1] *Privacy:* The keys maintained by a user as well as their key updates can be sensitive information. Accordingly, academic and industry proposals [4–6, 12, 16, 17] and recent standardization efforts [18] have emphasized privacy as an explicit goal for KT systems. Thus, we also aim for privacy as a goal of our system: in particular, lookups for a client's key should not leak anything about other keys stored by the system outside of what is returned by the lookup itself.

when moving from academic proposals to large-scale deployments. This is an important first step, but the design misses some key attributes as well as optimizations. In this paper, we present OPTIKS, a full-featured and optimized KT system. We show that OPTIKS achieves the same level of security and nearly equivalent privacy as Parakeet using a much simpler and more scalable design.

Prior work: CONIKS, SEEMless, and Parakeet. To better understand how we improve over prior work, we begin with a brief technical overview of previous designs. The first KT system with (content) privacy was CONIKS [17]. At a high level, CONIKS works as follows: at every epoch, the server computes a sparse Merkle tree-based hash digest of its entire directory and publishes it. Notably, CONIKS places the key for a client at the same position in the tree each time. Clients are then required to check their key is correctly represented in the digest each epoch.

SEEMless [5] removes this burden from clients by maintaining one tree storing all current and historical key updates. The client can then check a single tree and see exactly when and to what values their key was updated. SEEMless also improves privacy, by always appending any new key changes to the tree in new (random) positions; these positions are chosen using a verifiable random function (VRF) which guarantees a unique but pseudorandom position for each entry. But, this approach increases storage over time. Moreover, SEEMless's design requires the server to perform complicated bookkeeping that maintains, among other things, two copies of the tree, effectively doubling the storage and update costs. Parakeet [16] improves the storage expansion in SEEMless by optimizing the trees, but it still maintains two trees. Its approach to compaction is to increase the bookkeeping complexity by marking nodes as ready for deletion.

In more detail, SEEMless and Parakeet maintain two trees, which [5] refers to as the *all* and *old* trees. The all tree stores all keys ever added to the system, while the old tree only stores stale versions of keys. When a client looks up a key, the server provides a non-membership proof that the key's latest version is not in the old tree to show it is not stale. When the client monitors its own key, it checks that all outdated key versions are indeed added to the old tree, thus guaranteeing that a key lookup can only return the latest key.

OPTIKS-core: Algorithmic optimizations. We first present OPTIKS-core, a protocol which incorporates algorithmic optimizations over prior work. To this end, we make several key observations. First, we cut storage in half by changing the way the client verifies it is getting fresh keys. Second, we consider how the protocol will be used in practice and optimize for those usage patterns.

Recall that the goal of the server is to prove the key it serves has been logged against the specified username and is the latest version. We observe that the old tree is solely for proving this freshness guarantee. We can therefore completely remove the old tree by changing the freshness proofs. As our first optimization, we note that an equivalent freshness proof is to show that the current version is the latest version in the tree; we can do this by giving a non-membership proof for the next version number. This allows us to completely remove the old tree. Since the trees are nearly equivalent sizes, our approach immediately cuts the storage and update costs by half compared to SEEMless and Parakeet.

For the second optimization, consider how users might interact with the system. We expect that clients will occasionally update keys and look up keys of communication partners, but will regularly, and ideally frequently, monitor their own keys to ensure they have not changed unexpectedly. OPTIKS-core is thus optimized to minimize the cost of this latter, more frequent operation of client monitoring, at the cost of somewhat more expensive key lookups. This also allows us to significantly simplify the construction, which makes it easier to explain and implement.

Specifically, we eliminate the complex marker-based bookkeeping logic in SEEMless and Parakeet by changing the lookup and key history proofs. In particular, each key lookup now returns membership of all key versions and non-membership of the next version. Clients then verify all key updates for the queried user (in Section 5, we discuss how to reduce this overhead via client caching). Notably, client monitoring of its own key is then the same as key lookups, thereby reducing system complexity.

Notice that since the tree is append-only, the client only needs to check once that each key update has been included. After that (unless its key has changed), each time it monitors it only needs to check that the key has not been updated to the next version unexpectedly. This then reduces the typical expected client monitoring cost to that of verifying a single non-membership proof. In contrast, the cost of client monitoring for SEEMless and Parakeet scales with the number of client key updates and (logarithmically) with the number of epochs. Our approach of optimizing for the most common operation thus significantly reduces expected deployment costs and simplifies the protocol. We note that while this does slightly increase privacy leakage, we believe this increase is reasonable, particularly because it is further limited by the other features we propose.

We observe that ELEKTRA [13] takes a similar approach, although it adds the additional complexity of requiring signatures and hash chains. From that perspective, our result can be seen as extracting out and analysing security of the core algorithm beneath ELEKTRA, without the overhead and complexity that that work inherits from Keybase and from their stronger security goals. See Section 8 for more comparison.

The OPTIKS-core protocol described so far roughly matches with the functionality and security guarantees provided by CONIKS, SEEMless, and Parakeet[2]. Importantly,

[2]Parakeet does deal with storage overhead, which is the first of the OPTIKS-ext features that we will discuss.

by itself OPTIKS-core is significantly more efficient in the most frequent expected use case of the system. However, as discussed above, there are still significant limitations to deployment. We thus also present OPTIKS-ext, which aims to address these limitations.

OPTIKS-ext: Further improvements. Perhaps the most significant contribution of OPTIKS-ext is its approach to limiting storage growth. We modify the append-only *all* tree by integrating the notion of a longer time period. For example, if our epoch is on the order of a second, this time period might be on the order of a month. At the beginning of each time period, OPTIKS uses only the most recent key for each client to construct a new tree; it then appends any subsequent updates of the current time period to this tree. Clients are responsible for checking their keys every time period to make sure that the final key in each time period is indeed the same as the first key in the next. Implementers can choose which trees from old time periods to store and which to delete. Our design requires that clients be online frequently enough to perform these checks before the old time periods are deleted, which we view as reasonable since time periods will be long. We further note that [16] makes a similar assumption about its users to enable compaction. Notably, however, their compaction mechanism is more complicated and requires more bookkeeping compared to our time-period-based approach. Another benefit of this design over [16] is that it offers a limited form of post-compromise security for privacy, since each time period uses a new key for ensuring privacy. It also limits query leakage from our design, in that the query reveals the user's updates only in the current time period.

We highlight that the flexibility of deleting data from old time periods provides a trade-off in soundness guarantees. In particular, if implementers choose to delete data from old time periods and a user did not come online during some previous time period to check their keys, the user gets no security guarantee for that period. In other words, fake keys might have been distributed on that user's behalf during the missed time period, and the user could not detect this. However, the benefit of our design is that the time period is a tunable system parameter, so that systems with greater security concerns can elect to store data from older time periods. Thus, OPTIKS provides a way to smoothly trade-off security for more storage.

Additionally, OPTIKS addresses vital features for deploying KT that prior work does not, such as user account decommissioning or how to resolve the tension between external facing human-readable usernames and internal facing UUIDs (or equivalent identifiers) for indexing into the KT directory. At a high level, we address these by adding additional data structures, but this must be done carefully to avoid subtle issues. To illustrate the subtlety, let us take the decommissioning feature as an example. When a user stops using the system, they will presumably no longer be monitoring their own key history. Ideally, a KT system should still ensure that a malicious service provider cannot replace their key and impersonate them in future communications.

In OPTIKS, we enable this by maintaining an additional tree to keep track of the decommissioned user accounts. At first glance, this seems wasteful – one might ask why we cannot just add the decommissioned usernames to the same tree for each time period? This is because we want the tree of decommissioned usernames to persist through the lifetime of the system and not just between time periods, regardless of whether the decommissioned user is available to monitor it.

Architectural innovation. Prior work considers a monolithic service provider with no specifics on how it operates. OPTIKS contributes a novel system architecture, where we physically separate the query component from the update component. This distinction enables OPTIKS to use more optimal memory representations for the Merkle tree nodes in each component. The benefits are numerous, including better performance, more efficient parallelized updates, and minimal service downtime at epoch boundaries. Many of these ideas can improve other KT systems as well.

In more detail, for updates, we use a linked node representation, where the cost for looking up child nodes is simply the cost of random memory access. Our experiments show that this is at least 2.5 times more efficient than inserting in a hash table representation. It also lends itself to a much more efficient parallel update algorithm. For example, our experiments show that parallel updates on 16 vCPUs improves our batch update performance by 3.7x, whereas Parakeet (implemented using a hash map for node storage) only achieves a 1.3x speedup. On the other hand, a hash table representation is more practical for serving queries, as it supports very fast partial tree node updates, essentially only requiring pulling updated nodes from a database.

Another advantage is that this separation allows us to tailor the implementation separately to the case of updates or queries, in particular in terms of thread-safety. Instead of a monolithic system like Parakeet, for example, that must use extensive locking to make sure that incomplete updates do not produce inconsistent queries, our system trivially prevents this kind of conflict since update and query operations are performed on different machines. We need only worry about thread-safety within the query server and separately within the update server, allowing us to use much lighter-weight techniques. Indeed, our parallel update algorithm does not use any locks at all. On the query side, we need a single lock to indicate that some of the nodes are being updated with new data downloaded from a backing database, minimizing any downtime at epoch boundaries.

This separation also makes it trivial to scale the query service horizontally, just by adding more machines. In this case update downtime can be entirely eliminated by interleaving the query server updates, so that there are always sufficient machines available to respond to traffic. This does mean,

System	Storage	Lookup	Update	Audit	Client Monitoring
CONIKS [17]	$e \cdot n$	1	$k\log(n)$	1	e
SEEMless [5]	$2n$	3	$2k\log(n)$	$2(k+k\log(n))$	$v+\log(e)^*$
Parakeet [16]	$2n$	3	$2k\log(n)$	$2(k+k\log(n))$	$v+\log(e)^*$
OPTIKS	n	$v+1$	$k\log(n)$	$k+k\log(n)$	1

Figure 1: Asymptotic costs of OPTIKS in comparison with other KT systems. For client monitoring we assume clients may cache proofs they have already checked. We note that (*) represents worst case cost; the exact cost is $2^{\lceil \log(v) \rceil} - v + \log(e)$.

however, that these servers may serve slightly different commitments. We show how to modify our PAHD construction so that transparency can still be maintained – another novel feature.

A final important part in our architecture is a cache to store recently used VRF values on the query side, as evaluating the VRF is a heavy public-key computation. The benefit of a cache hit is immense, providing as much as 9 times higher query throughput for the key directory (ignoring networking and web service overheads).

Comparison to prior KT systems. We concretize our comparison of OPTIKS with prior related systems in Figure 1, which shows the algorithm asymptotics of each system. We assume a directory with n key-value pairs and e epochs. We also assume an update that will add k new key-value pairs, a lookup for a key with v versions, and a client monitoring its key when it has not changed. As we mentioned, this latter operation represents what we expect as the majority of client monitoring cases. For simplicity, we assume no VRF computation. Since the core data structure for each system is a Merkle tree, we measure most operations in the number of nodes affected. Specifically, we measure storage in the number of nodes throughout system life, lookup and client monitoring in the number of (non-) membership proofs to check, update in the number of nodes to modify, and audit in the size of proof provided to each auditor per epoch in the number of nodes to download.

OPTIKS achieves the best performance for storage, client monitoring, and update cost, the latter of which is the same as CONIKS. The algorithmic optimizations of OPTIKS enables it to halve the audit costs of SEEMless and Parakeet, although it is still greater than the constant-time audit cost of CONIKS, in which an auditor only needs to check the latest root of the tree has been added to a hashchain. However, this cost comes at the trade-off of clients needing to come online and verify keys every epoch.

As mentioned, the increased performance of OPTIKS in other categories comes at the trade-off of worse lookup performance. However, given that we expect the typical use case to have a single key version each time period for clients, v is likely to be 1 in most cases, which means we expect most clients to verify only 2 proofs when doing a lookup.

Our experiments further show that OPTIKS is significantly more performant and scalable than prior work. For example, for a key directory of 2^{20} keys, a single instance of our Query Service can serve more than 4000 queries per second at a bandwidth of around 20 MB/s, while our Update Service/Task can process more than 1000 updates per second while sustaining a latency of one second. For a much larger key directory of 2^{26} keys, our Query Service can still serve 2240 queries per second at a bandwidth of 13.89 MB/s, and our Update Service/Task can process still around 280 updates per second; in this case the latency remains still less than 4 seconds on average. All of these experiments include the cost of database access, networking, and REST API overhead. We note that the major bottleneck for our update rate is database write performance, since we use costly multi-table transactions to simplify our implementation.

To summarize, we make the following contributions:

- **OPTIKS-core.** We first present OPTIKS-core, a KT system that incorporates novel algorithmic optimizations which enables it to be significantly more efficient and performant than [5, 16, 17]. The key insight is that we optimize for the typical use case in practice when a client is expected to rotate its long-term key relatively infrequently, but where the client wants to monitor relatively frequently to verify that this key remains unchanged.

- **OPTIKS-ext.** We enhance OPTIKS-core with additional features important for deployment. The crucial features include: keeping the core data structure compact, adding user account decommissioning, and adding support for multiple usernames and user devices.

- **Split architecture.** OPTIKS uses a novel architecture, where the update and query services are physically separate from each other. This allows us to use different memory representations for the Merkle tree nodes in each of these components. We believe that our split architecture is generally applicable to many Merkle tree-based systems where the read and write workloads are unbalanced.

- **Experiments.** We provide detailed benchmarks for our system, dividing them into micro-benchmarks and full-system benchmarks. To demonstrate that our system is more scalable than prior work, we run it on benchmarks significantly larger than any presented in prior work.

2 System Setup and Overview

Our KT system models a central server that stores a directory of usernames and the corresponding public keys. There exist intermittent time intervals that we refer to as *epochs*, which

we expect to be on the order of seconds, during which the server updates the directory it stores with new key update requests and posts a commitment to this data. Our system also includes longer time intervals (e.g. a month) that we refer to as *time periods*, which we will discuss in Section 5. Users of the system can query the server to look up another user's key(s) or to get the history of the updates to their own key(s). We also assume that third-party auditors (though the users can play the role of the auditors as well) audits the commitments for consistency. We now describe this process in more detail, with an overview of our assumptions, the security properties we expect such a system to meet, and a summary of our solution.

Participants. Our system has the following participants:

- *Users.* A user can register an account with the server and also may permanently leave the system by decommissioning their account. Associated to each user is a *username*, such as an email or human-readable string, that represents their public-facing identity in the system. Also associated to each user is an internal, unique, and static *user id*, such as a UUID, that is not exposed to human users of the system. Note that in practice a username may change or multiple usernames may be associated with a user (*e.g.*, if they add an extra email to their account), so the user id always uniquely identifies the user within the system.
- *Client devices.* Each user has at least one device which they use to communicate (e.g. phones, computers, etc.), where each device has its own public key that must be stored and distributed by the system on the device's behalf. We do not assume any coordination between the user's devices. Clients may update their public keys, look up the keys of other clients in the system, and also check the history of updates to their keys. Associated to each client is an internal, unique *device id*, such as a UUID, that is not exposed to human users of the system.
- *Server.* The server maintains the directory mapping users to their public keys and distributes these keys among the users of the system when queried. It posts a public commitment to the data each epoch. In this work, we also refer to the server as the "service provider."
- *Auditors.* Auditors verify updates made by the server are well-formed via the publicly posted commitments. To ensure privacy, this verification does not involve checking the public keys themselves are correct (indeed, this task falls onto clients, as we mention above). Auditors can be third-party entities or security-conscious users.
- *Bulletin board.* The server posts the commitments to its directory on a public bulletin board to which other participants of the system have access. The bulletin board should be tamper proof as well as append-only and also all participants should have a consistent view of its contents.

Assumptions. As is standard in any KT system, we assume that the server can be malicious and distribute incorrect keys for its users (in the hope of mounting a MitM attack). However, the server is trusted to exercise access control and not give out every client's public key to everyone else. In other words, the server is trusted for privacy.

The client devices can be malicious in that they may aim to learn private information (public keys, how often a certain user changes her key, etc.) about other clients who are not on their contact list.

We assume there exists at least one honest auditor who verifies each update made by the server via commitments posted to the bulletin board.

Our system also relies on all participants having a consistent view of the commitments posted to the bulletin board, which we highlight is a core requirement in all KT systems. As discussed in [5, 10, 16, 17], this could be implemented, for instance, via a gossip protocol or by posting the commitments to a blockchain. Furthermore, we assume the clients, server, and bulletin board have approximately synchronized clocks.

Although we do not model this, we assume that the server enforces some kind of access control for clients querying its system, e.g. rate limiting key lookups or executing key lookups only if the requesting user is a contact of the user whose key is being queried.

Our system relies on users being able to verify the history of their key updates. Therefore, users must have some way of keeping track of their devices and the approximate times of their key updates. This is an assumption made of other KT systems like SEEMless [5]. One way to facilitate this is to enable users to add notes to their key updates, such as "added new laptop." Also crucial to our system is that clients must be online to check their key history each time period. We utilize this assumption as part of our scalability optimizations, which we discuss in Section 5. Given that time periods are long, we expect most clients will achieve this in practice and, indeed, this is a common assumption of KT systems [10, 16]. Moreover, this is an improvement over many KT systems which assume that a client must be online *each epoch* to check their keys [17].

Lastly, the core data structure underlying our KT system is a dictionary that uses a key-value abstraction. Since our construction involves public keys, wherever possible we disambiguate between the two by referring to them either as dictionary keys or public keys explicitly. However, where it is clear from context, we will simply say "key" to mean either dictionary key or public key.

Security Properties. At a high level, we expect OPTIKS to achieve the following security properties. We present these definitions in more detail in Section 3.

- *Completeness.* When the server is honest, a user that looks up another user's key should receive the latest value of that key, and this should be consistent with what other users of the system see. This also means that all proofs the server

provides during a lookup must verify.

- *Soundness.* Assuming that all epochs are audited, the server cannot lie about a key's value during a lookup without the inconsistency being caught during a history check.
- *Privacy.* A KT system should maintain privacy for the users of the system and updates to their keys. We model this with a definition that says participants of the system (excluding the server) should not learn anything from queries to the server except for some well-defined leakage function. For instance, a key lookup for a user should not leak anything about the keys of *other* users of the system.

3 Building Blocks

In this section, we introduce the primitives *Private Authenticated History Dictionaries* (PAHD) and *ordered zero knowledge sets* (oZKS) which form the core of our construction.

Private Authenticated History Dictionaries. We define *Private Authenticated History Dictionaries* (PAHD), a new cryptographic primitive which forms the basis for OPTIKS. This primitive extends the authenticated history dictionary introduced and used by VeRSA [21]. At a high level, a PAHD enables storing and committing to data using a dictionary key-value abstraction. A server can update what it stores, which begins a new epoch with a new commitment to the dictionary, by adding new key-value pairs or updating the values for existing keys. Notably, the structure preserves the history of changes for keys. Clients can look up a key to retrieve its latest value, along with a proof that the value is correct. Clients can also check the update history for a particular key to learn when it was updated and to what values—this can be used to verify that the recorded history of changes is accurate. We also assume that associated with a PAHD is a randomness space R from which a random seed can be chosen to initialize a PAHD. We provide an informal overview of this primitive below and a detailed description in the full version [14].

- PAHD.Init: The initialization algorithm outputs the initial commitment to the empty dictionary.
- PAHD.Upd: The update algorithm updates the dictionary with a set of key-value pairs and outputs the updated dictionary and update proof.
- PAHD.Lkup / PAHD.VerLkup: The lookup algorithm retrieves the value v for key k along with a membership proof if k is in the dictionary or non-membership proof if k is not. The lookup verification algorithm then verifies this proof.
- PAHD.Hist / PAHD.VerHist: The history algorithm returns the set of values that key k has been assigned over time, the epochs during which each value was assigned, and the membership proofs for each key-value mapping. The history verification algorithm verifies the proofs that are returned.
- PAHD.Audit: The audit algorithm verifies the update proof between two consecutive commitments.

Security definitions. We present an overview of the security properties that a PAHD should meet below and formalize the definitions in the full version [14].

- *Completeness.* Completeness captures the following correctness properties: if a PAHD is initialized and updated honestly, then auditing between any two epochs should succeed, the lookup for any key k should return its latest value v and should verify, and the history check for k should return the correct history of values and the epochs they were added and should also verify.
- *Soundness.* PAHD soundness guarantees that, assuming the data store has been audited successfully by an honest auditor each epoch, a lookup for a key k cannot return some value v that is inconsistent with what the history algorithm returns for k at that epoch. For a PAHD scheme that meets soundness, this means that the server cannot lie about a key's value during a lookup without the inconsistency being caught during a history check. However, this does mean that the user who added the key must perform such history checks to verify that the key's value is correct.
- *Privacy.* The privacy goal for PAHD is that the outputs of Upd (which is used for auditing), Lkup, and Hist should not leak anything beyond the answer and what is specified by a well-defined leakage function $\mathcal{L}$ on the directory's state. We model this using a real-ideal world computational indistinguishability game where a simulator must simulate the outputs of these algorithms using the given leakage.

To instantiate a PAHD scheme, we make use of *ordered Zero-Knowledge Sets*, which we define next.

Ordered Zero-Knowledge Sets. An *ordered Zero-Knowledge Set* (oZKS) is a primitive that lets a potentially malicious prover to commit to a collection of (label, value)-pairs such that the prover can later prove the membership or non-membership of labels in the collection succinctly. The primitive also enables append-only updates to the collection of pairs. This primitive additionally requires a strict ordering on elements inserted by attaching the epoch of insertion along with the label-value pairs and committing to this as part of the data. This primitive is zero-knowledge because the commitment does not leak information about the collection of data and the proofs do not leak information about any other data in the collection.

oZKS builds on the aZKS primitive introduced in [5]. Primitives closely related to oZKS were defined in [6, 16, 19]. For a detailed description of the related notions, see the full version [14]. We provide an informal overview of this primitive below and a detailed description in the full version [14].

- oZKS.Init: The initialization algorithm outputs an initial commitment to the empty datastore.
- oZKS.Update / oZKS.VerifyUpd: The update algorithm adds a set of new label-value pairs to the datastore, outputting the new commitment to the data and an update proof. The update verification algorithm then verifies the

update proof between consecutive commitments.

- oZKS.Query / oZKS.Verify: The query algorithm returns the value associated to the queried label, along with the query proof and the epoch that the label was added (or $\perp$ and a non-membership proof if the label is not a member). The query verification algorithm verifies the value returned by a query using the proof.

Construction. We construct an oZKS from an append-only strong accumulator (aSA), a simulatable verifiable random function (sVRF), and a simulatable commitment scheme (sCS), as in [5, 16]. See definitions in the full version [14].

The aSA is constructed from a Merkle Patricia Trie and serves to commit to a dictionary. The label-value pairs serve as the leaves of the tree, where labels are used to specify the location of the leaf. Instead of using the label directly (which could leak sensitive information), we use the sVRF to compute the positions of the labels in the tree. We then use the sCS to commit to the label's value; this commitment and the epoch when the label was added serve as the value stored for each label. For more detail see the full version [14].

Security Definitions. Just as for an aZKS, we expect an oZKS to meet *completeness*, *soundness*, and *privacy*. We describe these definitions in detail and show that our construction meets them in the full version [14].

4 OPTIKS-core: Core OPTIKS Protocol

In this section, we describe a simple, lightweight PAHD construction which we use as the core of OPTIKS, referred to as OPTIKS-core. For simplicity, we assume that each user has one client device and so we use usernames directly as the dictionary keys and the corresponding cryptographic public keys as the values. (We consider the multi-device setting in Section 5.) Our protocol relies on an oZKS as described in Section 3 for its core building block.

▷ PAHD.Init(r): The server chooses a random seed and initializes an empty oZKS via oZKS.Init by giving r as input. The oZKS commitment is returned as the initial commitment and the oZKS initial state is stored in the server's state. The server also initializes the epoch to 0 and stores this in its state.

▷ PAHD.Upd($\mathsf{st}_{t-1}, [k_j, v_j]_j$): The server adds the key-value pairs that are input to the oZKS to create a new commitment to the dictionary. It first checks that all the keys to be updated are unique; if not, it returns $\perp$. In order to differentiate between versions for a key, the server uses the key concatenated with its version number as the oZKS label. We assume that the server keeps track of the version number for each key in its state. Thus, for each key-value pair (k, v), the server first checks if the key already exists in the oZKS. If it does not, the server uses $(k \mid 1)$ as the label. Otherwise, if the key is already at version n, then the server uses $(k \mid n+1)$. Once all the label-value pairs have been formed, the server adds them to the oZKS via oZKS.Update. The server increments the epoch $t-1$ in its state to t, and the resulting oZKS commitment com_t serves as the PAHD commitment for epoch t. The oZKS update proof π^{upd} serves as the PAHD update proof Π_t^{Upd} for epoch t and is stored in the server's state. The server also stores in its state the new oZKS datastore and state.

▷ PAHD.Lkup(st_t, k): For a lookup request for key k, the server retrieves from its state the latest oZKS commitment com_t and the latest version number α for k (where $\alpha = 0$ if k is not in the PAHD). If k is in the PAHD, then the server forms labels $(k \mid 1), \ldots, (k \mid \alpha)$ and calls oZKS.Query for each label to get back $[(\pi_i, v_i, t_i)]_i^{\alpha}$. To retrieve the non-membership proof $\pi_{\alpha+1}$ for the next version of the key (or to prove that k is not in the dictionary when $\alpha = 0$), the server calls oZKS.Query for label $(k \mid \alpha+1)$. The server returns either v_α as the value for k if $\alpha > 0$ or $\perp$ otherwise.

The server returns as its lookup proof:

- **Correct version i is set at epoch t_i:** For each $i \in [1, \alpha]$, π_i serves as the membership proof for $(k \mid i)$ with value v_i and associated epoch t_i in oZKS w.r.t. com_t. This means the server must return $[(\pi_i, v_i, t_i)]_i^{\alpha}$ as part of the proof.
- **Server could not have shown version $\alpha+1$:** Proof $\pi_{\alpha+1}$ serves as the non-membership proof for $(k \mid \alpha+1)$ in oZKS w.r.t. com_t.

▷ PAHD.VerLkup($\mathsf{com}_t, k, v, \pi$): The client verifies each membership proof for labels $(k \mid i)$ for $i \in [1, \alpha]$ and non-membership proof for $(k \mid \alpha+1)$ w.r.t. com_t via oZKS.Verify. The client also checks that version α is less than the current epoch t, since otherwise this would imply multiple versions were added in the same epoch [3]. We want to preserve a total ordering of key versions and so wish to prevent this from happening. Lastly, the client verifies that the update epochs $t_1, \ldots, t_\alpha$ are monotonically increasing.

▷ PAHD.Hist(st_t, k): This algorithm proceeds the same as Lkup, except that in its syntax it explicitly returns all key versions rather than including them in the proof. Looking ahead, history checks will be different when we introduce our scalability optimizations in Section 5.

▷ PAHD.VerHist($\mathsf{com}_t, k, [(v_i, t_i)]_i^n, \Pi^{\mathsf{Ver}}$): This algorithm proceeds identically to that of VerLkup.

▷ PAHD.Audit($\mathsf{com}_j, \mathsf{com}_{j+1}, j, j+1, \Pi_{j+1}^{\mathsf{Upd}}$): The auditor verifies the oZKS update proof in Π_{j+1}^{Upd} via oZKS.VerifyUpd and then checks that $j+1 \leq t$, where t is the current epoch.

Security and Privacy of OPTIKS-core. We formally prove the security of privacy of OPTIKS-core in the full version [14]. Here, we give an informal description of the leakage of OPTIKS-core. During updates, our protocol leaks the number

[3] Since we have very short epochs, this is not a limitation

of keys to be updated and the set of keys that were queried to Lkup or Hist since the previous update. Both lookups and history checks leak the value and epoch of addition for each version of a key. Our leakage profile is therefore nearly the same as that for SEEMless and Parakeet, except that key lookups in their protocols leak only the version number for the key and the value and epoch of addition for the latest key version. Looking ahead, we will describe how to minimize such leakage for lookups in Section 5.

5 OPTIKS-ext: Full Featured OPTIKS

As described in Section 1, there is a lot more to making the system deployable beyond the base protocol. Here we discuss in detail how we address those challenges by describing our full-featured protocol OPTIKS-ext. In particular, we describe scalability and reliability optimizations as well as important feature additions to our core protocol.

Reducing storage. A major downside of OPTIKS-core is that it must store all past key updates, resulting in storage that grows indefinitely. To avoid this, we must find a way to safely delete old data, without compromising the transparency guarantees. Parakeet [16] does this with a complex system of bookkeeping. We propose a much simpler solution: we consider time periods of a fixed length (e.g., a month). At the beginning of each time period, we start a new PAHD structure, copying over each key along with its latest version. We assume that users perform a history check at least once a time period. (The only other system to consider limiting storage, Parakeet, makes a similar assumption.) The user is responsible for verifying that their latest key version from the previous time period is accurately copied to the current time period. The service thus only needs to retain the two most recent PAHDs—all earlier data can be archived or deleted.

Overall, this change means that lookups will only retrieve key updates from the current time period, which may significantly reduce lookup cost, particularly for users with frequent updates. History checks will return key versions from the current time period and the previous one. Finally, note that auditors will not need to audit the transition between time periods. We provide more details in the full version [14].

Post-compromise security. Because we generate a fresh PAHD with a fresh server secret every time period, we get a limited form of post-compromise security. In particular, if the service provider's state is revealed at some point, it will not affect the privacy of key updates from future time periods.

Queries w.r.t. different commitments. If we want to support a very high query throughput, one option (as described in Section 6), is to have multiple servers responding to oZKS queries (i.e. generating oZKS membership and non-membership proofs). However, this introduces the possibility that these servers might be slightly out-of-sync and thus answer queries w.r.t. different epochs. Note also that a PAHD lookup response actually consists of many oZKS query responses. Thus, we must consider the possibility that these oZKS query responses are distributed to different oZKS servers who respond w.r.t. different epochs. One option is to require strong consistency between servers, i.e. that they are always answering queries w.r.t. the same epoch, but this is expensive. Instead, we show in the full version [14] that we can relax our PAHD to account for this.

Client caching and reducing bandwidth overhead. At the end of Section 4, we discuss how OPTIKS-core makes storage and efficiency improvements that sacrifice some of the efficiency and privacy of lookups. We now describe some improvements that enable us to improve our lookup costs.

First, we observe that when a client performs a lookup, the client can record the latest version number; on subsequent lookups for the same key, the client only needs to retrieve membership/non-membership proofs for subsequent versions. The append-only property guarantees that the earlier versions will still be in the data structure. For example, if the client has already performed a lookup for a contact's key in the current time period and that key has not changed since, then the client only needs to retrieve and verify a single non-membership proof. If only a single key has been added since then, then the client only needs to check a membership proof for the latest key version and a non-membership proof.

The above cases indicate an efficiency improvement over the lookup protocols of SEEMless and Parakeet, which require always checking three membership/non-membership proofs. We note that for new lookups with many key versions, our algorithm remains more expensive; however we conjecture this is an outlier case, especially given that lookups return key versions only for the current time period. Clients could thus cache the most recent version numbers for their most frequent contacts and extend similar savings to history checks.[4]

For the second optimization, we note that our lookup as described in the core protocol requires sending *all* of the user's previous public keys in order to check membership proofs, which increases the bandwidth required for lookups. We can avoid this by modifying our oZKS primitive so that it checks membership proofs without also verifying the associated value. For a lookup the client just needs to know the current key and that the server stored prior versions of the key; knowing the values of the old keys is unnecessary. This would mean that lookups could send the membership proofs for old key versions without needing to send their associated values, reducing bandwidth.

These optimizations also reduce the leakage of lookups, since only the most recent value of the key and the epoch of

[4] ELEKTRA [13] does some similar client caching; in that case the goal is to reduce the signature verification costs as well as the communication. However, to implement this caching for ELEKTRA, the client must at least cache the set of keys currently authorized to sign updates, hence it would require more client storage than the caching in OPTIKS-ext.

addition for the new versions to be checked need to be leaked.

Account decommissioning. When a user stops using the system, they will presumably no longer be auditing their key history. We would still like to make sure that a malicious service provider cannot replace their key and impersonate them in future communications. To do this, we add an additional oZKS[5] which stores the usernames that have been decommissioned. This oZKS will not be reset at each time period; instead, the service provider will continue adding to the same oZKS throughout.[6] This means our storage will need to grow with the number of decommissioned accounts, but this growth will be much slower than the total number of key updates. A lookup for a key will return the usual oZKS proof and an additional proof that the associated username is not in the decommissioned-account oZKS. When the user requests that their account be decommissioned, we add their username to the decommissioned-account oZKS, and return a membership proof when this is done. See the full version [14] for more details.

Trade-offs of account decommissioning. Note that account decommissioning does have some significant trade-offs. Once a user decommissions their account, this would be irreversible (by design, since otherwise the server could potentially "reinstate" the account without the user's knowledge and use it to impersonate the user). This also means that there is no way for usernames to be reused – if the username is a phone number for example, and the user gives up that phone number, they could decommission their account, but if that number were given to another user they would be unable to use it for an account. This is somewhat by design – allowing account identifiers to be transferred between users significantly complicates both the transparency and the privacy guarantees.

In settings where account reuse is determined to be extremely important, we could modify our system to allow that at a cost of requiring some out-of-band checks and giving up some privacy. We describe in the full version [14] how this could be done, specifically in combination with our proposals for supporting multiple usernames as described below.

Supporting multiple devices and usernames. While our protocol thus far has assumed that each user has a single client device with a static username that can be mapped to their device's public key by the server, in practice it is often the case that a user will have multiple devices they wish to use with the same account. Furthermore, a user may wish to change the usernames associated with their account, *e.g.* if they use multiple email addresses, they may wish to associate an additional email with their account.

Because we want a single account corresponding to all of these usernames, it might seem like it makes more sense to index the user accounts based on an internal user id. However, this presents a serious problem for transparency, since users will have no way of knowing whether the internal user ids they are given are correct. It is crucial that these usernames are human-readable and human-memorable identifiers, such as phone numbers or email addresses, which the users can share with each other out-of-band. To understand why, let us consider a toy example. Say, both Alice and Bob are registered with the server with their usernames `alice` and `bob`, respectively. But, the (malicious) server tells Alice that Bob's username is `bobfake` and tells Bob that Alice's username is `alicefake`. The server can maintain 4 accounts now: `alice`, `bob`, `alicefake`, and `bobfake`. Since Alice will monitor her own account (`alice`) and Bob will monitor the account he thinks belongs to Alice (`alicefake`), no inconsistency will ever be caught by the KT system. In other words, a KT system can only ensure that a consistent view of the history of the key evolution is maintained for each username and that the username is unique within the system.

To meaningfully translate this guarantee for users, it is of paramount importance that the users know each other by the correct usernames. However, many E2EE communication systems have an internal immutable representation of a username (such as a Uniquely Universal Identifier, or UUID) and this is what they use to index the directory. This UUID is different from the public-facing username [15]. It is meaningless to expose these UUIDs directly to human users. Moreover, many services may choose to allow a user to pick multiple public-facing usernames that internally represent the same UUID (such as multiple email addresses). We argue that KT systems should aim for the stronger goal of providing security no matter which username a user's contact chooses for key lookups. Systems in deployment have acknowledged this as an issue [4] as well but no prior work exists integrating this into a KT system.

To address this, we change our key-update PAHD to map device ids to public keys and add two additional data structures. The first is an oZKS[7] (called username oZKS) that maps each username to its associated user id, and the other is a PAHD (called device-list PAHD) that maps each user id to a list of its associated device ids. This separation also allows a user to have multiple usernames tied to the same account in a straightforward way.

In response to a lookup for a particular username, the service will return the corresponding user id and a proof w.r.t. the username oZKS, the list of devices and a proof w.r.t. the device-list PAHD, and the current public keys for each device[8] along with proofs according to the key-update PAHD.

[5] We only need an oZKS, not a full PAHD, as we do not want entries in this datastructure to change once they have been added.

[6] Note that this reduces the PCS in that an attacker who gains the secret will be able to check whether accounts have been decommissioned, and this ability will persist even when we move to a new time period.

[7] As discussed above, we assume that usernames are not reused, and that once a username is associated with a particular user, that never needs to change. See the full version [14] for discussion of an alternative.

[8] Or if the Lookup specifies a particular device, it can just return the current key and proof for that device. In either case, it will return the list of

This provides the desired transparency and has the advantage that changing one device's public key, adding/removing a device, or adding a username requires an update to only a single oZKS entry. Note that if we want to combine this with the account decommissioning discussed above, we would be concerned with the case where the user wants to decomission his entire account and no longer do any monitoring. In this case we would user a decommissioning PAHD which stores the user ids corresponding to decommissioned accounts. When combined with time periods, we would want the username oZKS to be persistent and not regenerated every time period. See the full version [14] for more details.

Privacy analysis of OPTIKS-ext. We assume that the update proofs are publicly available. The leakage in our system comes from the two building blocks: oZKS and PAHD. oZKS updates reveal the number of items added each epoch. an oZKS query for an item reveals when that item was added, or (in case of non-membership) allows the user to recognize if that item is added in the future. PAHD updates reveal the combined total number of items added or updated each epoch. A PAHD query (with the second bandwidth optimization above) for an item reveals the item's current value, and the epochs at which any previous updates where made. It will also allow the user to recognize if/when that item is added later.

Based on this our OPTIKS-ext reveals the following information: The system reveals the number of decommissioned users in the system at every epoch (from the decomissioning oZKS), and the number of usernames, users, and devices in the system at the beginning of each time period (from the username oZKS, device-list PAHD, and key-update PAHD, respectively). For each epoch it also reveals the total number of keys updated/added, the number of device lists modified, and the number of usernames added (from the key-update PAHD, device-list PAHD, and username oZKS respectively). In addition, (from the PAHD query functionality and leakage), when Bob queries for Alice's key, he learns 1) how many devices she has, and what their current public keys are, and 2) any changes to her device list or public keys that have occurred since the beginning of the current time period. He will also be able to tell when she next updates her device list and when she next updates each of her keys if those changes happen during the current time period (again from PAHD query leakage), and recognize if/when she decomissions her account (from the decommisioning oZKS). He will learn nothing about updates to Alice's key or device list that occur outside of the current time period.

This is incomparable to the leakage in systems like SEEMless or Parakeet. One the one hand, those systems only reveal information about the single preceding key update, whereas we may reveal information about multiple updates if they occur in the same time period. On the other hand, they reveal information about the preceding key update no matter how long ago it occurred, while we limit leakage to updates occurring in the same time period. We are also strictly better in terms of leakage about future updates – we reveal when the next update occurs only if it is within same time period, while SEEMless/Parakeet always reveal this information. SEEMless and Parakeet also reveal information about some additional future updates because of the complex "marker" system that they user; we do not reveal any such information.

devices and proof w.r.t. the device-list PAHD.

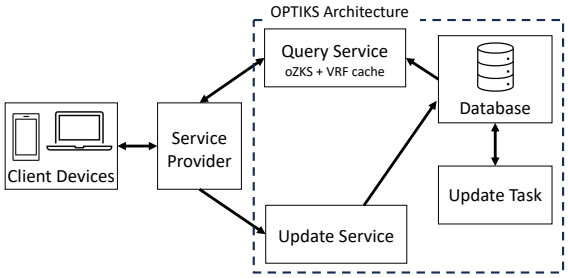

Figure 2: The system overview. The boxed area indicates the system architecture components introduced by OPTIKS.

6 System Architecture and Implementation

Prior works consider only monolithic service providers, avoiding details on how to efficiently handle both query and update requests, as well as how to scale both aspects of the system. We introduce an improved system architecture, which may be applied to other Merkle tree-based KT systems as well. Our oZKS implementation consists of roughly 5000 lines of C++. The rest of OPTIKS consists of roughly 2000 lines of C/C++, and roughly 1600 lines of ASP.NET.

System Components. We present a diagram with an overview of the OPTIKS system and architecture in Figure 2. At a high level, we physically separate the query component, called the *Query Service*, from the update component, composed of the *Update Service* and *Update Task*. This approach has several benefits. To understand why, note that the service provider of a KT system will likely need to support a vast number of concurrent key lookups, where the same key is likely to be queried multiple times within a short interval (*e.g.*, if a new group call or message thread is started). However, we expect that there will be far fewer update requests, which are only handled at epoch boundaries. Our split architecture design has the benefit that it can scale each component separately, responding more appropriately to the different needs of the different components. Since the different components benefit from different data layouts and caching mechanisms, the split architecture enables better use of compute resources, ultimately resulting in improved performance. Importantly, it avoids service interruptions for key lookups when updates take place at each epoch change. Finally, separating components in this way makes it easy to ensure data

consistency across the entire system, since the Update Task, as we will describe in more detail, is the only component that performs database transactions. Each component can be separately scaled up through multiple parallel threads, processes, or VMs, as needed.

In more detail, the Query Service and Update Service are implemented as web services providing REST APIs for key lookups and updates, respectively. The Update Task runs periodically to update data and write required changes to the database. When the Service Provider receives key lookup or update requests, it calls the Query Service or Update Service API, respectively, on behalf of client devices.

Next, we go over details of the oZKS and VRF cache, as the design of these includes most novel aspects and has a significant impact on the other components as well. In the full version [14], we provide more details on the Query Service, Update Service, and Update Task.

oZKS and VRF cache. Recall that the core building block for OPTIKS is a PAHD, which itself is built from an oZKS. (See the full version [14] for a detailed description.) We implement the PAHD as a combination of the oZKS primitive and logic embedded in the Query Service, Update Service, and Update Task. We implement the oZKS as a C++ library, using BLAKE2 [3] as our cryptographic hash function.

One of the important components for constructing the oZKS is a verifiable random function (VRF), defined in more detail in the full version [14]. In short, each key that needs to be stored is added as a label-value pair to the oZKS. The label is computed using the VRF so that all labels appear random. This means that much of the computational overhead of the system will be from VRF and VRF proof computations, which are expensive public key operations. Thus, a crucial challenge of a scalable KT system is handling the ever increasing load from VRF operations.

OPTIKS addresses this issue by integrating a built-in VRF cache for the oZKS to store recently used VRF values and proofs for fast repeated access. Looking ahead, this feature enables far higher key lookup throughput for the key directory. We implement the VRF by adapting the IRTF internet draft ECVRF [9] to use the fast Four$\mathbb{Q}$ curve [8] that allows for an extremely fast hash-to-curve implementation and variable-base scalar multiplication, as discussed in [7].

The Query Service and the Update Task both hold local copies (full or partial) of the oZKS data. However, these components interact with the data in very different ways. In particular, the Query Service needs to support quick horizontal scaling without requiring large database reads, and running instances must be able to quickly apply targeted updates to their internal data structures. The Update Task needs to be optimized for updating the entire oZKS data structure according to pending update requests. OPTIKS thus optimizes the oZKS for each component by running in one of two modes, one tailored to the demands of lookups and the other for updates. This ability to customize the oZKS is another benefit of our split architecture approach. The two oZKS modes are:

- *Stored mode.* In this mode, the Merkle tree nodes are held in a customizable storage system, *e.g.*, a hash table in memory or a database with a memory cache. While this mode is slower and has a higher memory overhead, a major benefit of this implementation is that updates to specific nodes can be easily retrieved from the storage as needed. Thus, the oZKS instance running in the Query Service uses stored mode to enable fast and flexible updates.
- *Linked mode.* Here, the Merkle tree nodes are all allocated in memory in a *linked tree*, which allows for very fast queries and updates. The nodes can still be mapped to storage, but partial updates to the linked tree are difficult to implement, making this approach unsuitable for the Query Service. Instead, our Update Task runs the oZKS instance in linked mode to leverage fast updates.

Our oZKS implementation includes a flexible storage mechanism that enables integration with almost any desired storage back-end. We instantiate this with a Microsoft SQL Server database with an adjustable in-memory cache. The description of the tables used in our implementation is in the full version [14].

7 Performance Evaluation

In this section we discuss the performance of our implementation. Since the oZKS forms the core data structure which commits to keys, we first measure benchmarks of its performance in isolation. Next, we evaluate the full OPTIKS system and then compare our performance to related prior work.

In our evaluation, we wish to answer the following questions about OPTIKS:

- *oZKS costs*: what are the computation costs and memory overhead for lookups and updates of the oZKS?
- *Lookup costs*: what is the maximum number of queries per second OPTIKS can support?
- *Update costs*: what is the maximum number of key updates per second OPTIKS can support? What is the average time required to create a new epoch?
- *Comparison*: how does the performance of OPTIKS compare with prior related systems?

7.1 oZKS Benchmarks

We first measure performance benchmarks of the oZKS in isolation. This includes microbenchmarks of VRF operations, server query and update costs, and client costs. The results are presented in Table 1.

Experimental setup. We run the oZKS benchmarks on an Azure `E16ads_v5` virtual machine, with 16 vCPUs @

Size	Server Query			Server Update			Client Query		Client Update	
	Memory	Throughput (10^3 queries/s)		Memory	Time	Throughput	Time	Size	Time	Size
(# keys)	(GB)	Cache hit	Cache miss	(GB)	(s)	(10^3 updates/s)	(μs)	(KB)	(μs)	(KB)
2^{20}	0.734	143	16.7	0.517	6.66	140	102.9	2.10	12.6	1.89
2^{22}	3.54	129	15.0	2.00	27.6	144	103.4	2.27	13.7	2.06
2^{24}	14.7	120	13.9	7.95	120	132	104.2	2.44	14.7	2.23
2^{26}	60.2	112	12.4	32.0	520	126	104.8	2.67	15.6	2.40

Table 1: Benchmarks for the oZKS implementation for different numbers of keys. It includes the memory and throughput for the oZKS as instantiated for the Query Service (stored mode); memory, time, and throughput for the oZKS as instantiated for the Update Task (linked mode); client overhead for oZKS query and update proof verification.

2.60 GHz and 128 GB of RAM. Recall from Section 6 that the oZKS runs in two modes: stored mode (for key lookups in the Query Service) and linked mode (for the Update Task). For measuring oZKS query costs, we run experiments in stored mode on a single thread. For measuring oZKS update costs, we run experiments in linked mode using 16 threads. (For details, see the full version [14].)

VRF microbenchmarks. Since the bulk of the computational overhead of the oZKS comes from VRF operations, we first measure these. The time to compute a VRF value (without a proof) is on average 20.5 μs. Computing the proof takes 47.0 μs, while verifying the proof takes 95.6 μs.

Server query costs. We measure the total memory footprint and query throughput for different oZKS sizes (*i.e.*, number of keys in the oZKS). Recall that the OPTIKS architecture includes a VRF cache to reduce the overhead costs of the server during queries. We thus measure query costs for both VRF cache hits and misses. We performed the experiment twice by querying for keys that are present and not present in the oZKS; we report numbers for the slower case (generally, for keys not present), although the difference is very small. Overall, we find that VRF cache hits enable nearly an order of magnitude greater oZKS query throughput for the server.

We also see from Table 1 that the stored mode oZKS used for queries requires more memory than that of the linked mode instantiation for updates. As explained in Section 6, despite the benefit in smaller memory overhead, linked mode offers less efficient updates to parts of the tree, as our Query Service requires. However, the stored mode oZKS memory overhead could be reduced, such as by storing only the most commonly accessed nodes in memory or dividing the service over several machines.

Server update costs. Our experiments insert new keys into the oZKS in batches of at most 1024 keys. For different oZKS sizes, we show the total memory footprint, the total time to insert all keys, and the update throughput in updates per second on 16 threads. These costs include VRF computations.

Our experiments indicate high performance for the server. Namely, with a single machine, the Query Service oZKS can process well over ten thousand (VRF cache miss) or a hundred thousand (VRF cache hit) queries per second. The Update Task oZKS can sustain a similarly high throughput. However, looking ahead, the picture changes significantly when we deploy this in the context of a full system including the overhead from database operations, the REST API, and the networking protocol.

Client costs. Finally, we measure the query and update proof verification time and data size. The experiments for querying include the time to verify the query result, which includes both the VRF proof and Merkle tree proof, on a single thread, and the size of the query response. The experiments for update include the time to verify the update proof for a single added key on a single thread and the data size of the update proof for a single added key. This is intended to measure the overhead for a client to verify that its key update was added to the system. The data sizes do not include networking protocol overhead or the time to download the proofs. We note that since the update proof results apply only to a single added key, they will scale linearly with the size of the batch inserted.

Overall, the client numbers in Table 1 indicate a nearly negligible cost from the oZKS operations. We note that a client would perform these operations only sporadically, *e.g.*, before joining an end-to-end encrypted meeting.

7.2 System Evaluation

We now evaluate a fully implemented system. We perform smaller benchmarks to enable direct comparisons with prior work as well as larger scale measurements to understand the performance of OPTIKS for realistic system loads.

Experimental setup. Our system implementation omits the Service Provider, as its role is to mainly mediate requests and implement authentication logic. We run the Query Service, the Update Service, the Update Task, and the database in Azure in the West US 3 region. We use a stress tester application running in Azure in the West US 2 region as the client.

For more technical details on the Query Service, Update Service, and Update Task implementations, see the full version [14].

Query rate. We measure the maximum query rate, *i.e.*, the maximum number of key lookups per second the Query Service could support. To test this, a small program was written that continuously sends query requests to the REST API. The number of instances of this program running simultaneously was increased until the maximum query throughput was found. We tested the maximum query rate when querying for keys with 1 version and 10 versions in their history. We also measured the average size of the key lookup response. These experiments were performed for key directory sizes ranging from 1M keys to 64M keys. The results are shown in Figure 3.

One takeaway from these experiments is that the Query Service performance is limited by networking overhead. In particular, the key lookup throughput of the full OPTIKS system for a single key version is much lower than that of just the oZKS from our benchmarks in Table 1. Another takeaway is that a key lookup for a key with many versions is less performant than that for a key with a single version. To explain this, we note that the communication cost is linear in the number of key versions and logarithmic in the size of the key directory, which adds to the overhead when querying for keys with longer histories. In practice, however, this overhead can be reduced by allowing client devices to cache previously retrieved key versions. Furthermore, the Query Service can be made more performant by scaling it horizontally to alleviate handling so many simultaneous network connections.

Update Service and Task. We set the Update Task to activate each second so that if no prior update is in progress, it takes a batch of at most 1024 pending updates from the database and starts processing them. This limits the epoch time from below to 1 second.

We measure the maximum key update rate, *i.e.*, the maximum number of key updates per second that can be supported. We also measure the average time it takes to create a new epoch. The results are in Figure 4a. They show the cost of adding keys increases logarithmically. Most of the epochs we observed took 1–5 seconds; some took longer due to unpredictable and fluctuating database response times. The longest epoch observed took 13 seconds.

We next measure the time needed by the Update Task to add 100K keys with different initial directory sizes, and how that time is spent in different operations. The results are in Figure 4b. The Update Service/Task performance is strongly limited by the database performance (compare to the oZKS update performance in Table 1). Indeed, our results show that the bulk of time is spent on database writes. For example, when the key directory has 500K keys, nearly 95% is spent in database operations. This cost is caused by the very expensive (and possibly avoidable) multi-table transactions that we used to simplify the implementation. This percentage decreases slightly when more keys are added, and generally hovers between 94–96%, which means that any improvement in the database (write) performance would almost directly translate to a performance improvement in OPTIKS.

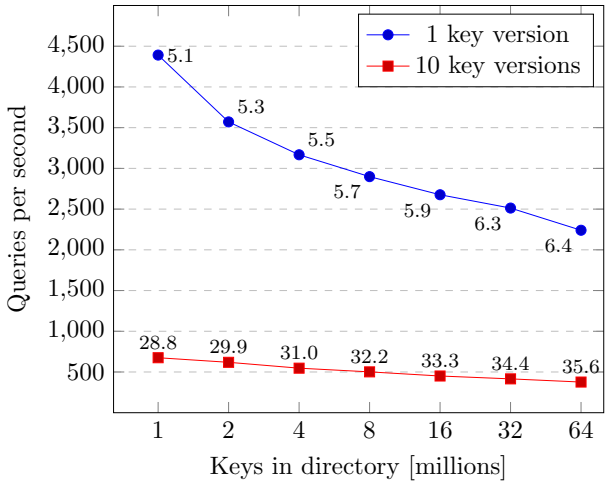

Figure 3: Key query rate as the directory grows in size from 1M to 64M, with a logarithmic scale on the x-axis. The number beside each point indicates the server response size in KB.

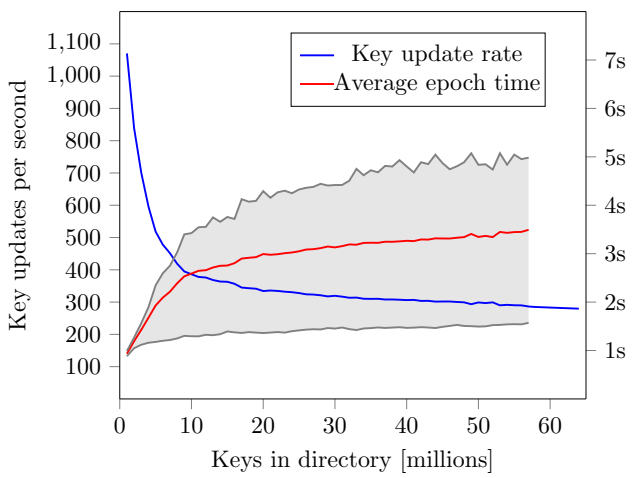
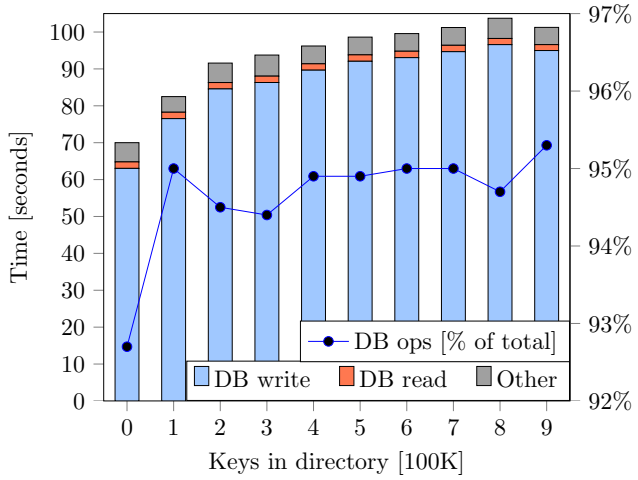
7.3 Comparison and Analysis



We analyze the results of our experiments and compare OPTIKS to Parakeet [16], the most relevant prior work. We then compare with Merkle^2 [10] and SEEMless [5].We omit comparison to CONIKS [17], as its client monitoring costs are prohibitively expensive for short epochs.

For the most rigorous comparison, we directly run the most recent public version of Parakeet, unless otherwise mentioned, and OPTIKS on the same VM with 16 vCPUs. In all cases, we insert into, or query from, a key directory of size 1M.



Summary. Overall, our results indicate that OPTIKS features a large performance benefit over Parakeet. This improvement comes from several core elements, most notably: (1) a more efficient protocol; (2) the split architecture of OPTIKS leveraging more optimal memory representations and more efficient parallel updates; (3) a faster VRF from using a curve that has particularly fast variable-base scalar multiplication and hash-to-curve implementation; (4) better engineering of performance-critical functions; and (5) a VRF cache that improves the Query Service performance. We next go into more detail on some of these improvement points.

VRF performance. The VRF value computation in Parakeet takes roughly 50μs, whereas OPTIKS takes only 20.5μs, so we are more than 2x faster. For proof generation, Parakeet takes 144μs, whereas OPTIKS takes 47μs; here we are more than 3x faster. In both cases, this is because we are using a curve that is much better suited for the VRF computations.

Update performance. For single-threaded execution on a hash map or hash table storage back-end, implemented both

(a) Keys update rate and average epoch time when the key directory grows in size from 1M to 64M. The shaded region shows the interquartile range for the epoch time measurements.

(b) Time it takes to add 100K keys. The bar graph shows the breakdown into database operations and a category *Other*, which includes the Update Task compute time. The line graph shows the database operations as a percentage of the total time.

Figure 4: Benchmarks for the key update performance.

in Parakeet and OPTIKS, our update (into key directories with 1M keys) takes 71ms per 1024 items, whereas Parakeet takes 347ms per 1024 items. This means that, even without improvements from our split architecture, OPTIKS is already 4.8x faster for updates than Parakeet. We believe this is explained primarily by our faster VRF and a better way to compute the common prefix of two labels.

In our split architecture, we store the nodes in a linked representation for the Update Task. For a single-threaded execution this takes our time down to 28ms per 1024 items, demonstrating the benefit of our architecture. This avoids more costly lookups from a hash table or hash map and can be leveraged by most Merkle tree-based transparency systems.

Another benefit is that multi-threaded batch update is much more efficient with our linked mode. Adding multi-threading in OPTIKS takes our update time down to 7.6ms per 1024 items (3.7x improvement), whereas adding multi-threading in Parakeet results in only a 1.3x improvement at 270ms per 1024 items. We believe this is explained by our implementation of multi-threading that requires no locks, while Parakeet implements multi-threading by spawning threads that need to wait for child tasks to be completed before continuing. We note that at this point we outperform Parakeet update performance by more than 35x. The situation is evened out by the full system overhead (*e.g.*, database), but even then, comparing to the results in the Parakeet paper, we achieve in many cases up to (or over) 10x better throughput.

Lookup performance. The Parakeet paper presents no query performance numbers. If we disable our VRF cache and compare single-threaded executions, we reach a rate of roughly 32 queries/s (from a 1M size key directory). Running Parakeet ourselves shows a performance of roughly 1.3 queries/s. Thus, OPTIKS is more than 24x faster.

Note, however, that our experiments are for the most common case, where we expect users' key to not change often. Recall that with v key versions, an OPTIKS key lookup requires $v+1$ proofs (without any client-side caching), whereas Parakeet always requires 3 proofs. When a user's key does not change, a lookup proof for OPTIKS requires only 2 Merkle proofs per query, less than the 3 proofs required by Parakeet. However, when a user's key changes multiple times within a time period, OPTIKS requires more proofs than Parakeet.

Thus, a better way to compare is to observe the cost of each Merkle proof. Measuring per Merkle proof, we are 16x faster, which we hypothesize is due to architectural differences between the two systems; see below for more discussion. This means that OPTIKS is more performant for lookups than Parakeet up to $v = 3 \cdot 16 - 1 = 47$ key versions. With time periods, it is unlikely typical users will require so many versions.

Enabling the VRF cache changes the situation a lot, improving our performance (upon cache hit) further by around 9x. Multi-threading queries is trivial in both works. Note that our architecture allows the query service to keep running seamlessly while an update is being processed, whereas it is not clear at all how Parakeet would handle that.

Engineering differences. We note that although much of the key lookup performance improvements of OPTIKS over Parakeet are from protocol and system improvements, some of this gap is explained by better engineering design. In particular, the monolithic architecture of Parakeet requires it to use

excessively thread-safe constructions in its implementation. Notably, the same system that supports queries (occasional locking required) is also used for updates (frequent locking required). These constructions end up being inefficient and do not provide an ideal solution in either case. Furthermore, Parakeet's implementation uses many dynamic arrays for data which creates unnecessary overhead as compared with using statically sized arrays.

Comparison to Merkle^2. Since Merkle^2 does not present full system benchmarks, we cannot directly compare the end-to-end performance of key lookups and updates, which would include database operations. Instead, we compare the append and lookup throughput in [10, Fig. 13] to the oZKS update and query throughput in Table 1. This gives a comparison of our core data structures without the extra system overhead costs.

For key updates, our reported update rates are more than 100 times that of Merkle^2. For key lookups, we note that each query to Query Service requires (with one key per user) two lookups from the oZKS. Thus, for fair comparison we divide our oZKS query rate by two to approximate our Query Service throughput. For 2^{20} keys, assuming VRF cache misses for the worst case performance, OPTIKS supports 8350 queries/s, while the Merkle^2 *Latest value* query supports fewer than 5000 queries/s.

We next compare to the approximate memory cost reported in [10, Fig. 12]. For 2^{20} keys, this is 22 GB – much larger than our 517 MB. The difference grows for larger key directories (2^{20} is our *smallest* example), as Merkle^2 has an asymptotically larger memory cost.

Finally, we compare our proof sizes and verification times to [10, Table III]. In their setting the key directory has 1 million keys; we compare this to a slightly larger 2^{20} size key directory. Merkle^2 has a very small append proof size of 42 B, whereas our update proof is significantly larger at 1.89 KB. Their lookup proof (for *Latest value* query) is 9.8 KB, whereas our proof is smaller at 4.20 KB. Here we have doubled the lookup proof size from Table 1 to account for the two oZKS lookup proofs each query to the Query Service requires.

Comparison to SEEMless. Just as for Merkle^2, SEEMless [5] also presents no full system benchmarks with which we can directly compare the full system experiments of OPTIKS. Thus, we again compare their results to our oZKS benchmarks in Table 1.

We first compare with their key update time [5, Figure 5]. For a key directory with 10 million keys, SEEMless reports an average update time of slightly under 0.3 seconds. At 2^{24} keys our average update time is roughly 7.6 milliseconds, or just 2.5% of the time of SEEMless.

For key lookups, we compare with [5, Table 2], again dividing our query rates by two for fairer comparison. At 2^{24} keys, our average query time is roughly 0.14 milliseconds, or just 2.4% of the 6.03 milliseconds reported for SEEMless. For query verification, our result of 104.2 microseconds is just 1% of the 10.51 milliseconds reported in [5, Table 2].

These performance differences are much larger than the asymptotic differences indicated in Figure 1 would suggest, and is generally explained by our more efficient implementation. In particular, our VRF operations are between 35–63 times faster than in SEEMless due to the more efficient elliptic curve we use and engineering differences in the VRF implementation itself. This has a huge impact, since a single VRF operation in SEEMless is reported to take between 1.3–3.4 milliseconds – a significant fraction of the total time. Note that the machine used in [5] was running at a slightly lower clock rate than ours (2.30 GHz vs. 2.60 GHz), but had more vCPUs. SEEMless was implemented in Java, whereas our implementation is mostly in C++.

In SEEMless, for 10 million keys, the authors report an average query response size of 8.40 KB. At 2^{24} keys our average query size is 4.88 KB, or 58% of that. Again, here we have doubled the lookup proof size from Table 1 to account for the two oZKS lookup proofs each query to the Query Service requires.

8 Related Work

We have already discussed how our KT system OPTIKS compares with Parakeet [16] and SEEMless [5].

Merkle^2 [10] is another KT system and is currently under consideration for standardization by the IETF working group on KT [18], so we briefly compare its protocol to OPTIKS. However, we emphasize that Merkle^2 cannot be truly compared to OPTIKS because their assumptions make it unsuitable for our use case, and it also lacks the strong privacy guarantees required for KT. In particular, [10] strongly relies on owner signing (and long term, non-resettable) signing keys to build a KT system. Since the fundamental goal of a KT system is building a transparent PKI for client keys, basing it on an external PKI does not serve the purpose.

At a high level, Merkle^2 trades off small update proof costs for large storage costs, while we opt for much smaller storage costs and larger update proof costs. We believe ours is the right trade-off because the large storage costs of Merkle^2 prove unscalable in practice, while auditing our update proofs are still practical even at large scale. We confirm this via experimental comparisons in Section 7.3 as well as offer a more comprehensive asymptotic comparison in Appendix A.

Now, we briefly describe the other KT systems from the literature. Keybase [11] was originally designed as an alternative to PGP key distribution and did not target privacy as a goal. CONIKS [17] was the first academic proposal for a KT system. The efficiency and privacy guarantees of CONIKS were improved in SEEMless [5]. VeRSA [20] and Verdict [22] are other KT systems that use SNARKs and RSA accumulators instead of Merkle trees, making them more expensive to deploy in practice. They also do not target privacy as a goal

and so leak update patterns of users. Chen *et al.* [6] was the first paper that introduced Post Compromise Security (PCS) for the underlying building block of our primitive: *ordered Zero-Knowledge Sets* (oZKS). We describe how we achieve a limited form of PCS security in OPTIKS-ext in Section 5.

In another recent work, ELEKTRA [13] adds privacy and formal analysis to the Keybase approach. The result is a system that provides stronger security in the multi-device setting by requiring that each change to a user's set of devices be signed by another of their devices; this provides stronger security against a malicious server, as long as the user has multiple devices. ELEKTRA also adds PCS security by using the rotatable zero-knowledge set from [6] mentioned above. (As mentioned in Section 5, OPTIKS provides only a limited form of PCS.) ELEKTRA provides formal definitions and proofs for the entire system, and uses a stronger (extractability) form of soundness definition compared with prior work. However, with the exception of multi-device support, it does not consider any of the issues we address in Section 5. And since the aim of the ELEKTRA implementation was an academic prototype rather than a scalable implementation, they did not consider the architectural optimizations that we discuss in Section 6. For example, their lookup query service reads from the database on every query (as opposed to using an in-memory cache), resulting in dramatically slower query times compared to OPTIKS.

At an algorithmic level, because ELEKTRA adopts the Keybase approach, each lookup for a username returns the full linear history of changes to that username's keys, which is similar to our lookup approach. As a result, similar to our construction, ELEKTRA also avoids the need for a second tree to provide freshness. On the other hand, it incurs some additional storage and computation costs from the need to store and verify public keys and signatures.

A Comparison of OPTIKS with Merkle^2

The design for Merkle^2 incorporates a forest of chronological Merkle trees where each key-value pair forms a leaf. Each internal node of this tree is associated with a separate prefix tree that stores key-value pairs arranged in lexicographic order that appear in the subtree rooted at the internal node.

The benefit of this design is that update proof sizes remain smaller in their structure because every epoch is an extension of those before it with nodes in the same order as before. For n key-value pairs, this means that auditing requires checking $O(\log(n))$ hashes. To minimize storage costs, however, our tree changes between epochs and internal nodes are also updated. Thus, for the audit proof in OPTIKS, auditors must download both the k nodes that have been added and the $O(k\log(n))$ roots of unchanged subtrees, which represent the nodes that have not been changed.

Nevertheless, these small update proof sizes come at the cost of significantly larger storage requirements. Merkle^2 requires $O(n^2\log(n))$ of unoptimized storage which can be optimized to $O(n\log(n))$ storage. In contrast, OPTIKS only ever needs $O(n)$ storage. Indeed, our experimental results in Section 7 support that OPTIKS requires far less storage.

For lookup costs, if a key has ℓ versions, then the proof size for Merkle^2 is $O(\ell+\log^2(n))$ in the unoptimized case, where the user must check ℓ signatures and $\log^2(n)$ membership or non-membership proofs. Merkle^2 offers an alternative algorithm that avoids checking the ℓ signatures but this assumes that each client must have a separate master key pair which it can never lose or change. We do not view such an assumption as tenable in practice.

OPTIKS instead requires lookup proofs of size $O(\ell\log(n))$ (excluding VRF proofs, which Merkle^2 does not use because it does not target privacy). When a client has few key versions such that $\ell < \log(n)$, then our lookup cost is less than that of Merkle^2. However, we do note that if a client has a particularly large number of key updates for a given time period, then the lookup cost for OPTIKS can be more expensive than Merkle^2. Our experimental results in Section 7 measure the former case and show that our lookup proof size is indeed smaller in this case.

Understanding the Security and Privacy Implications of Online Toxic Content on Refugees

Abstract

Deteriorating conditions in regions facing social and political turmoil have resulted in the displacement of huge populations known as refugees. Technologies such as social media have helped refugees adapt to challenges in their new homes. While prior works have investigated refugees' computer security and privacy (S&P) concerns, refugees' increasing exposure to toxic content and its implications have remained largely unexplored. In this paper, we answer how toxic content can influence refugees' S&P actions, goals, and barriers, and how their experiences shape these factors. Through semi-structured interviews with refugee liaisons (n=12), focus groups (n=9, 27 participants), and an online survey (n=29) with refugees, we discover unique attack contexts (e.g., participants are targeted after responding to posts directed against refugees) and how intersecting identities (e.g., LGBTQ+, women) exacerbate attacks. In response to attacks, refugees take immediate actions (e.g., selective blocking) or long-term behavioral shifts (e.g., ensuring uploaded photos are void of landmarks) These measures minimize vulnerability and discourage attacks, among other goals, while participants acknowledge barriers to measures (e.g., anonymity impedes family reunification). Our findings highlight lessons in better equipping refugees to manage toxic content attacks.

1 Introduction

Deteriorating socio-political conditions in many countries have resulted in a crisis of displacement. Many victimized populations have been forced out of their home countries, seeking shelter and safety in neighboring or distant regions. Referred to as refugees, this population has fled unsafe conditions in search of a new home. More recently, the usurpation of power in Afghanistan and the invasion of Ukraine have led to a refugee crisis impacting over 11 million refugees [4, 85].

[*] Authors Arunasalam, Farrukh and Tekcan have made equal contributions to this work.

Refugees share a commonality in their experiences as a vulnerable population. They face challenges in displacement (e.g., adjusting to a new culture and language, economic disadvantage, and power dynamics due to legal status). Although members within this population have varying levels of digital literacy, prior work has shed light on how technology use amongst refugees benefits them [7, 53, 94]. As such, it has become evident that refugees widely use technology and, by extension, social media. For instance, work has highlighted how refugees use social media to organize their migration and build a life in their new homes [6, 40, 55].

Forced displacement of refugees has propelled this population to the center of many conversations on social media, which can be neutral or positive in nature. However, toxic content about/against refugees has recently proliferated, fueled by social, economic, and political factors [11, 87] and fake news [69]. Attackers emerge in online spaces, perpetrating toxic content to express hate against refugees, intimidate, and even bully individual refugees, among other reasons.

Toxic content attacks are a form of online hate and harassment [81], and can negatively affect individuals (e.g., heightened anxiety, depression) [77, 78]. However, the experiences of marginalized populations, i.e., refugees, can lead to intricacies in toxic content exposure and security and privacy-driven responses. Prior research has focused on online hate's impact on general populations and groups such as content creators [81, 82], while another line of work has explored understanding narrative justifications behind toxic content against refugees [11, 87]. Within the context of refugees' computer security, one work examined challenges the population faces, e.g., low literacy, to protect their computer security and privacy as newly resettled refugees [73]. However, research examining how refugees' experiences can produce nuanced toxic content exposure and how this exposure influences their digital behavior, i.e., responses and barriers that prevent security-privacy mechanisms, is largely absent.

In this paper, we conduct the first study to explore: **what are the impacts of toxic content exposure on refugees and corresponding security and privacy measures they take?**

To answer this, we first conducted semi-structured interviews with refugee liaisons (n=12) - individuals who work closely with refugees from four countries. These interviews provided insight into how toxic content affects refugees' digital presence and their responses. We then conducted focus groups (n=9, 27 participants) and an online survey (n=29) with refugees themselves to gain a deeper understanding of the specific goals of refugees' actions and the barriers they face. Our recruitment faced challenges due to the load interested parties faced caused by the recent and tragic Afghanistan and Ukrainian refugee crises. However, over one year, we interviewed/surveyed diverse refugee liaisons and refugees whose experiences were grounded in their use (or served refugees' use) of social media, exposure, and response to toxic content.

Our qualitative coding and quantitative analysis revealed novel insights into refugees' experiences on social media. Participants' social media dependency extends beyond general population use; they use it to source aid from support groups (other refugees and NGOs), and to rejoin family/friends separated through the refugee crisis. Participants' toxic content exposure coincides with the emergence of online conversations centered on the refugee crisis; they find themselves targeted after commenting on hate directed at refugees by attackers, who infiltrate closed groups. Intersecting identities (e.g., gender, sexuality) exacerbate threats, which are often perpetrated by strangers but can also originate from affiliates (e.g., neighbors) due to ambiguity behind one's refugee status.

Participants take security and privacy responses towards attacks, broadly categorized into immediate responses, e.g., selective blocking of attackers, using various reporting channels, and long-term behavioral changes, e.g., platform withdrawal and rigorous privacy measures. Participants' experiences result in response intricacies. For instance, participants express how toxic content against refugees is interpreted/disguised as expressing a political opinion, resulting in unfavorable results after reporting. Similarly, decisions to ignore toxic content are due to power imbalance; participants fear responding against these attackers, who are often residents/citizens.

Our participants also express goals to minimize vulnerability and discourage toxic content while also detailing barriers associated with privacy and anonymity (e.g., inability to change usernames as it complicates family reunification). Participants also advocate for platform involvement in mitigating toxic attacks while also acknowledging shortcomings in existing methods. They raise themes such as flawed censorship due to the contextual nature of toxicity while expressing distrust of automated toxic content detection on online platforms.

Our study extends efforts to understand at-risk users' experiences and how they shape S&P concerns. We conclude by synthesizing lessons on toxic content threat models, detection, and enforcement for online platforms to create a better online experience for refugees. We outline the necessity for refugee aid organizations to disseminate security and privacy advice on toxic content for refugees.

In this paper, we make the following contributions:

- We design protocol to understand toxic content's S&P implications on refugees. We conduct 12 semi-structured interviews with refugee liaisons and leverage insights to organize nine focus groups with 27 refugees and survey 29 refugees.
- We understand how refugees' experiences shape their (1) toxic content threats, (2) corresponding responses and goals, (3) barriers, and (4) mitigation perspectives.
- We synthesize lessons for (1) threat models, (2) toxic content detection and mitigation, and (3) S&P guidelines. We also outline future directions and interventions to aid platforms and NGOs in combating toxicity.

2 Background

2.1 Refugees and Liaisons

In this paper, we use the UN Refugee Agency's (UNHCR) definition of refugee, "someone who is unable or unwilling to return to their country of origin owing to a well-founded fear of being persecuted for reasons of race, religion, nationality, membership of a particular social group, or political opinion" [86]. The country a refugee flees to is referred to as the "hosting country". As of 2022, there are 35.3 million refugees, comprising many nationalities, cultures and religions [66].

Refugee liaisons are those with established close working relationships with refugees, either through professional/volunteer service or interaction with them. They encompass various professions, e.g., medical doctors and lawyers who predominantly serve refugees. Refugee liaisons are also NGO workers who provide refugees aid/services, and researchers such as academics who closely interact with refugees for academic study. For our study, we only consider liaisons that: (1) have had direct interaction with refugees through service, research or work, and (2) have observed and discussed social media use with refugees.

2.2 Toxic Content

Toxic content is an online attack, that falls under online hate and harassment. Thomas et al. define toxic content as "a wide range of attacks involving media (e.g., images, text) that attackers send to a target or audience, without the necessity of more advanced capabilities (e.g., does not require privileged access or deception)" [81]. Toxic content has the ability to impose a variety of harm, such as damaging one's reputation, affecting sexual safety, coercion, and intent to silence. Toxic content can also be broken down into different types of attacks (e.g., bullying, hate speech, and threats of violence). For instance, trolling is defined as toxic content that intentionally

provokes someone/group of people with inflammatory remarks. A complete description of toxic content subcategories we cover in our paper can be found in Appendix Table 1.

The ability of toxic content to spread on online platforms has incentivized guidelines that discourage toxic content posts. For instance, social media platforms such as Twitter have hateful conduct guidelines that disallow *"violence against or directly attack or threaten other people on the basis of race, ethnicity, national origin, caste, sexual orientation ... [other at-risk minorities]"* [46]. Despite these guidelines, toxic content still proliferates in online spaces, harming various groups [43, 59], including refugees. Toxic content targeting refugees is defined as toxic content explicitly directed at a refugee or a group of refugees. In this paper, we refer to instances of such toxic content as "toxic content attacks", or just "attacks".

3 Related Work

Toxic Content and Online Hate. Researchers have extensively studied toxic content and other forms of online hate and harassment [81]. Several efforts have characterized and measured hate on platforms (e.g., Twitter, 4chan) [16, 18, 48, 65], and consider how factors such as attacker anonymity influence attacker behavior [96]. Hateful sentiment against specific groups such as women, the Jewish community, and other minorities [21, 88, 95] has also been studied. Similarly, Thomas et al. analyzed how content creators (online figures who produce media) deal with hate and harassment [82]. Another line of work has studied toxic content posts against refugees on online platforms, focusing on narrative justifications for anti-refugee sentiment [11, 52, 63, 83, 87]. However, the scope of their findings is limited to specific geographical regions and does not consider the effect this content has on its target - refugees. Community efforts have also explored automated mechanisms to detect toxic content [20, 26, 30, 32, 60] using machine learning-driven approaches.

Our work differs as prior efforts do not consider when targets of toxic content are refugees. Our research questions (which are previously unexplored) focus on how refugees' experiences shape the way they handle toxic content attacks and can differ from other groups (e.g., general users). Our protocol is also designed to gain insight into toxic content targeting refugees specifically because of their refugee status - we do not consider unrelated content (e.g., attacks solely exhibiting xenophobia/racism). We also understand refugees' perspectives on how toxic content mitigation strategies fail to meet the needs of this population.

At-Risk Users. The security community has long paid attention to at-risk users - individuals with "risk factors that augment their chances of being digitally attacked" [90]. Prior work has explored S&P factors and digital safety amongst communities including (but not limited to) domestic migrant workers [74], undocumented immigrants [42], LGBTQ+ communities [39, 72] and survivors of sexual assault [8, 61]. In understanding these communities, prior work has also shed light on the digital threats they face and how they navigate digital spaces (e.g., what data is considered sensitive) [15, 19, 36, 47]. Community responses to threats (e.g., blocking, social pleas), accompanying barriers [29, 57, 90], and how these individuals represent their digital selves (e.g., how the LGBTQ+ community identifies themselves online [34, 91]) have also been studied. Similarly, Simko et al. [73] investigated S&P for refugees and their reliance on digital technology (e.g., emails), interaction with threats (e.g., scams), and security practices (e.g., password creation techniques).

These efforts leverage interviews/focus groups to understand community-specific risks affecting marginalized populations and resulting threat models. We extend by focusing on (a) refugees, and (b) characterizing a highly specialized threat of toxic content. Our findings show how refugees have different experiences, S&P actions, and priorities than other at-risk communities when interacting with toxic content.

Refugees' Technology Usage. Community efforts to explore refugee interaction with technology have focused on how refugees use technology within refugee camps [93], and how refugees benefit from technology (e.g., smartphones, communication apps) in regard to the refugee crisis [40, 41, 80]. Efforts to outline challenges in HCI-refugee relations have also been conducted (e.g., challenges of computer club initiatives in refugee camps) [1, 2]. There also exists a body of work analyzing specialized use cases. For instance, Dyden-Peterson et al. [31] and Dahya et al. [25] focused on how mobile phones serve as an educational aid in refugee camps. Prior work has also examined refugee social media use in decision-making as they experience displacement [27, 40], and in grassroots/advocacy efforts [28].

We contrast prior research as we study online toxic content S&P implications on refugees' use of social media. Our carefully designed protocol understands how refugees use technology to enact S&P-focused actions and what S&P barriers exist in the technology they use.

4 Motivation and Research Goals

Refugees face unique challenges (e.g., fleeing from war, lacking an understanding of the local language, and economic hardship). These vulnerabilities are compounded by recent events (e.g., Afghanistan and Ukrainian refugee crises) propelling toxic rhetoric targeting them into mainstream channels (e.g., social media, news). We aim to unpack toxic content targeting refugees and answer the following research question:

RQ What are the impacts of exposure to toxic content on refugees and the corresponding security and privacy measures refugees take in response?

Given that we aimed to achieve an in-depth exploration of this research question, we divided it into four sub-questions:

SQ1 How do refugees interact with online toxic content and what actions do they take upon exposure?

SQ2 What are the security and privacy goals of refugees regarding toxic content?

SQ3 What security practices are barriers for refugees?

SQ4 What mitigation efforts would help refugees feel safer?

To answer these questions, we leverage a mixed-methods approach to investigate toxic content and its impact on this population. Through semi-structured interviews with n=12 refugee liaisons from four countries, we understand the security measures refugees take after exposure to toxic content. We then conducted focus groups with refugees (n=9, 27 participants) to validate liaisons' perspectives and obtain a detailed understanding (e.g., barriers in enacting countermeasures) across diverse participants.

Using these qualitative methods allows us to understand refugee experiences with toxic content from an S&P lens and the root causes of their decisions (e.g., reasons/goals behind actions) [38]. We also designed an online survey instrument (n=29) to provide an alternative for refugees who felt uncomfortable participating in focus groups. Answering our research question serves to help the S&P community better understand the threat of toxic content against refugees and what future directions researchers can take to combat this problem.

5 Study Methodology

We initially aimed to answer all four sub-research questions (**SQ1** - **SQ4**) by interviewing refugee liaisons, as they work with large and diverse refugee populations, and draw from years of experience. Their interactions provide us insight into how toxic content affects refugees' day-to-day lives in the digital world (**SQ1**) and refugee toxic content-related security and privacy goals (**SQ2**).

However, we find that liaisons are only able to provide generic answers to **SQ3** and **SQ4**. Refugees' toxic content-related S&P barriers are highly personal, and mitigation efforts that help refugees feel safer were hard to infer from their experiences working with refugees. To gain detailed insight into **SQ3** and **SQ4**, we followed liaisons' suggestions to conduct (1) focus groups with broad questions instead of topic guides and (2) online surveys for participants to maintain anonymity (available via *Qualtrics*).

5.1 Participant Recruitment

Refugee Liaison Interviews. We conducted semi-structured interviews with refugee liaisons, recruiting them from multiple countries and occupations, through a combination of snowball sampling and purposive sampling [68].

We reached out to 52 refugee liaisons from research foundations, refugee camps, and NGOs and also contacted personal contacts across eight countries: US, Turkey, Spain, Bulgaria, Germany, UK, France and Austria. 20 contacted liaisons did not respond. Among the 32 that did respond, 11 were unable to accommodate us due to scheduling difficulties. Nine liaisons communicated interest (via email) but believed they could not contribute due to lack of expertise in refugee social media use. The remaining 12 felt confident in their experience and observations regarding this sensitive topic.

Table 1: Overview of liaison participants.

#	Occupation	Experience (years)	Locality of Refugees Served†	Region of Service‡
P1	Lawyer	7	Middle East	Turkey
P2	Lawyer	8	Middle East	Turkey
P3	Medical Doctor	8	Middle East	Turkey
P4	Academic	41	Middle East	USA
P5	Academic	10	Middle East	Turkey
P6	Academic	5	Africa	USA
P7	NGO Worker	7	South America	Spain
P8	NGO Worker	14	Middle East	Bulgaria
P9	NGO Worker	2	Asia, Africa, Middle East	USA
P10	NGO Worker	4	Asia, Africa, Middle East	USA
P11	NGO Worker	3	Middle East	USA
P12	NGO Worker	7	Middle East	Turkey

† Region where refugees participants have worked with are from ‡ Region where liaison interacts with refugees (hosting country of refugees)

Table 1 overviews interviewed refugee liaisons. These liaisons comprise diverse professional experiences. NGO workers provide services to refugees via lessons (e.g., digital literacy, citizenship classes), coordinating operations in refugee shelters, or managing refugee aid (e.g., food, shelter). The lawyers we interviewed provided legal counsel to refugees in migration/resettlement centers. The liaison who worked as a doctor provided medical services in refugee camps. Academics conducted academic research studying refugee issues up close through workshops, fieldwork, and online interactions, offering unique insights compared to lawyers, NGO staff, and doctors. Interviewed refugee liaisons drew on many years of experience with an average experience of ~10 years and interactions with a large number of refugees.

Refugee Focus Groups. To recruit refugees, we contacted 21 NGOs that work with refugees through organizations and resettlement camps (across eight different countries). We also used our connections with all 12 interviewed liaisons. We prepared recruitment material, including a short video and a flyer, which were distributed to these parties. NGO workers and liaisons informed refugees of our study, with interested parties signing up to participate in our focus groups.

We faced challenges during the recruitment process. Due to the Afghan and Ukrainian refugee crises, NGOs had limited flexibility and time to coordinate and aid us in recruitment. However, over the course of one year, we were able to recruit a diverse participant pool for our focus groups. Table 2 describes the focus groups we conducted. We conducted nine focus groups (`FGs`) from three different affiliations. `FG1` comprised a family of three refugees. `FG2` comprised five refugees participating in government-sponsored lessons at a local university (where refugees learn the hosting country's native language). `FG3-9` consisted of 19 refugees participating in digital literacy/citizenship lessons conducted by an NGO.

Table 2: Overview of refugee focus groups conducted.

ID	Short Description	# Participants	# of Focus Groups	Region of Origin ‡	Hosting Country†
FG1	Family of settled refugees	3	1	Middle East	Turkey
FG2	Recently settled refugees at a language school	5	1	Middle East	Turkey
FG3-FG9	Settled refugees participating in NGO lessons	19	7	Asia (11), Middle East (5), South America (2), Africa (1),	USA

‡ Participants more commonly reported region of origin, instead of the country, when asked to self-report demographics † Country where participants currently reside

Table 3: Self-reported demographics of survey participants, reported as aggregates.

Region of Origins		Country of Settlement	Education Level	Gender Identity
Middle East 15	(Syria 8)	Turkey 17	Bachelor's degree 13	Male 15
	(Afghanistan 2)	USA 2	Associate degree 1	Female 11
	(Lebanon 3)	Dubai 1	High school degree or equivalent 4	n.a. 3
	(Turkey 1)	Netherlands 1	Less than a high school diploma 7	
	(Palestine 1)	Italy 1	Master's degree 1	
Europe 4	(Ukraine 3)	n.a. 7	n.a. 3	
	(Bulgaria 1)			
Asia 1	(Vietnam)			
South America 1	(Honduras)			
n.a. 8†				

† We mark n.a. (not applicable) for candidates who chose not to self-report specified demographics

Online Survey. We also provided the questions from our focus group in the form of an online survey. Survey recruitment was similar to that of focus groups. Our recruitment material included links to the online survey, as an alternative to focus groups. Liaisons in Table 1 distributed our survey. Here, we did not collect any organizational affiliation.

We prepared translated versions of our survey in Arabic, Turkish, Spanish, and Urdu. We chose these languages upon request from the 21 NGOs and 12 interviewed liaisons we coordinated with to recruit survey participants. Surveys were translated via Google Translate API [22], with translations verified/modified by recruited translators (fluent in the target language and English) referencing the English survey. Table 3 presents a detailed breakdown of the demographics of our participants. 29 refugees from the Middle East, Europe, Asia, and South America participated in our survey. Although an online survey limits direct interaction with refugees, it allowed us to consider perspectives from refugees who may not have felt comfortable sharing in a group setting.

5.2 Ethical Considerations

We worked with our IRB to ensure our materials were ethically designed. Our study was considered exempt after an initial review by a primary reviewer and analyst from the IRB office. Our study was designed after considering participants' privacy and the ethics of working with vulnerable populations.

First, we only collect personally identifiable information in recruitment (sign-up sheets) and our survey/interviews necessary for our study. For refugees, we collect self-reported age range, gender identity, education, and region of origin. For liaisons, we collected the region of origin of refugees they work with. Second, we de-identified transcripts by suppressing names and other personal data. Third, we audio-recorded interviews only after receiving the interviewees' consent. At every interview/focus group step, we ensured that dissemination of our data collection and results would not compromise the privacy and safety of participants, following heuristics to conduct research with vulnerable populations ethically [89].

We informed participants that they could skip any question due to the sensitive nature of our interview questions. Participants were not required to answer questions, and some chose the option of not answering. Translators acknowledged the unpleasantness of reading toxic content, but overall felt positive due to their research contribution.

5.3 User Study Procedures

Our questions focused on answering the four research questions we define (**SQ1**-**SQ4**). For both interviews and focus groups, our questions were purposefully wide and exploratory, allowing us to ask follow-up questions. For our online survey, we combined open-ended and multiple-choice questions.

Interviews with Liaisons. We conducted semi-structured interviews with liaisons remotely via video conferencing software, where each interview lasted 60 to 90 minutes. Each interview was conducted by two authors and audio recorded, transcribed and anonymized for data analysis. The interviews were conducted in English, Spanish, and Turkish. For non-English languages, we contacted researchers who were fluent in the language of the interviewee to join the interview, and they simultaneously interpreted our questions and interviewees' answers. We ask liaisons about their work with refugees, the types of refugees they work with, and their observations of toxic content directed at these refugees. A full list of initial questions for the interview is presented in Appendix B.1.

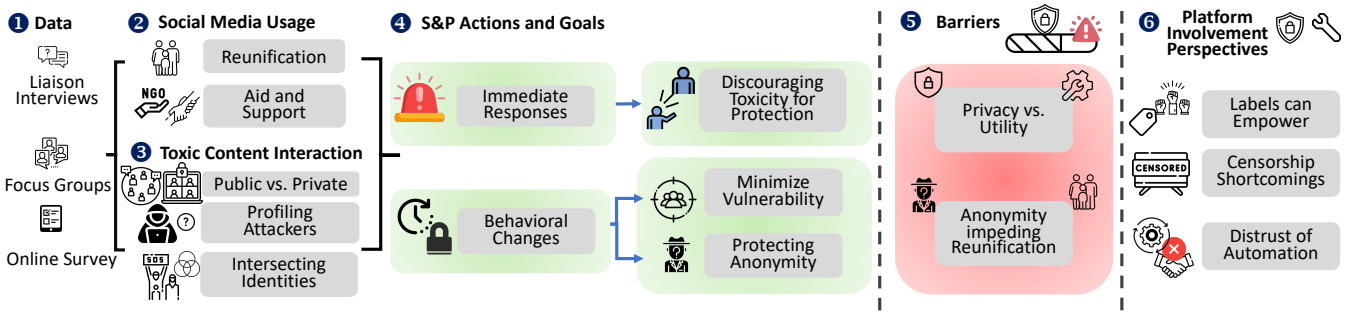

Figure 1: Overview of refugees' security and privacy implications due to toxic content, derived via a mixed-method approach. We discover nuances in participants' actions in response to toxicity, their goals, barriers, and perspectives on platform involvement.

Focus Groups with Refugees. Focus groups were conducted via video conferencing software and subsequently transcribed and anonymized. We did not allow third-party access (only study personnel) to transcripts. The interviews were conducted in English while working with native-speaker interpreters in the interviewees' language. We ask participants to self-report demographic data, and discuss their exposure to toxic content and responses. We also probed for their goals through these responses and factors preventing them from enacting responses. We note that data collection focused on content directed at participants because of their refugee status - we did not consider unrelated content (e.g., attacks *solely* exhibiting xenophobia and offline attacks). We conclude by asking for perspectives on platform mitigation. A full list of initial questions used can be found in Appendix B.2.

Online Survey. Our survey comprised two sections: (1) preliminary questions and (2) online toxic content-related questions asked in our focus groups. In (1), we ask participants to self-identify their status as a refugee to ensure only responses from refugees were considered.

5.4 Data Analysis

Transcripts. To thematically analyze transcripts (which were stored in a secure cloud service), we first used inductive coding. We produced one codebook each for liaisons and focus groups respectively. Two independent coders familiarized themselves with transcripts, and coded transcripts separately before discussing the code selections and settling on an intermediate codebook. Next, coders deductively coded using the online toxic content taxonomy (Appendix Table 1) and the intermediate codebooks to identify security measures refugees take. All interviews were double-coded, and coders stopped after every interview to discuss changes to the codes and themes until agreement. We do not present intercoder agreement as independently coded transcripts were reviewed together [58].

Through our intermediate codebook, we focused on (1) social media use, (2) toxic content exposure, (3) abusers and motivating sentiment for online hate and harassment, (4) toxic content impact and (5) refugees strategies for coping with online abuse. Coding occurred simultaneously with our recruitment and interviewing. We follow thematic saturation guidelines [71]. When no new codes emerged, and themes were repeated during coding, we ceased recruitment as additional interviews were unlikely to introduce new takeaways.

Survey Data. Non-English responses were translated by recruited translators fluent in response language. We code responses to open-ended questions while considering responses to multiple-choice questions. We merge themes extracted from open-ended questions with interviews/focus groups themes. When relevant to themes, we present percentages for multiple-choice questions.

6 Security and Privacy Impact on Refugees

Figure 1 presents an overview of our findings from interviews, focus groups, and online surveys (❶). We first outline participants' use of online platforms (❷). We then detail experiences with toxic content, focusing on toxic content types and contexts (e.g., where attacks occurred and what led to the incident) (❸). We also survey responses to toxic content, corresponding S&P goals (❹) and barriers (❺), and perspectives on mitigation efforts ❻). We detail below, referring to surveyed/interviewed refugees as *participants* and interviewed liaisons as *liaison participants*. For focus groups, we attribute findings to respective focus groups, not specific participants.

6.1 Online Platforms and Refugees

All participants we talked to had access to smartphones and/or a personal computer/laptop, which serve as a link to their online life. Devices are usually under the sole ownership or shared amongst families, as echoed in prior work [73]. For the purpose of our study, we consider social media as any online platform/app allowing users to interact with others, e.g., private one-on-one interactions, viewing publicly-shared content, and group settings (e.g., Telegram, WhatsApp). All participants partake in social media, using at least one social

media application daily. Facebook was the prime social media used (51% of survey participants and all participants in FG1-9). Social media platforms such as Twitter, Instagram, and TikTok were also popular. Participants also report using applications such as WhatsApp and Telegram to engage in social activities and communicate with friends/family. Social media was also used for a variety of secondary reasons (e.g., *"to find employment"*, *"for business"*). Refugee participants expressed confidence in using social media, suggesting digital literacy among our interview population. We note that we define digital literacy in the context of our research questions - we consider participants digitally literate if they self-reported comfort in using social media, and were aware of and understood how to access features (e.g., how to change privacy settings, how to block, how to report users).

Similar to general users, participants use social media for public activity, e.g., interacting/commenting on family/friends' posts or sharing a picture. Participants also engage in private settings, e.g., joining private groups. However, we find that, due to their experiences, participants' activity extends beyond common uses.

Means for Reunification. We find that participants rely on social media to stay connected with displaced family/friends in different regions, similar to social media use among immigrants [13, 42]. However, contrasting the experiences of other populations, refugee participants maintain a digital connection for future reunification - the rejoining of families separated by the refugee crisis. Here, participants note that the instability of the region they come from complicates this process (e.g., not always knowing where a loved one is currently residing) and thus increases dependency on social media. Participants express that interactions for the purpose of reunification usually begin as a public activity (e.g., commenting on a public post) but soon migrate to private settings.

Prior work highlights how refugees are dependent on technology, (e.g., mobile phones) to stay in touch with family/plan their journey [40, 41] and highlight limitations of using mobile phones to stay connected, due to dependency on SIM and mobile service providers [54]. We note that social media such as Facebook/Instagram are appropriate to aid in reunification as they overcome limitations (participants may not have access to a working phone number in all stages of their movement). The importance of staying online for reunification echoes other communities' needs to stay online for other vital needs, such as online creators who depend on online media for income [82] or trafficking victims who need social media to communicate with victim service providers [19].

Sourcing Aid and Support. Liaison participants highlighted how refugees prefer closed groups that only accept refugees/individuals affiliated with refugees. Liaisons participate in such groups to reach large groups of refugees and disseminate information. Participants use private groups as a source of support during resettlement - settling in another country as a refugee. Their involvement in these groups varies, ranging from requesting items for daily needs (e.g., house supplies) to accessing information on NGO-organized training programs or government aid such as stipend assistance.

6.2 Online Hate and Harassment

All participants acknowledged exposure to toxic content targeting the general refugee population, such as posts containing hateful sentiments targeting refugees. However, we discover that bullying (where the participant is targeted) is the more common attack they are exposed to. These targeted attacks usually begin as interactions with attacks targeting the general refugee population. For instance, participants note that commenting on a toxic post targeting refugees often leads to bullying. Interestingly, participants report that these attacks are often multi-fold, with a single post combining other secondary attacks, e.g., bullying *and* threats of violence.

Among secondary attacks, trolling and hate speech comprised the majority of toxic content participants experienced (FG1-9, 55% of survey participants). Attacks that leverage profane and offensive language were also common. Liaison participants noted racial slurs (offensive language) directed at the refugees they work with.

Other examples of attacks accompanying bullying include sexual insults and content mocking the participants' physical appearance. These attacks fall under sexual harassment and purposeful embarrassment. One liaison noted, *"The attackers use the word [race] as an insult; I see comments directed at my clients such as 'You are an ugly [race], you should go back to your country and many instances of similar comments"*

Liaison participants observe consistent interaction between refugees and toxic content; however, they also report that refugees face heightened exposure during specific seasons, e.g., an election season or religious holidays.

6.2.1 Public and Private Exposure to Toxic Content

Most participant interactions with toxic content occur in public settings, where any user with an online account can view this toxic content. 76% and 11.5% of survey participants experience toxic content attacks in public settings on social media and online forums, respectively.

Toxic content, however, also infiltrates private settings, where content can only be viewed by select users. 7.7% and 3.8% of survey participants faced toxic content on a dating website or messaging app, respectively. For instance, one participant using a dating app noted a benign experience that became toxic - *"There were people who harassed me [once finding out I] was a [refugee]. When [I refused] to meet ... [someone, they] insulted me."*.

Toxic content in private settings also affects participants within closed groups. Participants of one focus group reported an incident where their WhatsApp group (that can only be joined via invitation) had been *"hacked [infiltrated], and they*

started receiving offensive images targeting refugees." We posit this resulted from an unintentional leak of the group's "invite link", as speculated by participants. This experience of infiltration was the first of its kind for FG3, whose participants reported *"feeling very uneasy and worried about this attack."*

6.2.2 Profiling Attackers

In profiling attackers, participants highlight the following three factors: (*a*) affiliation with refugees, (*b*) association with organizations/ideology, and (*c*) demographics.

For affiliations, a majority of attacks against participants stem from strangers, people who have no prior affiliation with the refugee (e.g., FG1-9, 57% of surveyed participants had never met their attacker before). However, similar to victims of intimate partner violence [36], and trafficking [19], participants note more personal attackers. These include neighbors, acquaintances, or romantic interests. Participants expressed that the emergence of personal attackers stems from the ambiguity surrounding their refugee identity.

Prior work has studied self-disclosure of status in regards to online threats (e.g., some HIV-positive individuals are comfortable noting status in dating apps [91] while transgender individuals may opt against disclosure [34]). We find that participants opt against preemptive disclosure of their refugee status on their public profiles. Thus, perpetrators of attacks targeting the general refugee population may be unaware that the participant is a refugee and will be exposed to the attack. Participants expressed this can trigger an episode of bullying should the participant decide to respond. For instance, one participant who claimed that their neighbors were not aware of their status stated that *"neighbors made a [toxic] campaign against refugees [on] social media."* Association with political organizations was also a recurring theme when participants spoke of attackers. For example, one participant noted, *"[they] read a lot of posts contain[ing] hate speech about refugees on social media groups ... run by support[ers] of a [political party] in [country]."*

Liaisons specified that attackers' motivations vary based on their demographics, e.g., socioeconomic status. Upper-middle, middle, and working-class citizens in a hosting country have varying sentiments against refugees. One liaison highlighted how, *"If you were working class, you were more likely to worry about competition with [refugee] workers, [who are] willing to [or] exploited to work for less... but middle or upper middle class ... worry about invasion of cultural values."*

6.2.3 Intersecting Identities and Compounding Attacks

We observe that intersecting identities within refugee populations influence their toxic content experience, a theme consistent with the intersectionality framework [24, 51]. Participants with intersectional identities note that attacks are more severe as attackers leverage insults against additional identities beyond their refugee status.

Sexual Orientation and Gender. Sexual insults were commonly targeted at female participants, with one noting the violent threat of rape being a common threat (*" I have seen toxic comments like: 'We want to rape all the refugee women' "*). LGBTQ+ refugees face similar compounding threats. One liaison who interacted with refugees in Kenya noted the Free Block 13 campaign - an initiative to help persecuted LGBTQ+ refugees in a LGBTQ+-only camp, known as Block 13 Kakuma [35]. The campaign's social media presence on Facebook and involvement with LGBTQ+ refugees make it a prime target for attacks. Social media actions such as "tagging" another refugee result in targeted attacks against the tagged individual (an instance of bullying), suggesting that attacks vary between participants who are recently settled and those in refugee camps. In one event, a liaison noted *"[Someone] came on to the post about the evacuation of LGBTQ+ refugees to prevent persecution and attacked the refugee that was tagged in the post, basically saying, 'You know you don't belong here, you should leave, we don't want you here'."*

Language, Culture and Religion. Participants and liaison participants expressed how different cultures were prevalent themes in their toxic content experiences, with language and religion being common targets. Posting content in a language other than a country's native language can elicit toxic content responses, as attackers assume that the poster is a refugee. Liaisons noted that organizations are afraid to write social media posts in the *"language that refugees use"*, due to prior incidents where such posts were targeted by attackers.

Prior work [5] has highlighted how Muslim Americans are subjected to heightened religious discrimination. We extend these findings by showing that religion emerges as an important intersectional identity among the already marginalized group of refugees. For instance, one participant noted they *"posted something religious and several friends [wrote] negative things [about refugees]"*. Muslim participants noted insults against their religion often accompany attacks, suggesting demographic differences in what is considered toxic content (Christian participants did not consider attacks against their religion as toxicity against refugees).

The impact of intersecting identities is also exacerbated by recent phenomena. One liaison participant who primarily worked with Asian refugee students noted an uptick in complaints due to COVID-related anti-Asian sentiment. This sentiment has resulted in an increase in targeted attacks. This liaison expressed how *"[Their] Asian students were [reporting] having things said [directly] to them online."*

Despite a diverse participant pool, we acknowledge that our data might be limited to providing conclusive evidence of how intersectionality impacts refugee S&P implications and perceptions of toxic content (Detailed in Section 7.4). However, our data provide directional evidence of in-population differences (as outlined above), which warrants further study into how demographic differences can impact S&P implications.

6.3 S&P Actions and Goals

We discover a variety of responses to toxic content that participants take, grounded in preserving their security and privacy, as well as the goals associated with these approaches. Our findings can be divided into two types of actions: (*a*) immediate responses and (*b*) behavioral changes.

Immediate responses refer to the action a participant takes *immediately* upon seeing/interacting with toxic content. We find that participants' goals with a majority of immediate responses is to discourage toxic content. Behavioral changes refer to how toxic content leads to long-term changes in a participant's actions online, with their goal here being to either minimize vulnerability and/or protect their anonymity.

6.3.1 Immediate Responses to Attacks

We discover four immediate responses to toxic content attacks: (*a*) selective blocking, (*b*) engaging attackers, (*c*) using reporting channels, and (*d*) ignoring toxic content.

Selective Blocking. The most common immediate response by refugees who encounter toxic content online is to block the attacker (59% of surveyed participants). Participants state that they usually block attackers because they fear for their online safety (e.g., *"[I] got scared, and blocked [the attacker] after being threatened."*). While blocking is a common attack response mechanism for general populations and at-risk communities [29, 56, 70], and in some cases the *primary* form of privacy protection [67], this decision is seen as a "last resort" by participants. Participants prefer less critical immediate responses, such as "unfollowing" or removing themselves from the group. For instance, one participant noted that they would rather ignore the attacker than block as *"it is a softer resolution"*. Perception of an attack's severity can also influence a decision to block. Some participants noted that toxic content directed at refugees (instead of them alone) warrants a block. Other participants block attackers when bullied.

Engaging Attackers. Another immediate response that participants choose is to engage or communicate directly with the attacker (`FG3-9`). This response is similar to at-risk users' attempts at social pleas [90], but instead of requesting the attacker to stop attacks, participants expressed interest in engaging the attacker in conversation. Participants note that this is motivated by a desire to understand the attacker's motivation, e.g., *"I want to know why you are saying this"*, *"If you explain to me and I am wrong, I will say sorry."*. Contrasting work outlining preferences amongst online communities to avoid engagement [82], participants note that direct engagement is empowering, as it allows them to confront attackers who usually commit abuse unchallenged, e.g., *"if they just make fun or try to make [refugees] look bad, then I will [converse with] them on Facebook. That's the chance that I have."*

Direct engagement may escalate into further toxicity - participants express that attackers respond with further insults/profane language. One participant mentioned that their direct engagement attempt was met with efforts to "dox" them, with an attacker posting threats, *"You are from here [location]. This is your address? [address] I know your address"*. Despite this, the same participant also shared positive results from direct engagement, *"meeting [the attacker] in the middle after [the attacker] admitt[ed] [they] has been rude [and finally, they] said sorry."* Although attacker self-realization was uncommon (only 2 participants received apologies), accounts of these instances empowered other focus group participants who stated they were now more inclined to engage.

Reporting Channels. Participants' self-reported confidence in using social media extended to their familiarity in engaging with reporting channels (e.g., content or user profile reporting tools); 14% of surveyed participants stated they report attackers to the platform. For instance, one participant states *"Sometimes when [I] see this content, [I] will report it to Facebook or whatever the authorities of the application [I am] using"*. We find that participants depend on how a platform's policy is enforced, in the hopes that *"[using the feature] will result in the company [banning] that user."*.

Our findings complement research on user frustration with reporting [82] - participants express a lack of clarity on platform decisions when the reporting mechanisms they use yield no results. Participants attributed this to the ambiguity of what platforms consider toxic content. Participants believe that abuse directed at them is perceived as a contentious political discussion and exercise of free speech, especially in the United States, where censorship on social media and the right to express opinions are topics widely debated. To illustrate, one participant notes *"it's kind of tricky [to report] because I hear [America] has the First Amendment"*.

Unfavorable results (e.g., dismissed reports with the attacker facing no consequences) prompt participants to report to other authorities, such as law enforcement. This is especially true for more personal attacks and threats, including doxing and threats of violence. The involvement of law officers, however, causes further complications due to the legal status of the refugee, a hindrance not common among other communities [82]. For instance, one participant who experienced toxic content stated, *"That guy was blackmailing [me]. Because he [was claiming] I [was here] illegally. And [I cannot] report to police officers [although I wanted to]."*

Ignoring Toxic Content. Participants also practice nonintervention, where they choose to ignore toxic content (`FG1-9`, 10% of surveyed refugees). We note that given participants' confidence in social media use, ignoring toxic content did not stem from limited digital literacy. Instead, their decision not to intervene is influenced by one of three reasons. First, participants are concerned that responding could escalate a confrontation, causing more complications. Thomas et al. highlight how content creators, users who make digital content such as YouTube videos for income, avoid escalation as engaging can fuel further attacks [82]. Complementing this

study, and marginalization risk factors (negative treatment at societal level) outlined by Noel et al. [90], we find that participants attribute desire to avoid escalation to power dynamics between themselves and the attacker, who is likely to have citizenship / non-refugee status. To illustrate, one participant stated, *"[they] ignored [toxic content] because [they] did not want to make problems with residents of the country where [they] live."* Interestingly, we find this reason echoed among participants with intersectional identities. Similar to prior work showcasing how intersectionality shapes privacy responses [5], attacks against multiple identities are considered more severe and thus followed by nonintervention.

Second, nonintervention is motivated by the benefit of social media, with one participant sharing that social media is *"like medicine, sometimes it can be good, other times it can be bad."* These overwhelmingly positive aspects incentivize participants to *"turn a blind eye"* towards toxic content, seeing it as an unavoidable consequence of their identity/online presence and therefore believe it should be ignored.

Third, nonintervention is attributed to indifference (becoming accustomed to toxic content). Similar to sex workers [57], constant toxic content exposure can make participants apathetic towards attacks. One participant said that they chose not to block an attacker as *"[they] do not care about what they say"*, with another noting *"I ignore it. I don't want to waste my time with racist people."* Participants' decision to ignore is dependent on the severity of toxic content. For instance, one participant noted *"if the post is really outrageous, [I will respond]. Other content does not deserve a response"*.

Liaison participants admit that toxic content responses are largely absent from S&P guidelines/advice given to refugees. Current S&P advice for refugees outlines more traditional aspects of security (e.g., strong passwords, account sharing) [73]. Similarly, guidelines for social media focus on responsible use, e.g., one liaison participant working with refugees in a camp noted advice primarily involved avoiding pornography or minimizing online gaming. We posit that due to the absence of guidelines, participants do not intervene, feeling toxic content is unavoidable and requires no response.

Discouraging Toxic Content via Response. Participants' immediate responses are driven by their goal to discourage toxic content. Participants express how they are motivated to inform the platform and *"show their dissatisfaction with online hate"* (`FG1-9`). They intend to discourage toxic content by standing up to attackers (direct engagement, selective blocking) or instigating platform involvement (reporting).

Discouragement also indicates intent to protect community members. Similar to how toxic content against content creators can negatively impact their audiences [82], participants express how attacks may extend to others, e.g., *"[attackers] will not only go after me but [also my] close friends [and] family members"*. Just as victims of online hate and harassment attempt to stop attacks via social pleas [81], participants express dissatisfaction with online hate to prevent toxic content from affecting them and other refugees. Participants note a responsibility to prevent further attacks from affecting community members, e.g., *"I consider [my] friends and family members to, like, protect them from like, retribution"*.

6.3.2 Behavioral Changes Instigated By Toxic Content

Participants also enact behavioral changes in response to toxic content: (*a*) rigorous privacy measures, (*b*) activity in private groups, and (*c*) withdrawal from platforms.

Rigorous Privacy Measures. Noel et al. [90] note how at-risk communities often reconsider privacy measures, attempting to minimize digital footprints. We complement these findings as we discover that toxic content pushes participants to strengthen their privacy settings. Our participants state that restricting or redacting their personal identifiable information (PII) is the most common way they rethink their digital privacy presence (`FG1-9`), as PII can be used to track them. For instance, participants are wary of sharing visual content that can be used to identify them, e.g., their face picture or a photo of them at work. Liaisons also support this fact, saying that refugees' toxic online experiences result in the caution of sharing identifiable data. For instance, one liaison notes an incident where an attacker *"threatened a refugee after [they] posted [their] picture working at a local business."*

Refugee participants consider location data highly sensitive, a sentiment echoed by other populations (e.g., human trafficking survivors, undocumented immigrants [19, 42]). We find that participants' sensitivity towards location privacy is compounded as even generic location (e.g., city/district/state name) leaves them vulnerable. Given a region name, an attacker can associate the participant with a refugee camp or neighborhood with a high volume of refugees and subsequently use it to infer their fine-grained location.

However, we find that participants take extra precautions to obfuscate location data. Participants' caution extends beyond sharing explicit location data (e.g., street/building name) - liaison participants note that refugees limit access to information from which location can be inferred. We posit this attempts to strike a balance between privacy and utility - participants seeking to use social media still while preserving/obscuring their privacy-sensitive data. For instance, one liaison participant notes *"refugees do not post pictures ... near landmarks because it might be used against them."* Participants also note using privacy settings to delineate access to sensitive data on an individual basis. For instance, one participant noted *"If [it's for my] friends, I can share if strangers, so I can't, for safety reasons, and Yeah, that's about privacy"*.

Activity in Private Groups. We previously outlined (Section 6.1), how participants favor private groups that filter members. However, we find that *exclusive* and *increased* private group participation is a result of toxic content. This shift follows after a participant responds to a post, only to be tar-

geted by attacks. Private groups evolve from support sources (e.g., NGO coordination) to become participants' only form of online interaction. Liaison participants note inability to join some closed groups. Contrarily, closed groups with liaison participation emerge as a means to seek support and advice for refugees who are new to experiencing toxic content.

Withdrawal from Platforms. Participants also consider withdrawal from platform participation (e.g., deleting their account, or choosing a different but similar platform) when exposed to toxic content. For instance, one participant who experienced an attack *"deleted [their] old Facebook account [and] created a new one"* after *"hateful content was posted."*

Platform withdrawal as a response to online hate is common among demographics such as women [14] and even in specialized communities such as content creators [82]. There is an overlap with such communities in the impact of withdrawal (e.g., it can affect financial gain and platform enjoyment). However, refugee participants who withdraw are severed from integral support groups and the ability to reunify. Because of this, withdrawal is uncommon - only 10% of surveyed refugees practiced this behavioral change. Participants acknowledge preferring other behavioral changes, e.g., privacy measures, and moving towards private groups, as these changes allow them to still benefit from the platform.

Anonymity and Minimizing Vulnerability. Participants' behavioral changes focus on protecting themselves from future attacks via anonymity and minimizing vulnerability. Participants protect their anonymity by limiting other users' access to their PII via rigorous privacy settings, to protect their identity on social media. Anonymity may not reduce toxic content exposure – participants may still come across toxic content against refugees under an anonymous profile. However, it serves as a first line of defense to prevent escalation of attacks, e.g., repeated attacks or doxing. We also find participants' goal for anonymity is not solely focused on personal anonymity as they believe that protecting their own anonymity, in turn, protects the anonymity of their loved ones. For instance, one interviewed participant stated *"the whole point is to ... remain anonymous [otherwise] it will make it difficult for everyone [including] family from home country."*

Increased private group activity and withdrawal are motivated by an intent to minimize vulnerability and reduce toxic content exposure. For example, one participant who listed vulnerability-minimizing actions as responses to toxic content stated *"they don't like to get friendly on social media"* and *"try to avoid it"*. Here, participants note that limiting engagement on social media limits attack exposure. Interestingly, we note that withdrawal from the platform is the most severe method adopted by participants to minimize vulnerability. Participants share that withdrawal is the only foolproof method to eradicate interaction with toxic content attackers.

6.4 Barriers to Protective Practices

Although participants' protective actions are motivated by goals; they face barriers. Expectedly, digital literacy was not a barrier for our participants, given their self-reported confidence in using social media (Section 6.1). However, participants express two barriers related to trade-offs of protecting themselves from toxic content.

Privacy-Utility Trade-off. Similar to at-risk users, participants note basic needs as a barrier [90] to digital safety, with their unique necessities of social media becoming competing priorities that prevent S&P actions. Participants feel that strengthening their online privacy settings or moving to closed groups is a barrier depending on what these priorities are. For example, participants who depend on self-employment often rely on social media as a marketing tool for their services/products (e.g., *"they need to use social media to publicize their businesses"*). Additionally, as Geeng et al. [39] note, barriers may be impacted by intersecting identities (e.g., LGBTQ+). For instance, LGBTQ+ refugees who partake in advocacy groups, such as the Free Block 13 Campaign in Kakuma, rely on public exposure to gather support (e.g., *"Most people, I know, don't necessarily put Kakuma on their profile. And without that, you wouldn't necessarily be able to tell [preventing others from reaching out]"*. However, privacy and utility trade-offs inconvenience participants, who are forced towards more private and closed settings and forgo the use of social media. Similarly, withdrawal is difficult for participants who gain support via private groups.

Anonymity as a Barrier to Reunification. Although some restrict PII as a response to toxic content, some participants redact this PII to the point of anonymity (e.g., avoid using real names as usernames on social media platforms). However, this is a barrier for participants who need to remain identifiable to friends/family who seek to connect with them. Anonymity is especially challenging for participants who rely on social media for reunification - the rejoining of families separated by the refugee crisis. For instance, one participant expressed that their actions *"...the whole point is to like, remain anonymous ... [but] obviously makes it difficult for everyone. Family from [my] home [will not even know I] am fine."*

Finally, participants with no barriers attribute this to their lax implementation of toxic content protection mechanisms, as they use social media minimally.

6.5 Perspectives on Platform Involvement

Although prior work has argued for limiting digital-safety options [79], participants advocate for varying mitigation options, as more options provide tailored needs to individuals.

Labels can Empower. Warning labels can help in preventing attackers from posting toxic content while also protecting targets, as echoed in prior work [81]. Extending this, we find that labels can empower participants to contact platforms to either

express dissatisfaction or report an account. We also observe focus group participants actively advocate for warning labels because it can empower those who typically avoid reporting due to power dynamics (e.g., due to attacker's status). For instance, one participant who normally avoids reporting notes platforms should *"[tell us] this is ... toxic content [so] we can contact customer service"*, highlighting that labels are seen as "encouragement" to contact the platform.

Interestingly, one participant also expressed interest in labels for profiles (instead of posts), saying *"There could be some rating for every person ... if people [post] toxic content, you give them a low rating. So that when you visit [someone's] profile ... they have a percentage [score]."*, with other focus group participants agreeing that such an option would be beneficial. Here, we extend existing findings [81] by suggesting that presentations of labels can be updated to leverage existing information from user profiles (e.g., history of toxicity).

Censorship Shortcomings. Participants indicated support for stronger censorship of toxic posts, complementing other online communities' perceptions of toxic content moderation [82]. However, participants also outline shortcomings in existing censorship on platforms. To illustrate, one participant who experienced toxic content via online gaming stated they wanted better filtration of profane or offensive language. This participant expressed, *"[gaming service] should remove bad word(s) from the chat. Sometimes, they['ve] removed [it] already, but [miss some] words [because] it's in a different language."* "Different languages" not only references non-English languages but also "coded" hate words (e.g., slurs known amongst gaming communities or that target refugees). Participants attribute perceived shortcomings of existing moderation due to these nuances (a moderator may not necessarily recognize a slur). Although participants perceive censorship as flawed, it does help participants feel safer.

Distrust of Automation. Similar to suggestions for human moderation due to toxic content's contextual nature [90], participants' unique experiences result in a distrust of automated systems involved in reporting mechanisms. For example, one participant reported a post they felt was toxic against refugees but *"[were] quite surprised because [the system] said this is sensible content."* Although participants acknowledged a lack of familiarity with how automated systems worked, they shared that they would feel better if a human reviewed a report/complaint. For instance, one refugee who expressed an interest in technology and AI stated *"there could be more human checking ... on this toxic content ... relying on AI is not very applicable because it's not smart enough [to] detect these contents."* Though participants acknowledge that human involvement does not guarantee toxic content removal/censorship, participants place higher levels of trust in human moderation.

7 Discussion and Limitations

We now synthesize takeaways for combating toxic content against refugees and acknowledge our study's limitations.

7.1 Toxic Content Threat Models

It is important to consider at-risk communities' nuances in understanding threat models [57, 73, 75]. Participants' social media use cases, such as establishing private groups for support or public groups for advocacy (e.g., Free Block 13 Campaign) and dependency on reunification produce an intricate threat model. For instance, although strangers perpetrate attacks, personal attackers also exist, especially due to the ambiguity behind one's status. Participants also rely on social media platforms to network. Self-employed participants network for business, while others depend on members of local communities (e.g., neighbors), contributing to their vulnerability as these parties can turn out to be attackers.

Prior work highlights the importance of designing solutions that do not prevent user benefit of platform amenities (e.g., income generation, joining similar-interest social groups) [39, 82]. We extend this by arguing that existing attempts at designing inclusive threat models are incomplete. For example, platform guidelines often prohibit attacks against identities associated with different groups, which span from "protected characteristics" (e.g., race, religion) [50] to groups historically a target of abuse such as caste or sexual orientation [84]. However, platform guidelines do not consider how refugee-targeted attacks are interpreted as free speech - a concern raised by interviewed participants. The right to free speech is present in many countries (e.g., in the US, it refers to "the right to speak, write, and share ideas and opinions without facing punishment from the government" [23]) and consequently, free speech on social media is a widely debated issue [37]. Attackers often argue that any censorship violates this right, prompting lax moderation [12]. Similarly, existing privacy/anonymity features may be infeasible for some refugees - privacy and anonymity limit social media use and impede family reunification. Without knowledge of barriers, threat models may appear to have easy mitigation strategies (e.g., blocking, moving to private settings) when successfully implementing these solutions may be challenging.

We propose that social media platforms should have an open communication channel with refugee populations to ensure guidelines appropriately acknowledge toxic content threat models. For instance, knowledge of how refugee-related toxicity is interpreted as free speech is pivotal to reframing platform guidelines to account for this (e.g., appropriately delineating between free speech and toxicity against vulnerable populations). We also encourage future work to examine in-population differences within refugee communities, e.g., LGBTQ+ refugees, so platforms can develop a better understanding of toxic content threat models.

7.2 Detection and Mitigation Strategies

Despite guidelines against hateful content on social media platforms [44, 46, 49] and existing protective mechanisms to combat online hate, we find these guidelines are not grounded in refugees' experiences. Thus, toxic content persists on these platforms which we attribute to one of the following two reasons: inability (or delay) in detecting toxic content and lack of enforcement of platform guidelines.

Shortcomings of Detection. Work has explored automated detection of toxic content [20, 26, 30, 32, 60] and detecting attackers instead of their posts [16, 17, 33]. Community efforts, such as Perspective API [64], have also worked towards identifying online toxic content. However, automated mechanisms are often unable to capture the toxicity directed at specific groups (e.g., hateful hashtags against refugees). This can be mainly attributed to statistical or deterministic models used in these mechanisms not learning terms related to marginalized populations, varying cultural contexts across regions, and lacking representative datasets [81].

Despite Twitter disallowing attacks affecting marginalized groups [46], toxic hashtags against refugees (e.g., #NoRefugees, #Rapefugees) and other communities [9, 50] still exist. "Coded" hate words can also evade detection, as expressed by participants who are involved in gaming. However, we suggest that overcoming detection efforts' limitations is feasible through community collaboration. Prior work has shown that crowd-sourcing training data labels are often outsourced to specific regions [62]. We propose that social media platforms incorporate specific populations in enriching training data - platforms should include features for individuals/NGOs acutely aware of refugee-specific toxic content so that they can flag hashtags or coded slurs. Through this, developers of classification tools can design frameworks (e.g., annotation guides) to consider such nuances. This prevents imbalanced data and corresponding failure at detection which translates to participant distrust of automated detection mechanisms.

Building Towards Accessible Mitigation. Our study extends findings on the impracticality of one-size-fits-all approaches for marginalized communities [39], showing how participants have varying opinions on what mitigation works best and that unified strategies are impractical.

Participants advocate for labels against profiles (in lieu of per post). Similarly, some suggested moving from binary indicators toward numeric indicators that reflect severity. However, we recommend future work explore mitigation efforts in quantitative detail (e.g., via large-scale surveys) to fine-tune what exactly is shown in these labels/warnings. For instance, although warning labels embedded with an account's longitudinal information (e.g., previous violations) may benefit refugees, prior work shows that fewer/simpler digital safety options may prevent users from being overwhelmed [79, 92]. Thus, a large-scale study is required to decide what information can be presented to users to strike a balance between informing and not overwhelming them. Similarly, large-scale surveys are required to determine users' authority over labels (e.g., whether the ability to turn labels on/off is beneficial or what the default setting for the label should be).

Accessible mitigation should include refining automated censorship of toxicity. However, given automated detection's limitations and the contextual nature of toxic content, some participants prefer human moderation. Although it is unrealistic to manually parse every post/comment, human involvement in detection can bridge the gap that results from automation. Detection systems should continuously be updated to include community-driven information, such as toxic word lists from HateBase API [45] and regularly updated lists of hateful hashtags as suggested by recent work [81].

7.3 S&P Advice for Toxic Content

Prior work has exposed how access to guidelines and resources for dealing with online hate is imperative to online users such as creators [82]. We echo this, but note that the design of guidelines for refugees faces barriers. First, refugee organizations are in the early stages of developing S&P guidelines concerning toxic content. Second, advice given is intentionally limited to avoid burdening refugees beyond critical S&P, such as safe passwords. Third, guidelines should account for varying levels of digital literacy, refugee barriers, and their unique online use cases.

To overcome barriers, we suggest that S&P guidelines for refugees should include preemptive protective practices, e.g., secure distribution of group links to prevent infiltration, and removing location data from posts. Guidelines can also enumerate alternative mechanisms (e.g., when to avoid intervention and report, how to push back while maintaining privacy) that avoid impeding refugees' social media use.

Synthesizing guidelines is only the first step - guideline dissemination is also imperative to ensure refugees are exposed to advice. For instance, NGOs should incorporate mitigation strategies and information on toxic content threat models in classes often provided to refugees (e.g., digital literacy classes, citizenship classes). Refugee dependency on private groups makes groups appropriate sites to disseminate guidelines too. We also see a role for platforms in informing refugees. Guidelines, e.g., adjusting privacy to deal with toxic content, can be incorporated into website walkthroughs shown to refugees the first time they access the platform.

However, we recommend further large-scale interventions such as community workshops [76] to design and update proposed S&P guidelines. Guidelines should be iteratively improved with feedback from refugees to ensure that advice is actionable and does not burden refugees.

7.4 Limitations

Our study might be vulnerable to usual qualitative study constraints (e.g., observer bias, participant self-censorship). Additionally, prior work has outlined that online focus groups face barriers (e.g., technical difficulties, participant discomfort in front of the camera) [3, 10]. However, we conduct our best efforts to minimize these limitations' effects. Given that liaisons depend on recollections (observer bias), we survey and conduct focus groups with refugees who can comment on direct experiences. We interview liaisons for insights that refugees may be unwilling to share (due to self-censorship). We ensured initial/follow-up questions in focus groups were designed to elicit general responses first, with refugees providing detail when comfortable. We also conducted check-ins at the beginning, middle, and end of a session to ensure no technical difficulties were encountered.

We recruited participants from diverse regions of origin and settlement, employed a mixed-methods approach, and ceased recruitment upon our data's thematic saturation to improve generalizability. Our participants' experiences are grounded in the following commonalities. First, participants (or refugees liaison participants serve) use social media and online platforms. Second, they are exposed to toxic content in online spaces. Finally, their actions, goals, and barriers are influenced by their unique experiences as refugees. Our findings provide rich insight into toxic content's implications on refugees' security and privacy. We examine how in-population differences result in nuances in toxic content exposure (Section 6.2.3), but our participants skew Asian and Middle Eastern refugees who live in the Middle East or the US. Refugee participants also skewed towards those comfortable with using social media (high digital literacy) - those with lower literacy may have different actions and barriers. Additionally, our scope of social media may not account for additional toxic content experiences (e.g., when a refugee reads toxic comments on an online news website). Future work will examine differences in refugee toxic content exposure/action (1) across different settings (e.g., news websites vs streaming platforms), (2) in different countries and (3) with varying technical expertise in a demographically diverse in-depth study.

8 Conclusions

Toxic content attacks target refugees on social media, inflicting harm such as heightened anxiety and intent to silence. Through interviews, focus groups, and online surveys with refugees and liaisons, we discover participants' experiences shape S&P implications and responses. Their immediate responses and behavioral changes are motivated by goals such as minimizing vulnerability. Although actions have barriers, participants also outline mitigation efforts that may improve their online experiences. Our findings synthesize lessons to better refugees' ability to manage toxic content threats.

Acknowledgments

We thank our anonymous reviewers and shepherd for providing us with valuable feedback that helped improve our paper. We would also like to thank the participants for their generous time and contribution to our research. This work is supported by startup funding from Purdue University.

A Toxic Content Categories

We provide brief descriptions for toxic content subcategories in Table 1.

Table 1: Overview of Toxic Content Categories.

Toxic Content Type	Description
bullying	seek to harm or intimidate or coerce an individual perceived as vulnerable
trolling	intentionally provoke someone/group of people with inflammatory remarks
hate speech	contain abusive or threatening content that expresses prejudice targeting a group of people based on their race, gender, political/ideological affiliation, religion or a similar property
profane or offensive language	contain profane or offensive language (e.g., showing lack of respect to someone's religious beliefs, cursing, swearing, expletives, culturally offensive content)
threats of violence	content that physically threatens someone
purposeful embarrassment	content that tries to purposely embarrass someone
incitement	provokes unlawful behavior or urge someone to behave unlawfully
sexual harassment	sexually harasseses someone (e.g., Unwelcome sexual advances, requests for sexual favors)
unwanted explicit content	contains unwanted explicit content (e.g., sexting, violent and adult content)

B User Study Details

We provide our initial questions for both liaison semi-structured interviews and focus groups with refugees.

B.1 Interview Questions for Liaisons

We detail questions used in our interviews with refugee liaisons (Section 5.3). We note that our interviews were semi-structured, and the listed questions were only starting points of conversation, with follow-up questions asked based on participant responses.

1. What is your job title and role?
2. Can you tell us about the refugees you work with? You can provide any information you are comfortable sharing such as nationality, age range or country of origin. (We ask that you not use names or identifiable information.)
3. Which online platforms/apps do they use?
4. Have you ever witnessed/heard any toxic content directed at refugees you have worked with online?
5. Can you describe what you have witnessed/heard in your experiences of this kind?
6. When did this occur and on which platforms?
7. Was the behavior you described a result of any online campaign against refugees?
8. Can you list some reasons for posting this toxic content?
9. What are the impacts of online toxic content on social media usage of refugees?
10. What are the impacts of online toxic content on refugees' daily life?
11. Can you tell us about safety precautions taken by refugees in order to avoid this toxic content if there are any?
12. Do you give any advice to your clients in terms of social media usage? Do you have any documents/instructions containing this advice?
13. Assuming you work with refugees from multiple countries, are your observations any different for different countries?
14. Are you aware of any ongoing campaigns/attempts to discourage or stop posting hateful content?

B.2 Focus Group with Refugees

We detail questions used in our focus groups with refugees (Section 5.3). Similar to our semi-structured interviews with liaisons, these questions were only starting points, with follow-up questions based on refugee responses and discussion between refugees within focus groups. Questions were purposefully general and broad so as not to force refugees to detail information or experiences they were not comfortable sharing.

1. Can you please tell us about yourselves?
2. How often do you use social media? Which platforms do you use?
3. What is your main purpose of social media use?
4. What does online/digital security and privacy mean to you?
5. Has any toxic content/ online hate ever happened to you, personally online?

6. Can you describe what you have witnessed in your experiences of this kind?
7. In which of the following online environments did your experience(s) occur?
8. Did you use translation services to understand this content? If so, please specify what you used.
9. Do you think any of these experiences are a result of your race or ethnicity, gender, sexual orientation, political views, religion?
10. Thinking of the person or people involved, how did you know them?
11. Did you respond to this behavior or ignore it and why did you prefer to do so?
12. After the experience(s), did you continue to use the platform?
13. After the experience(s), did you lean towards other applications/platforms?
14. When posting online content, do you share your location or pictures? If not, why?
15. What are your (security/privacy) goals when adopting these practices?
16. Are any of the security practices you rely on barriers for you?
17. Is there anything else you would like to share about the precautions you take in order to avoid online toxic content?
18. Regarding toxic content, do you have any suggestions on how social media companies can improve the social media experience?

Understanding Help-Seeking and Help-Giving on Social Media for Image-Based Sexual Abuse

Abstract

Image-based sexual abuse (IBSA), like other forms of technology-facilitated abuse, is a growing threat to people's digital safety. Attacks include unwanted solicitations for sexually explicit images, extorting people under threat of leaking their images, or purposefully leaking images to enact revenge or exert control. In this paper, we explore how people seek and receive help for IBSA on social media. Specifically, we identify over 100,000 Reddit posts that engage relationship and advice communities for help related to IBSA. We draw on a stratified sample of 261 posts to qualitatively examine how various types of IBSA unfold, including the mapping of gender, relationship dynamics, and technology involvement to different types of IBSA. We also explore the support needs of victim-survivors experiencing IBSA and how communities help victim-survivors navigate their abuse through technical, emotional, and relationship advice. Finally, we highlight sociotechnical gaps in connecting victim-survivors with important care, regardless of whom they turn to for help.

Warning: This paper includes descriptions and quotes about image-based sexual abuse. Such material is disturbing.

1 Introduction

People increasingly share sexually explicit images with consent in intimate relationships [38], as cultural norms change and image sharing capabilities increase. However, this trend has coincided with a rise in *image-based sexual abuse* (IBSA): a continuum of harassment and scams involving the receipt, generation, and distribution of sexually explicit images [61, 62]. Examples include unwanted solicitations for sexually explicit images [81, 89], sextortion [23, 73], and nonconsensually sharing sexually explicit images [62]. In terms of scale, one in ten women under the age of 30 in the US has been threatened with or experienced the nonconsensual sharing of their nude images [51], and roughly one in twenty adult men in the US has experienced sextortion [27].

As with other forms of technology-facilitated abuse—including intimate partner abuse [93], stalkerware [34], and interpersonal surveillance [99]—the support needs of people experiencing IBSA (victim-survivors) are complex. Perpetrators can be intimate partners, peers, or strangers. Even against perpetrators with basic technical capabilities, preventing the distribution of sexually explicit images can be daunting. Support available today includes image fingerprint databases used by platforms to take down imagery [67, 90] and institutional guides on how to respond to IBSA [74]. However, victim-survivors may be unaware of these resources or find them ineffective, leading them to seek alternative support.

In this paper, we explore how adults seek and receive help for IBSA on Reddit, a popular social media platform for threaded dialogue. Given the scarcity of victim-survivors who turn to law enforcement or platforms for help [17, 83], social media provides an important avenue for disclosure and support. Expanding on knowledge from prior work studying help-seeking on Reddit for sexual abuse (e.g., rape) [2, 66, 72], we focus on help-seeking on Reddit across the continuum of *image-based sexual abuse*. Specifically we investigate:

RQ1: IBSA types. What types of IBSA do people seek help for on Reddit? What gender and relationship dynamics between perpetrators and victim-survivors do they disclose? How might differences between IBSA types influence the development of supportive solutions?

RQ2: Help-seeking. What help do they seek? How do their needs vary across IBSA types? What actions do they share that they have already taken?

RQ3: Help-giving. What help do they receive? How supportive is it? What gaps does this help fill compared to other interventions? What gaps remain?

To answer these questions, we used a mixed methods approach to sift through 5.7 million English-language Reddit posts shared on relationship and advice subcommunities over the last 3 years. Leveraging a novel large language model (LLM) data processing pipeline and extensive manual review,

we identified more than 100,000 queries for help related to IBSA—roughly 2% of posts on the subcommunities. This method allowed us to analyze a much larger sample than previous qualitative Reddit work. We drew on a stratified sample of these posts to qualitatively explore the continuum of IBSA including financial and nonfinancial sextortion, nonconsensual *synthetic* explicit imagery, pressurized sexting, cyberflashing, nonconsensual explicit imagery, and recorded sexual assault.

We found that although IBSA covered a wide range of contexts, perpetrators, and harms, victim-survivors nevertheless shared similar needs: to be heard and supported through life-changing experiences of abuse. Across types of IBSA, victim-survivors sought information about their options (technical, legal, or otherwise), advice for coping with distressing emotions, and suggestions for managing relationships. Timely support was crucial: in half of the cases we analyzed, victim-survivors were seeking immediate help for active IBSA. Though the help provided by the Reddit community was sometimes oversimplified and made limited use of institutional support resources, it was also largely empathetic and validated victim-survivors' experiences, helping to partially address their needs.

Our work characterizes IBSA to chart additional directions to support victim-survivors, in ways that complement the distinct avenues for help that exist today. We reflect on the role of technology in facilitating IBSA and identify opportunities for technologists and platforms to help prevent or mitigate IBSA, while also discussing how our insights can inform advocates in providing support for victim-survivors.

2 Related Work

2.1 Image-based sexual abuse (IBSA)

IBSA is an umbrella term referring to "taking, distributing, and/or making threats to distribute, nude or sexual image[ry][1] without a person's consent" [77, p. 1] (see also: [25, 61, 62, 75, 76]). For the purposes of our study, we expand this definition to include the unwanted receipt of and synthetic generation of sexually explicit[2] images, that is, images portraying nudity or sexual conduct. IBSA is a type of technology-facilitated abuse in which a person leverages technology to exert control over another [11, 25, 41]. We refer to the person enacting IBSA as the *perpetrator* and the person experiencing IBSA as the *victim-survivor*.

Continuum of IBSA. IBSA exists on a continuum, occurring in diverse relational contexts, with distinct motivations, and rapidly evolving threats [62]. The types of IBSA that inform our investigation include:

1. *Sextortion*: a perpetrator makes threats to distribute sexually explicit images of a person unless they comply with the perpetrator's demands [23, 31, 42, 73].
2. *Nonconsensual synthetic explicit imagery (NCSEI)*: a perpetrator uses software (e.g., photo editing or generative AI tools) to create sexualized depictions of a person (e.g., "deepfakes," "cheapfakes") [30, 44, 58, 71, 100].
3. *Pressurized sexting (PS)*: a person experiences unwanted solicitation for explicit images (e.g., "coerced sexting") [81, 89].
4. *Cyberflashing (CF)*: a person receives an unwanted explicit image [59].
5. *Nonconsensual explicit imagery (NCEI)*: a perpetrator uses explicit imagery for revenge or to enact control [62] (e.g., "revenge porn"); or otherwise nonconsensually creates, retains, or distributes explicit imagery (e.g., "upskirting," "downblousing") [7, 52].
6. *Recorded sexual assault (RSA)*: a perpetrator records or distributes imagery from a sexual assault [40].

Role of technology. Technology often plays a role in both the generation and distribution of IBSA. Outside of consensual sharing or nonconsensual recording, methods of obtainment include hacking [32], photoshopping [63], and using generative AI tools to create synthetic imagery [58, 95, 100]. Distribution channels used by perpetrators include—but are not limited to— websites [21, 39, 55, 94], social media platforms [32, 58, 85], and mobile apps [46, 60].

Harms. Harms from IBSA—as with other forms of sexualized violence—are not uniformly experienced, but are nonetheless serious and consequential [6, 10, 49, 83], carrying emotional, physical, financial, and social impacts [45]. When images are distributed, victim-survivors become visually recognizable to friends, family, co-workers, or others [45], and imagery is often shared with other personally identifiable information (e.g., names, social media handles, phone numbers, and/or addresses [20, 32, 91]). The often permanent nature of online material intensifies IBSA harms, as imagery can be repeatedly downloaded, saved, and shared, making "complete" removal challenging, or even impossible [5]. As IBSA often co-occurs with other forms of gender-based violence (e.g., intimate partner abuse, stalking, and sexual harassment) [60], harms may compound with other polyvictimizations.

2.2 IBSA help-seeking and help-giving

Overall, rates of IBSA help-seeking through peers and family, institutional support, and platforms are low [17, 83]. One potential reason is that in contrast to other forms of sexualized violence, targets of IBSA are inherently not granted anonymity, as they are facially (or otherwise) identifiable [45]. Another challenge is that help-givers may hold victim-blaming

[1] As with prior work [77], we use "imagery" to include photos and video.

[2] Sexually explicit imagery can be distinguished from intimate imagery, which also includes images of people in private or sensitive contexts (e.g., sleeping, in states of intoxication, or without religious coverings).

attitudes, which have been found among the general public [15, 29, 102], law enforcement [12, 103], and victim-survivors' friends and family [88].

Online help-seekers for topics such as health often look for specific advice or information, acknowledgement, or sympathy [3, 37, 68]. Prior work also studies online help-seeking for sexual abuse (e.g., rape); by contrast, our work considers online help-seeking for *image-based* sexual abuse. When disclosing online about sexual abuse (that was not image-based), victim-survivors perceived online fora as safer spaces to disclose stigmatized experiences and connect with others, with reduced interpersonal risk [1, 2, 50, 66, 72]. As we show, social media—specifically Reddit—has at least hundreds of thousands of posts related to IBSA help-seeking. Thus it is crucial to understand this support system and how best to enmesh it with other social, institutional, and platform resources.

3 Methodology

We conducted a mixed-methods study of IBSA help-seeking and help-giving experiences on Reddit. We discuss the process we followed to identify IBSA posts, our qualitative coding practices, and the ethics and limitations of our approach.

3.1 Data processing

We built a data processing pipeline that automatically identified help-seeking for several types of IBSA discussed on Reddit. We outline the full pipeline in Figure 1 and discuss each component below.

Dataset. The first step in our data processing pipeline was to identify Reddit posts and subreddits relevant to our research (Figure 1, ❶). Our Reddit dataset originates from a continuous Internet-wide crawl of public URLs in a way that respects robots.txt and other rules for crawlers. In order to reduce the search space for IBSA posts, we focused on 43 popular subreddits related to scams, advice, relationships, dating, and sex—including r/advice, r/askwomen, r/askmen, and r/sextortion—that we identified from an initial manual exploration (see Appendix A.1 for the full list). All of these subreddits had at least 1,000 members. In total, this dataset includes 5.7M English-language posts from 2.9M unique users (i.e., "original posters" on Reddit, posters in this work) published between April 1, 2020 and September 12, 2023.

Filtering. We analyzed each Reddit post using a suite of LLMs and prompts to identify those likely to be about help-seeking for IBSA (Figure 1, ❷). While we initially explored a keyword-based search, the terminology and context proved too nuanced to capture without a prohibitive number of false positives to manually review. Instead, we queried Google Cloud's lighter-weight Vertex AI text-bison LLM [35] with a prompt to identify posts generally discussing IBSA (Figure 2), then refined the search by repeating the prompt with a more accurate (but expensive) text-unicorn LLM [35].

We validated this approach using a manually curated test set of 80 posts that discussed IBSA (generated from our initial manual exploration and when exploring the feasibility of keyword matching), and 197 non-IBSA posts. Our chained prompt correctly identified 79 of the 80 IBSA posts (98.8% recall) and 194 of the 197 non-IBSA posts (98.4% specificity). While the final dataset of posts we use is manually validated to remove all errors, this high degree of recall and specificity gave us confidence that we did not incorrectly omit some IBSA concepts from our study, while at the same time reducing the toil of manual validation. When applied at scale, our filtering identified 113K Reddit posts likely discussing IBSA—2% of posts on the subreddits we analyzed.

Categorization. To ensure that our study captured distinct experiences in the continuum of IBSA, we queried text-unicorn to categorize each post by the type(s) of IBSA involved in order to support stratified sampling (Figure 1, ❸). We derived these types—listed in Table 1—based on our preliminary analysis of prior literature (Sections 2.1 & 3.2). We found that the LLM struggled with some concepts more than others. For example, *sextortion* was easy for the LLM to categorize, while *recorded sexual assault* was more error prone (and also more rare). To counteract this and account for posts that discuss multiple types of IBSA, we also created (more computationally expensive) per-type prompts with multi-stage reasoning to distinguish overlapping concepts (e.g., financial and nonfinancial sextortion). See Appendix A.2 for the general categorization and specialized prompts. We rely on manual review to validate these labels, discussed next. Given the potential for

Type	Key	Posts	Threads
Financial sextortion	FS	50	22
Nonfinancial sextortion	NFS	46	26
Nonconsensual *synthetic* explicit imagery	NCSEI	51	32
Pressurized sexting	PS	45	34
Cyberflashing	CF	41	33
Nonconsensual explicit imagery	NCEI	45	35
Recorded sexual assault	RSA	40	20
Total (Any type of IBSA)	–	261	160

Table 1: Our qualitative dataset consists of seven distinct types within the continuum of IBSA, as defined in Section 2.1. Prior work largely collapses FS and NFS into the single category *sextortion*. For our purposes, the differences were meaningful, so we split them into two distinct categories. For each type, we include the total number of stratified posts and comment threads that we analyzed. A single post could describe experiences with more than one IBSA type.

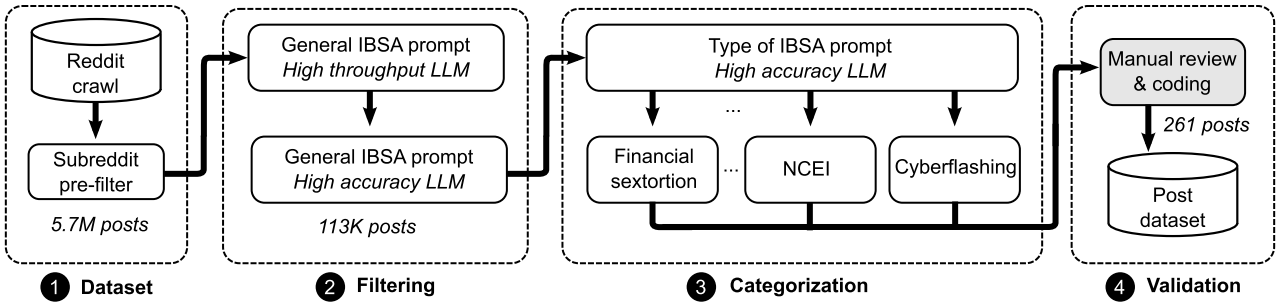

Figure 1: Data processing to identify help-seeking posts on Reddit. We relied on recent advances in LLMs to automatically sift through 5.7M Reddit posts to identify 113K posts likely related to help-seeking for IBSA. We automatically labelled each post with one of seven types of IBSA. Coders randomly pulled a sample of these posts to manually validate the LLM-generated metadata and reach a minimum threshold of 40 posts for each of the seven IBSA types. As a post could mention multiple types of IBSA, our *Post dataset* includes a total of 261 posts.

Title: [TITLE]
Article: [ARTICLE]

Question: Does the title or article discuss any form of image-based sexual abuse, such as sending or receiving unwanted nude images, unwanted flashing, being coerced into sharing nude images, fear of having nsfw or intimate images leaked or hacked, sextortion, nonconsensual image sharing, or revenge porn? Provide both an answer and a summary explaining your reasoning.
Answer:

Figure 2: Initial prompt designed to identify posts that contained any discussion of IBSA.

error with automated categorization (absent manual review), we avoid providing a relative breakdown of the types of IBSA at-scale, and focus only on our stratified sample.

Validation. During validation, we selected from the outputs of each categorization prompt and manually vetted the labels (Figure 1, ❹). Here, we corrected for any missed or erroneous labels and discarded any posts that were not related to help-seeking for IBSA. We also removed posts where the victim-survivor appeared to be under the age of 18.[3] We repeated this until we achieved a minimum of 40 posts for each of the seven types of IBSA,[4] resulting in a final dataset of 261 posts. We sampled 40 posts per IBSA type to achieve meaning sufficiency [14], balanced with reasonable researcher effort. Some posts involved multiple types of IBSA, thus requiring we label fewer than 280 posts to meet our minimum sample size. Each post in our sample on average contained 285 words (min: 24, max: 2,363).

[3]Some posts may originate from minors, but we cannot confirm. The advice we analyzed appeared targeted towards adults. The nuances of help-seeking and giving are fundamentally different for child sexual abuse (e.g., lack of agency, mandatory reporting) and thus beyond the scope of this work.

[4]We sampled independently per IBSA type. Some posts discussed multiple IBSA types, which is why there are more than 40 posts for some types.

For each post, we re-crawled the live site for the current state of discussion (i.e., all threads) on December 11, 2023. This yielded 2,159 threads consisting of 4,225 individual comments from 2,298 unique accounts. To allow for a robust qualitative analysis, we filtered this set down to the top three upvoted threads per post, and then randomly sampled 160 of these popular threads. We use *posts* to understand the types of IBSA for which people were seeking help and what help they were seeking, and *threads* to understand what help they received. We summarize our qualitative dataset in Table 1.

3.2 Qualitative analysis

We relied on a rigorous, qualitative analysis to describe and identify themes in our 261 posts and 160 threads. We used codebook thematic analysis (TA) that combined inductive and deductive approaches, which aligned to our mixed-methods approach [28]. We employed a five-stage codebook TA [82]: (1) sourcing initial codes; (2) developing initial codes; (3) codebook design; (4) codebook application; and (5) interpretation. For this study, use of a codebook enabled a refined and focused analysis of qualitative data [22].

Sourcing initial codes. As we developed our research questions, we conducted an initial analysis of IBSA literature and preliminary scan of IBSA help-seeking posts on Reddit – to summarize and identify potential codes [22] relevant to help-seeking needs, help-giving behaviors, and other characteristics of the data that applied to our research questions. Existing literature on IBSA types and risk factors informed our initial deductive codes; codes describing IBSA help-seeking needs and help-giving behaviors were developed inductively, as these are more emergent areas in the literature.

Developing initial codes. Next, one researcher familiarized themselves with the raw data, cumulatively reading thousands of Reddit posts about IBSA during the development of our data processing pipeline (Figure 1). This researcher then ap-

plied the initial codes to a random set of 100 posts stratified across IBSA types and then generated new codes from the raw data to identify more useful attributes of the data.

Codebook design. Next we developed the codebook, finalizing labels, definitions, and exclusions. All members of the research team reviewed the codebook; we took note of initial disagreements to iteratively update our codebook to account for these nuances. We segmented our codebook into three sections. The first section focused on the *nature of the IBSA*: the type of IBSA, the platforms involved, details about the perpetrator and victim-survivor, the origin of the IBSA imagery, and method of distribution. The second section focused on *help-seeking*: when help-seeking occurred, strategies already attempted, and what help was sought. The third section focused on *help-giving*: the type of support or advice offered and the interactivity of help-giving. See Appendix A.3 for details on individual codes and definitions.

Codebook application and reliability. Four coders applied the codebook to our posts dataset and three applied the codebook to our threads dataset, with two independently coding each post or thread. For reliability, we used *consensus coding* [18] for consistent judgment [13]. All coders iteratively discussed disagreements via meetings or online chat. Between discussions, one coder reviewed remaining disagreements, resolved obvious or already-discussed issues, and noted where discussion was still needed. We chose to ensure coding reliability through consensus coding and discussion because our codes were not mutually exclusive and the data were nuanced.

Interpretation. Lastly, we iteratively collated various codes, reviewed the data and memos, and discussed themes. Alongside our thematic analysis, we offer descriptive statistics. We report counts in the results with the notation *X of Y*, where Y is the total number of posts, threads, or people about which that code is specified, that is, excluding unspecified. In sections where Y is constant, only X is reported for brevity.

3.3 Ethics

Similar to prior work [8, 93, 99], we rely on data shared publicly by users on social media. We excluded all posts where it was clear that the poster/victim-survivor was under the age of 18. Our work does not directly recruit participants, but our study plan was reviewed by experts at our institution in domains including ethics, human subjects research, policy, legal, security, privacy, and anti-abuse. While the institution of the authors who conducted the data analysis does not require IRB approval, we adhere to similarly strict standards.

To mitigate potential harms that may come from victim-survivors' data being exposed to unexpected audiences, we rephrased all quotes to preserve meaning but obscure the original source. Strategies for disguising the source of content are increasingly common in research fields investigating social media data [26, 78], as well as recommended by digital-safety researchers [9], particularly when obtaining informed consent is not feasible. Scholars emphasize that disguise is an ethical practice for protecting participants' privacy [57]; additionally, contacting the original posters of the content we studied could unnecessarily re-traumatize victim-survivors. After rephrasing quotes, we searched each rephrasing to ensure the original source was not identifiable in the returned results. To balance protecting posters' privacy with data integrity, another researcher compared the rephrasing to the original quote to confirm the semantic meaning of the quote was not changed. This rephrasing was post-hoc and did not affect our analysis.

As this project involved sustained engagement with traumatic content, researchers involved in analysis took different measures to support their well-being, including: weekly individual and group check-ins, reading about secondary trauma [54], meeting with trauma-informed experts, having access to therapists, taking breaks (e.g., playing Tetris, which is being explored as a tool for reducing traumatic flashbacks [47, 86]), and restricting reading of traumatic posts to shared or designated workspaces. Our use of LLMs also reduced the amount of manual review required.

3.4 Limitations

As with all research, ours has limitations. Our crawl of Reddit may be incomplete, and our LLM-based search for IBSA help-seeking may miss some concepts. We attempted to minimize biases by validating our prompts on an independent sample of posts and by focusing on qualitative results rather than comprehensive quantitative findings. Additionally, our US-based research team—whose domain expertise includes computer security and privacy, human-computer interaction, criminology, gender-based violence, and social computing—apply our own interpretations to the stories shared on Reddit.

Our visibility into IBSA help-seeking and help-giving is also limited to what people mention when posting to Reddit in English. Reddit users are predominantly in the US, but also in the UK, India, and Canada [101]. Additionally, comments studied in Section 6 do not include those removed by Reddit mods, whose invisible labor contributes valuable content moderation [53]. Percentages are reported in the results for reader ease but should not be interpreted as generalizable to all cases of IBSA, given the limitations of our data collection.

How we report gender. Because IBSA can be a form of gender-based violence, we coded gendered terminology about the victim-survivor(s) and perpetrator(s) when specified.[5] One challenge inherent in analyzing social media data is that posts do not reliably or consistently provide gender disclosures. We inferred gender in five ways: Reddit conventions to self-identify (e.g., "21F" meaning a 21-year-old female), gendered nouns (e.g., woman, boyfriend, girl), gendered pronouns

[5] Gender was unspecified for 26% of perpetrators and 42% of victim-survivors.

(e.g., she, he), body parts (e.g., dick pic, breasts), or other (e.g., posting to a gendered subreddit, asking for opinions of "other women"). We most often inferred victim-survivor and perpetrator gender through gendered nouns (24%; 60%) or self-identifications (56%; 23%), but also inferred based on solely pronouns (8%; 17%) and body parts (26%; 1%). To avoid piecemeal reporting, we collapsed sex and gender, such that "man" includes all masculine terms, including gendered nouns and pronouns, and "woman" likewise includes all feminine terms. These codes should be interpreted as researcher inferences based on gendered terms in Reddit's broadly cisheteronormative context, which may or may not align with the gender identities of the individuals involved.

4 Characterizing IBSA Experiences

We begin by characterizing the IBSA experiences about which posters sought help. While prior work has identified the types of IBSA covered here, we contribute a description of all seven types from the same dataset, highlighting common, co-occurring, and distinguishing patterns across types. This approach provides an expanded understanding of a range of IBSA experiences and sets the stage for how to broadly support help-seeking needs.

In most cases, the poster identified as the victim-survivor (in 237 of 261 posts; 91%); in others (30; 11%), the poster was seeking help on behalf of the victim-survivor, e.g., a friend or intimate partner.[6] We synthesize these experiences, examining how abuse unfolded, perpetrators' apparent motivations, and gendered patterns between perpetrators and victim-survivors.

4.1 Financial sextortion (FS)

Financial sextortion occurred when a perpetrator threatened to expose explicit images of a victim-survivor unless the perpetrator was paid money.

Clear methods to obtain images. To initiate contact for financial sextortion, a perpetrator typically connected with a victim-survivor via a dating or social media app before moving to direct messaging or a communication app, engaging in a conversation with the victim-survivor within minutes to days. The perpetrator then coercively obtained, made claims about, or created explicit images following one or a combination of the following methods: they sent (inauthentic) explicit images to encourage the victim-survivor to reciprocate; they claimed to have an explicit image of the victim-survivor (with or without evidence); and/or they created an explicit image (e.g., by attaching the victim-survivor's face—such as taken from a profile picture—to someone else's body; such synthetic images are further discussed in Section 4.3).

[6] Counts do not sum to 261 because some posters were both a victim-survivor and seeking help on behalf of other victim-survivors of the same perpetrator(s).

Perpetrator	FS	NFS	NCSEI	PS	CF	NCEI	RSA
Stranger	48	18	31	12	26	6	8
Intimate partner	0	10	8	21	3	15	4
Friend	1	0	5	5	4	7	8
Ex-intimate partner	0	10	1	2	1	8	8
Colleague	0	0	1	2	4	1	4
Family member	0	0	1	1	1	2	0
Other	1	0	0	0	2	0	0
Unspecified	0	8	5	3	0	6	10

Table 2: Relationship of perpetrator(s) to victim-survivor, as described in posts.

Perpetrator	FS	NFS	NCSEI	PS	CF	NCEI	RSA
Woman	21	8	15	2	6	1	3
Man	3	20	16	39	27	31	31
Ambiguous	4	2	3	0	0	0	0
Unspecified	22	15	16	1	8	13	6

Table 3: Gender of the perpetrator(s), as described in posts. *Ambiguous* refers to posts where the poster initially described the perpetrator with feminine gendered terms but shifted to masculine gendered terms when a false identity was revealed.

Once the perpetrator had established or asserted that they had an explicit image, they issued a threat: either the victim-survivor had to pay or the explicit image would be distributed (e.g., *"Send me money or I'll share your nudes"*). Payment demands varied, but were typically the local equivalent of $100–1500 USD (specified in 28 of 50 posts; 56%).

Perpetrators were usually strangers, often women; victim-survivors men. Of the 50 posts, 48 identified the perpetrator as a stranger (Table 2). Of the 28 posts that specified the perpetrator's gender, 21 were believed[7] to be women (Table 3). Of the 27 posts that specified the victim-survivor's gender, 26 were men (Table 4).

Fear & self-blame. Perpetrators tried to exploit the victim-survivor's fear of embarrassment. Posters often emphasized the threatened scale of distribution: *"I'll send these masturbation videos to everyone you know, including your friends, colleagues, and relatives."* Victim-survivors often appeared to be in a state of panic when they posted, and they sometimes partially blamed themselves, claiming that they *"messed up"* or *"feel so stupid."*

What they've done; what else could they do. Posters sought

[7] Some posters, in line with prior work [31], acknowledged that perpetrators may be using this gender identity as a false persona.

Victim-survivor	FS	NFS	NCSEI	PS	CF	NCEI	RSA
Woman	1	13	11	25	18	27	26
Man	26	9	22	3	2	3	9
Unspecified	23	24	19	18	25	18	8

Table 4: Gender of the victim-survivor(s).

help to determine if the threat was credible, prepare for what to expect next, and ask for strategies to cope with their fear. When seeking help, victim-survivors often mentioned technical protections they had already taken, such as blocking the perpetrator, reporting the perpetrator to the platform, or bolstering their social media privacy and security settings. They then asked the community what else they could do.

4.2 Nonfinancial sextortion (NFS)

At a high level, nonfinancial sextortion was similar to financial sextortion except the threats were not financially motivated.

Personalized demands for more images or control. Nonfinancial sextortion tended to be customized to the particular victim-survivor and their situation. Perpetrators—who were often intimate partners—used the threat of exposing an explicit image to demand new images and/or to exert emotional, physical, or sexual control over the victim-survivor: *"he was obviously getting mad and eventually exploded and told me he'd send out my nude pics if I didn't have sex with him."*

Perpetrators often were intimate partners, usually men; victim-survivors women. Nonfinancial sextortion was usually perpetrated by a current (10 of 38 specified; 26%) or former intimate partner (10; 26%) (Table 2).[8] Victim-survivors often noted that the image the perpetrator threatened to expose was obtained with consent in a different context (8 of 43 specified), or nonconsensual secret recording (4). When specified, perpetrators tended to be men (20 of 30; 67%), victim-survivors women (13 of 22; 59%) (Tables 3 & 4).

Fear & helplessness. Like financial sextortion, perpetrators of nonfinancial sextortion attempted to control victim-survivors with fear of embarrassment. However, when compared to financial sextortion, posts about nonfinancial sextortion tended to include a more pronounced tone of helplessness: *"I feel suffocated with him and I don't see any type of future with him, but he has the power to ruin my life."*

Relationship & emotional advice. Victim-survivors expressed uncertainty about how to navigate their relationship with the perpetrator: *"should I cave to his demands so he doesn't dump me?"* They also asked for help coping with the emotional trauma associated with this type of IBSA.

[8] We coded posts about sextortion that did not mention a demand for payment as NFS. Such posts where the perpetrator was a stranger resembled (and may have been) FS, so we omit them from discussion here.

4.3 Nonconsensual *synthetic* explicit imagery (NCSEI)

Nonconsensual synthetic explicit imagery involved digitally manipulated explicit images. A majority of cases co-occurred with financial sextortion (27 of 51 posts, 53%; discussed in Section 4.1). Among other cases, a main theme appeared to be about the perpetrator exploring fantasies, especially when the victim-survivor and perpetrator were socially connected.

Simple manipulations. Posters explained that basic editing techniques were used to generate explicit images, using terms like *"photoshopped"* or *"filters with my face."* In cases of financial sextortion, perpetrators often sent victim-survivors a "collage" of explicit images and other media—a list of the victim-survivor's social media connections, screenshots of messages between the victim-survivor and perpetrator, or calls-to-action from the perpetrator to incriminate the victim-survivor (e.g., calling them a "pedophile")—to scare the victim-survivor into paying.

In other cases, posters found or learned about explicit images on the perpetrator's—usually the poster's intimate partner's—device, presumably for personal use such as the perpetrator's sexual gratification or exploration. In these images, victim-survivors' or other relations' faces were superimposed into explicit images: *"I recently found out [my intimate partner] had tons of pictures with my friends and family where their faces had been photoshopped onto sexually explicit photos to simulate porn scenes."*

The emergence of sophisticated manipulations. The (suspected) use of generative AI to create nonconsensual synthetic explicit imagery was mentioned in 3 of 51 posts (6%). In those cases, victim-survivors found the imagery's photorealism terrifying: *"Someone used a nudifying app to make naked photos of me from my social media pictures. I'm terrified."*

Nonconsent, fear, & disgust. The quality of the synthetic imagery was not a focus of posters; instead, they discussed the harm that even simple manipulations could create. In financial sextortion cases, victim-survivors shared that synthetic imagery might deceive family or peers: *"The nudes are fake, but it's not like my parents can tell that."* In other cases, posters expressed disgust because the synthetic imagery was nonconsensually created by people the poster knew, and the images portrayed people in sexually explicit ways that the poster found inappropriate or offensive. For example, one poster found synthetic images of a friends' family member, which left the poster *"in tears... I'm utterly disgusted and distraught by the situation."* Another poster discovered that their partner had been creating images of their friends and family for years, and despite knowing they were fake, viewed the creation of the images as a grave breach of trust: *"The*

files... were created a few years ago and I cannot believe how blind I was. I trusted him and now I am broken."

Navigating relationships & feelings. Posters sought help for how to deal with perpetrators (including asking for relationship advice) and to make sense of how they felt about the discovery of nonconsensual synthetic explicit imagery.

4.4 Pressurized sexting (PS)

Pressurized sexting occurred when a perpetrator coerced or demanded that a victim-survivor send explicit imagery. In a majority of these posts (29 of 45; 64%), victim-survivors claimed they had not sent the images; rather, they asked for help mitigating coercion.

Navigating relationship expectations. Pressurized sexting occurred primarily in relationships, that is, by current intimate partners of the victim-survivor (21 of 42 specified; 50%), or between strangers who were prospective partners via online dating or social media apps (12; 29%).

New vs. established relationships. When pressurized sexting occurred in the early stages of a (potential) relationship, posters expressed feelings of being manipulated or "used for nudes": *"I can't believe someone asks for nude pictures, and their only motivation in talking to me is trying to get nudes."*

When in established relationships, victim-survivors often attempted to resolve conflicts between what they were comfortable with and their intimate partners' expectations. For example, some asked if pressurized sexting warranted ending a relationship: *"My boyfriend asks for nudes and if I refuse he ignores me until I give in. Can someone tell me if we can fix this, or if I should just get therapy to help me break up with him?"* This was especially true if the pressurized sexting was perceived as the sole problem in a relationship. *"This guy is great except he asks me to send nudes... I don't want to break up but I hate when he does this. What should I do?"*

Perpetrators were usually men, victim-survivors women. Most perpetrators were presumed to be men (40 of 43 specified; 93%); victim-survivors tended to be women (25 of 27 specified; 93%) (Tables 3 & 4).

4.5 Cyberflashing (CF)

Cyberflashing occurred when a victim-survivor received unwanted sexually explicit imagery.

Online dating. Cyberflashing commonly occurred in the process of seeking romantic relationships online. Victim-survivors frequently discussed whether they were out-of-step with shifting norms around sending or receiving explicit images: *"Can someone please explain why people send unsolicited nudes?"* In some cases, cyberflashing occurred as part of pressurized sexting (Section 4.4), where a perpetrator would demand reciprocity after sending unwanted explicit images: *"I told him I didn't want any, but he sent dick pics anyways...he asked for a picture of my breasts but I said no cuz I never send naked pictures of myself."* The tone of these posts was often that of frustration, disgust, and disillusion.

Platonic relationships. Less often, cyberflashing occurred in platonic relationships (e.g., between coworkers or friends). In those cases, the poster was typically concerned about the ongoing relationship and if/how they should address the abuse.

Perpetrators were usually men, victim-survivors women. Most perpetrators were men (27 of 33 specified; 82%), while victim-survivors were women (18 of 20 specified; 90%).

4.6 Nonconsensual explicit imagery (NCEI)

Nonconsensual explicit imagery involved perpetrators producing or distributing explicit images without the victim-survivor's consent. It often involved abuse by an intimate partner, ranging from a one-time incident to ongoing abuse.

Perpetrators were usually men; often partners, friends, or peers. Victim-survivors were usually women. Victim-survivors were usually women (27 of 30 specified; 90%), while perpetrators were often men (31 of 32 specified; 97%). Most perpetrators were known to the victim-survivor (33 of 39 specified; 85%) rather than strangers (6; 15%).

Images were often recorded without consent. The trusted status many perpetrators had with victim-survivors enabled secret recordings (20 of 38 specified; 53%). Victim-survivors shared how perpetrators recorded them: *"took nude photos of me while sleeping"* and *"recorded me [naked] in my room."* Less frequently, images were recorded through coercion (6; 16%) or shared with consent in a different context (6; 16%).

Navigating relationships; fear of possession & distribution. Nearly half of the posts focused on how to navigate the relationship (e.g., whether and how to confront or break up with the perpetrator). Victim-survivors were concerned about the perpetrator's possession of the explicit imagery (18 of 41 specified; 44%) or its distribution, e.g., via messaging (14; 34%), social media (9; 22%), or public websites (3; 7%).

Victim-survivors concerned mainly with *possession* primarily sought help on how to negotiate with the perpetrator, delete any explicit imagery, know if the imagery had been shared, or know how many images existed: *"How can I find and delete as many as possible of the naked photos he has of me?"* Conversely, victim-survivors contending with *distribution* focused their help-seeking on what recourse, if any, existed: *I dunno what to do. He sent my mom my nudes because I was breaking up with him... Any advice would be appreciated.*

4.7 Recorded sexual assault (RSA)

Recorded sexual assault involved the creation or distribution of images of sexual assault. It frequently resulted in victim-

survivors experiencing ongoing sexual trauma in addition to trauma from images being created or distributed.

Perpetrators were often known men; victim-survivors tended to be women. Perpetrators were often men (31 of 34 specified; 91%) that victim-survivors identified as former intimate partners (8 of 32 specified; 25%), friends (8; 25%), colleagues (4; 13%), or current intimate partners (4; 13%), but also strangers (8; 25%). Victim-survivors were often women (26 of 35 specified; 74%), but sometimes men (9; 26%).

Co-occurred with other abuse. Victim-survivors shared that their assault was often secretly recorded (23 of 40; 58%), such as when they were unconscious, sleeping, drugged, or under the influence of a substance. Recorded sexual assault often co-occurred with other abuse (13 of 39; 33%)—sometimes prolonged intimate partner abuse—leaving victim-survivors in a state of severe trauma. Most victim-survivors shared that perpetrators retained recordings of the assault (26 of 40; 65%); some perpetrators distributed the recordings via messaging (7; 18%), social media (4; 10%), or websites (4; 10%).

Trauma, processing, & coping. All of these posts were deeply troubling and resulted in trauma to the victim-survivor and typically others who were exposed to the recording. Most victim-survivors asked how to cope with or understand what they had experienced, as a precursor to processing their emotions or taking a step towards remediation: *"Was this sexual assault?," "Did I just make poor decisions or was this wrong?," "I don't know how to feel,"* and *"I'm wondering if any part of this sexual assault was normal."*

4.8 Co-occurring IBSA types

54 posts described more than one IBSA type. Most prominently, of 51 posts on nonconsensual synthetic explicit imagery, 27 co-occurred with financial sextortion and 7 with nonfinancial sextortion, indicating that perpetrators commonly leveraged synthetic images to sextort. Cyberflashing and pressurized sexting co-occurred in 9 posts, indicating that perpetrators sometimes both sent and pressured the victim-survivor for explicit images. Nonconsensual explicit imagery co-occurred with multiple other IBSA types in 9 posts (out of 45 total); these posts mostly described multiple abusive events. One post described three types of IBSA (NCEI, cyberflashing, pressurized sexting), and one described four (NCEI, recorded sexual assault, pressurized sexting, nonfinancial sextortion).

5 Help-Seeking for IBSA

Across IBSA types, posts mentioned prior remediation efforts and included some common patterns of help-seeking questions, such as informational questions (Section 5.3), as well as how to cope with emotions (Section 5.4) or navigate relationships (Section 5.5)—these and other less common help-seeking types are summarized in Table 5.

5.1 When posters sought help

Using a theoretical framework [48], we can describe patterns in *when* people sought help for IBSA. This framework defines four states of users experiencing safety events: *prevention, monitoring, crisis,* and *recovery* (see details in Appendix A.3). People may move through the states nonlinearly and experience multiple events at once. When coping with *multiple safety events* (57 of 257 posts; 22%)[9], posters' panic and trauma were compounded.

Help was most often sought while the poster was in *crisis*, that is, when they were actively dealing with abuse (142; 55%). These posters expressed panic and needed immediate reassurance, as well as clear, simple guidance on the most critical steps to stop or limit further damage. Many posters also sought help while *recovering* from the abuse and feeling traumatized by it (112; 44%). Fewer posters described being in *monitoring*, for example, watching for new abuse or for images to appear in new places (42; 16%). Rarely, posters sought help *preventing* victimization (5; 2%).

5.2 Prior attempts at remediation

Posters mentioned prior attempts at remediation (in 176 of 261 posts; 67%), which were only partially successful or failed, prompting them to seek help on Reddit (Table 7 in Appendix B).

(Dis)engaging perpetrators. Of posts that noted prior attempts at remediation, nearly half mentioned engaging with perpetrators through negotiation or mediation (76 of 176 posts; 43%). This strategy often occurred when IBSA was enacted by an intimate partner, including NCEI and pressurized sexting. Another nearly half disclosed that the victim-survivor disengaged from the perpetrator, cutting off communication (82; 47%); some attempted engaging and then disengaging. Disengaging was common when the perpetrator was a catfisher or scammer, including financial sextortion and nonconsensual synthetic explicit imagery.

Technical strategies. Technical strategies, which included securing accounts or devices, platform reports, and deleting content, were sometimes employed (49 of 176 posts; 28%). They were infrequently reported across IBSA types, except for financial sextortion, for which victim-survivors more consistently reported deleting accounts or reporting. Often, sexually explicit images resided on a perpetrator's personal device or chat history, making it technically challenging for victim-survivors to access and for platforms to respond. As many help-seekers posed open-ended questions (e.g., *"what should I do?"* as described in Section 5.3), some may not have been aware of what technical strategies were possible.

[9] Number of posts here is 257 because four did not specify the user state.

Help Sought	Description	FS	NFS	NCSEI	PS	CF	NCEI	RSA
Informational	Seeking general advice about options or potential actions.	37	25	29	9	22	20	16
Therapeutic	Seeking advice about emotions or other distressing elements.	17	11	16	19	10	7	25
Relational	Seeking advice about interpersonal dynamics or managing relationships with others.	3	17	13	25	14	18	5
Legal	Seeking legal avenues of recourse or asking legal questions.	5	4	8	3	7	9	7
Technical	Seeking advice about mitigating the abuse through technical means, potentially to prevent primary or secondary sharing of the image, or tracking the past sharing of the image.	3	1	2	1	1	4	1
Other	Seeking a type of help not listed above.	4	3	2	1	0	0	1

Table 5: Types of help sought across the seven types of IBSA. Some posts discussed multiple forms of IBSA and were counted in multiple cells per row; some posts also included multiple types of help-seeking.

Social & institutional support. Victim-survivors rarely mentioned seeking or obtaining social support—a common practice used to cope with other forms of abuse [96, 84]—or broader institutional support. The small number of posts that did, mentioned filing police reports (20 of 176; 11%), reaching out to family or peers (19; 11%), or reaching out to the victim-survivors' workplace (6; 3%). A common reason for not seeking social or institutional support was embarrassment: *"I only told a few friends about what happened, but not with any specifics because it's so humiliating. I really have no one to discuss this with."*

5.3 Information: To understand & stop abuse

Nearly half of posters sought *informational* help (in 127 of 261 posts; 49%), with questions focused on making sense of the IBSA and determining how to make it stop.

What should I do? Many posts included open-ended requests (*"someone help me, i have no idea what to do"*), such as from victim-survivors who appeared panicked as they tried to stop or recover from IBSA.

What's happening to me? Another type of request—especially from those experiencing recorded sexual assault—asked whether their situation constituted assault, abuse, or coercion. These requests sometimes included misunderstandings, such as how intoxication affects consent: *"Was I sexually assaulted? I was okay going to his place even though I was totally wasted. When I was there, he made me do things and I consent after he convinces me. Then he takes out his phone to take a video, which I never consented to. Did I make the wrong choice or was it just wrong?"*

What can I expect? Posters also asked what to expect in the near and long term. For example, for financial sextortion, victim-survivors asked if perpetrators would follow through on threats to distribute imagery, if they were "safe" after waiting a certain period of time, or how they would know if the abuse was "over." For nonfinancial sextortion and NCEI especially, victim-survivors asked about what would happen if the explicit imagery were shared. They sought help anticipating and mitigating future harm.

Why did they do this? Questions about perpetrator motivations were common (e.g., why they created synthetic explicit imagery, or pressured people into sexting). Multiple cyberflashing victim-survivors—especially women—asked why it was *so* common in online dating: *"Why is it that within a few days of talking, men always send pen*s pics?"*

5.4 Therapeutic: Coping with emotions

About a third of posters sought emotional or *therapeutic* help (in 86 of 261 posts; 33%).

Trauma. Victim-survivors asked for help coping with intense feelings, particularly in cases of recorded sexual assault and NCEI. They were overwhelmed by emotions like shame (*"I'm melting from the shame and guilt"*) and disgust (*"I'm disgusted and feel so violated"*) upon discovering the details of the IBSA, such as who images had been shared with, or who possessed (and thus had control over) the images.

Empathy, self-doubt, & isolation. Posters sought empathy (*"Can anyone provide reassurance or share their experience, anything helps"*) and help with processing their feelings (*"I needed to vent to someone"*). Some felt conflicted and experienced self-doubt in understanding their own experiences: *"I don't know how to feel, I don't trust anything."* For many victim-survivors, experiencing IBSA was an isolating experience. They described being ostracized from social connections: *"I only wrote this post because I wanted to talk to someone. I have no friends right now"* or not receiving support from institutions like their employer's human resources department, their school, or law enforcement.

Fear of confronting the perpetrator. Posters recognized that confronting the perpetrator could result in even more harm and asked for help in managing fears while planning next steps: *"I'm scared he'll be mad and share my pics if I confront him."*

5.5 Relational: Navigating relationships

About a third of posters sought *relational* help (in 84 of 261 posts; 32%) for navigating situations where the victim-survivor was socially connected to the perpetrator.

Romantic relationships. Some victim-survivors experiencing NCEI as part of romantic relationships struggled with whether or not they should stay with their perpetrator-partner. In these posts, "love" was cited as a reason to stay, and victim-survivors questioned their own behavior: *"We really love each other. However I also feel bad because he's always spending time with me. Is he stressed out because we spend so much time together? Would it have been better if I broke up with him?"* Posters also cited the central role their intimate partner played in their lives (*"he's my everything"* and *"everything i've done was with his support"*).

Victim-survivors experiencing pressurized sexting and cyberflashing—typically when the perpetrator was an intimate partner—also asked about staying in the relationship (e.g., was the perpetrator's behavior a *"red flag"* or *"deal breaker"*?). They also commonly asked for help with how to effectively confront the perpetrator, such as to ask them to stop, resist pressure, or negotiate for images to be deleted.

Nonromantic relationships. When the perpetrator was socially connected to the victim-survivor, but not an intimate partner, such as a work colleague or friend, victim-survivors asked how to manage the relationship moving forward: *"My [22M] BFF [22F] flashed me and now won't talk to me. What should I do?"*

6 Help-Giving for IBSA

We now turn to comments on posts about IBSA, that is help-giving. Help-giving appeared to be community-oriented, as 55 help-givers (out of 2,298 total) supported multiple posters in our dataset, and all but seven of these commented within the same subreddit. Help-givers and help-seekers generally did not overlap (or they used throwaway accounts); only one account in our dataset created a post *and* commented on someone else's post.

6.1 Types of support and advice

Across our 261 posts, help was almost always given: only 15 posts received no comments, and the median post received five comments authored by four distinct users. However, few help-givers asked for more details to inform or tailor advice (14 of 160 threads). We discuss the most salient forms of help-giving below (Table 6 provides a summary; some posts and associated threads contained multiple IBSA types, so the row totals are greater than the denominators reported below).

Informational. The primary form of help-giving was sharing information (72 of 160 threads; 45%). For financial sextortion, informational advice highlighted the scripted nature of the attack: *"This scam is super common. You can't do anything except block them (and stop sending d*ck pics to randos)."* For cyberflashing and pressurized sexting, threads explained the changing norms around sexting and the choices available to victim-survivors (e.g., blocking, reporting). For NCEI and recorded sexual assault, threads instead focused on reinforcing that the experience was abuse: *"Revenge porn is pretty much always considered illegal"* and *"This is definitely sexual assault."* Help-givers' tone when sharing information, however, was not always comforting: *"Even if you told me to imagine the most fucked up thing I could, I still wouldn't think of that"*. Furthermore, help-givers rarely pointed the poster to other communities or resources (5 of 160 threads; 3%). We discuss these limitations more in Section 7.1.

Technical. Technical advice was common across most types of IBSA (52 of 160; 32%). Some threads focused on not engaging with the perpetrator (21) or blocking and reporting a perpetrator's account (26), e.g., in financial sextortion, pressurized sexting, or cyberflashing, where a perpetrator was a stranger or acquaintance. A less prevalent alternative was telling the victim-survivor to make their own account private to minimize contact (7). Such advice was mostly absent from IBSA involving an intimate partner, like nonfinancial sextortion, NCEI, and recorded sexual assault. Technical advice in these scenarios focused on how to delete photos if the victim-survivor had access to a perpetrator's accounts or devices (5), how to check for backups (2), or how to find and record evidence of abuse (9): *"Screenshot the convo in which your gf got the video before you delete it."* Advice to block or otherwise avoid perpetrators aligns with highly recommended advice by experts to stay safer online from harmful content [98].

Relational. Threads frequently discussed relationship advice (52 of 160; 32%), but not always in well-reasoned ways. Threads commonly directed victim-survivors to end their relationship (29) across all types of IBSA other than financial sextortion, no matter the circumstances shared by the victim-survivor, including their living or financial situation, their desire to make a relationship work (*"I love him so much, and I know he loves me too"*), or whether or not leaving was a safe option. For example, one victim-survivor clearly stated their desire to stay with their partner, who was not the perpetrator of the IBSA, but was still told to leave: *"That's fucking me up to the point I would dump her."* Furthermore, help-givers at times assumed worse behavior from the perpetrator than was specified in the post: *"Any guy who pressures you for nudes will share them with his friends."* Some threads were more nuanced, however, laying out how the victim-survivor had agency in setting boundaries in cases of cyberflashing or pressurized sexting (20). Others advocated engaging with a perpetrator (10), particularly for NCEI and pressurized sexting, to negotiate deleting images or ceasing requests: *"Send him a message asking him to delete what he filmed, that he didn't*

Help Given	Description	FS	NFS	NCSEI	PS	CF	NCEI	RSA
Informational	General details that explain a type of IBSA, a perpetrator's motives, or directing to a resource for more information.	15	11	17	12	17	14	7
Technical	Advice for security and privacy, blocking, reporting, deletion, and whether to engage with a perpetrator's account.	9	11	12	12	11	11	6
Relational	Advice for navigating relationships, whether to inform family and friends, or whether to reason with perpetrators.	4	7	10	16	11	14	5
Therapeutic	Advice for taking time for yourself, not to be afraid, that it is not your fault, and that you are not alone.	6	8	11	14	9	13	9
Institutional support	Advice around law enforcement, legal options, therapists, support centers, or human resources.	2	2	4	3	9	9	7
Counterproductive	Advice that cast blame on the victim-survivor, or otherwise ignored the needs of a victim-survivor.	5	2	4	4	1	2	5
Other	Help-giving in other ways not described above.	0	3	0	1	0	4	2

Table 6: Types of help given across the seven types of IBSA. Some threads responded to posts discussing multiple forms of IBSA and were counted in multiple cells per row; some threads also included multiple types of help-giving.

ask for permission and broke your trust." Finally, threads discussed creating a support network to prepare for the risk of leaked imagery or to intercede with the perpetrator (12).

Therapeutic. Therapeutic help-giving was also common (52 of 160; 32%), such as reassuring victim-survivors that a situation was not their fault (15) and telling them to not be alarmed (14) or look after themselves (12). Threads also reiterated that a perpetrator was harmful (8) or commiserated with similar experiences (8). In the case of financial sextortion, threads focused on reassuring the victim-survivor that not engaging was the right tactic and to not be afraid: *"If you haven't sent any money, they have no reason to go after you."* Meanwhile, threads responding to NCEI, recorded sexual assault, and nonconsensual synthetic explicit imagery emphasized general support of the victim-survivor as they navigated abuse: *"I hope that you heal and find sweet and honest love again."*

Institutional support. While less frequent, help-giving also encouraged seeking institutional support (31 of 160; 19%). This advice focused on contacting law enforcement (15) or accessing legal advice (13), therapists (8), advocacy groups (3), human resources (3), or immediate medical support (1). Such advice was largely given for cases of NCEI (9), cyberflashing (9), or recorded sexual assault (7).

Counterproductive. Not all help-giving was supportive of victim-survivors (19 of 160; 11%). Some community members admonished the victim-survivor for their behavior, asking what they expected by sharing explicit images with others: *"Honestly if you're sending dick pics to online randoms, does it matter that they're getting leaked?"*

Others minimized or de-legitimized victim-survivors, asking *"What's the worst that can happen?"* or claimed most recorded sexual assault videos found online are fake. While the majority of upvoted threads were helpful (144 of 160; 90%), these examples show how help seeking on social media can expose victim-survivors to additional shame or risk.

6.2 Victim-survivor reactions to help given

In general, the advice given on Reddit seemed to resonate with the poster. Of the 246 posts with at least one comment, at least 64 had one or more comments from the poster, that is, where the poster engaged in some way with help-givers.[10] The median engagement by posters was 50% of threads.

Posters expressed a range of reactions to help given, including providing or requesting more information (20 of 160; 13%), expressing appreciation for the help they received (16; 10%), and outlining a concrete plan of action based on the help they received (9; 6%). These reactions were spread roughly evenly across IBSA types. In many of these comments, the poster offered only a short thanks, even if there was no clear resolution. Some threads seemed to have helped them make sense of their experience: *"Thanks for confirming what I thought."* One back-and-forth sextortion thread helped the victim-survivor better understand the nature of the scam and feel reassured as a result: *"Thanks for the help and info, I learned something new."* In very few cases (4; 3%), posters expressed feeling hopeless even after receiving support: *"It's just so rough that there's nothing we can do."*

7 Discussion

We now reflect upon both the challenges in this space (Section 7.1) and possible roles of technology in solutions (Section 7.2). While our results provide insights into help-seeking and help-giving behaviors on Reddit, we argue that it is too early to speak definitively on the full set of challenges or solutions. Thus, we encourage readers to view our discussion here as a results-informed exploration of the possible parameters of the challenge and solution spaces.

[10] This number is a lower bound: our quantitative analysis was based on our delayed crawl of the live site and thus could not identify engagement by a poster who had later deleted their account, which was a majority of posters.

7.1 Existing challenges

Limited nuance or formalized advice. Victim-survivors were offered emotional support in the form of concern and empathy (Section 6.1), making it clear informal help-giving on Reddit provides a lifeline to those who might otherwise be unwilling or unable to disclose and seek help. This suggests findings from previous related work on online help-seeking for offline sexual abuse [1, 2, 36, 65, 72] are replicated for technology-facilitated sexual violence. Namely, the anonymity and visibility management often afforded by online spaces facilitates support seeking, both explicit and implicit. As in previous work [66, 97], we also observed the constraints associated with online support, such as help-givers who defaulted to certainty around the situation or the "right" outcome without asking for more details or centering the expressed needs or desires of the victim-survivor, thus overlooking important nuances. For example, the point at which a victim-survivor leaves an abusive partner poses the greatest risk of harm to the victim-survivor [92], so gender-based violence advocates typically scaffold the creation of a safety plan [16, 24]. However, help-givers commonly suggested leaving a relationship without mentioning safety plans or other risk mitigation strategies. Relative to other types of help given, referring to institutional support was the least common (Table 6). Formal organizations[11] may be better suited to providing long-term and holistic support, but it is clear that connecting victim-survivors to support outside Reddit remains a challenge.

On the other hand, our work contains hints of why victim-survivors may have sought help on Reddit rather than via institutions. Between the time at which our Reddit snapshot was collected and our crawl of the live site in December 2023, 99 posts and 146 poster accounts had been deleted. Further, 41 posts were from "throwaway" accounts, i.e., accounts not used again on Reddit, suggesting that posters valued Reddit's perceived anonymity or ephemerality. We also observed in Section 5.1 that posters most often sought help when in active crisis, and may have viewed Reddit as a faster way to get help than finding and reaching out to an advocacy organization. Of course, the fact that posters sought help on Reddit does not preclude them seeking help from other sources as well.

Underscoring challenges in technology-facilitated abuse. Our analysis of IBSA help-seeking on Reddit exemplifies two key challenges from broader technology-facilitated abuse literature. First, prior work emphasizes the weaponization of new technologies to expand the scope of potential targets [69]. For example, in most financial sextortion and cyberflashing posts in our dataset, the perpetrator was someone previously unknown to the victim-survivor before the IBSA (Sections 4.1 and 4.5); perpetrators leveraged new platforms and social discovery algorithms to find new victim-survivors. Another poster asked for preventative strategies against generative AI specifically, because they were concerned: *"with all the AI hype, many people around me are making nudes of others, especially of women."* More generally, the imagery was synthetic in all NCSEI cases and victim-survivors expressed distress over the ability of perpetrators to portray them in ways they had not consented to. Perpetrators will continue to leverage new technology, necessitating ongoing research to prevent its misuse.

Second, our findings reiterate the occurrence of polyvictimization, as studied in technology-facilitated violence literature [43, 56, 64]. Many victim-survivors described experiencing other types of abuse that co-occurred with the IBSA. Echoing research on intimate partner abuse [33, 93], supporting victim-survivors requires holistic and trauma-informed [19] approaches that do not regard technology as a panacea.

Aligning interventions with sites of harm. While some technological interventions exist for different types of IBSA, our analysis raises challenges for their reach. For example, StopNCII [90] helps victim-survivors get images removed from social media platforms, but in only nine (of 45) NCEI cases did posters mention that images had been posted on social media. More often, posters were concerned about perpetrators nonconsensually retaining images (18 of 45) or distributing them via messaging apps (14 of 45) (Section 4.6). Generally, IBSA incidents in our dataset were most frequently carried out via dedicated communication apps or direct messages on social media (143 of 247, see Table 8 in Appendix B). Fewer cases involved images being posted on one-to-many platforms: social media (72), porn websites (6), or unspecified websites (3). Nevertheless, reporting IBSA to platforms remains one of the few technical mechanisms to remove explicit images stored or shared on a platform, or to potentially take action against a perpetrator's account and prevent others from being targeted. Thus, while reporting can be an effective intervention in these cases, our findings suggest an additional need to create contextually specific technological interventions.

7.2 Role of technology in solutions

Expanding and integrating the support ecosystem. Our analysis shows IBSA help-seeking on Reddit occurs in hundreds of thousands of posts, some with tens to hundreds of comment threads. This creates a burden for communities to triage and potentially leads to inconsistent advice depending on who responds in the moment. Recent advances in LLM agents could amplify help-giving: triaging incoming queries, requesting additional information as needed, providing guidance where best practices exist (e.g., for financial sextortion), and connecting victim-survivors with relevant advocacy organizations who provide hands-on support. Results from our study could guide the design of such an agent

[11] Examples for tech-facilitated abuse more broadly include https://www.ceta.tech.cornell.edu/ and https://techclinic.cs.wisc.edu/

or other interventions, accounting for help-seekers' common emotional states, questions, and needs (Section 5). Such an agent may not replace the interpersonal therapeutic support that help-seekers received through other people on Reddit, but could be more consistently available while complementing other available help-giving pathways. Early research on a non-generative AI agent is underway,[12] but this remains a ripe area for exploration.

On-device detection and warnings. Given the complexity of remediating IBSA *after* an explicit image is shared, technology could play a *preventative* role. Given the privacy sensitivities—particularly around messaging where much of IBSA occurs (Table 8 in Appendix)—this technology would be best *on-device* to minimize explicit images being sent to platforms. To this end, Apple recently announced opt-in, on-device detection of sensitive (e.g., "nude") content [4]. While these technologies are in an early stage, they might take the form of nudges against sending explicit images (e.g., pressurized sexting, financial sextortion); or blurring explicit images upon receipt (e.g., cyberflashing). The effectiveness of these nudges—and expanding the detection capabilities to dangerous interactions (e.g., early detection of sextortion patterns)—remain to be explored. Smartphones could also extend current alertness-detection methods (e.g., as used in face biometric systems to assess whether a person is awake) to prevent or make more challenging the taking of nude or explicit imagery of people who are asleep or otherwise unaware.

Expanded controls around explicit content. Technology might also play a role in mediating how, for how long, and with whom explicit images are shared to reduce the risk of IBSA like sextortion and NCEI. Qin et al. discussed options such as disappearing messages, screenshot notifications, and watermarking to prove ownership or track the origin of a leaked image [79]. In practice, the effectiveness of these technologies hinges on the origin of an image (e.g., initially consensual vs. covertly recorded), and the willingness of perpetrators to adhere to tech-mediated norms. However, any increased friction for perpetrators can still reduce harm [80].

Audio-visual alerts around recording. Victim-survivors of NCEI shared that perpetrators often covertly captured explicit imagery. One intervention explored by device manufacturers in Japan and South Korea has been to emit a "shutter" sound whenever a cellphone records imagery [87]. This strategy is similar to the alert emitted by AirTags, intended to prevent stalking [70]. Such a feature could be paired with on-device detection of explicit content. Whether such a feature is acceptable to users, and to what degree it discourages NCEI, requires further investigation.

Preventing generative content. Specific to nonconsensual synthetic explicit imagery, generative AI technologies require safeguards to prevent their use in IBSA. Solutions likely require a combination of preventing harmful model outputs and also detecting synthetic explicit imagery.

[12] See Umibot, https://umi.rmit.edu.au

8 Conclusion

We examined Reddit conversations about IBSA experiences, exploring the (1) types of IBSA for which people sought help, (2) the help they asked for, and (3) the help they received. After identifying over 100,000 posts through combined LLM and manual review, we qualitatively analyzed a stratified sample of 261 posts about seven types of IBSA: financial sextortion, nonfinancial sextortion, nonconsensual *synthetic* explicit imagery, pressurized sexting, cyberflashing, nonconsensual explicit imagery, and recorded sexual assault. We synthesized similarities in types of help sought and given, finding that across the seven IBSA types we studied, victim-survivors most often asked for and were offered information, empathy and therapeutic support, and advice about managing existing relationships. Technical, legal, and other institutional support were comparatively less common, indicating opportunities for more comprehensive support. Our work informs existing challenges towards mitigating, preventing, and supporting recovery from IBSA, and we outline the role technology could have towards potential solutions.

Title: [TITLE]
Article: [ARTICLE]

Task: Categorize the Title and Article as either
- 1) Sextortion
- 2) Nude image taken without consent
- 3) Cyberflashing or receiving unwanted nudity
- 4) Manipulated media like deepfakes, photoshopped images, or cheapfakes
- 5) Pressuring someone into sending nude images
- 6) Unwanted attention
- 7) Recording of sexual assault
- 8) Other

Categorization:"""

Figure 3: Categorization prompt designed to identify the most relevant type of IBSA discussed in a Reddit post. IBSA type names and description differ from types shown in Table 1 due to experimental iteration with LLM prompts.

A Additional Methodological Details

A.1 Subreddits used

The subreddits we manually selected, as described in Section 3.1, were: r/advice, r/techsupport, r/legaladvice, r/legaladviceuk, r/legaladviceindia, r/legaladvicecanada, r/legaladviceeurope, r/legaladvicegerman, r/legaladviceNZ, r/legaladviceireland, r/legaladviceeu, r/relationship_advice, r/dating_advice, r/relationships, r/dating, r/marriage, r/sex, r/online_dating_advice, r/indian_datingadvice, r/femaledatingstrategy, r/onlinedating, r/tinder, r/bumble, r/hingeapp, r/grindr, r/onlyfansadvice, r/fansly_advice, r/camgirlproblems, r/antipornography, r/loveafterporn, r/pornfreerelationships, r/pornfree, r/sexualassault, r/sexualassaultsurvivor, r/creepyPMs, r/twoxchromosomes, r/thegirlsurvivalguide, r/askwomen, r/askwomennsfw, r/askmen, r/askgaybros, r/sextortion, r/scams.

A.2 Filtering: Keywords vs. LLM Prompts

As described in Section 3.1, we initially explored using keywords chosen from prior work, manual searches, discussion with experts, and our own domain expertise. We collected 60+ keywords and developed a three-part formula for surfacing relevant posts: >1 media keyword (e.g., *image, nude, screenshot, personal vid*), >1 IBSA keyword (e.g., *revenge porn, cyberflashing, without consent, sextortion, leak, threat, coerce*), >1 help keyword (e.g., *help, support, what should i do*). However, keyword searches introduced a prohibitive number of false positives to manually review, e.g., discussing IBSA in the news, posts that were not help-seeking.

Therefore, we developed the LLM-based filtering and categorizing approach described in Section 3.1; figures 3 and 4 show additional prompts. All posts were subsequently validated through manual review.

A.3 Codebook

The full list of codes applied to the 261 posts in our post dataset, and the 160 associated threads, with abbreviated definitions for each code. Codes were not mutually exclusive.

1) Codes about the Nature of IBSA
Perpetrator: current partner, ex-partner, friend, family members, colleague (work or school), stranger (unknown to victim-survivor prior to IBSA), other (none of the above), unspecified
Perpetrator(s)' and victim-survivors' gender, age, location: in terms used by post
Method of distribution

You are a content moderator for safety policies. Your job is to carefully inspect articles and answer each question below using the single word "Yes" or "No".

Title: [TITLE]
Article: [ARTICLE]

Question 1: Does the title or article discuss a threat to expose nude images unless a payment is made?
Question 2: Does the title or article discuss a threat to expose nude images unless the person sends more nude images or stays in a relationship?
Question 3: Does the title or article discuss taking, recording, or leaking a nude image without consent?

Your answer should be in json format seen below, where your answer should replace the "‘ :
{
"Question 1": "‘,
"Question 2": "‘,
"Question 3": "‘
}

Figure 4: Categorization prompt to determine whether a post discussed a specific type of IBSA (here, nonfinancial sextortion). A Python parser validated the sequence of Yes and No answers necessary for a category label to apply.

- Threat: Perpetrator threatens to share or distribute the image
- Possession: Perpetrator has possession of the image without threatening to or actually sharing
- Social media: Perpetrator posted the image to social media
- Website: Perpetrator posted the image to a website or elsewhere online
- Messaging: Perpetrator directly messaged the image to others
- N/A (no content): Perpetrator pressured the VS to send an image, but VS did not
- Unspecified

Image origin

- Consented: Shared for a different reason or in a prior context, but consent has been revoked
- Coerced: Sent or taken under coercion from the perpetrator including: under false pretenses; non-secret, non-consensual image taking; soliciting face images for abuse
- Coerced (not sent): VS has not sent image, but perpetrator attempted coercion
- Created: Synthetically created
- Hacked: Obtained through hacking or unauthorized access
- Sold: Available for sale by VS, but not for sharing
- Secretly recorded: Recording not known to VS when recorded
- Unconsented exposure: VS nonconsensually exposed to someone else's image
- Unspecified

2) Codes about Help-Seeking
Self-help: Yes (poster is the person experiencing the abuse), No (poster is NOT the person experiencing the abuse)
Strategies attempted

- Support: Talking with others in a support network, online or offline; does not include the Reddit post itself
- Platform report: Using online platform reporting mechanisms
- Police report: Contacting the police or making a police report
- Workplace report: Contacting HR or workplace supervisor
- Engage: Negotiating conditions of abuse with the perpetrator
- Disengage: Stopping contact or other means of engagement with the perpetrator to try to mitigate the abuse
- Securing accts: Taking actions to secure online accounts
- Evidence: Recording evidence of the abuse
- Delete content: Deleting images, even if not all copies
- Other
- Unspecified

Help sought: See Table 5.
When poster sought help: Based on the user states framework [48].

- Prevention: Aiming to prevent future exposure to digital-safety risks; often but not always during relatively calm state of mind.
- Monitoring: Watching for digital-safety events to quickly respond; often with low to moderate stress.
- Crisis / Active event: Actively experiencing a digital-safety event (possibly hours/days); likely want to stop event; often very high stress.
- Recovery: Digital-safety event stopped or it's been determined stopping it may not be possible; ready to address damage; possibly much later; often moderate to high stress.
- Multiple events: Complex cases with multiple or overlapping digital-safety events; often heightened stress and trauma.

3) Codes about Help-Giving: See Table 6.

B Additional Results

Tables 7 and 8 show, respectively and for each IBSA type, strategies previously attempted by victim-survivors and platform(s) involved.

Strategy	FS	NFS	NCSEI	PS	CF	NCEI	RSA
Disengage	22	18	22	18	10	8	12
Engage	16	10	11	22	8	15	6
Securing accounts	22	9	9	0	2	2	0
Social support	5	5	2	2	0	7	5
Police report	10	0	4	0	2	4	5
Platform report	9	1	6	1	1	2	1
Evidence	7	0	6	0	1	2	1
Delete content	2	1	0	1	0	4	2
Workplace report	0	1	1	2	4	0	0
Other	2	1	2	0	1	1	0
Unspecified	9	14	13	8	17	18	17

Table 7: Strategies attempted before posting on Reddit.

Platform	FS	NFS	NCSEI	PS	CF	NCEI	RSA
Messaging (apps, DMs)	42	26	30	31	32	15	8
Mainstream social media	31	16	23	3	5	10	4
Device	2	11	9	3	0	18	27
Dating app	11	2	5	7	6	0	0
Adult content (websites, apps)	0	1	2	0	0	3	4
Social discovery app	1	1	0	0	1	2	0
Financial / commerce	3	0	1	0	1	1	0
Website	0	1	0	0	0	2	0
Unspecified	0	4	1	7	2	1	1

Table 8: Platforms involved in the IBSA. Messaging also includes messages or images otherwise described in posts as "sent."

Enabling Contextual Soft Moderation on Social Media through Contrastive Textual Deviation

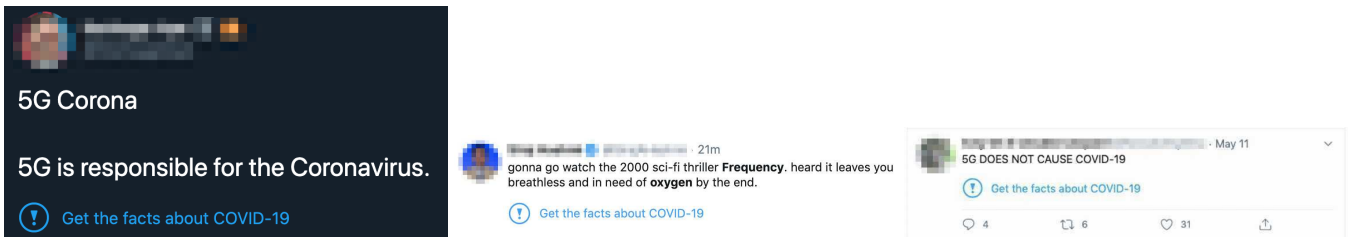
Abstract

Automated soft moderation systems are unable to ascertain if a post supports or refutes a false claim, resulting in a large number of contextual false positives. This limits their effectiveness, for example undermining trust in health experts by adding warnings to their posts or resorting to vague warnings instead of granular fact-checks, which result in desensitizing users. In this paper, we propose to incorporate stance detection into existing automated soft-moderation pipelines, with the goal of ruling out contextual false positives and providing more precise recommendations for social media content that should receive warnings. We develop a textual deviation task called Contrastive Textual Deviation (CTD) and show that it outperforms existing stance detection approaches when applied to soft moderation. We then integrate CTD into the state-of-the-art system for automated soft moderation Lambretta, showing that our approach can reduce contextual false positives from 20% to 2.1%, providing another important building block towards deploying reliable automated soft moderation tools on social media.



1 Introduction

"*Get the facts about COVID-19*." This message became a familiar sight for the users of Twitter during the pandemic surge in 2020. Added as a warning label by the platform to accompany potentially misleading tweets about COVID-19 (see Figure 1a), its goal was to allow users to seek more information and not fall for dangerous conspiracy theories and misinformation which could have compromised public safety [73]. This was an early example of *soft moderation*, which was later applied by Twitter on other important topics (e.g., the 2020 US Presidential election [83]) and has since been adopted by other platforms like Facebook [21], Instagram [9], and TikTok [32].

Platforms do not release details on how they identify tweets that need to receive soft moderation labels, but this includes getting input from reputable authorities like fact-checking organizations (e.g., Snopes) and public agencies (e.g., the CDC), applying automated tools like semantic matching and information retrieval to identify posts about known misleading claims, and relying on human moderators to vet content that should receive a warning [74]. Despite these efforts, however, recent work has showed that the methods adopted by online platforms fail to flag a large amount of misleading content that should be moderated [32, 54, 83].

Fully automated attempts by platforms to identify misleading content had shortcomings. We illustrate an example of this in Figure 1. To curb the spread of a conspiracy theory linking 5G technology to the spread of COVID-19, Twitter decided to add a warning label to any tweet that contained the words "*5G*" and "*oxygen*" [31]. Due to the generality of these keywords, this caused the platform to flag tweets that were unrelated to the conspiracy theory, like the one in Figure 1b. We call these irrelevant tweets mistakenly flagged for moderation *topical false positives*. In addition to irrelevant tweets, Twitter also applied warning labels to tweets that debunked the conspiracy theory, like the one in Figure 1c [82]. This can have adverse effects, for example by having the platform undermine the public trust in experts (e.g., health professionals) by mistakenly flagging their informative posts as misleading [37]. It would also discourage diligent users who actively debunk misinformation on social media (i.e., "wisdom of the crowds" [43, 55]), who would see their fact-checks marked as misleading. Finally, it can cause *warning fatigue* [45] in social media users, where users are bombarded with warning labels attached to the posts and stop paying attention to them, thereby reducing the intended effectiveness of the labels. We call this type of mistakenly flagged posts *contextual false positives*. We argue that an effective approach for the automated identification of content that should receive moderation should address both topical and contextual false positives.

Recently, the computer security community has focused on developing automated systems to flag content that should receive moderation labels. Lambretta [54] is a system that leverages information retrieval techniques (i.e., Learning to Rank) to identify the optimal set of keywords that represent

(a) Correct application of warning label. (b) Topical False Positive. (c) Contextual False Positive.

Figure 1: Three tweets discussing the debunked claim that COVID-19 is caused by 5G. Existing moderation systems might suffer from topical false positives as well as contextual false positives.

a misleading claim and identify social media posts that are discussing that claim. Lambretta outperforms alternative keyword retrieval and semantic search approaches, and largely addresses the problems of topical false positives, reporting a false detection rate of 3.93% on a dataset of tweets discussing the 2020 US Presidential Election. However, Lambretta does not address the problem of contextual false positives, being unable to ascertain if a social media post is supporting a false claim (and therefore should be moderated) or refuting it. In fact, the false detection rate from the perspective of contextual false positives on its original dataset is 20%. This limitation is not unique to Lambretta, but is also present in other content moderation systems powered by retrieval or semantic similarity approaches [19, 72].

To reduce contextual false positives, *stance detection* techniques can be integrated into soft moderation systems. Stance detection is a task where the objective is to learn a model that can identify whether a given piece of text is in favor of or against a set of target(s) [1]. In the context of fact-checking, the problem aims to automatically detect if a piece of text supports or refutes a misleading claim [23]. We find, however, that existing stance detection techniques are limited in their ability to generalize across unseen claims [48, 70] and different social media platforms [40], making them unfit to be applied on social media platforms at scale.

To address the shortcomings of existing stance detection approaches when dealing with content moderation on social media, we reframe the problem as a textual deviation detection one and propose *Contrastive Textual Deviation* (CTD). Our approach consists of developing, for each claim that we wish to moderate, a triplet composed of a consensus statement that is confirmed to be true (e.g., by health authorities or fact-checking organizations) and two contrastive markers, a piece of refuting evidence and one of supporting evidence. Our approach then leverages the *emergent* abilities of Large Language Models (LLMs) like zero-shot learning to identify if a piece of text supports or refutes the consensus statement.

Compared to conventional stance detection approaches, our method has two major advantages. First, we build a model that can identify patterns of deviation from an anchor text (i.e., the consensus statement) in a topic-invariant fashion, without depending on features specific to a certain topic (e.g., climate change denial or vaccine misinformation). This overcomes one of the main issues of traditional supervised stance detection pipelines, where researchers need to annotate samples for each claim as these methods fail to generalize well across multiple claims [48, 70]. Second, CTD can leverage the consensus statements curated by fact checkers and expert authorities as part of the stance detection process (through the use of the consensus statement), allowing us to keep experts in the loop in the case of evolving events like a global pandemic or misinformation stories that threaten public safety.

We first motivate the task of textual deviation detection by identifying the shortcomings of existing approaches for stance detection in the context of content moderation. We then perform preliminary experiments on the advantages of reframing stance detection as textual deviation by bootstrapping the task using the zero-shot learning capabilities of Large Language Models (LLMs). Motivated by the better performance of LLMs over alternative solutions and by the ease of generalizing across datasets, we further fine-tune the LLM for the task of CTD to boost its performance. Finally, we integrate our fine-tuned unsupervised stance detection model into the analysis pipeline of the state-of-the-art soft moderation system Lambretta [54], to improve its detection capabilities. We make all the labeled datasets curated in the work and fine-tuned models publicly available [1].

In summary, this paper makes the following contributions:

- We propose Contrastive Textual Deviation (CTD) as a new task to perform stance detection on social media. We show that CTD overcomes the limitations of existing stance detection approaches and that it generalizes across platforms by testing it on datasets collected from different platforms (Twitter and Reddit) and covering different topics (COVID-19, climate change, and politics).
- We fine-tune a LLM dedicated to the task of CTD and show that our approach improves over baseline methods, with an average improvement on the F1-score of over 7%.

[1] https://huggingface.co/collections/ppaudel/contrastive-textual-deviation-65e20c48680724cc9a809062

- We integrate CTD into the automated soft moderation pipeline of the state-of-the-art approach Lambretta, reducing contextual false positives from 20% to 2.1%, with a minimum impact on false negatives.

2 Datasets

We curate and collect multiple datasets throughout our work that i) come from multiple social media platforms (Reddit, Twitter), ii) cover different topics (e.g, Climate Change, COVID-19), and iii) contain different levels of granularity (i.e, fine-grained or coarse-grained claims). A summary of the datasets used in our work is presented in Table 1.

Global Warming Stance Dataset (GWSD) [38]. This dataset contains 1,177 "opinion spans" of news headlines about Global Warming annotated by human annotators as either accepting of global warming (e.g., "*We can't afford to wait until everyone is feeling the pain of the climate emergency before we do something about it*") or skeptical of it (e.g., "*Humans have negligible impact on the climate*"). The opinion spans are extracted from 56,000 news articles spanning a period of 20 years from news outlets such as the New York Times, Fox, Washington Post, Forbes, etc. We characterize this dataset as a "coarse-grained" stance dataset since the opinion spans in this dataset discuss climate change from the broader perspective of climate emergency and skepticism, and do not deal with granular causes or effects of climate change (e.g., *Urban Heat Island effect on Global Warming is negligible*.) This dataset is slightly imbalanced in its class labels as it contains 777 opinion spans supporting climate change and 400 opinion spans skeptical of climate change.

Climate Skepticism. The majority of stance detection datasets are topic-based or target-based in nature, with a very limited set of datasets on claim-based stance detection occurring on social media text. This existing gap motivates us to prepare a comprehensive claim-based stance detection dataset. We curate a dataset of climate change denial discussions, containing Reddit posts that support or refute three different claims related to different arguments used in climate change discussions. We query the Pushshift Reddit dataset [7] with curated keywords related to the claims, retrieving posts from Reddit that are discussing narratives related to three of the most popular climate denier claims: i) *Cosmic rays are causing global warming (GW)*, ii) *Antarctica is gaining ice*, and iii) *Urban Heat island (UHI) effect exaggerate global warming trends*. These claims are fine-grained and objective in nature, unlike high-level "topics" in the GWSD dataset such as "Global warming is a hoax," or "Climate change is not happening." [38, 44] For the goal of scalable and tractable soft moderation, these claims are very representative of misleading claims propagating on social media that can be easily refuted from scientific consensus, or authoritative sources (e.g. Skeptical Science). We then set out to annotate 1,000 Reddit posts for each claim by developing a codebook dedicated to climate skepticism. Our codebook was informed by the crowdsourced resource Skeptical Science, which provides pointers for understanding different narratives used by climate skeptics to deny a claim as well as examples of scientific support for confirmed claims. We do not include posts that are inquiring about the claim in question, are neutral towards it, or are topically irrelevant. Two researchers performed multiple rounds of annotation and reached a near-perfect agreement of $\kappa = 0.865$ [41]) Cohen's Kappa (i.e., strong agreement). This dataset also has value in evaluating the transferability of stance detection approaches as it contains multiple targets (claims), and different types of label distribution within the claims. A summary of the climate denial claims and the number of annotated Reddit posts for each claim is provided in Table 2.

COVID-FACT [66]. This dataset belongs to a family of datasets in the field of automated fact-checking known as FEVER (Fact Extraction and Verification). What makes it interesting for our work is that the FEVER dataset contains labeled text known as "evidences" that either supports or refutes a given claim. More precisely, the COVID-FACT dataset contains 4,086 claims concerning the COVID-19 pandemic, and both refuting (3,488) and supporting evidence (3,515) for the claims. These claims are obtained from the */r/COVID19* community of Reddit and are "fine-grained" in nature.

COVID-CQ [46]. In addition to creating our own dataset for identifying stance in climate denial claims, we also make use of an existing stance detection dataset of COVID-19 treatment tweets. The dataset, called COVID-CQ, contains 7,003 tweets and their respective stance on the efficacy of hydroxychloroquine as a treatment for COVID-19. The annotation criteria of this work closely align with the annotation criteria of our own data collection process, and this dataset fits the problem definition of claim-based stance detection very closely.

Stanceosaurus [85]. This dataset is a multi-lingual and multicultural corpus of tweets annotated with a stance towards 4,467 tweets discussing 190 misinformation claims from 9 fact-checking sources (Snopes, Poynter, FullFact, etc.) We use a subset of the dataset containing fact-checked claims and tweets in English, which either support or refute the claims, ignoring the tweets that are either *irrelevant* to the claim, or simply *querying* about the claim. For the posts that are *discussing* the claims in question, the dataset also contains annotation if the tweets are leaning towards supporting or refuting the claim, and we use tweets that are annotated as such with the label of their leaning.

Election denial [54]. This dataset contains 499 election denial claims and 101,353 tweets discussing the claims retrieved by the corresponding soft-moderation system Lambretta. We select the three most popular election denial claims by frequency present in the dataset and annotate a sample of 200 random tweets discussing the three claims for the stance of the tweets

Dataset	Platform	Topic	#Claims	#Refute	#Support
GWSD [38]	News	Climate	N/A	400	777
Climate Skepticism	Reddit	Climate	3	1,277	1,650
COVID-FACT [66]	Reddit	COVID-19	4,086	2,790	1,296
COVID-CQ [46]	Twitter	COVID-19	1	3,488	3,515
Stanceosaurus [85]	Twitter	Fact-Checking	190	1,442	3,025
Election Denial [54]	Twitter	Election	3	128	454
PERSPECTRUM [14]	Debates	Argument Mining	907	2,468	2,627

Table 1: Summary of datasets used.

Claim	#Refute	#Support
Cosmic Rays cause GW	577	439
UHI effect exaggerate GW trends	390	495
Antarctica is gaining ice	683	343

Table 2: Summary of climate skeptic claims annotated with stance labels.

Claim	#Refute	#Support
Wisconsin Voter Turnout above 90%	132	32
Illegal suitcase of ballots in Georgia	161	55
Dead Voters voted in Michigan	161	41

Table 3: Summary of election denial claims from [54] annotated with stance labels

concerning the claim in question. We adapt the codebook and annotation process used for annotating climate denial-related claims. A near-perfect agreement of $\kappa = 0.866$ [41] was reached among the annotators. A summary of the claims, and the number of supporting, and refuting tweets for each claim is presented in Table 3.

PERSPECTRUM [14]. Finally, we use a dataset from argument mining called PERSPECTRUM [14]. PERSPECTRUM contains 907 claims from online debate topics and 5,095 "perspectives" from search engine results presenting diversifying viewpoints about the claims. These "perspectives" are annotated with stance as either supporting or refuting the claim and cover more than 10 different topics such as Politics, Freedom of Speech, Environment, Science, Health etc. The structure of this dataset provides value in augmenting a large-scale stance dataset as it contains claims and multiple sides (perspectives) of the claims from different topics.

Summary. A summary of all the datasets curated and collected is listed in Table 1. We can observe that the datasets used by our work span across different use cases of misinformation such as climate denial, public health emergencies, civic processes such as elections, and general purpose fact-checking. This way, we aim to comprehensively evaluate our method on a variety of misleading claims occurring across two different social media platforms.

3 Motivation: Existing stance detection methods fall short

We identify three requirements that effective stance detection approaches should satisfy to successfully improve content moderation systems. Ideally, we would be able to leverage existing stance detection methods for this purpose. However, we find that previous work, including more sophisticated entailment-based methods [22], fall short in achieving one or more of these requirements. In a nutshell, the requirements and shortcomings that we identify are the following:

- **R1. Need for Granularity**: Supervised methods trained on coarse-grained claims fail on fine-grained claims.
- **R2. Need for Claim Invariancy**: Supervised methods trained on one claim do not generalize well on other claims.
- **R3. Need for Contrastive Context Awareness**: Supervised entailment-based methods fail to identify stance on social media despite being given context-aware hypothesis statements.

In the rest of this section, we discuss the shortcomings of existing approaches in achieving the three requirements, showcasing our preliminary experiments. Then, based on these observations, in Section 4 we present our solution, which overcomes the limitations of previous methods.

3.1 Need for Granularity (R1)

While coarse-grained claims (e.g., "*Climate change isn't real*") may generally describe broad categories of misinformation, finer-grained ones (e.g., "*Cosmic rays are causing global warming*") are often encountered online. An effective stance detection approach should be able to operate on both categories of claims.

To investigate the ability of stance detection to generalize between coarse-grained and fine-grained claims, we use the GWSD and Climate Skepticism datasets. These two datasets

Claim	F1
Antarctica is gaining ice	0.61
UHI exaggerate GW trends	0.44
Cosmic rays cause GW	0.41

Table 4: Performance of BERT model on GWSD claims evaluated on Climate Skepticism dataset.

both pertain to climate change, but GWSD contains coarse-grained claims while the Climate Skepticism one is built from fine-grained ones. We train a supervised model on the GWSD dataset and test whether this model can identify the stance of climate skepticism on the fine-grained claims of the Climate Skepticism dataset. Following the standard BERT fine-tuning recipe [64], we fine-tune a DistilBERT [68] model for five epochs with a learning rate of $5e^{-5}$ until the training loss converges. We balance the dataset by randomly undersampling the supporting claims, as the original dataset is imbalanced. We repeat the experiment five times and report the average evaluation of the fine-tuned BERT model on the three claims from the Climate Skepticism dataset.

Takeaways. The fine-tuning procedure on the GWSD dataset performs well when cross-evaluated on coarser claims (F1 score of 0.766 on 5-fold cross-validation). However, the model performance drops drastically when evaluated on the fine-grained climate claims from the Climate Skepticism dataset as seen in Table 4. This experiment shows that supervised models trained on coarse-level claims fail to evaluate the stance on fine-grained ones, despite having high domain and topic overlap with the training data. This motivates the need to design stance detection methods that are highly granular and specific in nature.

3.2 Need for Claim Invariancy (R2)

The second requirement that we identify is that a stance detection approach trained on a fine-grained claim about a topic must generalize to detect stance on other fine-grained claims about the same topic. This is important because false information is not static and new claims emerge all the time (e.g., the emergence of narratives advocating for Vitamin C, Hydroxychloroquine, and Ivermectin as effective cures against COVID-19 at different points in time during the pandemic).

To investigate if existing stance detection approaches can generalize between claims, we again use the Climate Skepticism dataset, as it contains three fine-grained claims. It is to note that all three corpora for the individual claims come from the same social media platform (Reddit), thus we can expect the corpus distribution of the evaluation setting to be similar to the training setting. As in the previous step, we train a DistilBERT model for each claim and evaluate the model on detecting the stance of posts on the other two claims that it was not trained on. The results are provided in Table 5.

Training Claim	F1 #1	F1 #2	F1 #3
#1 Antarctica is gaining ice	**0.828**	0.429	0.551
#2 UHI exaggerate GW trends	0.470	**0.7315**	0.578
#3 Cosmic rays cause GW	0.4183	0.589	**0.817**

Table 5: Stance detection performance across claims. Each line shows the F1 score for the model trained on one claim and tested on the three claims in the Climate Skepticism dataset.

Takeaways. We find that in all three cases, a model trained on one claim fails to generalize on other claims as the performance drops drastically. This motivates the need for building claim invariant stance detection methods that are not only learning features to detect stance specific to the training data of the claim it is trained on, but generic representations of support or refute towards a claim.

3.3 Need for contrastive context awareness (R3)

An effective stance detection approach must be able to accurately identify text that supports or refutes a given claim. A promising approach to achieve this is Natural Language Inference (NLI), which is also known as Recognizing Textual Entailment (RTE). NLI is a widely popular approach for detecting stance in NLP, where a claim is treated as a *premise* and a piece of evidence is treated as a *hypothesis*. The task then consists in checking if the premise entails (supports) or contradicts (refutes) the hypothesis [22]. Compared to the approach of fine-tuning BERT-based models for classification tasks, NLI can be adapted with a much more granular objective for stance detection, as each claim being evaluated can be directly subjected to the most relevant piece of evidence associated with the claim. One of the major reasons existing stance detection methods fail to generalize well on detecting stance on a new topic during inference is the lack of enough contextual information about the topic or target they are subjected in the out-of-domain or zero-shot setting [13, 28]. Prior research showed that providing enough context about the topic or claim being evaluated can bridge this context gap, improving stance detection models to generalize well on unseen topics [8]. Based on this, we investigate if we can leverage NLI methods for stance detection on social media by providing the most "context-aware" set of evidence (hypothesis) statements related to a claim (premise) getting evaluated. Our assumption is that if there is *sufficient* context provided in the *hypothesis* statement, NLI models should be able to detect stance well on new claims and topics.

We first train an NLI model on COVID-19 claims using the COVID-FACT dataset. We then evaluate the trained model on the COVID-CQ dataset. The FEVER setup of the COVID-FACT dataset is perfect for this task, as it already contains pieces of evidence supporting or refuting a claim. In addition to that, these claims are "context-aware," (e.g., about

the lack of studies confirming the effectiveness of Hydroxychloroquine to treat COVID-19) instead of being generic like "Covid-19 and mask" or "Covid-19 and HCQ." Also, COVID-FACT consists of claims and evidence that are semantically close to those being evaluated in the COVID-CQ dataset (e.g., "homemade remedies of COVID-19" or "alternative treatments of COVID-19"), therefore we can expect a high level of domain overlap, similar granularity, and semantic overlap between the training data and the evaluation data.

Following a similar methodology as in prior sections, we train a DistilBERT model for textual entailment using these pairs and evaluate the trained model on the COVID-CQ dataset. Since NLI only allows to specify one hypothesis for each premise, we evaluate the trained model on two different configurations using the following hypotheses: i) Another study has confirmed hydroxychloroquine to be effective in the treatment of COVID-19 (coronavirus), ii) No clinical studies have confirmed hydroxychloroquine as a cure for COVID-19 (coronavirus). We then consider a tweet as supporting the misleading narrative if it either entails with first hypothesis or contradicts the second hypothesis. Similarly, a tweet debunks the misleading narrative if it either contradicts the first hypothesis or entails the second hypothesis. This way, we setup an evaluation setting for a model that is trained on context-aware sentence pairs, and evaluate it under an identical setting, allowing us to understand if satisfying the criteria of "context-awareness" is sufficient enough for stance detection for content moderation.

Takeaways. We evaluate the trained DistilBERT model on the COVID-CQ dataset and find that the best-performing F1 score of this method is 0.53, which is only slightly better than random chance, despite having a high topical overlap with the training dataset, and further taking a granular approach of training entailment or contradiction aligned on claims. Moreover, we discover that the NLI model evaluated on the "context-aware" setting, providing the best set of hypothesis statements with "sufficient" information about the claim, is not adequate for stance detection on social media text. These results suggest that providing a context-aware hypothesis statement is not enough to build NLI models for precise stance detection. We argue that while context awareness through the best set of hypothesis statements gives a model important contextual signals about the claim, it would be beneficial for the model to be "contrastively context-aware," i.e., exposed to contradicting hypotheses, one supporting and one refuting the claim, which is what commonly occurs on social media.

4 Contrastive Textual Deviation

Based on the three requirements defined in the previous section, we aim to build an unsupervised stance detection model that overcomes the limitations of previous approaches by: i) detecting stance at a fine-grained level, ii) learning semantic representations of stance on a claim invariant fashion, and iii) encoding contrastive context awareness to learn higher level representations of stance. We first describe our proposed solution by formally defining a new task called Contrastive Textual Deviation (CTD) and discuss the different components of the task. We then bootstrap CTD by leveraging the zero-shot learning capabilities of Large Language Models (LLMs) through prompt engineering. Finally, we conclude the section by demonstrating the successful performance of bootstrapped CTD by comparing against multiple baselines from supervised learning.

4.1 Task Definition

We propose to reframe the problem of stance detection as a new task of "textual deviation" detection, which aims to satisfy all three requirements. First, for every misleading claim that we wish to moderate, we start from a *consensus statement* that has been confirmed to be true, for example by health authorities like the World Health Organization (WHO) in cases of public health emergencies or by fact-checking organizations in case of political events. Our intuition is that posts that refute the claim, spreading false information while doing so, will deviate from the consensus statement, while those that support (debunk) the claim will stick closer to the messaging of the consensus statement. We then extend the idea of "context aware" textual entailment to "contrastively context-aware" textual entailment by providing a pair of "contrastive markers" for each consensus statement associated with the misleading claim: a piece of refuting evidence and one of supporting evidence. Our idea is to leverage the zero-shot capabilities of Large Language Models (LLMs) to align social media posts discussing a claim with the piece of anchor "consensus" statement specific to the claim, while using the "contrastive markers" as additional context to aide the alignment decision. We call this task *Contrastive Textual Deviation* (CTD).

The core of CTD lies on formulating this triplet of i) a consensus statement, ii) a refuting evidence, and iii) a supporting evidence for each claim that we want to infer the stance of social media posts. Compared to traditional supervised learning approaches which need hundreds or even thousands of examples for training claim-specific or topic-specific stance models, we argue that curating this triplet is a much easier and *tractable* human effort, which could be easily carried out by fact-checking organizations or social media platforms. The consensus statements used to anchor the triplets are the "truth values" about the false claim in question. For each false claim in the datasets, we use the corresponding fact-checks and scientific explanations associated with the claim. For Climate Skepticism claims, we use fact-checks from `SkepticalScience.com` available under the "*What the science says*" snippet for every climate skepticism claim.

Dataset: Climate Skepticism

Urban Heat Island Effect has no significant influence on the record of global temperature trends.

Urban Heat Island effect significantly exaggerates global warming trends.

Urban Heat Island effect has been properly factored in climate models and does not biases global warming measurements.

Dataset: COVID-CQ

No clinical studies have confirmed hydroxychloroquine as a cure for COVID-19 (coronavirus).

Another study has confirmed hydroxychloroquine to be effective in the treatment of COVID-19 (coronavirus).

It is not medically proven that Hydroxychloroquine (HCQ) can treat COVID-19 (coronavirus).

Dataset: Stanceosaurus

There is no proof that the US military purchased Muslim app user data.

Recent news sources reveal that the U.S. military has purchased user location data on popular Muslim phone apps such as Muslim Pro.

Untrue: Muslim Pro app denies selling user data to US military.

Figure 2: Example claims from evaluation dataset and corresponding triplets.

Stanceosaurus contains fact-checked claims coming from several reputable sources (e.g. PolitiFact, Snopes, etc.), and we used the debunking article headline from the corresponding fact-checking sources as the consensus statement. For the COVID-CQ dataset, we used Google Fact Check Explorer to identify fact-checks and used their debunking title as the consensus statement. To complete the triplet for each claim, we formulate the contrastive markers as a positive affirmation and a negative reframing of the corresponding consensus statement. Figure 2 shows examples of triplets from three different claims from our evaluation datasets, with consensus statement, supporting evidence, and refuting evidence for each of the claims.

CTD allows us to satisfy all three requirements discussed in Section 3. R1 is addressed by allowing us to use customizable and well-informed consensus statements directly discussing the claim being moderated. To address R2, CTD learns semantic features of deviation from an anchor piece of text (consensus statements), rather than semantic features of support or refute towards a particular claim that the model is trained on, allowing us to scale our method across claims and achieve the property of claim invariancy. Finally, CTD addresses R3 by using a pair of contrasting evidence as context input for the classification task (refuting evidence and supporting evidence). This allows our approach to improve over entailment-based methods, which only use one piece of hypothesis statement and thus do not generalize to the case of content moderation on social media, as we showed in Section 3.3. Before bootstrapping Contrastive Textual Deviation as a NLP task, we empirically validate the underlying intuition motivating CTD by visualizing if tweets supporting a claim are semantically different than tweets refuting it. We utilize the tweets from the COVID-CQ dataset for this experiment and embed the tweets using the Sentence-T5 encoder [50], producing 768-dimensional embeddings. Note that these sentence embeddings are produced using the same encoder component of the LLM we will use for bootstrapping purposes i.e. (FLAN-T5-XXL), and thus serve as a useful tool for empirically testing our intuition. To this end, we center the embeddings of tweets from the COVID-CQ dataset using the embedding of the consensus statement and project the T-SNE embeddings of the supporting and refuting tweets. The scatterplot in Figure 3 shows a strong separation between the supporting and refuting tweets, with minimal overlap, indicating that the supporting tweets and refuting tweets are indeed semantically different. Additionally, we also compute the cosine similarity of the embeddings of the supporting tweets and refuting tweets with the consensus statement. Statistical analysis using a two-sample t-test to compare the means of the supporting and refuting tweets allows us to reject the null hypothesis (with $p <<< 0.01$ and $t-statistics >>> 0$). This further validates our intuition that the posts supporting the claim align more with the consensus than the posts that refute the claim.

4.2 Bootstrapping CTD using LLMs

Due to their zero-shot learning abilities [79], Large Language Models (LLMs) can be used off-the-shelf to leverage the triplet structure defined by CTD to detect stance in an unsupervised fashion. We argue that LLMs are particularly well suited for this task because: i) they have demonstrated performance competitive to supervised baselines in multiple NLP tasks [60, 79], ii) they can incorporate the proposed contrastive markers through in-context learning [80].

Background. Recent approaches showed that *prompting* a LLM to a specific *prompt* that defines the downstream task (e.g., sentiment analysis, textual entailment), and the possible label spaces for the tasks (e.g., positive, negative, or entailment, contradiction) can lead to performance comparable to supervised methods for text classification [60]. This ability of LLMs has been shown to be "emergent:" as the size and scale of these language models increases, so does their ability

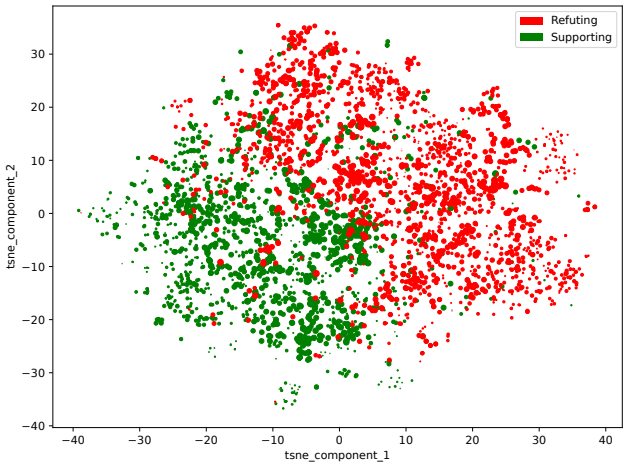


Figure 3: T-SNE embeddings of supporting and refuting statements from COVID-CQ

to generalize to unseen tasks [80]. Another emergent ability of LLMs is their capability to perform "in-context learning." By extending the *prompts* to include a few examples of the downstream task and the classification labels, LLMs can learn new tasks. Subjecting LLMs to demonstrative examples can give the model an idea of the label space, of the mapping between input and label space, and help generalize LLMs to a variety of tasks without the need for task-specific fine-tuning. In-context learning does not require any model update or fine-tuning and performs competitively with state-of-the-art methods for text classification problems [12].

Prompt engineering to bootstrap LLMs. To show the feasibility of our approach for soft moderation, we first bootstrap CTD with LLMs. To this end, we build our prompts as follows: For every social media post discussing a claim, we subject it to a consensus statement that explains the established consensus (e.g., a fact-check or a statement on the scientific consensus about the claim). Then, we proceed to show an example statement that refutes the consensus. Similarly, we show an example statement that supports the consensus. Finally, we end the prompt with the text that we wish to classify using the LLM, where the LLM is expected to return one of the stance labels (support, or refute). Figure 4 illustrates the prompt structure that we use for bootstrapping CTD.

Our intuition is that by doing so we can leverage the zero-shot classification capabilities of LLMs, while at the same time *ground* them towards incorporating the consensus and the contrasting evidence as additional context for classification.

Validating CTD bootstrapping. We use the open-source encoder-decoder model FLAN-T5 by Google for bootstrapping purposes [15], prompting, for each claim, the LLM with the prompt structure defined above. The underlying architecture of FLAN-T5 is a T5 model (Text-to-Text Transfer

> Classify if a statement supports or refutes the consensus statement: <Consensus statement>.
>
> Statement: <Refuting evidence>.
>
> Response: Refutes.
>
> Statement: <Supporting evidence>.
>
> Response: Supports.
>
> Statement: <Text from the test sample to classify.>
>
> Response:

Figure 4: Prompting structure for bootstrapping CTD.

Transformer), a new unified paradigm of transfer learning for text classification. By formulating challenging tasks like machine translation, summarization, etc. to be a text-to-text task, T5 has shown promising results in multiple NLP benchmark problems over encoder-based models like BERT [63]. FLAN-T5 is an improved version of the T5 model that has been "instruction finetuned" on more than 1,000 NLP tasks and thus can be used to perform zero-shot text classification by just "prompting" the model.

As a summary of our validation results, we present the results of the task bootstrapping on the Climate Skepticism dataset. We will comprehensively evaluate our task with a fine-tuned model against all three evaluation datasets and claims later in Section 5.

As baselines, we compare our bootstrapped task against two different prompt setups: i) LLM without contrastive markers, ii) LLM without consensus definition. Additionally, we also compare our method against two supervised methods for stance detection i) a DistilBERT [68] model fine-tuned on each claim, and ii) a fine-tuned NLI model on ClimateFever dataset [16] (following the identical procedure we fine-tuned NLI model on COVID-FACT dataset in Section 3.3). The purpose of evaluating the two added prompt configurations alongside the prompt configuration for CTD is to understand the role that each component of the triplets (consensus statement and the contrastive markers) plays in identifying stance. The prompt configuration of evaluating LLMs without contrastive markers will help us understand if the contrastive markers are an improvement over entailment-based approaches. For the DistilBERT model, which uses supervised fine-tuning, we perform 5-fold cross-validation for each of the claims and report the average score across the folds. We use the weighted F1 score as the evaluation metric as the label distribution of supporting and refuting labels for each of the three claims in the Climate Skepticism dataset is imbalanced.

Results. A summary of the bootstrapping results with the mean F1 scores for the three Climate Skepticism claims is presented in Table 6. We find that our bootstrapped method (which is unsupervised) performs better than supervised

Method	Mean F1
BERT Fine Tuning	0.786
Climate Fever NLI	0.626
LLM w/o Contrastive Markers	0.795
LLM w/o Consensus	0.771
Bootstrapped CTD	**0.836**

Table 6: Summary of F1 Scores for Different Methods

BERT-based fine-tuning baselines. Additionally, we find that our approach provides better performance over using the LLMs in their default state: without consensus grounding (LLM without consensus), and without contrastive markers (LLM without contrastive markers). The results also suggest that the triplet setup of CTD performs better than the conventional setup of entailment for stance detection. Additionally, we observe that having the contrastive markers by themselves without the consensus statement (LLM without consensus) is not nearly as effective for detecting stance. Overall, these results validate that the task of CTD can outperform existing methods for supervised stance detection. Moreover, the utility of our approach is validated in being fully unsupervised and requiring minimal setup needed for a claim (i.e. a consensus statement, and a pair of supporting and refuting in-context examples).

5 Evaluation

Following the successful bootstrapping of CTD through LLMs, we now further fine-tune the FLAN-T5 model to improve upon the bootstrapping performance and build a robust model for the task. First, we discuss the setup of this fine-tuning procedure and the process of augmenting an argument-mining dataset for the task of CTD. Next, we comprehensively evaluate the performance of this fine-tuned model against the prior bootstrapped LLM and various other baselines for the downstream task of stance detection in all three of our evaluation datasets. We then assess how the runtime and detection performance of CTD varies with increasing model size. Finally, we integrate our approach with the state-of-the-art soft moderation pipeline Lambretta [54], showing that it can improve its ability to limit contextual false positives.

5.1 Fine tuning FLAN-T5 for CTD

The bootstrapping experiments from Section 4 suggest that CTD can be a reliable approach to identify if a social media post is supporting or refuting a claim, enabling better content moderation. While LLMs bootstrapped on this task already perform better than multiple existing baselines by leveraging in-context learning, we can improve them further by fine-tuning LLMs that are specifically dedicated to the task of CTD. Previous work showed that even with little training data fine-tuned LLMs perform better on tasks [34, 63, 76].Additionally, fine-tuning can potentially allow the LLM to build a more specialized model representation associated with the CTD task, enabling the model to better generalize and also be adversarially robust [52]. Previous work showed that the performance of LLMs can be heavily affected by the components in the prompt, in our case the triplets used by CTD. For this reason, we aim to use the large number of triplet combinations available in our fine-tuning dataset, to learn a model that is decoupled from the phrasing of the prompt, and more focused and consistent on the CTD task itself.

There are two different approaches to fine-tuning LLMs: i) task-adaptive fine-tuning, and ii) behavioral fine-tuning. Fine-tuning a LLM directly on the downstream task is called task-adaptive fine-tuning [65]. Behavioral fine-tuning aims to teach a model to learn higher-level language representation by fine-tuning on a task that is behaviorally similar, or close to the downstream task, rather than fine-tuning on the downstream task itself. This approach is also called intermediate-task fine-tuning, and it works best with tasks that require high-level inference and reasoning capabilities [56, 59], like CTD. Thus, we argue that instead of fine-tuning a LLM for the task of stance detection (task-adaptive fine-tuning), which would suffer from similar limitations as BERT fined-tuned on the stance detection task discussed in Section 3, a LLM fine-tuned for textual deviation on a large number of claims will be able to reliably perform stance detection on general claims. Additionally, behavioral fine-tuning on textual deviation tasks solves the problem of the amount of data available for fine-tuning, as the augmentation of argument mining datasets for textual deviation allows us to generate a dataset that is orders of magnitude larger than any dataset available for specific stance detection topics. This way, our fine-tuned model is learning what *deviation* or *affirmation* to any piece of anchor claim looks like without relying on target-specific or claim-specific features, further helping us to achieve the need for claim invariancy (R2) (see Section 3.2).

We use the PERSPECTRUM dataset to fine-tune LLMs for the CTD task. This dataset contains both claims and multiple examples of evidences called *perspectives* either agreeing with the claims or disagreeing with them, as required by CTD. We augment this dataset to create a large-scale one (expanding up to millions of elements) containing the triplets for the textual deviation task. An example of a claim sampled from the PERSPECTRUM dataset alongside two randomly sampled supporting and refuting perspectives to the claim is presented in Figure 5. This particular claim contains 13 supporting perspectives and 22 refuting perspectives in total. With the claim being used as the anchor (consensus) statement, and the contrasting set of refuting and supporting perspectives, we can generate a combination of 9,438 triplets for this claim alone. This way, the PERSPECTRUM dataset containing 907 claims yields a total of 3,311,548 triplets that we use for fine-tuning a FLAN-T5 model for the CTD task.

Claim: All countries should have the right to pursue a nuclear defence.

Supporting Perspective #1: All countries are entitled to self defense with nuclear weapons, even when they do not have the capacity to carry conventional weapons.

Supporting Perspective #2: The pursuit of nuclear defence (respectively the possession of nuclear weapons) by more countries is a guarantee for peace.

Refuting Perspective #1: The threat of a state developing nuclear weapons could instigate pre-emptive strikes from its neighbours and rivals to prevent the acquisition of such weapons.

Refuting Perspective #2: It is very difficult to intercede in humanitarian crises in states wherein nuclear weapons are present.

Figure 5: Example claims and perspectives from PERSPECTRUM dataset.

It is to note that the claims present in this dataset are argumentative sentences used for debates and unrelated to the task of fact-checking or misinformation. We argue that the normalized argumentative structures used to fine-tune the model for CTD will help the model to better capture the intricacies of textual deviation from a canonical perspective, allowing CTD to generalize well and achieve claim invariancy (R2) when applied in the wild. As we will show later in Section 5.2, the representations learned through these triplets built from normalized argumentative structures indeed generalize very well in out-of-domain data on Reddit posts and tweets, confirming that higher-level language representations are learned via behavioral fine-tuning.

We fine-tune the FLAN-T5 model using a Parameter Efficient Fine-tuning (PEFT) technique known as LoRA (Low-Rank domain adaptation) [25]. LLMs like FLAN-T5 contain billions of parameters (11B) and fine-tuning the entire network is not feasible even under expensive GPU memory configurations. LoRA works by freezing the model weights of LLMs and injecting trainable rank decomposition matrices into each layer of the transformers, greatly reducing the number of trainable parameters for downstream tasks while achieving comparable or even better performance [26]. In our case, LoRA reduces the number of trainable parameters of the 11B FLAN-T5 LLM by 84% (from 11B to 18.8M).

Then, using the PEFT configuration of LoRA, we fine-tune the FLAN-T5 model on the augmented fine-tuning dataset. To make the task more manageable, we randomly sample 4 contrastive examples per claim to fine-tune the model, resulting in a dataset size of 36,000 triplets from 905 claims. We divide the fine-tuning dataset into 85-15 training and validation splits and fine-tune the FLAN-T5 model for 5 epochs until the validation loss stops decreasing further. Finally, we test this fine-tuned FLAN model on all three of our evaluation datasets (one coming from Reddit and two from Twitter). The results of this experiment are shown in Table 7. As it can be seen, the fine-tuned CTD model performs well, reporting F1-scores between 0.84 and 0.90 on the different datasets.

5.2 Comparison with existing baselines

We further evaluate the fine-tuned FLAN-T5 model against three types of baselines: task fine-tuned BERT, multi-task deep neural networks, and behaviorally fine-tuned baselines.

Task Fine-tuned BERT. This is a supervised learning setup where the BERT model is directly trained on a fraction of the evaluation dataset in a five-fold cross-validation setup. The evaluation configuration for the Climate Skepticism and COVID-CQ datasets has already been discussed in Section 3. It is to note that the third evaluation dataset we use, Stanceosaurus contains a large number of claims, and only a few tweets (in the order of 100) discussing a single claim. Fine-tuning a BERT-based model for classification for each claim with a limited number of tweets per claim is not possible, thus we fine-tune a BERT-based model for textual entailment instead (identical to NLI model trained on COVID-Fact in Section 3.3). We refer to this setup as "Task-BERT."

Multi-Task Deep Neural Networks (MT-DNN) based stance detection. A promising solution to DNN methods generalizing poorly outside their training domain (as demonstrated in Section 3.2) is a framework known as Multi-Task Deep Neural Network (MT-DNN) [35], where a variety of datasets from different domains are used to train a model to increase its robustness. This has helped in learning powerful higher-level representations across multiple Natural Language Understanding (NLU) tasks, and obtain state-of-the-art results in them. The MT-DNN framework has been adapted for stance detection by Schiller et al. [70], reporting improvement in stance detection performance. We use the best-performing MT-DNN model available in their work that is fine-tuned across 10 different datasets as a baseline.

Behaviorally fine-tuned baselines. The concept of using contrastive markers and an anchor statement proposed in our work is very closely associated with a framework in Deep Learning known as Triplet learning [71], which has been successfully applied in computer vision tasks [84] and NLP tasks [61].The fine-tuned BERT model we evaluated and compared on sequence classification (in Section 3.2) and sentence-pair classification (in Section 3.3) are pre-trained with the objective of Masked Language Modeling (MLM), and do not consider any type of contrastive loss in their design. However, a recent framework known as POLITICS (Pretraining Objective

Claim / Dataset	Method	F1
Climate Skepticism (Reddit)	Task-BERT	0.786
	MT-DNN	0.645
	POLITICS	0.734
	Bootstrapped CTD	0.836
	Fine-tuned CTD	**0.871**
COVID-CQ (Twitter)	Task-BERT	0.900
	MT-DNN	0.586
	POLITICS	0.831
	Bootstrapped CTD	0.810
	Fine-tuned CTD	**0.904**
Stanceosaurus (Twitter)	Task-BERT	0.731
	MT-DNN	0.656
	POLITICS	0.670
	Bootstrapped CTD	0.773
	Fine-tuned CTD	**0.848**

Table 7: Results of comprehensive evaluation.

Model	# params	Runtime (s)	Mean F1
FLAN-T5-Small	60M	0.008	0.492
FLAN-T5-Base	250M	0.012	0.555
FLAN-T5-Large	780M	0.018	0.589
FLAN-T5-XL	3B	0.043	0.811
FLAN-T5-XXL	11B	0.078	0.874

Table 8: Performance of different FLAN-T5 models on Contrastive Textual Deviation.

Leveraging Inter-article Triplet-loss using Ideological Content and Story) [36] leverages the concept of Triplet Loss [71] to pre-train a language model. This model modifies BERT to be trained on a large corpus of news articles discussing the same story, but from different ideologies and uses triplet loss to capture the ideological (dis)similarity among articles on the same story [36]. Furthermore, POLITICS has been fine-tuned for downstream tasks like stance detection, showing improved performance on various datasets over conventional BERT models. We therefore use POLITICS as an additional baseline to compare against CTD.

POLITICS needs to be fine-tuned on downstream tasks to be useful. To this end, we fine-tune the POLITICS model on the same dataset we fine-tuned the FLAN-T5 model on (PERSPECTRUM), adopting Natural Language Inference (NLI) as the downstream task setup. Similar to how we extracted triplets from PERSPECTRUM in Section 5.1, we generated combinations of around 11K pairs of claims and perspectives for fine-tuning the POLITICS model. The process of fine-tuning the POLITICS model closely mirrors that of the FLAN-T5 model, except for the PEFT configuration, which was not necessary for POLITICS.

Results. The summary of evaluation results of the fine-tuned FLAN model and other methods is presented in Table 7. We can observe that the fine-tuned FLAN model for CTD performs consistently better than all other baselines on all evaluation datasets, outperforming not only Task-BERT and other baselines but also the results from the bootstrapped CTD. First, this confirms our hypothesis that the zero-shot learning capabilities of LLMs can be further bolstered by behaviorally fine-tuning a LLM on the CTD task. Secondly, fine-tuned CTD has better performance than other stance detection approaches such as MT-DNN and POLITICS while being fine-tuned on the same dataset. This proves that the task formulation of Contrastive Textual Deviation leveraged by the fine-tuned CTD model meaningfully outperforms existing systems for stance detection. Additionally, it is interesting to note that the FLAN-T5 model, which was fine-tuned on normalized argumentative structures that are domain and platform-independent (as discussed in Section 5.1), consistently outperforms the Task-BERT models that were specifically fine-tuned on claim specific posts from social media text. This again affirms our hypothesis that a granular, topic-independent, and platform-independent stance detection model can be created by reframing the problem as a task of Contrastive Textual Deviation, which captures the semantics of stance detection much better on a foundation level. In summary, these results show that the FLAN-T5 model fine-tuned on the CTD task is a reliable, robust, and scalable stance detection method for the soft moderation of social media text.

5.3 Model size and performance tradeoff

Finally, we study how the runtime and performance of CTD varies based on the different models available in the FLAN-T5 family. Following the same methodology discussed in Section 5.1, we fine-tune four smaller models of CTD: i) FLAN-T5-Small, ii) FLAN-T5-Base, iii) FLAN-T5-Large, and iv) FLAN-T5-XL. This helps us better understand the scaling properties of the CTD task. Moreover, researchers and practitioners can use this to guide them in appropriate model selection based on their resource constraints and runtime requirements. Table 8 shows that the performance of CTD increases linearly as the model size increases along with the tradeoff on runtime. On the other hand, CTD fine-tuned on FLAN-T5-XL can be a viable option for practitioners as the performance dropoff from the best model (i.e. FLAN-T5-XXL) is relatively minor compared to the substantial reduction in model size (11B to 3B).

5.4 Integrating CTD into Lambretta

At this point, we have experimentally validated that a fine-tuned FLAN model on the CTD task has better performance than existing supervised baselines and LLMs bootstrapped for the task, making it the state-of-the-art approach in claim-based stance detection. Our motivation for designing CTD, however, is to enable soft moderation approaches to get rid

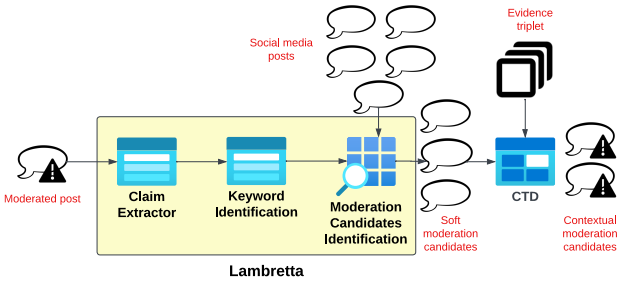

Figure 6: Our envisioned integration of CTD as a downstream component to Lambretta's soft moderation system.

of contextual false positives, allowing platforms to deploy more effective warnings that are only applied to content that is supporting a certain false claim. The state-of-the-art soft moderation tool Lambretta [54] is unable to discern this contextual information, and while it performs well in discarding candidate posts that are irrelevant to a given claim, it still flags a large fraction of posts that refute false claims as candidates for moderation: looking at the results reported by Lambretta on three false claims related to the 2020 US Presidential Election (see Table 3), we find that 20% of the candidates flagged by the system are contextual false positives.

To evaluate how much our approach can aid existing soft moderation approaches to incorporate contextual knowledge into their decisions, we add CTD as a downstream component to Lambretta [54], and use its stance detection capabilities to further refine the posts that it flags as candidates for soft moderation, filtering out posts that have a debunking (supporting) stance. Our goal is to reduce contextual false positives while keeping false negatives at a minimum. Our envisioned architecture is showed in Figure 6. It is to note that while we evaluate the approach on Lambretta, CTD can be added as a post-retrieval filter in any content moderation system after posts relevant to a claim or event for flagging are retrieved.

Setup. We use the annotated dataset of election denial tweets discussed in Table 3 for this purpose. These tweets were flagged by Lambretta as part of the evaluation in the original paper [54]. We can observe that the class of stance in the tweets is heavily skewed towards spreading the misinformation (***Refuting*** the fact-checks), and contains a smaller proportion of tweets that are debunking the misinformation (***Supporting*** the fact-checks). As discussed, Lambretta has no contextual understanding of its candidates for soft moderation, and when evaluating for contextual false positives, we find that the system reports a 20% False Detection Rate on average, with an F1 score on the three claims that ranges between 0.88 and 0.89 depending on the claim (see Table 9). Note that the False Negative Rate for the Lambretta baseline is 0 since the system does not perform any contextual filtering on the moderation candidates, and all retrieved tweets are considered matches for moderation.

Claim: Wisconsin voter turnout above 90%

The voter turnout in Wisconsin is within historical averages of 73% and does not indicate any voter fraud.

Fraud in Wisconsin as there were more votes than registered voters and irregular voter turnout around 90%.

Wisconsin did not have more votes than people registered and their voter turnout figures is 73%.

Claim: Illegal suitcase of ballots in Georgia.

Recently circulating viral video on social media doesn't show 'suitcases' of illegal ballots in Georgia.

Suitcases filled with illegal ballots were pulled out from underneath tables after election observers left in Georgia.

Officials have confirmed that there were no suitcases full of illegal ballots counted in the absence of election observers.

Claim: Dead voters voted in Michigan.

There is no credible evidence that dead people voted in the election or ballots were cast fraudulently by deceased voters.

There were many cases of voter fraud nationwide due to dead people's votes getting counted.

No evidence that 14,000 dead people cast ballots in Wayne County, Michigan.

Figure 7: Triplets used in our experiments on integrating CTD with Lambretta.

To evaluate CTD on the candidate tweets flagged by Lambretta, we follow the same methodology discussed in Section 4, curating a triplet of consensus statement, supporting evidence, and refuting evidence for each of the three election denial claims being evaluated, as showed in Figure 7. Note that in deployment, the only input that platform moderators need to use for our system is the triplet structure pertaining to a specific social media claim that they wish to moderate. In the case of a single social media post being the starting point, moderators need to first extract the claim contained in the post, which can be done by leveraging Lambretta's Claim Extraction component or other claim extraction tools such as OpenIE [18]. We then use the fine-tuned FLAN-T5 model presented in Section 5.1 with the three curated triplets to identify the stance on the tweets discussing the three claims. Note that for this experiment CTD is not fine-tuned on the tweets flagged by Lambretta, nor on any tweet discussing election fraud claims, further showcasing that our approach is context agnostic and generalizes across different topics.

Claim	Method	F1	FDR	FNR
GA suitcase of ballots	Lambretta	0.877	0.219	**0**
	Lambretta + CTD	**0.987**	**0.015**	0.010
Dead Voters voted in MI	Lambretta	0.887	0.203	**0**
	Lambretta + CTD	**0.9632**	**0.048**	0.024
WI Voter Turnout above 90%	Lambretta	0.891	0.195	**0**
	Lambretta + CTD	**0.988**	**0**	0.022

Table 9: Evaluation of the end-to-end component.

Results. The summary of the evaluation is presented in Table 9. As it can be seen, integrating CTD with Lambretta largely reduces the rate of contextual false positives, bringing down the average false detection rate by an order of magnitude from 20% to 2.1%. For the "Wisconsin voter turnout above 90%," the false detection rate after applying our approach is actually zero. At the same time, the false negative rate remains small, being 1.8% on average. This translates in F1 scores between 0.98 and 0.96, showing an improvement of about 10% over the baseline, showing that CTD can be effectively used to improve soft moderation systems for social media.

6 Related Work

We review related work on stance detection, LLMs for text classification, and use of stance detection for integrated fact-checking.

Stance detection. Stance detection is a foundational technique for various natural language understanding tasks [78] and has been used under various settings like argument mining [33], rumor detection [87], and fake news detection [57]. The majority of the existing work on stance detection focuses on topic or target-specific stance detection, where they aim to detect the stance of a text towards topic such as "gun rights," "atheism" [3] and public figures like "Donald Trump" or "Hillary Clinton." [44] Only a few works focus on claim-based stance detection [24, 75, 87], which is the focus of this work. Works on claim-based stance detection are mostly geared towards checking facts on formal text like Wikipedia [16, 75] or scientific knowledge bases [77]. Multiple works have used textual entailment for verifying claims on Wikipedia [75], scientific knowledge [10], and climate change conversations [16]. There are a few works on claim-based stance detection in multi-lingual settings like Arabic [2, 6], and Crotian [11].

LLMs for text classification. With the explosion of Large Language Models and rapid development of powerful LLM models like Open AI's GPT-4 [53], Google's BARD [39], Anthropic's Claude [5] etc., there has been a paradigm shift in approaching text classification problems. The massive amount of internet-scale data that LLMs see during their pretraining has been harnessed to fine-tune LLM models, producing state-of-the-art results in challenging benchmarks in Natural Language Understanding (NLU) [63, 78, 79]. In addition to the zero-shot capabilities of LLMs, researchers have also used strategies like in-context learning to improve their performance [42], making weakly supervised learning scalable and effective. This has made bootstrapping LLMs for custom text classification much easier, a process that we demonstrated successfully in our work. This way, LLMs have presented themselves as a viable alternative for multiple Natural Language Processing tasks such as classification, and summarization, while relaxing the constraint of task-specific training data needed for conventional NLP methods.

Stance detection as a fact-checking component. Prior works have used stance detection as a component of automated fact-checking pipelines. Works in this domain use stance prediction as one of the many components of their fact-checking pipeline, alongside other components and metadata such as user features and features of conversation threads. Zubiaga et al. [86] incorporated stance classification to detect the stance of tweets in a four-step rumor verification pipeline. Dungs et al. [17] leveraged the stance of conversational threads to predict veracity of rumors. CredEye, a system proposed by Popat et al. [58] used stance detection to automatically predict the credibility of textual claims retrieved from the Web. Another tool, developed by Nguyen et al. to assist fact-checkers [49], uses stance predicted from multiple articles alongside other attributes such as the reputation of the news sources to assess a claim's veracity. Similarly, FAKTA [47], a system for end-to-end fact-checking of claims, uses a stance detection model trained on FEVER setting alongside linguistic metadata for automatic fact-checking.

Remarks. In this paper, we showed that CTD outperforms existing stance detection mechanisms and that it could be easily integrated into existing moderation and analysis pipelines that make use of stance detection.

7 Discussion and Conclusion

In this paper, we presented Contrastive Textual Deviation, a new framework for detecting stance in social media posts discussing misleading claims. We tested the ability of existing stance detection systems to aid content moderation on social media and identified three major limitations of these systems in the context of applying them for content moderation. Motivated by the shortcomings, we developed the CTD framework as an unsupervised, platform, and topic-agnostic solution. By experimenting on datasets from two social network platforms (Twitter and Reddit) and multiple topics (e.g., politics, health, climate) we showed that our method consistently outperforms both supervised and unsupervised baselines. Most importantly, we demonstrated that CTD can be easily integrated into an end-to-end content moderation system, improving the performance of the state-of-the-art soft moderation system Lambretta [54] by reducing its contextual false positives tenfold.

We believe that CTD will both serve as a new paradigm for unsupervised claim-based stance detection and will be a valuable tool for researchers and online platforms aiming to improve their existing content moderation systems. Enabling context-aware soft moderation systems can go a long way in making our information ecosystems healthier, minimizing warning fatigue, and increasing the intended effectiveness of warning labels. We now discuss the ethical concerns of our work, design implications and limitations of our approach, and avenues for future work.

Ethics. All datasets used in this work were either publicly released by other researchers or were collected using publicly available APIs and following those API's terms of service. This work is not considered human subjects research by our institution, since we do not interact with humans and do not collect any private information. Nonetheless, we adhere to ethical standards by removing any personally identifying information when reporting examples of social media posts in the paper. While we advocate that our approach should be used to benefit society, following the *respect for public interest* and *beneficence* principles of the Menlo report [30], CTD could be misused by malicious parties. Potential adversarial misuse includes biased platform providers using CTD to identify and downrank dissident users, or state-actors applying CTD to amplify false narratives of interest or identify expert accounts that are correcting/debunking false narratives to be silenced. While these threats are real, automatically generating and posting content on social media at a large scale produces other artifacts that can be identified by alternative approaches [27, 51, 67].

Design implications. We envision CTD to be applied as a post-retrieval filtering tool for content moderation systems on social media after topically relevant candidate posts for a claim are retrieved, as illustrated in Figure 6. Since the approach of Contrastive Textual Deviation is designed for the task of claim-specific stance detection, CTD is mostly intended for claim-specific content moderation systems like Lambretta [54]. The process of integrating CTD as a tool to existing soft moderation systems is seamless, as we demonstrated in Section 5.4. For each claim a platform moderator wishes to apply warning labels to, the only input from their end is to craft the triplet consisting of the consensus statement, a refuting evidence and a supporting evidence. The triplet can then be used with the evaluation prompt in Figure 4 alongside the fine-tuned FLAN-T5 model for inference. It is to note that one of the major advantages of using CTD is that it does not need any further fine-tuning for new claims and new platforms. As demonstrated in the example triplets throughout our work (i.e. Figure 7 and Figure 2), the consensus statement for a claim can be formulated with the most succinct fact-check or scientific consensus about the misleading claim. Similarly, the contrastive markers can be simple statements that are positive affirmation and negative reframing of the same consensus statement. The final model was fine-tuned on normalized pieces of argumentative structures, and we expect it to be robust enough to handle different quality or phrasings of triplet semantic structure expected of a CTD triplet.

Limitations. There are some limitations that come with the task setup of CTD for stance detection. First, we expect that any claim a platform aims to contextually moderate has been determined to be false, and has an accompanying fact-check statement associated with it. This requirement of a corresponding fact-check statement used to build the consensus statement in a CTD triplet poses a practical challenge in cases of quickly emerging false claims or novel skeptical narratives, for which a consensus about the claim has not yet been established. For these cases, moderators could potentially use high-quality crowdsourced truth statements [4], or resort to applying previously proposed soft moderation techniques that do not take stance into account (e.g., Lambretta). The formulation of CTD can only handle posts that support or refute a misleading claim, while social media posts discussing misinformation and rumors might also contain posts that are of "querying" or "commenting" nature [62, 87]. However, for the purpose of soft moderation where the objective is to apply warning labels to posts that are spreading the misleading claim, we argue that finer-grained distinction within the nature of "support" of a claim might not be necessary. Upon manual inspection, we find that the majority of the misclassifications by CTD happen on posts that are sarcastic and satirical about the misleading claim being discussed, which are often misclassified as refuting the claim. Identifying satire and sarcasm is a challenging NLP task [29], and future work can explore fine-tuning CTD models to handle more nuanced cases of stance occurring on social media text.

Future Work. In the future, we plan to extend CTD on evaluating claim-based stance detection in multi-lingual settings. As LLMs become more powerful beyond the English Language, we can expect their learning capabilities to improve on multiple languages [69, 81]. We will also explore strategies to reduce the manual costs of curating the triplet structure needed for CTD by automatically matching the best set of fact checks and consensus statements for misleading claims spreading in the wild, and generating the best set of triplets automatically. The ClaimReview structured markup introduced by Google [20] is a promising avenue for this direction, and we will explore multiple ways of semantically matching a misleading claim with ClaimReview markups, and generating the piece of contrastive markers from the fact-check document.

Acknowledgments. We would like to thank the anonymous reviewers for their feedback. This work was funded by the Institute for Global Sustainability and the Rafik B. Hariri Institute for Computing and Computational Science & Engineering at Boston University under the *Data and Misinformation in an Era of Sustainability and Climate Change Crises* project, and by the NSF under grants CNS-1942610, CNS-2114407, CNS-2247868, and DEB-2200052.

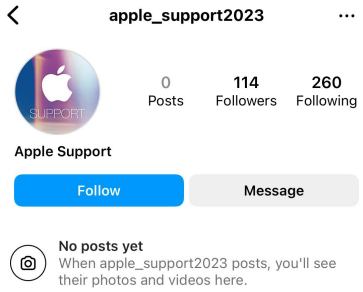
Abstract

The rise of social media users has led to an increase in customer support services offered by brands on various platforms. Unfortunately, attackers also use this as an opportunity to trick victims through fake profiles that imitate official brand accounts. In this work, we provide a comprehensive overview of such *brand impersonation attacks* on social media.

We analyze the fake profile creation and user engagement processes on X, Instagram, Telegram, and YouTube and quantify their impact. Between May and October 2023, we collected 1.3 million user profiles, 33 million posts, and publicly available profile metadata, wherein we found 349,411 *squatted* accounts targeting 2,625 of 2,847 major international brands. Analyzing profile engagement and user creation techniques, we show that squatting profiles persistently perform various novel attacks in addition to classic abuse such as social engineering, phishing, and copyright infringement. By sharing our findings with the top 100 brands and collaborating with one of them, we further validate the real-world implications of such abuse. Our research highlights a weakness in the ability of social media platforms to protect brands and users from attacks based on username squatting. Alongside strategies such as customer education and clear indicators of trust, our detection model can be used by platforms as a countermeasure to proactively detect abusive accounts.

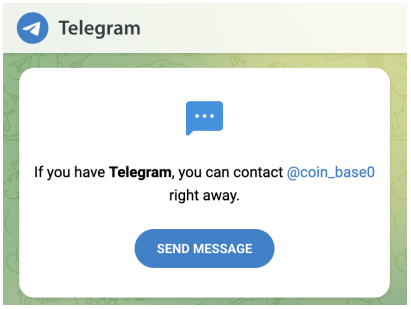
1 Introduction

Fraudsters perform social engineering attacks by mimicking popular brands and tricking victims into giving away sensitive information for financial gain. Traditionally, online brand impersonation attacks have been launched using website cloning (e.g., social engineering via phishing [21, 39] and typosquatting [3, 48, 74, 75, 81]) or offline engagement (e.g., fake technical support calls [47, 56, 72]). In both types of scams, fraudsters trick their victims into disclosing sensitive personal information that can be monetized. Over time, these brand impersonation scams have evolved and fraudsters have adopted increasingly complex methods to deceive their victims [43, 77, 80, 83].



Brand impersonation, also commonly referred to as *brand spoofing*, is a well-known problem in which cybercriminals perform social engineering tricks to represent themselves as official employees or brand owners [13, 51]. These impersonations are not limited to traditional email-based phishing attacks, but are also widely found in other areas such as technical support, e-commerce, job offers, law and legal entities, and social media [19, 20, 71]. Brand imposters often engage with brand users, posing as reputable brands to obtain sensitive information or to sell counterfeit products. Once users trust these imposters, they become susceptible to attacks, potentially resulting in the theft of financial and personal information.

As the number of social media users continues to increase, it is projected that there will be approximately 5.04 billion social media users worldwide in 2024 [16, 22]. Consequently, brands are using their social media profiles to handle customer support and engagement [28, 36]. Many companies use social media platforms such as X [7, 14, 23, 52] and Instagram [4, 24, 31] to actively communicate and connect with their customers through both private messaging and public responses. The expectations of customers have changed with time in engagement with the brand. For example, Sproutsocial reported in 2021 [28] that 80% of the users expect companies to interact through social media profiles. On the other hand, this has created imposters a perfect ground for imposters to launch social engineering-based attacks that target the users of these brands. Several brand impersonation examples are shown in Figure 1.



According to the Federal Trade Commission (FTC), there was an 85% increase in brand impersonation between October 2020 and September 2021, resulting in losses of $2 billion [26]. In 2022, imposter-based scams caused losses of $2.6 billion. Taking into account scams based on only social networks, losses of $2.7 billion were reported from January 2021 to June 2023, excluding unreported losses [37]. Regrettably, the number of fake social media profiles, which often

(a) Typosquatting attack targeting PayPal.

(b) Combosquatting attack targeting Apple.

(c) Fuzzysquatting attack targeting Coinbase.

Figure 1: Representative examples of brand impersonation attacks where fraudsters applied typosquatting, combosquatting, and fuzzysquatting to target PayPal, Apple, and Coinbase. We can observe that username squatting is a key factor in creating a profile impersonation. Moreover, by adding official brand logos (Figure 1a and Figure 1b), fraudsters try to establish a notion of trust.

include brand impersonators, is on the rise across various platforms [57, 61, 64, 65]. Efforts to combat these fraudulent accounts via various techniques, such as the introduction of verified account badges, have proven not only ineffective but also counterproductive. Imposters have exploited this system by obtaining verification badges, further deceiving users by appearing as official brand representatives [5, 6, 18, 59, 65]. Although such brand impersonation attacks are known, there is no systematic study that comprehensively analyzes their *modus operandi*, scale of abuse, and monetary impact.

In this work, we close this gap by collecting a dataset of brand impersonation attacks, analyzing account setup and user engagement processes, quantifying their impact using loss metrics, and proposing robust countermeasures. More specifically, we perform the first large-scale study of brand impersonators that target the top 10K Tranco domains [44] on four social media platforms (X, Instagram, Telegram, and YouTube). Through the brand's account name similarity search, we collected 1.3 million users and 33 million posts from all four social media platforms. We identified almost 350,000 usernames performing various squatting techniques to impersonate 2,625 popular brands across the four platforms. To understand the scam life cycle, we further analyzed the profile metadata and user engagement of these username-squatted profiles revealing key characteristics of account creation techniques and several emergent and traditional threats. Furthermore, we analyzed the effectiveness of detecting scam profiles on social media platforms and identified that more than 98% of the scam accounts were alive, ranging from account creation dates between 2007 and 2023. Our findings show that one-third of username squatting profiles display official logos and are common among technology-related brands that target the users of the brand with technical support issues. Finally, we recommend defense mechanisms to combat such scams.

In summary, our key contributions are as follows:

- We perform the first systematic and large-scale analysis of username squatting-based brand impersonating attacks across four social networks. Our method and implementation are scalable to finding popular and non-popular brands impersonating social media profiles.
- In our empirical measurement study, we uncover brand-impersonating abusive social media accounts that target the top 10K brands from nine web categories. We uncover active attacks that these abusive accounts are carrying out and detect new and old threats via username and engagement creation.
- We demonstrate that the impact of brand impersonation extends beyond the fraud landscape and poses security and privacy concerns for victims. In particular, we provide evidence that fraudsters obtain sensitive information from their victims, which is then monetized for identity theft or monetary gains.
- Finally, we provide recommendations and defense mechanisms to combat these fraudulent accounts to mitigate existing and emerging threats.

To foster research, we publish our implementation [73]. For data protection reasons, we will only share data on fraudsters with interested academics or entities upon request.

Ethical Considerations and Disclosure. We conducted a coordinated disclosure of the 100 most impersonated brands and reported the identified squatting accounts. This includes brands such as *Google*, *PayPal*, *Facebook*, *Netflix*, *Amazon*, and others. We also shared 5K email addresses and 22K *payme* links from engagement posts with *PayPal*. PayPal's internal analysis confirmed that at least 43% of the 16K reported data had already been restricted at the time of data sharing, thus further observing fraudulent activities on other accounts. Additionally, we received confirmation from Google and we were acting on it. Both Google and X showed interest in further collaboration to identify similar fraud. Overall, our work received positive recognition, validating the scam life cycle of these impersonating accounts.

2 Technical Background

In impersonation attacks, including those on social media platforms, scam profiles often employ the target brand's official logos and description texts without authorization. At first glance, this official content naturally imparts a notion of credibility to scam profiles. In addition, fraudsters opt for usernames closely resembling those of official accounts to further add legitimacy. This behavior largely reflects web-based typosquatting attacks, where fraudsters register misspelled names of popular domains to capitalize on the customers' typing errors (e.g., *amazn.com* or *paypsl.com*). However, username squatting in social media-based brand impersonation is more intricate than conventional web-based typosquatting, and it can be broadly categorized as typosquatting, combosquatting, and fuzzysquatting. In the following, we discuss each type of username squatting along with representative examples.

Typosquatting. Typosquatting is a well-known technique in which attackers set up a fake profile with minor changes to the username, in order to lure victims who make a typing error while searching for the target brand [3, 81]. For instance, a typosquatter can register the X profile https://twitter.com/paypal7 and intercept users who mistakenly type "7" after the intended profile name https://twitter.com/paypal. In Figure 1a, we show a typosquatting attack targeting PayPal.

Combosquatting. Combosquatting is a variant of typosquatting in which attackers concatenate two or more strings to encapsulate the target brand's name and provide some additional context. For instance, if "apple" is the username of an official profile, a scammer can create "apple_support_US" or "apple_helpdesk2024" to appear as an official Apple support account, which can trap unsuspecting Apple users requiring technical support. Combining official names with context nouns is called combosquatting [40], and in Figure 1b, we show a combosquatting profile that targets Apple.

Fuzzysquatting. In our preliminary evaluation of social media scam accounts, we identified usernames that could not be solely attributed to typosquatting or combosquatting. For instance, we found scammers targeting Amazon with usernames including amaz0n_h3lp_ds3k and a3mz0n@_supp0rt__dkz. Note that amaz0n_h3lp_d3sk contains a typosquatted brand name (amazon -> amaz0n) and a combosquatted context noun (help_desk -> h3lp_ds3k), with key letters (o and e) substituted with digits (0 and 3). We label these accounts as *fuzzysquatting*. To identify fuzzysquatting, we create two rules: (i) Initially, we apply similar techniques to identifying combosquatting to find a series of words (or segments), and (ii) For each of the words (or segments), we compare whether one of the words contains an official social media handle with a non-zero Damerau-Levenshtein distance of two or less. We choose fuzzysquatting techniques purely based on a manual analysis of impersonating accounts on exclusion to the typosquatted and combosquatted lists. We suspect fraudsters adopting such username-squatting approaches for two main reasons: (i) allowing a larger number of non-conflicting registers of a user handle in social media platforms and (ii) obfuscating and potentially thwarting mechanisms against social media in detecting the squatting-based logic. Previous works on squatting have explored typosquatting and combosquatting at great length [40, 63, 81]. However, this novel form of username squatting, particularly in the context of brand impersonation on social media platforms, has not been extensively investigated. In Figure 1c, we provide an example of a fuzzysquatting attack targeting Coinbase on Telegram.

3 Measurement Setup

To study brand impersonation attacks on social networks, we have developed an analysis pipeline, which we present in the following. Our data collection process involves (i) selecting popular brands that could be targeted with impersonation attacks, (ii) collecting accounts linked to those brands from four social media platforms, and (iii) obtaining a candidate set of scam accounts by removing potential false positives from our account population. We now elaborate on each step of the data collection process.

3.1 Brand Domain Identification

To identify brands that are frequently targeted by fraudsters, we examined the top 10K domains of the highest ranked sites listed on *Tranco* [44]. From these top 10K domains, we first automated the filtering process by excluding unreachable domains and querying the web category of each domain using an external API [41] that categorizes domains based on the web content [17]. Subsequently, we filtered out domains that were not associated with e-commerce or consumer-oriented categories. Our analysis revealed nine main web categories that could be lucrative targets for fraudsters. In Table 1, we present a breakdown of the nine web categories for the 2,847 brand domains collected after applying the filtering process.

Our motivation to focus on the top 10K brands was inspired by the 2023 Phishing Threats Report from APWG and Cloudflare [12, 25]. APWG's report provides an overview of phishing trends across various industry sectors (financial, gaming, crypto, e-commerce, payment, social media, etc.), while Cloudflare's data highlights the top 1,000 threats associated with brand impersonation. These sources indicated a preference among scammers for targeting popular e-commerce websites and consumer-oriented businesses due to their greater potential for financial gain. The curation of candidate domains for our study consists of the following two steps:

- **Automated Filtering.** For each domain, we initially performed a check whether a given domain is alive. We used the Python GET request call to ensure that the response received was alive. For each of the live domains,

Table 1: Web categorization results for the popular brands considered in our work. In this table, we present the total number of unique brand names that we study based on each web categorization. Note that most brands were categorized as Business & Industrial.

Web Categories	Unique Brand
Online Communities	65
Auto & Vehicles	15
Travel	75
Finance	163
Shopping	118
Arts & Entertainment	601
Internet & Telecom	340
Computers & Electronics	656
Business & Industrial	814
Total	2,847

we further queried to obtain web content categories using a third-party API service [41] which categorizes domains, based on the Interactive Advertising Bureau (IAB) classification [17]. From this, we obtained 27 different web categories of these domains such as adult, entertainment, auto and vehicles, finance, games, food and drinks, hobbies, news, online communities, etc.

- **Manual Filtering.** For each of the 27 categories collected from the automated filtering, we manually compare them against the phishing trend report from APWG and Cloudflare [12, 25] to identify whether those categories represented the industry sector belonging to e-commerce websites and consumer-oriented businesses that are targeted by the fraudsters. This resulted in 9 such web categories as listed in Table 1.

3.2 Social Media Accounts Collection

To collect social media profiles associated with each brand, we selected four social media platforms: X, Instagram, Telegram, and YouTube. Using API services [10, 11, 54, 55, 78], we collected data related to social media profiles (e.g., name, description, profile picture, date of creation, account status, etc.) between May 2023 and October 2023. We then combined the brand domain's second-level domain (2LD) name with eight popular keywords, namely *rewards*, *recover*, *hack*, *support*,*help*, *assist*, *contact*, and *team* to create a search query for account collection. For instance, given a domain name *paypal.com*, our search query contained the following keywords: *paypal*, *paypal hack*, *paypal support*, *paypal help*, *paypal assist*, *paypal contact*, *paypal team*, *paypal recover*, and *paypal contact*. We ran queries on each platform to collect accounts as well as their profile metadata, including profile pictures, posts, interactions, etc. In Table 2, we provide an overview of all accounts collected from each platform, along with the number of associated brands. In total, we collected 1,310,962 accounts from the four platforms.

Table 2: Overview of the raw dataset obtained by performing search queries across four social media platforms. We can observe that X hosts the largest number of accounts.

Platform	Unique Brand	Number of Accounts
X	2,628	1,206,250
Instagram	1,717	13,545
Telegram	2,847	63,187
YouTube	1,784	27,980
Total (Distinct)	2,847	1,310,962

In a cursory view, our data invariably reveal a large number of potential fraudulent accounts. For example, a simple estimate suggests that on average, there are about 460 accounts associated with each brand across all platforms (1,310,962 accounts / 2,847 brands). It is logical to assume that a brand will not own such a large number of social media accounts, as it would create confusion among customers. On the other hand, the numbers suggest that there must be scam accounts that impersonate legitimate brands to deliberately create confusion and lure customers. In Appendix A, we provide further details on the brand social media account collection process and the rationale of keywords search.

3.3 Data Filtration

Having gathered roughly 1.3 million accounts, we conducted a series of filtering experiments to clean up our dataset and eliminate potential false positives. In the following, we present our data filtration methodology.

Official Accounts. We conducted two experiments to collect official accounts of the 2,847 brands. In the first experiment, we crawled the web pages of these brands and parsed their content to extract accounts linked to available social media platforms. We collected a total of 8,527 social media handles from the three platforms that are related to the official brands X(3,537), Instagram (2,429), and YouTube (2,561). As for Telegram, it is also worth mentioning that prominent brands do not use Telegram as their preferred communication channel. However, Telegram is a popular communication medium among fraudsters, and we expected to find scam accounts shared on Telegram, as previously shown in Figure 1c. In the second experiment, we used an external third-party API service [41] that monitors the official social media pages of popular brands. During our account filtering process, we observed that not all brands maintain official accounts on all four social media platforms. As a result, if an official account, e g., from X, was observed in our dataset, we removed it during the filtering process while keeping all other accounts.

Verified Accounts. In the next filtering step, we remove all verified accounts from our dataset. Studies suggest that subscription-based account verification models have enabled fraudsters to easily obtain verified accounts [6, 18, 59]. However, in the absence of any empirical evidence that quantifies the volume of verified scam accounts, we adopted a conservative approach by implicitly assuming verified accounts as legitimate accounts and removing them from our dataset. In total, we excluded 8,415 verified accounts in this step.

Brand Subsidiary Accounts. It is a common observation that while searching for a particular brand (e.g., *PayPal*), social media platforms also return associated brands that could be the subsidiaries of the main brand (e.g., *Venmo* in this example). Such results are typically returned due to account associations inferred from user interests. Therefore, we anticipated that our search results could include such accounts, which may introduce false positives in our dataset.

To remove such accounts, we collected the top 1 million Tranco domains and extracted second-level domains as brand names. Our intuition was that for a popular brand in Tranco's top 10K domains, its subsidiary brand would at least be among the Tranco 1M domains. When observing an overlap between our dataset and the second-level domains of the top 1M domains, we removed 16,492 entries from our dataset.

Low-impact Accounts. In the final step of account filtering, we filtered the remaining dataset to identify accounts whose username handle creation does not align with the criteria of any of the squatting techniques (i.e., typosquatting, combosquatting, and fuzzysquatting) by cross-referencing them with the username of the official brand handle. These identified accounts are labeled as low-impact accounts. While conducting our manual inspection, we noticed accounts whose names are similar to our search query but whose usernames are not similar to the target brand. For example, if an account displayed the name *amazon tech support* but had an innocuous username (e.g., lead_vocalist701), this indicated that the account owner was not engaged in username squatting, which we consider a fundamental aspect of identifying brand impersonation attacks. Such accounts naturally have limited deception potential and are less likely to trap victims, so they are categorized as low-impact accounts. Using this heuristic, we removed 927,767 low-impact accounts.

Starting with 1,310,962 accounts, we removed 8,527 (official accounts), 8,415 (verified accounts), 16,492 (brand subsidiary), 927,767 (low-impact accounts), and 350 (API response as invalid accounts upon metadata query) entries in the different filtering steps. This narrowed down our analysis to a candidate set of 349,411 accounts in total. We acknowledge that our data filtration is conservative and we might have overlooked accounts that could be involved in brand impersonation or other types of scams. However, we wanted to limit our analysis to scammers that are very similar to legitimate brands and have a higher likelihood of entrapping users.

Table 3: Summary of username squatting accounts targeting the brands. Note that most usernames were involved in combosquatting, targeting 2625 unique brands.

Squatting	Squatted Accounts	Targeted Brands
TypoSquatted	8,473	1,572
ComboSquatted	342,892	2,625
FuzzySquatted	4,523	1,035
Total (Distinct)	349,411	2,847

4 Account Setup Analysis

Based on our dataset, we now analyze the key characteristics of our candidate accounts, including username squatting trends and unauthorized usage of official brand content. As mentioned in Section 2, username squatting and brand content analysis provide key insights into the onboarding strategies applied by fraudsters. In addition, we study the distribution of targeted brands and their platform-wise distribution across social media.

4.1 Username Squatting

In the first step, we analyze the number of accounts that performed typosquatting, combosquatting, and fuzzysquatting in their usernames.

4.1.1 Detection Methodology

For typosquatting detection, we measure the *edit distance* using the *Damerau-Levenshtein distance* of one, which measures the distance between two strings by counting the minimum number of deletions, insertions, and substitutions of characters required to transform one string into the other [3, 79]. We applied the Damerau-Levenshtein distance of one to check if a username had a missing character, character permutation, substitution, or duplication typo. For combosquatting detection, we compare the account usernames of the official brand and the impersonating brand using the *Word Ninja* [8] library, which uncouples strings containing multiple words. We applied *Word Ninja* on the account usernames to analyze the appearance of a target brand in the resulting text (i.e., amazon in amazonhelpdesk90). To identify fuzzysquatting, we first replicated the combosquatting detection method to split the strings, followed by the typosquatting detection method on the brand name. If the output contained a typosquatting brand name and a context noun, we labeled it as a fuzzysquatting username.

4.1.2 Results and Key Findings

Our analysis revealed that fraudsters apply all three forms of username squatting techniques, with combosquat-

ting being the most prevalent method accounting for 98.13% (342,892/349,411) of the accounts targeting 92.20% (2,625/2,847) brands. Typosquatting was the second most prevalent technique, and it was observed across 2.42% (8,473/349,411) accounts that targeted 55.21% (1,572/2,847) brands. Finally, fuzzysquatting was detected across 1.29% (4523/349411) accounts that targeted 36.35% (1,035/2,847) brands. In Table 3, we provide a breakdown of username squatting types along with the number of targeted brands. In the following, we report our key findings about each username squatting technique.

Typosquatting Techniques. In typosquatting, our key observation was exploiting unique username creation rules of social media platforms to amplify scam deception. The creation of typosquatting in the handle depends on the length and allowed characters as permitted by each social media platform [33, 34, 76, 85]. Our study revealed that among impersonating accounts using typosquatting, 87.65% (7427/8473) added a single character as a prefix or suffix, while the remaining 12.34% (1046/8473) used omission or replacement.

Combosquatting Techniques. In combosquatting, we observed four popular trends in scam profiles namely: (1) random digits suffixed to the brand name (e.g., paypal12233243), (2) multiple words concatenated with the brand name (e.g., paypalhelpdesknow), (3) alphanumeric characters added to the brand name (e.g., paypaldsk3434), and (4) combinations of the aforementioned techniques along with characters and identifiers allowed by the respective platform. In Figure 2, we present the distribution of each pattern in our dataset of combosquatting accounts. We also noticed affinities in the usage of English language words. For instance, across all prominent brands, the terms *help*, *desk*, *support*, and *deal* were most commonly used with the brand name. In Figure 3, we provide a breakdown of the top 25 English keywords used by the combosquatting accounts.

Fuzzysquatting Techniques. Although fuzzysquatting accounted for a small percentage of our dataset, it still revealed some interesting insights. Notably, 973 fuzzysquatting usernames were derived from combosquatting usernames, which we detected by reverse substituting digits with letters.

4.2 Profile Image Analysis

As discussed in Section 2, we consider username squatting as the baseline attribute of impersonating profiles. However, a scam profile may not be convincingly deceptive if—in addition to username squatting—it does not use official logos of the target brand. In this section, we analyze how scam profiles attempt to project an illusion of credibility by using the official logos of the target brands in their profile pictures. We believe that analyzing such profiles is pertinent for two main reasons: (i) Highly deceptive profiles will invariably trap a large number of unsuspecting customers, thereby posing a threat to legitimate brands and their customers, and (ii) By analyzing affinities among such profiles, we can propose account setup controls for social media platforms, which could prevent the scam account creation at the sign-up level.

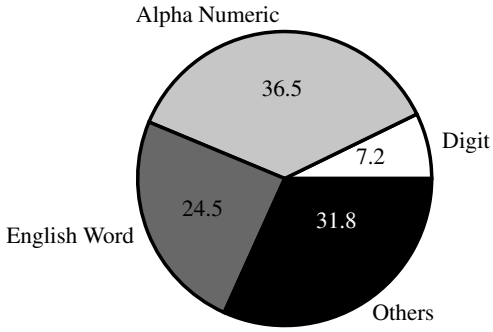


Figure 2: Distribution of combosquatting segments in usernames. Among five combosquatting segments, Alpha Numeric segments accounted for the most combosquatted usernames.

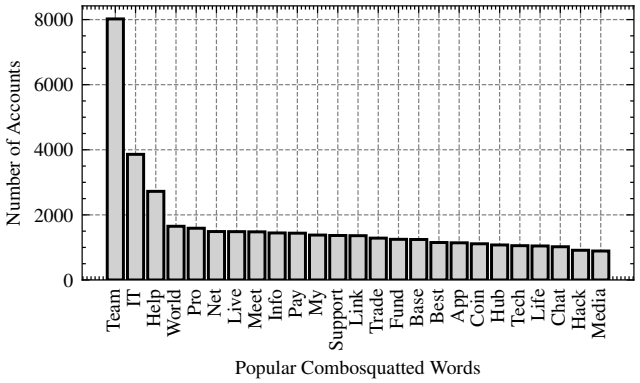

Figure 3: Overview of the top 25 keywords that combosquatters used to create user handles. Among these, the *Team* keyword was found most frequently.

4.2.1 Detection Methodology

In our analysis of profile images, we excluded pictures of squatted handles that use the default logo of the respective social media platform. This resulted in 219,465 squatted handle profile pictures belonging to the username creation of 2,484 brands. We employ the pre-trained visual model CLIP [66] [1] for feature extraction. We resized each profile picture to a resolution of 224×224 pixels, extracted the corresponding CLIP token embedding, and used cosine similarity to measure

[1] Specifically, we used a CLIP-ViT-B-16 model: https://huggingface.co/laion/CLIP-ViT-B-16-laion2B-s34B-b88K

their similarity to all CLIP token embeddings of the original logos [2, 70]. Subsequently, we sorted the obtained similarity scores for each picture and retained the most similar original logos. To enhance our pipeline's quality and reduce false positives, we filtered profile pictures where the affinity with the most similar logos scored below 80%.

4.2.2 Results and Key Findings

After conducting the profile picture analysis, we identified 9,473 accounts that impersonated 1,701 brands using their official brand logos as display pictures. In Table 4 we provide a breakdown of image impersonation attacks performed by the scam account. Overall across all four social media platforms, we found 59.74% (1701/2847) of the total brands impersonated via profile image creation by 9,473 username squatting handles. On Instagram, among the 1717 brands we studied, 483 brand profiles were found to be impersonated by 1065 squatted handles, resulting in the highest brand impersonation (28.13%). Among these 9,473 impersonated profile images from all four social media platforms, X was found to be the highest at 45.02% (4265/9473), and Telegram was second most impersonated at 43.33% (4105/9473). The image cluster size of impersonating accounts was found to be an overall median size of 5 and as high as 308 squatted handles in a cluster. Among these image clusters, X (308) and Telegram (228) were found to contain a higher number of image cluster sizes with a median of 9 and 6, respectively. In the following, we provide a platform-specific analysis to show the popular brands being targeted on each platform.

X. On X, we discovered 488 brands that were impersonated by 4,265 scam accounts. Among them, the top 10 brands were *Apple, Microsoft, Samsung, Binance, Netflix, AT&T, Slides, Salesforce, Accenture, and Walmart*, and they were targeted by 38.9% of the scam accounts. These results are unsurprising given that the top 10 brands are indeed high-profile brands with a larger customer base.

Instagram. On Instagram, we found 483 brands in total that were targeted by 1,065 scam accounts. The top 10 most frequently targeted brands were *Sony, Microsoft, DHL, Samsung, Unilever, TechnoMobile, Orange, Vivo, BSIGroup, and Garmin.*, and they were targeted by 11.9% of the scam accounts. A surprising finding in our results is the small overlap (2/10) between the top 10 brands on X and Instagram. The account following of these brands may vary across each platform, which eventually determines the targeting patterns of fraudsters.

Telegram. On Telegram, we observed 698 brands being targeted by 4,105 unique scam accounts. The top 10 most targeted brands were *BSIGroup, Netflix, Telegram, Instagram, Aliexpress, Facebook, Spotify, Paytm, Android, and Binance*, and they were targeted by 26.2% of the scam accounts. Similar to Instagram, we observed a small overlap in the top 10 targeted brands on Telegram compared to X and Instagram. In fact, 3 out of the top 10 brands on Telegram were common with other platforms namely Instagram, Facebook, and Telegram. This pattern complements our earlier statement that Telegram is not a preferred communication channel for the top brands. Telegram users (including scammers) might be aware of it and instead use Telegram to target popular non-ecommerce brands such as social media platforms.

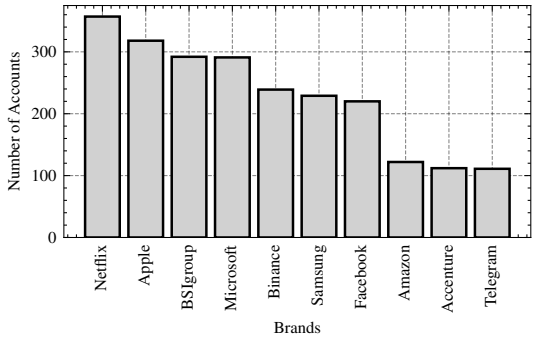

Figure 4: Top 10 most commonly targeted brands across all social media platforms. Technology-related brands such as Netflix, Apple, and Microsoft appear to have a high-risk exposure with over 200 scam profiles targeting each brand.

YouTube. Finally, on YouTube, we observed a small population of 32 brands being targeted by only 38 scam accounts. The top 10 targeted brands were *BSIGroup, Freshhooks, Sonicwall, PeacockTv, UPS, Tucows, USAA, Opensooq, Spotify, and Ushmm*. Compared to all other social media platforms, YouTube appears to be the least popular platform among fraudsters, and a plausible reason could be the limited user-to-user engagement on YouTube compared to other platforms. For instance, on X, users can easily search for other users, track their activities, and interact with them. However, YouTube users do not have a direct method to identify other platform users and most user-to-user interactions occur in video comments. Moreover, X and Instagram also provide direct messaging or private messaging options, which can be used by scammers to discretely communicate with their victims after luring them. YouTube does not offer such functionality to its users. Therefore, due to the limited target audience and lack of private communication options, scammers might not prefer YouTube as a medium for brand impersonation attacks. In the supplementary material [73], we provide further details on image clustering limitations and metrics.

4.2.3 Holistic Brand Risk Exposure

Taking into account the most commonly targeted brands across all platforms, we now consolidate our findings to present the overall risk exposure of the popular brands. For that purpose, we collect the top 10 brands based on the number of scam accounts and present our results in Figure 4. We

Table 4: Summary of image impersonation by squatted handles of social media profiles mimicking various official brands. In this table, we provide several search accounts that impersonated the official brands from each social media platform we studied.

Platform	Impersonated Brands	Scam Accounts	Scam Clstr. Median	Scam Clst. Max	Overall Brand Target %
X	488	4,265	9	308	18.56
Instagram	483	1,065	3	17	28.13
Telegram	698	4,105	6	228	24.51
YouTube	32	38	1	4	1.79
Total	1,701	9,473	5	308	59.74

can observe that Netflix is the most commonly targeted brand across all social media platforms, followed by Apple and BSIGroup. Our results strongly complement a recent report published by a software solution company called Egress [82], and they have observed a 78% increase in brand impersonation attacks on Netflix. They also observed that scammers targeting Netflix often use typosquatted user names along with context nouns such as "Help Desk." On one hand, similarities in our results with those reported in [82] acknowledge the correctness of our methodical approach in discovering scam accounts. On the other hand, it also raises concerns about the growing risks of brand impersonation attacks which mandate remedial actions to be taken by social media platforms.

Key Takeaways. Our analysis of account setups leads us to several important findings. X is the primary platform for brand impersonation attacks, with fraudsters frequently using combosquatting in their usernames. Roughly a third of these deceptive profiles also use official logos to appear more legitimate. While a variety of brands are impersonated on social media, technology brands are particularly vulnerable, often targeted because their users seek technical support.

5 User Engagement Analysis

To effectively understand these scams, it is crucial to thoroughly examine scam profiles, understand how they engage with users, learn about their victim demographics, and analyze the fake services they offer. In this section, we delve into the details of scam profiles to provide a comprehensive view of the entire scam lifecycle.

5.1 Profile Metadata Analysis

We start by analyzing scam profile metadata, including name, geolocation, account type, languages, external links, account creation timelines, and public metrics.

Display Name. We applied text similarity analysis to study patterns and affinities in the display names of scam profiles. We found notable patterns in display names, including the usage of (i) the brand name, (ii) the brand username as display name, (iii) the brand name followed by context nouns such as *help*, *support*, *deal*, etc., (iv) multiple brand names such as Netflix, Facebook Help, and (v) unrelated keywords including human names and job titles such as *Shopify Expert & Ecomm Strategist* and *Amazon Products Guru.*

Geolocation. Geolocations are voluntarily disclosed by social media profiles. Typically, official brands tend to put head office locations on their profiles. Since top brands in our dataset have their head offices in the US, unsurprisingly, we found the highest number of valid geolocations in scam profiles set to the US (56,348). Other prominent geolocations were the UK (8,925), Japan (5,456,), India (5,134), Nigeria (4,231), Indonesia (2,321), Canada (2,134), Australia (1,993), and France (1,243). Overall, we found 51,919 distinct geolocations mentioned on the scam profiles, with 50,549 invalid locations such as the north pole, gaming, blackhole, etc.

Languages. Account language usage is a significant component of our analysis, as it reveals specifics of the user segment being targeted. For instance, if an account language is set to "Germany, English", it would likely mean that the scammer is targeting users from the region of Germany who can communicate in English. Diversity in language usage can shed light on a wide range of user segments being targeted. Our dataset showed that 38.9% (135,820/349,411) of the accounts do not contain language settings. Among 61.11% (213,591/349,411) of the accounts where languages were found, we identified 273 distinct language settings targeting 56 language-speaking users from 66 different regions. Among the scammers who set languages,12.38% (26,447/213,591) specified targeted region but missing speaking language users whereas the remaining 87.61% (187,144/213,591) specified region and language. Overall, the top 5 regions are India (7,623), Indonesia (6,947), Iran (6,400), Russia (5,473), and Uzbekistan (3,127) and the top 5 languages are Russian (4,367), Farsi (2,968), English (2,076), Arabic (1,620), and Spanish (1,066).

External Link. The description section of the profile metadata allows profiles to embed URLs which often point to a website outside of the platform. Among the four platforms in our study, X creates tiny links (i.e., *https://t.co/****) upon adding a URL. Tiny links are always unique, even if they re-

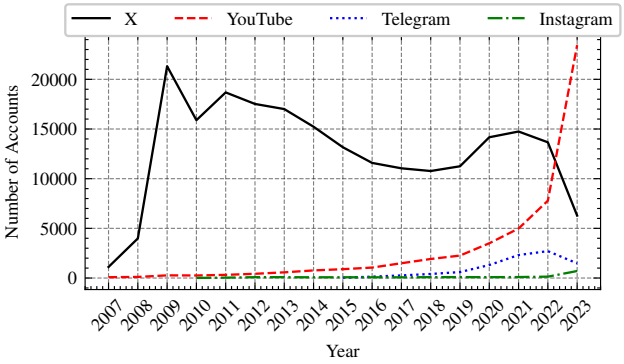

Figure 5: Yearly scam account creation volume for all four platforms. Note that X has the highest account volume with the maximum number of accounts reported in 2009. All the other platforms have been recently targeted by fraudsters, with YouTube showing exponential account growth.

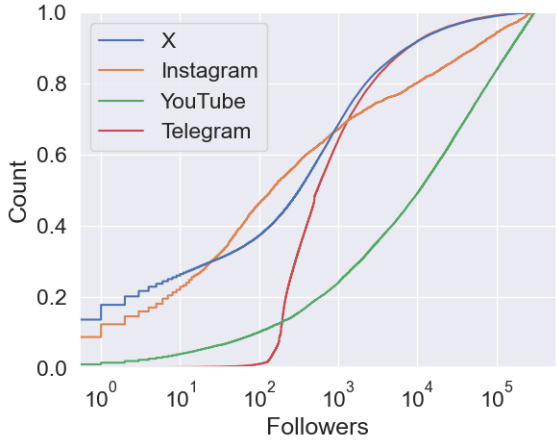

Figure 6: Followers count: This graph displays the number of followers on each social media platform that we studied.

solve to the same website. We collected 101,633 URLs from scam profiles and analyzed their security posture. We found 23,606 URLs that returned the 404 response code, indicating that the domains were taken down. For the remaining URLs, we performed extensive crawling to collect website metadata and other URLs mentioned on the websites. In total, we obtained 1,519 unique URLs through crawling, confirming that tiny URLs were indeed mapping onto the same set of websites. We then evaluated the security posture of 1,519 URLs using the VirusTotal API and found that 84 URLs were labeled as malicious, while others were labeled benign. A manual inspection of benign URLs revealed that they were linked to famous brands, indicating that scammers put legitimate URLs in their descriptions to add legitimacy to their profiles.

Account Creation Age. Account creation date is an important feature that sheds light on some of the key attributes of scam accounts. For example, if scam accounts have been operating for several years, this shows that their hosting platform needs to apply better controls to detect and restrict them. Moreover, if there are anomalous trends in the account sign-up timeline, this might indicate coordinated scam campaigns being launched to target brands. Our dataset showed that scam accounts were created between 2007 and 2023 with a median value of 16,158 per year. In Figure 5, we show the scam account creation timeline across all four platforms. In terms of year-wise distribution, the highest number of accounts created on the four different platforms represented by (year, total count) are X (2009, 21,316), Instagram (2023, 705), Telegram (2021, 23,113), and YouTube (2019, 23,443). The account creation trend on X was distinctly different from other platforms since the account volume varied over time. In contrast, other platforms showed a continuous growth of scam accounts over the years, with YouTube's count growing exponentially since 2022. From our results, we conclude that X has been historically a popular choice for scam account creation. However, the trend has recently been diminishing on X and growing across the other three platforms.

Followers and Posts. In the next step of our study, we analyzed the popularity and engagement tendency of scam profiles. A strawman method to measure an account's popularity is by observing its followers and following counts. Our analysis revealed that most scam accounts had a mundane outlook with few followers. In Figure 6, we present the number of followers across different social media platforms. We found that 70% of profiles on X, Instagram, and Telegram have fewer than 1,000 followers, while on YouTube, over 75% of accounts have more than 1,000 followers. The median follower counts for X, Instagram, YouTube, and Telegram were 321, 142, 10,700, and 547, respectively. Apart from YouTube, the follower count for all other platforms is considerably lower than the expected follower count of a popular brand account.

Similarly, account engagement tendency can be broadly analyzed by counting the number of posts generated by an account. We observed that more than 95% of the accounts had generated a post with a median post count of 472, 30, 33, and 394 across X, Instagram, YouTube, and Telegram, respectively. In Figure 7, we provide a CDF for all posts generated by scam accounts. Our CDF shows that many accounts ($>$80%) generated fewer than 20,000 posts. Hence, it can be concluded that $\approx$20% of the scam accounts are actively engaged on the platforms through posts.

5.2 Qualitative Evaluation: Account Age, Account Creation, and Long Tail Followers

Based on the profile data analysis of scammers on the date of creation, we perform further analysis to understand the scammers' account activity and ensure that the data does not contain false positives. Below we discuss three qualitative

studies we performed.

Random Account Analysis from Last Decade. We randomly picked 50 X accounts from 2007 to 2017 and inspected these accounts in the web UI. Overall, 13/50 of these accounts were found to be blocked on the X platform for some form of policy violation. For the remaining 37 accounts, we found that 6 accounts were either deactivated or had their user handle changed. For the 31 accounts, we observed that 9 did not contain any posts and had a similar logo to the squatted brands, while 22 accounts contained posts and interactions with users related to the squatted brands. All of these interacting accounts showed signs of maliciousness corresponding to the attack categories we will discuss in Section 5.3.2. However, the tweets interaction did not contain any interaction before 2023.

Buy and Sale of Social Media Profile. We observed that social media profiles on platforms such as X, Instagram, YouTube, and others can be bought and sold on multiple open marketplaces in public trading [1, 53, 86]. Scammers are also likely to create mass social media profiles and sell these accounts, which are later used for various types of scams.

Long Tail Followers. Additionally, we conducted a qualitative analysis of followers of squatted profiles from three popular brands: Netflix, Amazon, and Binance. From each of these brands, we selected 10 profiles from the X platform with over 300 followers. Below we provide details on our analysis of these profiles.

- **Followers with no posts.** 14/30 profiles had no posts on their timelines and did not interact with public posts, despite having over 300 followers. These accounts appeared to be suspicious, often protected, missing posts, or shared followers.
- **Followers with posts.** 16/30 profiles had between 3 and 117 posts. The posts from Amazon-related profiles often targeted job seekers with offers for work-from-home or remote jobs. Netflix-related posts promoted creating unlimited Netflix accounts, direct messaging for further information, or watching free movies without paying. Binance-related posts focused on growth, pump-and-dump schemes, and investment opportunities.

5.3 Scam Post Analysis

The last component of the scam lifecycle analysis is the study of scam posts to understand how fraudsters trap victims through fake incentives or offers. For this purpose, we collected all available posts from scam profiles and applied topic modeling techniques to group them in clusters. We collected 33,768,759 posts in total [X (33,588,977), Instagram (19237), Telegram (133,399), and YouTube (27,146)] and applied the following technique to extract prominent fake incentives offered in them.

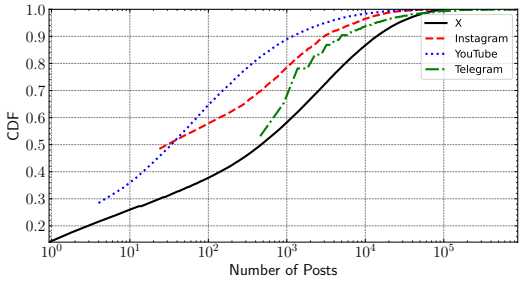

Figure 7: Graph of posts interaction on the social media platform. The graph provides a breakdown of the squatting profile posts count from four different social media platforms.

5.3.1 Clustering Methodology

First, we picked a maximum of 15 most recent posts from each account, acknowledging that not all accounts necessarily had 15 or more posts available. Consequently, the total number of posts analyzed in the clustering process amounted to 322,327 after excluding posts that were not in English. For language identification and filtering, we use the CLD2 library [15]. We then vectorized the posts using the *all-mpnet-base-v2* sentence transformer model [67]. Subsequently, we processed the posts using the BERTopic library [30] to remove redundant information, such as stop words. Finally, we combined UMAP [50] and HDBSCAN [49] for clustering, followed by the KeyBERT [29] model to refine topic representations within each cluster. We selected the top 100 clusters in our results, from which we extracted ten prominent scam categories that were prevalent in our results. Further details on the text processing and clustering are reported in the supplementary material [73].

5.3.2 Results and Key Findings

We now discuss the top ten most prominent scam offers observed in our clustering results. We performed manual analysis on each of these top ten clusters arranged by size and provided details on brand-impersonated attacks. The clusters that do not contain brand impersonation are excluded from our study.

Free Giveaways. The most common scam offer in our results was fake free giveaways, such as cryptocurrencies, free streaming service sign-ups, purchase deals, etc. A total of 3,735 scam accounts were involved in giveaways, frequently targeting brands including Amazon, Netflix, Binance, and Coinbase.

Fund Raiser. Fund raise scams include a request to support emerging businesses such as future health care, wealth summit, startups, etc. We found 3,053 accounts involved in such fundraising scams, and they mostly targeted Tesla, Salvation Army, Ford, GoFund, and John Hopkins.

Fake Technical Support. Fake technical support includes scammers offering fake account recovery or device diagnostics in return for a high fee. We found 2,115 accounts offering fake technical support and targeting brands including Moodle, Cloudflare, WhatsApp, and Amazon.

Third-Party Service Representative. In third-party service scams, fraudsters offer technical support for app or software installations of popular brands. We found 1,979 scam accounts targeting mostly finance-driven brands such as HDFS bank, PayPal, and Paytm.

Advertisement Booster. In this type of scam typology, fraudsters pretend to be an official representative of brand advertisement segments such as Google Ads or Facebook Ads. They use such fake affiliations to offer fake boosting services for other users. We found a total of 1,597 accounts that were involved in this scam.

Fake Recruitment. Recruitment scams involve fake job offers at the target brand. For instance, we observed fraudsters offering fake jobs such as Amazon drivers, sales and marketing leadership roles, and remote work. We found a total of 1,442 scammers in this category, and they mainly targeted Amazon, Sears, LinkedIn, and SalesForce.

Fake Discounts and Giftcards. In this scam type, fraudsters offer brand discounts on popular events or gift cards for VIP membership, store anniversaries etc. We found 1,367 scam profiles involved in fake discounts and gift card scams, primarily targeting Walmart, Amazon, Shopify, and GoDaddy.

Brand Union. In the Brand Union scam, fraudsters pose as the representative of a brand workforce union that supports various causes such as allowance, compensations, retirement perks, etc. They typically use noble causes to raise funds for their fake union. We identified 1,186 accounts linked to fake brand union scams.

Fan Page. In this type of scam, fraudsters claim to support fake events linked to a given brand. In general, their motivation is to either increase the profile followers or request payments for fake event organizations. We found 946 accounts in this scam type.

Sales Training and Leadership. In sales training and leadership scams, fraudsters pretend to be official brand representatives and offer paid training programs for leadership and growth opportunities. Unsuspecting users implicitly assume that receiving such training from popular brand officials will help them in their professional careers. However, as common with other scams, fraudsters receive training fees without providing a service in return. We found 931 accounts with posts indicating affiliations with such scams.

Key Takeaways. By combining account setup and user engagement analysis, we map out the end-to-end scam lifecycle and derive the following key insights: (i) Brand impersonation is a multi-step process in which fraudsters set up fake profiles using tactics such as username squatting and displaying official brand logos, (ii) Fraudsters engage with customers through posts and offer them phony incentives as bait, (iii) Scammers tend to target a wide range of victims, as indicated by the diverse geographical locations and language usage, and (iv) Brand impersonation scams have been ongoing for over a decade and are quickly proliferating from X to other social media platforms.

Table 5: Overview of blocked squatted profiles - The table provides the summary of the effectiveness of blocking username squatting from social media based on squatting techniques.

Squatting	Blocked Accounts	Blocked %
Typosquatting	65	0.76
Combosquatting	2,367	0.69
FuzzySquatting	57	1.26
Total	2,489	0.71

6 Scam Profiles Detection Efficacy

In this experiment, we analyze the efficacy of social media platforms in detecting and blocking scam profiles. We perform two experiments to analyze the control gaps that exist in detecting scam profiles and later apply our insights to propose effective countermeasures.

6.1 Control Gap Detection through Dataset

In the first experiment, we collected all scam profiles in our dataset (Section 4) and revisited their profiles after completing our analysis. We hypothesized that towards the end of our study (spanning seven months), it is possible that social media platforms have detected scam profiles and blocked them for violating the platform's terms and services. Surprisingly, only 2,489 (0.71%) of the scam profiles were blocked when we revisited them. In Table 5, we present the number of blocked accounts along with the type of username squatting they performed. Our results clearly show a control gap in social media platforms, as indicated by the low blocking rate despite the time lapse in our data collection and experiment completion.

We also cross-referenced the blocked accounts with our brand labels to check the famous brands being protected by account blocking. On X, the top 5 brands were Binance, Netflix, AirBnB, PayPal, and Toyota, with the total number of blocked accounts being 80, 73, 69, 65, and 57, respectively. The top 5 brands on Telegram were Netflix, Box, Sony, Download, and Marvel, with the total number of blocked accounts being 71, 36, 35, 33, and 32, respectively. On Instagram, the top 5 brands were Online (28), Business (21), Mail (18), Site (17), and WordPress (16), and for YouTube, the top brands were Ask (9), About (6), AT&T (6), Money (6), and NTV (5). Note

Table 6: Experiment evaluation of proactively finding brand impersonation accounts targeting the brands.

Web Cat.	Brand	Generated	NotFound	Suspended	Active
Arts & Ent.	Netflix	100	63	9	28
Auto & Veh.	Toyota	100	51	7	42
Bus. & Indus.	PayPal	100	62	4	34
Compt. & Electr.	Microsoft	100	52	5	43
Finance	Binance	100	67	10	23
Intr. & Telecom	Google	100	47	2	51
Online Comm.	Facebook	100	43	6	51
Shopping	Amazon	100	44	2	54
Travel	AirBnB	100	67	3	30
Total	-	900	496	48	356

that there is a small overlap between the top brands being targeted (Section 4) and the top brands being protected through blocking. Ideally, brands in both categories should have been the same due to scam account volume and consistently similar account setup techniques. However, we only observed a slight overlap, likely indicating varying rules applied to evaluate scam profiles.

6.2 Control Gap Detection through Shadow Profile Setup

Overview In our second experiment, we took a methodical approach to create *shadow* scam profiles and use them to measure the detection accuracy of social media platforms. We applied our knowledge from username squatting to mimic the account setup process flows and validated the corresponding username's status on the social media platform. Our second experiment served two main purposes, namely (i) Confirmation of control gaps identified in the first experiment, and (ii) Exposure to the methods used by fraudsters to evade detection, which can be applied for countermeasures.

Username Generation For account generation rules, we selected X as our evaluation platform since X hosted the largest number of scam accounts in our dataset. We selected nine random popular brands from each web category as listed in Table 1. For each brand, we selected all its squatted usernames and identified common patterns in those usernames. For instance, if the target brand is *paypal* and its squatted usernames are (paypal_39, pay_pal3, h3lp_paypal), the squatting patterns include (1) usage of underscores followed by suffixed digits, and (2) prefixed context noun before the brand name. We collected squatting patterns in a given brand name (e.g., PayPal) and applied those patterns to generate new usernames for another brand (e.g., Netflix). For each target brand, we generated 100 usernames and a total of 900 usernames across all brands. We ensured that the new usernames were not duplicated in our previous dataset. As a result, we generated fresh usernames that could likely be usernames of scam profiles.

Username Monitoring After selecting 900 usernames, we then queried X to check if (1) the username was present on the platform, and (2) X had taken any actions on those usernames. Please note that we did not register those usernames on X. Our exercise was intended to create usernames of scam profiles and check if they were present on X at the time and if X had taken any actions to block them. Moreover, since the experiment was conducted long after our previous dataset collection, it would mean the accounts would be fresh and, therefore, not captured during our dataset collection period. After querying X, we observed that out of 900 total usernames, 404 (44%) were present out of which only 48 (5.3%) were suspended. The remaining 356 were active and operational. Moreover, 496 accounts were not found on X, and we consider them as potential scam profiles that could be registered in the future. In Table 6, we present the results of our second experiment.

Key Takeaways Our analysis confirms that social media platforms do not efficiently detect scam profiles as indicated by a small percentage (0.71%) of suspended accounts in seven months. Moreover, there are control gaps in the account onboarding process which are exploited by fraudsters to set up scam profiles. An interesting observation in our experiments is the brand-based prioritization of scam profile detection on social media platforms. As shown in Table 6, X scam detection rules have better coverage of the finance category than the shopping category. Although the root cause for this gap in coverage remains opaque to us, the observation alone provides meaningful insights for scam countermeasures.

7 Scam Validation and Countermeasures

After examining the end-to-end scam lifecycle and identifying control gaps on social media networks, we performed scam validation to confirm that brand impersonation attacks indeed lead to monetary losses. For this purpose, we decided to partner with an organization that is a brand impersonation victim in our dataset and has insights into the payment ecosystem. We partnered with PayPal and shared our dataset containing 5,980 email addresses and 11,606 paypal.me profile links.

7.1 Scam Validation Results

As per our agreement with PayPal, they only shared aggregate data and insights with us, without providing account-level details or payment details. Using our data as seed intelligence, PayPal identified more than 22,000 accounts that either matched emails or paypal.me profiles in our dataset or were closely linked to them through other attributes, including phone numbers. More than 43% of the accounts were already restricted at the time of data sharing, indicating that PayPal was already observing fraudulent activities on those accounts. At the time of writing this paper, they were investigating the remaining account population and determining their risk posture.

Given that PayPal confirmed fraudulent activities performed by the accounts we escalated, their feedback also led to some interesting conclusions. Among the 43% of accounts they had restricted, prominent fraud and risk indicators included (i) Failure of mandatory Know Your Customer (KYC), (ii) Use of stolen identities, (iii) Credit card fraud, (iv) Scripted activities, (v) Violation of payment limits. In sharing the data, we assumed that fraudulent accounts would only be associated with payment fraud reported by victims and that this would be a sufficient outcome to show the impact of our work. However, the feedback we have received indicates that fraudsters are not just pickpocketing benign users. In fact, they are collecting sensitive information, including victims' identities and credit card details, to engage in other fraudulent activities, clearly demonstrating the security and privacy risks associated with brand impersonation attacks. In other words: if the fraudsters were simply receiving payments from their victims, we might have assumed a notable but small-scale impact of brand impersonation attacks. However, with the evidence provided by PayPal suggesting that in addition to receiving payments, fraudsters are also harvesting credentials and monetizing them for other nefarious activities, we argue that brand impersonation attacks pose a significant security and privacy threat to the ecosystem. It is therefore pertinent to address the problem through collaborative efforts, and in the following section, we propose a few recommendations as countermeasures.

7.2 Recommendations for Countermeasures

Consolidating all our insights, we now propose countermeasures against brand impersonation attacks. Our recommendations involve methods and techniques that can be adopted by social media platforms and brands to collaboratively mitigate brand impersonation attacks. In the following, we elaborate on those methods.

Brand-based Account Sign-up Rules. We recommend social media platforms perform brand validation at the account registration step. When a new account signs up, the social media platform can enforce official email address verification along with the 2LD domain name mapping. For instance, an account signing up with *Amazon* username must be verified through *@amazon.com* email, which can also be checked in the 2LD domain. Moreover, additional safety checks (e.g., domain age) can be applied when the account applies for official verification. As a result, only official brands can set up accounts on social media and acquire verified profiles. Once official accounts are set up, username squatting models (Section 4.1) can be applied to block any subsequent account that attempts to impersonate a brand. Finally, for account blocking, we suggest unbiased detection models to be enforced across all top brands. As shown in Table 6, scam account detection rules vary across different web categories, which can be invariably learned by fraudsters to select target brands that are not well-protected by the social media platform. A uniform account-blocking approach can prevent such situations and reduce the number of scam accounts on social networks.

Customer Education. We suggest brands communicate with their customers to be aware of standard engagement protocols and inform users not to share personal information on social media. Additionally, they can share key characteristics of scam profiles (e.g., username squatting techniques) with their customers to help them distinguish between scam accounts and legitimate accounts.

Auto-respond Adoption. Recently, popular brands including *Coinbase*, *MetaMask*, and *Google* have started using the auto-respond feature to reply to customers that post any technical issue. If more brands start using the auto-respond feature and social media platforms also prioritize their responses, official brands can engage with customers before scammers. It will give them a head-start advantage in establishing reliable communication channels with their customers before they are intercepted by scammers.

Active Monitoring and Reporting. We recommend that brands actively monitor the use of their brand name, logos, and products, as well as the creation of usernames that may be squatting on their brand identity. This will prevent fraudsters from impersonating individuals or carrying out social engineering attacks against the brand's users. By proactively monitoring these activities, fraudulent profiles on social media can be identified and reported to the relevant platforms so that they can take appropriate action, such as deletion.

Key Takeaways. Our collaboration with PayPal confirms the impact of brand impersonation attacks on victims and payment platforms. It is logical to assume that as more brands appear in the market and build social media profiles, the scale of abuse will likely increase. Taking into account the emerging threat and its ramifications, we propose effective techniques that require collaborative efforts between social media platforms and popular brands. Our propositions involve leveraging the techniques used in our study to strengthen official profile verification methods, indiscriminately block scam profiles, and enhance customer education.

8 Related Work

To the best of our knowledge, our work is the first attempt to perform a large-scale systematic study of social media-based end-to-end analysis on brand impersonation attacks. Below we reference some of the prior studies and provide the novelty of our work toward building scam validation across multiple social media profiles performed by these brand impersonators.

Early studies on squatting. Typosquatting has been a topic of interest for over 15 years [3, 38, 40, 58, 68, 74, 75, 81]. The early study on typosquatting from Wang et. al [81] dates back to 2006 which showed that attackers exploit typing errors to lure victims to a counterfeit domain through which

they harvest user credentials. In 2013, Nikiforakis et. al [63] studied *bitsquatting*, in which attackers abuse random bit-related errors in the memory and redirect traffic to the counterfeit domains. The study analyzed bit-squatted domains among the top 500+ Alexa domains and further provided abuse categorization. The authors continued following trails of domain-based squatters to study several alternative versions of squatting-based attacks through elaborated independent studies. In 2014, their work on *soundsquatting* [62] explored squatting based on words that sound alike. In 2015, a longitudinal study of typosquatting domains studied HTML page content usage for monetization strategies and showed that there is little protection against the registration of such domains that target trademark owners [3]. In 2017, an empirical study of combosquatting domains showed that attackers register domains by combining trademarks with words [40]. The study also highlighted that the domains were used for phishing and trademark abuse.

Email squatting. In the domain of email squatting, Janos et. al [74] studied email typosquatting by registering 76 typosquatting domain names. Throughout a seven-month study, the authors observed receiving millions of emails containing sensitive personal information. They also studied 1,200+ typosquatting domains in the wild by sending honey emails and found that most email responses received were used for spam.

Social media abuse and impersonation study. Towards username manipulation in social media, Jain et. al [35] studied the behavior of 8.7 million X users and monitored their username-changing behavior. They monitored 10% of users who changed their usernames to study the root cause for their behavior. They concluded X users often change handles for space gain, followers gain, and username promotion. Similarly, Lepais et. al studied username squatting profiles on X impersonating celebrity profiles [45]. The work from [27] studied the impersonation accounts on X where malicious attackers copy the profiles of legitimate users to create fake accounts that are later used for the illegal promotion of content on X. All these studies do not provide holistic measurements that target brands across multiple social media platforms.

Impersonation study on network. Impersonation attacks are well-studied in areas of communication and network protocol. For example, Antonio et. al studied a bluetooth impersonation attack exploited via missing permission and authentication [9]. In [69], Rupprecht et. al studied impersonation attacks in 4G networks that are exposed via cross-layer communication. Similarly, Yilmaz et. al studied impersonation attacks in the wireless network via spoofing signaling [84].

Squatting beyond domains. Squatting-based attacks have evolved over time, and they can be observed across multiple platforms. Nowadays, attackers are also targeting (i) mobile apps by registering similar app names and identifiers [32], (ii) software packages by mimicking package name imports [60], (iii) container technology by registering similar container images [46], and (iv) commercial Internet-of-Things (IoT) devices such as speech recognition-based commands [42]. Although all these notable works focus on some form of social engineering attack, our work is unique as it explores a pertinent and understudied attack type involving brand impersonation on social media using various deception techniques.

The above prior studies show a gap in large-scale studies of brand impersonation attacks across multiple social platforms. Our work illustrates the prevalence of ongoing impersonation attacks occurring in the real world and confirms scam validation through fraudulent payment-related association with these fraudsters' accounts via username and engagement creation. With this study, we lay the foundation for future research to further investigate brand impersonation-based attacks on social media platforms.

9 Conclusion and Future Work

In our research, we delve into the underexplored realm of brand impersonation on social media, focusing on well-known brands and abuse in this context. We found that scammers create fake profiles targeting popular brands, using tactics like username squatting and unauthorized use of trademarks to appear legitimate. We performed the first large-scale measurement study to examine the scam lifecycle on four social media platforms, analyzing the activities of 1.3 million users and their public interactions. We uncovered about 350,000 profiles engaged in username squatting, employing three distinct methods. The impersonators launch a variety of attacks against both high-profile and less well-known brands worldwide. Additionally, our scrutiny of major payment services highlights the financial damage within the scam lifecycle. Our findings indicate that social media platforms are currently ineffective in safeguarding brands and users from such threats, with over 98% of these deceptive accounts remaining active and their numbers growing annually. In a practical experiment, we applied our own rules for detecting unexposed squatting accounts and found that half of these are still active, continuing to conduct impersonation attacks. Drawing from our research, we offer recommendations for social media platforms to combat these fraudulent activities.

A Brand Social Media Accounts Collection and Search Keywords Rationale

In this section, we touch upon the technical aspect of the process for collecting social media accounts and discuss the rationale behind using specific keywords to identify accounts targeting brand impersonation on social media platforms.

Social Media Account Collection Process. To gather social media profiles associated with candidate domains, we utilize two methods. First, an in-house automated script scans the domain's webpage to collect profiles from platforms such as X, Instagram, and YouTube. Second, we utilize an external third-party API service [41] to retrieve additional social media profiles. We cross-reference the profiles obtained from both sources and manually review them for any discrepancies. We noted that not all domains host multiple social media profiles on their web pages or utilize multiple social media accounts. Domains lacking a particular social media profile are excluded from the corresponding platform study. For example, if a domain "example.com" maintains X and YouTube accounts but lacks an Instagram presence, it will be included in the X and YouTube analyses but not included in the Instagram lists. Additionally, we incorporate Telegram into our study, despite lacking Telegram presence on candidate domains' home page and external API [41] social media accounts fetch. Due to its widespread usage among generic users, we added Telegram as one of the social media for our study. This inclusion allows us to examine abusive groups that may conduct brand-based attacks through public Telegram channels.

Keywords Selection Rationale. The rationale for selecting 8 popular keywords was based on our incubatory investigation during the design of the experiment and prior research works. We visit each point below.

1. **Incubatory Investigation.** During the initial phase of the experiment, we searched similar accounts associated with over 50 popular brands such as PayPal, Netflix, and Amazon using the UI of X and Instagram. We conduct searches using the second-level domain of each brand as a keyword and observe that fraudsters commonly append keywords such as "recover," "hack," "support," and "help" to brand names as part of an impersonation attack.

2. **Previous Research.** Additionally, our methodology is influenced by two prior studies [2, 72]. Acharya et al. [2] investigated technical support scams prevalent on popular social media platforms such as X, Instagram, and Telegram. The authors found that scammers present themselves as experts, support groups, help desks, traders, and engineers as part of fake technical support scams. Similarly, Srinivasan et al. examined abuse related to technical support scams in search and advertising. They employed a similar technique to identify abusive advertisements as part of defining campaign levels.

Thus, from the above two points, we devised eight popular keywords, namely *rewards*, *recover*, *hack*, *support*, *help*, *assist*, *contact*, and *team* to create a search query for account collection.

Hermes: Unlocking Security Analysis of Cellular Network Protocols by Synthesizing Finite State Machines from Natural Language Specifications

Abstract

In this paper, we present Hermes, an end-to-end framework to automatically generate formal representations from natural language cellular specifications. We first develop a neural constituency parser, NEUTREX, to process transition-relevant texts and extract transition components (i.e., states, conditions, and actions). We also design a domain-specific language to translate these transition components to logical formulas by leveraging dependency parse trees. Finally, we compile these logical formulas to generate transitions and create the formal model as finite state machines. To demonstrate the effectiveness of Hermes, we evaluate it on 4G NAS, 5G NAS, and 5G RRC specifications and obtain an overall accuracy of 81-87%, which is a substantial improvement over the state-of-the-art. Our security analysis of the extracted models uncovers 3 new vulnerabilities and identifies 19 previous attacks in 4G and 5G specifications, and 7 deviations in commercial 4G basebands.

1 Introduction

The cellular standard body, i.e., the 3rd Generation Partnership Project (3GPP), designs, creates and maintains technical specifications for cellular network systems used by network operators and equipment vendors worldwide [1]. However, a wide range of cellular stakeholders and network entities, a vast diversity of use cases such as SMS, data access, and roaming connections, and tighter backward compatibility requirements make it difficult for 3GPP to maintain the specifications in a simple form. Especially, the natural language description of the cellular network design spreading over hundreds of documents makes it extremely laborious and often error-prone to create formal models necessary for security analysis. Moreover, the inherent ambiguities and complexities of natural language often lead to misinterpretations by the developers, resulting in deviations and exploitable flaws in implementations [43, 50, 51, 69]. Such deviations are difficult to identify without access to the baseline/gold standard. However, the cellular standard body does not provide any formal model of the system, thereby leaving the lack of a gold standard.

Although formal analysis of cellular network design has uncovered several new vulnerabilities, all of them rely on hand-crafted models [14, 29, 40, 42, 64, 71]. Unfortunately, manually constructing such formal models is tedious and error-prone due to the sheer size of cellular systems and the large number of documents. Moreover, these models require significant time and effort and are often limited by modeling flaws (incorrectly representing the system) [40], inconsistent levels of abstraction [14, 42], and oversimplified representations of complex protocol details [40, 42], leading to inadequate formal security analysis. Furthermore, although 3GPP introduces new generations (e.g., 3G, 4G, 5G) of cellular technology roughly every decade, within a generation, specifications are frequently updated, e.g., on average, the specification documents are updated 5-6 times each year, and each update includes several hundreds of line changes [44]. Despite not being major technology shifts, these changes in the protocol can often lead to new vulnerabilities. For example, changes in the collision resolution mechanism between two particular procedures introduced in the 4G specification [10] led to a new vulnerability [26]. Likewise, in this work, we find a new vulnerability in 5G (§8.4.1), stemming from a new cause of message rejections introduced in the 5G specification update [4]. Conversely, due to time and effort constraints, frequently updating hand-crafted models is not always feasible. In fact, these prior models have never undergone revisions to account for new changes as they have emerged. Thus, automated extraction of formal models from cellular specifications is pivotal for analyzing the security of cellular protocols.

Recently, researchers used Natural Language Processing (NLP) tools to identify *hazard indicators* in cellular specifications for creating concrete test cases [26] and to discover *security-relevant change requests* [24]. Unfortunately, none of them extract formal models automatically. Furthermore, among the attempts to extract structured representation from natural language in other domains, e.g., protocols [67], geographical questions [34, 47, 90], medicine [19], and database queries [34, 47, 88, 89], RFCNLP [67] extracts Finite State Machines (FSMs) from Request for Comments (RFC) docu-

ments, albeit for small protocols. In contrast, cellular protocols have a substantially large number of transitions, a myriad of use cases, variables, events, message fields, and complex interactions across layers and sub-layers, rendering RFCNLP ineffective. The absence of standardized datasets or benchmarks further compounds the difficulty in automatically extracting formal representations.

In this paper, we address these challenges by developing Hermes (Hermes was the God of translator/interpreter in Greek mythology) that automatically extracts the formal representation of cellular network protocols from the given natural language specification documents. We develop three main components: a neural constituency parser called `NEUTREX`, `IRSynthesizer`, and `FSMSynthesizer`. With these components, Hermes generates FSMs as a set of transitions containing states, conditions (e.g., received messages), and actions (e.g., sending messages) in a logical format. At a high level, Hermes first uses `NEUTREX`, developed with a domain-knowledge-informed grammar and deep-learning-based neural parsing model, to extract the portions of natural language texts related to transitions and detect components (e.g., states, conditions, actions) within them, along with their logical relations. Hermes then leverages `IRSynthesizer`, designed with a Domain Specific Language (DSL) and a neural dependency parser, to identify the key information items, including variables and events, and convert the conditions and actions to logical formulas or *intermediate representations (IR)*, which can be easily transpiled to specific formal language amenable for formal analysis. Finally, the `FSMSynthesizer` of Hermes combines the logical formulas corresponding to the transition components to construct complete transitions and the FSMs.

To demonstrate the efficacy of Hermes across multiple cellular layers, generations, and releases, we evaluate it on 4G NAS [11], 5G NAS [5], 5G RRC [6], and RFC documents [67]. Our results show that Hermes-generated FSMs achieve up to 87.21% accurate transitions compared to human-annotated transitions for 4G and 5G NAS specifications. Regarding identifying transition constituents from cellular specification, `NEUTREX` achieves 68.69% labeled F1-score, showcasing a substantial improvement over the state-of-the-art RFCNLP's 38.52%. We also evaluate Hermes on RFCs, and it achieves 57.06% labeled F1-score compared to 47.76% of RFCNLP.

To demonstrate that Hermes facilitates security analysis of cellular networks, we use it to perform two different security analyses of the cellular protocols. First, we transpile the generated formal models to SMV language [62] by applying prior tools [40,42] and perform model checking. This analysis identifies **19** previous and **3** new vulnerabilities in the 4G and 5G specifications. Second, we compare the Hermes-generated FSM with commercial 4G cellular baseband FSMs to identify flaws in the implementations. This analysis uncovers **7** deviations in 9 basebands with an accuracy of 78%.

Responsible Disclosure. We have shared our findings with the GSMA CVD panel, and they have confirmed and acknowledged our contributions with CVD-2023-0071.

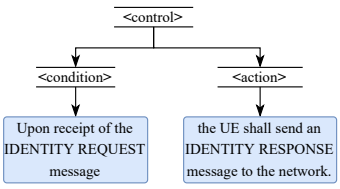

Figure 1: A constituency parse tree.

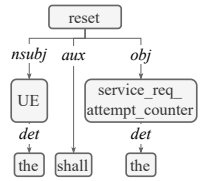

Figure 2: A dependency parse tree.

Contributions. We summarize our contributions as follows:

- We design and implement Hermes, a framework for automatically extracting formal models from natural language cellular specification documents. We show the effectiveness of Hermes across different cellular generations (4G and 5G) and layers (NAS and RRC), significantly outperforming state-of-the-art in both cellular and other domains.
- We demonstrate the use of the formal models extracted by Hermes in the security analysis of the *design* of 4G and 5G cellular network protocols. We identify 19 previous and 3 new issues in those design documents.
- We also show that the extracted formal representation of the 4G NAS specification effectively identifies 7 *implementation-level* flaws in 9 cellular devices by comparing those devices' FSMs with Hermes-generated FSM.
- We provide a curated dataset of natural language transition components in cellular specifications and the source code of Hermes, serving as a benchmark for future research. The dataset, source code, and properties are available at: https://github.com/SyNSec-den/hermes-spec-to-fsm.

2 Background

❑ **Cellular Network Architecture.** The User Equipment (UE), which includes USIM and cryptographic keys, is the device users use to access cellular services. A base station, gNB in 5G or eNodeB in 4G, provides cellular services to users and manages radio resources in a geographical cell area. Multiple base stations communicate with one another through a radio access network (RAN). The core network consists of several components or network functions (NF). The AMF (MME in 4G) is a major NF that is responsible for UEs' mobility management, e.g., registration, in the network through the Non-Access Stratum (NAS) protocol.

❑ **Word Embeddings and Pretrained Language Models.** Word embedding represents a word as a real-valued vector, which encodes its meaning. BERT [31] leverages Transformer [81] based encoders to learn contextualized word embeddings by pretraining over general-domain corpora. However, Liu et al. [60] reveal that the next sentence prediction objective of BERT degrades the embeddings, and the same words are masked in different training epochs of BERT, leading to sub-optimal training. They incorporated these decisions

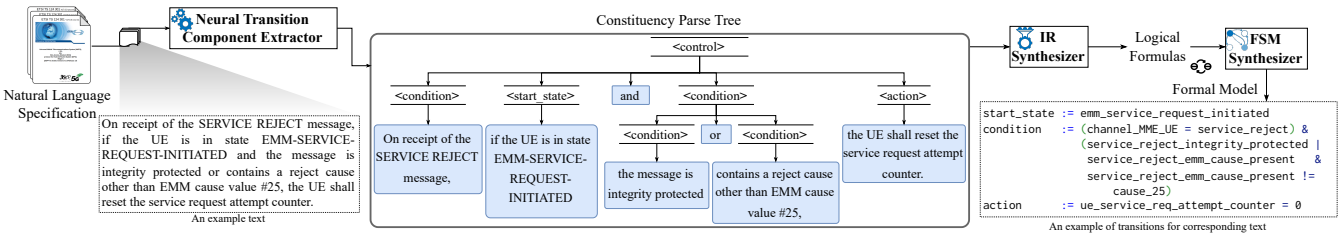

Figure 3: Overview of Hermes.

into RoBERTa to deliver stronger performances.

❏ **Constituency Parsing.** Constituency parsing builds a hierarchical tree, which describes the internal structure of a sentence, including *non-terminal* constituents and *terminal* input words. Figure 1 shows the input sentence parsed into its constituents– condition and action spans. Conventional constituency parsing methods [37, 79] rely on explicit grammar production rules demanding extensive domain knowledge without leveraging any constituent semantics. Neural constituency parsers [52, 53, 93] address this problem by learning those *grammar*s during training through marginal probabilities, which are utilized during inference.

❏ **Dependency Parsing.** While constituency parsing detects the constituent spans from a sentence, dependency parsing [23] provides the explicit relations that we need to synthesize FSMs from cellular specifications. For example, in Figure 2, if a span is detected as an *action* ("reset"), we also need to know the **subject** ("UE") and **object** ("service_req attempt_counter") associated with it. Accordingly, dependency parsing identifies the main **verb** word as the root node, and all other words have exactly one headword as their parent node. This gives a unique path from the root verb node to all other word nodes to facilitate the synthesis of logical expression.

3 Overview of Hermes

In this section, we define the problem, present an overview of Hermes, and discuss the challenges and insights.

3.1 Problem Statement

Given a cellular system specification in natural language, Hermes aims to generate a formal model, $\mathcal{M} = \langle \mathbb{P}, \mathbb{F}, \mathbb{H}, \mathbb{V} \rangle$:

- $\mathbb{P}$ is the set of protocol participants, $\{\mathcal{P}_1, \mathcal{P}_2, ...\}$, in the given specification.
- $\mathbb{F}$ is the set of synchronous communicating FSMs, $\{\mathcal{F}_1, \mathcal{F}_2, ...\}$, for each $\mathcal{P} \in \mathbb{P}$.
- $\mathbb{H}$ is the set of one-way communication channels between the entities in $\mathbb{P}$, i.e., $\{\mathcal{H}_{ij} | \forall \mathcal{P}_i, \mathcal{P}_j \in \mathbb{P} \wedge \mathcal{P}_i \neq \mathcal{P}_j\}$.
- $\mathbb{V}$ is the set of variables, $\{\mathcal{V}_1, \mathcal{V}_2, ...\}$, in $\mathcal{M}$.

We define each FSM in $\mathbb{F}$ as $\mathcal{F} = \langle \mathbb{S}, \mathcal{S}_0, \mathbb{T} \rangle$, where $\mathbb{S}$ is the set of states $\{\mathcal{S}_1, \mathcal{S}_2, ...\}$, $\mathcal{S}_0$ is the initial state, and $\mathbb{T}$ is the set of transitions. We further define each transition in $\mathbb{T}$ as $\mathcal{T} = \langle \mathcal{S}_i, \mathcal{S}_f, \mathcal{C}, \mathbb{A} \rangle$, where $\mathcal{S}_i$ is the starting state, and $\mathcal{S}_f$ is the ending state of the transition $\mathcal{T}$, $\mathcal{C}$ is the logical condition for the transition $\mathcal{T}$ to take place, and $\mathbb{A}$ is the set of actions, $\{\mathcal{A}_1, \mathcal{A}_2, ...\}$, which also occur when the transition $\mathcal{T}$ takes place. Here, an action $\mathcal{A} \in \mathbb{A}$ can be a message transmission through a channel $\mathcal{H} \in \mathbb{H}$ or an update to a variable $\mathcal{V} \in \mathbb{V}$.

3.2 Solution Sketch of Hermes

We address the problem in §3.1 with three primary components of Hermes: Neural Transition Component Extractor (`NEUTREX`), Intermediate Representation Synthesizer (`IRSynthesizer`), and Finite State Machine Synthesizer (`FSMSynthesizer`). The workflow is shown in Figure 3.

`NEUTREX` takes natural language texts and identifies the constituent spans (transition components in natural language, $\mathsf{TC}^{\mathsf{NL}}$s) corresponding to the states, conditions, actions, and the transition itself (`ctl_block`). For that, we extend a state-of-the-art neural constituency parser [93] and generate constituency parse trees for input natural language texts. Figure 3 demonstrates `NEUTREX` extracted $\mathsf{TC}^{\mathsf{NL}}$s (start_state, action, condition, and control) and logical relations (e.g., and, or) in the constituency parse tree corresponding to the input text.

In the next stage, `IRSynthesizer` takes $\mathsf{TC}^{\mathsf{NL}}$s (state, condition, or action) within the `ctl_block`, identified as constituent spans by `NEUTREX`, and constructs corresponding transition components in intermediate representations (IR), $\mathsf{TC}^{\mathsf{IR}}$, in a logical format. Finally, the generated IRs are compiled with `FSMSynthesizer` to create the transitions, ultimately constituting the formal representation of the cellular specification.

3.3 Challenges and Insights of Extracting FSM

C1: Complex associations of FSM transition components in natural language. Identifying transition components ($\mathsf{TC}^{\mathsf{NL}}$s), i.e., start state, end state, conditions, and actions of an FSM's transitions from natural language specifications is challenging. This is because the associations among the components are highly complex and depend on both syntactic features and semantic relations. For example, consider the sentence "*The UE initiates attach procedure* by sending an ATTACH REQUEST to the network" in TS 24.301 [11]. It can have two interpretations: (1) "the UE shall initiate the attach

```
par       ::= ctl_block par | text par | text
ctl_block ::= "<control>" ctl_unit "</control>"
ctl_unit  ::= ctl_block ctl_unit | start_state_tag ctl_unit |
              end_state_tag ctl_unit | act_tag ctl_unit |
              cond_tag ctl_unit | text ctl_unit | text
start_state_tag ::= "<start_state>" text "</start_state>"
end_state_tag   ::= "<end_state>" text "</end_state>"
cond_tag        ::= "<condition>" cond_unit "</condition>"
cond_unit       ::= cond_tag cond_unit | text cond_unit | text
act_tag         ::= "<action>" act_unit "</action>"
act_unit        ::= cond_tag act_unit | text act_unit | text
text            ::= token text | ε
```

Figure 4: Defined grammar for annotated data.

procedure", and "the UE shall send an ATTACH REQUEST to the network", resulting in two actions by a UE without any condition, or (2) The first part is treated as "when the UE initiates attach procedure" and thus can be considered as a condition for the second part–"sending the ATTACH REQUEST message". Therefore, domain knowledge is required to disambiguate such cases of complex associations.

❍ **Insight (I1)**: We adopt a domain-knowledge-informed grammar for transition components and a neural model to extract them automatically. First, we define a nested grammar for $\mathsf{TC}^{\mathsf{NL}}$s considering complex and nested associations prevalent in cellular specifications. We curate an expert-annotated dataset by labeling $\mathsf{TC}^{\mathsf{NL}}$s in cellular specifications accordingly. Next, we design a neural constituency parsing-based transition component extractor (NEUTREX) that extracts complex nested structures by comprehending semantic information. The resulting parse tree (as in the parse tree in Figure 3) precisely maintains the hierarchy of different constituent spans ($\mathsf{TC}^{\mathsf{NL}}$s), allowing us to automatically handle the nested grammar for cellular documents. In contrast, existing neural models for network protocols [67] fail to automatically detect and handle such complex associations and nested constituents.

C2: Limitations of existing NLP models on cellular specification. Off-the-shelf constituency parsers face several challenges when extracting cellular $\mathsf{TC}^{\mathsf{NL}}$. As cellular specifications are written in a highly technical language with 3GPP-specific abbreviations and terms, existing word embeddings trained on general-purpose corpora are inadequate owing to the domain shift. Also, existing constituency parsers do not perform reasonably well in the cellular dataset because of complex nested associations. Finally, transformer-based embedding models often face token limits surpassed by cellular document paragraphs. This requires appropriate measures to avoid truncated parse trees and inaccurate FSMs.

❍ **Insight (I2)**: To close the domain gap in the embedding model, we curate and clean a large natural language dataset consisting of 22,000 cellular documents, including technical specifications, change requests, and technical reports, for unsupervised pretraining of a RoBERTa [60] embedding model. Second, while training the constituency parser [93], we observe that it struggles to extract both span boundaries and labels simultaneously in the first few steps. Therefore, at the beginning of the training, we prioritize labeling the tokens and gradually give the same priority to identifying spans as the training progresses. Lastly, long datapoints are handled by splitting and generating embeddings for all input tokens.

C3: Absence of annotated cellular datasets for translation from NL phrases to logical form. Transition components ($\mathsf{TC}^{\mathsf{NL}}$s) are not directly usable for any formal security analysis and need to be converted to logical expressions and statements, such as $\mathsf{UE\_service\_req\_attempt\_counter} := 0$. Existing data-driven approaches for such translation [33,45,54,78] are largely domain-specific and fail to generalize across domains or capture complex logical relations [88]. Further, no dataset exists for translating natural language to logical formulas for cellular systems, and annotating such a large dataset is tedious and error-prone.

❍ **Insight (I3)**: To circumvent the lack of annotated datasets, we simplify the NL-to-logic task and take an intermediary step similar to schema-based translations [72,73]. Accordingly, we define a Domain Specific Language (DSL) (partially shown in Figure 7) that enables parsing and translating $\mathsf{TC}^{\mathsf{NL}}$s to precise and consistent logical representations. Moreover, the DSL postulates a structure for the translation and highlights the required information for each logical formula through commands and corresponding arguments. If any information is missing in $\mathsf{TC}^{\mathsf{NL}}$ due to natural language ambiguities or constituency parsing inaccuracies, the DSL can guide the search for them through metadata, e.g., type information.

C4: Text to DSL rule mapping requires explicit arguments. The DSL provides a pathway to logical formulas from natural language strings. However, it has a strict syntax and fixed arguments, whereas natural language is inherently diverse and imprecise. For example, different sentence structures may express the same meaning, such as "the MME shall send an ATTACH ACCEPT message to the UE", "an ATTACH ACCEPT shall be sent to the UE by the MME", and so on. Mapping such diverse texts to the same DSL rule is non-trivial.

❍ **Insight (I4)**: The DSL commands are inherently tree-structured and can be represented as Abstract Syntax Trees (AST). Conversely, natural languages follow sequential patterns. To map them to DSL, a tree format is a reasonable intermediate step. Among the different natural language tree representations, dependency trees extract useful relations among the tokens and often demonstrate similar structures as the DSL ASTs. Figures 8 (a) and 8 (c) show such similarities. Here, the primary verb–"receive", is the root in both trees, and the messages are their descendants. Even in cases where a similar meaning is represented by different sentence structures (e.g., examples in C4), these relations are preserved reasonably well. These similarities indicate that dependency parsing on the transition components ($\mathsf{TC}^{\mathsf{NL}}$) can help in mapping texts to DSL rules and, thereafter, generating logical formulas.

4 Extracting Transition Components

The neural transition component extractor (NEUTREX) takes each paragraph of a cellular specification as input and extracts the constituency parse trees based on the grammar in Figure 4. It identifies ctl_block with transition components (TC^{NL}s) and simultaneously refrains from including natural language texts that do not contain any transition information.

4.1 Grammar and Annotated Dataset

As discussed in §3.3, the TC^{NL}s are interrelated through complex associations and require domain expertise for correct interpretations. To address this challenge, we define a grammar for TC^{NL}s as shown in Figure 4 and annotate three specification documents, namely 4G-NAS-Release16 [11], 5G-NAS-Release17 [5], and 5G-RRC-Release17 [6]. The annotation is done by manually inspecting each paragraph and sentence, and identifying states, conditions, and actions in them. Further, we consider their semantic relations and dependencies, and follow the defined grammatical structure during annotation.

A string in the language defined by this grammar can consist of English tokens (token) or can have one or more control blocks (ctl_block). Here, the control block is the primary construct for transitions and contains TC^{NL}s (i.e., start_state_tag, end_state_tag, cond_tag, and act_tag). Figure 3 illustrates an example control block with multiple condition spans (cond_tag), start state span (start_state_tag), and action spans (act_tag). Moreover, our grammar supports nested spans and facilitates extracting complex logical relationships among them, as demonstrated in the example in Figure 3.

4.2 Constituency Parsing - NEUTREX

We build NEUTREX, a neural constituency parser that extracts ctl_block and corresponding TC^{NL}s from natural language texts. As cellular specifications contain rich and complex associations of transition components, which pose a significant challenge for existing NLP models trained on general domains, we propose the following innovations to adapt and enhance state-of-the-art constituency parser [93] for our task:

(i) Instead of the original RoBERTa model [60] that cannot recognize most cellular-specific technical words and phrases, we pretrain a new embedding model, CellulaRoBERTa, from scratch with cellular-specific documents, as described in §4.3. This ensures that the constituency parser can correctly comprehend the tokens used in cellular specification documents.

(ii) We reformed the loss function so that it properly integrates span semantics and span structure information during objective optimization. We demonstrate that this is critical in improving performance in detecting the constituents.

Workflow. NEUTREX works in a two-stage scheme, as shown in Figure 5. In the **Bracketing** stage, the parser takes an input sentence and outputs an unlabeled tree housing all the

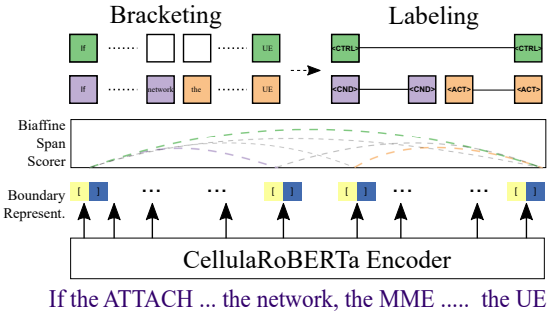

Figure 5: Detailed architecture of NEUTREX.

constituents. In the **Labeling** stage, these constituents are classified into different labels to get the output tree. In this way, we not only get the tags of different constituents for the input, but also preserve the structural association.

Bracketing. Given a sentence x, the conditional probability of an unlabeled tree y is calculated as: $P(y|x) = \frac{\exp^{S(x,y)}}{\sum_{y'} \exp^{S(x,y')}}$, where $S(x,y) = \sum_{(i,j)\in y} s(i,j)$ is the sum of the scores of all constituent spans (i,j) under the tree y, and y' enumerates all possible trees using the CKY algorithm [38]. For each word w_i, we use multi-layer perceptrons over domain-specific CellulaRoBERTa embeddings to produce left boundary representations u_l^i and right boundary representations u_r^i for this word. Then, for a given span (i,j), we calculate the biaffine score using the left boundary word representation w_i and right boundary word representation w_j to determine the score for the span: $s(i,j) = u_l^{i\top} W u_r^j + b$, where W and b are trainable parameters. After calculating the score of all possible trees, the best tree $\hat{y}$ is chosen as: $\hat{y} = \arg\max_y P(y|x)$.

Labeling. Given an input sentence x and a tree y, the label is predicted for each of the constituents (i,j) in the tree independently. We denote a label as $l \in \mathcal{L}$, where $\mathcal{L}$ is the label set in our grammar. For a constituent (i,j) and a label l, we calculate a biaffine score $s(i,j,l)$ similarly as done in the bracketing stage, and we have $|\mathcal{L}|$ biaffine heads for all the labels. We pick the best label as: $\hat{l} = \arg\max_{l\in\mathcal{L}} s(i,j,l)$.

Training. Given a sentence x with the corresponding ground truth constituency tree y and label l, the vanilla loss [93] is calculated as $L = L_{\text{bracket}} + L_{\text{label}}$, where L_{bracket} denotes the global conditional random field (CRF) loss in sentence level, and L_{label} is the cross entropy loss for labeling using teacher forcing by training only with ground truth trees. However, we found that L_{bracket}, which encodes the bracketing loss to encode the tree structure, does not work well in the early stages of training, and the model quickly converges to local minima where it only generates trivial span prediction with suboptimal performance (labeled F1 score of only 0.2849).

Consequently, we postulate that the constituent label information from L_{label} could enhance the integration of span semantics that is lacking in the early training phase, which can later facilitate the model to learn structured informa-

tion by training with L_{bracket}. Thus, we emphasize labeling training in the early stage by modifying the loss as $L = \lambda_1 L_{\text{bracket}} + \lambda_2 L_{\text{label}}$. In the first few stages, when bracket loss is unstable, we give high weights to L_{label} (i.e., $\lambda_2 > \lambda_1$). Later, we normally train with $\lambda_2 = \lambda_1$. This ensures smooth training, resulting in accurate constituency parsing.

4.3 Pretraining `CellulaRoBERTa`

The original RoBERTa [60] model used in prior constituency parser [93] fails to perform satisfactorily on cellular documents because of many unknown tokens and new domain knowledge, such as the frequent use of 3GPP-specific words, abbreviations, and technical terms. Therefore, we pretrain a RoBERTa model from scratch on cellular documents so that it can accurately generate embeddings for cellular specification tokens. Accordingly, we curate a large dataset of cellular documents consisting of more than 22,000 documents, including cellular specifications, change requests, technical reports, etc. We preprocess these documents by removing page headers and footers, non-ASCII characters, tables, and figures. We then pretrain a RoBERTa model on our cleaned corpus. In this manner, we create `CellulaRoBERTa`, a RoBERTa-based specialized language model providing domain-specific contextualized word representations of cellular specifications.

5 Synthesizing IR from $\mathsf{TC}^{\mathsf{NL}}$

For each `ctl_block`, `IRSynthesizer` takes in the transition components ($\mathsf{TC}^{\mathsf{NL}}$s) extracted by `NEUTREX` and generates corresponding intermediate representations (IR) as logical formulas. `FSMSynthesizer` then uses the IRs to build FSMs.

The architecture of `IRSynthesizer` is illustrated in Figure 6. At first, it extracts keywords (e.g., messages, variables, events, etc.) from natural language specifications and links those keywords to $\mathsf{TC}^{\mathsf{NL}}$ strings with `Keyword Extractor`. After that, the `DTGenerator` converts these strings to dependency trees, which is used by `IRTranslator` for mapping the $\mathsf{TC}^{\mathsf{NL}}$s to DSL commands and extracting the arguments in order to finally generate logical IRs ($\mathsf{TC}^{\mathsf{IR}}$).

5.1 Domain-Specific Language

For IR, we consider the conditions as logical expressions (e.g., $\mathsf{chan\_ue\_mme} = \text{AUTHENTICATION FAILURE}$) and actions as logical or arithmetic statements (e.g., $\mathsf{counter} := \mathsf{counter} + 1$). However, these expressions and statements are often not syntactically/structurally similar to their corresponding natural language texts (e.g., "if the UE returns AUTHENTICATION FAILURE", "increment counter"). As a result, direct translation from natural language to logical formulas is challenging. Further, the lack of generalizability of existing data-driven approaches (discussed in §3.3) makes it even more challenging to generate logical formulas directly from natural language in the cellular domain.

To address these disparities, we define a Domain Specific Language (DSL) to reliably translate $\mathsf{TC}^{\mathsf{NL}}$s to logical formulas. The DSL is partially shown in Figure 7. Hermes relies on DSL because its commands can encode logical and linear integer arithmetic expressions and logical operations, and allow the use of variables, constants, and quantifiers. For example, the NL string–"the *UE* shall *reset* the *service_req_attempt_counter*" can be mapped to the DSL command $\mathsf{reset}(\mathsf{UE},\ \mathsf{service\_req\_attempt\_counter})$ and corresponding arguments, which can then be easily translated to $\mathsf{UE\_service\_req\_attempt\_counter} := 0$. While defining the DSL, we observe that the operations or conditional checks usually occur as action verbs in $\mathsf{TC}^{\mathsf{NL}}$s. Thus, we extract action verbs as DSL command names from the specification using a neural parts-of-speech tagger [74], and examine the $\mathsf{TC}^{\mathsf{NL}}$s containing these verbs to identify required arguments. Finally, we manually define the output logical forms for each DSL rule and implement an interpreter to generate them.

5.2 Keyword Linking

Identifying arguments of DSL commands is an integral step in applying the DSL rules. These are various identifiers, such as variables, states, messages, etc., consisting of multiple natural language tokens, whereas an argument is a unit. Although 3GPP defines a few abbreviations, messages, etc., the list is not complete and often misses important identifiers (e.g., *"service request attempt counter"*). As manual extraction of these identifiers is tedious and error-prone, we take an automated approach to identify and link them in $\mathsf{TC}^{\mathsf{NL}}$ strings with a single token keyword, which can be used as arguments to DSL commands. We observe that the identifiers are usually noun phrases, so we use a neural phrase-structure constituency parser [59, 74] to identify all noun phrases. After further filtering, processing, and applying cellular specification-specific heuristics, we extract the desired identifiers and assign types to them by combining automated and manual efforts.

While linking single token keywords to identifiers in $\mathsf{TC}^{\mathsf{NL}}$s, we observe slight variations in identifiers with the same meaning (e.g., "tracking area updating accept" and "tracking area update accept"), smaller identifiers within larger ones (e.g., IMEI, IMEISV, and IMEISV request), typographic errors, and inconsistent uses of punctuation. To address these challenges, we utilize Levenshtein distance [57] to correctly identify the keyword. We also embed type information to the keywords for the next phases of `IRSynthesizer`.

5.3 Constructing Dependency Trees

As discussed in §3.3, DSL rules require specific arguments, and representing natural language transition components ($\mathsf{TC}^{\mathsf{NL}}$s) as a dependency tree helps identify these rules and

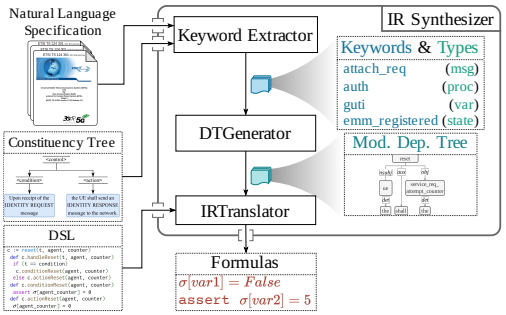

Figure 6: Architecture of `IRSynthesizer`.

```
m := receive(t, src, msg, dst)
def m.handleReceive(t, agent, msg, dst)
 if (t == condition)
  m.conditionForReceiveMsg(src, msg, dst)
 else m.actionForReceiveMsg(src, msg, dst)

def m.conditionForReceiveMsg(src, msg, dst)
 if (msg == constant)
  then assert σ[chan_src_dst] = msg
 elif (msg == logical_operator(msg1, msg2))
  logical_operator(
   m.conditionForReceiveMsg(src, msg1, dst),
   m.conditionForReceiveMsg(src, msg2, dst))

def m.actionForReceiveMsg(src, msg, dst)
  σ[chan_src_dst] = msg
```

```
c := reset(t, agent, counter)
def c.handleReset(t, agent, counter)
 if (t == condition)
  c.conditionForReset(agent, counter)
 else c.actionForReset(agent, counter)

def c.conditionForReset(agent, counter)
 assert σ[agent_counter] = 0

def c.actionForReset(agent, counter)
 σ[agent_counter] = 0
```

Figure 7: Definitions of DSL commands–receive and reset. σ denotes the variable store, and t denotes if the current use case is a condition or an action.

arguments. For that purpose, `DTGenerator` takes each $\mathsf{TC}^{\mathsf{NL}}$ with clearly mapped keywords and type information as inputs. As output, it generates representative dependency trees for DSL mapping.

Usage of dependency parse trees. The DSL commands and arguments are inherently tree-structured [16] and can be represented with abstract syntax trees (AST). Therefore, generating ASTs from natural language strings is naturally the first step toward mapping them to DSL. Based on this insight, `IRSynthesizer` first aims to map the sequential strings to DSL ASTs. We observe that *dependency parse trees* can discover internal grammatical relations (e.g., subject-verb, verb-object, etc.) between tokens of a natural language string and represent it as a tree that has main verbs, e.g., "send", "reset", etc., at the central node, and the arguments at its children. We leverage this hierarchical structure to map them to ASTs as it is similar to the DSL command and argument relations in the ASTs.

To demonstrate this insight, we consider the string "If the UE receives auth_reject or tau_reject", whose dependency tree is shown in Figure 8 (a). Conversely, the desired DSL command is receive(UE, or(auth_reject, tau_reject)), whose AST is shown in Figure 8 (c). These two trees have several common features, such as, *"receive"* is the root, *"UE"* is its child, and *"auth_reject"* and *"tau_reject"* are *receive*'s descendants. Based on this observation, we utilize the dependency tree to reach DSL rules from natural language strings.

Off-the-shelf dependency parsers are not enough for cellular specifications. Although dependency trees [23,74] largely correspond to our translation scheme, we require some modifications before adopting them for obtaining DSL rules. This is because of semantic differences in how conjunctions, prepositions, or adverbs are used in typical English sentences in contrast to formal languages. For example, "and", "or", "not", etc. are generally leaves of dependency trees in natural languages, while these words denote logical operations similar to verbs in formal languages. To illustrate, in Figure 8 (a),

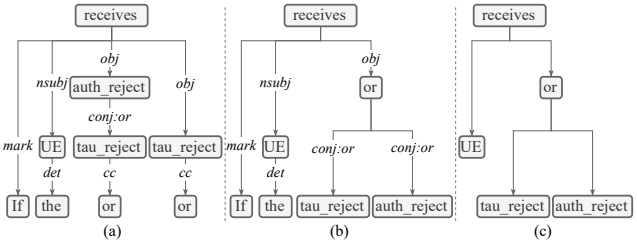

Figure 8: (a) Original dependency tree, (b) Modified dependency tree, (c) Abstract syntax tree.

the extracted parent-child relation between "auth_reject" and "tau_reject" is not applicable in a logical translation setting. Rather, "auth_reject" and "tau_reject" should be siblings under the "or" operation, as shown in the AST in Figure 8 (c).
Solution. Based on these observations, we perform a post-order traversal to find the logical operators and move the logically connected tokens under their subtree. We show the modified dependency tree for the discussed example in Figure 8 (b), where "or" is changed to the suitable position. Finally, the `DTGenerator` produces dependency trees for each $\mathsf{TC}^{\mathsf{NL}}$ and passes them to the `IRTranslator` for DSL mapping.

5.4 Synthesizing Intermediate Representation

The `IRTranslator` takes dependency trees corresponding to each transition component ($\mathsf{TC}^{\mathsf{NL}}$), maps these trees to DSL ASTs, and finally produces logical formulas or IR ($\mathsf{TC}^{\mathsf{IR}}$) for $\mathsf{TC}^{\mathsf{NL}}$s by following the DSL semantics.
Mapping dependency parse tree to AST. A dependency tree, although similar to the target AST, does not directly represent the target DSL command. For that, `IRTranslator` first identifies the corresponding DSL command and its arguments. Consequently, `IRTranslator` recursively traverses the dependency tree using a top-down approach, i.e., it matches the DSL command first and then the arguments. It also considers syntactic information from dependency

trees and type information from Keyword Extractor to map the arguments based on their type and produce the correct TC^{IR}. For the example in Figure 8, IRTranslator first matches the rule receive(t, src, msg, dst) and recursively finds arguments. Using the subject-object relation and *agent* type information, IRTranslator decides the dst. The final output is "assert σ[chan_ue_mme] = auth_reject | assert σ[chan_ue_mme] = tau_reject", where σ is the variable store.

Diverging dependency trees. Natural language may have many forms of text expressing the same meaning, e.g., "The UE, after receiving auth_reject or tau_reject", "If auth_reject or tau_reject is received by the UE", etc. The corresponding dependency trees are structurally different as well. The first one has "UE" as the left child, whereas the other one has it as the right child of "receive". However, a reliable interpreter must generate the same TC^{IR} for both. We ensure this by mapping dependency trees to DSL rules in a position-independent manner by using type information and syntactic information, e.g., part-of-speech and dependency relation. In this example, "UE" has type *agent*, and "auth_reject" and "tau_reject" have type *message*, which help map them as DSL arguments.

Cellular specification directives. Cellular specifications often use the directives– "may", "should", and "can", which signify that the operation is recommended or implementation-dependent [2]. Prior works [69] identify these recommendations as ambiguities and potential security flaws. IRTranslator addresses these directives by adding uniform random variables to the corresponding conditions [40, 42]. These variables enable an automated reasoner to non-deterministically explore and test all possible options, resulting in a comprehensive security analysis.

Addressing missing information. IRTranslator works with each TC^{NL}, but it may not contain all the information necessary to generate the corresponding TC^{IR}. For instance, in Figure 3, the condition–"the message is integrity protected" does not mention the message name, which needs to be inferred from the overall context. Conversely, in many cases, the ctl_block, or even the whole paragraph, may not be sufficient for accurately inferring the information (e.g., actions for cause #7 in Section 5.5.1.2.5 TS 24.301 [11]). Consequently, it needs to be inferred from previous paragraphs. For these reasons, we implement a context resolver in IRTranslator to find any missing information and produce the correct IR. For that, IRTranslator first checks the context of the concerned ctl_block, then the whole paragraph, and follows a heuristic backtracking mechanism to search previous ones.

Modeled actions and granularity of FSM. Modeled actions and the granularity of the extracted FSMs largely depend on the defined DSL rules and arguments. If necessary, Hermes can adopt more actions and more detailed modeling easily. In this work, we consider security-critical actions, such as sending/receiving messages, activating/deactivating services, incrementing counters and sequence numbers, starting timers, etc., totaling 94 DSL commands provided in [8]. In contrast, limitations in our logical abstraction do not allow us to model some actions, e.g., list modifications (adding or removing).

Further, Hermes models the specifications with more details than existing works [40, 42] by considering more message fields and the corresponding protocol behavior. Hermes also models 13 services (e.g., emergency bearer, EPS, etc.), 11 modes (e.g., EMM-CONNECTED, etc.), etc., along with states, procedures, counters, sequence numbers, timers, etc. However, compared to prior works [14, 29, 64, 71], Hermes does not model interactions among multiple base stations or multiple network functions in the core network. Instead, Hermes abstracts these interactions because the analyzed specifications mainly involve interactions between UE and AMF (or MME) and between UE and gNB. Certain procedures, such as handover, span multiple documents [71]. Although Hermes has the ability to extract an FSM from multiple documents, the current instantiation of Hermes extracts FSMs from individual documents. As a result, 5G NAS and 5G RRC FSMs provide a partial representation of the handover procedure.

6 Synthesizing FSM

The FSMSynthesizer combines the intermediate representations corresponding to the transition components (TC^{NL}) generated by IRSynthesizer to produce complete transitions. It also compiles all the transitions and performs logical checks to ensure the consistency of generated FSMs.

Constructing a transition by combining its components. As mentioned in §4.1, ctl_block is the primary construct for transitions, so FSMSynthesizer combines the IRs of each TC^{NL} for a ctl_block. While doing so, it deals with multiple logically connected condition and action spans. For instance, the example in Figure 3 contains two condition spans connected with "or", and the whole condition is connected with another condition using the "and". FSMSynthesizer first finds these logical relations from the constituency parse tree, combines them into a single condition expression, and compiles the actions for that transition. Moreover, FSMSynthesizer identifies the start state and end state from corresponding IR from IRSynthesizer by considering them as conditions and actions, respectively. This is useful for logical connections (e.g., or, not, etc.) between the states. For the running example in Figure 3, after combining the outputs from the components, the transition with a condition, a start state, and an action is the output. Note that if the end state is not mentioned, the FSM remains in the same state.

Compiling all transitions. To generate a complete formal model, FSMSynthesizer follows the above procedure and constructs all possible transitions identified by NEUTREX in a given specification document. Further, as defined in §3.1, these documents describe protocol interactions among multiple participants (e.g., UE and AMF). Ac-

Component	Libraries Used	Lines of Code

UEGEN		1000+

Table 1: Implementation efforts for Hermes components.

cordingly, FSMSynthesizer partitions the list of transitions and generates separate FSMs for each participant. Finally, FSMSynthesizer outputs each FSM as a graph, where the states are represented as unique nodes, and the transitions are represented as directed edges from the start state node to the end state node. We also label these edges with IR representations (TC^{IR}) of corresponding conditions and actions.

Addressing split transitions. Hermes takes input in natural language at the paragraph level since each paragraph in the cellular specifications usually discusses a particular scenario (start state, conditions, and corresponding actions). However, actions in these documents are oftentimes mentioned across multiple paragraphs. For instance, in Section 5.5.1.2.4 of 4G NAS specifications [11], when ATTACH REQUEST is accepted, the network behavior is discussed in multiple paragraphs, leading to a divided transition. As a result, formal analysis of the extracted FSM may not execute all of the actions, potentially failing to explore all possible paths. We observe two cases of such complicated transition pairs where the start state is the same. First, when the conditions in any two transitions T_1 and T_2 are logically equivalent ($C_1 \iff C_2$), we merge the transitions into one by combining the actions. Second, the conditions are not equivalent, but one implies the other, i.e., $\neg(C_1 \iff C_2) \wedge (C_1 \implies C_2)$ (e.g., $C_1 = x \wedge y$ and $C_2 = x$). Here, whenever C_1 is TRUE, both transitions T_1 and T_2 are valid. Thus, we extend the list of actions in T_1 with the actions from T_2 and change the condition in T_2 to $(C_2 \wedge \neg C_1)$. This ensures that the formal analysis explores all possible paths in the FSM.

Recovering missing transitions. NEUTREX sometimes fails to recognize a few action spans in natural language texts, leading to missing transitions. To recover such actions, we introduce a rule-based mechanism into FSMSynthesizer. Specifically, within a ctl_block, if we find a string with no act_tag, we scan it for action verbs and corresponding arguments covered in the action DSL commands of IRSynthesizer. If such a DSL command can be mapped, we consider the string as an action TC^{NL}, generate the corresponding TC^{IR} with IRSynthesizer, and add it to the output FSM.

7 Implementation

We annotate cellular specification datasets with 4G-NAS Release16 [11], 5G-NAS Release17 [5], and 5G-RRC Release17 [6] documents according to the grammar shown in Figure 4. These three annotated documents have ∼16,000 datapoints, and it required a total of ∼2800 man-hours to complete the annotations, which are executed by four cellular systems researchers and verified by two domain experts.

For NEUTREX, we use neural CRF-based constituency parsing [93]. To train NEUTREX with the annotated documents, we use a learning rate of $lr = 5e^{-5}$ with a warmup of 0.1. During the initial stages of training, when the bracketing loss is unstable, we use $\lambda_1 = 0.1$ and $\lambda_2 = 0.9$. During the rest of the training, we use $\lambda_1 = \lambda_2 = 0.5$, giving equal importance to both loss components. All models are trained for 200 epochs, and the best model is chosen based on a held-out dev set. The summary of the implementation efforts is shown in Table 1.

8 Evaluation

To evaluate the performance of Hermes, we aim to answer the following research questions:

- **RQ1.** What is the efficacy of NEUTREX to automatically annotate a cellular specification document, and how it compares with existing baselines (§8.1)?
- **RQ2.** What is the efficacy of IRSynthesizer and FSMSynthesizer to translate TC^{NL} to IR (§8.2)?
- **RQ3.** What is the accuracy of the Hermes extracted FSM, and how it compares with existing formal models (§8.3)?
- **RQ4.** How effective is the extracted FSM in identifying attacks and finding noncompliance (§8.4, §8.5, and §8.6)?
- **RQ5.** How efficient is Hermes in extracting FSMs and performing security analysis with these FSMs (§8.7)?

8.1 Effectiveness of NEUTREX

To answer RQ1, we compare NEUTREX with the BIO entity tagger in RFCNLP [67] in terms of identifying constituency spans. For this comparison, we report traditional precision, recall, and F1-score metrics [75]. We consider both unlabeled and labeled metrics– in **unlabeled** comparison, we use these metrics for the detected spans without any consideration of the labels assigned to them. In **labeled** comparison, we also take into consideration the labels assigned.

Results on cellular specifications. We compare RFCNLP [67] and NEUTREX using 3 different training and testing combinations of annotated documents reflecting the generalization capabilities of NEUTREX across layers, releases, and generations. We first train NEUTREX on annotated 4G-NAS-Release16 specifications [11] and evaluate on the 5G-NAS-Release17 [5]. Again, we train a separate NEUTREX model from scratch on 5G-NAS-Release17 specifications and evaluate on both 4G-NAS-Release16 and 5G-RRC-Release17 [6]. We consider each paragraph of the documents as separate datapoints during the training and the evaluation.

We show these results in Table 2, and NEUTREX significantly outperforms the BIO entity tagger in RFCNLP. We

Hermes FSM (M_{Hermes})	81.39	86.40	81.14	87.21

Table 4: Transition accuracy against M_{Gold}: M_{Syn} for IR & FSM synthesizers, M_{Hermes} for Hermes.

find that **BIO** entity tagging in RFCNLP has no explicit span handling mechanism, and thus, it suffers in the challenging cellular dataset containing complex structure and several levels of nested constituents. Moreover, RFCNLP breaks sentences into chunks using an off-the-shelf chunker, often providing erroneous results in highly technical cellular specifications. In contrast, NEUTREX shows stable performance across different generations, protocols, and releases of the cellular specifications, reaching $64-74\%$ precision, recall, and F1 score. This enables our method to be used in future generations of cellular systems as well. The lost accuracy is mainly due to the distribution shift resulting from the domain change (e.g., 4G to 5G or NAS to RRC) and the difficulty of the dataset stemming from the increasing degree of nested constituents, which complicates the semantic relationship between hierarchical spans. Additionally, compared to 4G NAS specifications, we find that there is a slight accuracy drop in 5G NAS, which can be attributed to the increased difficulty (length and nesting).

Results on the RFC dataset. To show NEUTREX's generalizability to other domains, we train and test it using the RFC dataset (TCP, DCCP, SCTP, PPTP, LTP, BGPv4) with the same dataset split as RFCNLP [67]. For comparison, we compute the same metrics on the predictions by RFCNLP [66]. Table 3 presents these results and shows that although NEUTREX is primarily designed for cellular specifications, it outperforms RFCNLP even in the RFC dataset. This manifests NEUTREX's applicability to other domains.

8.2 Effectiveness of IR and FSM Synthesizers

To answer RQ2, we use human-annotated ground truth transition components instead of using NEUTREX, and leverage the IRSynthesizer and FSMSynthesizer components of Hermes to synthesize transitions and generate FSMs (M_{Syn}). The annotations are from 4G NAS [11] and 5G NAS [5] specifications. We check M_{Syn}'s accuracy against the formal models manually constructed by prior works [40, 42]. These works, however, abstracted away a lot of details from the original specification. As a result, a head-to-head comparison with these models is not plausible. Thus, to evaluate M_{Syn}, we manually construct ground truth Gold FSMs (M_{Gold}) with the same actions and scope as these prior works but matching the same abstraction as M_{Syn}. We use the ground truth annotations of the same paragraphs within the scope of M_{Gold} to generate M_{Syn}. These include procedures covered by prior works, such as (de-)registration, service request, security mode control, etc. Finally, we compute the accuracy of conditions, actions, and states in the transitions of M_{Syn}, considering M_{Gold} as ground truth. The summary of the FSMs is provided in Table 5, and details of computing this accuracy are in Appendix A.

The results of M_{Syn} in Table 4 show $92-94\%$ accuracy of transitions extracted by IRSynthesizer and FSMSynthesizer as compared to the transitions manually crafted in M_{Gold}. This proves that our approach is better than the state-of-the-art framework on network protocols, RFCNLP [67], which achieves $67-80\%$ accuracy. The lost accuracy of $6-8\%$ in M_{Syn} can be attributed to the wide diversity of natural language strings, imperfections in Keyword Extractor, and off-the-shelf dependency parsers. Instead of overfitting the DSL rules to these rare cases, we strive to design IRSynthesizer generic to the cellular specifications across different generations, layers, and releases.

FSM	TC^{NL} Generated By	TC^{IR} Generated By
Gold FSM (M_{Gold})	Human	Human

8.3 Accuracy of the Extracted FSM

We address RQ3 by extracting FSMs end-to-end with Hermes (M_{Hermes}) for 4G NAS [11] and 5G NAS [5] specifications. We compute the accuracy of conditions, actions, and states in Hermes FSM (M_{Hermes}) against the Gold FSM (M_{Gold}).

Annotated span	NEUTREX prediction	Generated IR
<control> <action> The network shall stop timer T3522 </action> <condition> upon receipt of the DEREGISTRATION ACCEPT message . </condition> </control>	<control> The network shall <action> stop timer T3522 </action> <condition> upon receipt of the DEREGISTRATION ACCEPT message . </condition> </control>	condition: chan_ue_amf = deregistration_accept actions: timer_t3522_started = FALSE

Table 6: Examples of spans with incorrect NEUTREX prediction, but correct IR [5, 11].

As shown in Table 4, M_{Hermes} has an overall accuracy of $81-87\%$, demonstrating the robustness of the approach because Hermes achieves a higher holistic accuracy than the F1-score of NEUTREX ($65-68\%$ in Table 2). This improvement can be attributed to cases where NEUTREX makes errors in identifying the conditions or actions span boundaries, but includes the action verbs and arguments in them (discussed in §5.4). In these cases, the rest of the framework is robust enough to capture the logical meanings of the identified TC^{NL}s and correctly produce the transitions. Moreover, FSMSynthesizer identifies strings in ctl_block without any tag and scans it to find action verbs and DSL arguments. A few such cases are shown in Table 6. However, despite the efforts in IRSynthesizer and FSMSynthesizer, we find that 16 transitions are missing in M_{Hermes}. We analyze such cases by consulting with the specification and find that they can be attributed to errors in NEUTREX and IRSynthesizer (details with examples are given in Table 7).

Conformance Testing. To further test the extracted FSM's accuracy, we translate M_{Hermes} to the nuXmv model following the procedure in §8.4 without instrumenting adversary capabilities into the model. Then, we translate 43 security-related conformance test cases provided by 3GPP to Linear Temporal Logic (LTL) properties and check them against the model. Violations of a property signify nonconformance/inaccuracies in M_{Hermes} transitions. We found that the 5G NAS FSM passes in 33 test cases and 4G NAS FSM passes in 32.

8.4 Effectiveness of FSMs Extracted by Hermes

To answer RQ4, we leverage the approach provided by prior works [40, 42], which automatically transpiles compatible FSMs to nuXmv [22] model and incorporate Dolev-Yao adversary capabilities [32] (drop, modify, inject, or replay) into communication channels based on sent/received messages. These adversary-instrumented nuXmv models are amenable to formal model checking of security properties on the FSMs. Thus, to ensure compatibility with the transpiler, Hermes outputs FSMs for cellular specification documents in a Graphviz-like format with conditions and actions as propositional logic expressions, which are then translated to nuXmv and checked against security properties. After performing the model checking, nuXmv spits out traces of counterexamples when any of the properties are violated.

Counterexample verification and vulnerability detection. A counterexample from nuXmv is basically a trace of message exchanges and internal variable updates leading to the violation of the property. However, FSMs, even manually crafted ones, often include erroneous transitions [40], as is the case with Hermes-extracted FSMs. Thus, after a counterexample is extracted, we manually verify it by consulting the specification document. Further, when we find an erroneous counterexample, we manually refine the model and correct the related incorrect transitions. This process is counterexample-guided model refinement, which facilitates further checking security properties on the refined model and identifying more counterexamples. Finally, we follow prior works [40, 42] and manually model the remaining counterexamples in ProVerif [18] to verify their feasibility under cryptographic assumptions.

Experiment setup, properties, and procedures. We extract separate FSMs from 4G-NAS-Release16 [11], 5G-NAS-Release17 [5], and 5G-RRC-Release17 [6] specifications, and generate separate adversary-instrumented nuXmv models. While extracting the 5G-NAS-Release17 FSM, we use NEUTREX trained with 4G-NAS-Release16 specification, and while extracting the FSMs from 4G-NAS-Release16 and 5G-RRC-Release17 specifications, we use NEUTREX trained with 5G-NAS-Release17 specification (the same setting as §8.1).

In this experiment, we check the 20 security properties from prior works [40, 42] and 7 new properties that cover the scope of other related works [20, 27, 28, 51, 70, 76, 80, 87] written in Linear Temporal Logic (LTL). Moreover, for model checking, adversary-instrumented nuXmv models are cre-

Cause	Example	#missing transitions
NEUTREX missed <action>	<control> <action> The MME shall initiate the GUTI reallocation ... </action> and starting the timer T3450. </control>	6
NEUTREX merged two separate <action>s together	<control> <action> The MME initiates the NAS security mode control ... and starting timer T3460 (see example in figure 5.4.3.2.1). </action> </control>	2
NEUTREX divided unit <action>	<control> <action> the UE shall include ... in SERVICE REQUEST message, </action>, or in the REGISTRATION REQUEST message. </control>	2

Incomplete set of DSL rules in IRSynthesizer	a) the UE shall check the authenticity of the core network by means of the AUTN ... AUTHENTICATION REQUEST message.	1

Table 7: Examples of missing transitions [5, 11].

ated from the FSMs extracted from 4G-NAS-Release16 [11], 5G-NAS-Release17 [5], and 5G-RRC-Release17 [6] specifications. These models cover 9 NAS and 10 RRC layer procedures, including registration, deregistration, configuration update, service request, RRC Setup, Reconfiguration, paging, and Resume. The properties and procedures are listed in the full version of this paper [44].

Results. The formal analysis identifies 19 previous and 3 new vulnerabilities in the extracted FSMs. Table 8 shows the list of attacks and summarizes the findings of the security analysis on the extracted FSMs. We also list the previous vulnerabilities (within the scope of the analyzed specification) not detected by the analysis with Hermes FSMs.

Among the not identified ones, attacks #15 and #30 are due to errors in transition component extraction by NEUTREX, and attack #10 is due to underspecification of the specifications. For the rest of the non-identified attacks, a manual inspection uncovered that the corresponding vulnerabilities are not present in the analyzed release of the specifications, and thus, Hermes does not model those behaviors. For example, the 5G-RRC specification was updated due to the report of the AKA-Bypass attack [51], so the version we analyzed does not contain the related vulnerability. In addition, due to the imperfection in the extracted FSM, the counterexample verification process, as discussed above, finds 8 erroneous counterexamples from nuXmv model checker. We correct 47 transitions to refine the model through the counterexample-guided refinement process. On the other hand, attacks #20-21 and #35 are new attacks identified using Hermes FSMs. These new attacks are identified using properties from prior works [40, 42], which further bolsters that Hermes-generated FSMs exhibit larger scopes and details than prior manually crafted models. Note that similar issues as 20 and 21 are concurrently reported in change requests [39, 65], but these reports do not discuss the exploits.

Table 8: Vulnerabilities identified in Hermes extracted FSMs. N: New, D: Detected.

8.4.1 Identified Three New Vulnerabilities

(1) Deletion of allowed CAG list. When a UE in a closed access group (CAG) cell sends a REGISTRATION REQUEST message through a gNB, the AMF determines whether any of the CAG ID(s) from the gNB are in the list of Allowed CAGs for that UE. In case this check fails, the AMF rejects the registration and sends a REGISTRATION REJECT message with 5GMM cause #76. Upon receiving this message, if the integrity check is successful, the UE deletes its allowed CAG list [5]. An adversary can exploit this behavior and force the UE to delete the allowed CAG list, resulting in a denial of service (DoS).

Root cause. The AMF sends the REGISTRATION REJECT based on the received information from the gNB. However, the UE has no means to verify the CAG IDs for which the AMF sends the REGISTRATION REJECT message. Without this knowledge, the UE cannot identify if there is a mismatch in CAG ID(s) when it receives the REGISTRATION REJECT with 5GMM cause #76. Thus, the vulnerability stems from a design flaw.

Attack. The adversary, at first, lets the victim UE connect to a benign base station (gNB_1) and complete registration with the AMF. After that, the adversary lures the victim to connect to a machine-in-the-middle (MitM) fake base station. She then finds a gNB with a different set of CAG IDs (gNB_2) and relays the REGISTRATION REQUEST to it (Figure 9). gNB_2 for-

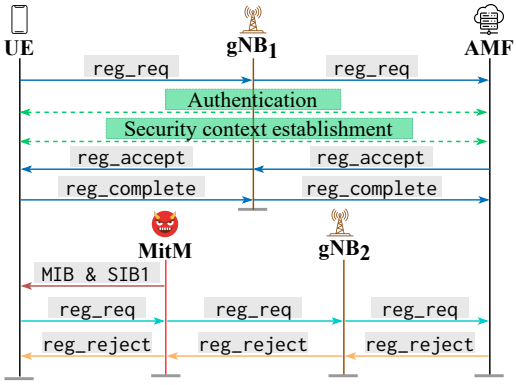

Figure 9: Deletion of allowed CAG list.

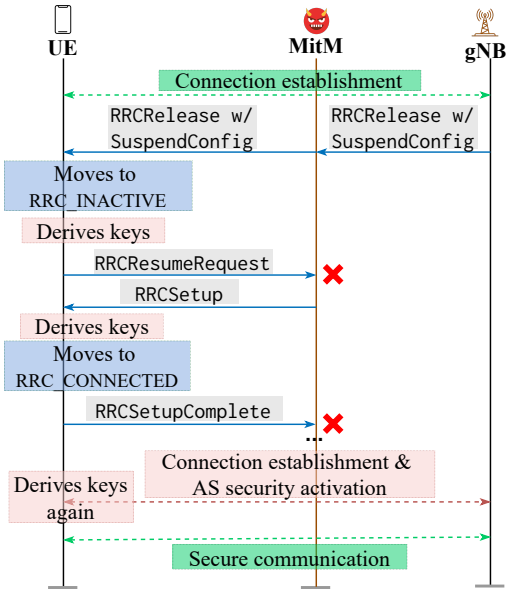

Figure 10: Energy depletion using RRCSetup.

wards the message to the benign AMF, and the AMF checks the CAG list from gNB_2. After finding a mismatch, the AMF responds with integrity-protected REGISTRATION REJECT with 5GMM cause #76. By forwarding this message to the UE, the adversary forces it to delete the allowed CAG list. Note that the initial registration through gNB_1 ensures that the AMF responds with integrity-protected REGISTRATION REJECT. Without integrity protection, the UE does not accept this message [5].

Impact. The deletion of the allowed CAG list results in DoS. Without the allowed CAG list, the UE cannot get access to the non-public network (NPN) that it is originally permitted to. Repeating this attack will cause a prolonged DoS.

(2) Energy Depletion using RRCSETUP. The RRC resume procedure, introduced in 5G, strives to reduce power consumption and connection setup overhead. However, during this procedure, the UE accepts insecure RRCSETUP messages in response to RRCRESUMEREQUEST. Upon receiving this message, the UE deletes RRC security contexts and releases radio bearers. Reestablishing a secure RRC connection requires expensive cryptographic operations, leading to energy depletion.

Root cause. The root cause of this vulnerability can be attributed to the specification allowing non-integrity-protected RRCSETUP messages in response to the RRCRESUMEREQUEST [6].

Attack. As the RRCSETUP messages are not integrity protected nor ciphered, an adversary can easily craft a plaintext RRCSETUP message. Thus, she listens for an RRCRESUMEREQUEST message in the communication channel. After that, as shown in Figure 10, when she detects an RRCRESUME message from the legitimate base station, she drops the message and spoofs a plaintext RRCSETUP. As a result, upon receiving this message, the UE deletes its RRC security contexts and releases radio bearers.

Impact. By interrupting the RRC resume procedure, the adversary forces the UE to perform redundant, expensive cryptographic operations to set up the security context again. This leads to extraneous energy consumption. An adversary can repeatedly perform this attack and cause battery depletion.

(3) NAS COUNT update attack. 5G NAS specification [5] allows a UE to store the estimated NAS COUNT, i.e., the NAS COUNT used in the *last* successfully integrity-verified NAS message. However, the adversary can exploit this behavior to manipulate the NAS COUNT and perform replay attacks.

Root cause. The root cause is a design flaw– UE stores the NAS COUNT of the *last* integrity-verified message [5]. This allows the UE to accept integrity-protected NAS messages that have been delayed and are received out of sequence.

Attack. The adversary sets up a MitM fake base station (gNB) between the victim UE and a benign AMF. Then, she can arbitrarily delay any message to update the NAS COUNT to a lower value. For example, in Figure 11, the NAS COUNT of msg_1 is $X||a$, where X is the overflow counter, a is the sequence number, and $||$ denotes concatenation. The adversary delays msg_2 (NAS COUNT: $X||a+1$) and sends it after msg_4 (NAS COUNT: $X||a+3$). This message (msg_2) is valid and integrity-protected by the AMF. Thus, this out-of-sequence message causes the victim to update its NAS COUNT to $X||a+1$. This opens the scope of replayed messages with NAS COUNTs $X||a+2$ and $X||a+3$.

Impact. As the UE becomes vulnerable to replayed NAS messages, the adversary can exploit this to perform traceability attacks to extract a victim's presence in a target area [12, 14, 42]. This violates security requirements in 5G networks [7].

8.5 Analysis of Unannotated Document

We also analyze an unannotated document, i.e., 5G-NAS-Release15 [3], by using NEUTREX trained on the 4G-NAS-Release16 and extracting the FSM of 5G-NAS-Release15. Following the formal analysis technique discussed in §8.4, we check the same properties and procedures. This analysis finds the attacks migrating from 4G to 5G (attacks #22-25

in Table 8), and five previous 5G attacks (attacks #12-14 and #16-17 in Table 8). The analysis also found 5 spurious counterexamples, handled similarly as discussed in §8.4.

8.6 Analysis of Cellular Implementations

To further address RQ4, we analyze the security of 4G NAS FSM [11] of 9 cellular baseband implementations (M_I) using M_{Hermes}. We run DIKEUE's equivalence checker [43] between M_{Hermes} and M_I and detect exploitable deviations in M_I from M_{Hermes}. As shown in Table 9, M_{Hermes} identifies 7 deviations, which were also identified by DIKEUE. However, the other two deviations that M_{Hermes} misses (#3 & #4), but DIKEUE detects result from conflicts between two separate documents [43]. In addition, due to imperfect FSM, we face 3 false positive deviations, which we manually verify.

8.7 Efficiency of Hermes

To address RQ5, we compute the time required for FSM extraction and subsequent security analysis by Hermes. On an NVIDIA RTX A6000 machine, training `NEUTREX` takes ∼4 hours, and prediction takes less than a minute for each document. `Keyword Extractor` takes 8-12 hours of computation on a machine with an Intel Core i7-10610U processor and 48 GB RAM and around 5 hours of manual effort. `IRSynthesizer` and `FSMSynthesizer` require 1.5-2 hours, and formal model checking requires 1-2 minutes. Finally, manually verifying the counterexamples requires ∼5 hours for each FSM. These requirements are detailed in Table 10.

Component	Document	Time required
`NEUTREX` training	4G-NAS-Release16	4 hour 3 minutes
	5G-NAS-Release17	4 hour 9 minutes
`NEUTREX` prediction	4G-NAS-Release16	42 seconds
	5G-NAS-Release17	33 seconds
	5G-NAS-Release15	16 seconds
	5G-RRC-Release17	19 seconds
`Keyword Extractor` computation	4G-NAS-Release16	13 hour 6 minutes
	5G-NAS-Release17	13 hour 39 minutes
	5G-RRC-Release17	7 hour 8 minutes
Keyword type assignment	4G-NAS-Release16	5 hour 27 minutes
	5G-NAS-Release17	5 hour 19 minutes
	5G-RRC-Release17	5 hour 46 minutes
`IRSynthesizer` & `FSMSynthesizer`	4G-NAS-Release16	43 minutes
	5G-NAS-Release17	43 minutes
	5G-NAS-Release15	35 minutes
	5G-RRC-Release17	12 minutes
Formal model checking	4G-NAS-Release16	78 seconds

9 Related Work

Security Protocol Analysis Using NLP Methods. RFC-NLP [67] extracts FSMs from RFC documents with a BIO entity tagging mechanism. However, it fails to address nested constituents nor identify control blocks. Some works [46, 85] also parse RFCs to extract source code, ambiguities, or test cases. Chen et al. [25] analyze payment system guidelines to find logical flaws. Several works also leverage explicit rules to extract permissions, inputs, or ontology from software documentation [68, 83, 84]. Atomic [26] finds proof-of-concept of vulnerabilities using hazard identifiers, while CREEK [24] identifies security-relevant change request documents. These works do not extract any formal model of the analyzed system. Another group of works uses NLP tools and program analysis on source code to extract logical errors or formal models [58, 91, 92]. In contrast, Hermes aims to build a formal representation from the specifications.

Text-to-logic conversion Using NLP. Several works use semantic parsing to transform natural language into logical forms, such as lambda calculus [90], meaning representation [13], programming language [45, 88, 94], and first-order logic [36]. Variations of neural encoder-decoder models have been adopted for these tasks [34, 78, 86]. However, these works are not easily applicable to the extraction of formal representations from cellular specifications because of the domain gap, lack of cellular text-to-logic dataset, or increased complexity.

Security Analysis of Cellular Specifications. Several works manually build formal models from cellular specifications [14, 29, 40, 42, 64, 71], and use model checkers to detect vul-

nerabilities. Some works also extract formal models from white-box [49] or black-box [43] cellular implementations. In contrast, Hermes generates a formal model from the specifications. Further, LTEFuzz [51] generates test cases from security properties. DoLTEst [69] provides a comprehensive negative testing framework for UE implementations using properties and security-relevant states. Moreover, several works test baseband implementations [35, 50, 61, 82]. These works focus on testing cellular systems but do not build formal models, which is the primary objective of this work.

10 Discussion and Limitations

❏ **Underspecifications, ambiguities, and conflicts.** Hermes does not deal with identifying underspecifications (e.g., implicit reject, unspecified reject cause, etc. [69]), and we consider this orthogonal to this work. For ambiguities stemming from directives, e.g., "should", "may", etc., in cellular specifications, Hermes utilizes uniform random variables, and resulting security analysis can consider all possibilities equally likely, uncovering potential security flaws. For ambiguities or inconsistencies originating from table information or information from multiple specification documents, we consider these as our future work as we currently do not incorporate table data into the generated FSM or perform security analysis on FSMs from multiple documents.

❏ **Multiple documents.** One of the challenges of extracting FSMs for cellular systems is that the protocols are described across multiple documents. Although Hermes has the capabilities to handle text from multiple documents and extract the corresponding transitions constituting the full FSM, we restrict our experiments to single documents to facilitate comparison with prior works [67]. In the future, we plan to incorporate multiple documents and evaluate Hermes.

❏ **Manual efforts.** In `Keyword Extractor`, after automatically extracting the keywords from a document and assigning types to most of them, the user needs to assign types for the rest. This effort is significantly less than manually extracting and typing *all* the keywords from scratch. For new functionalities or operations, the user needs to define the syntax and semantics for new DSL rules. Furthermore, security analysis on the extracted models requires manual efforts to define security properties and to analyze model checker outputs. In case a spurious counterexample is identified, relevant transitions are manually traced and fixed according to the specifications. Further, to check the feasibility of the counterexamples, we manually model them in ProVerif [18].

❏ **Utility of Hermes generated imperfect FSM.** In the absence of 3GPP-defined standard formal models, prior research focuses on manually modeling the specifications and verifying security properties [14, 29, 40, 42, 64, 71]. However, due to frequent updates, changing the formal models demands strenuous efforts. Conversely, although imperfect, Hermes-generated FSMs can significantly reduce this effort. When the formal model checker provides any output, we manually verify them by consulting the specifications and detecting any errors. In case of errors, we track the relevant transitions in the FSM and correct them according to the specification. Compared to manually building the FSM from scratch, which may also entail errors [40], this effort is reasonable.

❏ **No gold FSM.** If the standard body, i.e., 3GPP provides a gold FSM and it is sufficiently detailed for comprehensive formal analysis, it could potentially provide better results than hand-crafted or automatically extracted FSMs. However, 3GPP does not provide any such FSM for cellular protocols. In fact, 3GPP plans against that since constructing such a gold FSM is extremely tedious, often error-prone, and may cause inconvenience in handling interoperabilities among stakeholders as the specifications leave many details to the developers' discretion.

11 Conclusion and Future Work

We present Hermes, a novel framework that automatically extracts FSMs from cellular specifications. Its `NEUTREX`, leveraging `CellulaRoBERTa`, provides large improvements to capture transition components in natural language compared to existing works. The transitions generated by Hermes achieve 81-87% accuracy, and security analysis on the extracted FSMs enables us to identify 3 new attacks and 19 previous attacks exploiting design flaws. For future work, we will extend Hermes to detect underspecifications and conflicting sentences in cellular specifications. We will also incorporate multiple documents while extracting FSMs with Hermes.

A Evaluation Metric To Compare FSMs

For a paragraph in the specification, we have a set of ground truth transitions $\mathsf{S_{GT}}$ and a set of inference transitions $\mathsf{S_I}$. The Boolean expression present as the condition can be complex, and inferring quantitative accuracy from it is non-trivial. Thus, to make the conditions in $\mathsf{S_{GT}}$ and $\mathsf{S_I}$ consistent, we convert them to disjunctive normal form (DNF). Moreover, in this DNF form, if there is a disjunction, we split it into multiple conditions, leading to multiple transitions with the same actions. This further ensures that the conditions from $\mathsf{S_{GT}}$ and $\mathsf{S_I}$ are mapped consistently. We also append the start state to conditions and the end state to actions to take them into account while computing the transition accuracy. After these conversions, we have revised sets of transitions $\mathsf{S'_{GT}}$ and $\mathsf{S'_I}$. For each transition $T_{GT} \in \mathsf{S'_{GT}}$, we compare it with each transition $T_I \in \mathsf{S'_I}$. We then obtain the following match scores:

Conditions. The modified conditions in $T_{GT} \in \mathsf{S'_{GT}}$ and $T_I \in \mathsf{S'_I}$ only have terms connected with conjunctions. We count the number of terms in the ground truth condition c_{GT} of T_{GT} accurately present in condition c_I of T_I. We finally divide this count with the number of terms present in c_{GT} to obtain a *match score* for each transition T_I. Thus, the match score is $\frac{|m_{GT,I}|}{|c_{GT}|}$, where $|m_{GT,I}|$ is the number of matched terms, and $|c_{GT}|$ is the number of terms in c_{GT}. We finally compute the average of the highest match scores for each $T_I \in \mathsf{S'_I}$ for all $T_{GT} \in \mathsf{S'_{GT}}$ and report as the condition accuracy of $\mathsf{S_I}$. The computation is discussed in more detail with an example in the full version of this paper [44].

Actions. For each action $a_{GT} \in T_{GT}$, we consider the inference transitions T_I where $a_{GT} \in T_I$. We again compare the condition expressions for all the obtained T_I, and report the average of the highest match scores (similarly computed as the condition accuracy above) as the action accuracy of $\mathsf{S_I}$. An example of this computation is provided in the full version of this paper [44].

On the Criticality of Integrity Protection in 5G Fronthaul Networks

Abstract

The modern 5G *fronthaul*, which connects the base stations to radio units in cellular networks, is designed to deliver microsecond-level performance guarantees using Ethernet-based protocols. Unfortunately, due to potential performance overheads, as well as misconceptions about the low risk and impact of possible attacks, integrity protection is not considered a mandatory feature in the 5G fronthaul standards. In this work, we show how vulnerabilities from the lack of protection can be exploited, making attacks easier and more powerful than ever. We present a novel class of powerful attacks and a set of traditional attacks, which can both be fully launched from *software* over open *packet-based* interfaces, to cause performance degradation or denial of service to users over large geographical regions. Our attacks do not require a physical radio presence or signal-based attack mechanisms, do not affect the network's operation (*e.g.,* not crashing the radios), and are highly severe (*e.g.,* impacting multiple cells). We demonstrate the impact of our attacks in an end-to-end manner on a commercial-grade, multi-cell 5G testbed, showing that adversaries can degrade performance of connected users by more than 80%, completely block a selected subset of users from ever attaching to the cell, or even generate signaling storm attacks of more than 2500 signaling messages per minute, with just two compromised cells and four mobile users. We also present an analysis of countermeasures that meet the strict performance requirements of the fronthaul.

1 Introduction

Modern 5G cellular networks are maturing in new and expanding deployments across the globe [50, 55, 57, 69]. They facilitate substantial increases in data rates, higher network capacity, ultra-low latency, and improved availability, ushering in a new era of emerging real-time applications, such as VR/AR, self-driving cars, and unmanned aerial vehicles.

* The first two authors contributed equally to this work.

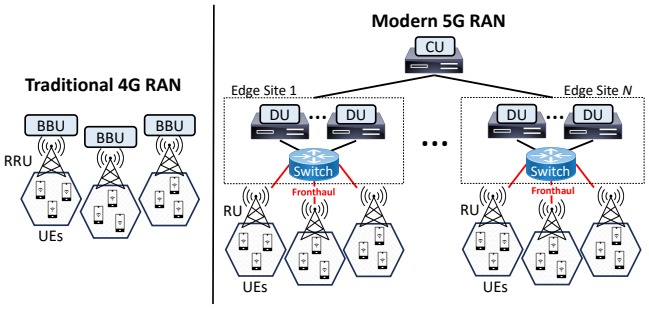

Figure 1: Disaggregated 5G RAN architecture: each CU handles multiple edge sites with racks of DUs, each DU connects to one or more RUs (over the packet-based *fronthaul* network), and each RU provides coverage for all UEs in their cell.

One major industry trend in 5G cellular networks is the *disaggregation* and *virtualization* of radio access network (RAN) functions. As shown in Figure 1, the baseband unit (BBU) and colocated remote radio unit (RRU) of traditional RANs (*e.g.,* used in 4G) are disaggregated into a Radio Unit (RU), Distributed Unit (DU), and Centralized Unit (CU) in modern 5G RANs, where one CU can serve multiple DUs. The RAN functions that previously ran on proprietary vendor-specific hardware are now virtualized, running in software on commodity off-the-shelf (COTS) servers, reducing vendor lock-in and enabling more rapid innovation [9, 34, 44].

A key part of the 5G RAN architecture is the fronthaul network, which transports user and control data between the DU and RU, to be converted into wireless signals for transmission to user equipment (UEs). Unlike traditional RANs, where fronthaul connectivity is realized using a proprietary link-layer protocol called the Common Public Radio Interface (CPRI), the 5G fronthaul uses *Ethernet-based* enhanced CPRI (eCPRI) [18], which was designed for performance and to enable emerging technologies, like Massive MIMO [27].

However, as an Ethernet-based interface, the fronthaul is vulnerable to packet manipulation attacks. Adversaries that have gained access to the physical RAN infrastructure [19, 38] can insert themselves between the DU and RU, acting as a

man-in-the-middle (MITM) adversary. From there, they can manipulate fronthaul packets to cause service degradation or connection disruption (*e.g.,* denial of service to attached UEs).

To protect against MITM attacks, integrity protection of fronthaul packets via solutions like MACsec and IPSec would be a natural approach. However, integrity protection of fronthaul traffic is currently *optional* in the protocol standards, due to concerns of increased processing delay incurred by potential security mechanisms, which could break the stringent performance requirements of the eCPRI protocol [38, §5.4.1.2, §5.5]. According to the O-RAN Security Work Group, the standardization body responsible for formulating security specifications for fronthaul [11, 12], lack of integrity protection over fronthaul is acceptable for three perceived reasons [38, §7.4: T-UPLANE-01]:

R1 Low likelihood for MITM attacks over fronthaul

R2 Costly sophistication required on the part of an adversary to launch attacks

R3 Low severity of potential attacks

In this work, we show for the first time that the above perspective on optional fronthaul integrity protection is flawed. Leveraging an enterprise-scale 5G testbed built on our premises with commercial-grade, standards-compliant RAN functions and RUs, we performed an extensive study, complete with both novel and traditional attacks. We make the following observations, which directly challenge the commonly accepted security stance:

O1 MITM fronthaul attacks are practical and feasible to launch, in a manner that bypasses the port-based network access control of IEEE 802.1X [3], on which the standards rely for their security stance (§3.2)

O2 Adversaries do not need to be overly sophisticated to launch meaningful attacks, and can directly manipulate vulnerable fronthaul traffic that is left unsecured by higher-layer protection mechanisms such as Packet Data Convergence Protocol (PDCP) (§3.3)

O3 Attacks exploiting the lack of fronthaul integrity can be severe, impacting RAN processes at a higher layer than that of the targeted DU, expanding over vast geographical regions, and affecting mobile users in cells that are not even directly under attack (§3.3)

To fully support our above observations, we introduce FRONTSTORM, a new, highly severe class of availability attacks that can impact higher layers of the RAN through signaling storms (**O3**) [25, 45]. We demonstrate that by carefully modifying and routing fronthaul packets, we can initiate higher layer processes (*e.g.,* cell reselection, handover) at a massive scale, equal to the number of the UEs attached to the cells, and at a very high rate. This leads to signaling storms at the CU that cover extensive geographical regions, impacting *many* DUs and all associated RUs and UEs. Such high-severity attacks can affect UEs not even associated with the targeted cells. Additionally, we present FRONTSTRIKE, a family of traditional attacks that breaks the fronthaul physical layer (in a similar manner to fake base station attacks, radio link jamming, and signal overshadowing) [31, 49, 71], but without requiring high levels of sophistication and hardware overheads from adversaries, who can directly modify fronthaul packets at line rate (**O2**). Unlike previous methods for launching these attacks, which require the use of transmitters (*e.g.,* a physical radio presence) and only target one cell at a time, our attacks operate at the *packet* level, making them much harder to detect and scalable to several cells at a time, since several RUs can be linked to the same affected DU.

Based on our findings, we conclude that integrity protection of the fronthaul traffic should be mandatory in the standards. Given the standardization bodies' concerns regarding the potential overhead of integrity protection on eCPRI traffic, we study the impact of the MACsec protocol to fronthaul performance. Our study demonstrates that, due to recent software and hardware advances, it is possible to achieve the necessary integrity protection at low cost and with minimal overhead, making it a practical solution. Finally, and to cover scenarios where integrity protection is absent, we present lightweight countermeasures leveraging real-time RAN analytics.

Responsible disclosure. We believe that knowledge of the vulnerabilities of an unprotected eCPRI-based fronthaul and the concrete high-impact attacks exposed in our study will be highly valuable to the broader 5G community and to the standards bodies. Thus, we have shared our report with the vendors of the equipment we worked with, and also disclosed our results to the standards bodies (ETSI [8] and O-RAN [10]), to bring awareness towards addressing these issues.

2 Background

In this section, we provide a brief background with relevant details on the 5G RAN architecture and 5G RAN fronthaul.

2.1 5G RAN Architecture

The O-RAN architecture is a widely accepted reference 5G architecture driven by the O-RAN Alliance [10] and 3rd Generation Partnership Project (3GPP) [6] standards bodies, which provide specifications for interfaces and protocols. O-RAN is globally supported by many major network operators, adopted by the European Telecommunications Standards Institute (ETSI) [8], recognized by hundreds of other operators, vendors, research and academic institutions, and is being deployed in many large-scale networks around the world today [29, 50, 55, 57, 69].

This subsection briefly provides relevant background on O-RAN principles of the 5G architecture.

Disaggregation & open interfaces. As mentioned previously, one of the key architectural changes of the 5G RAN is disaggregation, which splits the previously centralized baseband unit (BBU) and colocated remote radio unit (RRU) into three logically separate units: a software-based centralized unit (CU), software-based distributed unit (DU), and hardware-based radio unit (RU) (see Figure 1). These disaggregated RAN elements are connected by *fronthaul*, *midhaul*, and *backhaul*, bridging communication between RU to DU, DU to CU, and CU to core, respectively. O-RAN also breaks open all previously closed and proprietary interfaces, instead using open protocols built on an Ethernet-based transport.

Virtualization. In traditional architectures, RAN functions were tightly integrated with vendor-specific hardware, effectively acting as embedded devices. In 5G, these "blackbox" elements can be abstracted as native functions running on commodity off-the-shelf (COTS) servers. As shown in Figure 1, software-based DUs can be hosted in a server rack at the edge and connected to other edge infrastructure (*e.g.,* switches). The decoupling of RAN software from dedicated hardware platforms encourages less vendor lock-in, more flexible RAN provisioning, simpler management, and improved cost efficiency, attracting an increasing number of cellular operators to follow this trend [29, 51, 57, 70].

2.2 5G RAN Fronthaul Design

2.2.1 5G Fronthaul Standards

As shown in Figure 2, modern fronthaul protocols run over Ethernet, making the packet structure of the fronthaul highly accessible (*i.e.,* publicly known). In the case of the control and user planes, packets are encapsulated using either eCPRI [18] or IEEE Radio over Ethernet (RoE) [2], with the eCPRI variant having met the most widespread success.

The eCPRI specification has been a cooperative effort amongst the biggest telco vendors (*e.g.,* Ericsson, Nokia, Huawei, NEC) [18], and defines the structure of the Ethernet frame carrying the fronthaul data (*e.g.,* types of eCPRI packets). However, certain implementation details (*e.g.,* the exact contents of the payload) are left out of the specification, meaning that eCPRI is not interoperable across vendors. To fill this gap, in recent years, the O-RAN Alliance and ETSI standardization bodies have built on top of eCPRI and have provided a full specification, which enables interoperability between the RUs and the DUs of different RAN vendors [8, 53]. The popularity of eCPRI-based O-RAN is apparent by the adoption that it is starting to see in the networks of major telco operators, like AT&T [29], Deutsche Telekom [15], DISH Wireless [47], O2 Telefonica [30, 62] and Vodafone [69]. For example, AT&T and Ericsson recently announced a major deal to see the AT&T RAN powered by Ericsson network functions using the O-RAN fronthaul protocol [29]. Given the widespread adoption of the eCPRI-based O-RAN fronthaul, we focus on this variant for simplicity in this paper. However, it should be noted that all of our observations also apply to the more general eCPRI specification.

2.2.2 O-RAN Fronthaul Specification

Now, we provide some details about the O-RAN fronthaul specification that are relevant for the remainder of this paper.

Communication planes. The fronthaul network enables the communication of the DU and the RU through downlink (DU-to-RU) and uplink (RU-to-DU) transmissions. The O-RAN fronthaul specifies four different communication planes: synchronization plane (S-plane), management plane (M-plane), control plane (C-plane), and user plane (U-plane). In this paper, we focus on the U-plane, which transfers waveforms transmitted to and from the radio in the frequency domain, carrying both user and cell data. While the C-, S-, and M-plane traffic is entirely internal to the fronthaul (remaining between the DU and RU) and is thus invisible to UEs, U-plane traffic carries data to and from the UEs and can have the most immediately obvious impact on UEs.

U-plane message details. The U-plane transports baseband signals between the RU and the DU. These signals are transferred in the form of *I/Q samples* in the frequency domain,

which are complex numbers with a real (I) and an imaginary (Q) part. Figure 3 shows a representative U-plane packet captured using our O-RAN testbed (§4.1). The number of I/Q samples each U-plane packet carries depends on the RU and cell configuration (*e.g.,* cell bandwidth, number of antenna ports, *etc.*). Each U-plane packet carries a set of I/Q samples that fit into one *symbol*. All DUs and RUs must transmit U-plane messages using a rigid symbol-based schedule, characterized by a specific strict transmission window (*e.g.,* 35 µs). The exact latency tolerance of the fronthaul depends on the supported use cases, but generally, it should not exceed 100 µs for typical deployment scenarios [52].

Among other fields, each U-plane packet has a source and destination MAC address (that of the DU or the RU) carried as part of an Ethernet frame (see Figure 4 for the transmission process). U-plane packets also contain an RU (logical) port ID, as part of their eCPRI header, that designates the antenna port that the I/Q samples are being transferred to/from.

Higher-layer signaling. Baseband signals transmit data to/from the higher layers of the RAN. This includes user application data and broadcast and control messages transmitted by RUs in the downlink direction from higher layers and requested by UEs on-demand in the uplink direction. Broadcast messages are required for downlink and uplink synchronization and carry real-time control signals that allow UEs to discover the cells and provide UEs with technical instructions on attaching to cells. The loss of these broadcast messages affects the ability of UEs to successfully attach to a cell.

To provide context for the attacks we demonstrate later, we briefly introduce here two important control messages transmitted in the downlink direction over fronthaul: the Synchronization Signal Block (SSB) and System Information Block 1 (SIB1). These are the first message blocks decoded by the UE during cell search, enabling it to identify the cell, synchronize timing, discover cell uplink and downlink configurations, and determine how to decode future message blocks.[1] For uplink, we study the Physical Random Access Channel (PRACH), which allows the UE to achieve uplink synchronization and align transmission timing with the radio.

3 MITM Attacks over 5G Fronthaul

In this section, we present our threat model, discuss the feasibility of MITM attacks, and introduce practical, high-impact fronthaul attacks (both novel and traditional), contrasted against the stance of the O-RAN standards body.

3.1 Threat Model

Setting. We consider a fronthaul network with one or more software-based DUs running on commodity servers in an edge site. For a single DU server, one or more commercial RUs can be directly connected (one RU per physical NIC port). In the case of multiple DU servers, the DUs can be interconnected via physical Ethernet cables, potentially through an Ethernet switch, to one or more RUs, which broadcast radio signals to all UEs in their coverage region. The adversary's goal is to insert herself as an MITM on the link between the DU(s) and RU(s) to stealthily modify fronthaul packets and cause connection degradation or disruption for users. The adversary could be placed on any of the available links (*i.e.,* on the direct connections between the RUs and the single DU server, on the links between the RUs and the switch, or on the links between the switch and the DU servers). We assume multiple RUs for our FRONTSTORM (§5) attacks, but not for our FRONTSTRIKE (§6) attacks. We assume the fronthaul network is secured using IEEE 802.1X, and that adversaries can bypass this protection by obtaining an initial foothold for MITM attacks through on-site access to the 5G edge site, through insider threats motivated by competition or financial gain, or through supply chain vulnerabilities, particularly from untrustworthy vendors, as discussed in §3.2.

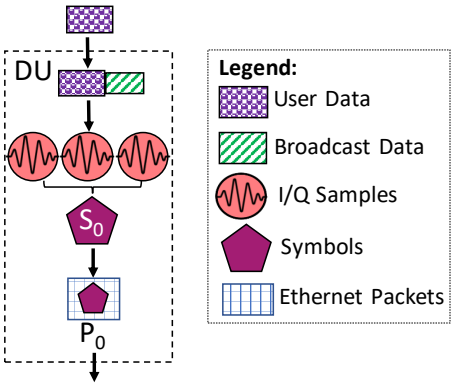

Figure 4: User data from higher layers are combined with data from lower layers (*e.g.,* broadcast data) at the DU. These are converted into I/Q samples and transmitted at structured times (*i.e.,* symbols). I/Q samples for a given transmission window are sent over fronthaul as encapsulated Ethernet packets.

Cell configuration. We assume that frequency and bandwidth configurations are common across cells, but this requirement can be relaxed for most of our attacks. Our FRONTSTRIKE attacks (§6) will work regardless of how the cell is configured with frequency or bandwidth. Additionally, one of our FRONTSTORM attacks (attack A2, §5.3) could work even with cells of different bandwidths, as long as they have overlapping frequencies. We make no assumptions about the configuration of the cells in terms of radio-related parameters.

Stealthiness. Our definition of stealthiness is that our attack methods (*e.g.,* packet modification) do not trigger incorrect behavior on the RU or UE, but directly exploit appropriate responses from the RU and UE to cause undesirable behavior.

[1] We focus on these messages for simplicity, but our attacks can also generalize to other messages.

We note that similar to existing DoS and signaling attacks, an operator can see the *effect* of our attacks (*e.g.,* service outage, cell swapping, etc.). However, our attacks remain stealthy since the *cause* of the attack is not directly apparent and could be from benign activities (*e.g.,* signaling storm due to a flash crowd event, like a large number of UEs attaching to a cell simultaneously after an airplane landing).

3.2 Feasibility of MITM Attacks

The O-RAN security standards body deemed the likelihood of MITM attacks to be low (**R1**) because of existing security requirements: port-based authentication of RAN equipment with IEEE 802.1X [38, §7.2, §7.4]. However, our investigation reveals that this assumption does not hold in various scenarios, creating vulnerabilities that could be exploited.

On-site 802.1X bypassing. O-RAN requires a device to be authenticated and authorized through IEEE 802.1X [3] before it can connect to the fronthaul network, which prevents illegal access and potential security breaches from rogue devices. However, in the case of wired networks, IEEE 802.1X is vulnerable to interceptors that introduce passive devices in the link with on-site access [24]. On-site access is a feasible and likely entry point for 5G fronthaul, where server clusters are typically co-located with base stations and spread geographically over thousands of edge sites. Due to the location and distribution of edge sites, particularly in public spaces, obtaining physical access to fronthaul infrastructure (akin to accessing outdoor IoT devices) is easier than accessing other parts of the network or traditional centralized cloud data centers [26]. Most fronthaul deployments are located on sidewalks, rooftops, or basements of buildings [20], and because of this, major vendors are strongly advocating for Zero-Trust Architectures for O-RAN security [28]. Adversaries with physical access to the 5G edge site can bypass IEEE 802.1X by inserting a rogue server with two network interfaces (*e.g.,* a mini PC [5]) into the fronthaul. Figure 5 illustrates an example scenario. As demonstrated in prior work [24], the rogue device could work as a network bridge that modifies and forwards traffic using the original connections already authenticated by IEEE 802.1X.

Insider threats. In addition to external threats, fronthaul MITM attacks can be enabled by insider threats, which originate from within the targeted organization. This can include current or former employees, contractors, or business associates with inside access to the company infrastructure. A recent survey revealed that insider threats have become more frequent, and more than 50% of surveyed organizations experienced such threats at least once in 2023 [40]. Insider threats facilitate the ease of launching MITM attacks by installing malicious devices within the fronthaul cluster. This method parallels the previously discussed 802.1X bypass but with the added advantage of legitimate on-site access. Moreover, insiders could even bypass 802.1X remotely by installing

Figure 5: An adversary can intercept and manipulate fronthaul traffic without violating IEEE 802.1X by introducing a rogue server with two network interfaces into the fronthaul network. To stay stealthy, the rogue server can be a mini PC (*e.g.,* GoWin R86S Pro [5]) with low power consumption. It works as a network bridge, enabling the adversary to view and modify the fronthaul traffic. Solid arrows indicate normal traffic, while dashed arrows represent manipulated traffic.

malicious software on the DU servers to enable packet interception. Example motivators for employees to engage in such attacks could include financial gains from service competitors or harbored resentment for former organizations.

Supply chain vulnerabilities. With 5G infrastructure being built by multiple global vendors, supply chain security becomes a major concern. A recent government report [4] identified 5G supply chain attacks as a significant threat vector. Using fronthaul hardware and software from untrusted providers (*e.g.,* adversarial countries) provides a foothold for MITM attacks. For instance, an adversary could leave a backdoor on the fronthaul switch hardware to manipulate the fronthaul traffic. Notably, such breaches will not result in detection from 802.1X protocol violations, making them particularly stealthy.

3.3 Practical, High-Impact Attacks

Recall that the standards group deemed that because of the existing security requirement for the Packet Data Convergence Protocol (PDCP), which is expected to provide integrity protection of user data at higher layers between the *CU and UE*, an adversary would need to be sophisticated to bypass this protection and launch attacks (**R2**) [38, §7.2, §7.4]. They also deemed that potential attacks on the fronthaul would only have low severity (**R3**), with the expectation that any impact on the RAN would be minor or unnoticeable and that only *one* DU/RU pair could be affected [38, §7.1, §7.4]. In contrast, we show how the PDCP security mechanism does not safeguard all fronthaul traffic between the *DU and RU*, leaving critical messages and traffic generated from layers lower than that of PDCP unsecured and vulnerable to adversaries that are not overly sophisticated. We also show several practical, high-impact attacks over fronthaul, which break the existing security assumptions, and can impact *many* DU/RU pairs.

Limitations of PDCP integrity protection. As shown in Figure 6, PDCP is an L2 protocol in the 5G protocol stack that operates between the CU and the UEs. PDCP provides several services, including integrity protection, to ensure that data

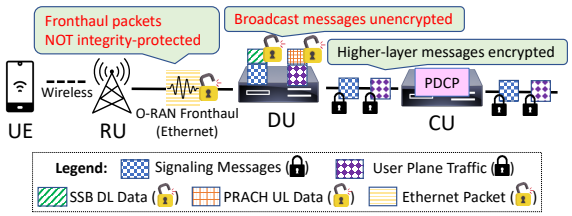

Figure 6: While higher-layer messages (*e.g.,* user data and control-plane signaling messages) are encrypted, broadcast messages (*i.e.,* lower-layer control data related to initial cell search and attachment) are unencrypted. Meanwhile, all I/Q samples encapsulated into Ethernet-based packets and sent over fronthaul are not integrity-protected.

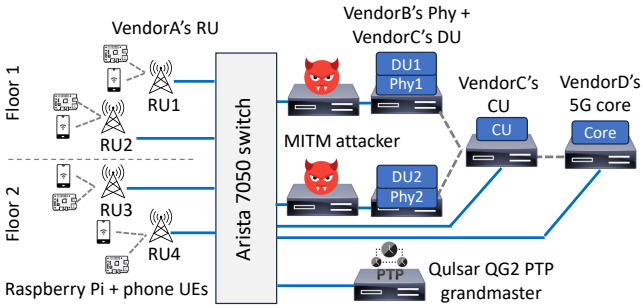

Figure 7: Testbed setup, with emulated MITM adversary.

packets are not tampered with during transmission. It achieves this by generating and validating a Message Authentication Code (MAC-I)[2] for each data packet, ensuring detection of unauthorized modifications to the contents of the data packets.

However, our study shows that PDCP is insufficient to protect the open fronthaul from MITM attacks, even from relatively unsophisticated adversaries. First, certain fronthaul traffic originates from layers lower in the 5G protocol stack than PDCP. For example, as shown in Figure 6, broadcast messages (*e.g.,* SSB data carrying cell selection information needed for UE attachment) or reference signals used for channel estimation and signal quality are generated by the MAC and PHY layers of the DU. This type of traffic falls outside the purview of PDCP, thus remaining unsecured, and exposing the system to packet modification attacks that target the intermediate RU and DU. Second, even for higher layers, the MAC-I generation and validation require the senders and receivers to use a negotiated key, which is only attainable *after* UEs attach to a cell, leaving all *pre-attachment* messages entirely unprotected. In other words, all traffic associated with the initial UE attachment procedure, particularly all broadcast messages, remains unprotected by PDCP.

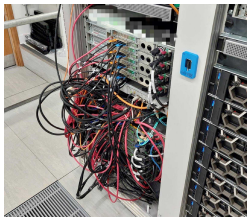
This vulnerability enables relatively unsophisticated adversaries to launch high-impact MITM attacks as follows:

FRONTSTORM attacks. Leveraging the fact that each CU handles multiple edge sites, we demonstrate a novel class of high-impact attacks called FRONTSTORM. These attacks introduce signaling storms [25, 45] at the CU, significantly degrading CU performance through fronthaul routing manipulation and I/Q sample multiplexing. The attack impact extends to vast geographical regions, impacting all DUs and their associated RUs and UEs, even those that are not directly associated with the cells where the attacks are initiated.

FRONTSTRIKE attacks. We further present a family of traditional attacks we call FRONTSTRIKE attacks, which target breaking the physical layer. Once an adversary has gained the status of MITM, she can easily attack the system by directly viewing and modifying the fronthaul traffic on the fly, using only "simple" packet capture and modification techniques, without additional hardware or sophisticated signal-processing mechanisms. This can leak critical information about the cell, degrade the cell's performance, or cause denial of service to all UEs within the cell. Our FRONTSTRIKE attacks achieve similar goals and effects as traditional physical layer attacks (*e.g.,* fake base station attacks, radio link jamming, and signal overshadowing) [43,46,48,59–61,63,64,67]. However, unlike prior work, it does *not* require a transmitter and can operate on a much larger scale, encompassing all the cells that are under the control of the affected DU.[3]

Next, we describe our setup and steps for launching attacks (§4). We then extensively demonstrate and evaluate FRONTSTORM and FRONTSTRIKE attacks in §5 and §6.

4 Setup and Attack Preparation

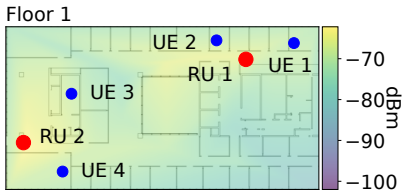


4.1 Commercial-Grade Multi-Cell Testbed

We demonstrate our attacks leveraging the infrastructure of an enterprise-scale O-RAN testbed [14] (Figure 7). Our study leverages commercial-grade O-RAN RUs from VendorA[4] with 100 MHz 4x4 MIMO operating at 3.5 GHz. Our cluster has a rack of HPE Telco DL110 servers, each featuring Intel Xeon 6338N CPUs, an Intel E810 100 GbE NIC, and an Intel ACC100 accelerator for PHY forward error correction (Figure 8a). The servers were optimized for real-time performance, running Linux kernel v6.1 with real-time patches applied. They run VendorB's PHY layer, VendorC's 5G stack for the DU and CU layers, and VendorD's 5G Core, all of which are O-RAN compliant components. The RU and servers are interconnected via a 100 GbE Arista 7050 switch. To achieve time synchronization between the RUs and DUs, we use a Qulsar QG2 PTP grandmaster clock, that feeds the synchro-

[2]We use MAC-I to denote a message authentication code scheme for integrity protection, and MAC to denote RAN's L2 medium access control.

[3]Typical deployments could span a minimum of 3-6 cells per DU.



[4]Considering that the attacks we study are related to the fronthaul specifications and not to a vendor implementation, we have anonymized the vendors we used during our evaluation for fairness. All the vendors we used are amongst the O-RAN compliant vendors listed in the TIP Exchange [68].

(a) 5G server cluster

(b) Phone and Raspberry Pi

(c) RU/UE locations & signal coverage

Figure 8: Our commercial-grade multi-cell 5G O-RAN testbed. (a) is our O-RAN server cluster. (b) shows a phone UE and a Raspberry Pi UE. (c) plots the cell signal coverage and UE placement on one of the floors in our building. The rest of the RUs and UEs in our testbed are at similar locations on another floor; their images are omitted.

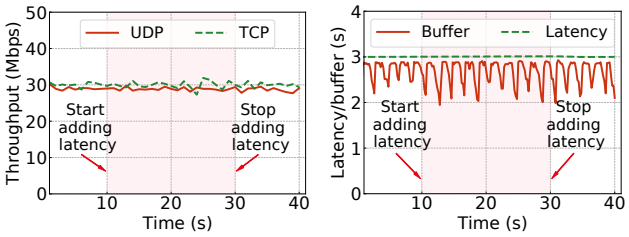
nization signal through the Arista switch. To emulate a realistic deployment scenario, we use four RUs and eight UEs distributed across two floors within our building. Each floor accommodates two RUs and four UEs. All cells use a subcarrier spacing of 30 KHz (*i.e.,* each slot is 500 µs) and are configured with the same central frequency of 3.46GHz. The UEs are OnePlus Nord N10 5G smartphones and Raspberry Pis equipped with Quectel RM502Q-AE modems (Figure 8b). The signal coverage and locations of RUs and UEs on one of the floors is shown in Figure 8c.

We emulate an MITM adversary by deploying an additional server with identical configurations within the rack. This server sits between the Arista switch and the DU server (as shown in Figure 7), and it has two 100G Intel E810 NIC ports. We connect the DU to NIC port one and the Arista switch to NIC port 2. It is worth noting that in practical scenarios, adversaries typically do not need to use such powerful servers and NICs. A more modest setup, such as a mini server with dual 25G NIC ports (*e.g.,* GoWin R86S Pro [5]), is often sufficient to manage most 5G O-RAN deployments.

4.2 Manipulating Fronthaul U-Plane Packets

We have implemented our attacks in approximately 1000 lines of C++ code based on DPDK for high performance. Our attacks capitalize on the lack of integrity protection of both the header and payload of U-plane messages, stealthily modifying fronthaul I/Q samples at line rate without raising an alarm. For traffic that does not need to be modified, we perform passive eavesdropping and simple forwarding, *i.e.,* each packet received from the DU is passively forwarded to the RU, and vice versa. To launch the different FRONTSTORM (§5) and FRONTSTRIKE (§6) attacks, we implemented the following low-level packet manipulation capabilities, toward the goal of causing UE misbehavior or service disruption:

`C1`: Ethernet header manipulation. We modify the source and destination MAC addresses of U-plane packets to reroute them to different RUs or to make the DU believe that the packet arrived from a different source RU than it did.



`C2`: I/Q sample multiplexing. We sum the values of I/Q samples carried in the U-plane packets for two cells. Recall that I/Q samples are represented as complex numbers, so this operation corresponds to an element-wise addition, *e.g.,* the first I/Q sample of cell 1 is added to the first I/Q sample of cell 2. This operation is equivalent to having both cells transmit and receive signals in overlapping regions, causing interference with each other.

`C3`: I/Q sample scaling. We multiply the values of I/Q samples carried in a U-plane packet by a scaling factor. The amplitude of the signal vector in the complex plane captures the signal's power. Thus, scaling the I/Q samples by a factor is equivalent to scaling the signal's power (*e.g.,* attenuating) by the square of that factor.

`C4`: I/Q sample replacement. We replace the payload of U-plane packets with a different set of I/Q samples. The I/Q samples could be completely random, actual I/Q sample traces captured and replayed from the same or a different cell, or I/Q samples manipulated through `C2` and `C3`.

Compression. I/Q samples carried in U-plane packets are typically compressed using standardized lightweight compression techniques (*e.g.,* Block Floating Point (BFP) and μ-law compression). Thus, to perform operations on I/Q samples, we must first decompress them before modification, and then recompress them before forwarding. We implement BFP-based (de)compression, which our RU supports. To reduce latency overhead, we accelerate I/Q sample manipulation with Intel Advanced Vector Extensions 512 (AVX-512) instructions.

Timing sensitivity. We note that the operations `C1`–`C4` used by our attacks are lightweight and thus do not violate the stringent latency constraints of the fronthaul. Specifically, for all the operations above, the processing overhead introduced in the fronthaul ranges from approximately 80 ns up to 20 µs, including the compression/decompression step. Such a delay is invisible to the higher-layer protocols, allowing us to launch our attacks without breaking the RU to DU connection. To demonstrate this, we measured the downlink TCP and UDP throughput, as experienced by an attached Raspberry Pi UE, while introducing 20 µs of extra latency in the U-plane packets. As shown in Figure 9a, both TCP and UDP throughput remain unaffected throughout the experiment. To further assess the impact of this latency on real-world applica-

(a) TCP and UDP throughput (b) DASH latency and buffer

Figure 9: Processing overheads of 20 μs incur no observable performance disruption for TCP, UDP, and DASH streaming.

tions, we used our phone UE to measure the performance of DASH.js [35], a live video streaming application that plays low-latency streams and reports streaming quality metrics including live latency, video bitrates, and video buffer sizes. We set a target latency of three seconds, which requires the DASH player to stream the video with a delay of at most three seconds behind the live event. For other settings, we adhere to the values recommended by the framework. Figure 9b presents the buffer size and lag latency during the experiment, demonstrating that the overhead we introduced had no visible impact on the application.

5 FRONTSTORM: Amplification Attacks

In this section, we first describe a passive information retrieval attack (A0), which an adversary could use to support all of our other attacks. We then present FRONTSTORM, a new family of amplification attacks leveraging capabilities C1–C4. FRONTSTORM attacks can cause signaling storms that affect the availability of the CU. The high-level idea behind these attacks is to force UEs to generate a high rate of signaling messages toward the CU. Consequently, the CU can become unresponsive, negatively impacting users in a wide region beyond the cells that are directly under attack.

5.1 A0: Cell Information Collection

In our simple forwarding state (before any packet manipulation), an adversary can perform passive eavesdropping on fronthaul traffic, obtaining cell information that could be used in other attacks. For example, by collecting sufficient downlink traffic samples in a DU-RU fronthaul connection, adversaries can capture periodically transmitted and unencrypted Master Information Block (MIB), SSB, and SIB1 messages within these samples. Using the same signal processing techniques as those employed by the base station, which are openly standardized and easily accessible through open-source implementations like OpenAirInterface and srsRAN [13, 65], adversaries can infer important cell configurations such as the cell numerology, physical cell ID

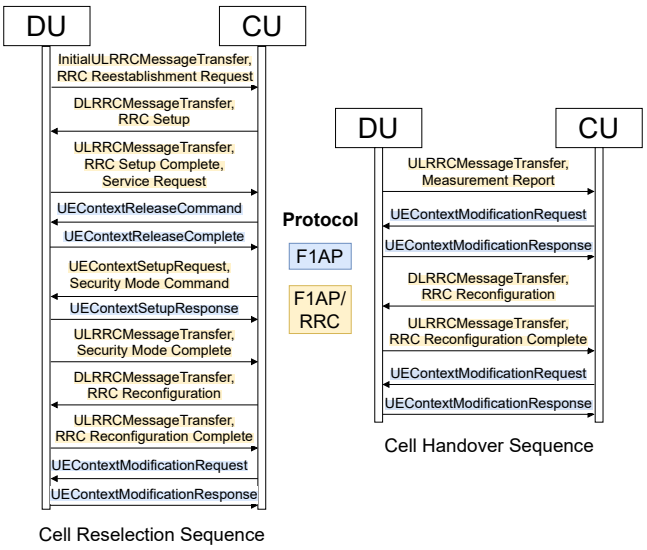


Figure 10: Message sequences for a single UE during cell re-selection and cell handover, taken from a Wireshark trace captured in our 5G testbed.

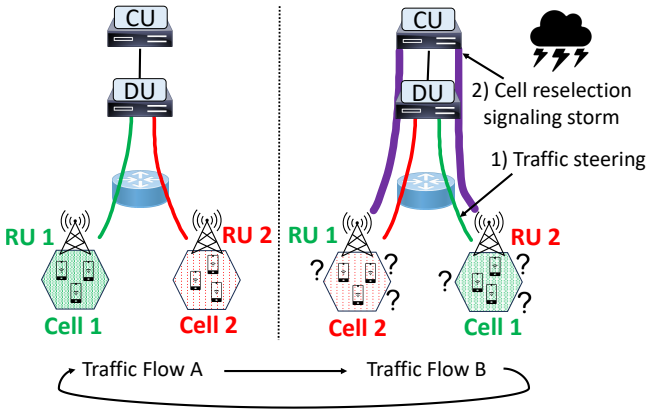
(PCI), Public Land Mobile Network (PLMN) ID, I/Q sample compression scheme, and symbol positions for PRACH data. Moreover, this information enables adversaries to launch more targeted attacks. Specifically, the above information allows a motivated adversary to create a complete map of all the cells hosted by the DU and then designate which cells to attack based on a range of cell IDs.

5.2 A1: Signaling Storm via Cell Reselection

In this attack, we utilize a radio event called Radio Link Failure (RLF) [32, §5.3.10], which occurs when the radio link between the UE and the DU is lost, *e.g.,* due to interference, bad coverage, and failed handovers. When this happens, the UE will seek to recover the signal and sets an RLF timer for this process. If the recovery fails and the timer expires (typically in a few hundred milliseconds), the UE will trigger a process called *cell re-selection*. In this re-selection process, the UE measures the signal strength of available cells within its range and selects the one with the best signal for attachment. Then, the UE establishes a connection with the chosen cell, triggering message exchanges between the DU and the CU. This process can be seen in the left part of Figure 10 for a natural cell-reselection trace captured in our testbed, spanning 12 messages (7 DU-to-CU and 5 CU-to-DU). At a high level, the UE triggers the process by sending an *RRC Reestablishment Request* message to the CU via the DU, followed by a sequence of messages by which the CU tears down the context of the UE from the old cell and creates a new context at the new cell.



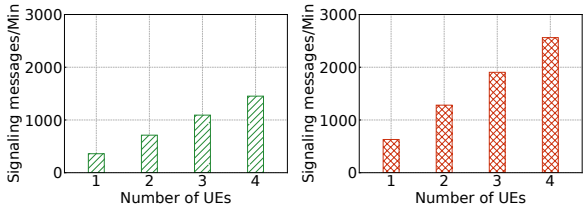


Figure 11: Signaling storm attack via cell re-selection. *Traffic Flow A* shows the DU transmitting fronthaul packets destined for Cell 1 and Cell 2 through RU 1 and RU 2, respectively.[5] *Traffic Flow B* shows our traffic steering, which causes traffic destined for *Cell 1* to go through *RU 2*, while traffic for *Cell 2* goes through *RU 1*. UEs attached to the respective cells believe they have lost their connection since they begin to receive traffic inconsistent with their existing cell configuration. All UEs then initiate the cell re-selection process, generating dozens of messages *per device*, and placing the CU under a signaling storm. After two seconds (allowing time for all UEs to reassociate to the new cell), *Traffic Flow A* is again adopted. While not shown in this figure for simplicity, returning to this traffic steering pattern would again cause cell re-selection and continue the signaling storm.

The cell re-selection process and RLFs have been used in the past for attacks trying to determine the precise location of users [63]. In contrast, in this work, we leverage the fact that the cell re-selection process generates a long sequence of messages to/from the CU, and a single cell can have hundreds of UEs attached or in an active state [56], forcing all UEs to perform cell re-selection to cause a signaling storm to the CU. We achieve this using capability `C1`, which periodically steers the fronthaul packets of cells from one RU to another by swapping the MAC addresses. This action makes the RUs transmit the signal of a different cell every few seconds, making the UEs experience an RLF and periodically trigger the cell re-selection process. This attack is illustrated in Figure 11, for the case of two cells. During time window t1, we simply forward the traffic between the RUs and the DU, with RU 1 communicating with cell 1 and RU 2 with cell 2. However, in time window t2, we swap the MAC addresses of fronthaul packets, steering all the traffic of cell 1 to/from RU 2 and all traffic of cell 2 to/from RU 1. As a result, the UEs lose the signal of their original cell and are forced to trigger the cell re-selection process and attach to the new cell that is visible to them. In time window t3, we return to the same

[5] For visual clarity, flows for each cell are shown as separate streams, but in practice, all flows traverse a single port on the switch link.

(a) Via cell re-selection (`A1`) (b) Via handover (`A2`)

Figure 12: The effectiveness of FRONTSTORM attacks (generated signaling messages per minute) linearly increases with the number of UEs.

MAC address assignment as in t1, making the RUs transmit their original signal and triggering another cell re-selection. This process is repeated periodically, every few seconds, generating a constant volume of control plane traffic to/from the CU proportional to the number of active UEs in the affected cells.

Validation. We validated the feasibility of this attack using two cells (Figure 7 and Figure 8c show the setup), initially mapping cell 1 to RU 1 and cell 2 to RU 2. We swapped the signals of the two cells every two seconds and captured all the messages exchanged between the DU and the CU during the attack. First, we verified that the attack works by analyzing the captured trace and observing that, for each UE, the message sequence of Figure 10 was indeed generated approximately every two seconds. For higher confidence in our results, we analyzed UE-level traces using QUALCOMM eXtensible Diagnostic Monitor (QXDM) logs and correlated them with the CU-side traces to validate that an RLF triggered the message sequence. It should be noted that the choice of two seconds for traffic swapping was driven by the observation that for lower values (*e.g.,* swapping every one second), cell re-selection would not be triggered consistently for all UEs, leading to the generation of a smaller number of signaling messages. We believe this is due to the RLF timer's value, which might not be set high enough to trigger the cell re-selection process before the traffic is swapped again. Different UE and cell configurations could cause the most effective timing interval for traffic swapping to vary, but this can be tuned quickly.

Using the above setup, we measured the impact of this attack on the CU by counting the number of messages exchanged between the DU and the CU for a varying number of UEs for one minute. The results can be seen in Figure 12a for up to four UEs (total number of UEs for both cells). As we can observe, the number of signaling messages increases linearly with the number of UEs. We could generate more than 1400 signaling messages with just four UEs in just one minute. To put these numbers into perspective, according to an Ericsson report, just 500 IoT devices generating more than 100 signaling events per hour could lead to network congestion [25]. Considering that, according to recent measurement

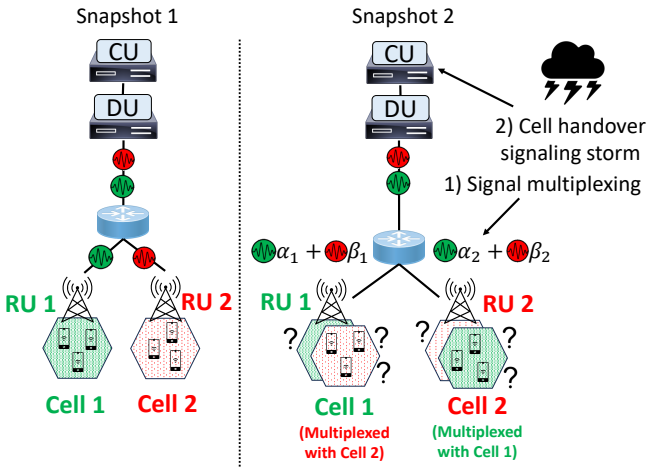

Figure 13: Signaling storm attack via cell handover. Snapshot 1 shows the normal behavior of DUs transmitting I/Q samples (in packet payloads) over fronthaul. The I/Q samples carry signals uniquely associated with respective RUs and associated cells. In Snapshot 2, we perform signal multiplexing, scaling the I/Q samples by α_1 and β_1 for Cell 1 and by α_2 and β_2 for Cell 2, and transmitting the sum of the two signals to the cells. The α and β factors are smaller than 1, thus effectively attenuating the individual signals and causing an overlapped signal to be delivered to the UEs. In this example, by choosing $\alpha_1 < \beta_1$, the signal for Cell 1 can be made to appear weaker than that of Cell 2, causing all the UEs in Cell 1 to initiate a cell handover process, generating many messages to the CU and causing a high-severity signaling storm. Simultaneously, by making $\alpha_2 > \beta_2$ for the signal transmitted to Cell 2, the signal for Cell 2 can be made to appear weaker than that of the signal for Cell 1, causing all the UEs attached to Cell 2 to initiate another handover process.

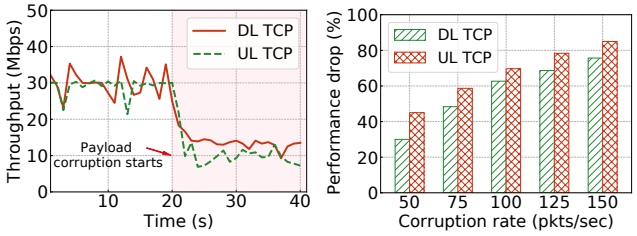
studies, real cells typically have more than 40 UEs active at any point in time [56], our attack could generate up to 30K signaling messages per minute (1.8M per hour) for just the two cells of the validation experiment.

5.3 A2: Signaling Storm via Handover



As noted in A1, while the attack was successful, we were limited in the number of times we could trigger the cell re-selection (*i.e.,* approximately once every two seconds in our setup). Here, we demonstrate how we can place even more stress on the CU by leveraging a different 5G process, namely intra-DU handovers (*i.e.,* UE handovers between cells of the same DU). As shown in the following, this enables us to generate nearly twice the number of signaling messages compared to attack A1, all within the same time frame.

The idea behind this attack is to give UEs the "illusion" that the signal quality of their attached cell goes below some threshold compared to a neighboring cell. This event triggers the handover process illustrated in the *Cell Handover Sequence* trace captured in our testbed (shown in the right part of Figure 10). Once the UE detects that the signal quality of the current cell is below some threshold compared to a neighboring cell, it sends a measurement report to the CU (first message of the *Cell Handover Sequence* in Figure 10). The CU then triggers a handover (last six messages of the *Cell Handover Sequence* in Figure 10), which involves the CU notifying the DU about the cell change and re-configuring the context of the UE.

While the handover process requires fewer CU-DU signaling messages than the cell re-selection process (seven messages for handover vs. twelve messages for cell re-selection), it can be performed more frequently, leading to a larger total number of CU signaling messages. The handover frequency is (among others) driven by three CU-configured parameters called *Hysteresis*, *TimeToTrigger* and *reportInterval* [32]. *Hysteresis* indicates a condition that must be met for the UE to move to a new cell (*e.g.,* new cell has *N* dB higher signal quality). *TimeToTrigger* indicates how long this condition has to be met for the handover to be triggered (*e.g., M* ms), to avoid ping-pong effects, while *reportInterval* specifies how frequently the measurements should be reported. The *TimeToTrigger* value is typically configured to be a few tens or hundreds of milliseconds, and the *reportInterval* hundreds of milliseconds up to a few minutes. Thus, a handover could be triggered several times per second, assuming the *Hysteresis* condition is met.

To launch this attack, we multiplex the I/Q samples of fronthaul traffic between multiple cells, by leveraging capabilities C2-C4. Specifically, as illustrated in Figure 13, we combine the payload of U-plane packets targeting the same slot and antenna port of two cells by scaling their I/Q samples by some factor (capability C3), summing up the results (capability C2), and then using the result as the new payload of the packet (capability C4). Capability C2 allows us to overlap the coverage area of two cells on the same RU, allowing all UEs in the range of the RU under attack to detect both cells. By frequently re-adjusting the signal quality of each cell through the scaling factor of capability C3, we can manipulate the signal quality of the cells and, consequently, the observed *Hysteresis*, making one cell appear to have a stronger signal quality than the other and triggering a handover. A few hundred milliseconds later, we re-adjust the scaling factors of the two cells, forcing all the UEs to move back to the original cell through another round of handovers.

Validation. As with A1, we verified the feasibility of this attack in our testbed using two cells. In our setup, the *Hysteresis* parameter is set to 0.5dB, the *TimeToTrigger* to 40ms, and the *reportInterval* to 480 milliseconds. We used a scaling factor of 1 for cell 1 (no signal attenuation) and 0.8 for cell 2, swapping the scaling factors of the two cells every 700ms. Similar to A1, we verified this approach by capturing the Cell Handover Sequence shown in Figure 10 and QXDM logs at

(a) TCP throughput (b) Performance degradation

Figure 14: The performance impact of attack A3. Data is measured on a Raspberry Pi UE. DL: downlink; UL: uplink.

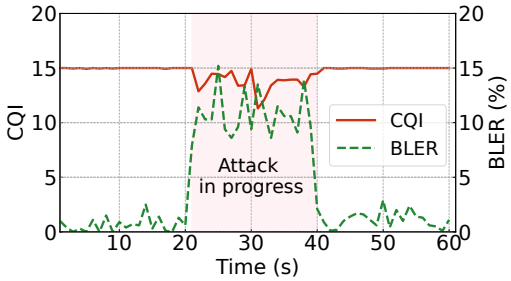


Figure 15: Payload corruption leads to lower Channel Quality Information (CQI) and higher Block Error Rate (BLER).

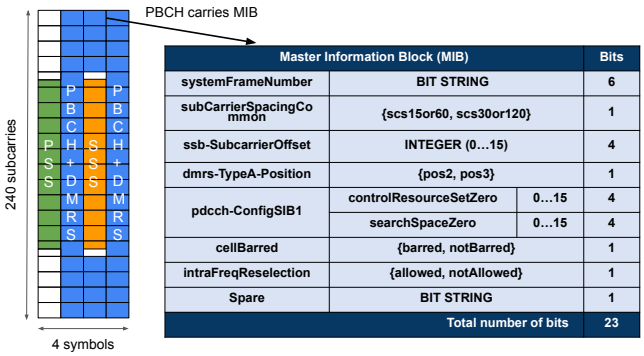
the UE side and by observing that a handover was triggered approximately every 700 ms due to a UE measurement report, once the scaling factors of the cells under attack were swapped. We then measured the impact of the attack on the CU by counting the number of messages exchanged between the DU and the CU for a varying number of UEs (up to four) within one minute. As illustrated in Figure 12b, similarly to A1, the number of signaling messages increased linearly with the number of UEs, but in this case, we were able to generate more than 2500 signaling messages for four UEs (approximately three handovers every two seconds), a number almost double that of attack A1.

6 FRONTSTRIKE: Signal Modification Attacks

FRONTSTRIKE attacks leverage capabilities C3 and C4 to modify radio signals (at the packet level) and break the connection and/or performance of UEs in the cell region. We introduce three attacks (A3-A5) targeting distinct aspects of the fronthaul traffic, *e.g.,* user packet payload (A3), downlink SSB symbols (A4), and uplink PRACH symbols (A5). While achieving similar effects as physical layer attacks in the literature (*e.g.,* fake base station attacks, signal overshadowing [31, 49, 71]), these attacks possess the capability to extend their impact to all cells controlled by the victim DU.



6.1 A3: Payload Corruption

The most straightforward FRONTSTRIKE attack is to corrupt regular packets by replacing I/Q samples with invalid user payloads using capability C4 (*e.g.,* with random or all-zero payloads). The rationale behind this attack is that the modified I/Q samples could result in decoding failures and packet drops during the signal processing at the physical layer. From the perspective of UEs, the effects of the modified packets manifest as packet loss at the RAN L2 layer or as noise into their communication channels, which forces the base station to perform retransmissions and to use more robust and less efficient modulation and coding schemes. Both effects eventually lead to the reduction of the UEs' traffic rates.

Validation. We implemented this attack in both directions by corrupting randomly selected symbols that carry user data and/or signal quality reference signals. Figure 14a shows the `iperf` TCP throughput during the attack, with the adversary corrupting packets at a rate of 75 packets/sec. As shown, the attack significantly reduced connection throughput by 57% on average for downlink and by 71% on average for uplink. Figure 14b plots the percentage of throughput drop at various modification rates. It shows that the attack's effectiveness increased with the corruption rate, leading to a throughput drop of up to 76% for downlink and 85% for uplink with a corruption rate of 150 packets/sec. To further understand why performance dropped, we measured the Block Error Rate (BLER) and Channel Quality Information (CQI) of the UE under study. As shown in Figure 15, during the attack, the CQI dropped from 15 to 13.5 on average. This means the quality of the channel, as perceived by the UE, degraded, forcing the radio resource scheduler to choose more robust, but less efficient, modulation and coding schemes. Meanwhile, the BLER increased from almost 0% to more than 10% when the attack started, meaning a higher fraction of erroneous blocks were received and had to be retransmitted.

6.2 A4: Downlink SSB Modification

As briefly discussed in §2.2, 5G relies on periodically broadcasted control signals for initial access, collectively called the Synchronization Signal Block (SSB). This block comprises four parts: Primary Synchronization Signal (PSS), Secondary Synchronization Signal (SSS), Physical Broadcast CHannel (PBCH), and PBCH DeModulation Reference Signal (PBCH-DMRS). When 5G UEs try to attach to a cell, they rely upon the PSS and SSS signals to attain both time and frequency synchronization and obtain the cell PCI. After that, UEs decode the Master Information Block (MIB) from PBCH, a succinct 23-bit structure containing eight parameters crucial for cell selection (Figure 16). Notably, the `pdcch-ConfigSIB1` parameter dictates which time and frequency resources UEs need to decode SIB1, encompassing additional essential information along with the MIB. The `cellBarred` determines whether UEs are permitted to select this particular cell, while

Master Information Block (MIB)			Bits
systemFrameNumber	BIT STRING		6
subCarrierSpacingCommon	{scs15or60, scs30or120}		1
ssb-SubcarrierOffset	INTEGER (0…15)		4
dmrs-TypeA-Position	{pos2, pos3}		1
pdcch-ConfigSIB1	controlResourceSetZero	0…15	4
	searchSpaceZero	0…15	4
cellBarred	{barred, notBarred}		1
intraFreqReselection	{allowed, notAllowed}		1
Spare	BIT STRING		1
	Total number of bits		23

Figure 16: The structure of SSB and MIB.

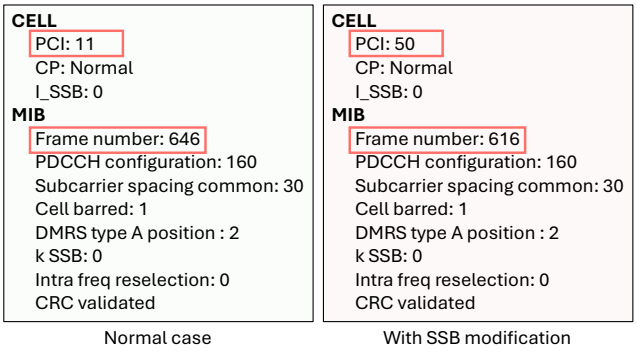


Figure 17: The cell configuration sniffed by our USRP sniffer.

the `intraFreqReselection` bit signifies if intra-frequency cell selection is allowed in the presence of cell barring.

Any failure in the receipt or decoding of SSB elements will render UEs unable to attach to the cell. As mentioned in §3.3, SSB belongs to the broadcast messages that lack protection from PDCP, so adversaries can tamper with these signals to disrupt the initial access procedures. Various attacks are conceivable. A naïve approach is to modify the I/Q samples containing the SSBs with meaningless content to obscure the normal ones, similar to attack `A3`. This disrupts the ability of UEs to decode the block, leading to failures in synchronization and subsequent steps. A more advanced adversary could achieve similar effects by selectively altering specific bits within the SSB. For instance, adversaries can introduce SSBs with incorrect PCIs or erroneous SIB1 configurations. It is particularly potent to manipulate the `cellBarred` parameter, as it enforces a 300-second restriction period before UEs can re-check the MIB. These attacks render new UEs unable to establish attachments with the cell, and they cause already connected UEs to detach from the cell.

Validation. We implemented one type of SSB modification in which the adversary replaces the I/Q samples carrying SSB packets with an incorrect PCI. This manipulation disrupts the attachment of new UEs to the cell and causes existing UEs to detach from the cell due to the PCI mismatch. For verification, we employed a USRP device with an open-sourced 5G stack [21] to capture and decode the cell's SSB signals under normal and attack conditions. Figure 17 presents the decoded results. As shown, the modified SSB led to the USRP decoding of the wrong PCI. Consequently, neither the phone nor Raspberry Pi UEs could attach. We also checked the QXDM logs on the UEs, confirming that the UEs decoded the spoofed PCI.

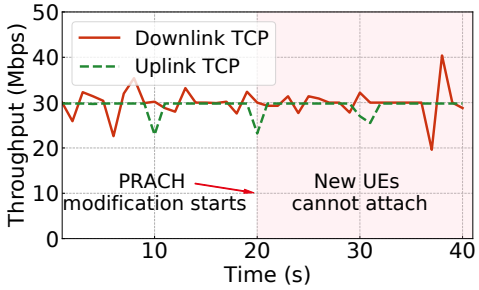

Figure 18: PRACH modification disrupts cell attachment for new UEs but keeps previously attached UEs unaffected.

6.3 A5: Uplink PRACH Modification

The uplink PRACH also plays a vital role in 5G's initial access procedure. It enables UEs to establish synchronization with the network, initiate connection requests, and efficiently identify themselves to the base station. The precise periodicity and location of PRACH data transmissions can be determined from the information captured in the SIB1 data block. UEs can begin uplink synchronization with the cell by transmitting PRACH preambles at pre-specified times, allowing the cell to detect their presence, estimate timing and frequency synchronization, and assign initial identifiers. Upon successful preamble reception, the cell responds with uplink grants, specifying resources for further communication. This procedure ensures seamless and efficient access to the 5G network, facilitating the establishment of robust connections for data transfer and communication. As a result, by manipulating uplink PRACH packets, adversaries can prevent new UEs from attaching to the cell while permitting already connected UEs to continue using the cell without interruption.

Validation. We validated the attack using a phone UE and a Raspberry Pi UE. Prior to the attack, we attached the Raspberry Pi UE to the cell and initiated a TCP/UDP connection using `iperf`. Subsequently, we started the attack by corrupting PRACH packets using capability `C4`, and then attempted to attach the phone UE to the cell. The results of our experiment are presented in Figure 18. As shown, the `iperf` throughput of the Raspberry Pi UE remained unaffected during the attack, while the phone UE failed to attach to the cell. We further examined the QXDM log on the phone UE and found that it sent out the attachment request but failed to get a response

because the adversary corrupted its PRACH symbols.

6.4 Amplifying Impact via Multi-Cell Attacks

According to the 5G O-RAN deployment principles [54], an O-RAN edge data center typically deploys a cluster of DU servers to serve a group of neighboring cells, improving energy- and cost-efficiency. As a result, FRONTSTRIKE has the advantage of amplifying the attack impact by attacking multiple cells served by the same DU together or employing multiple rogue machines to attack multiple DUs and their associated cells. This could allow FRONTSTRIKE adversaries to disrupt cellular network services for a large geographical region, such as an entire campus or small town. Moreover, adversaries could also attack multiple cells by employing different attack vectors, *e.g.,* targeting some cells using SSB modification while using PRACH modification for others. This would expand the impact area and increase the complexity of diagnosing and mitigating the attacks.

Validation. We validated the feasibility of multi-cell attacks by deploying four cells across two floors within our building, with two cells per floor and two UEs per cell. Figure 8c illustrates the positioning of the cells and UEs on one floor, and the location of FRONTSTRIKE adversaries is shown in Figure 7. We comprehensively tested FRONTSTRIKE attacks (A3-A5) in this setup, confirming they exhibit the same effectiveness, but with their impact area extending to all four cells. In addition, we conducted testing of targeted attacks A3-A5 to subsets of the cells and verified that only the UEs of the cells under attack were affected, while the rest of the cells operated normally.

7 Countermeasures

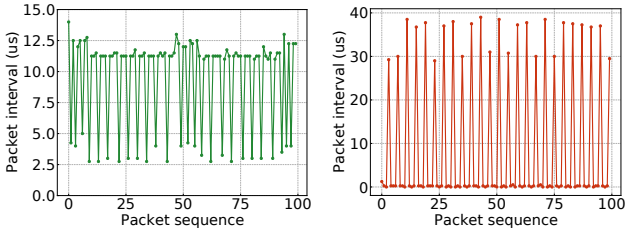
As discussed at the outset, the analysis and attacks presented in §3–§6 demonstrate that MITM fronthaul attacks are practical, require low levels of sophistication, and can introduce severe availability issues, impacting higher layers of the RAN and large regions. In this section, we discuss countermeasures that could address and combat the demonstrated attacks.

7.1 Protection via MACsec

The most obvious and effective way of securing the fronthaul network from our proposed attacks is to make integrity protection of the fronthaul packets mandatory in the standards. To this end, Media Access Control Security (MACsec) [1] is a widely adopted security protocol that provides frame data integrity and data origin authenticity at the data link layer. MACsec computes an Integrity Check Value (ICV) and attaches it to each packet, enabling devices to identify and discard modified packets with incorrect ICVs.

As explained in §1, the standardization bodies have raised several concerns regarding the implications of MACsec performance, which has led to the decision to make integrity protection an optional feature. Motivated by this claim, we performed benchmarks for MACsec encoding/decoding on jumbo-sized Ethernet frames that resemble the fronthaul packets of the 5G RAN. For our benchmarks, we considered two options: (i) basic software-based encoding/decoding on an Intel Xeon 6338N CPU, and (ii) encoding after enabling Advanced Encryption Standard Instructions (AES-NI), which accelerate the AES algorithm (*i.e.,* AES128-GCM) execution on Intel CPUs [58].

Our results show that the MACsec computation can take up to 80 µs on average for the basic software-based encoding/decoding, making integrity protection prohibitively costly for the fronthaul traffic, since it cannot meet the real-time requirements of the 5G standards, as discussed in §2.2.2. However, in the case of AES-NI, the MACsec computation time drops down to approximately 2.4 µs, which, according to the experiments we performed in our testbed, is acceptable.



A more effective way to overcome the aforementioned performance concerns with even lower overhead could be to add MACsec protection to selected parts of the fronthaul packets, which would be enough to mitigate the most critical attacks discussed in §5, but with much lower overhead, which would be important for larger scale scenarios (*e.g.,* Massive MIMO cells with 32 or 64 antennas). For example, by adding MACsec protection to the parts of the packets that are not integrity protected by the higher layers (*e.g.,* eCPRI headers, the MIB/SIB and the radio resources carrying signal quality measurements), one could mitigate the most severe attacks, like A1 and A2, by integrity-protecting a few tens of bytes per fronthaul packet. According to our measurements, this can reduce the latency overhead per integrity-protection operation to less than 0.3 µs on average, which makes integrity protection practical for all scenarios of interest.

Furthermore, MACsec provides two protection modes: integrity only, and integrity with confidentiality. Our measurements were conducted using the latter mode to assess the maximum overhead. Using the integrity-only mode could further reduce computation time. These observations align with recent works [23, 37], which discuss the potential use of MACsec to protect fronthaul.

7.2 Real-time RAN Anomaly Detection

While MACsec is an effective proactive countermeasure, mandating its inclusion in the standards and upgrading O-RAN's software and hardware for its implementation will take time. In the meantime, more focus can be placed on reactive countermeasures (*i.e.,* detection and mitigation of MITM attacks).

With the recent advances in RAN telemetry tools, real-time RAN anomaly detection has become a compelling, cost-efficient alternative [41, 42, 66]. For instance, the state-of-

(a) Uplink (b) Downlink

Figure 19: The inter-packet delay pattern of U-plane traffic.

the-art RAN telemetry tool, Janus [36], provides a fully programmable monitoring and control system for 5G RANs. It allows inserting userspace eBPF programs at specified hookpoints in the RAN functions, providing a safe way to collect user-defined telemetry. Utilizing this approach, MITM attacks could be identified with continuous monitoring of real-time RAN metrics, and subsequent detection of anomalies in these measurements. Once suspicious behavior is detected, alerts could be raised and manual or automated remediation actions could be taken (*e.g.,* block all the traffic to/from the culprit RU, dispatch support to the DU site for visual inspection). Below, we describe a few representative examples of anomaly detection methods that could be employed for this purpose:

Deviations in fronthaul traffic characteristics. C-plane and U-plane packets present highly predictable traffic patterns, in terms of packet inter-arrival delays. As discussed in §2.2.2, this predictability is due to the way in which the symbols are generated in alignment to the fronthaul specifications. This is illustrated in Figure 19, for U-plane fronthaul traffic, using measurements we collected from our testbed deployment. As shown, the inter-packet delay between fronthaul U-plane packets is predictable. In the setup under study, and in the case of the uplink traffic, the inter-packet delay always ranges between 1 and 14 µs. Similarly, in the downlink, the traffic also follows a pattern, where there is a higher inter-packet delay for every fourth packet arrival. Any significant changes introduced in these patterns could be identified, by monitoring the traffic at the RU and DU side, and could raise alerts. Note that these patterns can vary for different deployments, depending on the RU and cell configuration (*e.g.,* TDD pattern, cell bandwidth, *etc.*). However, the patterns of each deployment could be easily learned through simple statistical analysis.

Correlation with higher-layer KPIs. In several cases, the aforementioned deviations could be attributed to benign root causes unrelated to security issues, such as faulty NICs, network contention with other traffic sources, or CPU contention at the cores generating the packets. By correlating fronthaul traffic deviations with higher-layer Key Performance Indicators (KPIs), one could increase the confidence in the detection of security-related anomalies. For instance, FRONTSTORM attacks (*i.e.,* `A1` and `A2`) can be detected more accurately by correlating the abnormal increase of signaling messages in the system with spikes in the inter-packet delays of the fronthaul traffic. Similarly, the payload corruption attack (`A3`) can be detected by correlating the deviations of the fronthaul traffic with significant changes of CQI and BLER (Figure 15).

8 Discussion

Additional attacks. This paper focuses on highlighting representative attacks, instead of an exhaustive list of all possible attacks. Thus, while we presented examples of SSB and PRACH modification attacks, alternative attacks via tampering of other messages (*e.g.,* RLC and MAC control elements, like in [67]) can also be conducted. We leave this as future work. Additionally, note that more straightforward attacks, like selective packet dropping DoS attacks, are also possible in our setting. However, for this study, we chose to limit our scope to attacks specifically related to integrity protection.

Vendor response. We shared our report with telco vendors, who have acknowledged the feasibility of our attacks and felt that our work could put pressure on the standards bodies to take action. Some vendors also shared concerns regarding the feasibility of making integrity protection mandatory in the standards, due to the additional compute overhead and its associated cost, which can be prohibitive (*e.g.,* for smaller RU vendors, enterprise 5G deployments, *etc.*). We believe that these concerns can be alleviated to a large extent with the countermeasures that we propose (*i.e.,* selective integrity protection and real-time RAN anomaly detection).

9 Related Work

Physical signal injection attacks. Traditional attacks against cellular networks required direct injection of physical wireless signals [31, 43, 46, 48, 49, 59–61, 63, 64, 67, 71] to impact performance, reliability, availability, and even privacy. These can be accomplished by either setting up a fraudulent base station to attract victim UEs to connect [43, 46, 59, 63, 64] or utilizing capable devices to inject spoofed radio signals [31, 49, 71]. These existing attacks on 4G and traditional 5G suffer from several limitations: they are not stealthy (requiring high-power attack signals), have high overhead (demanding specialized devices and a physical radio presence, which are costly in both compute and power), and have limited scalability (targeting only a single cell). In contrast, our attacks execute remote fronthaul packet modification entirely in software on compromised machines, with no extra overhead to the adversary.

RAN security landscape. 3GPP standardizes general security requirements for 5G architectures [33], but these are not specific to O-RAN architectures and fronthaul. Government agencies such as NIST, FCC, ENISA, NTIA, ITU, and the DoD also provide security guidelines and reports. Similarly, however, these groups put out security specifications for generic

3GPP 5G architectures and interfaces. They do not discuss the fronthaul protocol specifically. The O-RAN Security Working Group is actively defining the security requirements [39] for O-RAN, including the fronthaul. However, the current security mechanisms are insufficient to defend against our attacks. Meanwhile, several recent works, including those of major vendors, have outlined the security landscape of the fronthaul [7, 16, 17, 22, 23, 66], and have theorized the possibility of attacks exploiting the lack of fronthaul integrity protection. However, these works have remained at a high level and have not studied the details, implications, and severity of any potential attack. Our work is the first to exploit concrete vulnerabilities, present practical high-impact attacks, and propose specific countermeasures for O-RAN fronthaul.

10 Conclusion

The fronthaul network of modern 5G RANs suffers from insufficient protection of critical messages. In this work, for the first time, we study the vulnerabilities of the lack of mandatory integrity protection and present two classes of attacks (FRONTSTORM and FRONTSTRIKE). Our attacks can be launched remotely from software, do not require a physical radio presence, and can impact vast regions. We evaluate our attacks using a commercial-grade 5G O-RAN testbed, showing that our attacks can significantly degrade the network performance or cause denial of service to UEs with negligible latency added to the fronthaul traffic. We shared our results and recommendations for mandatory integrity protection with the relevant vendors and security standardization bodies, encouraging a reassessment of the criticality of fronthaul integrity protection. We believe that this work is the first step in the emerging and important, but as yet fully unexplored, space of modern RAN security.

Acknowledgments

We thank our anonymous reviewers and shepherd for their insightful feedback. Additionally, we thank Jennifer Rexford, Ang Chen, Stefan Saroiu, and Bozidar Radunovic for their valuable comments on the earlier draft. SIMURAI: Slicing Through the Complexity of SIM Card Security Research

Tomasz Piotr Lisowski [†], Merlin Chlosta[‡], Jinjin Wang[†], Marius Muench[†]

[†]*School of Computer Science, University of Birmingham*

Abstract

SIM cards are widely regarded as trusted entities within mobile networks. But what if they were not trustworthy? In this paper, we argue that malicious SIM cards are a realistic threat, and demonstrate that they can launch impactful attacks against mobile devices and their basebands.

We design and implement SIMURAI, a software platform for security-focused SIM exploration and experimentation. At its core, SIMURAI features a flexible software implementation of a SIM. In contrast to existing SIM research tooling that typically involves physical SIM *cards*, SIMURAI adds flexibility by enabling deliberate violation of application-level and transmission-level behavior—a valuable asset for further exploration of SIM features and attack capabilities.

We integrate the platform into common cellular security test beds, demonstrating that smartphones can successfully connect to mobile networks using our software SIM. Additionally, we integrate SIMURAI with emulated baseband firmwares and carry out a fuzzing campaign that leads to the discovery of two high-severity vulnerabilities on recent flagship smartphones. We also demonstrate how rogue carriers and attackers with physical access can trigger these vulnerabilities with ease, emphasizing the need to recognize hostile SIMs in cellular security threat models.

1 Introduction

Today's connected society relies on the uninterrupted availability and security of cellular networks, and their perpetually connected mobile devices. Regardless whether these end devices are feature-rich smartphones, low-power IoT devices, or highly reliable industrial components—they all employ Subscriber Identity Modules (SIMs)[1] for authenticating and connecting to mobile networks. Owing to their small size, perceived narrow feature-set, and apparent single purpose—authentication—SIMs are generally trusted to the point where they may start acting as the root of trust [5, 8, 21].

[1]We refer to the ubiquitous notion of a 'SIM card', collectively as 'SIMs'.

Conversely, in this paper, we highlight the prospect of attacker-controlled SIMs, an often overlooked yet realistic attack vector. For instance, consider tourists traveling abroad, and purchasing a local SIM card from an unfamiliar operator to avoid roaming charges. Whether they get a prepaid SIM card from an untrusted store, or an eSIM from a carrier they haven't heard of before; their phone is now attached to a small networked computer that has a direct connection to their phone's baseband.

Typically, mobile networks are feature-rich, covering diverse use cases and offering specific capabilities for niche subscriber groups. While some features may become obsolete, their implementations remain within the protocols and software of the network. Modern operating systems, both for desktop and mobile computers, made major leaps in compartmentalization, sandboxing, and permission management, enhancing the overall security of end devices. However, real-time operating systems driving cellular baseband firmware, that manage nearly all aspects of mobile networks, often lack these modern security features [38]. Nonetheless, mobile operating systems, such as *Android* or *iOS*, prevent most apps and outside entities from directly interfacing with the baseband. SIMs, however, have a direct, privileged, and unfiltered interface to the baseband. Hence, we explore baseband security from the perspective of hostile SIMs. Contrary to popular belief, SIMs do more than just store keys; authentication is only one of their many offered facilities. Among other capabilities, they can also run Java applets, send and receive Short Message Service (SMS) messages, or open TCP/IP sockets.

Until now, research and testing with SIMs often relied on self-provisioned hardware SIMs, or rudimentary software stubs, with the sole task of authenticating to the network. While SIM contents can be programmed onto special physical SIMs, the card's operating system behavior is locked-down to be inflexible and standards-compliant, which limits the freedom of experimentation. Software SIMs can fill that gap, however, until now, there was no software SIM that would act as an analog to a standards-compliant SIM by default, while having the ability to violate that behavior when desired.

We close that gap by designing and implementing SIMURAI, a software research platform specializing in SIM card security exploration. Its main components are an open-source software SIM—swSIM—powered by the underlying smart card framework—swICC. These software components are standards-compliant by default but do not enforce this behavior, which provides the flexibility required for them to work as a research platform.

We evaluate SIMURAI in a series of experiments in common physical 2G/4G/5G cellular test beds, and a virtualized 4G setup, showcasing that SIMURAI is compatible with COTS smartphones and provides a viable alternative to hardware SIM cards in the lab. In addition, we also demonstrate SIMURAI's capabilities for security research: First, by replicating a SIM-based spyware. Then, using SIMURAI in combination with the FirmWire emulation platform [22] to enable a fuzzing campaign against emulated User Equipment (UE) images, we discover two high-severity memory corruptions that were acknowledged by the affected vendor. Motivated by the vulnerabilities found in baseband implementations, we evaluate the practicality of SIM-originating attacks against baseband implementations with two experiments: First, we analyze a *SIM interposer* and patch its firmware to launch an attack, illustrating that SIM attacks are feasible with short *physical access*. Second, we update the SIM card remotely to install a malicious applet, showing that *hostile SIMs* are a relevant threat to baseband security.

In summary, we make the following contributions:

- We stress the urgency to begin considering hostile SIMs as an attack vector, and the resulting need for security-focused SIM research tooling.
- We design and implement SIMURAI; an extensible software research platform for SIM security research, consisting of two main components: swSIM, a software SIM, and swICC, the underlying smart card layer.
- We demonstrate two case studies in which we use SIMURAI for security research. In particular, we implement a fuzzing campaign against commercial baseband firmware implementations, leading to the discovery of high-severity security vulnerabilities.
- We demonstrate that our discovered vulnerabilities can be exploited either through *(i)* physical access or *(ii)* a hostile SIM, and outline potential mitigations against SIM-based attacks.

We provide the full source code and research artifacts for SIMURAI at https://github.com/tomasz-lisowski/simurai.

2 Background

2.1 Cellular Baseband

Smartphones typically employ specialized processors for various tasks. The *baseband processor* handles mobile communication in its entirety. Its firmware is considered particularly complex by functionality and size, as it typically implements the full 2G, 3G, 4G and 5G network stacks, with the exception of the physical layer. This requires parsers for complex binary formats (e. g., ASN.1), an IP stack, an IP Multimedia Subsystem (IMS) stack, and more.

Across all these layers and protocols, the baseband firmware handles untrusted input. For instance, fake base stations may send SMS messages to nearby phones when using the 2G standard, or they might inject malicious 4G or 5G messages before mutual authentication occurs between the network and end devices.

Google notes that bugs in baseband implementations "may potentially be abundant," and calls for the adoption of additional security measures such as using updated build toolchains, deploying sanitizers in critical code, and transitioning to memory-safe languages [38]. At the same time, despite recent advances, security testing of baseband firmware remains a challenging and ongoing area of research (e. g. [24, 25, 31, 32, 34, 52]).

2.2 Subscriber Identity Module

Smart cards, i. e., SIM cards, bank cards, biometric passports, etc, are often built on top of an Integrated Circuit Card (ICC), extended with domain-specific augmentations to perform specialized tasks. ICCs contain a CPU, ROM, RAM, a file system, and a Card Operating System (COS) to manage resources and enforce hardware-assisted security mechanisms.

SIMs implement technologies in a layered fashion, which reflects the layering of standards used to define them. ETSI standardizes the UICC[2], which is a hardware and software architecture based on the ICC and intended for use in telecommunication applications such as SIM cards [13]. In the context of 3G, 4G, and 5G, 3GPP-issued standards extend the ETSI documents for SIMs operating on 3GPP networks. SIMs supporting the older, second-generation mobile telecommunication technology (2G), must instead implement GSM standards maintained by ETSI and 3GPP.

Communication Protocol. All communication between terminals[3] and SIMs aims to exchange Application Protocol Data Units (APDUs). Table 1 shows the structure of APDUs, highlighting that each APDU is divided into two parts: *(i)* The

[2] UICC is not an acronym [13], although sometimes incorrectly referred to as a Universal ICC; similar to Universal SIM (USIM).

[3] In cellular networks, end devices are commonly referred to as *UE*, or *terminal* in the context of SIM communication.

Table 1: Structure of short command and response APDUs.

Command		
Field	**Description**	**Size in Bytes**
CLA	Command Class	1
INS	Instruction	1
P1	Parameter 1	1
P2	Parameter 2	1
L_c	Encodes length of command data	0 or 1
	Command Data	$0 \leq N_c \leq 255$
L_e	Encodes length of response data	0 or 1

Response		
	Response Data	$0 \leq N_e \leq 256$
SW1	First byte of the status word	1
SW2	Second byte of the status word	1

Command APDU (C-APDU), a command that is sent from the terminal to the SIM, and *(ii)* the Response APDU (R-APDU), a response sent from the SIM back to the terminal. Together, a C-APDU and R-APDU form a Command/Response Pair (C-RP) which completes the APDU. Note that in this protocol, the SIM may never issue C-APDUs and the terminal may never issue R-APDUs [12, 27].

Proactive Commands. APDUs are always initiated by the terminal, but the SIM's optional proactive features enable it to issue *proactive* commands, which the terminal executes. Once the SIM creates a proactive command, the next 9000 status word in the R-APDU is overwritten with a special 91XX value, that informs the terminal that it can fetch a proactive command. When timely execution of proactive commands is important, the terminal may be requested to begin polling the SIM with periodic STATUS APDUs; polling may also be enabled by default [10, 12].

Proactive commands are different from APDUs, but they remain feature-rich; for instance, they allow the SIM to display a menu, open the web browser, send an SMS message, or obtain the terminal's location [3, 10]. The proactive features supported by a terminal are communicated to the SIM via the TERMINAL PROFILE command.

Consider the PROVIDE LOCAL INFORMATION command shown in Figure 1. This instruction allows the SIM card to obtain a variety of information from the terminal, including: Date, time, time zone, IMEI of terminal, charge state of the battery, network measurement results, or, as seen in this example, location information. Note that all proactive commands are encoded with ASN.1 BER-TLV rules [28]: BER-TLV byte strings describe Data Objects (DOs). Each DO contains a tag, length, and value; where the value contains as many bytes as indicated by the length field. The value of a DO can itself be a DO, a list of DOs, or a binary blob [12, 27].

```

└─8202 Tag: Device identities
       Length: 2
       Value:
    ├──81 Source: UICC
    └──82 Destination: Terminal
```

Figure 1: Example of a BER-TLV-encoded PROVIDE LOCAL INFORMATION proactive command. This command reads location information from the UE based on the current Network Access Application (NAA), i. e., USIM in most SIM cases.

File System. Files are organized into a forest of trees, with Application DFs (ADFs) and one Master File (MF) at the root, each sitting at the root of their respective trees, with Dedicated Files (DFs) and Elementary Files (EFs) nested in each of them. DFs are similar to directories and EFs are comparable to files. The MF is a root of the whole forest, while also being a root of one of the trees. This is important as it hints at the older structure of the File System (FS), where ADFs did not exist, and the MF contained all files.

eSIM. An embedded SIM (eSIM) is based on the embedded UICC (eUICC), that is intended to be a non-removable replacement for the UICC with identical core functionality. This comprises applications, file system, and all other features described in Section 2.2, which remain present in the eUICC and work in largely the same manner. The core difference is that subscriber credentials—packaged into a 'profile'—need to be remotely provisioned onto the eUICC. Each profile is a representation of a file system and applications similar to those stored on a regular UICC. Installed profiles can be enabled and disabled, and they are isolated to avoid cross-profile communication [11].

Interposers. Interposers are paper-thin Machine-in-the-Middle (MITM) devices placed between SIMs and phones; they can be used to intercept and manipulate terminal-SIM communications (see Appendix B), and they are often sold to bypass SIM-locks, i. e., a lock that restricts the device to *exclusively* using the network of a specific operator.

SIM Research Tooling. Carrier-issued SIM cards can only be programmed by the carrier and thereby are not suitable for experimentation. As a result, suppliers like Sysmocom offer SIMs with administrative pins necessary for altering file contents and installation of smart card Java applets (cardlets) [63]. They can be programmed with any smart card reader and compatible software (e. g., *pySIM* [48] and *shadySIM* [35, 49] for cardlets). Additionally, specialized hardware, such as *SIMtrace2* [50], can function as a *SIM breakout board* to enable tracing of communication between SIMs and the terminals, or to provide an interface to the terminal's SIM reader.

3 Motivation

From a security perspective, SIM cards occupy a unique and crucial role in protecting UEs and ensuring user safety. They offer a comprehensive range of features and are widely regarded as a trustworthy component within the telecommunications stack. In this paper, we challenge this trust and make a case for considering *hostile SIMs* in modern telecommunication threat models.

Although, at first glance, controlling SIMs appears to put strong assumptions on the attacker, this capability can be achieved through various methods:

1. Physical access to a UE or SIM. Attackers can, with brief access, not only exchange the SIM card, but also install interposers manipulating the communication between a benign SIM and the baseband.

2. Remote SIM administration features. This is a standardized feature of SIMs which enables rogue or compromised carriers to provision malicious additions to SIMs deployed in the field.

3. Supply-chain attacks. Access to the SIM at any stage between manufacturing and distribution would allow an attacker to implement backdoors on SIM cards.

4. Vulnerabilities in a SIM's software stack. Attackers can exploit vulnerable implementations to compromise the SIM and launch further attacks.

Note that all of these types of attacks were already observed in the wild: SIM interposers are sold to bypass carrier-lock restrictions on iPhones, leaked documents suggest attacks against SIM manufacturers [59], network operators were previously compromised [55], and the recent Simjacker malware leveraged vulnerabilities in a pre-installed SIM Application Toolkit (SAT) cardlets to distribute spyware [60].

Nonetheless, research elaborating on the threats of hostile SIMs and potential defenses is sparse; we partially attribute this to the lack of *security-centric* tooling for SIM card research. While both physical, and minimal software research SIM platforms exist, none of them provide the flexibility (e. g., to holistically violate standards), and tooling required to effectively carry out security research. Nevertheless, previous research in the domain of cellular security highlighted the importance of test beds and versatile tooling: This line of research saw many vulnerabilities discovered only after Software-defined Radio (SDR) projects made radio protocol stacks *modifiable*. With that in mind, this paper introduces tooling that improves accessibility to dynamic testing of SIM-related functionality and baseband implementations in the context of *attacker-controlled* hostile SIMs.[4]

4 Design

We aim to directly support further security research by designing SIMURAI to be *extensible* and *customizable*. While the implementation generally adheres to the relevant standards, our platform does not enforce standards-compliance, as such, it aims to provide researchers with sufficient *flexibility*. Altogether, SIMURAI embodies all core functionality in hopes that it becomes *useful*, *accessible*, and that it contributes towards the development of end-to-end cellular setups.

4.1 Overview

We provide an overview of SIMURAI in Figure 2 and showcases the logical flow of an APDU traversing the framework. At its core, SIMURAI comprises of three main components: *(i)* SWICC, a flexible platform for creating emulated ICCs, *(ii)* SWSIM, which drives SWICC and offers SIM-specific functionality, and *(iii)* an I/O layer which facilitates the connection between a PC/SC-connected SIMURAI, running on a host PC, and UEs.

4.2 SWICC

SWICC is SIMURAI's component for creating various types of smart cards on top of an emulated ICC. It handles all the complexity associated with the transport and application layers, provides a variety of utilities that support processing of APDUs, and uses a Finite State Machine (FSM) to simulate a real ICC device. SWICC also provides a file system which generally follows the standardized definition, while allowing the hierarchy and content definitions to be imported and modified at run-time. It also supports the interindustry class of commands that all ICCs need to recognize, but allows these default implementations to be overridden. Due to the architecture of the APDU demultiplexer (demux), SWICC detects when an instruction should be handled by a proprietary APDU handler. In this case, the message will be delegated, via the APDU demux, to the proprietary handler registered by a user of the framework. Lastly, SWICC offers a *response rewriting* API that allows direct modification of raw R-APDUs with user-defined logic.

[4] i. e., we do not seek out to explore SIM implementations themselves.

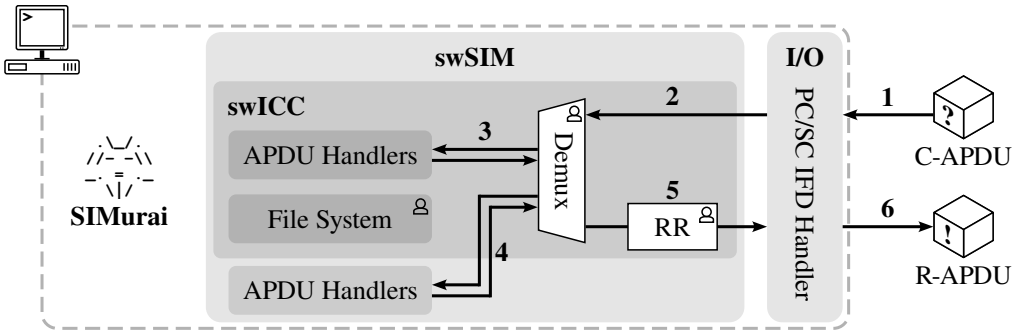

Figure 2: Overview of the SIMURAI architecture, showing the main components and the path of an incoming Command APDU (C-APDU) from the UE to the resulting Response APDU (R-APDU): **1** the PC/SC component provides the interface to, e. g., a physical UE and forwards data to **2** the demultiplexer that routes the command to the appropriate component, i. e. the APDU handlers **3** or **4**, depending on the command. The APDU handlers implement most of the logic. The Response Rewriter (RR) **5** allows users to inspect and override R-APDU contents on the fly. While all code can be modified, the icon denotes components that explicitly allow users to register custom extensions.

4.3 swSIM

SIMURAI leverages swSIM to implement command classes described by ETSI and 3GPP to handle APDUs sent by mobile telecommunication devices such as cellular basebands. swSIM registers the APDU handlers it implements with swICC, effectively turning the ICC into a SIM card by extending its functionality. Furthermore, swSIM provides SIM specific applications, such as the USIM and proactive applications, that can be toggled on and off, or completely overridden with custom implementations of the user.

4.4 I/O Interface

The last part of the SIMURAI platform is the I/O layer that serves as an interface between swICC and the UEs. Its core is the IFD handler, connecting to a PC/SC middleware (e. g., *pcscd*). swICC receives C-APDUs from the PC/SC middleware via a custom network protocol and maps these to one or more Transmission Protocol Data Unit (TPDU) messages. These TPDUs are then sent to the swICC card for processing. Eventually, an R-APDU will be received from swICC and forwarded back to the PC/SC middleware, completing the C-RP. Our architecture allows SIMURAI to flexibly connect to different endpoints. For instance, we can attach swICC-based cards to a PC as if they were physical cards inserted into a smart card reader, or use hardware breakout boards such as the SIMtrace2 to connect to physical COTS UEs.

5 Implementation

The code running on smart cards is considered an implementation detail by the standards describing the ICC, UICC, and SIM. Consequently, it is likely that any two ICC cards will not operate identically, including swICC, any swICC-based smart card, as well as any other SIM card emulator. We implement SIMURAI in 14,449 lines of C code, with swICC accounting for ~55%, swSIM for ~41%, and the PC/SC IFD handler for ~4%.

5.1 swICC

We implement swICC with a variety of utilities and self-contained modules to work with ICC data and behaviors. Additionally, we provide interfaces to ease card development. At the core of swICC sits an FSM tying together all the modules and utilities to parse and handle incoming commands.

Network. The protocol implemented for swICC provides the ability to transfer raw TPDU data, contact states, control requests, and control responses. It is designed such that a receiver obtains a constant-width header, followed by as many data bytes as indicated in the header. Control requests allow for mocking a cold or warm reset of the ICC. This is useful when working with software operating at the application layer, since in this case, contact states and transmission layer details are extraneous. swICC uses its FSM and APDU handlers to determine the length of command data that should be received from the terminal. The responses reuse a one byte control field to indicate success or failure states.

TPDU Parsing. swICC implements a flexible transport layer that communicates an expected data length with the physical layer, but will accept longer and shorter buffers. The number of parts in which a TPDU is received, can be arbitrarily large or small and the number of parts does not influence how the TPDU will be processed. For simplicity, our current

Listing 1: A simple SWICC file system defined in JSON. It contains one tree (one MF); inside the tree is one file.

implementation of SWICC, offers only the $T = 0$ transmission protocol, drastically reducing complexity as it allows to trivially map between TPDUs and C-APDUs. In regards to our choice of T, to the best of our knowledge, the $T = 1$ transmission protocol is rarely supported by commercial SIMs.

Handling C-APDUs. Within the set of valid command classes, the SWICC implementation only supports the interindustry class, with all others being marked as proprietary (adhering to [27]). The instruction class of incoming commands can contain additional information such as a secure messaging indication, a desired logical channel, or a command chaining indication. SWICC delegates the extraction of additional information from proprietary instruction classes to the proprietary C-APDU handlers registed by the user (e. g., the handlers provided by SWSIM or a user). Each C-APDU handler may decide what procedure bytes to send, and therefore, how to receive command data. Additionally, the C-APDU handler is responsible for tracking sent procedure bytes and ensuring that the correct amount of data is received. SWICC supports these operations by counting procedure bytes, validating universal status words, and buffering data to simplify handling of C-APDUs.

BER-TLV. Many instructions in the universal and interindustry classes encode their responses as BER-TLV objects [12,27]. In order to alleviate the complexity of encoding and decoding such objects, we include an easy-to-use utility as part of SWICC which is directly used by multiple C-APDU handler implementations.

File System. SWICC implements a file system that closely (although not exactly) models the standardized FS for ICCs; we highlight all noteworthy divergences in Section 8. To offer a flexible and human-configurable interface to the FS, SWICC enables the generation of its internal file system from a JSON description. Listing 1 illustrates a small example of a file system definition for SWICC.

5.2 SWSIM

SWSIM implements C-APDU handlers for a minimal set of instructions contained in classes defined by ETSI and 3GPP standards. These classes contain the common instruction set of 3G/4G/5G, and dedicated instructions for 2G. While 2G-only SIMs have a very simple file system, 3G (and newer) SIMs host a more substantial FS hierarchy, with most complexity coming from the introduction of the USIM application (ADF). SIMURAI's SWSIM implementation includes examples of JSON file system definitions for both cases.

Supporting Custom Proactive Commands. SWSIM provides a default proactive application that can be disabled or overridden with a user-defined implementation. When the default application is enabled, the APDU demux of SWSIM will execute a 'step' function provided by the proactive application. This function may generate a new command and place it inside an internal buffer. Subsequently, SWSIM will attempt to override the next R-APDU status word indicating success with the value indicating the availability and length of the proactive command. In case that the terminal does not directly react, SWSIM will repeatedly override status words until the terminal retrieves the proactive command with a FETCH C-APDU.

5.3 I/O: The PC/SC IFD Handler

SIMURAI's IFD handler connects to a PC/SC middleware which exposes an interface to connect—usually physically—card readers as PC/SC devices. The IFD handler takes care of card connections, ensures that C-APDUs get delivered correctly, and that all states presented by the connected card get translated into valid R-APDUs. Commodity PC/SC middleware (e. g., Linux's *pcsc-lite*) requires all drivers to contain a list of supported devices, such that when any of them is attached, the correct driver can be loaded. SIMURAI's virtual reader has no hardware dependencies; therefore, our driver lists `/dev/null` as the only supported device. Because the null device is always present, the PC/SC middleware is tricked into automatically loading the SIMURAI IFD handler.

6 Evaluation

Recall that our goal is to demonstrate not only the advantages of SIMURAI for security research, but also the critical need to consider SIM-based attacks as a potential attack vector for baseband firmware. As such, we set out to answer two main research questions:

RQ1 Can SIMURAI aid security research?

RQ2 Are malicious SIM cards a realistic attack vector?

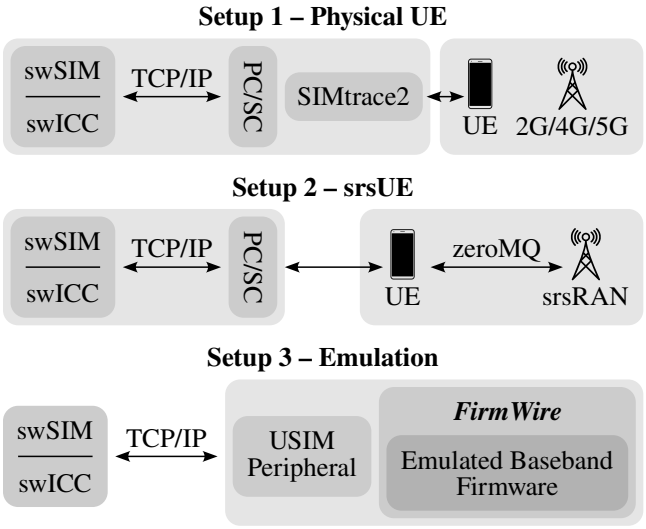

Figure 3: We integrate SIMURAI into three common cellular research setups. Setup 1 consists of 2G (Yate), 4G (srsENB and srsEPC), and 5G (srsGNB and Open5Gs) networks, and COTS UE with SIMtrace2 and cardem-firmware acting as the bridge to PC/SC-attached SIMURAI. Setup 2 contains an emulated srsRAN network and srsUE with SIMURAI attached via PC/SC. Setup 3 integrates SIMURAI with FirmWire, a baseband emulation platform.

To answer *RQ1*, we first integrate SIMURAI in representative cellular research lab setups and connect it to an emulation platform to demonstrate its core functional capabilities (Section 6.1). Then, using these setups, we demonstrate that we can carry out security-relevant experiments. In particular, we first reproduce crucial components of SIM-based spyware and then carry out a fuzzing campaign against commodity baseband implementations (Section 6.2).

To answer *RQ2*, we implement two case studies of attacks originating from a hostile SIM, exemplifying the capabilities of physical attackers and rogue operators (Section 6.3).

6.1 Integration into Cellular Test Beds

We integrate SIMURAI into three common research setups: A physical 2G/4G/5G test bed involving COTS UE, an emulated srsRAN network with srsUE, and FirmWire-emulated basebands. We outline these in Figure 3.

Setup 1: Physical UE in 2G/4G/5G Networks. We perform experiments with multiple COTS smartphones to evaluate if they can successfully communicate with SIMURAI as their SIM. Figure 4 shows our setup which consists of SIMURAI connected directly to commodity smartphones through SIMtrace2. The SIMtrace2 device runs on *cardem* firmware which changes the behavior of the device, from passively tracing communication, to actively intercepting and forwarding messages over USB to a PC/SC-connected card [51]. SIMtrace2 then provides the electrical and transmission-layer interface necessary for valid data exchanges, but does not perform processing of the exchanged APDUs; all SIM-related information is passed to the SIMURAI implementation where we have full control over how it is processed. The networks are based on Yate [45] for 2G, srsENB and srsEPC for 4G [20,62], and srsGNB and Open5Gs [47] for 5G.

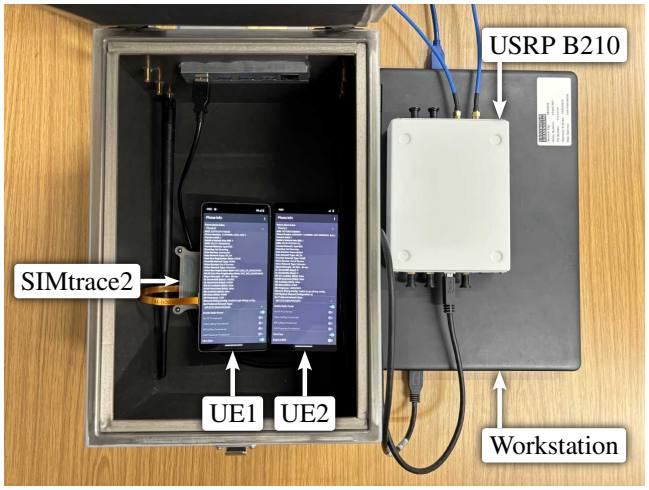

Figure 4: SIMURAI integrated into a 4G/5G cellular test bed.

We verify that each smartphone can successfully connect to our test networks. With respect to SIMURAI, this shows that the smartphone can successfully access the SIMURAI FS when interacting with required files, and that it can use the SIM to run the authentication algorithm (Milenage for 4G/5G, *none* for 2G). Table 2 summarizes our results for all tested smartphones. As demonstrated, SIMURAI proved to be a widely compatible SIM replacement. In practice, this means that SIMURAI contains the files, and supports the subset of instructions required to establish a connection with the network, and provides a functional implementation of Rijndael and Milenage functions. If any of these core components misbehaved, no connection would be established.

Our testing also solidified the fact that no two UE implementations are the same. At first our iPhone 15 tests were unsuccessful because SIMURAI was missing an UPDATE RECORD APDU handler. We added this missing feature and observed no further negative results. All remaining devices only required SIMURAI to be reconfigured with different keys and file contents, no source changes were necessary.

Setup 2: Emulated, SRS-based Network. srsRAN is a comprehensive software framework that provides a nearly complete end-to-end cellular setup. It includes implementations for the core network, an eNodeB, and a UE, making it a

preferred choice for research setups. Similarly to *Setup 1*, the UE component, srsUE, can integrate with a card reader to access hardware SIM. This capability allows for the integration of SIMURAI via SIMtrace2. To further test the versatility of SIMURAI, we attach it directly to the SIM layer of the UE implementation, srsUE, using its PC/SC interface. This direct attachment bypasses the need for any hardware, facilitating the direct exchange of APDUs between the UE and SIM. This integration was straightforward and successful. The addition of SIMURAI represents a step towards achieving a fully virtual, end-to-end cellular setup.

Setup 3: Emulation Platform. Our third experimental setup integrates SIMURAI into FirmWire [22], a recently published full-system emulation platform for baseband firmware images. The authors of [22] explicitly note that *"to enable a fully virtual UE, USIM peripheral support would need to be prototyped into FirmWire. This would yield more accurate processing of messages, especially those which require a SIM card such as SMS or USSD"*. Hence, we believe that integrating SIMURAI with this emulation platform can play a crucial part in fully virtualizing COTS UEs for security testing.

Unfortunately, unlike the tools discussed in the previous two case studies, FirmWire lacks a PC/SC interface or any means of connection a physical or virtual SIM, further compounding the issue. Therefore, we reverse engineered the baseband firmware for Samsung Exynos-based UEs supported by FirmWire and identified how it would interact with a physical SIM card. Based on our insights, we implemented a USIM peripheral, which uses SIMURAI's low-level interfaces to exchange TPDUs between our platform and FirmWire.

Our USIM peripheral implementation, consisting of 299 lines of Python code, enables successful data exchange between the frameworks at the TPDU level. We experimentally verified compatibility of our SIMURAI integration for the different Shannon-based UEs supported by FirmWire and present the results in Table 3. The log messages of FirmWire indicate a successful initialization of the baseband's USIM task and elaborate accesses to SIMURAI's file system for all successfully tested firmware versions. In the case of firmware targeting Samsung Galaxy S7 and Samsung Galaxy S7 edge phones, the interaction between the firmware and USIM peripheral changed sufficiently to render our current peripheral implementation inoperable. While we expected that a single USIM peripheral is unlikely to work with all emulated UEs due to changes in hardware and firmware, we note that our implementation already spans multiple phone models and generations, indicating that physical USIM peripherals are rarely subject to drastic changes.

6.2 SIMURAI as a Research Platform

6.2.1 Simulating SIM Spyware

Previous research has shown the potential for spyware-like features to be embedded in SIM applications. Notably, Monkeycalendar and Gopherset are two examples of SIM-based

spyware identified in the NSA's ANT catalog (which became public in 2013) [6]. These SIM-based spywares exfiltrate sensitive information—such as a victim's location, phonebook, SMS messages, and call logs—using SMS SUBMIT messages. A similar technique was observed in the more recent Simjacker attack [41, 60]. We chose to re-implement the crucial part of the Simjacker spyware to test the adaptability of SIMURAI. Our intuition is that an open-source mimicry implementation of the spyware can help the research community to assess the severity of this threat and investigate tractable countermeasures, especially as SIMURAI can closely monitor and modify individual operations.

For our implementation, we use *Setup 1* described in Section 6.1. The core functionality of the spyware, i. e., location retrieval and data exfiltration via SMS, is realized using proactive commands (i. e., PROVIDE LOCAL INFORMATION and SEND SHORT MESSAGE). We extended SIMURAI to send these proactive commands to the UE, as shown by Figure 5, and could observe the location information being sent via the network to the second UE. The ease of re-implementing this spyware—overall, our proof-of-concept consists only of 89 lines of C code—demonstrates not only are there severe privacy issues when considering malicious SIM cards as an attack vector, but also the upside of having a research platform to evaluate attacks in a quick and flexible manner.

6.2.2 Fuzzing UE Implementations

In the last decade, fuzzing has become one of the most prevalent techniques for uncovering implementation flaws, a trend which is also noticeable in cellular security research [17, 18, 22, 40, 52]. Hence, we set out to use SIMURAI to enable an efficient fuzzing setup to test the robustness of proactive command handling embedded in commodity baseband firmware. We deliberately chose these proactive commands as the fuzz target because: They can be triggered directly from a malicious SIM card, they provide a variety of different functionality, and they require complex parsers for many different binary formats, as outlined in Section 2.2.

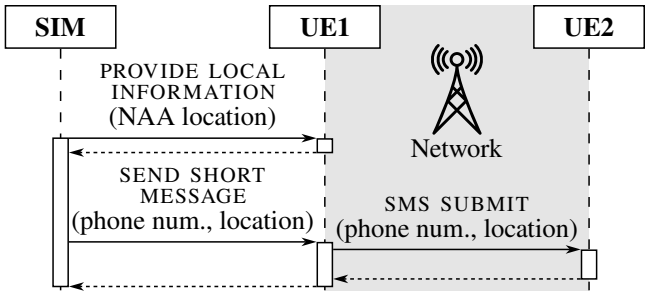

Figure 5: Message exchange for the location-stealing spyware. The SIM implementation is provided by SIMURAI.

Attempt 1: Physical Setup. Our first, naïve approach was to connect a physical phone to SIMURAI (i. e., using *Setup 1*). Unfortunately, our experiments on a Motorola One Vision[5] quickly unveiled that terminals throttle the connection to the SIM when repeatedly receiving malformed data, resulting in execution speeds of less than one test case per second. Additionally, the lack of fast reset mechanisms and transparent feedback channels created further challenges: We cannot know the state of the target when a given input is processed, and without additional feedback, such as coverage, we cannot rank inputs for further mutation and testing.

We conclude that while technically possible, fuzzing in this case proved limited and ineffective.

Attempt 2: Emulated Setup. Given the roadblocks of physical fuzzing, we decided to leverage emulation, i. e., our *Setup 3* consisting of SIMURAI connected to FirmWire. With this setup, we tested the most recent firmware available for the Motorola One Vision[6] in a long-lasting fuzzing campaign. We used AFL++ v4.09a [16] as the fuzzer and distributed the fuzzing efforts across 10 cores on an AMD EPYC 7662 64-Core CPU running Ubuntu 18.04; we fuzzed the target for 18 days. Additionally, we used SIMURAI to generate an expansive multi-thousand entry corpus of valid proactive commands to be used as seed inputs.

Approach. Implementing a fuzzing campaign against the proactive command handlers in FirmWire is not straightforward. The fuzzing methodology of the emulation platform expects that fuzzers are implemented as *tasks* for the emulated baseband real-time operating system, and that fuzzing inputs are sent via the operating system's message queues. However, we noticed that sending messages directly to the *USAT* task, which dispatches incoming proactive commands, would fail because the task was missing important state initialization.

As a result, we decided to pivot our fuzzing to a hybrid approach: We use SIMURAI to serve SIM-related requests to

[5] M3BA0, Baseband S337AP_KANE_SGCS_QB4946070
[6] XT1970-3_KANE_RETEU_11_RSA31.Q1-48-36-23

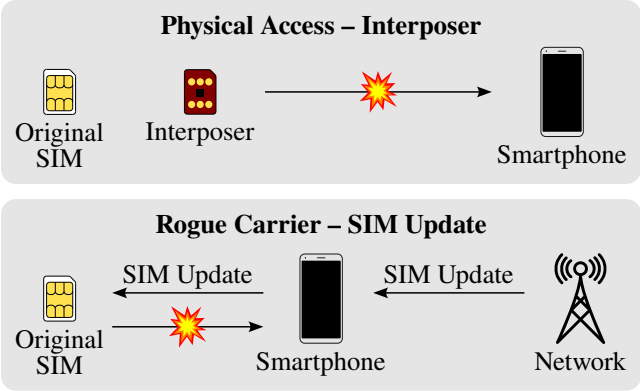

Figure 6: We use two separate setups to demonstrate the feasibility of SIM-originating attacks against basebands. The Interposer in the first setup is inserted between original SIM and smartphone. In the second setup, we update a SIM card over-the-air to showcase the threat of *rogue carriers*.

FirmWire until initialization is completed, and the emulated baseband would assume the presence of a SIM card. Then, we create a snapshot of the emulated baseband state and use it as basis for fuzzing. During fuzzing, we prefix the fuzzing input with the baseband internal indicator for proactive commands and provide this modified input to the USAT task. We note that this approach would also be possible by connecting a physical SIM, via SIMtrace2, to FirmWire for initialization. However, before our work, FirmWire neither exposed a PC/SC interface nor included a USIM peripheral, preventing the use of SIMtrace2 altogether. Additionally, eliminating the need for hardware eases the creation of powerful and parallelizable fuzzing setups.

Results. During our fuzzing campaign, the fuzzing instances cumulatively executed 490 million test cases and found 63 crashes. After manual deduplication, we could narrow down the root cause for the crashes to two distinct vulnerabilities: *(i)* A null-pointer dereference during handling of the SEND SMS command, and *(ii)* a heap buffer overflow during handling of the SEND SS proactive command.

To verify whether the discovered vulnerabilities were present on more recent devices, we replayed the crashing inputs using SIMURAI on Google Pixel 6 and Google Pixel 8 devices. We could verify the presence of vulnerability *(i)* on both devices, and vulnerability *(ii)* on the Pixel 6. Interestingly, for vulnerability *(ii)*, the device would, with some inputs, also crash indicating a PREFETCH ABORT error message, which indicates a possible corruption of the program counter. Both vulnerabilities were acknowledged by Google as high-severity, and got assigned the following identifiers: CVE-2023-50806 and CVE-2024-27209.

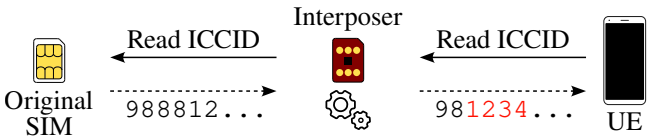

Figure 7: An interposer intercepts and selectively manipulates the communication between a phone and SIM card.

6.3 SIM Attack Case Studies

In the previous section, we find vulnerabilities in baseband implementation reachable through malicious, SIM-originating, messages. Consequently, we want to assess and demonstrate the practical feasibility of these attacks. Figure 6 summarizes our case studies.

6.3.1 Physical Access: Interposer

Threat Model. For our first attack case study, we assume an attacker with short-term physical access to the victim's phone. While this may appear like a strong attacker, this scenario can be relatively easily achieved for highly targeted attacks.

The Attack. We base our attack on a SIM interposer; a "thin SIM" that is positioned between the SIM card and the phone's card reader, as shown in Figure 7. The attacker could insert it by gaining access to the phone's SIM slot. We found that certain commercially available interposers are *(i)* updateable using a smart card reader, *(ii)* the update files contain the raw, unencrypted, and unobfuscated, firmware of the interposer, and *(iii)* the card does not perform any integrity checks on the received firmware update.

We found out that the interposer runs an unidentified RISC-V CPU, and through analysis of the update process, we found commands that: Boot the chip into a bootloader, delete memory regions, and flash new firmware. We were able to analyze the firmware, particularly the portion that performs the interception of SIM communication. With that knowledge, we create a patched firmware that triggers the vulnerability we found in Section 6.2.2. Overall, our binary patches required the modification of 57 bytes to trigger vulnerability *(i)*, and 42 bytes to trigger vulnerability *(ii)*, with the core difference being the crashing proactive command itself.

Evaluation. We prepare the patched firmware and flash it to an interposer. We open the SIM tray, sandwich the interposer and SIM together, and close the SIM tray with both the original SIM and the interposer attached to the phone's SIM reader. In our experience, this takes only a few seconds and requires no further manipulation of the SIM tray (i. e., it fits well inside all devices we were able to test).

This experiment showcases that anybody with physical access can sneak-in the interposer inside the phone, and potentially launch attacks from this platform. In our proof-of-concept interposer firmware, the vulnerability is triggered immediately when the phone accesses the SIM card; in some cases (e. g., when the phone is powered off), it might happen with a delay. A more complex firmware patch could allow a deliberate, attacker-controlled delay. Usually, interposers only inject or manipulate selectively, and pass other SIM card communication through. Thereby, the attack could be launched without impeding the functionality of the original SIM card.

6.3.2 Rogue Carrier: Over-the-Air SIM Card Update

Threat Model. For our second case study, we showcase the capabilities of rogue carriers in more detail. From a user's perspective, there are multiple possible ways to encounter such carriers, for instance via insider threads, supply chain attacks, or law enforcement with access to the network.

The Attack. Carriers can update both the file system content and applications on a SIM card *remotely* [1]. These procedures are secured with pre-shared keys, programmed into the UICC and known to the operator. To remotely load applets onto a SIM card, the operator can use a special class of Short Messages (SMS), commonly known as *binary SMS*. While this update procedure is well-known and documented by the academic community [35], we could not find any openly available implementations of remote OTA updates.

Remote SIM Updates. The SMS header indicates that the message is addressed to the SIM card (rather than the phone, like a regular text message). The phone forwards the contents of the SMS to the SIM and thereby acts like a remote card reader. It is important to note that the SMS payload is encrypted and integrity protected, so that only the issuer of the SIM card can run remote APDU commands and thereby push updates to the SIM. Generally, the remote update procedure is similar to an update through a card reader. Figure 8 shows the encapsulation of APDUs within an SMS-DELIVER packet. The phone wraps the whole SMS into a GlobalPlatform ENVELOPE command and sends it to the SIM card. Locally, one would directly send the ENVELOPE with the SMS to the SIM.

Setup. Our setup consists of an srsEPC core network and an srseNB base station connecting to a LimeSDR Mini SDR inside a faraday cage. We modify srsEPC to enable SMS delivery through NAS Downlink Messages. The core network is greatly simplified in our experiment, i. e., commercial networks would typically use a separate entity that manages the delivery of SMS. Furthermore, we use the most modern and simple form of SMS delivery using NAS Downlink Messages. Other ways exist (e. g., SMS-over-IMS); however, these differences do not affect the OTA update mechanism.

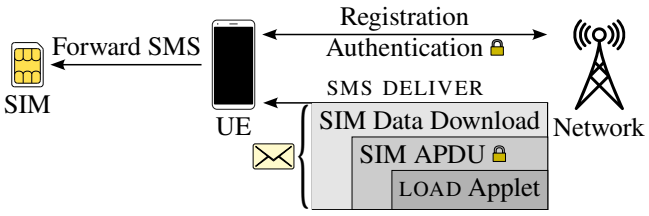

Figure 8: Process of installing a cardlet OTA.

Evaluation. We prepare a SIM applet that triggers the vulnerability through a proactive command, and compile that applet into the Java Card CAP format. We then identify the targeted card to retrieve the necessary keys to update the SIM. Using the keys, we create encrypted, SMS-wrapped APDUs that load the applet chunk by chunk onto the card. These APDUs are then fed to the core network, which encapsulates the SMS and delivers them to the SIM card.

In our experiment, the remote installation was successful, and the applet successfully sent the malicious commands to the baseband. The experiment demonstrates that a rogue carrier—as the issuer of the SIM card inside the phone—can push remote updates and trigger the SIM-exposed baseband vulnerability. After successful installation, we can remotely remove the applet from the SIM again to make the entire operation more covert.

7 Mitigation

We are not aware of mitigations currently in place to inhibit the threat of SIM-originating attacks under our assumed threat model of rogue carriers or with physical access. The inclusion of SIM-originating attacks into threat models would justify the hardening of cellular basebands, as called for by Google [38, 39], and thereby reduce the susceptibility of this attack surface in the future.

Currently proposed, SIM-related security advancements largely target aspects other than baseband security: Jinghao et al. propose to secure the channel between SIM card and phone to stop interposers from intercepting and manipulating the data in transit [66]. If deployed and enforced, this would indeed render the local attacker with physical access ineffective. The SecureSIM scheme, however, is primarily designed to protect the SIM card, not the baseband. Hence, it would require further evaluation if the scheme could also protect the baseband or if the interposer could launch an attack *before* the (secured) communication with the original SIM starts. The introduction of the *eSIM* is sometimes associated with gains in security—and indeed, an *embedded SIM* does not *easily* allow placing an interposer inbetween (however, many eUICC are *surface-mounted*, so access is not impossible). While this certainly raises the bar for physical attackers, the issue with

potential rogue carriers remains, as the eSIM has the same baseband communication capabilities and is also controlled by the carrier. RILDefender, Simjacker, and others discuss threats related to binary SMS—and call for filtering by the carrier or in the Android system [60,65]. While these defenses work against *third-party*-originating SMS, they do not protect against the *rogue carrier* that we assume.

One effective mitigation could be to *disable the processing of proactive commands* in the baseband. This mostly reduces the functionality of SIM cards to a file system and breaks legitimate use-cases of proactive commands, but greatly reduces the available attack surface. If basebands expose that option to the smartphone operating system, the smartphone could selectively disable them. Similarly to the option to disable 2G, disabling proactive commands could be a user-facing option, or part of a *lockdown mode* as found in iOS.

Additionally, during our analysis of the vulnerabilities, we noticed that commodity baseband firmware appears to ship code that—according to the TERMINAL PROFILE—is not supported, and, hence, *never* needed by the smartphone. Therefore, we think that even without reducing functionality, basebands have potential for de-bloating the code shipped within the firmware. Similarly to Google's call for updating the build toolchains [38], baseband firmware developers and integrators could disable unused features at build time.

8 Discussion

Scalability. Security tooling, especially when used for fuzzing, needs to allow for scalability and SIMURAI is no exception. In physical setups, the main bottleneck for scalability is the required hardware: Each instance of SIMURAI would require a dedicated SIMtrace2 device to connect to a UE. For emulated settings, however, each emulator instance can be paired to a unique instance of SIMURAI, allowing for easy scaling. The main roadblock to scaling emulated fuzzing to arbitrary UEs is FirmWire support and the need to create a USIM peripheral for the targeted hardware platform. This requires a significant amount of manual engineering and reverse engineering efforts. Nevertheless, as shown in Table 3, a single implementation is likely to cover multiple generations of UEs from a given vendor.

Realism of Presented Attacks. In our experiments, we show two example attacker models leveraging hostile SIMs. Attackers with physical access can use an interposer to inject an arbitrary payload into the communication between the phone and the original SIM card. Rogue carriers can use their ability to update SIM cards remotely to install malicious SIM card applets and launch the attack from there.

We cannot assess the real-world possibility of obtaining physical access to relevant phones or access to remote SIM management. However, previous incidents demonstrated misuse of telecom infrastructure for attacks against subscribers [55, 59] and the *technical* challenge of programming an interposer for physical access is relatively low. In our experiments, SIMURAI allowed for quick prototyping of proof-of-concept attack implementations for both scenarios, showcasing the threats posed by hostile SIMs.

Additional Proactive Attack Surface. During our fuzzing and dissection of proactive commands, we found two additional curiosities with security relevance. First, the standard explicitly defines an OPEN BROWSER proactive command, which would attempt to open a browser visiting a specified URL. We found this proactive command to be supported by most modern COTS UEs, with the caveat that the user would be asked for confirmation to open the browser. However, the text in the notification asking for confirmation is completely SIM-controlled. Given that modern smartphone exploit chains often require victims to visit attacker-controlled websites in the process, this feature could provide an additional 1-click exploit attack surface.

Second, the standard also defines a RUN AT proactive command which would directly execute a SIM-specified AT command on the UE. Previous research has shown that attacker-controlled AT commands can have severe consequences (e. g., lock screen bypass [64] or flashing of compromised firmware [53]). Although none of the UEs we tested reported support for this proactive command in their terminal profiles, we still found the code paths handling this command in the baseband firmware images we reverse engineered. Even if this code is not reached under normal operation, we argue that its presence introduces an unnecessary attack surface which could be used by attackers during exploitation. Given that the UEs do not report support for this feature, we believe that debloating according parts of the baseband firmware to remove unsupported parts would be a viable step to improve its overall security, as discussed in Section 7.

Limitations. The SWICC file system does not model the ICC file system exactly. SWICC considers File IDentifiers (FIDs) globally unique. Unfortunately, we later observed that due to FID reuse between DF.GSM and ADF.USIM, this prevented SIMURAI from supporting both DF.GSM and ADF.USIM at the same time. Another limitation is that SIMURAI is not designed to be a replacement for production SIMs, as it lacks security features like file access conditions.

The core design of SIMURAI also relies on a maximum message length aligned with regular APDUs, this makes it difficult to extend the design to support extended APDUs, i. e., APDU messages with a maximum length of around 65k bytes. For a similar reason, we believe that implementing additional transmission protocols would also be challenging.

9 Related Work

Cellular Security. Multiple studies focus on cellular standards, either by studying the standard itself or the implementation of its procedures. Some authors model the cellular standard and compare that with models inferred from an implementation, showing implementation issues and deviations from security goals [9, 23, 24, 29, 32, 34, 52]. Hussain et al. identify that many previously discovered flaws are based on an insecure connection establishment procedure [56]. In an overview study, Rupprecht et al. analyze the various protocol weaknesses and identify several root causes [58].

Software SIM. A notable development in simulation of smart cards is the VSmartCard project [43], which provides an implementation of a generic ICC. In that regard, it is similar to our swICC component. However, we consider swICC to be an improvement as it supports file system persistence and TPDU-level communication, while VSmartCard operates only at the application layer with APDUs. Concurrent to our work, the Onomondo SoftSIM, a software-only SIM implementation, was released [46]. SoftSIM provides a partially overlapping feature set with SWSIM, but primarily targets the needs of commercial IoT vendors rather than security research. vSIM by Kasper & Kuntze et al. [30] is a theoretical software SIM architecture which relies on a trusted platform module (TPM) to achieve security guarantees similar to those offered by a physical SIM card. The authors conclude that a software-only SIM is possible, but they do not provide a publicly available prototype. SIMulator [57] is one notable SIM simulation project that uses a hybrid approach where a real SIM card would process most commands, and only selected commands would be intercepted and handled in software. While this does indeed fulfill the need to selectively manipulate commands, requiring a hardware SIM limits scalability, especially with the fuzzing use case in mind.

SIM-Related Security. To our knowledge, there are only a few academic works in the context of SIM cards. Most related to our work is a study by Jinghao et al. that identifies the issue of unprotected SIM-smartphone communication, and designs an improved access control for SIM cards [66]. While they do identify interposers as potential threats, they consider them a threat to the secrets stored on the SIM card. In contrast, we use them to highlight the risks *towards the baseband*. Related to the capabilities that smartphones expose via binary SMS, Wen et al. propose RILDefender to detect and block SMS attacks in Android's Radio Interface Layer (RIL) [65]. In our case, the harmful payload could not be filtered at the RIL as it comes directly from the SIM.

There are notable contributions at non-academic venues that discuss SIM-related threats. The "Simjacker" analysis exposes multiple on-SIM applets as vulnerable to remote code execution, and shows how this allowed localization of phones [60]. ShadySIM [35, 49] by Koscher and Butler provides a valuable tool for provisioning of applets. We use Simjacker as an example and implement a similar spyware within our SIMURAI framework to evaluate its extensibility. The same author presents an overview of past attacks that used *binary SMS* and calls, for better protection of SIM applets, and network-side filtering [41]. Nohl points out that OTA updates may use weak protection and, among other measures, calls for carriers to filter binary SMS from unknown sources [44]. Burgess reports the use of proactive commands on various carrier applets [7]. In a talk at 35C3, Sesterhenn finds Linux driver vulnerabilities triggered by a smart card [61].

Baseband Fuzzing. Fuzzing work in context of baseband firmware include ARIstoteles [36], LTEFuzz [33], Berserker [54] and 5Ghoul [18]. Besides this, re-hosting [15] is a relatively new approach for security analysis of embedded systems, which enabled fuzzing of emulated baseband firmware as shown with Basesafe [40] and FirmWire [22]. In contrast to SIMURAI, none of these approaches consider the SIM card as an attack vector in their fuzzing setup.

Mobile Ecosystem. Many aspects of cellular network security are defined by non-technical phenomena: Lee et al. find that flaws within customer authentication processes of US-based carriers enable *SIM swapping*, i. e., associating a phone number with a new SIM with the goal of identity fraud [37]. McDonald et al. analyze the issues users face with phone numbers being a de-facto identifier for online services [42].

10 Conclusion

In this paper, we argued for the inclusion of hostile SIMs, as an attack vector, in cellular security threat models. Various scenarios can lead to a compromised SIM, including rogue operators, physical attackers, and vulnerabilities in the SIM itself. To demonstrate the importance of this revised threat model and to facilitate additional research, we design and implement SIMURAI, a first-of-its-kind research platform that provides security analysts with flexible control over SIM card communication.

We integrate SIMURAI in common cellular test bed setups and demonstrated its capabilities for security research: Among others, we showed how SIMURAI enabled us to perform a fuzzing campaign against COTS UE implementations leading to the discovery of two high-severity security vulnerabilities in recent Google smartphones, affecting millions of devices.

Finally, we demonstrated how various attackers could exploit hostile SIMs to trigger the identified vulnerabilities, and we proposed potential mitigations to address these issues.

Coordinated Disclosure

We reported the vulnerabilities identified during our research to Google. These vulnerabilities were assigned CVE-2023-50806 and CVE-2024-27209 with patches released as part of the Google Pixel updates in March 2024.

Acknowledgements

We would like to thank the anonymous reviewers and shepherd for their insightful and constructive comments. We would further like to thank Bedran Karakoc, Daniel Klischies, and Dominik Maier (in no particular order) for their help, comments, and discussion. This research was funded in part by UKRI EP/V000454/1 and supported via an Android Security and PrIvacy REsearch (ASPIRE) Award from Google. The results feed into DSbDtech.

A SIMs: Additional Technical Details

In the following, we provide an additional technical description of the inner workings of SIMs as supplementary material.

A.1 Transmission Protocols

ICCs can offer one or more transmission protocols by advertising them in the Answer-to-Reset (ATR). Every protocol is assigned a unique number called the protocol type T. Three most common types are as follows [26]:

- $T = 0$ offers a half-duplex transmission of characters. This means that only one side may transmit at any time, and that the smallest unit of transmitted data is a byte.
- $T = 1$ offers a half-duplex transmission of blocks. This means that only one side may transmit at any time, and that the smallest unit of transmitted data is a collection of characters, i. e., multiple bytes that form a block frame.
- $T = 15$ indicates that the ATR contains the global interface bytes, i. e., additional properties describing the parameters of the integrated circuit of the card. While not a protocol, it shows that the protocol type must not only refer to communication protocols.

SIMs support protocols $T \in \{0, 1, 15\}$, but $T = 0$ and $T = 15$ are often the only two that get implemented. We tested 10 different commercial SIMs, from different vendors and dates of production, and have not found a single card offering $T = 1$.

A.2 Communication Protocol

SIMs have one electrical contact dedicated to I/O (as shown in Figure 9). This single wire acts as the physical layer for the half-duplex data transfer protocol used for all terminal-to-SIM communications.

TPDUs are used to transfer APDUs but contrary to contemporary computer networks, layers of the network do not wrap the payload in progressively more headers to achieve encapsulation. Instead, the transmission layer introduces procedure bytes, i. e., a type of acknowledgement, that controls all data transmissions [12, 26].

All TPDUs sent to the card are mapped to C-APDUs that are structured as shown in Table 1. Field P3 of the TPDU is particularly important as it encodes fields L_c and L_e of the C-APDU, i. e., it indicates lengths of command and response payloads.

Once a TPDU is received, the ICC creates a R-APDU per Table 1 where the data is optional and the status word conveys success, errors, or warnings concerning the processing of the command [27]. The R-APDU is sent as-is, directly to the terminal (no transmission-layer interference).

The ICC receives TPDUs in one or more 2-step exchanges; it is done this way to ensure that both sides know how many bytes will be sent over the data line, and to minimize the amount of exchanged data if the card would like to reject or process a command early. In step one, the interface transmits a header to the ICC, and in step two, the ICC responds with a procedure byte. The value of the procedure byte dictates how the data exchange will proceed; the possible values are as follows [26]:

- **ACK** (= INS of the TPDU), indicates that all remaining data bytes shall be sent.
- **ACK** $\oplus$ `0xFF` (= INS $\oplus$ `0xFF`), indicates that the next (one) data byte shall be sent.
- **NULL**, indicates that no more data shall be sent.
- **SW1** followed by **SW2** completes the command.

Depending on the procedure byte sent, the interface will proceed by: Sending the remaining chunks of the command data, sending another command header, or waiting for a response. In any case, after every chunk transmitted by the interface, the ICC must respond with a procedure byte until it receives all TPDU data. Once a TPDU is received, the ICC forms an R-APDU and sends it back to the interface in a single message. Crucially, an application layer message may require multiple TPDUs to get fully transmitted, therefore the intermediate R-APDUs are considered part of the transmission layer; only the final R-APDU will be considered as a response to the C-APDU.

A.3 Commands

The communication protocol is designed such that every exchange forms a C-RP out of a C-APDU and an R-APDU. For any C-RP, the fields of the R-APDU are always interpreted in the same way, conversely, the C-APDU is interpreted in one of four ways, depending on the INS and CLA fields contained in the command header [12, 26, 27].

Every instruction, in every command class, may take a length N_c of data as input, and offer N_e data bytes as output. N_c and N_e are encoded by fields L_c and L_e of the C-APDU respectively; four possible command encodings dictate the absence or presence of L values:

Table 4: Fields of a TPDU message for protocol $T = 0$.

Command			
	Field	**Description**	**Size in Bytes**
Header	CLA	Command Class	1
	INS	Instruction	1
	P1	Parameter 1	1
	P2	Parameter 2	1
	P3	Parameter 3	1
Data		Command Data	$0 \leq n \leq 255$

Response			
		Response Data	$0 \leq N_e \leq 256$
	SW1	Status word byte one	1
	SW2	Status word byte two	1

1. L_e and L_c are absent, hence $N_e = 0$ and $N_c = 0$.
2. L_e is present and L_c is absent, hence $N_e > 0$ and $N_c = 0$.
3. L_c is present and L_e is absent, hence $N_c > 0$ and $N_e = 0$.
4. L_c and L_e are present, hence $N_c > 0$ and $N_e > 0$.

Values of N are encoded by L according to Equation 1 and Equation 2. Furthermore, $L_c = 0$ is reserved for the extended APDU, therefore it is undefined within SWICC or assumed empty ($N_c = 0$) [27].

$$N_e = \begin{cases} L_e & \text{if } 0 < L_e \leq 255 \\ 256 & \text{if } L_e = 0 \end{cases} \quad (1)$$

$$N_c = \begin{cases} L_c & \text{if } 0 < L_c \leq 255 \end{cases} \quad (2)$$

A.4 Mapping APDUs to TPDUs

A C-APDU is transmitted using one or more TPDUs, therefore, it is important to describe how each case of the C-APDU is mapped to TPDUs messages.

Case 1 requires a single TPDU header with P3 = `0x00`. No payload is present in neither the C-APDU nor R-APDU. The final status word (R-APDU) is sent in response to the first TPDU.

Case 2 requires a TPDU header with P3 = `0x00`, then depending on L_e, the card will respond with a status word that conveys the expected value of P3, or a response containing 256 bytes and a status word. In the first subcase, another TPDU is sent with P3 = L_e, and only then, the card will send the desired response.

Case 3 Transmission of a case 3 C-APDU with P3 = L_c, requires the use of the ACK procedure. The header must first be acknowledged before the command data can be transmitted to the card.

Case 4 In order to transmit a case 4 C-APDU, the command chaining mechanism is necessary. Command chaining works by first sending a case 3 C-APDU, to which the card will respond with the status word: SW1 = `0x61` and SW2 = L_e, then sending one or more case 2 C-APDUs (with INS = GET RESPONSE = `0xC0`, P1 = `0x00`, P2 = `0x00`, and P3 = L_e) that retrieve the L_e bytes from the card. This mechanism may also be used in cases where the response data is oversized, therefore does not fit in a single R-APDU [12, 27].

A.5 Java Card

SAT is an optional extension of SIMs, that allows installation of applications on the card. These applications are often packaged into cardlets. Every cardlet is constrained to a very narrow subset of the Java language where even string literals are forbidden. This is done so that cards can contain a stripped-down version of a Java Virtual Machine (JVM) for executing the application when certain APDUs are received. The COS provides standard and proprietary APIs for the application to use when interacting with card hardware and software [2, 4, 14, 19].

B SIM Interposer

Figure 10 shows a commercially available interposer for bypassing iPhone carrier locks.

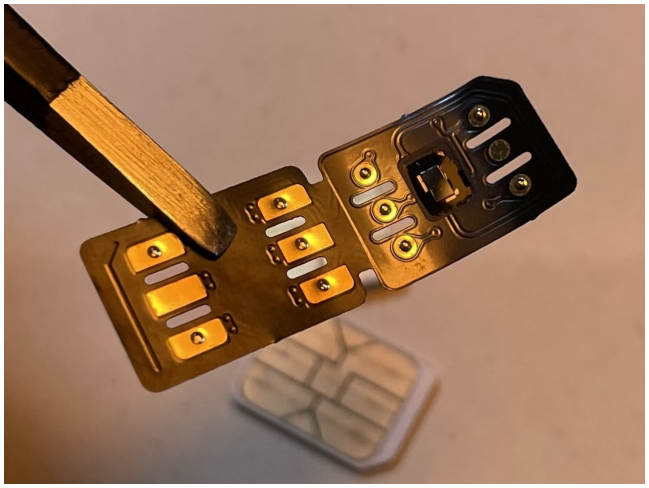

Figure 10: An interposer; a very thin, flexible smart card with contacts on both sides. It is typically placed between a SIM and the phone to intercept and rewrite communications.

Finding Traceability Attacks in the Bluetooth Low Energy Specification and Its Implementations

Jianliang Wu[1,2], Patrick Traynor[3], Dongyan Xu[1], Dave (Jing) Tian[1], and Antonio Bianchi[1]

Abstract

Bluetooth Low Energy (BLE) provides an efficient and convenient means for connecting a wide range of devices and peripherals. While its designers attempted to make tracking devices difficult through the use of MAC address randomization, a comprehensive analysis of the untraceability for the entire BLE protocol has not previously been conducted. In this paper, we create a formal model for BLE untraceability to reason about additional ways in which the specification allows for user tracking. Our model, implemented using ProVerif, transforms the untraceability problem into a reachability problem, and uncovers four previously unknown issues, namely IRK (Identity Resolving Key) reuse, BD_ADDR (MAC Address of Bluetooth Classic) reuse, CSRK (Connection Signature Resolving Key) reuse, and ID_ADDR (Identity Address) reuse, enabling eight passive or active tracking attacks against BLE. We then build another formal model using Diff-Equivalence (DE) as a comparison to our reachability model. Our evaluation of the two models demonstrates the soundness of our reachability model, whereas the DE model is neither sound nor complete. We further confirm these vulnerabilities in 13 different devices, ranging from embedded systems to laptop computers, with each device having at least 2 of the 4 issues. We finally provide mitigations for both developers and end users. In so doing, we demonstrate that BLE systems remain trackable under several common scenarios.

1 Introduction

Bluetooth Low Energy (BLE) wirelessly connects billions of devices. While BLE makes connecting devices with a range of user interfaces (e.g., from headless systems such as speakers to mobile phones and laptop computers) simple, the protocol's designers understood that such connectivity could make device owners traceable. To avoid this problem, BLE MAC addresses are randomly generated and periodically changed. In practice, however, this defensive measure has been broken repeatedly due to inconsistent adherence to the standard or poor implementations [13, 14, 22, 25, 33].

While MAC address tracking for BLE users has been well studied, a systematic analysis of traceability across the entire protocol has not yet been performed. Accordingly, this paper conducts the first comprehensive analysis of untraceability for BLE. To begin, we define untraceability as the inability of a passive or active adversary to use specification-defined[1], protocol-level unique identifiers to de-anonymize/track a device. From this, we build a formal model by abstracting two operating roles (i.e., central and peripheral[2]), three relations between a tracker and a target device (i.e., the target device has *never* paired, is now *paired*, and was paired but is *unpaired* with the tracker), and five communication scenarios (i.e., pairing, scanning, connection establishment, encrypted communication, and authenticated communication). We then follow each potential identifier as it passes through the protocol to determine whether it represents a traceable attribute. As such, our model covers all connectivity scenarios across the entire lifecycle of BLE communications while removing impossible conditions (i.e., false positives).

In so doing, we make the following contributions:

- **First Comprehensive Study of BLE Untraceability:** We develop a formal model for BLE untraceability that covers all communication modes (e.g., advertising/scanning/encrypted communication, etc.) and all roles. We then implement our model in ProVerif [9] by transforming the untraceability problem into a reachability problem, and identify four design limitations in the specifications, namely IRK reuse, BD_ADDR reuse, CSRK reuse, and ID_ADDR reuse, enabling a total of eight different tracking attacks against BLE. Compared with a diff-equivalence model, our reachability model is sound, as we will discuss in Section 3. Our model is publicly available [3].
- **Confirm Vulnerabilities in Real Devices:** We validate

[1]This paper is based on Bluetooth version 5.3. The findings and mitigations in this paper may also be applicable to other versions.

[2]Central and peripheral correspond to the now deprecated "master" and "slave" roles previously used in the protocol.

our findings using 13 different BLE-enabled devices (ranging from embedded devices and cell phones to laptop computers) and demonstrate that all such implementations contain at least two of these vulnerabilities. Externally, Google rated two of our vulnerabilities as severe, assigned two CVEs, and awarded us a bug bounty.

- **Propose Mitigations:** We have reported our discoveries to the Bluetooth Special Interest Group (SIG), which is responsible for maintaining the standard, and proposed possible updates to the standard. While the SIG considers longer-term fixes, we also discuss several steps that developers and end-users can take to limit their exposure to these vulnerabilities.

A comprehensive understanding of how BLE devices can be tracked is crucial. Especially, the advent of systems like COVID-19 Exposure Notification [28] means that some connectivity scenarios previously considered unlikely (e.g., regularly connecting with devices owned by someone else) are now both practical and can result in a BLE device being tracked. We provide two videos [1, 2] to show how an adversary can track a target device through our newly disclosed vulnerabilities.

2 Background

Bluetooth Classic (BC) uses a fixed Media Access Control (MAC) address, allowing a tracker to trivially track the device by passively sniffing the traffic [18, 45]. Bluetooth Low Energy (BLE) introduces a privacy feature based on the resolvable MAC address mechanism to provide anonymity and prevent naïve device tracking based on a fixed MAC address. The core idea of this feature is that a BLE device uses Resolvable Private MAC Addresses (RPAs) [11, p.2668] generated based on an Identity Resolving Key (IRK). A BLE device must also have an Identity Address (ID_ADDR) [11, p.2666] representing its unique identity. During pairing, the BLE device uses the key distribution to share its IRK and ID_ADDR with a peer device so that the peer device can associate the IRK with the ID_ADDR. By switching to different RPAs, the BLE device's MAC address appears random to a tracker, while the paired peer device can use the IRK associated with the BLE device's ID_ADDR to *resolve* the RPA and recognize the BLE device. Note that if the BLE device enables this privacy feature, it should not include its ID_ADDR in any of its messages [11, p.275] to avoid naïve tracking.

2.1 BLE Privacy Feature

To enable the resolvable MAC address feature, two procedures, RPA generation and resolution, are needed. A target device generates RPAs based on an IRK and uses these RPAs to gain anonymity. Meanwhile, a paired peer device can use the same IRK to resolve the RPAs and identify the target device to guarantee general communication with the target device.

Figure 1: Format of a Resolvable Private Address (RPA). The hash part (h) is generated by a hash function using the random part (r) and a secret key (IRK).

RPA generation. An RPA has two major parts, a random part (`r`) and a hash part (`h`), as shown in Figure 1. To generate a valid RPA, the device first randomly generates `r`. Then the device calculates `h` based on `r` and the IRK using the formula: $h = ah(IRK, 01||r)$, where $ah()$ is a hash function defined in the specification [11, p.1559] based on the AES-128 block cipher. Lastly, a new RPA is generated as `rpa=01||r||h`.

RPA resolution. When the peer device receives an RPA, it extracts `r` and `h` from the RPA. Then, the peer device calculates a `localh` value following the same formula based on `r` and the stored IRK. Lastly, the peer device compares `localh` with `h`. If they match, the peer device resolves the target device's RPA successfully and thus identifies the target device. The device repeats the above steps for each of the IRKs if it has multiple IRKs stored. If `localh` is different from `h` after trying with all stored IRKs, the peer device cannot resolve the RPA and thus cannot identify the target device.

2.2 Key Distribution and Removal

As mentioned, to enable the privacy feature of BLE and use RPAs, a device must have an IRK to generate its RPAs. To ensure a paired peer device can resolve the RPAs and recognize the BLE device, the BLE device shall distribute its IRK to the peer device. The key distribution is performed through the *pairing* procedure, during which two devices establish a mutually trusted relationship. Besides the IRK, the two devices may also generate or exchange other keys, including the *Long-Term Key (LTK)*, which is used for encryption, and the *Connection Signature Resolving Key (CSRK)*, which is used for signing messages. After pairing, the two devices can recognize each other when using RPAs as well as perform encrypted communication using LTK.

For example, consider two devices, Alice and Bob, that have never been paired. If they want to communicate, they pair with each other to establish a trusted relationship. During pairing, Alice stores the keys received from Bob so that she can reuse them (e.g., using the LTK for encryption) when she communicates with Bob again. Similarly, Bob also stores Alice's keys. If Alice does not communicate with Bob anymore, she unpairs from (or forgets) Bob to terminate the trust with Bob. When Alice unpairs from Bob, Alice removes all keys related to Bob. Since the unpairing depends on Alice (i.e., the initiating party) and does not involve any communication with Bob, Bob is unaware of the unpairing and still stores Alice's keys after the

unpairing. Nothing prevents a peer device from keeping these keys after unpairing.

2.3 Threat Model

We define an adversary, which we will refer to as a *tracker*, that intends to de-anonymize and track a *target* device using the protocol-level information of BLE.

To be comprehensive, we consider a target BLE device supporting both the central role (e.g., smartphones) and the peripheral role (e.g., smart locks [17]). Additionally, we assume the target device supports all communication scenarios defined in the specification for each role, such as encrypted communication. The target device can be a BLE-only device (e.g., a smart lock) or a BC/BLE dual-stack device (e.g., a smartphone). For a dual-stack device, we assume it does not initiate BC communications since prior research [18, 45] has shown that a BC device can be tracked. In other words, we assume the BC stack is not in use and is in the non-discoverable mode [11, p.1258] on a BC/BLE dual-stack device. Note that a BC device can still respond to requests containing its MAC address (i.e., paging requests [11, p.257]). Likewise, we assume the target device always uses RPAs and does not use a fixed MAC address to prevent naïve tracking by monitoring messages carrying its MAC address. This configuration is the default setting on modern mobile devices, such as iPhones and Android phones (e.g., Google Pixels).

For trackers, we consider both passive and active trackers. A passive tracker is an observer who can only eavesdrop on the BLE channel, while an active tracker interacts with the target device following the specification. We assume that the tracker can deploy one or more devices to track the physical location of the target device, which is a common setting for tracking attacks [22, 25, 33] and real-world tracking scenarios, such as indoor positioning [36, 37, 40].

3 Research Questions

Systematically studying BLE untraceability at the protocol level requires answering fundamental questions (Q) regarding BLE traceability and exposes unique challenges (C). Solutions to these challenges will pave the way to a better understanding of BLE untraceability and privacy.

Q1. Is a BLE device traceable? Existing research [22, 25, 33] considered a device as traceable if and only if its messages carry a fixed MAC address. As such, it is unclear if a BLE device is still traceable when it changes its MAC addresses by enabling the BLE privacy feature. In fact, besides the tracking based on the MAC address, nothing guarantees that there are no other ways to track a privacy feature-enabled BLE device. For this reason, **(C1) without a clear definition of BLE traceability (or untraceability), it is impossible to determine whether a BLE device is traceable or not.**

Approach: Instead of considering only the MAC address as a device's identifier, we consider a piece of information a privacy-sensitive identifier if it is unique per device. After determining these identifiers, we consider a device trackable not only if a tracker can directly observe messages containing any identifier but also if a tracker can identify messages that are indirectly generated using any identifier. In terms of the tracker, we consider two scenarios where a tracker can track a target device, either passively or actively. We define a BLE device as untraceable if neither a passive tracker nor an active tracker can identify and track this BLE device by linking any messages it sends to any of its identifiers. We will present more details in Section 4.1.

Q2. In which communication scenario can a BLE device be tracked? A BLE device may support several communication scenarios, such as encrypted and authenticated communication. In addition, a BLE device can act as different roles behaving differently (i.e., the central role vs. the peripheral role). Moreover, the specification allows various implementation choices. For instance, a BLE stack can use either a public address or a random MAC address as a device's ID_ADDR. Ideally, a BLE device should be untraceable in all BLE communication scenarios no matter what role it is in. For this reason, **(C2) the complexity of BLE communication imposes challenges for comprehensively and systematically studying BLE untraceability.**

Approach: To address this challenge, we use formal analysis techniques and build a symbolic model by abstracting five communication scenarios covering the whole BLE communication lifecycle. In each communication scenario, we model a target BLE device with two different roles, the central role and the peripheral role. Moreover, we explore all three possible relations between a target device and a tracker. With our communication and relation abstractions, our model comprehensively covers all the scenarios of a target device defined in the specification. We will present more details in Section 4.2.

Q3. How do we formally verify BLE untraceability? Formal untraceability usually refers to the notion of "strong unlinkability" [5], which is defined based on Process Equivalence (PE). However, since PE involves relations between traces rather than one single trace, automatically verifying PE is challenging [7, 8, 26, 31]. To avoid the challenges posed by proving PE, existing work defined untraceability in an alternative way. They abstract untraceability into three conditions that can be represented by reachability properties [7, 30]. This definition improves the PE-based definition in several ways. However, these three conditions are themselves difficult to verify, and they require either restriction to a narrow set of protocols [30] or providing multiple manually-defined lemmas [7] (using a theorem prover such as Tamarin [35]). In order to automate untraceability verification, other work [21, 23, 46] adopted a definition of untraceability by using Diff-Equivalence (DE) properties [24], which are another type of reachability properties. If a protocol's DE

properties hold, it means that among different executions of the protocol, the message they exchange is the only difference. Though DE-based properties can be automatically verified, this approach may lead to false attacks [10, p.124] [44, p.129]. In Section 5.2, we will further show that modeling BLE untraceability based on DE properties can lead to both false attacks and missed attacks. All these reasons lead to: **(C3) verifying untraceability based on DE properties may lead to false attacks**.

Approach: In this paper, we consider a protocol as untraceable if a tracker cannot distinguish two instances of the protocol she interacts with. Instead of using DE properties to verify untraceability, we explicitly model the tracker's capabilities (e.g., injecting probing messages) and the Bluetooth protocol's states, and transform the untraceability of a BLE device into a reachability problem that can be proved without false attacks. In this way, we can use existing verification tools (e.g., ProVerif or Tamarin) to automatically verify the untraceability of a BLE device, as a sound technique for finding attacks. Specifically, we first extract five pieces of information from the specification as the device's identifiers. Then, we build tracker modules corresponding to each identifier to check whether a received message can be linked to the corresponding identifier of a target device. Lastly, we model a device as it emits a *receiving event* each time it receives a message and emits a *sending event* each time it sends a message. In the tracker modules, the tracker emits a sending event when sending a probing message and emits a receiving event when receiving a message that can be linked to an identifier. In this way, the untraceability of a device can be represented by the *reachability of corresponding event combinations*.

Note that our definition of untraceability is narrower than the DE-based definition, which is narrower than the PE-based definition that is similar to the three-condition-based definition. In theory, the DE-based, the PE-based, and the three-condition-based definitions can capture the attacks discovered based on our definition. Nonetheless, using a more specific definition, our approach overcomes the challenges of the complexity or inability to automate verification in the three-condition-based and the PE-based definitions and the inclusion of false attacks in the DE-based definition. More details can be found in Section 4.3.

4 Model Design and Implementation

In this section, we present our definition of BLE untraceability at the protocol level followed by the design and implementation of our model to verify the BLE untraceability. We implement our model using ProVerif [9] due to its modeling features, such as the *event* feature (which we will introduce in detail in Section 4.3.3). We believe other symbolic reasoning tools, such as Tamarin [35], are also suitable here.

4.1 Definition of BLE Untraceability

We consider BLE untraceability regarding all protocol-level information that can be used as a device's unique identifiers. Furthermore, we call the messages that can be linked to identifiers *linked messages* (LKDmsgs) and others *irrelevant messages* (IRRmsgs). A tracker can link a message to an identifier if the message *contains* this identifier or the tracker can *derive* the identifier from the message. For example, one BLE device may use RPAs for advertising. The advertisement is a LKDmsg of the corresponding IRK since the RPA contained in the advertisement is derived from this IRK.

We consider both passive and active trackers and summarize the following two tracking scenarios:

T1: (Traceability in Passive Tracking) When the target device is communicating with another BLE device, a passive tracker can observe LKDmsgs.

T2: (Traceability in Active Tracking) When the target device is not communicating with another BLE device: 1) an active tracker probes the target device with LKDmsgs and receives any replying messages; 2) an active tracker probes the target device with IRRmsgs and receives LKDmsgs.

Accordingly, we define a BLE device as *untraceable*, if **neither a passive tracker nor an active tracker can identify and track this BLE device by linking any messages to any of the device's identifiers (both T1 and T2 are false)**.

We use K, B, Δ, and A to represent all communication scenarios, roles of the target device, the relations between the target device and the tracker, and the tracker's capabilities, respectively. One BLE communication scenario of the target device θ can be represented by a three-tuple $\langle \kappa, \beta, \delta \rangle$, where $\kappa \in K, \beta \in B, \delta \in \Delta$. We use $untrace\_passive(\theta, \alpha)$ and $untrace\_active(\theta, \alpha)$, where $\alpha \in A$, to denote that the target device is untraceable when it performs communication θ with the tracker α in the passive tracker and active tracker scenarios, respectively. Therefore, whether a BLE device is untraceable can be represented with the following formula:

$$\begin{aligned} &\forall \kappa \in K, \forall \beta \in B, \forall \delta \in \Delta, \forall \alpha \in A, \\ &untrace\_passive(\langle \kappa, \beta, \delta \rangle, \alpha) \wedge untrace\_active(\langle \kappa, \beta, \delta \rangle, \alpha) \end{aligned} \tag{1}$$

4.2 BLE Communication Abstraction

According to the specification, we abstract BLE communication into five scenarios, namely *pairing* (PAIR), *scanning* (SCAN), *connection establishment* (CE), *encrypted communication* (ENCC), and *authenticated communication* (AUTHC) covering all BLE communication scenarios, as shown in Figure 2. If the BLE device is BC/BLE dual stack, we also add BC *paging* as an extra scenario, since a BC device can still perform paging, as explained in Section 2.3.

In addition, we cover all possible relations between two devices during the entire lifecycle of their BLE communication. Specifically, we assume the target device may have three relations with a tracker: 1. The target device has never paired with

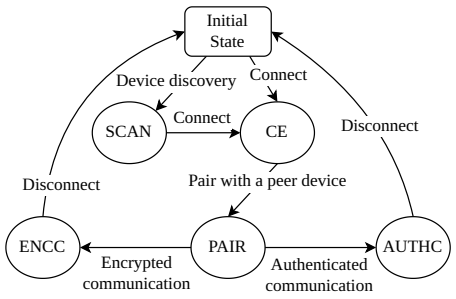

Figure 2: Transitions between the five communication scenarios in the lifecycle of a BLE communication.

a tracker (*never*); 2. The target device is currently paired with the tracker (*paired*); 3. The target device was paired with the tracker but is unpaired now (*unpaired*). Our implementation can be found in our code repository [3].

Pairing (PAIR). Since the security of the pairing procedure is not the focus of this paper and has been explored in prior work [48], we use the out-of-band (OOB) association model in our model and assume that the OOB channel is secure.

In the last step of pairing, the target device shares its IRKs, CSRKs, and ID_ADDRs with a peer device. The LTK is derived by the two devices individually, and thus not shared. As we will discuss in Section 4.3.1, it is not clear in the specification whether a device should use a per-pairing or per-device CSRK. In our model, we consider both cases. In the per-device design, the target device uses one randomly generated CSRK for all pairings, while the target device randomly generates a CSRK for each pairing in the per-pairing design. We also model both the per-device and the per-pairing designs for IRK.

The target device and the peer device are implemented as *process macros* in ProVerif communicating through an open channel. The LTKs, IRKs, CSRKs, and ID_ADDRs are stored in corresponding *tables* (databases for storing data in ProVerif) after the key exchange so that they can be reused in other communication scenarios.

Scanning (SCAN). The scanning starts with a peripheral device broadcasting advertising messages containing its MAC address. Upon receiving the advertising message, a central device sends a scan request message containing the central device's MAC address. Finally, the peripheral device replies with a scan response. All the target device's MAC addresses in the messages are RPAs, as discussed in Section 2.3.

The target device and peer device are also implemented as *process macros*. The target device retrieves its IRK from the IRK *table* to generate RPAs. Since the messages are sent over the air, all messages are exchanged via an open channel.

Connection Establishment (CE). Connection establishment also starts with a peripheral device advertising. Once receiving the advertising message, a central device sends a connection request message containing its MAC address to a peripheral device to establish a connection. Like scanning, the target device also uses RPAs in its messages and retrieves its IRK from the IRK *table* to generate RPAs. The two devices are also implemented as *process macros* and exchange messages via an open channel.

Encrypted Communication (ENCC). After the establishment of a connection, if the upper-layer application requires encryption to guarantee message confidentiality and authenticity, two devices can start encrypted communication. The two devices first derive a session key and a session nonce from two exchanged nonces and the LTK. Then, they encrypt messages using the session key and session nonce and transmit. To generalize the message transmission, we model the central device sending a request message and the peripheral device replying with a response message. The two devices are implemented as *process macros*, and they obtain their LTKs from corresponding LTK *tables* where the LTKs are stored. All nonces and messages are exchanged over the air, and thus modeled as exchanged via an open channel.

Authenticated Communication (AUTHC). After connection establishment, besides ENCC, two devices can also perform authenticated communication to provide authenticity guarantees (without confidentiality). The central device retrieves its CSRK from the CSRK *table* and generates a signature of its message. Then, the central device appends the signature to the message and sends it to the peripheral device. Finally, the peripheral device retrieves the central device's CSRK from the corresponding *table* and verifies the signature. Both devices are implemented as *process macros*, and the authenticated message is sent via an open channel.

Paging (PAGE, BC/BLE only). In the non-discoverable mode, a BC/BLE dual-stack target device does not respond to BC inquiries, but it still responds to BC page requests [11, p.1258]. If the target device receives a page request that contains its BD_ADDR, the target device replies with a page response. Paging on the target device is also implemented as *process macros*. Since the page request and page response are sent over the air, we model that these messages are exchanged via an open channel.

4.3 Verification of BLE Untraceability

To verify BLE untraceability, we first extract all protocol-level information that can be used as a device's unique identifiers (Section 4.3.1). Then, we transform the untraceability of a BLE device into reachability properties by modeling a tracker's capabilities (Section 4.3.2) and representing untraceability as a reachability problem (Section 4.3.3). In this way, we can verify BLE untraceability using existing tools without worrying about false attacks, as we will explain in Section 5.2.

4.3.1 BLE Protocol-Level Identifiers

We systematically study the specification by examining all protocols that must be implemented by a BLE device (i.e., the BLE link layer [11, p.2653], the attribute protocol [11,

Table 1: Protocol-level identifiers of a BLE device and their corresponding major properties. Per-device: a device uses the same value in different pairings. Per-pairing: a device uses different values in different pairings.

Name	Value	Spec. Rec.	Type	Usage
PK	Public Key. Randomly generated	Per-pairing	Short-term	Calculate Diffie-Hellman key
LTK	Long-Term Key. Derived from exchanged values of the two pairing BLE devices, e.g., MAC addresses and nonces	Per-pairing	Short-term	Derive a session key that is used for encryption
IRK	Identity Resolving Key. Randomly generated or assigned during manufacturing [11, p.1588]	Per-device	Long-term	Generate and resolve RPAs
CSRK	Connection Signature Resolving Key. Randomly generated or assigned during manufacturing [11, p.1588]	Per-pairing/ Per-device	Short-term/ Long-term	Generate and verify signatures for authenticated communication
ID_ADDR	Identity Address. Public address or static random address	Per-device	Long-term	Device identity

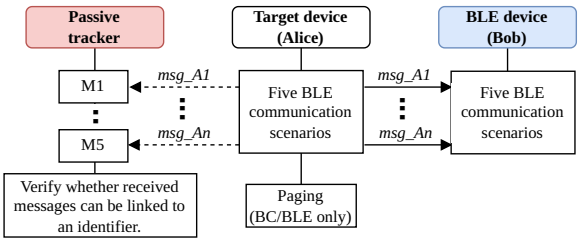

Figure 3: Illustration of the five passive tracker modules (M1-M5) in our model.

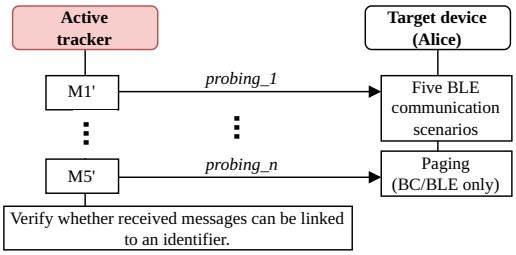

Figure 4: Illustration of the five active tracker modules (M1'-M5') in our model.

p.1406], the generic attribute profile [11, p.1464], and the security manager protocol [11, p.1549]). Based on this study, we extract five pieces of information that can be an identifier of a BLE device due to their uniqueness, as listed in Table 1. We categorize the identifiers into two types, i.e., long-term and short-term. The long-term identifiers are permanent or valid until a device revokes them, while the short-term ones are one-time identifiers or identifiers valid per-pairing. Note that all these identifiers will be sent to a paired peer device during pairing.

As the table shows, some identifiers are supposed to be unique per-pairing while others are per-device. Particularly, the specification recommends a BLE device changing its Public Key (PK) after every pairing (per-pairing) [11, p.974]. Since the nonces used to derive the Long-Term Key (LTK) are different in each pairing, the LTK should also change in each pairing (per-pairing). Unlike the PK and LTK, the specification [11, p.1622] states that, "The distributed IRK shall be the same for all devices it is distributed to", which indicates that a device should distribute the same IRK to all devices it pairs with (per-device). The Connection Signature Resolving Key (CSRK) is used to support sending authenticated data over an unencrypted connection [11, p.274]. It is not clear in the specification whether the CSRK should be per-pairing or per-device. We interpret this ambiguity in the specification as both are allowed. Finally, the ID_ADDR, which represents a device's identity, can be either a public address [11, p.2666] or a static random address [11, p.2666]. In a BC/BLE dual-stack device, the public address is also the MAC address of BC (BD_ADDR) [11, p.2122].

4.3.2 Tracker Modeling

Figure 3 and Figure 4 illustrate the overall design of the tracker. We design the tracker following the generic passive and active trackers modeling and offering different tracker instantiations to be plugged in. Specifically, we instantiate one tracker module for each identifier (M1-M5 and M1'-M5' in Figure 3 and Figure 4 respectively). Each tracker module follows the usage of the corresponding identifier according to the BLE specification when checking whether a received message is a LKDmsg of the identifier. We design five tracker modules corresponding to the five identifiers. Each module comprehensively covers all specification-defined ways to check whether a message is a LKDmsg of an identifier. These five modules are adjusted accordingly in the passive and active tracker scenarios and when the target device acts as the central role and the peripheral role, resulting in 20 (5x2x2) tracker modules in total. We now present the detailed design of each of the tracker modules. Our implementation can be found in our code repository [3].

PK tracker module. According to the specification [11, p.1630], a device's PK is shared in plaintext and only used to calculate the Diffie-Hellman key during pairing. Therefore, this tracker module checks whether an eavesdropped or received message is a LKDmsg of the target device's PK by checking whether they are equal.

LTK tracker module. The only use of an LTK is to derive a session key for encrypting the data transmitted in ENCC. Accordingly, the LTK tracker module verifies whether a received message is a LKDmsg of the target device's LTK by trying to derive a session key from the LTK and to decrypt this message using the session key. A message is a LKDmsg of the LTK if this message can be successfully decrypted with the derived session key.

IRK tracker module. The specification uses the IRK to generate RPAs and allows for a distribution of the encrypted IRK to a peer device during pairing. Accordingly, the IRK tracker module leverages two ways to verify whether a received message is a LKDmsg of the target device's IRK. First,

for messages that contain RPAs, this tracker module tries to resolve the RPA with the target device's IRK. The message is a LKDmsg of the IRK if the RPA can be resolved. Second, for encrypted messages, our module tries to decrypt the message and check whether the decrypted message is equal to the IRK.

CSRK tracker module. Like IRK, the specification defines two ways to use the CSRK. The first one is to generate a signature of a message during the authenticated communication, and the second one is to distribute the encrypted CSRK to a peer device during pairing. Accordingly, our module verifies the signature of a message (if a signature is present) using the CSRK. The message is a LKDmsg of the CSRK if the signature verification is successful. Our module also tries to decrypt the message and check whether the decrypted message is equal to the CSRK.

ID_ADDR tracker module. According to the specification, to prevent tracking, a target device should not use its ID_ADDR in any of its messages [11, p.2889]. Therefore, the only usage of ID_ADDR by the target device is to send to a peer device during pairing (protected by encryption when sent over the air). Accordingly, the ID_ADDR tracker module tries to decrypt received over-the-air messages and check whether the decrypted message is equal to the ID_ADDR. As discussed in Section 2.3, if the target device is BC/BLE dual-stack, it can still accept BC page requests. As such, this tracker module also constructs and sends a LKDmsg of the ID_ADDR (BC page request) to probe the target device.

4.3.3 Event-Based Untraceability Representation

In ProVerif, an *event* can be used to mark a specific stage of a protocol without affecting its execution. During the verification, events can be *emitted*. If an event is emitted, it means that all operations *before* this event are executed.

To represent untraceability as a reachability property, in the model of Alice (the target device), Alice emits a sending/receiving event after sending/receiving a message. In the passive tracker model, the tracker emits a receiving event if the received message is a LKDmsg of an identifier. Therefore, T1 can be transformed into the following reachability property in ProVerif:

P1: `query msg: bitstring; event(alice_send(msg)) && event(tracker_receive(msg))`

If and only if **P1** is violated (reachable), both events (`alice_send` and `tracker_receive`) happen in a single trace, meaning that the message sent by Alice can be received by the tracker, and that this message is a LKDmsg of one of Alice's identifiers. Thus, the tracker can track Alice. Accordingly, Alice is untraceable by a passive tracker if **P1** holds.

In the active tracker model, the tracker emits a sending event after sending a probing message and a receiving event if receives a replying message. Therefore, T2 can be transformed into the following reachability property in ProVerif:

P2: `query probe: bitstring, rsp: bitstring; event(tracker_send(probe)) && event(alice_receive(probe)) && event(alice_send(rsp)) && event(tracker_receive(rsp))`

Similarly, **P2** can be violated (reachable), if and only if these four events (`tracker_send`, `alice_receive`, `alice_send`, and `tracker_receive`) happen in one single trace. In this trace, Alice receives a probing message from the tracker and replies with a message received by the tracker. Since either the probing message or the replying message is a LKDmsg of one of Alice's identifiers, the tracker can track Alice. Conversely, if **P2** holds, Alice is untraceable by an active tracker.

Note that **P1** and **P2** can be violated in multiple ways since Alice emits an event for *each* message she sends or receives. To find all violations (all the possible ways to track a BLE device), after a violation is revealed, we disable the corresponding events of Alice and run the verification again until no violations are detected. In summary, by combining the tracker modules (M1-M5 and M1'-M5') and the untraceability transformation (**P1** and **P2**), we can automatically verify the untraceability of a BLE device in a systematic and comprehensive manner.

5 Model Evaluation

To discover potential privacy issues leading to device tracking attacks, we use our model to verify the untraceability of Alice (the target device) by querying the two reachability properties (i.e., **P1** and **P2**). We first verify these two properties in the one-session setting, i.e., each process runs once. If a property holds, we will further verify if it still holds in the two-session setting, i.e., each process runs twice. Note that if a property is violated in the one-session setting, it will also be violated in the two-session setting. Therefore, we do not need to re-verify it in the two-session setting. We will discuss the property verification in the settings of three or more sessions in Section 8. Using our model, we were able to identify four privacy issues that allow a tracker to track Alice if she has been paired with a device under the tracker's control. In this section, we present our verification results corresponding to these privacy issues. Lastly, we build an alternative model attempting to verify the untraceability of Alice using DE (diff-equivalence) properties, and we will show the issues of this alternative modeling approach.

5.1 Identified Privacy Violations

When a violation is detected, ProVerif provides a corresponding attack trace. We first analyze these traces and categorize similar traces into the same attack if, in these traces, the tracker follows the same procedure to conduct the tracking attack. In the same attack, Alice might act as different roles in different communication scenarios. Based on the attacks, we summarize four issues (root causes) that enable these tracking attacks.

Among these attacks, some are straightforward (i.e., Attack 1 and Attack 4) because they do not require extra user

Table 2: Detected privacy violations, their corresponding root causes and affected communication scenarios. 1, 2, 3, and 4: violation caused by Issues 1, 2, 3, and 4, respectively.

actions nor specialized hardware. Others require additional steps due to the extra prerequisite of the attack, such as user actions in Attacks 2, 3, 6, 7, and 8 and a Software-Defined Radio (SDR) in Attack 5. Among the 8 attacks, Attack 4 is expected when we noticed that BD_ADDR is not used in BLE yet shared during pairing in our earlier BLE experiment. Our analysis further concretizes the violation by generating attack traces. Conversely, all the other 7 attacks are discovered by our formal modeling and analysis without any prior hints. In the rest of this section, we will focus on explaining the detected privacy violations listed in Table 2, the corresponding tracking attacks, and the summarized issues causing these violations. The full result of the verification is shown in Table 7 in Appendix B. All the attack traces can be generated using our code [3].

Issue 1: IRK reuse. The violations indicated by 1 in Table 2 are caused by Alice reusing the IRK for different devices she pairs with. Thus, she distributes the same IRK to all devices (Bob and the tracker) she pairs with. Since the IRK is per-device, the same IRK remains valid even after Alice unpairs from the tracker, and Alice still uses this IRK for future connections. Hence, the tracker can use this IRK to identify and track Alice even after Alice unpaired from the tracker. This issue affects both the central role and the peripheral role because both roles can send messages containing RPAs generated using the IRK. Because IRK is a long-term identifier, the attacks (i.e., Attacks 1, 2, and 3) exploiting this issue are valid until the device explicitly revokes it (e.g., reset network configurations or factory reset).

Violations in the Passive column, rows #4, 5, 12, and 13 share a similar trace, representing the same device tracking attack (**Attack 1**). We will elaborate on this attack and provide a concrete tracking scenario based on this attack trace in Section 6.2.1. In this example, we will demonstrate that a tracker can track an Android phone when its COVID-19 Exposure Notifications system is enabled.

The traces of violations in rows #1 and 9 are similar, leading to the same attack (**Attack 2**). As the trace indicates, after Alice unpairs from the tracker, the active tracker can initiate a new pairing with a random BLE device. The tracker can identify this random BLE device as Alice if the received IRK in the new pairing is Alice's IRK, which is obtained during the previous pairing with Alice.

Violations in the Active column, rows #4, 5, and 9 also share a similar trace, resulting in the same attack (**Attack 3**). The trace shows that when Alice is not communicating with Bob, after Alice unpairs from the tracker, the active tracker can send probing advertising messages to Alice. If Alice replies to the advertising messages with either scan request or connection request messages, the tracker can receive these messages. Since Alice's IRK obtained by the tracker is still valid after Alice unpairs from the tracker, the tracker can use this IRK to resolve the RPA in the message and identify Alice. Compared to Attack 1, Attack 2 and Attack 3 are less practical since they require Alice to perform certain actions, such as replying to an advertising message or accepting a new pairing.

Issue 2: BD_ADDR reuse. The issue leading to the violations denoted by 2 in Table 2 is that Alice reuses her public address, which is also her BC's MAC address (BD_ADDR [11, p.2122]) if Alice is BC/BLE dual-stack, as its ID_ADDR in BLE communications. The traces of these two violations are similar, resulting in the same attack (**Attack 4**). We will detail this attack and provide a concrete attack example in Section 6.2.2, where a tracker can track a BC/BLE dual-stack Android phone as long as its Bluetooth is enabled. Since BD_ADDR is a long-term identifier (e.g., even unchangeable on some devices, as we will further demonstrate in Table 5), Attack 4 remains valid until the device changes its BD_ADDR, or even *forever*.

Issue 3: CSRK reuse. The violations indicated by 3 in Table 2 are caused by the design limitation which allows the CSRK to be long-term (i.e., allowing a BLE device to reuse the CSRK when pairing with different devices). In this case, Alice uses the same CSRK for all devices she pairs with. Like IRK, Alice distributes the same CSRK to all devices she pairs with, and this CSRK remains valid after Alice unpairs from the tracker. As a result, the tracker can use this CSRK to identify Alice by verifying the signature in an authenticated message or directly comparing two CSRKs. This issue only affects the central role since only the central role can send authenticated messages [11, p.1511]. Because CSRK can be a long-term identifier, attacks exploiting this issue (i.e., Attacks 5, 6, and 7) are applicable until the device explicitly revokes its CSRK (e.g., reset network configurations or factory reset).

The violation in the Passive column, row #7 shows that after Alice unpairs from the tracker, the passive tracker can still track Alice when she sends authenticated messages to Bob (**Attack 5**). The attack trace suggests that, when Alice sends authenticated messages to Bob, these messages may be eavesdropped by a passive tracker. Since after Alice unpairs

from the tracker, the CSRK stored on the tracker is still valid, the tracker can use this CSRK to verify the signature in the eavesdropped authenticated message. Thus, the tracker can identify Alice if the signature verification is successful. Since Alice sends Bob authenticated messages on general-purpose channels [11, p.2670] with frequency hopping, this attack requires an SDR to sniff the authenticated messages.

The violation in the Active column, row #7 shows that the unpaired active tracker can identify Alice using her CSRK (**Attack 6**). The generated trace indicates that, after unpairing, the active tracker can send probing advertising messages first. If Alice connects to the tracker and sends authenticated messages to the tracker, the tracker can use the same way to verify the signature and identify Alice using her CSRK. Compared to Attack 5, Attack 6 does not require an SDR because Alice directly communicates with the tracker. However, it needs Alice to initiate the connection to the tracker.

The traces detecting violations in rows #2 and 10 are similar, resulting in the same attack (**Attack 7**). After Alice unpairs from the tracker, the active tracker can initiate a new pairing with a BLE device. The tracker can recognize this BLE device as Alice if the received CSRK in the new pairing is the same as Alice's CSRK obtained during the last pairing with Alice. Though Attack 7 does not need an SDR, it requires Alice to approve a new pairing with the tracker.

Issue 4: ID_ADDR reuse. The issue resulting in the violations denoted by 4 in Table 2 is that Alice reuses the ID_ADDR for all devices she pairs with, and this ID_ADDR remains valid after unpairing. These two violations share a similar trace and lead to the same attack (**Attack 8**). As the trace suggests, after Alice unpaired with the tracker, the tracker can proactively initiate a new pairing with random BLE devices and identify a device as Alice if the received ID_ADDR in the new pairing is the same as Alice's. Attack 8 requires Alice to approve a new pairing with the tracker. This issue affects both roles since both roles would distribute the ID_ADDR during pairing. Since ID_ADDR is a long-term identifier (e.g., does not change until resetting network configurations or factory reset), attack 8 is valid until the device explicitly changes its ID_ADDR .

5.2 Comparison with DE-based Model

As discussed in Section 3 and Section 4, verifying BLE untraceability using reachability properties can avoid false attacks identified by existing tools. To better understand the effectiveness of avoiding false attacks, we implement a privacy model of BLE (per-device identifier design) based on DE properties.

In this model, we model the five types of BLE communication and verify the DE properties of the identifiers listed in Table 1. We use the `choice[id,rand_id]` functionality provided by ProVerif to verify DE properties. If the property holds (ProVerif outputs `True`), the tracker cannot tell if the target device uses `id` (the target device's identifier) or `rand_id` (a random identifier) during the communication. It means that the tracker cannot use `id` to track the target device. Since ProVerif verifies a stricter condition than the actual condition when DE properties hold [10, p.62], it may generate false attacks where the stricter condition fails but the DE property holds. We consider an attack as false if and only if the following two conditions are both true: 1) ProVerif outputs `Cannot be proved` but still generates an attack trace, and 2) the attack indicated by the attack trace is not feasible for tracking upon validation. ProVerif may also find a true attack that both the stricter condition and the DE property are violated. In these two cases (i.e., finding false or true attacks), ProVerif outputs `Cannot be proved` because it is not sure whether the DE property is actually violated or not. Note that in these two cases, ProVerif may or may not be able to find an attack trace (no matter false or true attack trace).

Table 3: Results comparison between our reachability-based model and an alternative DE-based model. ●: the alternative model generates false attacks (i.e., false positives). ■: the alternative model cannot generate an attack trace (i.e., false negatives). Cen: central; Per: peripheral; P: passive tracker; A: active tracker

Alice's relation with the tracker, Alice's role, and tracker's type				Communication					
				PAIR	SCAN	CE	ENCC	AUTHC	PAGE
Never	Cen	P		●		●	●	●	
		A		●	●		●	●	
	Per	P		●			●	●	
		A		●			●	●	
Paired	Cen	P		●			●		
		A		●			■		
	Per	P		●		■			
		A		●			■		
Unpaired	Cen	P		●			●		
		A		●			■		
	Per	P		●		■			
		A		●			■		

Table 3 shows the comparison between the verification results generated by our reachability-based model and the alternative DE-based model. As the table shows, compared to our reachability-based model, the DE-based model generates both false attacks and missed attacks. The full verification results of the DE-based model are shown in Table 6 in Appendix B. Internally, DE properties are also represented by reachability properties in ProVerif. However, since our reachability properties implying untraceability are more specific and precise, our model can avoid the false attacks that are inevitable in the DE-based model. Note that, in some cases, false attacks can also be avoided by modeling the operations of a device more precisely, such as the modeling in the three-condition-based definition, as proposed by previous research [7, 30].

For the scenarios denoted by ● in the table, the results of our reachability-based model show that the untraceability holds. However, the results of the DE-based model indicate that the untraceability is violated. After inspecting the corresponding attack traces, we found that these attack traces are false attacks. With further investigation, these false attacks are caused by

the stricter condition adopted in proving the DE properties of a protocol with branches. If a protocol contains two branches (i.e., *if* and *else* branches), ProVerif proves the DE property only when the two protocol instances always take the same branch. Thus, ProVerif detects it as a violation if the *if* branch is executed in one protocol instance while the *else* branch is executed in the other instance. However, the protocol still preserves untraceability if the tracker cannot distinguish the *if* branch from the *else* branch.

In the scenarios where the untraceability can be violated (indicated by ■), the DE-based model cannot find an attack trace. On the contrary, our reachability-based model can successfully find the correct attack trace. After further study, we believe the failure of attack trace construction of the DE-based model might be caused by other approximations in ProVerif. For example, ProVerif implements the private channel [10, p.123], which is used in the DE-based model, in a way that ignores the order and number of sent messages. The DE-based model and the results can also be found in our code repository [3].

6 Real-World BLE Stack Evaluation

To better understand how the four identified issues affect real-world devices, we perform a comprehensive evaluation covering mobile operating systems (OSes), desktop OSes, embedded OSes, and a Bluetooth stack implementation that is available on a variety of platforms. As shown in Table 4, we select the two most popular mobile OSes (i.e., Android and iOS) [42] and the two most popular open-source embedded OSes that support BLE (i.e., Mbed [6] and Zephyr [19]) [38]. Additionally, we include the three most popular desktop OSes (i.e., Windows, macOS, and Linux) [41] in our evaluation set. Lastly, we evaluate BTstack [27] due to its cross-platform and open-source nature, popularity, and detailed documentation.

We first evaluate whether these 13 devices are affected by the four identified issues in Section 6.1. Then, we present two case studies exploiting IRK reuse and BD_ADDR reuse respectively to demonstrate the practicality of device tracking in the real world in Section 6.2. Lastly, we talk about our reports to related vendors of the devices and their corresponding responses in Section 6.3. In Appendix A, we investigate BLE implementations of tested devices to understand how these devices can change their identifiers to prevent the tracking.

6.1 Evaluation Results

We use one Linux laptop to emulate Bob (i.e., a benign device) to communicate with Alice (i.e., the device to evaluate). We use another Linux laptop to emulate the tracker. We pair Alice with Bob and the tracker, and then unpair Alice from the tracker. Alice is affected by IRK reuse if Bob and the tracker receive the same IRK from Alice. We verify whether Alice is affected by BD_ADDR reuse by comparing the ID_ADDR received by the tracker and Alice's BD_ADDR. Alice is affected if these two MAC addresses are the same. Like IRK reuse, Alice is affected by CSRK reuse if Bob and the tracker receive the same CSRK from Alice. To check whether Alice is affected by ID_ADDR reuse, we compare Alice's ID_ADDR received by Bob and her ID_ADDR received by the tracker. Alice is affected if these two ID_ADDRs are the same.

Table 4 shows the results of our evaluation of the tested devices. As we can see, *all* the tested devices are affected by at least two issues. Note that if a device is affected by one issue, it is vulnerable to all tracking attacks exploiting this issue. For example, if a device is affected by IRK reuse, it is vulnerable to Attack 1, Attack 2, and Attack 3.

During our experiment, we find devices #5, 6, 7, and 11 do not distribute the CSRK during pairing, and thus are not affected by CSRK reuse. Devices #8 and 9 are not affected by BD_ADDR reuse because Zephyr and Mbed do not support the BC stack. Through the experiment and code analysis, we find that Zephyr's BLE stack employs a different IRK and ID_ADDR design. In the default setting, the device is affected by IRK reuse and ID_ADDR reuse. However, it also allows the upper-layer application developers to generate and use several combinations of IRKs and ID_ADDRs at the same time on a BLE device. In this case, whether the device is affected by IRK reuse and ID_ADDR reuse is up to the application developers.

During the evaluation, we also find an implementation issue on Windows 11, caused by not strictly following the specification to implement BLE's privacy feature [11, p.1353]. Specifically, Windows 11 uses its BD_ADDR rather than RPAs as its MAC address when it is the central role. Therefore, a tracker can sniff scan request messages or connection request messages and identify device #10 by simply observing whether its BD_ADDR appears in these messages. In addition, the tracker can also get the BD_ADDR of device #10 by sniffing these two types of messages and track this device by actively probing with page requests using the BD_ADDR.

6.2 Case Study

In this section, we present two practical tracking attacks exploiting IRK reuse and BD_ADDR reuse, respectively. The first case study shows that a tracker can track a target device that enables system services based on BLE advertising, such as the COVID-19 Exposure Notifications system, by launching the Attack 1 attack exploiting IRK reuse. The second case study demonstrates that a tracker can track a BC/BLE dual-stack device even when the target device is *not running any Bluetooth applications* by launching Attack 4 exploiting BD_ADDR reuse.

For these attacks, we assume the tracker can obtain the victim device's identifiers under two scenarios. First, the tracker gets identifiers if the victim device pairs with a device under the tracker's control. Second, the victim device pairs with a benign device which is compromised by the tracker later.

Table 4: Result of whether tested devices are affected by the four discovered issues and the design choice of the identifiers on each tested device. Per-D: per-device design choice. Per-P: per-pairing design choice.

#	Device	Operating System	Stack Implementation	Design Choice			Affected by			
				IRK	CSRK	ID_ADDR	Issue 1	Issue 2	Issue 3	Issue 4
1	OnePlus 8 Pro	Android 13	Gabeldorsche	Per-D	Per-P	Per-D	✗	✗	–	✗
2	Galaxy S21+ 5G	Android 12L	Fluoride	Per-D	Per-P	Per-D	✗	✗	–	✗
3	Pixel XL	Android 10.0	Fluoride	Per-D	Per-P	Per-D	✗	✗	–	✗
4	Pixel 3	Android 9.0	Fluoride	Per-D	Per-P	Per-D	✗	✗	–	✗
5	iPhone 13	iOS 16.2	iOS stack	Per-D	–	Per-D	✗	✗	–	✗
6	iPhone SE (2nd gen)	iOS 14.7.1	iOS stack	Per-D	–	Per-D	✗	✗	–	✗
7	iPhone 8	iOS 13.3.1	iOS stack	Per-D	–	Per-D	✗	✗	–	✗
8	nRF52840 DK	Zephyr 2.7	Zephyr stack	App Dep.	Per-P	App Dep.	✗	–	–	✗
9	nRF52840 DK	Mbed 6.15	Mbed stack	Per-D	Per-D	Per-D	✗	–	✗	✗
10	ThinkPad X1 Yoga	Windows 11	Windows stack	Per-D	Per-P	Per-D	✗	✗	–	✗
11	MacBook Air (M1, 2020)	macOS 13.1	macOS stack	Per-D	–	Per-D	✗	✗	–	✗
12	ThinkPad X1 Yoga	Ubuntu 22.04	BlueZ 5.64	Per-D	Per-P	Per-D	✗	✗	–	✗
13	Dell Latitude 5480	Ubuntu 22.04	BTstack 1.3.1	Per-D	Per-P	Per-D	✗	✗	–	✗

These scenarios are not uncommon in the real world. For example, a user may pair her phone with a BLE smart lock when she moves into an Airbnb apartment and unpair it upon leaving [17]. Similarly, a user may also pair her phone with a rental car and unpair it upon returning the car. In these cases, the smart lock and the rental car could be under the tracker's (e.g., the smart lock or car vendors) control when the user pairs her phone with them. It is also possible that the smart lock and the car are compromised after the user pairs her phone with them. Note that after obtaining the identifiers, the tracker can use other devices, such as Raspberry Pis, to track the phone. For example, the tracker can deploy several devices to perform location tracking or deploy just one device at a specific location (e.g., near the target user's home) to monitor the user's presence.

6.2.1 Attack 1: Tracking a Device with Background Services based on BLE Advertising

Currently, BLE advertising is widely used in the background services of mobile operating systems. Once enabled, these services are running in the background continuously without the user explicitly starting them, such as the COVID-19 Exposure Notifications System [28] on Android and iOS, and the Apple Continuity [4, 14, 43] services. If those devices use RPAs for advertising, they can be affected by IRK reuse.

We take the COVID-19 Exposure Notifications system on Android as a concrete example to show how a tracker can track Alice (e.g., an Android phone). The tracker can take the following steps to identify and track Alice:

1. Alice pairs with the tracker to perform data transmission and sends her IRK (`irkA`) to the tracker during pairing.
2. Alice unpairs from the tracker after data transmission.
3. Alice's COVID-19 service broadcasts advertising messages using RPAs generated from `irkA`.
4. The tracker sniffs the advertising messages and uses `irkA` obtained in step (1) to resolve the RPA in the message.
5. If the RPA resolution is successful, the tracker can identify and track Alice.

We provide a video demo for this tracking attack [2].

This attack is applicable under the real-world Airbnb case mentioned earlier. In this case, the smart lock vendor or the owner of the apartment could be the tracker who obtains the phone's IRK during pairing. Upon leaving, the user unpairs her phone from the lock, however, the IRK obtained by the tracker is still valid. After unpairing, if Alice gets, at any time in the future, physically close to the lock, this lock may receive advertising messages. This is possible, especially when the phone enables background services, such as COVID-19 Exposure Notification. In this case, the lock can resolve the RPAs in the advertising message and identify this phone.

Our experiment shows that the COVID-19 Exposure Notifications system running on devices #2, 3, and 4 is affected by this tracking attack. In addition, the Apple Continuity service running on devices #5, 6, 7, and 11 is also affected. The Exposure Notifications system on iOS (devices #5, 6, 7) is not affected because iOS does not use RPAs for advertising.

6.2.2 Attack 4: Tracking a Bluetooth-Enabled BC/BLE Dual-Stack Device

According to the Bluetooth Special Interest Group (SIG), BC/BLE dual-stack devices, such as smartphones and laptops, account for more than half of all Bluetooth-enabled devices [12]. In this case study, we demonstrate how a tracker can launch Attack 4 to track a dual-stack device *forever*.

We use an Android phone (Alice) as a concrete example to show how a tracker can track this phone when it is *not running any Bluetooth application*. The tracker can follow the following steps to launch the attack:

1. Alice pairs with the tracker to perform data transmission and sends her ID_ADDR, which is also her BD_ADDR, to the tracker.
2. Alice unpairs from the tracker after the data transmission finishes and removes all its identifiers.
3. The active tracker probes Alice with page requests (via `HCI_Create_Connection` commands) using Alice's BD_ADDR obtained in step (1).
4. The tracker can identify and track Alice if she replies with a page request (either the connection can be established,

or the connection is rejected).

We also provide a video demo to demonstrate the practicality of this tracking attack [1].

This tracking attack is also feasible in the Airbnb scenario explained in Section 6.2.1. Compared to the tracking attacks based on IRK reuse, this attack is effective as long as Bluetooth is enabled, and it does not require the target device to run any Bluetooth application, including the background services based on BLE advertising. Our experiment shows that *all* dual-stack devices (devices #1 to 7 and 10 to 13) are affected by this tracking attack.

6.3 Responsible Disclosure

We responsibly disclosed the issues we found to the Bluetooth SIG. The Bluetooth SIG does not consider IRK reuse, BD_ADDR reuse, and CSRK reuse as significant. The reason is that, in order to track a target device, the tracker needs to pair with the target device first, during which explicit user approval is needed. We agree that pairing implies trust, and for this reason, a paired device can trivially track its paired peer devices. However, we believe *a device should not be able to track a previously paired and now unpaired peer device*, as we will further discuss in Section 8. At the time of paper writing, Bluetooth SIG is still investigating ID_ADDR reuse.

We also disclosed our findings to related vendors. Specifically, we reported IRK reuse and BD_ADDR reuse to Google. Google has confirmed our findings, rated both issues as *high severity*, assigned two CVEs (CVE-2021-39673 and CVE-2023-21307), and rewarded us *$10,000 ($5,000 for each issue) as a bug bounty*. At the time of paper writing, Google has fixed IRK reuse with an update for Android 13 by adopting the same strategy as Windows 11, i.e., using a new randomly generated IRK after unpairing from the last paired BLE device [29] (see Appendix A). Though this fix improves the privacy of Android devices, we believe that fundamentally addressing IRK reuse needs specification modifications (as we will explain in Section 7.1). Google has also fixed the BD_ADDR reuse issue, but the fix is not publicly available at the time of paper writing. We also reported these two issues to Apple. Apple considers the tracking based on IRK reuse as matching the Bluetooth standard. In addition, Apple has acknowledged BD_ADDR reuse and is actively working on fixing it. We also reported IRK reuse, BD_ADDR reuse, and the use of BD_ADDR in BLE connection establishment to Microsoft, which has also confirmed our findings. Specifically, Microsoft considers BD_ADDR reuse as a general bug and will fix it in the future. Since Windows does not proactively advertise using RPAs or initiate connections, Microsoft thinks IRK reuse and the use of BD_ADDR do not meet the bar of security vulnerabilities. Moreover, we also reported IRK reuse and BD_ADDR reuse to BlueKitchen (the vendor of BTstack). BlueKitchen has confirmed our findings and considers the tracking based on these two issues as aligned with the current specification. Finally, we also reported IRK reuse and BD_ADDR reuse to BlueZ, Zephyr, and IRK reuse, BD_ADDR reuse, and CSRK reuse to Mbed developers. These vendors are still investigating these issues.

7 Mitigations and Recommendations

To mitigate the four identified privacy issues, we propose updates to the specification. We also provide suggestions to developers and end users on Bluetooth implementation and usage respectively to better protect users' privacy.

7.1 Suggested Specification Updates

To fundamentally address the four revealed privacy issues, updates to the current specification [11] are necessary.

1. Use per-pairing IRKs. The current specification recommends using a per-device IRK, as shown in Table 1, which is the root cause of IRK reuse. To fundamentally address this issue, we propose to update the specification by suggesting that a device should use a fresh random-generated IRK for each pairing to have better privacy protection. In this way, when unpairing from a paired peer device, the target device can revoke the IRK sent to the peer device to prevent tracking attacks based on IRK reuse. Our verification also proves that (rows #32, 33, 40, and 41, columns 7 and 10 in Table 7), the target device cannot be identified or tracked by a peer device after unpairing from it. Therefore, the per-pairing design can significantly improve the privacy of a BLE device.

The per-pairing IRK design works well for the central role but may introduce performance overhead for the peripheral role. The reason is that the central device first scans for advertising messages and then determines which IRK to use. However, the peripheral device has to broadcast advertising messages first, without knowing which central device may connect to it. Therefore, to be recognized by all paired central devices, the peripheral device needs to advertise using RPAs generated by all valid IRKs. Accordingly, it takes longer for two paired devices to reconnect.

2. Use random-generated ID_ADDR. For BC/BLE dual-stack devices, the current specification requires using BD_ADDR as BLE's ID_ADDR [11, p.1615], which is the root cause of BD_ADDR reuse. Therefore, to fundamentally address this issue, a dual-stack device should use a random-generated MAC address (different from its BD_ADDR) as its ID_ADDR for BLE. In this case, when pairing with a tracker, the target device's BD_ADDR will not be leaked to the tracker, preventing tracking attacks based on BD_ADDR reuse, as indicated by our verification in Table 7 (rows #36 and 44, column 10).

Though improving privacy, using random-generated ID_ADDR can affect user experience in the scenario where two dual-stack devices communicate with each other using both BC and BLE. The reason is that these two devices

cannot use the Cross-Transport Key Derivation (CTKD) [11, p.1366] feature to derive the link key of BC from the LTK or vice versa because the ID_ADDR is different from the BD_ADDR. As a result, the user needs to pair these two devices twice, once for BC and once for BLE.

3. Use per-pairing CSRKs. The current specification allows using a per-device CSRK, as shown in Table 1, which is the root cause of CSRK reuse. The fundamental mitigation to this issue is using per-pairing CSRKs, as proved in Table 7 (rows #30 and 35, columns #7 and 10). Per-pairing CSRKs is also the implementation choice for most tested devices. As such, we propose to update the specification by disallowing using per-device CSRK and requiring using a fresh random-generated CSRK for each pairing.

4. Use per-pairing ID_ADDR. The current specification suggests using a per-device ID_ADDR, as shown in Table 1, which is the root cause of ID_ADDR reuse. Since the ID_ADDR should not be included in any BLE messages when the privacy feature is enabled [11, p.275], it does not affect the device identification and connection establishment process. As such, we suggest using per-pairing ID_ADDRs to fundamentally address ID_ADDR reuse, as indicated by Table 7 (rows #31 and 39, column 10).

7.2 Suggestions to Developers

We propose the following implementation suggestions to developers to improve BLE privacy while being *compliant with the current specification*.

1. Do not use BD_ADDR in any BLE message. A tracker can sniff a device's BD_ADDR if it is used as the MAC address in a BLE message, such as the use of BD_ADDR on Windows 11 (Section 6.1). As such, a BLE device should use random addresses [11, p.1355] rather than BD_ADDR in BLE communication to prevent leaking a device's BD_ADDR to a tracker when only using BLE.

2. Do not derive IRK from IR. Deriving an IRK from an Identity Root (IR) may result in a fixed IRK, such as the IRK derivation on the nRF52840 DK development board with Zephyr OS (see Appendix A). Therefore, a BLE stack should randomly generate IRKs rather than deriving from the IR.

3. Refresh the IRK after unpairing from the last paired device. As described in Section 6.3, Android 13 refreshes its IRKs when unpairing from the last paired BLE device to mitigate IRK reuse. Windows 11 also adopts the same implementation choice. Though this choice cannot fundamentally address IRK reuse, it can still improve the device's privacy.

7.3 Recommendations to End Users

1. Turn off Bluetooth if not in use. Turning off Bluetooth is an effective way to defend against all tracking attacks based on Bluetooth. For BC/BLE devices, tracking based on BD_ADDR is always effective since a device's BD_ADDR is always valid, especially for unrooted mobile devices. Since devices cannot selectively disable BC while using BLE [34], turning off Bluetooth might be the only way to stop the tracking based on BD_ADDR. Compared with other approaches, turning off Bluetooth is arguably the most practical one for end users.

2. Reset Bluetooth after unpairing. For an Android device, "Reset Wi-Fi, mobile & Bluetooth" revokes its current IRK (Table 5 in Appendix A). Therefore, it is helpful for the device's privacy to perform this resetting after unpairing from a potential tracking device, especially when enabling the COVID-19 Exposure Notifications System. However, resetting Bluetooth on Android also has side effects, such as losing Wi-Fi configurations and information about other paired Bluetooth devices.

3. Unpair from and re-pair with all paired BLE devices after unpairing from a BLE device. For Windows 11 and Android 13 devices, unpairing from all BLE devices will revoke the current IRK (Table 5 in Appendix A). Therefore, after unpairing from one potential tracking device, we suggest unpairing this device from all currently paired BLE devices to refresh the IRK and re-pairing with them. Accordingly, unpairing and re-pairing will mandate extra operations from users.

4. Factory reset after unpairing. For devices running Mbed or Zephyr, factory resetting may remove the stored key database and revoke the current IRK. Similarly, factory resetting an iOS device can also revoke its IRK (Table 5 in Appendix A). Therefore, after unpairing an IoT device, an iOS, or a macOS device from a potential tracking device, factory resetting this IoT device or iOS device can prevent the identification and tracking based on IRK or CSRK. Concretely, factory resetting may be feasible for IoT devices after unpairing, but it might be impractical for other devices.

8 Discussion

Meaning of unpairing. As we discussed in Section 6.3, if a user pairs device A (target device) with device B, it means the user trusts device B. On the contrary, if the user unpairs device A from device B, we claim that the trusted relation is revoked. Thus, after unpairing, device B should not be able to track a previously paired device A. Concretely, there are many scenarios where a user may trust (i.e., pair her device with) a device *temporarily*. For example, in the Airbnb example (Section 6.2.1), the user trusts the smart lock temporarily. A rental car is another example where the user pairs her phone with the car when using it and unpairs her phone from the car when returning it. However, the user currently has no clear way to revoke this trust, since in many cases, the user's device can still be tracked after unpairing. Fundamentally, these issues reveal that the semantics of unpairing is not well-defined in the specification nor implemented coherently across vendors.

Limitations. Our model focuses on BLE untraceability at the protocol level. Thus, it does cover the application level, since

it is device-specific, and it is not available at the protocol level. For this reason, device tracking based on the application-level information, e.g., Universally Unique IDentifiers (UUID), has been explored in existing research [25, 33, 50], and is orthogonal to our work. Additionally, our model limits the attacker's capabilities to those modeled in the tracker modules, which are weaker than the capabilities in the Dolev-Yao model. As a result, our model can only discover tracking attacks related to the identifiers covered in the tracker modules. Our model cannot reveal attacks that are not related to the identifiers we extracted from the specification. Nonetheless, since we enumerated all possible usages of the identifiers according to the specification, we believe the modeling of the tracker capabilities related to the identifiers is complete. Our model does not support the setting with three or more sessions. We have tried to verify the properties in the settings of three sessions and an unlimited number of sessions. However, in these two settings, we found that the verification of some properties (e.g., Row 10 Column 8 in Table 7) cannot terminate even after running for 600 hours. Finally, our model does not cover privacy issues caused by side channels, such as timing [16].

9 Related Work

Bluetooth privacy. Fawaz et al. [25] and Kolias et al. [33] studied the privacy information contained in BLE's advertising messages and realized that the fixed field in the advertising message can be used for user tracking. Das et al. [22] found that most fitness trackers utilize fixed MAC addresses for BLE and are vulnerable to user tracking. While none of the existing works systematically studied BLE privacy, our work conducts a systematic study and identifies new privacy issues.

Cominelli et al. [18] and Tucker et al. [45] demonstrated that a BC device can be tracked if BC is in use or in the non-discoverable mode. Ludant et al. [34] showed that the traffic of BC and BLE from the same device can be captured and linked together by a tracker exploiting the traffic transmission timing information. Different from existing attacks [18, 34] that require BC being used to track a device, device tracking based on BD_ADDR reuse is still effective even when the BC is in the non-discoverable mode and not being used.

Formal analysis of Bluetooth. Formal analysis has been applied to the Bluetooth domain, but existing works focused on security properties rather than privacy properties. Several works [15, 20, 39, 48] analyzed the pairing procedure of Bluetooth and found its design weaknesses. Others [47, 48, 49] modeled and analyzed the communications after pairing and revealed new design weaknesses. Our work focuses on the privacy properties of Bluetooth, a field that has not been systematically studied in existing research.

Formal analysis of privacy properties in other protocols. The privacy of other protocols has been studied and analyzed based on different definitions. Arapinis et al. [5] analyzed the Basic Access Control protocol in the French e-Passport based on the PE definition and realized that anyone carrying such a passport can be physically traced. Delaune et al. [23] formally verified three privacy properties that are also based on PE in existing electronic voting protocols. Baelde et al. [7] extended the work of Hirschi et al. [30] and verified the RFID authentication protocol based on the three-condition definition. Dahl et al. [21] analyzed the CMIX protocol [32] using DE and found that it does not preserve privacy in many cases. Wang et al. [46] also used DE to verify a privacy-preserving 5G authentication and key agreement protocol, and proved the protocol resistant to linkability attacks. Different from these, our work proposed a more specific definition of untraceability for BLE, which overcomes the limitations of using aforementioned definitions in automatic verification, as discussed in Section 3.

10 Conclusion

In this paper, we conduct a systematic study of BLE traceability at the protocol level by conducting a formal analysis of BLE untraceability, and we uncover four new privacy issues allowed by the BLE specification. We further evaluate 13 real-world BLE devices and found that *all* of them are affected by at least two of these issues. To mitigate the issues we found, we propose mitigations to address these issues and recommendations to end users.

Appendix

A Identifier Revocation Investigation

As mentioned, the issues in Section 5 stem from the fact that the target device's identifiers received by the tracker are still valid after the target device unpairs from the tracker. Therefore, if the target device revokes (i.e., stops using) such identifiers after unpairing, it can avoid these issues. For this reason, to better evaluate the impact of the tracking attacks based on these issues, we want to figure out *"how often and under what circumstances does a device revoke its shared identifiers?"*

We dynamically test each of the 13 devices listed in Table 4. Specifically, we first pair each of the tested devices with two Linux laptops and then unpair the tested device from the two laptops. During pairing, we capture the traffic on the two laptops, from which we can get the IRK, CSRK, and ID_ADDR

Table 5: IRK, CSRK, and ID_ADDR revocation policies.

#	When the device changes its		
	IRK	**CSRK**	**ID_ADDR**
1	Reset Wi-Fi, mobile & Bluetooth or Factory reset or Unpair from last paired BLE device	Unpair	Never
2	Reset Wi-Fi, mobile & Bluetooth or Factory reset	Unpair	Never
3	Reset Wi-Fi, mobile & Bluetooth or Factory reset	Unpair	Never
4	Reset Wi-Fi, mobile & Bluetooth or Factory reset	Unpair	Never
5	Erase all content and settings	–§	Never
6	Erase all content and settings	–§	Never
7	Erase all content and settings	–§	Never

9	Remove stored key database	Remove stored key database	Remove stored key database
10	Unpair from last paired BLE device	Unpair	Never
11	Erase all content and settings	–§	Never
12	Remove stored IRK	Unpair	Never
13	Remove stored key database	Unpair	Never

§: CSRK is not distributed during pairing. †: The default IRK is fixed. ‡: The default ID_ADDR is fixed.

of the tested device. Then, we perform pairing and traffic capturing for a tested device under different scenarios, such as rebooting, resetting settings, factory resetting, and removing the key database. Lastly, we compare the IRKs, CSRKs, and ID_ADDRs in the traffic captured under different scenarios. Besides dynamic testing, we also analyze the source code of the implementations (if available) to confirm our results.

Table 5 shows the results of our experiment. All devices except devices #1 and 10 require performing resetting operations to revoke their IRK, such as "Reset Wi-Fi, mobile & Bluetooth" or factory resetting on Android (devices #2-4). It is noteworthy that, on iOS and macOS (devices #5, 6, 7, and 11), the IRK is revoked only after performing the "Erase All Content and Settings" operation. The IRK remains the same after conducting either the "Reset Network Settings" operation or the "Reset All Settings" operation. For devices #8, 9, 12, and 13, the user needs to explicitly remove the file storing the IRK to revoke it.

The BLE stack on Windows 11 (device #10) uses a different strategy from others to revoke its IRK. The IRK remains the same as long as, at least one BLE device is paired with device #10. After unpairing from the last paired BLE device, device #10 automatically revokes its IRK. Compared with other BLE stack implementations, Windows 11 may still be affected by IRK reuse, but it provides better protection against it. For example, if the user unpairs device #10 from the tracker when no other BLE device is paired, device #10 revokes its IRK after unpairing. Consequently, the tracker cannot identify device #10 using the obtained IRK since it is no longer valid. In a security update [29] for Android 13, Google adopted the same strategy to fix the IRK reuse issue.

The BLE stack on Zephyr has a default IRK calculated from an Identity Root (IR) value defined in the specification [11, p.1624]. Zephyr first tries to read this IR value from the Bluetooth controller. If the controller returns the IR value, Zephyr calculates the default IRK based on this IR value. Otherwise, Zephyr randomly generates the default IRK. In this case, if the IR value returned from the controller is fixed, the default IRK will be fixed. During our experiment, we find that the IR value on the nRF52840 DK development board is fixed, leading to a fixed default IRK. For this reason, the tracker can identify and track the device *forever* if she can get the device's fixed default IRK.

In general, our experiment indicates that different vendors interpret the specification differently. In turn, different BLE stacks implement different strategies to revoke these identifiers offering different privacy guarantees, making it almost impossible for an end user to understand the privacy consequences of using a specific Bluetooth device.

B Full Results of Untraceability Verification

Table 7 lists the full results of the verification using our reachability-based formal model. Note that all the properties that hold in the one-session setting still hold in the two-session setting. Table 6 shows the full results of the verification based on an alternative (diff-equivalence-based) formal model.

Table 7: Verification results of property **P1** and **P2** under all communication scenarios, runtime of the verification under one-session and two-session settings (if needed), and the corresponding identifier if a property is violated. ✗: expected violations. ✗[1]: violations caused by Issue 1. ✗[2]: violations caused by Issue 2. ✗[3]: violations caused by Issue 3. ✗[4]: violations caused by Issue 4.

Abstract

With the mobile phone market exceeding one billion units sold in 2023, ensuring the security of these devices is critical. However, recent research has revealed worrying delays in the deployment of security-critical kernel patches, leaving devices vulnerable to publicly known one-day exploits. While the mainline Android kernel has seen an increase in defense mechanisms, their integration and effectiveness in vendor-supplied kernels are unknown at a large scale.

In this paper, we systematically analyze publicly available one-day exploits targeting the Android kernel over the past three years. We identify multiple exploitation flows representing vulnerability-agnostic strategies to gain high privileges. We then demonstrate that integrating defense-in-depth mechanisms from the mainline Android kernel could mitigate 84.6 % of these exploitation flows. In a subsequent analysis of 994 devices, we reveal a widespread absence of effective defenses across vendors. Depending on the vendor, only 28.8 % to 54.6 % of exploitation flows are mitigated, indicating a 4.62 to 2.95[1] times worse scenario than the mainline kernel.

Further delving into defense mechanisms, we reveal weaknesses in vendor-specific defenses and advanced exploitation techniques bypassing defense implementations. As these developments pose additional threats, we discuss potential solutions. Lastly, we discuss factors contributing to the absence of effective defenses and offer improvement recommendations. We envision that our findings will guide the inclusion of effective defenses, ultimately enhancing Android security.

1 Introduction

Over the past decade, the mobile phone market has reached an all-time high, with more than one billion units sold in 2023. Given our daily reliance on mobile phones for communication, financial transactions, and personal data storage, this surge in device adoption underscores the critical need for robust security measures protecting these devices.

[1] Factors of $\frac{1-0.288}{1-0.846}$ and $\frac{1-0.546}{1-0.846}$, respectively.

Figure 1: The exploitation flow ***EF*** is a vulnerability-agnostic chain of exploitation techniques ***ET***, with one ***ET*** elevating a primitive to a more powerful form [8]. ***EF*** leverages the capabilities of a vulnerability to gain root privileges ultimately.

Despite the importance of mobile security, recent studies [13, 27, 43, 61, 67] have revealed that Android's security-critical kernel patches often lag significantly behind the mainstream Linux kernel. In over 20 % of cases, delays exceeding one year occur [61], mainly due to the downstream approach of most Android vendors. This delayed deployment of security-critical patches creates opportunities for malicious actors to attack the Android Linux kernel. While these attacks would be classified as one-day exploits due to the known nature of their vulnerabilities, they effectively function as zero-day exploits during the extensive unpatched period. The severity of this situation is underscored by findings from Google Project Zero [9, 49] and Threat Analysis Group [50], which highlight a prevalence of exploits in the wild targeting these unpatched vulnerabilities in the Android kernel.

On the defensive side, the mainline Android kernel has seen an increase in vulnerability-agnostic defenses preventing one-day exploits. While these defense-in-depth mechanisms may be readily available, *their integration and effectiveness in vendor-supplied kernels are unknown*. Consider, for example, the case of the Pegasus spyware. Using BadBinder, an exploit [46] known since 2019, malicious actors can infect target devices with their payload. While an effective defense has been available for over 10 years [47], its rollout status in vendor-provided kernels is entirely opaque. The questionable deployment or absence of such defenses leaves devices vulnerable to one-day exploitation flows (see Figure 1), thus creating a significant security gap in the Android ecosystem. Malicious actors can exploit this and mount attacks against insufficiently protected devices based on public exploits.

In this paper, we address the inadequate protection of Android devices against one-day exploitation flows through comprehensive analysis. We systematically analyze all publicly available one-day exploits targeting memory safety vulnerabilities in the Android Linux kernel over the past three years, comprising 26 exploits. In doing so, we unveil the diversity of these one-day exploits and classify 10 distinct exploitation techniques. In a subsequent analysis, we examine 8 defense-in-depth mechanisms present in the mainline Android kernel and find that they effectively prevent 84.6 % of the previously identified one-day exploitation flows. This percentage serves as the ground truth for how secure mobile devices could be if their kernels were up to date with the defenses enabled. Given the maximum achievable security, we can *quantify the level of security that is actually reached in Android devices*.

For this, we conduct the first large-scale analysis on kernel-level defense-in-depth mechanisms for Android devices via a mostly automated approach. We demonstrate a widespread absence across vendors and uncover flaws in vendor-specific defenses. In our analysis, we cover Android devices from all top 7 vendors (e.g., Samsung, Xiaomi, and Huawei), along with three recognized vendors (i.e., Google, OnePlus, and Fairphone), covering more than 84 % of the global Android device share [6]. We analyze devices from 2018 to 2023 using Android versions 9 to 14 and kernels ranging from v3.10 to v6.1. In total, we analyze 994 device firmwares and 1533 Android kernel source codes. Our results suggest that *the level of security that is actually reached is severely lacking* compared to the mainline Android kernel.

Our work presents four novel findings. First, we provide in-depth insights into the absence of effective defenses in vendor-provided kernels. On average, only 41.5 % of our analyzed one-day exploitation flows can be mitigated. This varies across vendors, from 28.8 % for the least (i.e., Fairphone) to 54.6 % for the most secure (i.e., Google) vendor, indicating a 4.62 to 2.95 times worse scenario than the ground truth.

Second, we unveil advancements in two exploitation techniques, enabling malicious actors to bypass the defense intended against the base technique. These advancements are applicable in all one-day exploitation flows that use the base technique. While these advancements pose additional threats to Android devices, we discuss potential mitigations.

Third, we uncover 4 and 2 distinct weaknesses in Samsung's and Huawei's vendor-specific defenses, respectively. These issues impact Samsung devices ranging from Galaxy A04/A14 to Galaxy S23 5G/Ultra, and, thus, the entire range of low-end to high-end devices, as well as the entire range of Huawei devices. We demonstrate that these defenses do not fully prevent the targeted exploitation technique, or we demonstrate modified exploits that bypass the defense.

Fourth, we discuss factors that may contribute to the lack of effective defenses. While we observe a correlation between older kernel versions and higher one-day susceptibility, we reveal that susceptibility extends beyond mere version correlation. We present factors such as a lack of importance of security features and vulnerable configurations, as well as performance costs (confirmed by Google, Samsung, and Huawei), which are particularly relevant for low-end devices. We also make recommendations to Google and downstream vendors to improve Android security.

We open source[2] our tools that detect the widespread lack of included and effective defenses.

Contributions. The main contributions of our work are

(1) One-Day Exploitation Insights: We analyze 26 one-day exploits and classify 10 different exploitation techniques.

(2) Defense Insights: Based on these insights, we demonstrate defenses for the identified techniques.

(3) Defense Inclusion and Effectiveness Analysis: We unveil a significant gap between the maximum available security and that reached by vendor-supplied kernels.

(4) Novel Findings: We present in-depth insights into the absence of effective defenses in vendor-supplied kernels, exploitation advancements, weaknesses, and factors likely contributing to the absence of defense.

Disclosure. We disclosed our findings to all 10 vendors. While some did not respond (e.g., Oppo and Xiaomi), others (i.e., Google, Fairphone, Motorola, Huawei, and Samsung) acknowledged our findings (fully or partially), and some of these patched unsecured phones to enhance Android security.

Outline. Section 2 provides background. Section 3 shows the high-level workflow. Section 4 presents the one-day analysis and defense identification. Section 5 presents the large-scale defense analysis. Sections 6 and 7 discuss potential solutions and related work. Section 8 concludes our work.

2 Background

2.1 Android Ecosystem and Android Kernels

Android is primarily designed for mobile devices and undergoes active development led by Google. The Android kernel is based on the Linux kernel. For major platform releases, Google specifies compatible launch kernels for new devices and upgrades kernels for existing device updates.

Historically, vendors maintained separate Linux kernel trees for each product model, hindering upstream bug fixes due to vendor-specific code and hardware drivers. Despite the introduction of monthly Android Security Bulletins in 2015, prior research [24, 67] indicates continued delay in patch integration. In response, Google introduced the Generic Kernel Image (GKI) project in Android 11 on kernel versions above or equal to v5.4, aiming to overcome slow patch adoption. This initiative separates the Android kernel into a hardware-agnostic core maintained by Google and vendor-specific modules loaded dynamically. Moreover, it restricts the Android kernel to some constraints, such as ABI compatibility.

[2] https://github.com/IAIK/DefectsInDepth.

2.2 Kernel Exploitation

Fundamental Kernel Defenses. The Linux kernel employs defense-in-depth mechanisms to make vulnerability exploitation more difficult. These are included via the configuration file `.config`. One fundamental defense is the W^X policy, which dictates that sections may never be writeable and executable. Consequently, an attacker cannot simply inject instructions for privilege escalation. Kernel Address Space Layout Randomization (KASLR) randomizes the location of binary sections at boot time. Thus, an exploit typically breaks KASLR through a read primitive or a side channel [21]. Lastly, Privilege Access Never (PAN) prevents access to user-accessible memory while in kernel space, mitigating the control-flow redirection to userspace.

Kernel Exploitation on Android. The exploitation flow (see Figure 1) of most Android kernel exploits consists of three stages: First, an adversary *breaks KASLR* to identify the locations of critical structures. Second, the adversary obtains an *arbitrary read-and-write primitive* that allows them to perform the third step, which is gaining *full root privileges*.

To *break KASLR*, an adversary typically triggers a memory safety vulnerability, e.g., Use-After-Free (UAF) or Out-Of-Bounds (OOB) access, to leak a kernel address. By knowing the Android kernel binary under attack, the adversary then computes the kernel base address. Depending on how powerful the underlying vulnerability is, the adversary either continues or re-triggers this (or another) vulnerability to obtain an *arbitrary read-and-write primitive*. They then typically manipulate credentials to elevate their privileges. Furthermore, they tamper with kernel memory to disable SELinux's Mandatory Access Control (MAC), obtaining *full root privileges*.

Kernel Heap Attacks. Since most memory-safety vulnerabilities concern heap-allocated memory [65], dynamically allocated during runtime, it is a popular attack target.

Use-After-Free. UAF vulnerabilities occur when a resource that is still referenced is freed. A typical UAF exploit works as follows: First, an adversary causes the memory slot of a *vulnerable object* that is still in use to be freed. Freeing the memory slot causes the allocator to reuse the slot for future allocations. Second, they allocate a *reallocated object* such that the vulnerable and reallocated objects simultaneously use the previously freed slot. Third, they use either the vulnerable or the reallocated object to obtain a read or write primitive for the slot. Exploiting a Double-Free (DF) or Invalid-Free (IF) vulnerability (which are special cases of a UAF, where the slot is either freed twice or with an offset) works similarly.

In practice, several challenges render such attacks more difficult to execute. Most vulnerabilities grant only weak write capabilities, such as zeroing out memory at a particular offset. Additionally, to successfully exploit a UAF, the adversary requires knowledge of how the kernel's allocator (i.e., slab allocator) reuses memory slots.

There are generally two ways to exploit this reuse: With *in-cache reuse*, the adversary reuses the freed memory slot for another object that lives in the same slab cache. This only works in caches that contain the vulnerable and reallocated objects, e.g., `kmalloc-*` caches. Hence, the adversary is limited to objects that have the same (or similar) size and the same allocation properties as the vulnerable object.

The other way is to use a *cross-cache reuse* [33, 38, 60] attack. Here, the adversary frees all slots of a slab page, prompting the slab allocator to return the slab page that contains the vulnerable object to the page allocator. The page is then allocated either as a different type of page or to another slab cache. This allows them to reuse a memory slot between slab caches of different types, allocation sizes, and allocation properties.

Out-Of-Bounds. Exploiting an OOB vulnerability [12,65] with write capabilities follows a similar process. An adversary triggers the OOB write, often in the form of a linear overflow, to manipulate sensitive data in an adjacent memory slot (i.e., victim object). This sensitive data typically references a vulnerable object, e.g., through a reference counter or data pointer [38,42]. The adversary then forces the memory slot of the vulnerable object into a state where it is referenced twice. This upgrades the OOB write to be exploited analogously to the UAF three-stage exploitation flow typically.

3 High-Level Workflow

This section presents the high-level workflow of our study, depicted in Figure 2. It consists of three main components: the *One-Day Exploitation Analysis* and *Defense Inclusion and Effectiveness Analysis*, both of which yield *Novel Findings*.

In the *One-Day Exploitation Analysis* (see Section 4), we manually analyze all publicly available one-day exploits targeting memory safety vulnerabilities in the Android Linux kernel from the last three years. Our goal is to identify the exploitation flows employed in these exploits. In this context, we refer to an exploitation flow (see Figure 1) as a vulnerability-agnostic chain of exploitation techniques that exploit a vulnerability to gain full root privileges. An exploitation technique is a reusable and reasonably generic strategy for transforming an exploit primitive into a more powerful one [8]. In our study, we analyze 26 one-day exploits and uncover a diverse range of exploitation flows, with 10 used exploitation techniques. In a subsequent analysis, we identify 8 defense-in-depth mechanisms present in the mainline Android kernel v6.1, mitigating most exploitation techniques and, hence, 84.6 % of exploitation flows. This percentage serves as the ground truth for the maximum achievable security of mobile devices.

In the *Defense Inclusion and Effectiveness Analysis* (see Section 5), we collect Android kernels released by all top mobile phone vendors (i.e., Samsung, Xiaomi, Oppo, Vivo, Realme, Huawei, Motorola, Google, OnePlus, and Fairphone) between 2018 and 2023. Our goal is to determine the inclusion and effectiveness of defense mechanisms in protecting these mobile devices. For this, we collect 994 device firmwares and

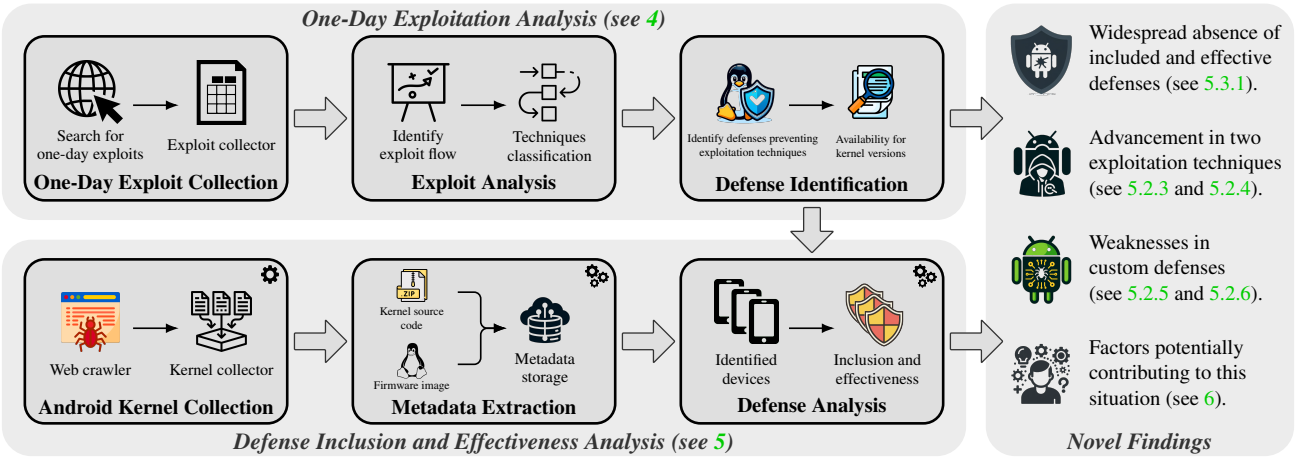

Figure 2: The high-level workflow of our study where ⚙⚙ indicates fully automated and ⚙ indicates mostly automated.

1533 kernel source codes. Our analysis reveals that a significant portion of the analyzed device firmwares lacks multiple defenses, and some of the defenses are flawed, leaving devices vulnerable to multiple of the one-day exploitation flows analyzed in our one-day exploitation analysis.

Our analysis reveals four *Novel Findings*. First, we reveal the widespread absence (see Section 5.3.1) of included and effective defenses against one-day exploitation flows across vendors. Second, we demonstrate advancements in two exploitation techniques (see Sections 5.2.3 and 5.2.4). While these advancements enable bypassing the defense intended against the base techniques, we discuss potential solutions. Third, we uncover 4 and 2 weaknesses (see Sections 5.2.5 and 5.2.6) in Samsung's and Huawei's custom defense, respectively. Lastly, we discuss (see Section 6) factors potentially contributing to the absence of effective defenses and offer improvement recommendations.

4 One-Day Exploitation Analysis

In this section, we elaborate on our systematic analysis of all publicly available one-day exploits targeting memory safety vulnerabilities in the Android Linux kernel over the past three years. We identify and examine 26 exploits, demonstrating that their exploitation flow uses one or more of the 10 exploitation techniques outlined in Section 4.1. These techniques follow a generic strategy for transforming an exploit primitive into a more powerful one. In Section 4.2, we demonstrate that defense-in-depth mechanisms present in the Android kernel v6.1 can mitigate 22 (i.e., 84.6 %) one-day exploitation flows. Lastly, Section 4.3 demonstrates that the remaining 4 one-day exploits either exploit substantially powerful vulnerabilities or can be mitigated by a defense currently in development [44].

One-Day Exploits. We obtained 26 one-day exploits (see Table 1) from public sources, e.g., Google Project Zero [49], Blackhat [35], Github [41], or other websites [58]. Our selection consists of one-days exploiting memory safety vulnerabilities, as the Android kernel has established defenses to prevent their exploitation. By including other vulnerabilities, such as logical (e.g., CVE-2022-22706) and GPU (e.g., CVE-2023-33107) flaws, we expect that the susceptibility to one-day exploits increases as the mainline Android kernel does not yet effectively mitigate them. Our study spans the last 3 years, from 2020 to November 2023. This aligns with Google Project Zero's efforts to track zero-day exploits targeting Android devices. Earlier public exploits are less documented, so we focus on this more recent timeframe [48].

4.1 Identified Exploitation Techniques

We observe that most one-day exploits have distinct exploitation flows to convert one or more memory safety vulnerabilities into either an arbitrary read-and-write primitive or code modification (see Table 1). By examining these exploitation flows, we identify 10 exploitation techniques.

We refer to an exploitation technique as a strategy for turning one exploitation primitive into a more powerful one, with examples of primitives being n-byte OOB write, UAF write, program counter control, or arbitrary read and write. We classify exploitation techniques based on strategies that recur over multiple one-days and are reasonably generic [8]. An example of a technique is control-flow hijacking, which turns program counter control into code execution and is used by multiple one-days. Another example is the unlink operation, which may turn an OOB or UAF write of a double-linked list into a once-triggerable write or read primitive.

ET1: Unlink Operation. By exploiting a vulnerability, an adversary ensures that a victim object resides in the same memory slot as a double-linked list, i.e., `list_head` with `next` and `prev` (see Listing 1). The adversary then initiates the unlinking via `list_del`, resulting in a write to the victim object. The one-days CVE-2019-2215, CVE-2019-2025, and

Table 1: Exploitation flow used by publicly available one-day exploits, where defense-in-depth mechanisms present in the Android Linux kernel v6.1 can ✓ or cannot ✗ prevent the exploitation flow. The exploitation flow is preventable depending on ✶ Samsung's RKP [15] variant. Two one-day exploits ☆ exploit the same CVE with different exploitation flows.

```
1 struct list_head {
2   struct list_head *next;
3   struct list_head *prev;
4 };
5 /* Unlinks element e */
6 void list_del(list_head *e) {
7   e->next->prev = e->prev;
8   e->prev->next = e->next;
9 }
```

Listing 1: Unlinking operation.

```
1 struct binder_thread {
2   struct list_head wait;
3   struct task_struct *task;
4 };
5 void remove_wait_queue(
        binder_thread *bt) {
6   /* Trigger unlinking */
7   list_del(&bt->wait);
8 }
```

Listing 2: Trigger unlinking.

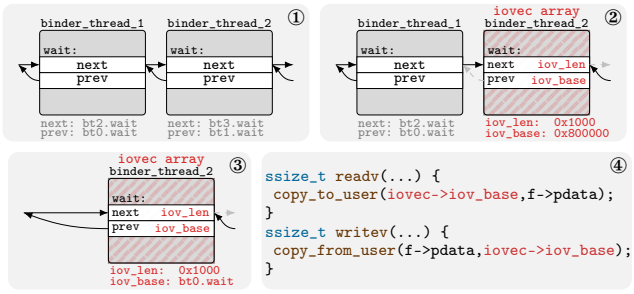

Figure 3: Exploitation example of the unlink operation.

CVE-2020-0030, for example, leverage this unlink operation to first leak `binder_thread->task`, whose layout is shown in Listing 2, and then overwrite `task->addr_limit` (**ET2**).

Figure 3 illustrates an exploitation example [46], where initially, an adversary prepares a double-linked list ①. They then exploit a vulnerability to ensure that the second `wait` entry (`binder_thread_2.wait` or short `bt2.wait`) resides in the same memory slot ② as an `iovec` object. This `iovec` stores a user buffer, with `iov_base/len` being the user buffer's pointer/size, commonly used for file reading or writing. Executing `remove_wait_queue` on the first `wait` entry (`bt1.wait`) overwrites the `iov_base` of the second `wait` entry with `bt1.wait->prev` ③ (at Line 7 of `list_del`). Consequently, the buffer `iovec` now points to `binder_thread_0.wait` (short `bt0.wait`). These exploits then use the `iovec` read-/write functionality ④ (e.g., `readv` or `writev`) to write to or read from the `iovec->iov_base` and, hence, `bt0.wait`. This approach is used to leak `binder_thread->task` and overwrite `task->addr_limit`. While this example shows the usage of `iovec` (which has been fixed for v4.13 [2]), other security-critical objects can also be misused, e.g., `msg_msg` [42] or `pipe_buffer` in CVE-2021-0920.

```
1 u64 access_ok(const void __user *addr, u64 size) {
2   return (u64)((u65)addr + (u65)size <= (u65)current->
        addr_limit + 1);
3 }
4 u64 copy_from_user(void *to, const void __user *from, u64 n) {
5   u64 res = n;
6   if (access_ok(from, n))
7     res = raw_copy_from_user(to, from, n);
8   return res;
9 }
```

Listing 3: Userspace data copy function validates with `access_ok` whether `addr` refers to userspace memory.

ET2: `addr_limit` Overwrite. This technique turns a `task->addr_limit` overwrite into an arbitrary read and write. AArch64 kernels below v5.11 include `addr_limit` in `task`, which holds the highest address accessible within user-data copy functions, e.g., `copy_*_user`. These functions call `access_ok` to validate that the user address is lower than

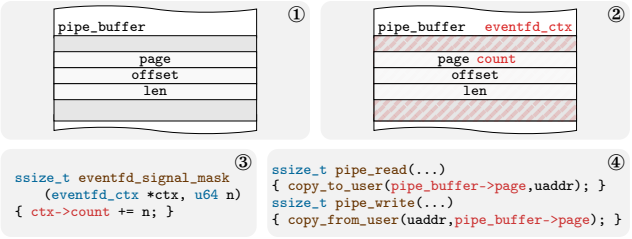

Figure 4: Exploiting `pipe_buffer` to obtain an arbitrary r/w.

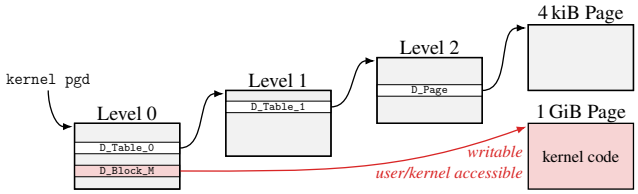

Figure 5: **KSMA:** Due to a write capability to page table level 0, an adversary maliciously overwrites the `D_Block_M` entry to refer to kernel code as writable and user accessible.

`addr_limit` (see Line 6 of Listing 3), aiming to ensure user address access. However, by overwriting `addr_limit` with `KERNEL_DS` (i.e., -1), an adversary can deceive the kernel into legally accessing kernel memory within these copy functions. Hence, syscalls (e.g., `read` and `write`) using these copy functions can be misused as an arbitrary read-and-write primitive.

ET3: `pipe_buffer` Overwrite. Overwriting the `pipe_buffer` yields an arbitrary read and write as follows. Initially, an adversary requires an arbitrarily triggerable overwrite capability for a `pipe_buffer` object that is still in use. One approach is to exploit a UAF vulnerability so that a `pipe_buffer` and a specific object (e.g., `eventfd_ctx` or `signalfd_ctx`) reside in the same memory slot. Since this specific object is writable from userspace, it enables manipulating `pipe_buffer` (e.g., `eventfd_ctx` for CVE-2021-22600). Another approach enforces the coexistence of a `pipe_buffer` and the backed physical page of another `pipe_buffer` in the same slot (cf. CVE-2022-22265).

Figure 4 illustrates the exploitation of CVE-2021-22600. In ①, the memory layout of a `pipe_buffer` is shown with its members `page`, `offset`, and `len`. Step ② exploits the vulnerability where afterward `pipe_buffer` and `eventfd_ctx` reside in the same memory slot, and `page` and `count` coexist on the same address. Calling `eventfd_signal_mask` ③ allows to change `count` and, hence, `pipe_buffer->page`. Consequently, `pipe_read/write` ④ read from or write to this controlled address, granting an arbitrary read and write.

ET4: Control-Flow Hijacking. Various one-day exploits perform a Control-Flow Hijacking (CFH) attack, leveraging an overwrite capability of either a function pointer or a pointer to a function pointer. Compared to x86_64 exploitation, they do not resort to Return-Oriented Programming (ROP) [10]. Instead, they identify an execution path resulting in an arbitrary read-and-write primitive. For instance, CVE-2023-0266 overwrites the `f_ops` pointer (referencing a table of function pointers for file interactions) of `ctl_file`. As a result, the syscalls `read` and `write` confuse the `void *pdata` member of `ctl_file`, leading to a misuse of `copy_*_user` and yielding an arbitrary read-and-write primitive.

ET5: Ret2bpf. Ret2bpf serves as an alternative to ROP, offering a similarly potent capability [7, 28]. Its prerequisites [28] involve hijacking the control flow (**ET4**), partial control of the first argument register, control over the second argument register, and a controllable data region. In ret2bpf, a data region is crafted to contain valid eBPF [7] instructions, performing, for instance, an arbitrary read and write. With the CFH primitive and the crafted eBPF instructions, ret2bpf performs a CFH attack to execute `___bpf_prog_run(regs, inst)`. This function interprets the crafted eBPF instructions as if the eBPF verifier had validated them. Here, `inst` is the data region holding the crafted eBPF instructions, and `regs` represents a writable section used for registers.

ET6: Slab Freelist Corruption. This exploitation technique turns a once-only OOB or UAF write into a memory slot overwrite capability. It requires a memory slot that is currently in the freed state. By exploiting a write capability on this free slot (e.g., zeroing memory due to a UAF or OOB write), an adversary manipulates a freelist pointer stored within the free slot. Then, by allocating an object, the adversary illegally reclaims the memory slot referenced by the corrupted freelist pointer. This allocated object typically grants overwrite capabilities for the reclaimed memory slot.

ET7: KSMA. Yong et al. [63] introduced the Kernel-Space Mirroring Attack (KSMA), which transforms a once-triggerable write primitive into a kernel code manipulation capability. This transformation is done by manipulating a page table level 0, called Page Global Directory (PGD) (e.g., `swapper_pg_dir`), representing the kernel address space.

Specifically, KSMA forges an entry within the kernel's page table level 0, designating its address range as accessible from user and kernel space. This forged entry is marked as a 1 GB huge page and references kernel code. Consequently, the entire kernel code (including kernel data) is readable and writable from userspace. The page-table layout after performing KSMA is shown in Figure 5 with a 3-level page-table translation (i.e., 39 bit Virtual Address Size (`VA_SIZE`) and 4 kiB page size, but it works similarly for other configurations). This kernel code modification is then utilized to disable SELinux and manipulate a syscall to elevate the privileges.

ET8: Dirty PageTable. Dirty PageTable [58] shows how page-table tampering results in an arbitrary read and write on Android (where Maar et al. [38] show generic page-table manipulation). It exploits a UAF (cf. CVE-2022-28350 and CVE-2020-29661) or DF (cf. CVE-2023-21400) for a cross-cache attack [60]. This causes an object with arbitrary overwrite

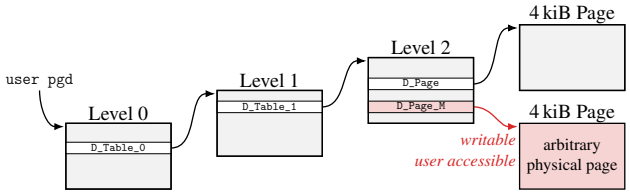

Figure 6: **Dirty PageTable:** With an arbitrary page table level 2 write capability, an attacker tampers the `D_Page_M` entry to refer to an arbitrary page as writable and user accessible.

capabilities (e.g., `signalfd_ctx` for CVE-2023-21400) to reside in the same memory slot as a page table used for user address translation. Figure 6 shows this, where an adversary has an arbitrary overwrite to the page-table entry `D_Page_M` due to the cross-cache attack. By triggering the overwrite, they gain control over the page frame number of this entry. Reading or writing to the user address using this page-table entry gives them arbitrary physical memory access.

ET9: DirtyPipe. The DirtyPipe attack [30] exploits an uninitialized variable to escalate privileges. The CVE-2022-0847 vulnerability allows to use the `pipe_buffer.flags` variable uninitialized. Consequently, this vulnerability allows overwriting of any file contents in the page cache, also in the case of read-only files, which results in privilege escalation.

ET10: DirtyCred. The DirtyCred exploit [34] allows an attacker to escalate privileges. It exploits a file UAF to free a writable file currently in use. Prior to this invalid free, it performs a write operation to the file and stalls this write operation. After the free, it reclaims the file object for a read-only high-privilege file. Continuing the stalled write operation now writes to the read-only high-privilege file. With this file manipulation, DirtyCred can, e.g., overwrite a kernel module with malicious code to construct an arbitrary read and write.

4.2 Defenses to Prevent Exploitation Flows

We identify 10 defense-in-depth mechanisms present in the Android kernel v6.1 or provided by vendors. They prevent exploitation techniques and, hence, exploitation flows, with the findings shown in Table 1 and detailed in Table 2.

DM1: `CONFIG_DEBUG_LIST`. This defense includes checks in `del_list` whether `e->next->prev == e` and `e->prev->next == e`. If these checks fail, the entry will not be unlinked. Thus, it mitigates the unlink operation (**ET1**). In Figure 3, for instance, overwriting from step ② to ③ is prevented as `iovec->iov_base` is not equal to `bt1.wait`.

DM2: `CONFIG_ARM64_UAO`. User-Access Override (UAO) [9] is a hardware-enforced defense that aims to mitigate `addr_limit` overwrite (**ET2**). It introduces new unprivileged load and store instructions that behave like privileged ones when the UAO bit is set. This restricts user-data copy functions, e.g., `copy_*_user`, from being misused to read from or write to kernel addresses directly.

Table 2: Mitigation of one-day exploits, using ✓ to indicate defenses that prevent used exploitation techniques. Conversely, ✗ indicates ineffective defenses (see Sections 5.2.3, 5.2.4 and 5.2.6). Samsungs's defenses ✗/✶ are either ineffective or only effective in certain variants (see Section 5.2.5).

DM1: `CONFIG_DEBUG_LIST` **DM2:** `CONFIG_ARM64_UAO` **DM3:** `kmalloc-cg-*`
DM4: `CONFIG_CFI_CLANG` **DM5:** `CONFIG_BPF_JIT_ALWAYS_ON`
DM6: `CONFIG_SLAB_FREELIST_HARDENED` **DM7:** `CONFIG_INIT_ON_ALLOC_DEFAULT_ON`
DM8: KSMA protection **DM9:** Samsung RKP **DM10:** Huawei HKIP

DM3: `kmalloc-cg-*`. Linux kernels above v5.13 support heap segregation at the allocator cache level. It separates caches to provide a designated cache for security-critical data marked as accounted, such as for `msg_msg`, `pipe_buffer`, `file`, and `task_struct`. For generic caches, a cache for non-security-critical data (i.e., `kmalloc-*`) and a cache for security-critical data (i.e., `kmalloc-cg-*`) are created. Free and available cached objects will never share the same memory slots within these caches. Hence, this mitigates the `pipe_buffer` overwrite (**ET3**) and unlink operation (**ET1** with security-critical objects), as these techniques rely on security-critical and non-security-critical data sharing the same memory slot. While adversaries might consider cross-cache attacks, three challenges arise with this approach, making the transition infeasible. First, for generic caches, the success rate significantly decreases to 40 % [60], with failure scenarios potentially resulting in a crash. The small success rate makes this approach impractical since the cross-cache reuse only pertains to a small part of the exploit and may need multiple repetitions. Second, exploits that engage in cross-cache attacks typically rely on prior in-cache reuse attacks to stabilize the exploit. For instance, CVE-2022-22265 stabilizes by in-cache reallocating the double-freed slot of the `pipe_buffer` as an `iovec` multiple times. Separating the `pipe_buffer` from objects intended for stabilizing, such as `iovec`, makes the exploit unstable, mostly resulting in a crash,

successfully preventing exploitation. A similar applies to CVE-2023-21400, where `seq_operations` (accounted) are prevented from being in-cache reallocated as `signalfd_ctx` (not accounted). Third, various UAF exploits (e.g., CVE-2021-0399) offer a tight time window in which an in-cache attack is exploitable. In contrast, cross-cache attacks require more time due to the recycling/reclaiming of the slab page to/from the page allocator [60], making small windows not exploitable.

DM4: `CONFIG_CFI_CLANG`. Control-Flow Integrity (CFI) [1,3] restricts the control flow to an approximate Control-Flow Graph (CFG), limiting the targets for CFH attacks (**ET4**). The Android kernel uses Clang's implementation [3], providing function-signature-grained CFI. It prevents CFH attacks that overwrite function pointers with arbitrary functions, e.g., CVE-2021-1905 and CVE-2021-0399.

DM5: `CONFIG_BPF_JIT_ALWAYS_ON`. To mitigate ret2bpf (**ET5**), this defense mechanism forces BPF to always use the JIT engine instead of the interpreter. Consequently, the `___bpf_prog_run` function used by ret2bpf is not compiled and, therefore, cannot be called, preventing ret2bpf.

DM6: `CONFIG_SLAB_FREELIST_HARDENED`. To mitigate the manipulation of slab allocator metadata, this defense hardens the slab allocator by adding sanity checks. This includes XORing the freelist pointer with a pseudo-random number, preventing slab freelist corruption (**ET6**).

DM7: `CONFIG_INIT_ON_ALLOC_DEFAULT_ON`. It zeroes out the memory slot for both allocations by the page and slab allocator. Consequently, it greatly minimizes the exploitability of uninitialized values. It prevents the exploitation of DirtyPipe (**ET7**) as the uninitialized `pipe_buffer.flags` cannot be misused to overwrite file content in the page cache.

DM8: KSMA Protection. In response to KSMA (**ET8**), researchers proposed to move all kernel level 0 global page tables (e.g., `swapper_pg_dir` and `tramp_pg_dir`) to a read-only section [62]. As a result, these page tables cannot be manipulated for a huge kernel memory mapping (e.g., 1 GiB) that is writable from userspace, thus preventing KSMA.

DM9: Samsung RKP. Samsung's Real-time Kernel Protection (RKP) [15] employs hypervisor-based protection designed to mitigate code modification, data modification, and control-flow hijacking in the kernel. To address kernel code modification, RKP ensures the integrity of page tables (**ET8** and **ET9**) and code by mapping them as read-only, protected by the hypervisor. Hypervisor calls permit legitimate writes to these protected pages. RKP also limits CFH attacks (**ET4**) by including checks before indirect branches that restrict control-flow transfers to a function-grained CFG.

DM10: Huawei HKIP. Huawei Kernel Integrity Protection (HKIP) [25] employs hypervisor-based protection that protects kernel code and critical kernel data. It also limits privilege escalation and protects additional control-flow-related data. To achieve this, HKIP ensures the integrity of certain page tables (**ET8** and **ET9**), `addr_limit` (**ET2**), CFI metadata, and eBPF interpreted code by protecting them via the hypervisor. Hypervisor calls or exceptions to the hypervisor permit legitimate writes to these protected pages. Protecting CFI metadata only provides additional protection for modules and not against the CFH technique. Similarly, protecting the eBPF-interpreted code does not prevent against ret2bpf, as it only safeguards the already interpreted instructions.

Further defenses. The ongoing research in improving kernel security yielded results with various kernel defenses. For instance, `CONFIG_HARDENED_USERCOPY` restricts `copy_*_user` from reading and writing out of bounds [59]. Other examples include `CONFIG_INIT_STACK_ALL_ZERO` mitigating uninitialized stack variable exploitation [37] and `CONFIG_STACKPROTECTOR_STRONG` providing stack protection [45]. While these defenses cover a broad range of vulnerability mitigation, our focus is specifically on defenses against one-day exploitation flows on the Android kernel (**DM1-10**).

4.3 Unpreventable Exploitation Flows

We identify 4 one-day exploitation flows targeting the Android kernel that remains unpreventable by mainline defenses. Among these, DirtyCred (cf. CVE-2021-4154) presents a powerful technique that falls beyond the defense prevention scope. A similar applies to the CFH one-day (cf. CVE-2023-26083,-0266), redirecting the control flow to perform an arbitrary read and write without violating signature-based CFI.

While our identified defenses do not effectively prevent two other one-days (Dirty PageTable, cf. CVE-2022-28350 and CVE-2020-29661), researchers are actively developing a new defense mechanism specifically designed to counter cross-cache reuse attacks [44]. This mitigation strategy involves switching the allocation of memory slots cached by the slab allocator from physical to virtual pages, thereby preventing the reuse of slab pages returned by the page allocator.

5 Defense Inclusion & Effectiveness Analysis

In this section, we outline our systematic analysis demonstrating a *widespread deficiency of included defense mechanisms across vendors* as well as *shortcomings of certain defenses*. Our approach (see Figure 2) consists of three mostly automated stages: Initially, we collect kernel source codes and firmwares (see Section 5.1) for Android devices from 10 vendors. We then analyze kernel codes (see Section 5.2) to assess the effectiveness of defenses provided by the mainline kernel or vendors. Lastly, we analyze firmwares (see Section 5.3) to detect included effective defenses in devices.

Android Devices. For our analysis (done in November 2023), we cover Android devices from vendors that constitute more than 84 % [6] of the global market. These include the top 7 vendors [6], i.e., Samsung, Xiaomi, Oppo, Vivo, Huawei, Realme, and Motorola, along with Google, OnePlus, and Fairphone. We assess devices released between 2018 and 2023, utilizing Android versions 9 through 14 and kernels ranging

from v3.10 to v6.1. These Android versions account for a share of more than 86 % [5], with specific percentages for Android 13, 12, 11, 10 and 9, being 25.7 %, 21.3 %, 17.3 %, 13.9 %, and 8.7 %, respectively. Android 14, while at a negligible market share at the moment, is also considered.

We decided to start with phones released in November 2018 (5 years from the start of this work), as the lifespan of Android phones is 4-6 years (4y for Huawei, 5y for Google, and 6y for Samsung) [17, 54]. Hence, our selection ensures a comprehensive overview of the current device landscape.

5.1 Collection of Firmwares and Kernel Codes

This step automatically collects firmwares (not protected by captchas) and kernel code. To achieve this, we implement a Python script using Selenium that crawls web pages to collect firmwares and kernel source code from our 10 vendors. We manually collected firmware protected by captchas or other automation detections (i.e., ≈ 45.3 %).

Firmwares. Our 10 vendors produced 1698 devices between November 2018 and November 2023 (see Table 4). For 1109 of them, firmwares were provided, where we only considered the most recent release either officially (e.g., Google) or via an intermediate supplier (e.g., Oppo).

Kernel Codes. We collected 1533 kernel codes (see Table 4) with different releases for the same device (e.g., Samsung and Huawei) where available. Other vendors (e.g., Google and Vivo) use the same kernel code for multiple devices, resulting in less collected code than firmwares.

5.2 Analysis of Kernel Source Codes

We examine kernel source codes for efficacy against exploitation techniques. Initially, we provide evidence that our identified defenses (see Sections 5.2.1 and 5.2.2) reflect the real world of mitigating exploitation techniques. However, we also identify shortcomings in these defenses. We show that they can be bypassed, indicating that their efficacy is less than intended due to advanced techniques (see Sections 5.2.3 and 5.2.4) or weaknesses (see Sections 5.2.5 and 5.2.6).

5.2.1 Mainline Defenses in Downstreamed Kernels

7 of the 8 mainline defense mechanisms are intrinsically tied to the core functionality of the Android kernel:

- Associating specific defenses with versions (i.e., **DM3**).
- Not compiling dangerous functions (i.e., **DM5**).
- Replacing non-hardened with hardened functions (i.e., **DM1/4/6/7/8**).

For example, `CONFIG_DEBUG_LIST` (**DM1**) uses the hardened function `__list_add_valid` to validate metadata in double-linked lists. Another example is `kmalloc-cg-*` (**DM3**), which utilizes a segregated set of allocator caches for kernel versions 5.13 and above. The exception is

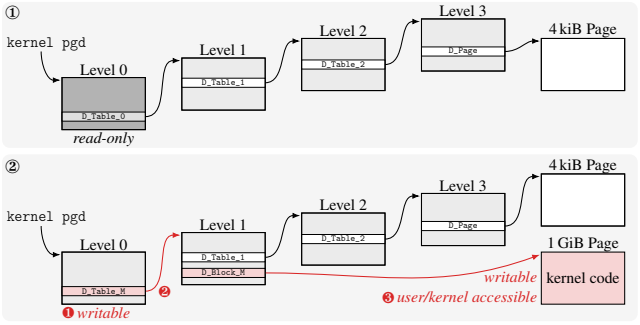

Figure 7: **Advanced KSMA:** ① Initial 4-level page table translation with the level 0 table mapped as read-only. ② Modifies the level 0 mapping to mark it as writable ❶, overwrites `D_Table_M` ❷, and appends `D_Block_M` ❸, to have a 1 GiB mapping accessible from userspace.

`CONFIG_ARM64_UAO` (**DM2**), which is hardware-dependent. Although our analysis might identify this defense as present, this defense can be bypassed, as we demonstrate in Section 5.2.4. Hence, regardless of whether it is enabled, it does not protect `addr_limit` overwrite (**ET2**).

5.2.2 Identified Downstream Defenses

Some vendors provide custom defenses to improve kernel security. We semi-automatically analyze the 1533 collected kernels and provide evidence of 3 vendor-specific downstream defenses against the identified exploitation techniques. The analysis works as follows: First, we automatically collect the configuration flags in the `./security` subdirectory and in the files that require changes to mitigate exploitation techniques, e.g., `vmlinux.ld.S` and `mmu.c` to prevent KSMA (**ET8**). Second, we manually analyze those flags collected from downstream kernels that are not present in the mainline kernel (i.e., Google). Our analysis results in Samsung RKP (**DM9**), Huawei HKIP (**DM10**), and `CONFIG_PG_DIR_RO` from Vivo (which we consider in the firmware analysis as **DM8**). We also received confirmation from Fairphone and Motorola that they do not include vendor-specific defenses.

5.2.3 Advanced Kernel-Space Mirroring Attack

Despite the KSMA mitigation patch, we present an advancement in reenabling KSMA. Its prerequisite is the same constraint write capability as the base KSMA (**ET8**), but it uses it twice: First, it changes the mapping of the level 0 PGD to writable, and second, it maliciously inserts the page-table entry into the PGD. For a 48 bit `VA_SIZE` system with 4-level translation, our technique triggers the write three times, as depicted before ① and after ② the attack in Figure 7. The first write changes the PGD mapping to writable ❶, while the second changes the PGD entry to user accessible ❷. The third write inserts then the entry ❸ in the page-table level 1.

For this technique, the locations of three page-table pages (*level 0*, *level 1*, and *level 3'* corresponding to the mapping *level 0* as read-only) are crucial. Depending on whether `CONFIG_UNMAP_KERNEL_AT_EL0` is active, `swapper_pg_dir` or `tramp_pg_dir` is used as a *level 0* page. A KASLR code leak, combined with knowledge of the kernel binary under attack, is sufficient to obtain these locations since both locations are mapped to a fixed offset to the kernel base address. This step is also needed for the base KSMA.

Both *level 1* and *level 3'* are allocated via the page allocator during the early initialization stages and accessed via the Direct-Physical Mapping (DPM) [39], which is a virtual memory mapping to the entire physical memory. Since the page allocator returns the same physical page during different boots, their locations can be determined. The DPM may be randomized on newer Android kernels (e.g., v6.1). To overcome randomization, a heap address leak is typically sufficient to derandomize the DPM, as the kernel heap uses the DPM directly. Typically, leaking a heap address requires no additional effort beyond leaking the kernel base address.

Armed with the three page-table locations, our advanced KSMA uses the write capability three times to obtain kernel code modification, which no mainline defense can prevent. The level of difficulty of our advancement is similar to the base KSMA, but the write capability is triggered three times, and for recent Android versions, a heap leak is required.

Experiments. Our setup involves a buildroot filesystem with an Android kernel (aarch64 with a 48 bit `VA_SIZE`), specifically v5.15 and v6.1. We run it inside a virtual machine with 4 cores and 4 GB RAM via QEMU 6.2.0. We introduce a write primitive and run our exploits as an unprivileged user, giving them the same capabilities as the base KSMA version. As a result, we successfully execute our advanced KSMA and obtained an arbitrary code modification primitive.

Mitigation. Our advanced KSMA requires the locations of all mapping page tables that are not randomized during the early initialization process. Hence, an adversary can still deduce their location by knowing the kernel binary under attack (and a heap leak for v6.1). To counteract the advanced KSMA, we propose randomizing the locations of the page tables during this early initialization stage, ensuring that adversaries cannot obtain information about the page's location.

5.2.4 Shortcoming of User Access Override

The UAO feature is believed to prevent the `addr_limit` overwrite (**ET2**) [36] effectively. This technique manipulates `addr_limit` with `KERNEL_DS` to facilitate, for example, pipes for arbitrary kernel reads and writes. Specifically, it first writes the pointer to a userspace buffer to one pipe end. It then performs a `read` syscall with a kernel address as an argument, prompting the userspace copy function to write the userspace buffer's content to this kernel address. With UAO enabled, setting `addr_limit` to `KERNEL_DS` prevents the first write operation. Moreover, setting `addr_limit` to `USER_DS` prevents the second write to kernel memory.

However, since `addr_limit` operates at thread granularity, we spawn two threads, *T1* and *T2*, where we only illegally overwrite the `addr_limit` of *T2* with `KERNEL_DS`. We leverage *T1* to perform the first write and *T2* for the second write. As a result, we can bypass UAO without further restrictions. Prior work [9] has presented similar bypasses.

Mitigation. A mitigation would be to remove the `addr_limit` functionality or use kernels above v5.11, which do not support `addr_limit` anymore.

5.2.5 Samsung RKP Weaknesses

We inspect Samsung RKP [15], designed to prevent page-table manipulation and limit CFH attacks. However, we demonstrate that various RKP variants only protect certain page tables and, thus, do not mitigate page-table manipulation. They also provide less CFH protection than the mainline defense.

Analysis. For each of these findings, we provide statistical data on their occurrence, collected using the following approach. We first perform automated source code analysis, followed by manual verification. We then conduct experiments to demonstrate the severity of these identified problems.

Findings. First, some kernels have RKP disabled and do not map `tramp/swapper_pg_dir` or `tramp_pg_dir` as read-only. Compared to the mainline defense, this results in less security as an adversary can directly perform KSMA. We found this weakness mostly in low-end devices such as Galaxy A04/A14 (i.e., released 2022/2023), missing both pages and Galaxy M10 (i.e., released 2019), missing `tramp_pg_dir`, representing 25.4 % and 1.7 % of kernels, respectively.

Second, while some variants protect page tables used for userspace address translation, we observe a strong tendency to exclude this protection towards new high-end devices such as Galaxy S23 5G. Specifically, we observe that less than 53 % of devices include this protection, indicating that more than 47 % are vulnerable to Dirty PageTable [58].

Third, `CONFIG_FASTUH_RKP` is a performance-optimized RKP variant included in over 60 % of all v5.4 kernels, providing a maximum number of read-only pages protected by the hypervisor. If the system demands more, RKP resorts to allocating unprotected pages. An adversary can exhaust these read-only protected pages and, subsequently, perform Dirty PageTable. This performance-optimized RKP variant is available for lower-end devices, e.g., Samsung Galaxy J6, and for high-end devices, e.g., Samsung Galaxy S20 FE and S21+ 5G. Similarly, `CONFIG_TIMA_RKP` provides similar weak protection for page tables, mainly used by older devices.

Fourth, `CONFIG_RKP_CFP_JOPP/_ROPP` aim to mitigate CFH attacks [15] by providing function-granular CFI (`JOPP`) and return address protection (`ROPP`). However, our analysis of exploitation flows reveals that all 6 CFH attacks redirect the control flow with at least function granularity. Hence, both

defenses are ineffective in mitigating any of the CFH attacks.

Experiments. For the first weakness, we use the same setup as for our advanced KSMA technique and overwrite unprotected page-table pages to perform KSMA. We then implement POCs for the other weaknesses on a Samsung Galaxy S20 FE, where we modify the kernel code to obtain the corresponding primitive. For the second weakness, we use the introduced write primitive for a page table used for a userspace address translation to successfully perform Dirty PageTable. For the third weakness, we demonstrate that we can drain the protected pages with memory exhaustion. We then prompt the kernel to allocate a page that should be protected, but this is not due to memory exhaustion. For the fourth weakness, we demonstrate that RKP does not mitigate control-flow hijacking to arbitrary functions. As a result, control-flow protection does not prevent the 6 CFH attacks we analyzed.

5.2.6 Huawei HKIP Weaknesses

We examine Huawei's HKIP [25], particularly regarding the protection against KSMA and Dirty PageTable.

Analysis. We observe that HKIP is only included in certain devices and enabled in about 62 %. In the following, we analyze HKIP and experimentally demonstrate the absence of protection for crucial page-table pages.

Findings. First, HKIP protects page-table pages that are allocated for kernel address translations (e.g., via `pte_alloc_one`) in a specific virtual address range. As a result, HKIP does not protect page tables for userspace address translations, leaving devices vulnerable to Dirty PageTable.

Second, while HKIP protects the ttbr (hardware register that stores the current PGD for address translation) switch, it may not be compatible with frequent ttbr switching defenses, i.e., software PAN (`CONFIG_ARM64_SW_TTBR0_PAN`) switches the ttbr for each `copy_*_user` and Meltdown protection (`CONFIG_UNMAP_KERNEL_AT_EL0`) for each user kernel switch. No device has HKIP with either one of these two enabled, leaving these devices vulnerable to KSMA.

Experiments. We could not run experiments with the Huawei kernel source codes as they either had compilation errors, no `defconfig` (e.g., `ranchu64`) viable for virtual environments or failed to boot in QEMU. Therefore, we adapted a Google kernel v4.14 to tag pages that HKIP would have protected. For our page-table manipulation attacks, we experimentally observed that HKIP does not protect page-table pages that KSMA and Dirty PageTable manipulate.

5.3 Analysis of Firmwares

This work refers to the firmware as the stock ROM, the original software loaded onto the device by the vendor. It consists of multiple images [4], such as the system and boot image. Figure 8 shows the automated workflow of our implemented Python script, extracting the necessary metadata for defense

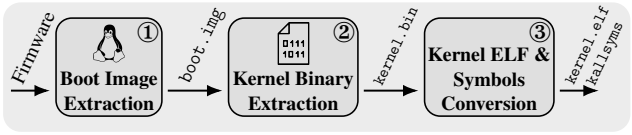

Figure 8: Workflow of extracting `kernel.elf` and `kallsyms` from the firmware, required for the defense detection.

detection. It first extracts the boot image ① using open-source tools, which requires different tools [22, 31, 32, 51, 55] as vendors encode the boot image differently. It then extracts the kernel binary ② using `unpack_bootimg` [35]. Lastly, it uses `kallsyms_finder` and `vmlinux_to_elf` to reconstruct the symbols (i.e., `kallsyms`) and convert the kernel binary to an analyzable ELF (i.e., `kernel.elf`) ③ [40].

The `kallsyms` and `kernel.elf` components form the basis of defense detection. Our Python script uses `kallsyms` to identify global functions within the kernel binary, allowing us to deduce the active defense mechanisms. The presence of `__list_add_valid` in `kallsyms`, for instance, indicates the status of `CONFIG_DEBUG_LIST` (**DM1**). Our script does similar assessments for other defenses (see Table 3). It uses the `kernel.elf` to determine the status of KSMA protection (**DM8**) and `CONFIG_SLAB_FREELIST_HARDENED` (**DM6**). For KSMA protection, all PGDs (e.g., `swapper_pg_dir`) must be mapped in a read-only section. The presence of calling `get_random_long` within `__kmem_cache_create` indicates the status of `CONFIG_SLAB_FREELIST_HARDENED`.

Our evaluation also includes five features for system security; KASLR (`CONFIG_RANDOMIZE_BASE`), code write protection (`CONFIG_STRICT_KERNEL_RWX`), freelist randomization (`CONFIG_SLAB_FREELIST_RANDOM`), restricting user access in kernel (`CONFIG_ARM64_(SW_TTBR0_)PAN`), and Meltdown protection (`CONFIG_UNMAP_KERNEL_AT_EL0`).

Evaluated Firmwares. Out of the 1698 released and 1109 collected devices, our analysis extracted 994 firmwares, resulting in a collection rate of 58.5 %, which aligns with prior work on reverse engineering firmwares [11, 14, 64].

Due to the unavailability of certain firmwares, our analysis could not cover all released devices. However, we observed that the missing firmwares are distributed either normally regarding device age, such as those from Huawei and Vivo, or tailored to older devices, as seen with Xiaomi and Realme. Given our finding that older devices tend to include fewer defenses, our analysis provides conservative results. Thus, we anticipate the real-world scenario to be even more concerning.

5.3.1 Analysis Results

We fully automate the detection of included defenses. Table 5 presents the defenses included for each vendor's firmwares. Our results indicate a lack of basic defenses (e.g., PAN and KASLR) and a significant lack of defenses against one-day ex-

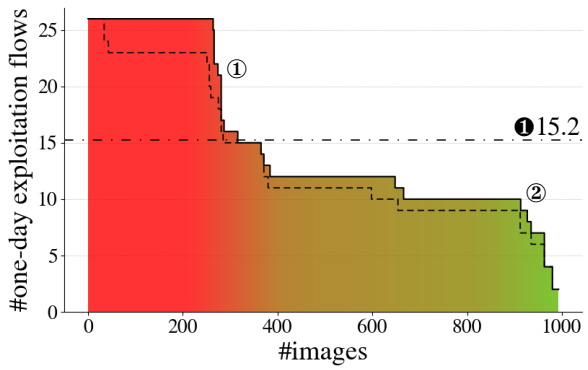

Figure 9: Susceptible one-day exploitation flows of all device images. While ① indicates that 281 images are susceptible to 21 or more one-day exploitation flows and ② indicates 913 images to 10 or more, the ❶ line represents the average susceptibility of 15.2 exploitation flows of all 994 images.

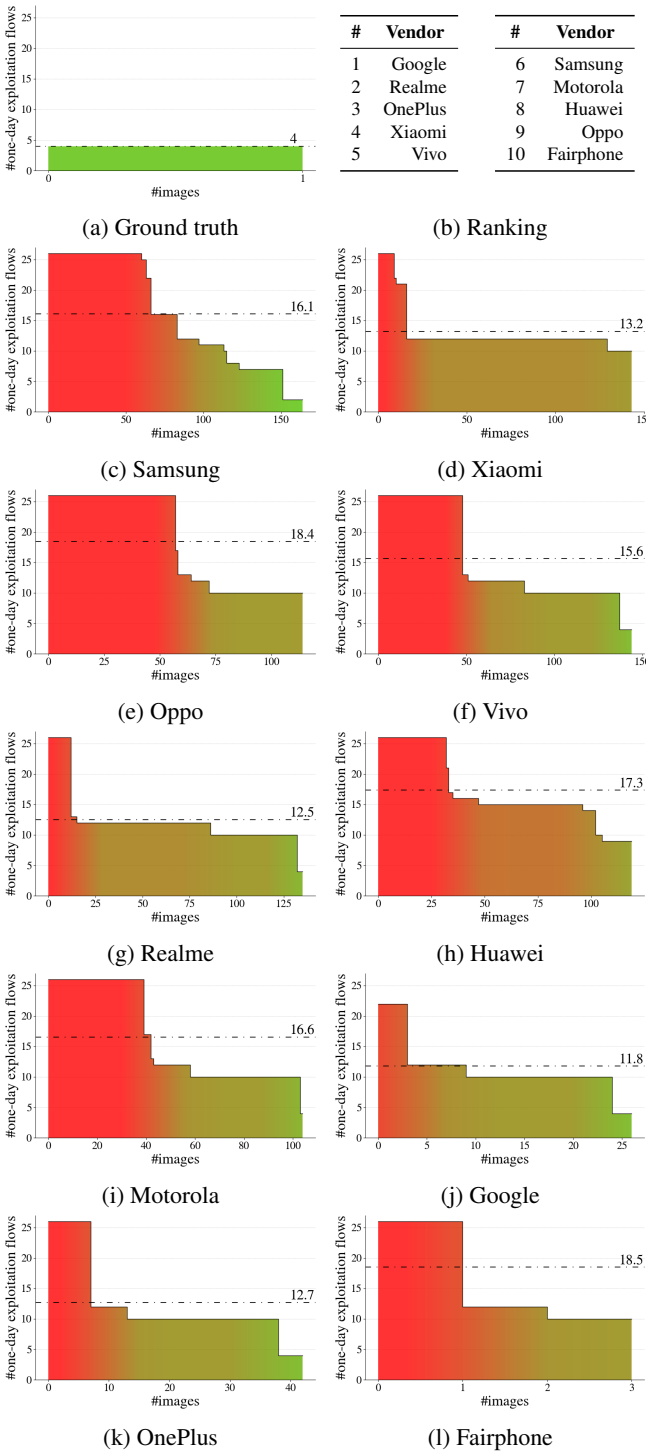

ploit flows. In particular, significant portions of the firmwares do not include defenses such as `CONFIG_DEBUG_LIST`, which is critical to mitigate BadBinder [46].

Susceptibility. Using data from Section 5.2 and Table 2, we evaluate the effectiveness and assess the susceptibility of firmwares to one-day exploitation flows. We consider a firmware to be susceptible to a one-day exploitation flow if it does not include a defense that can prevent the vulnerability-agnostic exploitation flow. Figure 9 illustrates the overall susceptible one-day exploitation flows per firmware with two curves. The dashed line depicts the impact of the widespread defense lack, while the outer line incorporates both the lack and efficacy shortcomings (see Section 5.2), providing a more comprehensive view. Without these shortcomings, on average, nearly two one-day exploitation flows could have been prevented. Both findings highlight the worrying situation and lack of effective defenses to prevent exploitation flows.

Takeaway 1

Even though effective defenses (see Table 2) for a large share of the one-day exploitation flows are available, they are rarely activated in vendor-provided kernels.

Susceptibility per Vendor. We further organize the results by vendor, presenting each in Figure 10. Figure 10a depicts the ground truth, showcasing the maximum achievable security with all available mainline defenses. Figure 10c-10l show each vendor's susceptible one-day exploitation flows, including the lack of defenses and efficacy shortcomings. We specifically highlight Google, Fairphone, and Samsung, representing the most and least secure, and with the highest market share. Their susceptibility is 11.8, 18.5, and 16.1, respectively, while the ground truth has 4. We compute the factor by which they are worse than the ground truth, resulting in 2.95 ($\approx \frac{11.8}{4}$), 4.62, and 4. Figure 10b presents the ranking of vendors according to this deterioration factor.

#	Vendor	#	Vendor
1	Google	6	Samsung
2	Realme	7	Motorola
3	OnePlus	8	Huawei
4	Xiaomi	9	Oppo
5	Vivo	10	Fairphone

Figure 10: Analysis results per devices for each vendors.

Takeaway 2

Protection against one-day exploitation flows is highly vendor dependent, varying between a 4.62 to 2.95 worse scenario than applying all available mainline defenses.

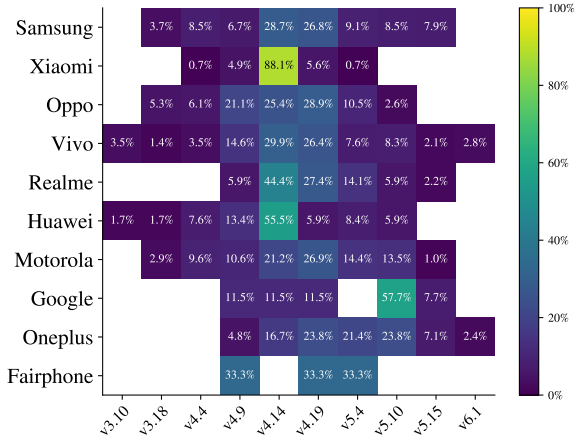

Figure 11: Applied Android kernel versions for each vendor.

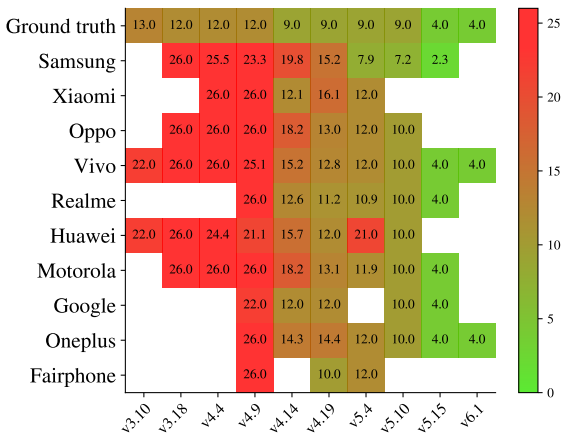

Figure 12: Susceptible exploitation flows per version/vendor.

Susceptibility per Kernel Version. To illustrate a version dependency, we initially obtain the used kernel versions. Figure 11 shows the results covering v3.10 to v6.1. For context, v4.19 was released in 2018, while v3.10 was released in 2014. We then analyze the susceptibility to one-day exploitation flows, organized by kernel version and vendor (see Figure 12). The figure includes a ground truth, representing how many exploitation flows remain susceptible for a given kernel version with all available defenses integrated (see Table 6).

Three findings emerge from this analysis: First, almost no device kernel prior to v4.14 includes any defenses. Since ret2bpf (**ET5**) is not exploitable on v3.10, it may be less susceptible than v3.18. Second, newer kernels tend to have more active protection against exploitation flows, observed across almost all vendors. This is particularly true for those obeying the GKI constraints ($\geq$v5.4 for GKI-1.0 or $\geq$v5.10 for GKI-2.0). Third, although newer kernels provide more defenses, a v3.10 kernel with all available defenses enabled would protect more flows than 38.1 % of our analyzed kernels.

Takeaway 3

While newer kernels provide more defenses, a v3.10 kernel with all available defenses enabled would mitigate more exploitation flows than 38.1 % of vendor-supplied kernels.

Susceptibility per Low/High-End Device. We differentiate the susceptibility according to whether it is a low-end or a high-end device: We initially compute the average one-day susceptibility of the latest low-end and high-end devices from vendors offering both classes, i.e., all except Google and Fairphone (see Table 7). We then compute the susceptibility reduction of high-end compared to low-end devices. For instance, with a susceptibility score of 4.5 and 5.5 for high-end and low-end Samsung devices, respectively, the reduction is 18.2 %. Overall, the reduction is between 0 % to 63.6 %, with an average value of 23.8 %, which indicates a significant reduction of high-end to low-end devices.

Takeaway 4

There is a significant gap of 23.8 % between the one-day susceptibility of high-end and low-end devices.

6 Discussion

Factors Potentially Contributing to the Absence of Effective Defenses. Our analysis, highlighted in Takeaway 1, reveals a concerning reality: vendors lack the inclusion and effectiveness of defenses against one-day exploitation flows. Here we discuss potential factors contributing to this situation.

First, as indicated by Takeaway 2, there is variability in susceptibility to one-day exploitation flows across vendors. While Google and OnePlus demonstrate lower susceptibility, others like Huawei show higher ones. As these vendors utilize different kernel versions, we observe a correlation between higher susceptibility and the use of older versions. Hence, a potential contributing factor is the *use of older kernel versions*.

Second, as emphasized in Takeaway 3, susceptibility extends beyond mere kernel version correlation. Even the deprecated kernel v3.10 (released about ten years ago) would mitigate more one-day exploitation flows, if properly configured, than 38.1 % of vendor firmwares. Huawei underscores this statement with their v5.4.86 kernels, nearly twice as bad as the properly configured v3.10. This lack of proper configuration appears prevalent across multiple vendors. Hence, the second potential contributor is *a lack of importance regarding security-relevant features for the Android kernel*.

Third, as shown in Takeaway 4, we observe that low-end are more susceptible to one-day exploitation flows than high-end devices, as observed by most vendors. On the one hand, low-end devices tend to be less powerful than high-end devices, and on the other hand, enabling defenses increases the performance overhead. To compensate for this performance cost, vendors may deliberately not enable defenses for performance

gains. Therefore, the third potential factor is *performance cost, especially for less powerful low-end devices*.

Recommendation to Improve Android Security. With these insights, we propose that Google updates the Android Compatibility Definition Document (CDD), which outlines the requirements for devices to be compatible with Android. While for Android 14 some fundamental defenses are recommended (e.g., `CONFIG_CFI_CLANG`) or required (e.g., `CONFIG_STRICT_KERNEL_RWX`), other critical ones are absent (e.g., `CONFIG_DEBUG_LIST`). By including our findings, we anticipate a substantial improvement in Android security.

Responses. Google responded that they are aware of this problem and are gradually enforcing kernel defenses that will be integrated. However, as defenses can come at a performance cost, enforcing them across all vendors is difficult, especially for low-end devices. They pointed out that `CONFIG_DEBUG_LIST` has been enforced in the past, but vendors complained about the performance hit. This resulted in critical defenses not being integrated. Samsung and Huawei responded similarly, as integration comes at a performance cost, i.e., Samsung for not activating RKP on all (especially low-end) devices and Huawei for not protecting all page tables. These responses highlight our third potential contribution factor. Fairphone and Motorola acknowledged our findings and integrated defenses, while the others did not respond.

Automation and Standardization. Fully automating the analysis process would enhance the demonstration of the effectiveness of defenses. We have already automated several steps, such as parts of the firmware and kernel code acquisition, metadata extraction, and defense analysis, all of which are scalable. Challenges remain in the acquisition and analysis of zero-days and the acquisition of all firmware. Our work addresses these challenges manually and encourages standardization, drastically reducing manual effort. Therefore, our work addresses current technical challenges and encourages progress for future identification of effectively integrated defenses, ultimately improving Android security.

False Negatives/Positives. A false negative occurs when we interpret a device as being susceptible to an exploitation flow when it is not. This could have happened if we have overlooked defenses. To ensure we identified all mainline defenses, we executed each exploitation technique (**ET1-10**) with security measures enabled, resulting in the defenses (**DM1-8**) preventing these exploits. To ensure that we have identified all downstream defenses, we performed a semi-automated analysis of the 1533 downstream kernels in Section 5.2.2, which yielded 3 vendor-specific defenses. While misinterpreted firmware analysis could also lead to false negatives, most defenses are intrinsically tied to the kernel's core functionalities. As described in Section 5.2.1, those defenses that are not intrinsically tied can only lead to false positives, i.e., we interpret a device as mitigating an exploitation flow when it does not. This means our results can be interpreted as conservative, and the real world may be even more worrying.

7 Related Work

Large-scale Firmware Analysis. Possemato et al. [43] investigated compliance with Android's compatibility guidelines and found customizations as security drawbacks. Subsequent work [24] has highlighted delays in adopting critical patches. Other studies scanned ROMs for insecure access policies [16, 23] or privacy-intruding apps [20, 24, 52]. For embedded systems, researchers have uncovered vulnerabilities at a large scale [14, 19] and revealed a reluctance to activate attack mitigations in Linux-based IoT devices [64].

Android Security Patch Ecosystem. Prior works studied the deployment of security updates to Android systems. Wu et al. [57] noted that most Android Security Bulletin (ASB) issues stem from native code. Farhang et al. [18] found that CVEs in the kernel took the longest to propagate to vendor ASBs, while other researchers [29, 67] reported weeks to months of delay in deploying Android security updates.

Patch Detection. Researchers proposed strategies to detect patches in kernel binaries. Zhang et al. [66] presented a detection approach by deriving a signature from the mainstream version, which is then compared with target kernels. PDiff [27] statically extracts the semantics of source-level patches and uses a similarity-based measure to detect patches in compiled kernels. Dynamic approaches [26, 68] automatically adapt existing PoC exploits to different kernel variants.

Vulnerability Patching. Researchers have proposed solutions to address the long delays in kernel patch deployment. Wang et al. [56] prevented bugs discovered by a sanitizer from being triggered and, hence, exploited till a patch is available. Talebi et al. [53] instrumented vulnerable syscall implementations to undo harmful side-effects. Other researchers focused on downstream Android kernels. Chen et al. [13] proposed hot-patching with Lua code to filter vulnerable function arguments. Xu et al. [61] extended this by suggesting automated binary hot patches from source-level upstream fixes.

Zero-Day Analysis. Google Project Zero [9, 45, 49] and Threat Analysis Group [50] hunt for zero-days in the wild. They release public findings covering various entities, e.g., Android phones, significantly enhancing system security.

8 Conclusion

This work conducted a one-day analysis of Android devices, combined with an analysis of defense inclusion and effectiveness. Our findings unveiled a significant gap between the current state of Android security and its maximum potential. We discussed potential contributing factors and offered recommendations for improvement, enhancing Android security.

A Detailed Statistics

A.1 Detailed Defense Detection of Kernels

Table 3 illustrates the comprehensive list of how we assess the state of our identified defense mechanisms. We follow the procedure to identify symbols of globally reachable functions within the `kallsyms` file. This file contains all globally reachable functions and variable symbols used in the kernel binary, e.g., marked with `EXPORT_SYMBOL`. For instance, the presence of `__list_add_valid` in `kallsyms` indicates the status of the `CONFIG_DEBUG_LIST`. As another example, the symbol `cache_random_seq_create` indicates the presence of `CONFIG_SLAB_FREELIST_RANDOM`. A similar assessment stands true for detecting the other defenses. Additionally, to identifying symbols `kallsyms`, our approach also detects defense mechanisms which do not contain globally reachable

Table 3: Symbols and used additional information for our defense detection approach. The defense feature ☆ is enabled if this symbol (e.g., globally visible function or variable) is present within the `kallsyms` containing all kernel symbols.

Defense Feature	Kernel Executable	Present within `kallsyms`☆	Information
`CONFIG_DEBUG_LIST`		`__list_add_valid`, `__list_del_entry_valid` `__list_add`, `__list_del_entry`	≥v3.18 <v3.18
`CONFIG_CFI_CLANG`		`cfi_module_add`, `cfi_module_remove`	
`CONFIG_BPF_JIT_ALWAYS_ON`		`___bpf_prog_run` `__bpf_prog_run`	≥v4.14 <v4.14
`kmalloc-cg-*`			available for ≥v5.13
`CONFIG_INIT_ON_ALLOC_DEFAULT_ON`		`init_on_alloc`	
`CONFIG_ARM64_UAO`		`uao_thread_switch`, `cpu_enable_uao`	no `addr_limit` for ≥v5.11
`CONFIG_SLAB_FREELIST_HARDENED`	`get_random_long`		called within `__kmem_cache_create`
KSMA Protection	`swapper_pg_dir`, `tramp_pg_dir`	`swapper_pgdir_lock`, `swapper_pg_dir`, `tramp_pg_dir`	`*_pg_dir` mapped as read-only
Samsung RKP		`rkp_init`	only for Samsung devices
`CONFIG_RANDOMIZE_BASE`		`module_alloc_base`, `kaslr_early_init`	
`CONFIG_STRICT_KERNEL_RWX`		`set_debug_rodata`, `mark_readonly`, `mark_rodata_ro`	named as `CONFIG_DEBUG_RODATA` for <v4.14; on v3.10 only for 32 bit systems
`CONFIG_ARM64_PAN`		`cpu_enable_uao`	
`CONFIG_ARM64_SW_TTBR0_PAN`	`"emulated: Privileged Access Never (PAN) \ using TTBR0_EL1 switching"`	`reserved_ttbr0`	<v5.4; available for ≥v4.10 ≥v4.19
`CONFIG_SLAB_FREELIST_RANDOM`		`cache_random_seq_create`, `cache_random_seq_destroy`	
`CONFIG_UNMAP_KERNEL_AT_EL0`		`tramp_pg_dir`	

Table 4: Statistical results of firmware extraction and kernel code collection.

Vendors	Firmware Extraction			Kernel Code
	#devices	#available	#extracted	#collected
Samsung	197	190	164	654
Xiaomi	278	151	143	188
Oppo	229	145	114	29
Vivo	307	178	144	30
Realme	307	137	135	135
Huawei	182	121	119	218
Motorola	115	112	104	246
Google	26	26	26	9
OnePlus	54	46	42	21

symbols. For instance, `CONFIG_SLAB_FREELIST_HARDENED` only includes inline functions and member variables. To detect the presence of this defense, our approach analyzes the kernel binary, more specifically, the function where these inline calls are executed, e.g., `get_random_long` within function `kmem_cache_open`. Executing the call indicates the presence of this defense. To detect the presence of the KSMA protection, `swapper_pg_dir` and `tramp_pg_dir` must also be mapped read-only. For instance, these pages might be mapped between `__start_rodata` and `__init_begin`.

A.2 Statistical Results of Firmware Extraction

Table 4 illustrates the extractable firmwares. Our success rate of 58.5 % (with a collection and extraction rate of 65.3 % and 89.6 %) from produced devices to extractable firmwares aligns with prior work [11, 14, 64]. The two main reasons for extraction failure were that our approach did not recognize the correct format or that part of the firmware was corrupted.

Table 5: Included defenses averaged over all firmwares for each vendor. ✶ inidcates that it is ineffective while ☆ indicates that it is ineffective for kernels <v5.11.

Abstract

Third-party tracking plays a vital role in the mobile app ecosystem, which relies on identifiers to gather user data across multiple apps. In the early days of Android, tracking SDKs could effortlessly access non-resettable hardware identifiers for third-party tracking. However, as privacy concerns mounted, Google has progressively restricted device identifier usage through Android system updates. In the new era, tracking SDKs are only allowed to employ user-resettable identifiers which users can also opt out of, prompting SDKs to seek alternative methods for reliable user identification across apps. In this paper, we systematically explore the practice of third-party tracking SDKs covertly storing their own generated identifiers on external storage, thereby circumventing Android's identifier usage restriction and posing a considerable threat to user privacy. We devise an analysis pipeline for an extensive large-scale investigation of this phenomenon, leveraging kernel-level instrumentation and UI testing techniques to automate the recording of app file operations at runtime. Applying our pipeline to 8,000 Android apps, we identified 17 third-party tracking SDKs that store identifiers on external storage. Our analysis reveals that these SDKs employ a range of storage techniques, including hidden files and attaching to existing media files, to make their identifiers more discreet and persistent. We also found that most SDKs lack adequate security measures, compromising the confidentiality and integrity of identifiers and enabling deliberate attacks. Furthermore, we examined the impact of Scoped Storage - Android's latest defense mechanism for external storage on these covert third-party identifiers, and proposed a viable exploit that breaches such a defense mechanism. Our work underscores the need for greater scrutiny of third-party tracking practices and better solutions to safeguard user privacy in the Android ecosystem.

1 Introduction

Third-party tracking refers to the process of collecting data about a user's online behaviors and activities, by an entity distinct from the website or platform being used by the user [44]. In Android, the entity refers to a third-party tracker other than the app and the Android system. These trackers could be advertisers, data brokers, or other service providers that collect user data across multiple apps for various purposes, which generally include targeted advertising that is personalized to users to enhance the likelihood of users engaging with the ad, or analytics that help improve user experience and retention. Although beneficial to app developers and increasing their revenue, third-party tracking also poses a significant threat to user privacy, as it requires profiling users based on their behaviors or interests. In the process of third-party tracking, cross-app user identification plays a crucial role as it allows trackers to connect disparate pieces of information harvested from different apps to a single user for profiling.

Third-party trackers achieve cross-app user identification through user identifiers. In Android, trackers provide app developers with their own SDKs (Software Development Kits) [46] to be integrated into the app to facilitate the acquisition of user identifiers. These identifiers generally include non-resettable hardware device identifiers (e.g., IMEI) and user-resettable identifiers (e.g., Google Advertising ID [12]). To enhance the protection of user privacy, Google has gradually imposed restrictions on the use of device identifiers throughout the development of Android. Initially, apps only needed the necessary permission to obtain hardware identifiers, which would not change even after a system reset. However, due to growing privacy concerns, Google tightened control over hardware identifiers, first mandating user authorization before obtaining hardware identifiers, and then outright prohibiting access to them, while recommending advertising identifiers as an alternative. Compared to hardware identifiers, advertising identifiers are more unstable: firstly, users can manually reset these identifiers at any time; secondly, users can opt out of advertisement personalization, which directly prevents apps from accessing them.

In this new era where the use of hardware identifiers is heavily restricted, third-party trackers are compelled to seek alternative approaches to reliably identify users across different

apps. In our manual analysis of popular third-party tracking SDKs, we have identified cases where tracking SDKs store their own identifiers on Android's external storage. Typically, these SDKs generate an identifier and store it in a specific shared directory location on external storage when it does not already exist on the device. Other apps with the same SDK can then access this identifier to facilitate cross-app user identification. Although apps must obtain the relevant permissions (which require user authorization at runtime) to access external storage, it is common for apps to request such permissions, and users usually do not deny such requests. Moreover, Android's inadequate management of external storage, particularly shared directories, results in numerous files accumulating on external storage, leaving users unable to determine whether deleting these files would affect app functionality or the Android system. Consequently, these generated identifiers may persist in external storage for a long time.

This type of third-party identifier contravenes Google's restrictions on device identifier usage and poses a huge threat to user privacy. Therefore, we intend to conduct an exhaustive, large-scale investigation into such identifiers in real-world scenarios. Our primary goal is to delve into these covert identifier practices, providing an in-depth analysis of their storage, generation, and security measures, as well as their potential implications. We have developed an analysis pipeline to facilitate our large-scale experiment. First, we devise a dynamic analysis framework that leverages kernel-level instrumentation and UI testing techniques to automate the recording of apps' file operations at runtime. Subsequently, we pick out file candidates that are potentially related to third-party identifiers from a collection of file operations recorded across all apps using heuristics. Next, we re-inspect apps that accessed these candidates to locate the code facilitating the file operations, thereby enabling us to attribute the file operations to a specific party. Finally, we perform an in-depth manual analysis to determine if the file candidate is indeed related to third-party identifiers and further delve into the storage, generation, and security aspects of these identifiers.

By adopting our pipeline to 8,000 Android apps, we identified 17 third-party tracking SDKs that store identifiers on external storage. Furthermore, we discovered that these SDKs employ a variety of methods to store identifiers on external storage, including hidden files and attaching to existing media files, in order to make identifiers more covert and persistent. In terms of security, most SDKs lack sufficient protective measures, leaving the confidentiality and integrity of identifiers vulnerable, which opens doors for deliberate attackers to tamper with identifiers and further compromise user privacy, as demonstrated by the two potential attack vectors we proposed in Section 3.2. We also assessed the influence of Scoped Storage, Android's latest defense mechanism for external storage, on these covert identifiers in Section 5.4, and further proposed a viable exploit that can bypass this defense mechanism, thus posing a risk of reliable third-party user identification even after Scoped Storage's enforcement.

In summary, this work offers these major contributions:

- We highlighted the phenomenon of third-party tracking SDKs covertly storing their identifiers in Android's external storage, which significantly threatens user privacy.
- We developed an analysis pipeline to investigate such covert tracking practices extensively on a large scale, and successfully identified 17 third-party tracking SDKs that store their identifiers on external storage.
- We provided an analysis of how these identifiers are stored, generated, and (not) secured.
- We analyzed the implications of these identifiers post Scoped Storage, and further proposed a feasible exploit breaching Scoped Storage to identify users.

2 Background

2.1 Identifier Evolution

During the progression of Android development, the use of identifiers, especially hardware identifiers, has undergone several significant updates to enhance user privacy. However, before delving into the evolution of identifier usage, it is crucial to first recognize that Android's permission management system allows the app and its integrated SDKs to share the same permissions, which means permissions granted to apps also extend to SDKs. To date, this situation persists[1] even though several permission isolation prototype schemes have been proposed [35, 50, 52]. As a result, when referring to permission-related topics, the terms "apps" and "SDKs" are used interchangeably.

Prior to Android 6.0, tracking SDKs could identify users through a variety of hardware identifiers, such as IMEI, IMSI, serial number, and MAC address. These hardware identifiers would remain unchanged even if the user resets the device completely (i.e. factory reset). Additionally, accessing these hardware identifiers was quite easy for apps. Apps only needed to request the READ_PHONE_STATE permission from users upon installation. Users had to accept all permissions displayed or would be unable to install the app. Once granted the permission, the app would have unlimited access to these hardware identifiers which could not be revoked. In addition to hardware identifiers, SDKs could also use ANDROID_ID to identify users. ANDROID_ID is a 64-bit hexadecimal string generated when the device is first set up. ANDROID_ID would change after a factory reset, however, no permission is required to access it.

Starting from Android 6.0 (API level 23, released in 2015), Google has tightened restrictions on the usage of hardware

[1] We further discuss Google's beta program Privacy Sandbox [24] and its SDK Runtime feature [27] in Section 6.3.

identifiers. The required permissions to obtain hardware identifiers are listed as runtime permissions, which require user consent at runtime and can be revoked at any time.

Subsequently, starting from Android 8 (API level 26, released in 2017), ANDROID_ID was changed to have a different value for each app, effectively ending its use for cross-app user identification.

Lastly, starting from Android 10 (API level 29, released in 2019), apps must have privileged permission to access hardware identifiers, a permission level unavailable to third-party apps. Up to this point, Google has imposed strict restrictions on accessing all hardware identifiers and ANDROID_ID. As an alternative, Google recommends apps use advertising identifiers for advertising and analytics purposes. However, users can reset or even opt out of advertising identifiers at any time, making it difficult for third-party trackers such as advertising and analytics companies to achieve reliable user identification using advertising identifiers.

Until January 2023, a significant majority of Android devices (68%) were running Android 10 or a later version [16]. Tracking SDKs are forced to seek alternative approaches for reliable cross-app user identification in the new era.

2.2 External Storage

The storage system is a crucial component of Android, which allows apps to store data persistently. The storage of Android can be classified into two categories: internal storage and external storage. Apps always have access to their own private directory within internal storage (i.e., /data/data/<package name>) and do not require any permission. Moreover, files stored in internal storage can only be accessed by their owner. Therefore, apps generally use internal storage to store data that they do not want other apps to access.

On the other hand, external storage can be divided into two parts, app-specific directories (e.g., "/storage/emulated/0/Android/data/<packagename>") and shared directories. Unlike internal storage, even app-specific directories can easily be accessed by other apps before Android 10 [39]. Therefore, external storage is often used to store non-sensitive files or those meant to be shared.

Prior to Android 10, reading and writing files on external storage only requires the necessary permissions, namely READ_EXTERNAL_STORAGE and WRITE_EXTERNAL_STORAGE. These two permissions are used so frequently, users tend to grant apps these permissions. Consequently, a lot of apps, and their integrated SDKs, have unlimited access to external storage before Android 10. However, this changes when a new protection mechanism called `Scoped Storage` [26] is introduced in Android 10 (and fully deployed in Android 11 [28]). With Scoped Storage, an app-specific directory can only be accessed by its owner app. On shared directories, an app can only access files it created (no permission required), except under the following conditions: (a) with READ_EXTERNAL_STORAGE[2], apps can read **media** files created by other apps [10]; (b) writing (i.e. modifying) **media** files created by other apps require user consent on a file-by-file basis at runtime [29]; (c) accessing non-media files in shared directories created by other apps require user manual selection via file browsing [11][3]. However, accessing all files in shared directories is still feasible with MANAGE_EXTERNAL_STORAGE, a permission strictly regulated by Google and is granted only to apps with specialized functions such as file management apps [21].

3 Motivation

3.1 Motivating Example

While exploring the Android system, we came across some unusual files stored in hidden directories on external storage. Upon further investigation, we discovered that these files store identifiers generated by the Alibaba Identifier SDK (package name: com.ta.utdid2) that was utilized across different apps. Alibaba is a major Chinese internet company with billions of app downloads to its name. The Alibaba Identifier SDK has a long-standing history, with the earliest information found on search engines dating back to 2015. We will now delve into its identifier generation and management process, which takes place in the `getUtdid` method of the `com.ta.utdid2.device.UTDevice` class.

The Alibaba Identifier SDK employs a four-step process for identifier generation and management, a pattern commonly observed in many other SDKs we examined, as illustrated in Figure 1. This figure also contains a simplified code representation of the `getUtdid` method and highlights the research concerns associated with each step:

Step 1: Initially, the SDK tries to obtain the identifier from two key values in both system settings and `SharedPreference`, with one plaintext and one AES-encrypted version for each. If both attempts fail, the SDK seeks to access the identifier in file `/storage/emulated/0/.UTSystemConfig/Global/Alvin2.xml` and file `/storage/emulated/0/.DataStorage/ContextData.xml` on external storage, again with one plaintext and one encrypted.

Step 2: The SDK checks the validity of the identifier upon each obtainment. The research concerns for this step involve parts of the security aspect of the identifier, namely its integrity, which verifies that the identifier has not been tampered with. However, Alibaba only performs basic format verification, which can only determine if the identifier is damaged but

[2]Starting from Android 13, this permission becomes obsolete and is superseded by media permissions with finer granularity READ_MEDIA_* [15,20].

[3]There are also other functionality-specific exceptions. For instance, with certain media-related permissions and users' explicit consent, apps can write all media files without file-by-file consent [19]. However, discussing these exceptions in detail would be too verbose, and would digress from our research topic. Readers interested in learning more about these exceptions can refer to our citations for further details.

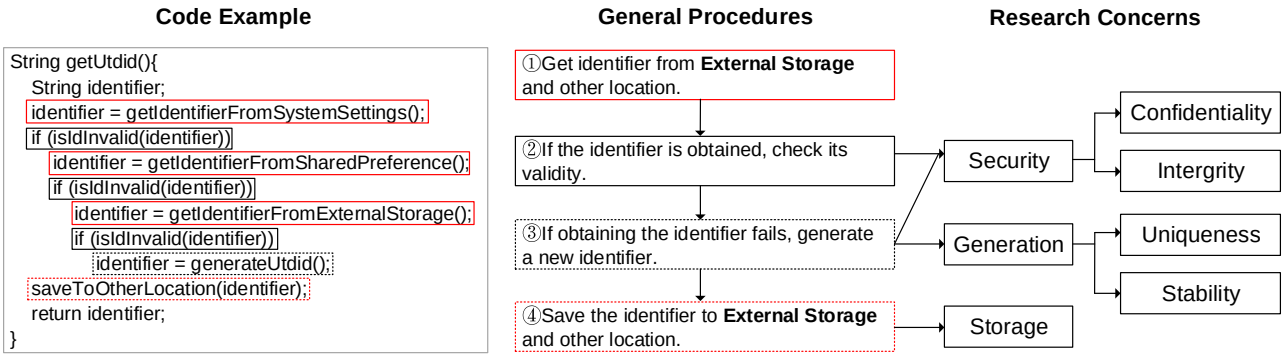

Figure 1: Identifier Generation and Management in Alibaba Identifier SDK: Code Example, Procedures, and Research Concerns

is vulnerable to deliberate attacks elaborated in Section 3.2.

Step 3: If the identifier remains unattainable or invalid from any of the locations mentioned in Step 1, the SDK generates the identifier (based on IMEI or a random value if IMEI cannot be obtained). The research concerns for this step involve: (a) the uniqueness of the generated identifier; (b) whether the same identifier can be generated for a specific device after identifier deletion; (c) the second aspect of the identifier's security, specifically the confidentiality of the identifier. Here, Alibaba ensures uniqueness but cannot generate the same identifier if IMEI cannot be obtained, and only partially considers confidentiality since only one of the two identifiers is encrypted, as mentioned in Step 1.

Step 4: The SDK tries to synchronize the generated identifier across all locations mentioned in Step 1. The research concerns for this step focus on the identifier storage tactics which these tracking SDKs may apply to make their identifier more discreet and persistent. For instance, here, Alibaba stores their identifiers with two backups on external storage, both locations being hidden files users cannot directly access.

Generally, apps do not have access to the system settings as it requires signature-level permission, and `SharedPreference` will be deleted upon the app's uninstallation. Therefore, the primary identifier storage location for the Alibaba Identifier SDK's stable user identification is the two files on external storage, which only require commonly granted storage permissions and can happen stealthily without users' consent, while bypassing Android's system restrictions on identifier usage. This motivating example showcases the importance of thoroughly investigating the research concerns in each step to better understand such identifier practices.

3.2 Potential Threat and Attack Vectors

Tracking users via external storage not only significantly violates user privacy and contravenes relevant identifier policies, but also presents opportunities for deliberate attackers if identifiers are inadequately protected.

Violating Market Policies and Infringing User Privacy: The SDK stores the identifier on external storage, resulting in a long-lasting, relatively stable cross-app identifier accessible to the SDK with only external storage permissions, which stands in contrast to Google's consistent efforts to restrict device identifier usage. Furthermore, this practice also breaches the identifier usage policies established by app stores. For instance, Google Play mandates the use of the Google Advertising ID (when available on a device) over other device identifiers for any advertising purposes [12]. Similarly, Xiaomi Store stipulates that identifiers used for advertising and analytics should be revocable [30]. These identifiers clearly defy this rule, as users cannot manually reset these identifiers or opt out as they can with the Advertising ID. Moreover, such covert user identification can occur without users' consent, and it is almost impossible for an average user to notice such acts. This clearly infringes upon users' privacy choices.

Potential Attacks: Storing identifiers on external storage also opens doors for attackers if the identifiers' confidentiality and integrity are not ensured. We propose two potential attacks.

First, an attacker can use a malicious app on the user's device to modify the identifier on external storage to an identifier carefully crafted by the attacker. After the modification, the SDK will recognize the user's device as the attacker's, leading to the SDK pushing advertisements personalized for the attacker's device to the user. Attackers could thus promote their products and potentially profit from this tactic. The malicious app executing the attack does not require high privileges or dangerous behaviors—only permission to write to external storage and modify the file storing the identifier.

Second, the attacker can read the identifier on external storage, save it on their device, and install an app with the integrated SDK. When using the app, the SDK recognizes the attacker's device as the victim's device since it contains

the victim's identifier, resulting in the attacker receiving advertisements targeted at the victim. By analyzing the content of these ads, the attacker can infer details about the victim's privacy, such as their interests or viewed products. Similar attacks have already been proved feasible both on the web and on the mobile [45, 47].

4 Approach

In order to investigate such covert user identification by third parties through external storage on a large scale, we carefully devised an analysis pipeline, the overview of which is depicted in Figure 2. This pipeline, which takes Android .APK files as inputs, comprises four modules: 1) Dynamic Analysis: in this module, we employ a combination of app automating techniques and kernel-level instrumentation, focusing on one app at a time to capture all file operations during the app's runtime; 2) Candidate Finding: this module is based on the collected file operations from the Dynamic Analysis module, where we pool together file operations derived from a large set of apps to pick out files that could potentially serve as candidates for storing identifiers using heuristics; 3) Candidate Attributing: we further re-inspect the apps that accessed these candidate files to locate the code facilitating the file operation behavior utilizing Frida [18]. This step allows us to attribute potential identifier behavior to a specific component within the app, for instance, a component belonging to a tracking SDK. 4) Manual Analysis: in this final module, we conduct a thorough manual analysis through reverse engineering, to verify if the candidate is indeed related to identifiers, and to further dissect the identifiers in-depth to understand how these identifiers are stored, generated, and (not) secured. It is worth noting that while the first three modules of our approach are largely automated, the threshold selection (detailed in Section 4.2) and the attributing module do require human intervention. We now detail each module as follows.

4.1 Dynamic Analysis

The Dynamic Analysis module facilitates our experiments on large-scale apps and allows us to comprehensively record the file operations of apps at the kernel level. Prior to commencing the analysis, we first initialize our testing devices to simulate the usage patterns of daily-used devices. We then use app automating techniques to traverse apps and record their file operations at runtime for further analysis leveraging instrumentation.

4.1.1 Initialization Settings

To prevent apps from exhibiting abnormal behavior in a completely empty environment (e.g., with no other apps installed, no photos in albums, etc.), we carry out a set of initialization procedures for our dynamic testing environment. Specifically, we begin by installing several widely-used apps on our devices. We then populate the devices with contacts, phone call logs, and SMS message records. Additionally, we take a few photos with the camera and generate some screenshots.

4.1.2 Kernel-Level Instrumentation

To comprehensively capture the file operations performed by the app, we customize the Linux kernel and integrate it into the Android system running on our devices. We monitor file operations at the kernel level since all file operations are eventually handled by the kernel [49]. This approach also allows us to circumvent common instrumentation detection, which generally runs at the framework level [31, 37]. Specifically, we record all system calls invoked by the app that is related to file operations. We achieve this through the following steps:

First, as we aim to record the file operations of the target app only, we flag the threads of the target app with a customized tag at the Zygote process [9] (where all Android apps init) through the system call `prctl` [7], and enable our kernel-level instrumentation only for the flagged threads. This allows us to reduce the impact of other running apps, performance overhead, and log file size.

Second, we configure the kernel to perform system call tracing when a system call (a) originates from a thread containing the aforementioned customized flag, and (b) is related to file operations. There are various types of system calls for different file operation types (e.g., `openat` for opening, `read` for reading, 120 system calls in total for both ARM and ARM64 architectures). The kernel will then call functions `syscall_trace_enter` and `syscall_trace_exit` before and after the execution of the system call respectively, and we can access the relevant information regarding the invoked system call, including parameters and return value, in both functions. We then determine the file operation type based on the type of the system call, and extract the file path from the system call parameters.

Finally, we add a logging module to the kernel that allows us to store the obtained file operations for further analysis. More specifically, we create a file within the `proc` filesystem for logging file operations. `Proc` is a virtual filesystem that provides an interface to access internal data structures in the kernel memory [25]. Initially, we attempted to employ the `printk` function, which is commonly used for logging output in the kernel. However, we discovered that the `printk` function, which stores logs in a circular buffer, is inadequate for handling extensive or high-frequency output [5]. In contrast, our approach of logging within the kernel memory effectively overcomes these limitations, offering enhanced reliability and scalability with respect to the volume of log output.

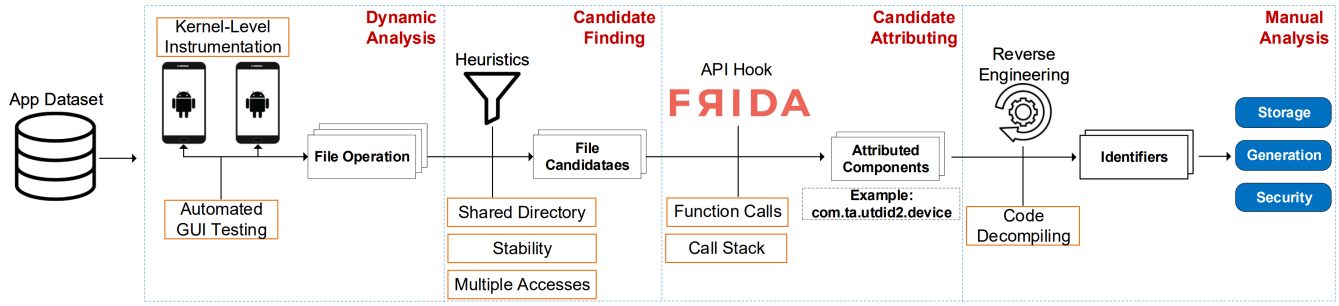

Figure 2: Overview of Our Analysis Pipeline

4.1.3 Automated Testing

Our Dynamic Analysis module aims to record apps' file operations during runtime. To facilitate large-scale analysis, we employ Fastbot [17], an automated GUI testing tool developed by ByteDance. Distinct from other state-of-the-art testing tools, Fastbot is monkey-based (enabling fast action input), and is enhanced by reinforcement learning, therefore outperforming its counterparts in terms of code coverage [42]. During the automated testing, we focus on one app at a time, recording the app's file operations with our instrumentation. After the testing is complete, we uninstall the target app and reboot the device to restore the testing environment for the next app.

4.2 Candidate Finding

After running all the apps in our dataset utilizing our Dynamic Analysis module, we have collected a large number of file operations of these tested apps. It is crucial to automatically identify files on external storage that are potentially associated with identifiers from this large collection of file operations for further analysis. Upon examining the motivating examples and manually probing patterns within the collected file operations, we have derived insights that can help us identify these potential candidates. Finally, we have summarized these insights into the following heuristics to streamline this identification process:

- Files associated with an identifier should be stored in a shared directory on external storage, rather than in an app-specific directory. The file location for storing an identifier should be (a) readily accessible by all apps on the device, and (b) steady enough for consistent user identification. However, files within an app-specific directory are no longer accessible by other apps since Scoped Storage, and more importantly, they are subject to deletion upon the app's uninstallation, making them unsuitable for storing identifiers.

- Files associated with an identifier should not be subject to frequent deletion. Ideal identifiers are device-specific information such as IMEI and serial number, which will remain unchanged even after a factory reset. Files associated with an identifier should also maintain stability, otherwise, it cannot serve its identification purpose.

- If a file is associated with an identifier, it should be accessed by multiple different apps during a large-scale experiment. A tracking SDK needs to be integrated into a large number of apps to facilitate cross-app user identification. As a result, the generated file for storing the identifier is likely to be accessed by a number of different apps in our experiments.

We implement our heuristics as follows. Recall that the collected file operation logs contain both the file operation type and the accessed file path, we first pick out file operations on files in a shared directory on external storage based on the accessed file path. We then eliminate files that are frequently deleted, as indicated by the type of file operations. Next, we count the number of distinct apps each remaining file is accessed by, and utilize this number for our candidate selection. It is vital to note a specific observation from our study: some apps iterate through files on external storage, inevitably inflating the access count for all files. This behavior underscores the need for a heuristic approach when setting the threshold, tailored to the scale of each experiment. For our study, we determined the threshold by sampling files at varying counts. Our rationale for choosing a threshold of 100 is based on the following observations: (a) we found no identifier-related files in sampled files accessed by fewer than 100 apps; (b) our further examination of the top 50 files accessed by fewer than 100 apps yielded none identifier-related; and (c) with the threshold set at 100, we successfully obtained a concise list of only 30 file candidates accessed by 100 or more apps.

4.3 Candidate Attributing

After identifying potential file candidates, we perform a re-inspection of apps to attribute the corresponding file operation to a specific component within the app. To accomplish this,

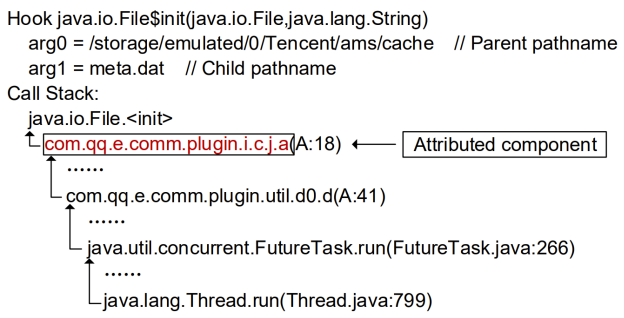

Figure 3: An Example of the Call Stack

we use Frida [18], a dynamic code instrumentation toolkit that allows us to hook common file processing APIs, including Java APIs such as `java.io.File` and `FileInputStream`, as well as the Native API `open` in `libc`. While monitoring calls to these APIs, we also obtain the call stack before the API is executed. The call stack enables us to accurately attribute the file operation to a specific component within the app, as illustrated in Figure 3, where the attributed package name belongs to the Tencent Advertising SDK (package name: com.qq.e). Note that the file processing functions we initially instrumented may not be comprehensive, as it is difficult to enumerate all related APIs. If we fail to attribute a file operation to a specific component, we manually analyze the app to identify the missing file processing API and add it to our hooking list.

In this module, for the apps selected for re-inspection, we re-run the automated testing in the Dynamic Analysis module. During this phase, we utilized Frida for attributing. This decision stemmed from our understanding that directly accessing the caller's package through kernel-level instrumentation (as employed in our preceding module) is infeasible. Consequently, we cannot directly perform the attributing during the app's initial run in the Dynamic Analysis module.

However, it is essential to highlight that Frida's instrumentation, unlike kernel-level instrumentation, can be readily detected by apps, especially those that have undergone app packing. Some developers, in order to enhance app security, may employ app packing techniques that often incorporate anti-dynamic analysis measures, such as running environment detection and anti-debugging techniques [34, 51]. Such measures can effectively thwart our attributing using Frida. Given this context, for each file candidate, we selected one unpacked app that had accessed this file for attributing (and the subsequent manual analysis). This strategy was driven by the strong correlation between the file for identifier storage and the SDK. We deem the attributing successful if we could trace the file operation to a third-party component within the app. If the attributing failed, we'd pivot to another unpacked app to continue attributing.

4.4 Manual Analysis

After attributing the file operations of our selected candidates to a specific component within the app, we perform a thorough manual analysis on the corresponding component. Our analysis consists of two key aspects: first, we ascertain if the file subject indeed contains identifiers; second, we delve deeper into the storage, generation, and security methods applied to these identifiers.

In terms of storage, Android's ineffective management of files on external storage often leads to an accumulation of files in a disorganized manner. Typically, users do not perform thorough cleanups of files on external storage. Consequently, files stored in external storage receive minimal interference from users. Nonetheless, tracking SDKs desire their identifiers to remain as covert and persistent as possible. As such, they may implement protective measures regarding the storage of identifiers. Our manual examination seeks to explore this aspect in greater detail.

For identifier generation, tracking SDKs could effortlessly access unique and stable hardware identifiers via simple API calls in the past, therefore eliminating their concerns over identifier generation. However, in the new era where access to hardware identifiers is restricted, SDKs must generate identifiers of their own. Two primary factors should be considered during identifier generation: uniqueness and stability. Uniqueness is the fundamental requirement for identifiers, as assigning the same identifier to multiple devices would prevent the tracking of a distinct device. Stability in identifier generation means that the same identifier can be generated for a specific device even after the identifier's deletion, app reinstallation, or system reset. While hardware identifiers inherently ensure uniqueness and stability, SDKs must carefully design the identifier generation method to maintain these attributes.

Security should be a vital concern for SDKs when storing identifiers on external storage. This encompasses two key aspects: confidentiality, to prevent unauthorized access or theft of the identifier, and integrity, to ensure the identifier remains unaltered and genuine. Given that files on external storage can be readily accessed by apps with commonly granted permissions, identifiers are at risk of being stolen or even manipulated by other apps on the device or deliberate attackers, which could affect user tracking or even introduce new attack vectors as mentioned in Section 3.2.

Our Manual Analysis module is implemented as follows: since we choose unpacked apps as our analyzing target, we can directly decompile the app using reverse engineering tools. For java code, we use GDA [13], a powerful Dalvik bytecode decompiler, while for native code, we employ IDA Pro [23]. With the rich functionality provided by the decompilers (e.g. string searching, cross-referencing), we start the analysis with the file operation function identified in the Candidate Attributing module, and backtrace the call stack for the caller functions of the file operation function until we

found the file content stored on external storage is consumed (for instance, decrypted and sent to the server). During the backtracing process, we analyze all the code within the control flow, looking for evidence that the contents of the file are identifiers (e.g., usage, function names, log messages). If we establish that the file is indeed related to identifiers, we locate all instances of identifier consumption and further investigate code associated with identifier storage, generation, and security measures. Additionally, in this module, we also filter out potential file operations stemming from external storage scans, and map the package name of the attributed component with its SDK or provider name through a manual lookup of the package name and the associated information.

5 Experimental Results

To facilitate our large-scale investigation, we collect 8,000 Android apps from Google Play and several third-party markets' top listings as inputs to our pipeline. The market split for the apps collected and violating apps with such tracking behaviors are summarised in Table 1. Our experiment is primarily conducted on five Google Pixel3 smartphones running our instrumented Android 9 system, This choice is driven by the introduction of Scoped Storage in Android 10, which could potentially impede the functionality of these third-party tracking SDKs and thereby restrict our ability to fully observe their behaviors. To supplement our study, we further retest a selected group of apps on Android 12 to evaluate the impact of Scoped Storage on these illegitimate tracking behaviors, as detailed in Section 5.4. In our Dynamic Analysis module, we configure Fastbot to perform automated GUI testing on each app for 5 minutes, as we empirically discover that identifier-related file operations are usually executed shortly after app launch, and for scalability concerns.

In total, we collected over 640K file operations for the 8,000 apps in our dataset during the Dynamic Analysis module. Our Candidate Finding module enables us to select 30 file candidates corresponding to 13,735 file operations using heuristics. Through our Attributing and Manual Analysis modules, we verify that 22 of the file candidates contain third-party identifiers. Of the 8 file candidates that did not pass our manual verification, 2 were temporary files for identifier processing[4], while the remaining 6 were unrelated to identifiers, from which we also have some intriguing findings (elaborated in Section 5.5). Therefore, 80% (24/30) of the file candidates are indeed related to identifiers, demonstrating the effectiveness of our heuristics. These 22 confirmed file candidates correspond to 17 tracking SDKs (one SDK might store the identifier in multiple locations, as demonstrated in our motivating example). Among the 8,000 apps subject to our testing, we found 3,337 apps accessed at least one of these identifier files, and 1,947 apps accessed files from multiple tracking SDKs. The name and the number of involved apps for each SDK, along with its storage, generation, and security attributes, are summarized in Table 2. We also list the SDK split for each market and the SDKs' package names in our Appendix. Additionally, we have disclosed the associated apps hosted on Google Play to Google's Trust & Safety Team. They have identified it as an "Abuse Risk". We now detail our findings regarding the storage, generation, and security aspects of the identifiers in the following sections.

5.1 Storage

We empirically find out that tracking SDKs employ a range of storage techniques to ensure their identifiers remain covert and persistent on user devices.

Hidden Files. Out of the 17 SDKs we discovered, 13 of them, including Alibaba, Baidu, and Amap SDKs, store their identifiers in hidden files, which is a relatively common yet effective approach. By default, hidden files are not visible to users. Users need to install third-party file management apps and enable specific settings to access hidden files on external storage. Consequently, this method greatly reduces the possibility of users deleting their identifiers.

Storage Path. Some SDKs store their identifiers in specific directories that could potentially give the impression the file containing the identifier is essential for app functionality.

For example, the ByteDance SDK store its identifier in the directory `/storage/emulated/0/Android/data`, which is the root directory of app-specific directories for all apps. Therefore, users tend to believe that files in this directory are for valid use. In addition, Getui SDK stores the identifier in a file with a "db" suffix in the directory `/storage/emulated/0/libs`, which is a directory commonly used by apps to store databases. After the completion of our experiment, we find hundreds of "db" files in this directory on each of our testing devices. Hiding the identifier file among them can also effectively confuse users.

Multiple Backups. Though users typically do not clean files in shared directories on external storage, there is still a possibility that these files may be lost or damaged. Following the adage, "don't put all your eggs in one basket", 9 SDKs ensure the persistence of their identifiers by backing up the identifier in multiple files, as shown in our motivating example [5].

On top of that, 12 SDKs, such as the Alibaba identifier SDK mentioned in Section 3, go a step further to protect their identifiers by also storing them on internal storage (e.g., using `SharedPreference`), which is accessible only by the host app. After the initial run, the SDK copies the identifiers from

[4] Specifically, the files "Alvin2.xml.bak" and "ContextData.xml.bak" are later renamed to "Alvin2.xml" and "ContextData.xml", respectively, both of which are associated with the Alibaba Identifier SDK, as shown in Table 2.

[5] Certain SDKs from the same organization, namely the two from Baidu and another two from Mob, employ a shared identifier with multiple backups.

Table 1: Distribution of Apps and Violations Across Markets

	# Apps Collected	# Violating Apps	% Violating Apps	# Cumulative Downloads of Violating Apps	# Violating SDKs
Google Play	3,000	102	3.40%	Over 1.9B	16
Huawei	1,000	704	70.40%	Over 84.3B	17
Xiaomi	2,000	1,382	69.10%	Over 11.0B	17
Wandoujia	2,000	1,042	52.10%	Over 529.5M	17
Total	8,000	3,230	40.38%	Over 97.7B	17

Table 2: Summary of Our Findings on Identifiers of the 17 Tracking SDKs

SDK Name	# Involved Apps	Generation Method	Stability	Uniqueness	Security	Storage Method
Alibaba ID	1,647	System-provided Identifier	○	●	○	/storage/emulated/0/.UTSystemConfig/Global/Alvin2.xml
					◎	/storage/emulated/0/.DataStorage/ContextData.xml
ByteDance AD	1,206	Random	○	●	○	/storage/emulated/0/Android/data/com.snssdk.api.embed/cache/clientudid.dat
Tencent AD	722	Random	○	●	◎	/storage/emulated/0/Tencent/ams/cache/meta.dat
						/storage/emulated/0/Android/data/com.tencent.ams/cache/meta.dat
Baidu Mobstat	542	System-provided Identifier	◎	●	◎	/storage/emulated/0/backups/.SystemConfig/.cuid2
Baidu Map						/storage/emulated/0/backups/.SystemConfig/.cuid
Amap	294	Remote Server	○	/	◎	/storage/emulated/0/backups/.adiu
Mob Share	171	System-provided Identifier	◎	●	○	/storage/emulated/0/Mob/comm/dbs/.duid
Mob SMS					◎	/storage/emulated/0/Android/data/.mn_1006862472
DCloud	173	Random	○	●	○	/storage/emulated/0/.imei.txt
						/storage/emulated/0/.DC4278477faeb9.txt
Umeng*	453	System-provided Identifier	○	●	●	/sdcard/Android/obj/.um/sysid.dat
						/sdcard/Android/data/.um/sysid.dat
Alibaba Quick Login	330	Random	○	●	○	/storage/emulated/0/.pns/.uniqueId/<id>
Kuaishou	265	Remote Server	○	/	◎	/storage/emulated/0/.oukdtft

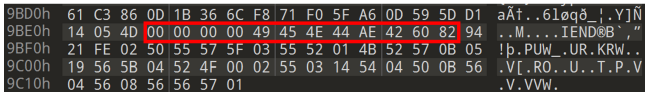
						/storage/emulated/0/LMDevice/lm_device_id
Shuzilm ID	56	Random	○	●	◎	The earliest created screenshot or photo file



Note: ○ stands for "none", ◎ stands for "partial", ● stands for "complete"
*: Unlike other SDKs, the Umeng SDK generates a new identifier for each app, and only saves the SHA1 hash of the identifier on external storage. Therefore, it does not employ an actual external storage identifier for user tracking. We will discuss this further in Section 5.3.

the external storage to internal storage. When the identifier is used later, the identifier in the internal storage takes priority, and the value of the identifier is synchronized with the file in external storage once retrieved successfully. In our manual analysis, we attempted to delete the file storing the Alibaba identifier on external storage, but quickly discovered that the file was recreated by the Taobao app running in the background, one of the most popular shopping apps in China, and the identifier value in the file remained the same.

Attached to Existing Media Files. Most SDKs store their identifiers separately in individual files, but one SDK employs a more discreet approach. The Shuzilm SDK conceals the identifier within an image file of users. Figure 4 shows the data at the end of a PNG image before and after the SDK embeds its identifier. If a screenshot exists on the user's device, the SDK stores the identifier in the earliest created screenshot; otherwise, the earliest created photo is selected as the storage medium. The SDK stores its identifier by inserting specific data at the end of the image file (either JPG or PNG format). For example, a PNG file starts with an IHDR chunk and ends with an IEND chunk. Adding data after the image end flag typically does not cause the image to display incorrectly. The Shuzilm SDK adds 40 bytes of data to the end of the image file: the first 4 bytes serve as a signature flag, while the remaining 36 bytes store the encrypted identifier.

(a) The End of Image before SDK Inserts Identifier.

(b) The End of Image after SDK Inserts Identifier.

Figure 4: Shuzilm SDK Identifier Storage.

5.2 Generation

In terms of identifier generation, we focus on the uniqueness and stability of identifiers (here, stability means that the same identifier can be generated for a specific device even after the identifier's deletion, app reinstallation, or system reset, as previously mentioned in Section 4.4). Ensuring identifier uniqueness is relatively simple. In our experiment, the majority of SDK identifier generation methods can guarantee uniqueness. However, ensuring the stability of an identifier

is more challenging for SDKs. We observe that no SDK can entirely guarantee identifier stability.

Uniqueness. 5 SDKs employ UUID (i.e., Universally Unique IDentifier) for generating their identifiers. UUID is a 128-bit value generated by the Java class `java.util.UUID` and can guarantee uniqueness across space and time. Some SDKs directly use UUID as the identifier (e.g., Tencent and ByteDance), while others use variants of the UUID. For example, the Alibaba Quick Login SDK uses the MD5 hash of the concatenated UUID, the package name and signature of the app that initially generated the identifier, and the timestamp as its identifier.

```
String generateIdentifier(){
  String systemProvidedIdentifier = "";
  if (APILevel <= 23) {
    systemProvidedIdentifier = getIMEI();
    if (isEmpty(systemProvidedIdentifier)){
      systemProvidedIdentifier = getMacAddress();
      if (isEmpty(systemProvidedIdentifier)){
        systemProvidedIdentifier = getAndroidId();
        if (isEmpty(systemProvidedIdentifier)){
          systemProvidedIdentifier =
              getSerialNumber();
        }
      }
    }
  } else if(APILevel >= 29) {
    systemProvidedIdentifier = getAdvertisingId();
    if (isEmpty(systemProvidedIdentifier)){
      systemProvidedIdentifier = getAndroidId();
      if (isEmpty(systemProvidedIdentifier)){
        systemProvidedIdentifier = getSerialNumber
            ();
        if (isEmpty(systemProvidedIdentifier)){
          systemProvidedIdentifier = getMacAddress
              ();
        }
      }
    }
  } else {
    ......
  }
  String identifier = MD5(systemProvidedIdentifier
      );
  return identifier;
}
```

Figure 5: Code Snippet of Umeng SDK Identifier Generation.

Another 7 SDKs, including Baidu, Umeng, and iFLYTEK, attempt to generate their identifiers using the identifiers provided by the system. For example, the Umeng SDK adopts different identifier generation strategies depending on the system version, as shown in Figure 5. As mentioned in Section 2.1, different types of identifiers are allowed to be accessed on different Android versions. When the Android API level is less than or equal to 23, the Umeng SDK sequentially tries to obtain IMEI, Mac address, ANDROID_ID, and serial number from the system, and uses the first available one to generate its identifier. For API levels between 23 and 29, Umeng changes the acquisition order to IMEI, serial number, ANDROID_ID, and Mac address. When the API level is greater than or equal to 29, the SDK first attempts to obtain the Advertising ID, followed by ANDROID_ID, due to the system restriction on accessing hardware identifiers. Since system-provided identifiers ensure uniqueness, generating identifiers based on them also guarantees uniqueness.

It is worth noting that the iFLYTEK SDK also tries to generate its identifier using system-provided identifiers: it attempts to obtain IMEI and ANDROID_ID. However, if both attempts fail, the SDK simply generates the identifier with a timestamp, potentially compromising the uniqueness.

In addition, 4 SDKs (Kuaishou, Amap, Linkedme, and Getui) do not generate identifiers locally. Instead, they request identifiers directly from remote servers. In this case, the uniqueness of the identifier is determined by the remote server. Lastly, the Shuzilm SDK employs its proprietary algorithm to generate random UUID-style identifiers in the native code.

Stability. As mentioned above, some SDKs use the UUID to generate their identifiers. Since UUID is given a unique value in each generation, these identifiers possess no stability.

Generating identifiers using system-provided identifiers, particularly hardware identifiers, is more likely to maintain stability. However, in the new era where hardware identifiers become inaccessible, their stability is also compromised. From Android 10 onward, ANDROID_ID and the advertising identifier are the only accessible system-provided identifiers, both of which change upon system reset. As ANDROID_ID is given distinct values for different apps, identifiers generated using ANDROID_ID will lose stability if the app that originally generated the identifier is uninstalled. Identifiers generated using the Advertising ID will lose stability when the user manually resets the Advertising ID or the system.

For SDKs that obtain their identifiers from a remote server, their stability is determined by the remote server.

5.3 Security

We proceed to examine the security aspects of these identifiers in terms of confidentiality and integrity. Our findings reveal that almost all (16/17) SDKs do not implement effective protective measures, some even disregard security considerations entirely. Specifically, 8 SDKs entirely neglect the confidentiality of their identifiers, while 7 SDKs overlook the integrity of their identifiers completely. Even among the SDKs that do consider these security aspects, their protective measures are largely ineffective against deliberate attackers.

Confidentiality. 8 SDKs, including Tencent, DCloud, and Getui SDKs, store identifiers on external storage without any encryption. Since no confidentiality protection is in place,

other apps on the device can directly access the identifier, which poses privacy risks and enables new attack vectors as described in Section 3.2.

The remaining SDKs employ encryption for the identifier. However, they all resort to hard-coded keys locally stored within the SDK. This practice compromises the intended confidentiality, especially in the face of determined attackers. For example, the Amap SDK implements AES in CBC mode with a hard-coded static key (the binary format of the ASCII code of a specific string) and an all-zero initialization vector, and further uses string obfuscation techniques to protect the static key and the initialization vector.

Integrity. 7 SDKs (e.g., Alibaba Quick Login, Kuaishou, and Linkedme) do not take identifier integrity into account. After retrieving the identifier on external storage, the SDK directly utilizes it without any input validation. Other apps on the device can directly modify the identifier, and the SDK remains oblivious to any potential tampering.

The other 6 SDKs (e.g., Alibaba, iFLYTEK, and Jiguang SDKs) only perform basic format verification on the identifier and do not examine the actual identifier value. For instance, the ByteDance SDK, which uses the UUID directly as its identifier, only checks the identifier's length and verifies if each character is a number, letter, or hyphen. Moreover, the Amap SDK saves the MD5 hash of a specific string at the beginning of the file where the identifier is stored and checks it when accessing the identifier. In essence, these format verification methods can only to an extent determine if the identifier is damaged but cannot fully ensure integrity. When an attacker alters the identifier value, it can still pass the verification.

```
// Example of file content: {"v":1,"u":"d4c22e74
    -4762-4ad1-afce-3ee2b7525308","t
    ":1667216542434,"m":"
    C9863EB3B042C74A1374EC82F231A869"}
boolean integrityCheck(String fileContent){
  JSONObject fileContentJson = new JSONObject(
      fileContent);
  String fileVersion = fileContentJson.getString("
      v");
  String identifier = fileContentJson.getString("u
      ");
  String timestamp = fileContentJson.getString("t"
      );
  String fileSignature = fileContentJson.getString
      ("m");
  String fileSignatureCalculated = MD5(identifier
      + timestamp + "[a_specific_string]");
  if (fileSignature == fileSignatureCalculated) {
    return true;
  }
  return false;
}
```

Figure 6: Integrity Checking of Tencent SDKs.

Additionally, 3 SDKs (Tencent, Mob share, and Mob SMS SDKs) use hashing algorithms to perform integrity checks on identifiers. We take the Tencent SDK as an example, whose integrity checking method is shown in Figure 6. Tencent stores a JSON string on external storage that contains the file version, identifier, timestamp, and file signature. Upon generating the identifier, the SDK calculates the file signature, which is a hash of the concatenation of the identifier, file version, timestamp, and a specific string, and stores it in a file. When using the identifier, the SDK calculates the file signature in the same way and compares it with the value in the file. If the two signatures match, the SDK assumes the identifier has not been tampered with. While this method can to an extent verify the identifier's integrity, it cannot defend against a deliberate attacker who analyzes the SDK's verification method. A critical weakness of this approach is storing both the signature and identifier together on external storage, enabling the attacker to tamper with the identifier and modify the file signature simultaneously according to the signature calculation method to pass the validation. A more reliable alternative would involve storing the signature in a secure location, such as internal storage. However, it is difficult for SDKs to find a location that is both secure and shareable by other apps that integrate the SDK.

One exception is the Umeng SDK, which ensures both the confidentiality and integrity of the identifier. Upon our manual analysis, we confirm that Umeng generates a new identifier using available system-provided identifiers (as detailed in Section 5.2) for each app. The SDK then stores the identifier's plaintext in each app's internal storage, and only saves the SHA1 hash of the identifier on external storage, potentially for verifying if the device can be identified cross-app. Umeng's approach does not employ an actual external storage identifier for user tracking.

Other Security Issues. In addition to the missing or ineffective identifier confidentiality and integrity protection measures, we found inconsistencies in security measures in Alibaba and Mob SDKs. For example, the Mob SDK stores the identifier in two files on external storage. One of the files (`/storage/emulated/0/.mn_1006862472`) adopts a higher level of security protection (using AES encryption in ECB mode for confidentiality and file signature verification for integrity). However, the other file (i.e., `/storage/emulated/0/Mob/comm/dbs/.duid`) stores the identifier in plaintext and is retrieved by the SDK directly with no integrity check, rendering the protection on the first file ineffective.

5.4 Impact of Scoped Storage

As discussed in Section 2.2, Scoped Storage is introduced in Android 10 (and fully deployed in Android 11 [28]) to restrict the use of external storage. Since accessing non-media files in shared directories created by other apps requires the strictly regulated MANAGE_EXTERNAL_STORAGE or user con-

sent on a file-by-file basis, Scoped Storage should, in theory, prevent SDKs from identifying users through external storage. We thus retest a selected group of apps integrated with these SDKs on Android 12 to assess its impact. As expected, when Scoped Storage is active, the external storage identifiers of all the SDKs we identified become inoperative. However, we find that most SDKs can still track users via external storage under certain conditions: (a) apps targeting Android 10 or lower can opt out of the shared storage restrictions imposed by Scoped Storage, leaving their integrated tracking SDKs unaffected [28]; (b) certain apps from third-party markets (even job-hunting apps and medical apps) significantly abuse the `MANAGE_EXTERNAL_STORAGE` permission, which is intended solely for apps with specialized functions as mentioned in Section 2.2. We further unpack the implications of such tracking practices post Scoped Storage in Section 6.1.

One exception is the ByteDance SDK, which stores identifiers in a folder under the root directory of the app-specific directories. Although this directory does not belong to any specific app, it still becomes inaccessible after Scoped Storage is introduced and cannot be opted out of.

Exploit post Scoped Storage. In summary, Scoped Storage only offers partial protection against these illegitimate identifiers—when an app targets Android 11 or higher and does not request `MANAGE_EXTERNAL_STORAGE`. With some optimism, we can envision a future where opting out of Scoped Storage is disallowed and the `MANAGE_EXTERNAL_STORAGE` usage is rigorously controlled. However, even in that scenario, Scoped Storage still cannot entirely eradicate user identification via external storage. As detailed in Section 5.2, the Shuzilm SDK utilizes the earliest-created image files to conceal its identifier. While this method becomes ineffective post Scoped Storage, as writing to media files not created by the host app requires file-by-file consent, it has enlightened us to propose a new exploit. An adversarial SDK could hide the identifier within a media file generated by its host app with no permission required. Other apps integrated with the same SDK can then access this identifier using commonly granted read permissions. We have developed a demo app that proves the viability of this exploit and reported this to Google's BugHunter Team. They acknowledged and thanked us, but ultimately categorized this exploit as "Won't Fix". We speculate it is because devising a fix for this exploit on system level is very challenging, given the difficulty of implementing controls more rigorous than the present Scoped Storage to an app or SDK (a) writing superfluous data to their self-generated media files, or (b) reading other apps' media files with relevant permissions.

Nevertheless, the Shuzilm method, along with our proposed exploit, represents an adaptation to Android's evolving security measures, indicating an ongoing arms race between both sides. There is also nothing preventing other tracking SDKs from adopting this exploit in the future. The Android system must devise more effective solutions to gain the upper hand in this never-ending struggle.

5.5 Other Findings

In addition to the identifiers on external storage, we have also found that some SDKs share other types of data between apps through external storage.

Sensitive User Data. Some SDKs store sensitive user data on external storage. For example, the Amap SDK stores encrypted detailed device location data (including latitude, longitude, and place names nearby) in a file on external storage. Other apps with the SDK can access user location data (although possibly outdated) by reading this file, even without location permission. In our experiment, we have captured cases where apps integrated with Amap retrieve user location information from this file without location permission, which significantly infringes upon user privacy. Additionally, malicious actors can also gain access to user location data by decrypting this file.

SDK Log Data. Some SDKs export log data to files on external storage. For example, the Meizu push SDK outputs a large amount of logs generated during app execution to external storage. These logs contain server response data and what appears to be a secret key used in network communications. Upon closer inspection, we found that this "key" correlates with a component in the source code named "HttpKeyMgr". This component is subsequently referenced multiple times across different app runs. Storing these logs on external storage is not only superfluous but also poses potential risks to the SDK and user privacy.

6 Discussion

6.1 Implications

By storing identifiers on external storage, these third-party tracking SDKs could circumvent Android's identifier usage restrictions to track users cross-app stealthily, therefore posing significant risks to user privacy.

The latest Android defense mechanism for external storage, i.e., Scoped Storage, should effectively eliminate such illegitimate identifier usage, in theory. However, it falls short in practice. Firstly, this protection is only activated when an app targets Android 11 or higher and does not request the MANAGE_EXTERNAL_STORAGE permission. Although Google Play enforces strict target API level and permission requirements, other third-party markets do not share the same level of scrutiny. For example, SAMSUNG's markets only recently (late 2022) mandated their apps to target Android 8 or higher [8], while HUAWEI and other Chinese app markets require Android 9 [3]. Furthermore, no explicit restrictions on MANAGE_EXTERNAL_STORAGE permission control have been implemented for the two markets, to our knowledge. In addition, Android devices such as smart TVs, tablets, VR devices, and smartwatches running lower system versions are still exposed. Android's fragmentation issues severely un-

dermine the effectiveness of its proposed defense mechanism, making it likely that such practice will persist for a relatively long time.

Moreover, our proposed exploit demonstrates that even in the best-case scenario where all enforcement measures are in place, the latest Android defense mechanism for external storage can still be breached. These concerns call for the development of more robust solutions to safeguard user privacy.

6.2 Chinese SDKs

A notable observation from our study is the predominance of tracking SDKs originating from China, as highlighted in Table 1. While our experimental dataset encompasses 3,000 top-listed apps from Google Play, which undoubtedly utilize major SDKs from other regions, it was primarily the Chinese SDKs that exhibited such tracking behavior. In fact, among the 102 Google Play apps that we discovered with such tracking behavior, the responsible SDKs were still from China. This phenomenon resonates with findings from previous research, such as that by Reardon et al. [49].

From our experiences, Chinese SDKs do tend to be more aggressive in general. This could partially be attributed to the unavailability of Google Play in China. However, while Google's Advertising ID hinges on the Google Play service and is thus inaccessible in China, this factor alone cannot justify the aggressive tracking strategies employed by these Chinese SDKs. Upon our further investigation, we found that China has introduced an alternative: the OAID (Open Anonymous Device Identifier) [6]. Launched in 2019 by the China Mobile Security Alliance and backed by major Chinese smartphone manufacturers like Xiaomi and Huawei, the OAID mirrors Google's Advertising ID functionally, with capabilities for end-users to reset or disable it. Notably, global advertising SDKs such as AppsFlyer [14] and Adjust [2] have integrated support for OAID since late 2019.

Upon scrutinizing the 17 Chinese SDKs from our study, we found that 12 do access the OAID. However, they also employ external storage identifiers, possibly to circumvent OAID's reset or disable features. While the exact motivation remains elusive due to the opaque server-side processing logic of both identifiers, the simultaneous collection of these identifiers alone raises concern. Moreover, the remaining 5 SDKs have yet to adopt OAID, even four years since its debut.

These tracking methodologies also contravene the policies of Chinese app stores. Apart from Xiaomi Store's requirement for identifiers to be revocable as mentioned in Section 3.2, both Xiaomi and Huawei mandate that a new advertising identifier, once reset, should not correlate with the previous identifier or its derived data without explicit user consent [22, 30]. Such a stipulation can be easily violated when an SDK gathers both OAID and external storage identifiers.

Additionally, 16 out of the 17 SDKs neither disclose such external storage tracking in their EULAs nor offer reset or disable features akin to OAID or Google's Advertising ID. We further sampled 50 violating apps and found no disclosure of such tracking practices in the apps' privacy policies.

In conclusion, while regional differences might influence SDK practices, the tracking techniques employed by these Chinese SDKs still raise significant concerns about user privacy. It underscores the need for more transparent practices and robust regulatory oversight to ensure user data protection.

6.3 Mitigation

To counteract the privacy risks posed by third-party tracking SDKs storing identifiers on external storage, we propose the following mitigation suggestions:

Further expanding security requirements for third-party markets. While Google Play enforces strict requirements for apps, such as targeting recent API levels and conducting rigorous permission reviews, third-party markets often do not uphold the same standards. Given that these markets also serve as popular venues for app downloads, it is imperative they align their security requirements with those of Google Play. In early 2019, we have already seen a collective effort by major Chinese app markets to expand the API level requirements up to Android 8.0, a commendable move highlighted by Google [4]. However, subsequent progress has been stagnant over the years. As Android's fragmentation continues to amplify security and privacy concerns, it is vital for Google to take the initiative in expanding these stringent security requirements across more app markets worldwide. This effort could involve enhancing communication between third-party markets, offering technical support, and advocating for a uniform adoption of rigorous security standards. In doing so, we can ensure a consistent application of security measures, thereby reducing the avenues for SDKs to exploit user identifiers.

Permission separation on Android. Although the implementation of Scoped Storage has made strides toward a more secure and organized external storage, our identified exploit has demonstrated that it still remains possible for SDKs to illegitimately identify users through external storage even with the full enforcement of Scoped Storage. One potential solution could involve the adoption of a permission management system on Android to separate SDK permissions from app permissions. Although several permission isolation prototype schemes [35, 50, 52] have been proposed over the years, the current Android system still allows integrated SDKs to share the same permissions as their host apps, thereby enabling them to covertly exploit sensitive permissions requested by the apps. Luckily, in early 2023, Google initiated a beta project called the Privacy Sandbox on Android [24], which they envision as a "multi-year effort". A standout feature of this project is the SDK Runtime [27], which runs app SDKs in a separate process from the app. By doing so, it meticulously governs the permissions and data access rights of SDKs, effec-

tively curbing potential misuse of external storage and other critical system resources.

Collective efforts between end-users and phone vendors/app stores. While the aforementioned mitigation strategies are promising, their realization involves collaborations between Google, third-party markets, and advertising companies that could easily take years. Thus, we advocate for a more immediate mitigation strategy, pivoting on the collaboration between end-users and their phone vendors or app stores. Firstly, app stores can harness our approach to periodically scrutinize their apps, identifying and subsequently addressing tracking malpractices by the responsible SDKs and the apps that integrate them. Secondly, leveraging the identifier file paths located by our approach, phone vendors or app stores can devise tools that exploit the identifier's lack of integrity to continuously reset these files. Such tools can be integrated into market apps or system ROMs to empower users to routinely clean these identifier files.

6.4 Threats to Validity

Several threats to the validity of our study should be considered. First, the Android ecosystem is vast and fragmented, encompassing numerous third-party app stores that do not adhere to the strict guidelines imposed by Google Play. Our analysis includes 8,000 apps, which, although sizable, cannot cover every third-party tracking SDK or strategy due to the sheer scale and complexity of the Android app ecosystem. Also, our pipeline relies on automated GUI testing, which is inherently subject to the limitations of dynamic testing. Therefore, it cannot achieve full code coverage or trigger all relevant functionality within an app. Consequently, we may not obtain a comprehensive view of how each app and its integrated tracking SDKs interact with external storage. Moreover, while our pipeline is largely automated, manual analysis is still required to examine the storage, generation, and security of identifiers, which, to some extent, limits our ability to expand the scope of our experiments and may introduce potential biases in our findings. In addition, despite our pipeline's ability to identify a significant number of covert identifier storage instances, it might not capture every instance or technique. There may be more sophisticated strategies that remain undiscovered. Therefore, our analysis should serve as a foundation for understanding the current landscape and a starting point for further research into third-party tracking SDK practices in the Android ecosystem.

While our heuristics were effective in identifying file candidates associated with identifiers, there is still a possibility of false negatives. Evaluating the recall of our approach is challenging, as this study is the first to investigate this issue on a large scale, and no ground truth dataset is available. However, before our experiment, we found references to three SDKs exhibiting this behavior: Alibaba (from a blog [1]), Salmonads, and Baidu (from Reardon et al. [49]). Our experiment successfully identified two of these SDKs, with Salmonads being the exception due to it being out of service. This, to some extent, demonstrates the recall of our approach and is the best validation we can provide.

Lastly, our dynamic analysis environment is deployed in an AOSP userdebug version of the Android system, which could potentially impact the validity of our results. Although we have made specific modifications (e.g., system properties and system fingerprint) to resemble a release version, it is uncertain whether these adjustments sufficiently evade all detection techniques employed by apps.

6.5 Future Work

Exploring such tracking practices from multi-dimensional perspectives. By examining a set of apps during a specific timeframe, our study captures a snapshot of such tracking behaviors of that period, thus naturally confining the scope of our analysis. It is essential to highlight that the identifier restrictions that led SDK developers to seek workarounds have been in the Android ecosystem for quite some time. To attain a more holistic view, future investigations should examine these tracking methods through various dimensions. This would encompass (a) temporal analysis: delving into the historical trajectory of these tracking methods and SDKs to identify when these techniques initially emerged and observe their progression over time; (b) SDK interrelationships: investigating the intricate dependencies and dynamics among different SDKs to reveal collaborative or potentially competitive nuances within the SDK landscape; (c) emerging practices: as technological landscapes evolve, new tracking methods, for instance, through other covert channels, might surface. Monitoring these developments will ensure our analysis remains current and relevant.

Branching out to other mobile platforms, such as iOS. The iOS system might also be susceptible to such tracking practices. Achieving such tracking would necessitate a shared location accessible by other apps for storing identifiers. While iOS already enforces a sandboxing mechanism to ensure app isolation, crafty methods might find their way around these barriers. For instance, one could employ a method similar to the one we proposed under the inspiration of Shuzilm in Section 5.4. In the iOS system, apps with commonly granted photo access permissions can read any image without users' attention (though, akin to Android post Scoped Storage, they generally cannot write to photos created by others). This opens up a potential avenue for covert tracking on iOS. We plan to further investigate this in our future research.

7 Related Work

Our study investigates how third-party tracking SDKs covertly store identifiers on external storage to bypass Android's identifier restrictions. In this section, we briefly review relevant

literature, including user identifiers and tracking practices, security issues on external storage, and other covert channels in mobile app ecosystems.

User Identifiers and Tracking Practices. Numerous studies have investigated user identifiers and third-party tracking practices in mobile apps. Binns et al. [32] presented an empirical study of the prevalence of third-party trackers on 1 million apps from Google Play. The authors found widespread user tracking in apps but concentrated on a few trackers such as Google and Facebook. Kollnig et al. [38] presented a study of 24K Android and iOS apps, and compared the performance of Android and iOS in terms of user privacy, observing widespread usage of user identifiers in both mobile operating systems. Rahaman et al. [48] proposed a novel taint analysis technique to address inaccurate static analysis resulting from the use of device identifier variants in Android apps, revealing the abuse of identifiers by popular apps and libraries. Leith et al. [40] investigated the data sent to manufacturers by mobile operating systems, finding that device identifiers and other user data were transmitted to back-end servers even when users configured their systems for minimal data sharing. While these studies examined the use of identifiers in user tracking by Android apps and the Android system, they did not explore the application of identifiers beyond those provided by the system.

External Storage Security. Many previous studies have examined the security issues arising from the use of external storage in mobile apps. Liu et al. [41] investigated sensitive user information stored in external storage by apps, and proposed three attacks that exploit the sensitive data to compromise users' privacy. Du et al. [33] systematically analyzed app usage of external storage, discovering that most apps failed to perform valid input validation when accessing sensitive files on external storage, which enabled various attacks with severe impacts on users. Reardon et al. [49] discovered the behavior of unauthorized sensitive information exchange using external storage, and briefly mentioned third-party tracking SDKs storing identifiers (e.g., IMEI) on external storage. However, they did not investigate this issue in depth. These studies primarily focus on high-level sensitive user data stored on external storage without addressing the more basic yet highly sensitive identifiers stored on external storage.

Other Covert Channels. Outside of external storage, there have been some notable investigations into potential covert channels within the Android system. In 2012, Gasior and Yang [36] implemented a network covert channel within an Android app that could potentially allow data leaks. A more recent exploration by Reardon et al. [49] identified various covert channels in Android that were utilized to bypass permission restrictions to access sensitive information. They observed that certain SDKs utilize a range of covert channels, including ioctl (UNIX "input-output control"), UPnP/SSDP discovery protocols, and the ARP table, to obtain the device's MAC address. Furthermore, some SDKs were found to extract geolocation data from photographs by reading the embedded the EXIF metadata. Lyons et al. [43] systematically examined the presence of sensitive information within another covert channel: the Android system log, and found that high-privileged apps could leverage the log to obtain sensitive data such as the WiFi Router's MAC address and user locations. However, the required high privilege is exclusive to pre-installed apps. In summary, while prior studies have revealed sensitive data, such as hardware identifiers, that could be utilized for user tracking, being obtained through covert channels, these channels alone cannot be exploited for the tracking methods highlighted in our study, owing to the fact that they cannot serve as a shared location to store identifiers where other apps can readily access.

In contrast to existing work, our study specifically investigates the practice of third-party tracking SDKs covertly storing identifiers on external storage, examining the techniques they employ and the implications for user privacy. We contribute an extensive large-scale analysis of this phenomenon, which has not been previously explored in the literature.

8 Conclusion

In conclusion, our research has shed light on the covert practices of third-party tracking SDKs in the Android ecosystem, revealing their persistent efforts to bypass Android's identifier usage restrictions by storing identifiers on external storage. Our study not only highlights the need for enhanced defense mechanisms on Android but also underscores the importance of greater scrutiny of third-party tracking practices to protect user privacy. Through our extensive analysis on 8,000 Android apps, we have identified 17 tracking SDKs employing various storage techniques to make their identifiers more discreet and persistent. Our work provides a valuable foundation for understanding the current landscape of third-party tracking SDKs and serves as a starting point for future research. As user privacy continues to be a growing concern in this digital age, it is essential for the research community, industry stakeholders, and policymakers to work together to develop robust solutions and enforce stricter scrutiny to safeguard user privacy in the ever-evolving mobile app ecosystem.

Availability

Our artifact, including the implementation of the first three modules in our approach and all file operations collected in the experiment, is available at https://github.com/security-pride/tpt.

Abstract

Contactless payments are now widely used and are expected to reach $10 trillion worth of transactions by 2027. Although convenient, contactless payments are vulnerable to relay attacks that enable attackers to execute fraudulent payments. A number of countermeasures have been proposed to address this issue, including Mastercard's relay protection mechanism. These countermeasures, although effective against some Commercial off-the-shelf (COTS) relays, fail to prevent physical-layer relay attacks.

In this work, we leverage the Ultra-Wide Band (UWB) radios incorporated in major smartphones, smartwatches, tags and accessories, and introduce PURE, the first UWB-based relay protection that integrates smoothly into existing contactless payment standards, and prevents even the most sophisticated physical layer attacks. PURE extends EMV payment protocols that are executed between cards and terminals, and does not require any modification to the backend of the issuer, acquirer, or payment network. PURE further tailors UWB ranging to the payment environment (i.e., wireless channels) to achieve both reliability and resistance to all known physical-layer distance reduction attacks against UWB 802.15.4z. We implement PURE within the EMV standard on modern smartphones, and evaluate its performance in a realistic deployment. Our experiments show that PURE provides a sub-meter relay protection with minimal execution overhead (41 ms). We formally verify the security of PURE's integration within Mastercard's EMV protocol using the Tamarin prover.

1 Introduction

Contactless payments have greatly improved and streamlined the digital payment experience. Given their convenience, their number is expected to grow by 221% between 2022 and 2026, reaching $10 trillion worth of transactions by 2027 [30]. The preference for contactless payment and withdrawal methods was further accelerated by the need to minimize contact with payment terminals during the COVID pandemic [45].

With the emergence of contactless payments, the awareness and the threat of relay attacks on card payments have also increased [2]; Drimer et al. [47] demonstrated already in 2007 that such attacks were not only possible, but could be accomplished for as little as $500 worth of hardware and with just moderate engineering skills. Since then, the cost of relay attacks has further declined [9].

In the simplest relay attack, the victim does not intend to use their card (e.g., it is in their wallet) but an attacker establishes a relay channel between the victim's card and a terminal of the attacker's choice, thereby charging the victim's card for the purchase. In some countries and for some banks, the damage of such attacks is limited by the contactless payment limit, although not all US banks impose limits [24].

In more sophisticated relay attacks, similar to the chip-and-PIN fraud [13, 17, 47], an attacker plays the role of a (malicious) merchant who presents a fake terminal to the victim customer. By relaying the communication, and even the victim's PIN, the attacker can use the victim's card to pay for more valuable goods at a legitimate terminal or to withdraw a large sum of money from an Automatic Teller Machine (ATM). Mobile payments are especially vulnerable to this kind of fraud because unlocking the phone is generally accepted as a Cardholder Verification Method and thus allows the attacker to arbitrarily increase the amount, e.g., up to the card's daily or monthly limit. With the advent of on-device (smartphone) terminals, like Apple's tap-to-pay [29], the attacker's cost and challenge of creating a fake terminal have been significantly reduced.

Hence, relay attacks on contactless payments, irrespective of whether they are executed against cards, phones, watches or other wearables, remain a concern, and may even increase in the future both in frequency and severity.

There are two main ways of addressing relay attacks. The first involves reducing the usability of payments by requiring additional checks or confirmations by the user on the phone or watch, which is not possible in case of cards or tokens. The second is to prevent relays by technical means using secure distance measurement between the card and the legitimate

terminal. Since usability is one of the main benefits and features of contactless payments, defenses focus on the technical prevention of relay attacks.

The most established technical standard for smart cards and contactless payments is the EMV standard. This standard describes different implementations, called kernels, by which cards and terminals or ATMs can interact. EMVco, the consortium maintaining the EMV standard, has recognized the severity of relay attacks on contactless payment systems and has proposed a relay protection extension for the Mastercard kernel known as the Relay Resistance Protocol (RRP). This proposal has been further improved in [43]. These relay protections, although effective against adversaries equipped with COTS hardware, fail to prevent physical-layer relay attacks. Namely, these protections tolerate relays of μs to $10ms$, allowing physical layer relays over many kilometers.

The recent introduction of UWB ranging radios in many personal devices opens up the possibility of building a more effective relay protection that is not restricted to Near Field Communication (NFC). In particular, smartphones, smart watches, and tags from Apple, Samsung, and Google are now equipped with UWB, allowing sub-decimeter ranging accuracy between devices.

Given this, it is natural to consider using UWB radios to protect payments against relay attacks. However, ensuring that this results in a secure, usable, and deployable relay protection mechanism requires tailoring UWB ranging to contactless payments as well as careful enhancements to the EMV protocols.

In this work, we address this challenge and introduce PURE, a set of relay protection mechanisms that extend EMV contactless payments in a secure, usable, and easy-to-deploy manner. We make the following contributions:

- We propose PURE, the integration of (UWB) physical-layer mechanisms into the EMV kernel, which are the first to provide protection against all relay attacks, including those on the physical layer, for contactless payments.
- We formally verify the integration of PURE mechanisms within EMV protocols in Tamarin [39].
- We implement a prototype of PURE on modern smartphones and evaluate it in realistic deployments.
- We show that PURE provides sub-meter (ca. 50 cm) relay protection, adds very low (41 ms) latency to the payments ($\approx$ 630 ms), and has no noticeable impact on the usability of payments.
- We demonstrate that PURE provides protection against all known distance reduction attacks on UWB IEEE 802.15.4z High Pulse Rate (HRP) secure ranging systems, which are present in modern devices.
- We design PURE so that it can be easily integrated into the existing EMV ecosystem and requires only changes to the payment terminal / device, but no changes to the payment backends. For terminals already supporting UWB (such as an iPhone with Apple's Tap to Pay [29]), only software changes are required.

2 Overview

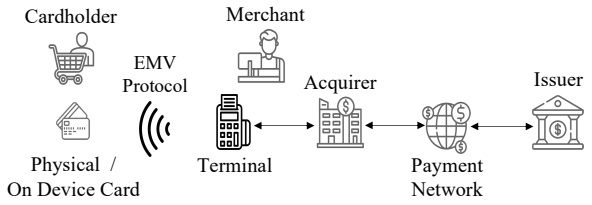
Contactless payments use NFC to trigger backend financial transfers from the cardholder accounts to accounts of corresponding terminal owners. Having established an NFC connection, the card and terminal negotiate a protocol to initiate the payment and to securely exchange the necessary parameters to trigger the backend financial transfer, following one of the EMVCo Kernels. Currently, there are seven different Kernels for different payment networks, such as Mastercard or Visa. As a result of a successful protocol execution, the card provides a cryptographic token to the terminal that proves to the card's issuer that the card indeed has been involved in a payment at the given terminal.

The proximity of the cardholder to the payment terminal effectively acts as a transaction confirmation. Relay attacks can compromise these payments by relaying communication without compromising payment cards. These include simple attacks that relay communication from the unsuspecting user's card to a payment terminal, and more sophisticated attacks that involve the use of fake terminals and can steal funds from the user up to their daily card limit.

The goal of relay protection mechanisms is to prevent such attacks and ensure that a payment can be successfully executed only if the two devices, the card, and the legitimate terminal, are physically close. In particular, the maximum accepted relay must be sufficiently small ($\approx 1m$) so that relays are prevented simply by the spatial awareness of merchants and cardholders.

PURE achieves this by using UWB ranging, which provides decimeter ranging accuracy. Therefore PURE specifically targets on-device cards (e.g. smartphones) on which UWB radios are already widely deployed [23]. Leveraging UWB ranging for relay prevention in the context of contactless payments is, however, not straightforward. PURE integrates UWB into EMV payment protocols such that it (i) does not noticeably increase the latency of payments, (ii) does not reduce the reliability or convenience of payments, (iii) integrates securely with EMV protocols, and (iv) is easy to deploy within the broader EMV payment network ecosystem (see Figure 1). Finally, UWB radios deployed in most devices implement 802.15.4z HRP, which was shown to be vulnerable to distance decreasing attacks [36]. PURE also addresses these attacks (v).

In what follows, we first specify the attacker model, and then provide an overview of the changes that PURE makes to the EMV protocols and to UWB ranging to achieve (i-v).



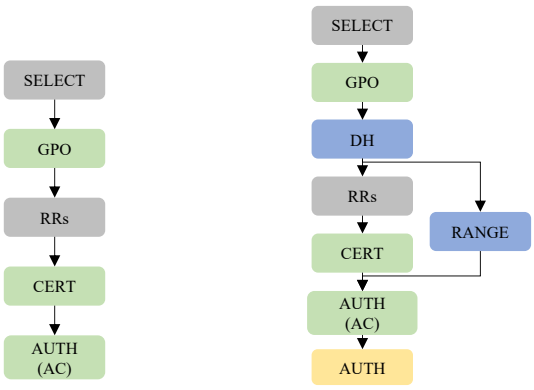


Figure 1: **The Payment Ecosystem.** The stakeholders involved into the payment process.

(a) EMV protocol. (b) Extended EMV protocol.

Figure 2: **EMV and PURE.** Gray boxes denote elements of the original standard not affected by PURE. Elements of the original standard used by PURE are colored green. Blue boxes are required and newly added by PURE. The yellow block is required by PURE, but can be smoothly integrated into the existing authentication step of the standard.

Attacker Model. The attacker's main goal is to establish an unintended connection between a legitimate card and an attacker-chosen terminal, without triggering any relay protection.

We assume a Dolev-Yao-style network attacker that fully controls the communication between the card and the terminal, both on the NFC and UWB channels. The attacker can eavesdrop, intercept, modify, and inject signals and messages, as well as initiate transactions between the card and the terminal. We further assume that all legitimate parties (i.e., issuer, payment network, acquirer, merchant, registered terminals, card, cardholder) are honest and that all communication channels except the ones between the terminal and the card are secure. We exclude attacker-owned, registered terminals from our threat model. Since the flow of money can be tracked, a malicious owner of a registered terminal would eventually be convicted of fraud charges pressed by cardholders. Further note that attackers who own a registered terminal need not relay communication, but could simply place the terminal close to the victim's card to initiate a payment.

We consider a strong relay attacker that can operate on the physical layer and introduces only negligible processing delays. Francillon et al. demonstrated in [25] that a similar relay can be implemented in practice with simple analog equipment. The only effect introduced by such a relay is a delay proportional to its length divided by the speed of light. The attacker is also capable of all state-of-the-art attacks on round-trip time or distance measurements, including those at the physical layer.

PURE: Protocol Overview. To establish a reliable upper bound on the distance between an honest terminal and a card (and therefore to prevent relay attacks), UWB ranging requires the involved parties (here the payment card and the legitimate terminal) to share a secret key. For this purpose, we have designed and implemented an extension of the existing EMV Kernel that builds on EMV's Public Key Infrastructure (PKI) and allows the card and terminal to establish a shared key. By extending existing (NFC) EMV messages, PURE introduces little overhead to the EMV protocol. Figure 2 illustrates PURE's key exchange extension to the original EMV protocol and the added UWB ranging phase. Note that PURE makes no changes to the protocols and messages to the payment backend; it only modifies the card-terminal interaction defined by the EMV standard.

We introduce the existing Mastercard kernel together with our extension in more detail in Section 3. The card and terminal negotiate the use of PURE according to their capabilities in an early stage of their NFC-based communication. If either of the two does not support UWB, they fall back and execute the existing protocol. The card's support of PURE is announced as part of an integrity-protected data-element sent by the card. As a consequence, an attacker cannot downgrade PURE-capable devices to omit the relay-protection phase. If the card and terminal are UWB capable and support PURE, they execute a Diffie-Hellman (DH) exchange. At this point, the key shares are not yet authenticated, but the shared secret can already be used for ranging, while the rest of the transaction continues in parallel over NFC. Running the ranging process in parallel with the payment nullifies the additional overhead introduced by the ranging. This ultimately leads to a fast execution of the combined protocol that does not introduce a significant delay for the user to complete a transaction.

As a result of the ranging extension, the terminal derives a reliable upper bound on the distance to the entity it shares the secret with. As part of the authentication/authorization step of the original protocol, the card authenticates to the terminal critical transaction parameters and the DH values. This binds the previously executed ranging to the specific transaction and card. The terminal blocks the transaction if the cryptographic verification fails (possible Machine-in-The-Middle (MITM) attack) or if the measured distance is too large (due to a relay attack).

	Uncertainty Δt	App Relay	Phy Relay
RRP [20]	$\approx$ ms	$\approx km$	$\approx$ 100 km
L1RP [43]	$\approx us$	0	$\approx$ km
This paper	$\approx ns$	0	50 cm

Table 1: **Relay Protections on Contactless Payments.** The larger the measurement uncertainty Δt on the Round-Trip Time (RTT), the larger the error on distance, and the longer the relays that remain undetected. A physical layer relay with negligible delay achieves the longest relay, while an application layer relay has the disadvantage of introducing an additional processing time (e.g., $T_{comp} = 1ms$). Using highly-accurate UWB measurements PURE provides excellent protection from both, and is also secure from distance-reduction attacks.

Comparison to Existing Relay Protections. By specifically targeting on-device cards, PURE provides significantly better guarantees than existing relay protection mechanisms. A comparison can be found in Table 1.

In broad terms, both PURE and previously proposed relay defenses measure the Round-Trip Time (RTT) between the card and the terminal with a nonce exchange. The exchanged nonces are unpredictable and authentic to prevent potential attackers from interfering with the RTT measurement. Based on the signal's Time of Arrival (ToA) measurement and the reply time, the Time of Flight (ToF) and, hence, the mutual distance can be computed. The protocol's reliability and security heavily depend on the accuracy of the ToA measurement. Indeed, measuring an earlier ToA results in a shorter measured distance, which could make a relay undetectable, while a later ToA leads to an overestimated distance measurement, potentially compromising system reliability. Intuitively, even a small uncertainty in the measurement of the RTT (e.g., μs) leads to large errors in the measurement of distance (e.g., km), leaving even long relays undetected (see Appendix B). Existing solutions have low accuracy and tolerate long relays.

The Relay Resistance Protocol (RRP) proposed by Mastercard [20] implements a timed nonce exchange at layer 3 of NFC, achieving milliseconds accuracy. Radu et al. [43] in their Level 1 Relay Protection (L1RP) moved the nonce exchange to the physical layer of NFC, which improved the accuracy to microseconds. Both L1RP and RRP can prevent application-layer relay attacks, which introduce substantial delays due to computation time; however (as recognized by both Mastercard and the authors), it would not stop specialist, expert-built relay/MitM attacks that relay signals on the physical layer [25]. The root cause of vulnerabilities for both solutions is the same: long NFC symbols result in inaccurate ToF measurements and are susceptible to Early-Detect and Late-Commit (ED/LC) attacks [34, 40]. Both solutions also rely on an estimate of the reply time for each card model, which introduces additional errors.

UWB Ranging in PURE. PURE does not simply integrate off-the-shelf UWB ranging into EMV protocols. Widely deployed UWB (IEEE 802.15.4z HRP) chips were found to be vulnerable to physical layer attacks such as Ghost Peak attack [36]. This attack stems from a security-reliability trade-off typical in cyber-physical systems: if the link budget is low, a ranging system will typically sacrifice security in favor of reliability.

With PURE, we show that the short distance and wireless channels between card and terminal during payments are particularly favorable for secure UWB ranging. We devise a simple Leading Edge Detection (LED) algorithm on top of 802.15.4z HRP that maintains the reliability of contactless payments while being secure against known distance reduction attacks. More precisely, we show that PURE limits the success probability of the Ghost Peak attack to 2^{-48}, a suitable security level for payment applications [36].

3 EMV and PURE

We focus on the integration of PURE in the Mastercard kernel, known as the C-2 kernel [20]. Since all kernels rely on the same cryptographic primitives (asymmetric algorithms for offline authentication and symmetric algorithms for online authorization), similar extensions are possible for the other kernels. Moreover, the latest proposal for a new, unifying contactless standard, known as the C-8 kernel [21], includes the central elements needed by PURE.

3.1 The Mastercard Contactless Standard

Conceptually, a contactless payment consists of four stages:

- *Application Selection.* The card and the terminal agree on a kernel that specifies the capabilities of the card and the protocol executed by them.
- *Synchronization.* The card provides a list of data elements required by the issuer to process the transaction, such as the amount and currency. Furthermore, the terminal learns a set of certificates that allows it to validate the card's public key using a hard-coded list of root certificates. Critical data elements, such as the supported *Cardholder Verification Method*s (CVMs), are contained as data elements in the card's certificate and are thus integrity-protected.
- *Cardholder Verification.* Given the CVMs learned in the synchronization step, the terminal verifies the cardholder. For physical cards, this includes PIN or signature verification. For on-device cards, the terminal typically relies on the device's identification methods, e.g., the mobile phone's PIN or facial recognition.

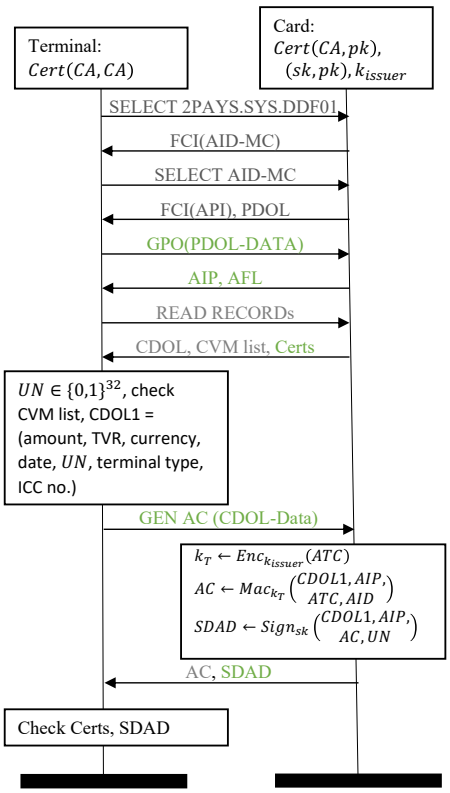

Figure 3: **Mastercard Kernel.** In green are the messages that PURE piggybacks onto. Messages in gray are specific to EMV and are not used by PURE.

- *Authentication/Authorization.* The terminal completes integrity checks of transaction critical data exchanged with the card based on digital signatures, so-called offline data authentication. In addition, the terminal sends transaction-related data (including a Message Authentication Code (MAC) provided by the card) to the issuer for authorization. All involved stakeholders (acquirer, payment network, and issuer) use fraud-detection systems to prevent fraudulent transactions.

The communication between the card and the terminal is depicted in Figure 3. Whereas the application selection and synchronization steps of a contactless payment are integral parts of the protocol executed between the card and the terminal, cardholder verification as well as parts of the authentication/authorization step involve communication between the cardholder and the terminal (or mobile phone) as well as communication between the terminal and back-end services (acquirer, payment-network, or issuer) and are therefore not shown in the figure.

In Figure 3, the terminal starts the communication by requesting the so-called Dictionary Definition File (`2PAYS.SYS.DDF01`), a Payment System Directory that contains one or more *Application Definition File*s (ADFs). The card responds with the *File Control Information* (FCI) containing an *Application Identifier* (AID) that allows the terminal to select the kernel to execute (in the figure depicted as `AID-MC`, where `MC` stands for Mastercard).

The issuer defines transaction-relevant data elements in so-called data object lists (DOLs) on the card. This includes a *Processing Options Data Object List* (PDOL) of terminal resident data elements and the *Card Risk Management Data Object List 1* (CDOL1) that contains transaction-relevant data elements that are later integrity protected using cryptographic algorithms.

The terminal then initiates the transaction by sending a *GET PROCESSING OPTIONS* (GPO) command containing the PDOLs requested by the card in the previous step. The card's response includes the *Application Interchange Profile* (AIP), a byte vector encoding the card's capabilities and an *Application File Locator* (AFL). The AFL enables the terminal to access the CDOL, the CVM list, and the card's certificate using *Read Record* (RR) commands.

In a next step, the terminal creates an Unguessable Number (UN) for the transaction and sends the required CDOL-data as part of the generate *Application Cryptogram* (AC) command, thereby defining the format of the cryptogram required to complete the transaction. The most common and secure form, Combined Data Authentication (CDA), requires successful offline and online authentication/authorization. The AC included in this form is a MAC on transaction-critical data elements that uses a secret key shared between the issuer and the card. Furthermore, it includes the *Signed Dynamic Application Data* (SDAD), a signature on transaction-critical data elements signed with the card's private key that can be verified by the terminal.

If the transaction's transcript passes all cryptographic tests, the cardholder (if necessary) is successfully authenticated, and the transaction does not trigger other security alerts (such as fraud detection system alerts in the payment network or at the issuer), then the payment is approved and triggers a corresponding back-end transaction at the issuer.

3.2 PURE Stand-Alone

We start by describing the stand-alone version of PURE before showing how to smoothly integrate it into the existing Mastercard kernel in a way that ensures backward compatibility with the current version of the standard. PURE comprises two main components: a key exchange and a ranging session. After a successful key exchange, the card and the reader share a secret key. This shared key is then used for ranging, where the reader accurately measures an upper bound on the distance to the card. Note that the term *card* refers to any token able to execute a contactless payment, however, PURE can only be applied to on-device cards because physical cards do not have a UWB radio.

PURE uses a Sign-and-Mac (SIGMA) key exchange [33]

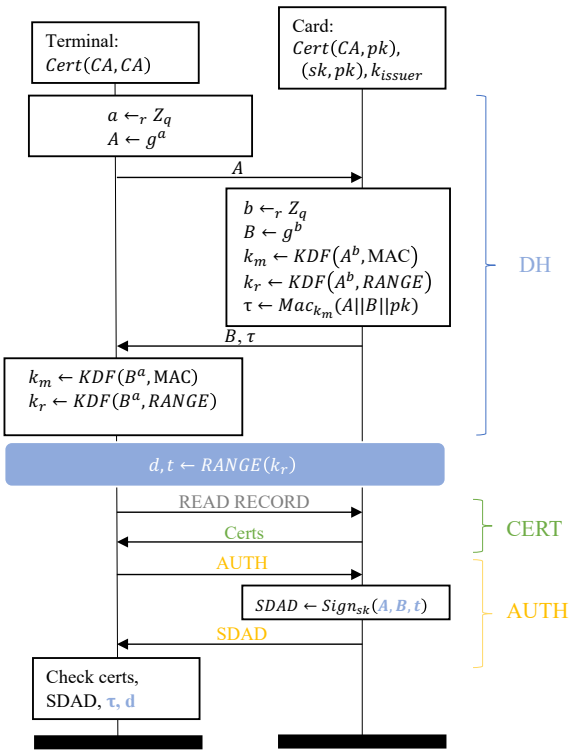

Figure 4: **Stand-Alone PURE.** Messages labeled in green and yellow (CERT and AUTH) can be integrated into data elements of the current Mastercard kernel. The blue elements (DH and RANGE) require specific extensions of the Mastercard kernel.

together with a ranging session to establish a reliable upper bound on the distance between the honest card and the honest terminal. Figure 4 depicts the protocol as a sequence diagram describing messages exchanged between the card and the terminal.

For clarity, we split the protocol into four stages:

- *DH Key Exchange (DH).*The two parties exchange freshly generated DH shares and derive fresh ranging (k_r) and tagging (k_m) keys. Upon reception of the terminal's share, the card computes τ, a MAC over the concatenation of the DH shares and its public key using k_m and appends it to its own DH share.
- *Ranging (RANGE).* Both parties execute UWB ranging using k_r for generating the nonces.
- *Certificate Exchange (CERT).* The card provides a certificate for its public key *pk* signed by the card's issuer that can be validated by a certificate authority *CA* known to the terminal.
- *Authentication (AUTH).* The terminal requests a signature over the concatenation of the DH parameters and the timings t. The protocol terminates with the reader checking the signature *SDAD*, the certificate *certs*, and the MAC τ. If any of the cryptographic checks fail, the terminal aborts the protocol.

As a result of a successful protocol execution, the terminal derives a reliable upper bound on the distance to the card with which it is executing the protocol. Distances below a predefined threshold convince the terminal that communication with the card has not been relayed. In contrast, distances above the threshold are considered suspicious and suggest a possible relay attack.

Note that our threat model assumes the terminal completing the transaction with a given acquirer and the card issuer to be honest, thus providing guarantees to the cardholder, since honest terminals would decline transactions that are likely to be relay attacks.

3.3 Integration in the Mastercard Kernel

We present our integration of PURE in the C-2 (Mastercard) kernel. Given that all kernels use a public key infrastructure for offline authentication, and that the AIP is integrity-protected, similar extensions of other kernels are straightforward.

The C-2 kernel integrated with PURE is illustrated in Figure 5. The sequence diagram shows how to integrate the elements of the stand-alone version (compare with Figure 4) into the existing Mastercard standard.

The protocol remains unchanged until the card announces its processing capabilities to the terminal with the AIP bit-vector. Currently, this bit-vector includes three bits reserved for future use (RFU). Our extension uses one of these bits to indicate the card's secure ranging capability. Note that a malicious downgrade is prevented because the AIP's value is integrity protected as a static element by the card's certificate. Adversarial changes of the AIP are thus detected by the terminal resulting in the protocol's abortion. Note also that the terminal initiating the transaction at the issuer is assumed to be honest. Provided that both the card and terminal support UWB relay protection, the terminal executes the DH block in Figure 5. In case UWB relay protection is not supported by either the terminal or the card, the terminal follows the existing C-2 standard.

The next deviation from the original EMV standard is introduced in the AUTH section, where the content of the modified SDAD element is extended with the Diffie-Hellman parameters of the card and the terminal. We execute the DH early in the protocol to ensure that double-sided two-way ranging (DS-TWR) can be run in parallel to NFC communication between card and terminal, thereby nullifying any additional delay possibly caused by the UWB ranging step.

Note that the CERT phase uses the existing certificate exchange of the C-2 kernel and integrates smoothly into the original data elements of the standard.

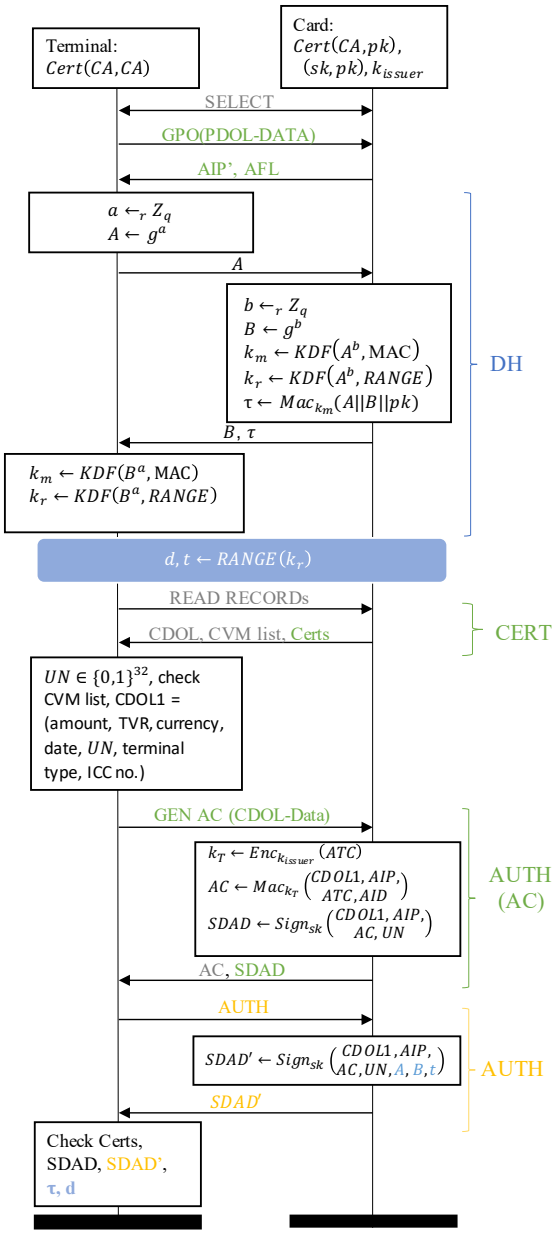

Figure 5: **Mastercard Kernel Extended.** This diagram integrates the stand alone protocol from Figure 4 into the Mastercard kernel in Figure 3. The color coding is consistent with the previous images, see Figure 2.

We emphasize that cryptographic linking of the values from the extension with those identifying the transaction (such as CDOL1, UN, and AIP) is essential. This way, we ensure that the shared secret and the corresponding ranging session are bound to a specific transaction. As a consequence, the UWB and NFC phases of a transaction cannot be decoupled by the attacker. In addition to the cryptographic checks that the terminal makes, depicted in Figure 5, the terminal checks that the measured distance is lower than a given threshold.

Note too that PURE requires offline authentication to prevent a MITM attack within the DH exchange. In theory, protection against MITM attacks, when offline authentication fails, could be achieved in the online authorization phase, where the issuer could validate the correctness of DH parameters in the message authentication code provided by the card and the DH parameters sent by the terminal. This approach would however require changes in the backend logic of the payment process outside of the EMV standard.

Integration in the C-8 Kernel. As explained in the preceding section, the smooth integration of UWB into Mastercard is achieved with three additional messages to establish the DH-based shared secret; all other messages are already in the C-2 kernel. In October 2022, EMVco published a proposal for the new C-8 kernel. This kernel is intended to unify the existing kernels and will become the new standard for future contactless transactions. Without delving into C-8's details, we point out that it includes a key exchange between the card and the terminal to establish an ephemeral Diffie-Hellman key, known as "Blinded Diffie-Hellman." The purpose of the shared secret is to encrypt the messages exchanged between card and terminal to protect sensitive data such as the Primary Account Number (PAN). Similarly to the key exchange we proposed, the reader and card establish a shared secret and the reader authenticates the card.

The established shared secret could be used to derive a ranging key. Hence, extending the C-8 kernel with UWB ranging requires no additional NFC messages. Given that UWB ranging can execute in parallel with the NFC message exchange, the overhead introduced for the C-8 kernel is again negligible.

Formal Model and Security Proofs in Tamarin. To increase the trustworthiness of PURE and formally prove the claimed security properties, we have modeled the extension of the C-2 kernel in the Tamarin prover [39]. Tamarin is a powerful verification tool that allows one to model and reason about security properties of protocols. Tamarin supports, in particular, equational specifications of Diffie-Hellman exponentiation, used by PURE. When using Tamarin, the central goal is either to obtain a formal proof for the security properties stated for the protocol or to find counterexamples, which are attacks that violate the stated properties. Tamarin provides fully automated strategies for constructing proofs or counterexamples but requires manual interaction in complicated cases.

Our model[1] is based on the formal model of the C-2 kernel provided from [7]. We have extended this model with the additional SIGMA key exchange as well as the corresponding

[1] https://github.com/daniCoppola/pure-models

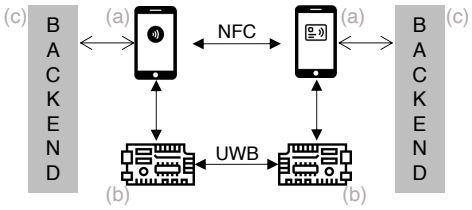

Figure 6: **Proof-of-Concept Setup.** (a) Android phones; (b) UWB chip; (c) backend generating EMV messages.

extension to offline authentication. Although the confidentiality and authenticity of the shared key inherently result from the security of the well-studied SIGMA key exchange [33], our model further establishes the secure integration of SIGMA into the C-2 kernel. Since Tamarin uses a symbolic message model that abstracts away from physical-layer properties fundamental to the security of a ranging scheme [37], our formal model of the protocol extension does not include the ranging phase. We analyze ranging separately in Section 4, given the properties of the derived shared secret proven with Tamarin.

In addition to the security proofs of the original protocol, the following theorems have been proven with Tamarin:

- Authenticity of the DH share: Whenever the terminal concludes that it has received a key share from a card, the card has indeed provided this key share in the current run of the protocol. Actually, we prove a strong version of authenticity, known in the literature as injective agreement [38] that also provides replay protection.
- Secrecy of the shared secret: If the terminal and card have agreed on a shared secret, the attacker cannot derive this secret.
- Authenticity of the AIP: Given that the terminal has successfully executed the protocol with a given card, they both agree on the same value of the card's AIP. Since the card's capabilities are encoded in the AIP, this property ensures downgrade protection of our extension.

The corresponding theorems are proven to hold for the case where CDA has been completed successfully and for the case of offline acceptance, where the card returns a Transaction Certificate (TC).

3.4 Proof-of-Concept Implementation

We show that PURE can be easily integrated into the existing C-2 kernel introducing low overhead and maintaining backward compatibility with a Proof-of-Concept (PoC) implementation.

We have implemented the standard and integrated version of PURE as Android apps on mobile phones. Although UWB is already widely deployed in Android and iOS devices, they lacked the necessary UWB software APIs to implement our extension at the time of writing. We thus have equipped each of the Android phones with an external Qorvo DW3000 board that provides us the necessary low-level access to the chip. Note that software APIs for UWB are constantly improving, for example, as of June 2023, Android allows to set the ranging key[2]. With adequate access to the UWB chip on mobile device, the LED algorithm described later in Section 4.2 could be implemented directly on the UWB chip integrated in phones.

Figure 6 depicts our setup, where the backends are responsible for generating EMV-specific messages. The backends generate EMV transaction data either (i) by replaying a prerecorded real transaction or (ii) by connecting live through NFC to real EMV-executing devices. The backends thus bridge our implementation of PURE to real EMV implementations, thereby proving the correctness of our implementation when connecting to a real terminal and a real card.

The stand-alone implementation follows exactly the protocol described in Section 3.2. Since the card's private key cannot be extracted, the SDAD' signature is created and validated with a self-created public/private key pair. For the real protocol, we can assume the terminal knows and trusts the card's public relying on the successful validation of the corresponding certificate.

Transaction Execution Time. Our PoC implementation shows that PURE adds only a negligible time delay compared to a regular transaction time. As a consequence, the time required for a user to keep his phone close to the terminal is not significantly increased. Table 2 shows the timings of the stand-alone and of the integrated implementation using a prerecorded transaction as backend. We run the apps on a Samsung S21 and a Pixel 4, respectively acting as a card and as a terminal. Ranging requires on average 30 ms; however, it is executed in parallel to the NFC exchange and thus does not introduce any overhead.

Integration with Real Payments. We use the live backends, to prove that PURE can be integrated into existing real-world transactions. The backend of the UWB-enabled terminal consists of a phone that forwards all communication from a real registered terminal to a front-end UWB-enabled phone that in turn executes PURE with a UWB-enabled card (see Appendix A for further details). Similarly the backend of the UWB-enabled card, is implemented with a phone that forwards all NFC communication to a real card. The extended EMV protocol (over NFC) and the UWB ranging are executed between the two front-end phones. If the protocol is

[2] https://developer.android.com/reference/kotlin/androidx/core/uwb/RangingParameters#sessionKeyInfo()

[3] https://gitlab.com/practical_emv/timing-data [43]

	Stand-alone	Integrated A	Integrated B
DH (ms)	46.8 ±9.3	41.0 ±7.5	41.0 ±7.5
CERT (ms)	44.5 ±10.8	-	-
AUTH (ms)	38.6 ±6.9	37.7 ±6.3	-
Overhead	-	10 - 16%	**5-9%**

Table 2: **Transaction Execution Time of PURE.** PURE introduces at most 78 ms delay. The Integrated version B achieves the lowest overhead of 41 ms by authenticating the DH and timings with the existing SDAD. We report the relative increase in time introduce by PURE with respect to the typical execution time of a Mastercard transaction of (630 ±151) ms[3].

executed successfully, a real transaction is executed on behalf of the real card at the real terminal. We could not use this fully integrated implementation for the measurement of the transaction excecution times due to the substantial overhead introduced by the forwarding of messages. However, the PoC with live backends shows in practice that a UWB-enabled phone can successfully execute real transactions with a UWB-enabled terminal. Additionally, it shows PURE's backward compatibility, since normal cards were still able to execute transactions with our UWB-enabled terminal.

4 UWB and PURE

PURE uses UWB to measure the distance between the card and terminal. UWB chips are now largely deployed in smartphones and other devices [23]. In PURE we make this measurement accurate, reliable, and secure against all known attacks [3, 36]. For this, we leverage the favorable wireless channels in the specific case of contactless payments.

4.1 Background on HRP UWB

HRP is the UWB mode of the IEEE 802.15.4z standard [28] deployed in current smartphones. UWB devices measure the distance between themselves based on the ToF of ranging messages. In essence, the first transceiver sends a message and estimates the round-trip time by measuring the ToA of the response. Since the second device provides its local processing time, the first can estimate the ToF with high accuracy.

As a secure ranging scheme, HRP can be used to derive an upper bound on the distance between two trusted ranging devices. An external attacker successfully breaks this scheme if it can convince the ranging devices they are closer than they actually are. Specifically, if the ranging devices measure an upper bound that is smaller than their true distance.

Scrambled Timestamp Sequence. Every HRP message contains a scrambled timestamp sequence (STS) consisting of 4096 pseudo-random pulses. The STS has two purposes: measuring the ToA accurately and, by making the ranging message unpredictable, preventing trivial distance reduction attacks. Following the IEEE 802.15.4z standard [28], given an authentic fresh shared secret, the ranging devices derive the STSs using AES in counter mode (AES-CTR). Note here the connection between the properties proven in Section 3 and the requirements posed by HRP. Despite the messages being unpredictable, the security of the scheme relies on the security of the ToA measurement, which we describe next.

Channel Impulse Response. When an HRP receiver detects a ranging message, it cross-correlates the received signal $RX[t]$ with a local template of the expected STS:

$$CIR[t] = (STS \star RX)[t] = \sum_{\tau} \overline{STS[\tau]} \cdot RX[\tau + t]. \quad (1)$$

The result is referred to as the Channel Input Response (CIR), in which correlation peaks indicate timestamps at which STS copies were received. Several such copies can exist due to the multipath effects (e.g., reflections) of the wireless channel. More precisely, the obtained CIR is only an approximation of the real channel: similarities between different parts of the STS (i.e., auto-correlation noise), interference, and other factors may result in non-zero correlation noise. Figure 7 depicts a CIR of a multipath channel.

Leading Edge Detection. To obtain an accurate ToF, it is crucial to find the ToA of the first STS copy. Since the highest peak in the CIR is not necessarily the first, HRP receivers perform LED. Starting from the highest peak, they try to identify a potential first peak (i.e., the *leading edge*) within a pre-defined backsearch window. LED algorithms are closed-source and vendor-specific, but they all have to distinguish between peaks and correlation noise, likely involving some threshold [46]. This is a non-trivial classification problem, especially in severe Non-Line-of-Sight (NLoS) scenarios, where low leading edges are to be expected. Prior work has shown [36, 41] that an attacker signal may result in correlation noise being misclassified as an earlier leading edge, effectively reducing the measured distance.

4.2 UWB Ranging in Contactless Payments

For contactless payments, UWB devices generally benefit from excellent signal reception because they are in close proximity. Nevertheless, transmissions may still be affected by the devices' close surroundings (e.g. reflecting surfaces) and how the user holds the phone.

Consequently, leading edge detection is still indispensable for accurate distance measurements. In PURE, we use these insights to build an LED based on a fixed, absolute CIR threshold, independent of specific channels or CIR noise. While this approach is not applicable to other ranging use cases, we

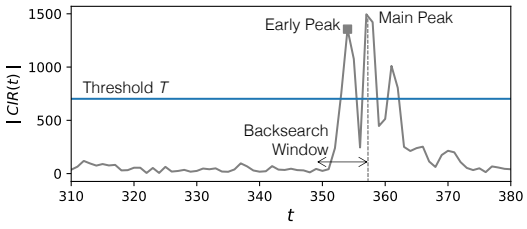

Figure 7: **Leading Edge Detection in PURE.** Each peak in the CIR denotes the arrival time of a copy of the signal. PURE identifies the first copy, corresponding to the distance between transmitter and receiver, using a fixed threshold T. Due to its high threshold independent from the CIR, PURE is robust against any manipulation by an attacker. It is also reliable because channels in contactless payments typically exhibit high CIR peaks.

show how it enables accurate, reliable, and secure ranging for contactless payments. Figure 7 depicts a CIR in which the leading edge is identified using a fixed threshold. We show analytically how such a threshold can be chosen to make the LED robust against distance reduction attacks. We use this CIR threshold within a commercial HRP receiver, and show that only minor adjustments to the threshold are sufficient to build a practically secure and reliable LED.

Intuition. A peak in the CIR is a measure of the similarity between the received signal and the expected STS for a given arrival time. If the contribution of each pulse on the generated peak is limited, then an absolute threshold on the peak height is equivalent to a threshold on the number of correct pulses in the STS. Indeed, each pulse's maximum contribution to a peak is constrained by the receiver's tolerated maximum power. Signals exceeding this limit are clipped by the receiver front-end, as illustrated in Figure 8. In the following, we assume without loss of generality that the output of the ADC is normalized to the range of $[-1,+1]$ and the maximum contribution of a pulse is capped at 1. Under these assumptions, setting an absolute threshold on the amplitude of the peak equates to setting the minimum number of pulses that the attacker has to guess correctly. This is a problem with a well-defined success probability, decreasing in the threshold on the peak height.

LED with an Absolute Threshold. We denote the number of pseudo-random pulses in the STS as n, and the number of received pulses with the correct polarity as n_c. Given that the receiver strictly limits the contribution of a single pulse to the CIR, setting a threshold T on the peak height requires an adversary to guess at least

$$n_c = (n+T)/2 \tag{2}$$

out of n pulses correctly.

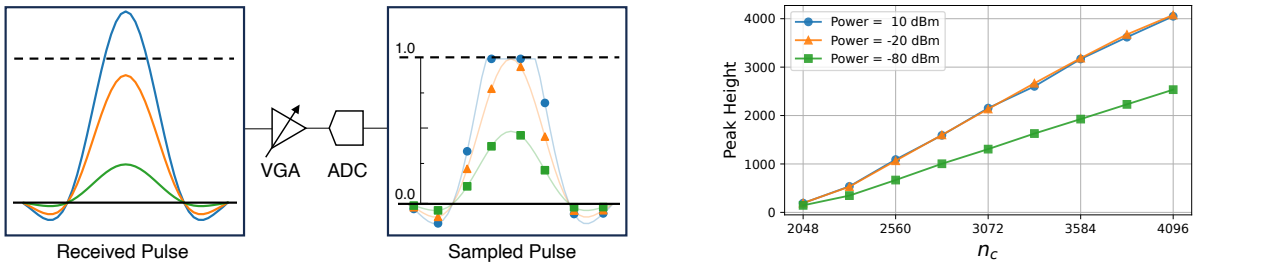
The definition of n_c follows from the fact that a signal with $n/2$ correct pulses (i.e., the expected outcome of n random binary guesses) should result in a CIR value of 0, while a fully correct STS can, at most, generate a peak of height n. Therefore, a valid peak can only be generated if the number of correct pulses is sufficiently larger than the expected value $n/2$ of a random guess.

Implications for security. For every pulse the receiver expects, the attacker can add at most 1 to a potential correlation peak. This property forces the attacker to guess at least n_c binary pulses correctly to reach the threshold, even if their transmission power is optimal. Setting a high threshold then limits the attacker's success probability. This result is independent of factors like pulse shapes, signal power, or channel effects. We define the threshold for a desired security level and evaluate it experimentally in Section 4.3.

Implications for reliability. To preserve ranging accuracy, the threshold must be low enough such that the leading edge (i.e, the first peak) of a genuine ranging message exceeds it with high probability. In other words, the link budget must be high enough for the receiver to identify the first STS copy in the overwhelming majority of expected wireless channels. Luckily, this condition is usually met in contactless payment scenarios due to the devices' proximity. We verify this experimentally in Section 4.3, where we implement a LED with an absolute threshold on the Qorvo DWM3000.

Choosing a Threshold. The threshold T is chosen to make the probability of passing the threshold by random guessing negligible. This probability can be written as

$$p(|CIR| > T) = 2 \cdot p(X > n_c) = 2(1 - F_X(n_c)) \tag{3}$$



where $X \sim \mathcal{B}(n, \frac{1}{2})$ is a random variable following the binomial distribution and F_X is its cumulative distribution function.

Note that $n_c > n/2$ n_c correct pulses and n_c wrong pulses are equivalent.

This equation describes the probability of exceeding the threshold at a specific CIR index, but the attacker's signal could cause a peak anywhere in the back-search window. To bound the probability of this event, we can multiply $p(|CIR| > T)$ by our chosen window length of $9 \simeq 2^4$. This is an overestimation in favor of the attacker, since neighboring CIR values are generally not independent. Considering that the attacker could advance the ToA of any of the $3 \simeq 2^2$ ranging messages, we can conservatively bound the probability of a successful attack by

$$p(success) \leq 2^6 \cdot p(|CIR| > T) \tag{4}$$

In Section 4.3 we will estimate the success rate empirically on a real receiver.

(a) Pulse before and after the receiver frontend.

(b) Peak height for different powers and correct pulses n_c.

Figure 8: **Receiver Front-end.** The Variable Gain Amplifier aims at adjusting the received pulse amplitude to match the dynamic range of the Analog-to-Digital Converter. If the pulse is too strong, it is clipped (a). If it is too weak, the VGA fills less than the dynamic range of the ADC. Therefore, each correct pulse contributes less than 1.0 to the CIR peak, which grows linearly with the number of correct pulses (b). Increasing the power from -20dBm to 10dBm does not bring any advantage because of clipping.

4.3 Experimental Analysis

In this section, we prove that the idea of an absolute threshold works in practice. We provide empirical evidence for our security argument and show that, at the same time, reliability and accuracy of the distance measurements do not deteriorate, analyzing its security, reliability and accuracy.

Security Against Distance-Decreasing Attacks. We show that, with a suitable choice of the absolute threshold, PURE is secure against the Ghost Peak distance-reduction attack [35]. We assume an adversary that: (i) transmits a random STS hoping to guess enough pulses to create a fake early peak above the threshold, (ii) has an ideal channel to the victim, and (iii) transmits at the maximum power before clipping occurs at the receiver. Figure 9 shows the results of our empirical evaluation of the success rate for increasing the absolute thresholds on the peak height. Accepting peaks higher than $T = 702$ bounds the success rate to a maximum of 2^{-49}.

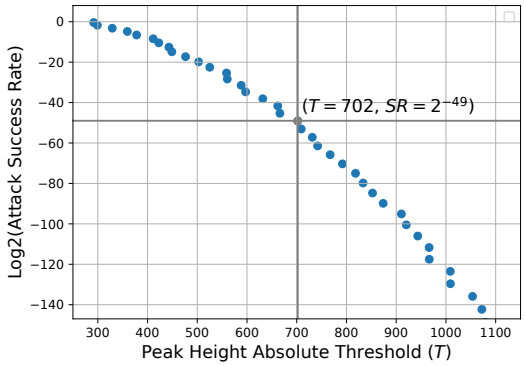


Figure 9: **Success Rate.** Empirical success rate of a Ghost Peak attack for different choices of the absolute threshold. A threshold $T = 702$ limits the success rate to 2^{-49} while still maintaining high reliability and accuracy (see Table 3).

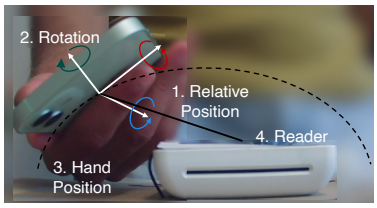
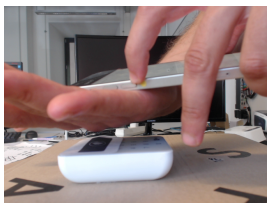


To estimate the success rate of Ghost Peak even when a high threshold makes it extremely low, we take the following strategy, inspired by importance sampling [32] and other similar approaches in security evaluations [11, 16]. First, using a signal generator connected to a Qorvo DWM3000 receiver, we measure the CIR peak amplitude distribution for varying numbers of correct pulses (n_c) in the transmitted signal. The generator uses the maximum power before clipping occurs at the receiver (-21dBm). Then, we identify the minimum n_c necessary to obtain a peak above the threshold (T). More precisely, we make the conservative choice of considering n_c sufficient to pass the threshold as long as the queue of the measured peak distribution for n_c is above T. Finally, following Equation 3 we estimate the probability of having obtained n_c by random guessing. We further multiply it by 2^6 to consider all ranging messages and all indices in the backsearch, as explained in Section 4.2.

Figure 9 depicts the success rate for different thresholds. These results, obtained experimentally, already take into account the effects of measurement noise and other possible nonidealities of the receiver.



PURE is also not vulnerable to Mix-Down [3] because it uses DS-TWR, in which clock drift compensation is done implicitly by measuring the RTT on both sides.

Overall, known distance-reduction attacks are prevented and cannot be used by an attacker to bypass the relay protection provided by PURE.

Reliability and Accuracy in Payment Channels. We show next experimentally that the threshold chosen for security does not hamper the ranging reliability in the contactless payment scenario. To this end, we equipped various readers with a Qorvo DWM3000, and used an iPhone 12 to perform ranging between the two. The current API offered by Apple [4] enables UWB ranging with fixed nonces but does not allow setting the ranging key necessary for secure ranging. However, the API is sufficient to execute ranging with a Qorvo board

(a) Variability introduced during CIR collection

(b) Deliberately obstructed antenna

Figure 10: **CIRs in Payment Scenarios.** We collected CIRs covering a wide range of payment scenarios modifying the parameters shown in Figure 10a. We consider holding the phone with the hand covering the back realistic. For comparison, we generate artificially hard cases by explicitly obstructing the antennas located at the top of the phone (10b).

and extract the measured CIR with a modified version of the Qorvo Nearby Interaction application [42]. This setup was used to collect a total of 300 CIRs by scanning the half-space in front of the reader, modifying the phone angle and position to cover a wide range of payment scenarios (see Figure 10a).

In Figure 11, we contrast the CIRs collected during contactless payments with CIRs collected in the following different scenarios: in Line-of-Sight (LoS) at a 20 cm distance, with deliberately obstructed UWB antennas as shown in Figure 10b and in NLoS at a distance of 3 meters. A qualitative examination already indicates that the peaks in realistic payment channels are visibly easier to detect than the peaks measured in severe NLoS where, in other use cases, UWB is still expected to perform reliably.

We use the extracted CIRs to analyze the performance of our LED with the chosen threshold ($T = 702$) and consider the ToA measured by the Qorvo as the ground truth.

The maximum accepted measured distance d_{th} must be set to ensure reliable payments within their operational range (terminal to card distance < d_{max} = 5 cm [19]). Specifically, let Δd^+ represent the maximum overestimation of distance beyond the error introduced by the chip accuracy Δd_{qorvo}. The maximum distance measured from within the payment range is given by $d_{th} = d_{max} + \Delta d^+ + \Delta d_{qorvo}$. Since we never underestimate the distance with respect to the chip, the worst underestimation error is given by the chip's accuracy. The longest undetected relay is located at $d_{relay} = d_{th} + \Delta d_{qorvo}$ distance because, due to an underestimation error, the measured distance falls in the accepted range.

Table 3 relates the accuracy with which we can detect a relay with the False Rejection Rate (FRR) over the measured channels. Our LED achieves 46 cm relay protection maintaining a small FRR (2%) in common payment scenarios. Although we tuned the system not to support unlikely interactions and channels (like the one in Figure 10b), where the hand fully covers the antennas, our system would still work reliably in most of these cases (with a FRR of 16% and $d_{relay} = 46$ cm). In general, the few failed measurements can be easily handled in the same way as failed contactless payments: by prompting the user to reposition their phone.

FRR	FRR_{blk}	d_{relay}	Δd^+	d_{max}	Δd_{qorvo}
0.5%	8.1%	95 cm	70 cm	5 cm	10 cm
1%	8.6%	85 cm	55 cm	5 cm	10 cm
2 %	16%	**46 cm**	21 cm	5 cm	10 cm

Table 3: **Reliability and Accuracy.** Trade-off between reliability and accuracy in contactless payments with an absolute threshold of 702 on the peak height. The table reports the FRR for realistic payment scenarios and for deliberately blocked antennas (FRR_{blk}).

5 Limitations and Future Work

In general, one limitation of PURE and other relay protections is that they are useful to cardholders only if they are largely deployed in all terminals. Otherwise, cardholders either have to use only a small subset of protected terminals, which is impractical, or cards must support backward compatibility, remaining vulnerable to a relay to an unprotected terminal. In practice, the backward compatibility of PURE can facilitate deployment until old terminals are phased out. The increasing availability of UWB and on-device cards/terminals is also expected to favor a rapid deployment.

A second limitation of PURE is that, while it prevents relays by an external attacker, it does not prevent attacks where one of the parties is dishonest. Malicious terminals could also operate without relays and their attacks are traceable; hence they are generally out of scope in the context of payments. A malicious cardholder could, for example, attempt to extract the ranging key from the card and share it with an accomplice. Merchants/terminals should therefore not use PURE as a proof of the distance of the cardholder. The practical realization of distance bounding in presence of a malicious prover is an open challenge, requiring physical layer capabilities that are currently not available in commercial technologies (e.g., analog processing with negligible delay [44]). At the system level, the use of Trusted Execution Environments (TEEs) could help reduce the trust assumptions on user and device, as it is already the case for on-device cards.

Finally, due to its wide-spread availability, PURE uses HRP UWB, for which a closed-form expression of the security level has not been found yet. We have demonstrated that HRP UWB can be both reliable and secure against known attacks in contactless payments, thanks to favorable channel conditions. However, our results do not automatically apply to other use cases, such as Passive Keyless Entry and Start Systems (PKES). In addition, stronger (e.g., adaptive) attacks on HRP UWB might be identified in the future. Ideally, future efforts in secure ranging will provide a theoretical framework

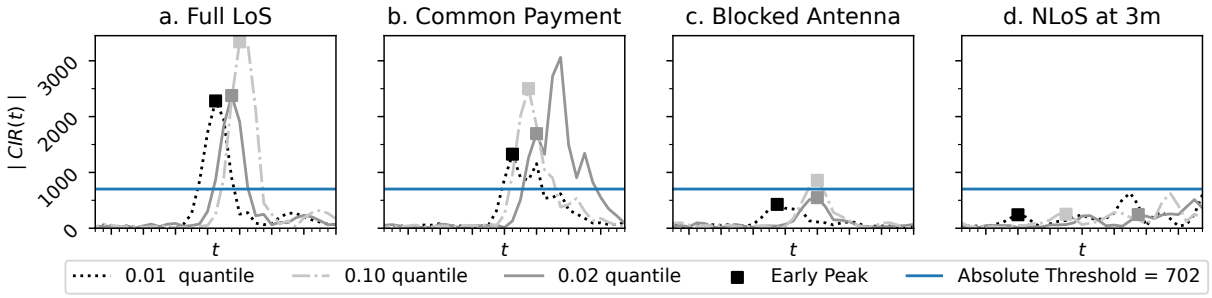


Figure 11: **CIR Comparison.** LoS (a) and Common Payment (b) scenarios show visibly better peaks than in other cases (c, d). In payments, it is thus possible to identify the early peak securely and reliably with an absolute threshold. CIRs were ranked based on the amplitude of the earliest peak. For each setting, we report the 0.01, the 0.02, and the 0.20 quantile CIR.

for the analysis of HRP UWB against any attack.

In the future, PURE could leverage the strengths of upcoming standards. For ranging, the IEEE802.15.4ab standard [27] is being developed with a focus on a higher link budget, for example, thanks to the multi-millisecond packets proposed by Apple [22]. This will facilitate deployment in a wide range of scenarios, further improving usability. It could also help enable novel wireless payment use cases, with seamless user interaction from larger distances. For payments, the C-8 Kernel [21] proposed by EMVCo in 2022 aims at unifying existing kernels and becoming the new standard. To protect sensitive data, it encrypts the card-terminal communication with an ephemeral Diffie-Hellman key. PURE could then derive the ranging key from the existing shared secret.

6 Related Work

Distance Bounding. Distance bounding protocols provide an upper bound on the physical distance between communicating parties under various threat models (e.g., external attacker, honest/dishonest prover) [5, 10, 14]. Narrow-band distance-bounding systems were implemented over Bluetooth [1], but their accuracy is significantly lower than in UWB. Moreover, a narrow band system does not fundamentally prevent Early Detect/Late Commit attacks [34, 40]. PURE focuses on integrating HRP UWB ranging in EMV contactless payments, achieving relay protection even against physical-layer attackers.

Relay Protections in EMV. Relay attacks on payment systems were demonstrated in 2005 in [31]. Several works [9, 26, 47] followed, showing their practicality. In the context of payments, distance bounding protocols were proposed to defend against an external attacker [43] or in the setting where readers can be dishonest [12, 18]. We discussed Mastercard RRP [20] and its improved version L1RP [43] in Section 2. Visa's relay protection does include a proper distance bounding protocol and only relies on the assumption that L1 NFC messages are hard to manipulate with COTS devices [48]. The card sends a random byte string to the terminal both at Level 1 and 3 of NFC. The terminal detects a relay if the bytes received at the two layers do not match.

EMV formal modeling. There are various symbolic models of the EMV standards [6, 7, 15]. These models helped to discover and patch protocol flaws that allowed attackers to bypass the CVMs [6, 8, 43]. We prove the security of PURE extending the formal model of the C-2 kernel provided in [7].

Attacks on HRP UWB. An initial security analysis of HRP UWB shows a complex reliability-security trade-off [46]. Attacks that forge early cross-correlation peaks by injecting random pulses [36, 41] questioned the security of cross-correlation for ToA estimation. Single-sided two-way ranging (SS-TWR) is vulnerable to attacks exploiting the non-ideality of clocks in the ranging devices [3]. We address these vulnerabilities in Section 4.

7 Conclusions

Relay attacks have been a constant threat to card payments and are now especially relevant with the increased popularity of contactless payments. This study proposed PURE, the first concrete proposal on how to integrate UWB-ranging techniques into EMV kernels. The integration of PURE within EMV protocols was formally verified in Tamarin. Our prototype showed that PURE can be deployed on real smartphones with negligible overhead on transaction time and without any modification to the backend. We tailored UWB-HRP to be secure and reliable in contactless payment. We provided an analytical and experimental analysis of the introduced absolute threshold demonstrating that PURE is secure against all known distance reduction attacks. In conclusion, PURE provides a practical and effective solution to relay attacks on contactless payments.

A Integrated Implementation Details

This section aims to clarify the setup used to test the functionality of PURE between a real card and a real terminal. As explained in Section 3, we use a backend to generate EMV messages, instead of re-implementing the Mastercard Kernel. Figure 12 shows the setup for the integrated implementation with real, live backends. A UWB Terminal consists of a registered terminal issuing EMV commands to a phone that reports the commands to the front-end phone via WiFi. Similarly, the UWB card consists of a registered card responding to the commands received them from the front-end phone over WiFi. The UWB-protected EMV transaction happens between the UWB card and the terminal identified by the blue boxes. Figure 12 highlights the UWB negotiation showing that the innermost phone of the UWB-Card sets the UWB bit to communicate to the UWB-Reader its ability to execute ranging. The innermost phone in the UWB-Terminal registers that the card can execute ranging and unsets the UWB bit to ensure that the check on the issuer side would not fail. Recall that the AIP is an authenticated value. If the card supports ranging, the innermost phones execute the DH exchange and the ranging. Finally, when the registered terminal issues the `GEN AC` command, the innermost phones exchange the signature over the DH parameters, the transaction parameters, and the timings. The `GEN AC` command is forwarded only if the signature verification succeeds. In conclusion, from the point of view of the registered card and terminal the transaction is a normal Mastercard transaction and the innermost phones are transparent because all the modifications and additions are not forwarded to the backend. This ensures that our integrated system can execute real transactions. We tested this with a Mastercard and a Sumup terminal as registered card and reader. The EMV trace including PURE is highlighted between the two innermost phones. The distance is measured between the two innermost phones. If a relay is detected, the transaction is blocked by sending an error message in response to the `GEN AC` command.

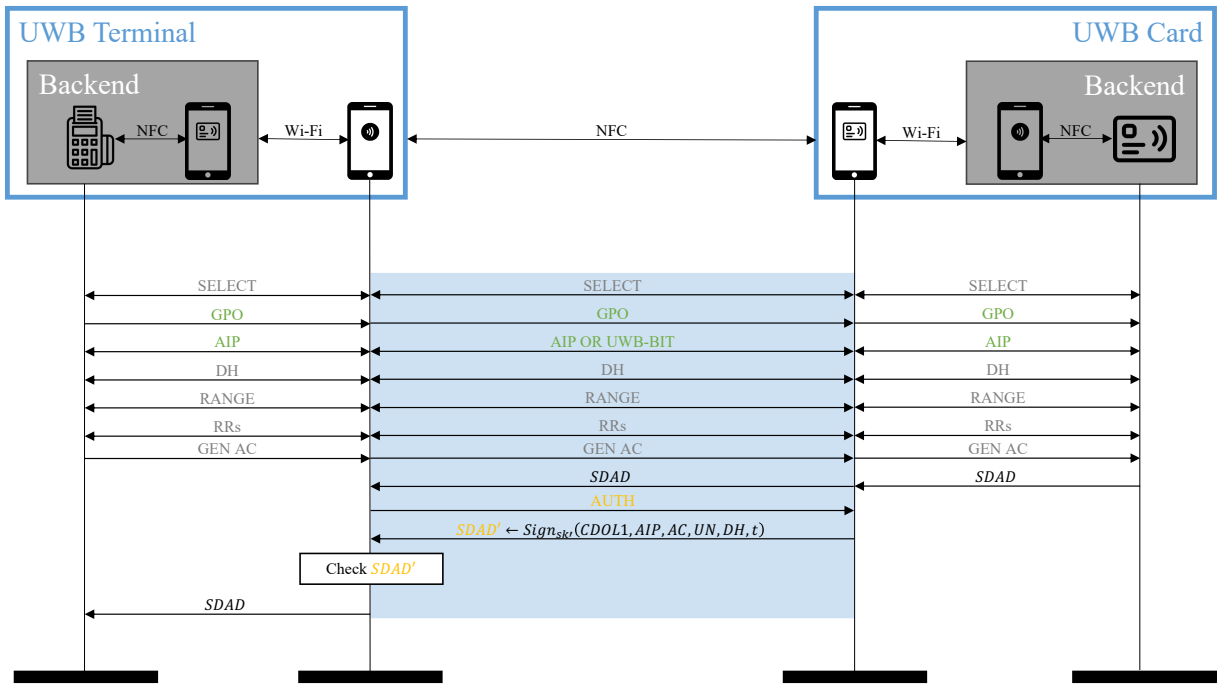

Figure 12: Proof-of-Concept transcript of a transaction using PURE with real card and terminal backend.

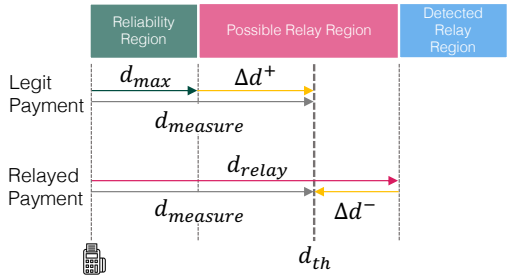

Figure 13: Maximum relay protection achievable by a relay protection system measuring distance with uncertainty. The legitimate payment with maximum distance overestimation Δd^+ determines the maximum accepted measured distance d_{th}. The longest undetected relay happens when the distance measured is affected by the maximal distance underestimation Δd^-.

B Analysis of RTT-based Relay Protection

This section provides the derivation of the shortest relay that an RTT-based relay protection can achieve. Let T_{reply} be the processing time of the responder, $(\Delta t^-, \Delta t^+)$ be the maximal absolute underestimation and overestimation of the RTT due to the uncertainty of the measurement. In a relay protection system based on RTT, the maximal accepted RTT is

$$T^*_{round} = \frac{2d_{max}}{c} + T_{reply} + \Delta t^+ \tag{5}$$

where d_{max} is the maximum distance accepted by the relay protection system. T^*_{round} must include the uncertainty on the measurement to ensure the reliability of the system. Overall, the relay protection system will have to accept all measured distances d such that

$$d < d_{th} = \frac{c}{2} \cdot (T^*_{round} - T_{reply}). \tag{6}$$

If the messages are relayed over d_{relay} meters by an adversary, who additionally adds T_{proc} seconds of processing time, the minimal round-trip time measured by the victims would be

$$T_{attacker} = 2 \cdot (\frac{d_{relay}}{c} + T_{proc}) + T_{reply} - \Delta t^-. \tag{7}$$

The receiver, burdened with the task of detecting a relay attack on an exchange of messages, can only reliably detect relays such that

$$\begin{aligned} T_{attacker} &> T^*_{round} \\ d_{relay} &> d_{max} + T_{proc} \cdot c + \frac{c}{2}(\Delta t^- + \Delta t^+) \end{aligned} \tag{8}$$

With $\Delta d^+ = \frac{c}{2}\Delta t^+$ and $\Delta d^- = \frac{c}{2}\Delta t^-$ being the maximal distance overestimation and underestimation, Equation 8 can be rewritten as

$$d_{relay} > d_{max} + T_{proc} \cdot c + \Delta d^- + \Delta d^+. \tag{9}$$

Figure 13 provides an intuitive interpretation of the last derived bound.

Do You See How I Pose? Using Poses as an Implicit Authentication Factor for QR Code Payment

Abstract

QR code payment has gained enormous popularity in the realm of mobile transactions, but concerns regarding its security keep growing. To bolster the security of QR code payment, we propose PQRAUTH, an innovative implicit second-factor authentication approach that exploits smartphone poses. In the proposed approach, when a consumer presents a payment QR code on her smartphone to a merchant's QR code scanner, the scanner's camera captures not only the QR code itself but also the smartphone's poses. By utilizing poses as an additional factor, in conjunction with QR code decoding, the scanner verifies the authenticity of the smartphone presenting the QR code. Our comprehensive evaluation demonstrates the effectiveness of PQRAUTH, affirming its security, accuracy and robustness.

1 Introduction

The widespread adoption of smartphones has significantly changed the way commercial activities are carried out. In particular, Quick Response (QR) codes, which enable contactless mobile payment, have been widely utilized. As many as 1.5 billion shoppers worldwide used QR codes to pay in 2020 and the number is predicted to be 2 billion by 2025 [54]. The market of QR code payment is projected to reach $35.07 billion by 2030 [55]. QR codes have become commonplace among mobile payment service providers, such as Venmo, PayPal, AliPay, and WeChat.

QR code payment provides fast and touch-free experiences, obviating the necessity for carrying cash/credit cards or manual receipt signing. As shown in Figure 1 (a), a consumer only needs to show a QR code generated by a mobile payment app to a scanner to complete the transaction. The code encodes information, such as the user account ID and timestamp [39]. The scanner sends the decoded bits with other transaction information, such as the transaction amount and currency type, to the back-end of the payment system for verification. If the QR code is deemed valid, the payment is authorized.

(a) QR code payment

(b) Replay attack

Figure 1: (a) A consumer presents a payment QR code for a transaction. (b) An attacker sneakingly obtains the consumer's QR code and replays it to initiate a payment, without deciphering the encoded information.

Attacks against QR code payment systems have been frequently reported [8, 39, 46, 52, 74, 80]. As shown in Figure 1 (b), an attacker sneakingly acquires the victim's QR code displayed on the victim's smartphone, and then displays it on the attacker's smartphone to check out. The attacker does *not* need to decipher the encrypted data (such as the user account ID) in the QR code, but simply re-displays the victim's QR code. As the QR code is an exact copy of the code generated by the victim and thus considered valid, the transaction proceeds, but the server charges the victim's account.[1]

Similar to the notorious relay attacks targeting chip card payment systems [4], replay attacks pose a significant threat to QR code payment systems. Replay attacks against QR code payment are not only feasible, but also cheap [8]. Attackers can use affordable commercial off-the-shelf smartphones or cameras to record QR codes [8]. Additionally, replay attacks are often stealthy, as a QR code can be sent to a remote attacker to conduct a fraudulent transaction. Due to the widespread use of QR codes by various entities, including

[1] This is called a *replay attack* in prior work [39, 52, 74], as the QR code is first displayed on the victim's phone and then *re-displayed* on the attacker's phone. We use the same term, and clarify that the QR code is **not** used *twice*.

large retailers like Walmart and Starbucks, as well as financial organizations such as Paypal and AliPay, replay attacks against these systems are on the rise and can cause substantial financial losses [39, 52, 74].

To defeat replay attacks in QR code payment, researchers have proposed various solutions [8, 39, 52, 74, 80]. Unfortunately, these methods are vulnerable, face challenges in real-world deployment, or require users to change their habits. More details about these works are discussed in Section 2.

We present a novel QR code authentication system, named PQRAUTH, which leverages the poses of a smartphone displaying a payment QR code as a second authentication factor. PQRAUTH provides an additional layer of security for QR code payment based on the simple yet solid fact: What the scanner sees (i. e., the observed poses of the smartphone presenting the QR code) should correlate with the actual poses of the *account owner*'s smartphone (sensed by the built-in sensors of the account owner's smartphone).

The poses sensed by the built-in sensors of the account owner's smartphone serve as the *ground truth*. PQRAUTH checks whether the scanner-observed poses of the smartphone displaying the QR code match the ground truth. Specifically, when a consumer displays a payment QR code on the smartphone, the Inertial Measurement Unit (IMU) in the smartphone collects information regarding the smartphone's poses, which is employed as the ground truth. When a scanner scans the QR code, it estimates the smartphone's poses by analyzing the recorded video. By examining whether the scanner-estimated poses match the ground truth, PQRAUTH determines whether the payment should be authorized.

PQRAUTH carries multiple prominent properties. First, PQRAUTH is secure against replay attacks. An attacker who displays a victim's QR code would also need to mimic the poses of the victim's smartphone, *in real time*, in order to fool. However, studies have shown that people tend to overestimate acute angles and underestimate obtuse angles when reproducing angles, even if there are no real-time constraints [14, 27]. Thus, it is unlikely that attackers can reproduce the poses of the victim's smartphone in real time. Second, PQRAUTH is a software-based solution, which requires no special hardware on the consumer side. Third, PQRAUTH provides an implicit authentication factor that does not change any user habits, maintaining the excellent usability of QR code payment. With PQRAUTH, a user is *not* restricted to presenting their smartphone in any specific positions or orientations. Instead, the user presents a payment QR code in the same way as specified by current QR code payment. Fourth, PQRAUTH can be generalized to other scenarios. QR codes are utilized in various other scenarios, including gate access control in buildings, ticketing services, and profile sharing in social media apps. PQRAUTH can also be applied to these scenarios.

It is worth clarifying that PQRAUTH requires zero permissions from smartphone users, as it merely uses zero-permission motion sensors. In addition, the data collection is only conducted while a user is using the QR code, which alleviates privacy concerns.

We build a prototype of PQRAUTH and evaluate its performance in real-world scenarios. Below are some of the questions that our evaluation has studied. *Does the system work for different smartphones and scanners? Is the system resilient to attacks? Is the latency overhead negligible?* The results give positive answers to all the questions.

The contributions of this work include:

1. We propose a novel authentication system named PQRAUTH. It provides an implicit authentication factor for QR code payment without changing user habits.

2. We present a technique that translates 2D images captured by a monocular camera to fine-grained 3D pose information. Plus, an effective method that determines the correlation between pose data is devised.

3. We implement a prototype of PQRAUTH and perform a comprehensive evaluation in real-world environments. Extensive experiments demonstrates its accuracy (>0.99), robustness, and resilience to attacks.

The rest of the paper is organized as follows. We present related work in Section 2 and introduce the background of QR code payment schemes in Section 3. We present the threat model and outline the system overview in Section 4. Section 5 shows the design details. The experiment settings for data collection are presented in Section 6 and the evaluation is presented in Section 7. Section 8 details the user study. We discuss the limitations, improvements, and other potential attacks in Section 9. The paper is concluded in Section 10.

2 Related Work

QR code security. To mitigate replay attacks, most mobile payment apps, such as WeChat and Alipay, set a valid time period for each payment code, which is around 90 seconds. Moreover, mobile payment apps restrict that a code can only be used once, which means any attempts to launch attacks after the code has been used will be in vain. However, as replaying a victim's QR code can be conducted in a matter of sub-seconds, attackers have rich opportunities to have the replayed code scanned before the legitimate user [39, 52, 74]. Moreover, a variant of replay attacks, called *Synchronized Token Lifting and Spending* [8], describes various means to disrupt the legitimate transaction, ensuring the attacker to use the QR code first.

As we aim at a secure and usable authentication approach, we assess QR code security enhancement approaches based on the following criteria: **(C1) resilience to attacks**, such as replay attacks; **(C2) no requirement for special hardware on the consumer side**; **(C3) no alteration of user habits; and (C4) good generalizability.** The results are summarized in Table 1.

Table 1: Comparison. ✓: true, ✗: false, ✓̸: partially true, **?**: unclear.

Technique	C1	C2	C3	C4
mQRCode [52]	✓	✓	✗	✗
ScreenID [39, 74]	✗	✗	✓	✗
AnonPrint [80]	✓	✓	✗	✗
POSAUTH [8]	✓	✓	✗	✗
Secret Handshakes [19]	✗	✓	✗	✓
RF-based technologies [56]	✗	✓	✓	✗
Distance bounding [11]	?	✗	✓	✗
PQRAUTH	✓	✓	✓	✓̸

Existing approaches detect replay attacks by examining unclonable characteristics of either the QR code or the screen displaying the code. For example, mQRCode [52] proposes to use moiré patterns to camouflage the original QR code. This makes it challenging for attackers to decipher the camouflaged code when it is not in a designated position. However, to use mQRcode, users must follow specific orientation and positioning requirements, which requires changes in their established habits (**C3**: ✗). As users needs to learn how to use mQRCode and change their habits, it is difficult to generalize it to other QR code applications (**C4**: ✗).

ScreenID [39, 74] utilizes the pulse width modulation (PWM) frequency of screens to establish a distinct screen fingerprint to enhance QR code security. Nevertheless, attackers can mimic the victim's PWM frequency by using an external lighting device, which can go unnoticed by cashiers in self-checkout scenarios. Alternatively, once knowing the rolling shutter interval of the QR code scanner, which is a constant value, attackers can add rolling stripes over the QR code to mimic the victim's PWM frequency [39, 74] (**C1**: ✗). Furthermore, many smartphones are not equipped with PWM screens, as PWM dimming can cause discomfort such as eye strain, nausea, and headache [1] (**C2**: ✗), which limits the generalizability of ScreenID (**C4**: ✗).

AnonPrint [80] fingerprints screens with unique brightness levels of pixels across the display area, but it only works in completely dark environment (**C4**: ✗) and requires the smartphone to cover the whole scanner, which negates the advantage of touch-free characteristics of QR code payment (**C3**: ✗). In addition, it is susceptible to pixel aging issues [80].

POSAUTH [8] involves attaching a unique QR code to each POS terminal, which encodes its ID. Without POSAUTH, the consumer directly displays a QR code. With POSAUTH, however, the consumer needs to first scan the POS terminal's QR code and then displays a QR code that encodes the POS terminal's ID. This approach requires changes of user habits (**C3**: ✗). This significant change also harms its generalizability (**C4**: ✗). For example, it can hardly be applied to a busy subway station that requires fast authentication.

Unlike existing approaches, our work is the first that enhances QR code payment security through correlation (without using fingerprints). Correlation-based authentication has led to many famous works [37,38,41,42,61,72,73,75,76]. As interpreted in Section 1, PQRAUTH carries multiple prominent properties. However, we admit that it has a limitation (**C4**: ✓̸): PQRAUTH can only be used with hands-free scanners (or hand-held scanners with built-in IMU, such as smartphones). According to our survey, all the retailers have hands-free scanners (see Section 9).

Alternative methods. One potential approach to QR code payment security is to generate the payment QR code only after the user presents it to a scanner. Like Secret Handshakes [19], which enhances RFID security by activating RFID tags only after a secret gesture is recognized, QR code security could be bolstered by generating the QR code only after detecting secret gestures. However, since replaying a victim's QR code can be executed rapidly [39, 52, 74], it remains a significant threat even if the QR code is generated after secret gestures are recognized (**C1**: ✗). Additionally, enforcing secret gestures alters user habits (**C3**: ✗).

To authenticate the proximity of a smartphone to a QR code reader, a straightforward approach is to utilize radio frequency (RF) based wireless technologies, such as received signal strength indicator, phase-based distance estimation, and radio frequency fingerprinting. However, researchers have repeatedly demonstrated the insecurity of these RF-based proximity-proving techniques [20, 23, 24, 28, 56, 67] (**C1**: ✗). For instance, radio relay attacks [23] against the keyless entry system of modern cars, without cracking crypto-keys, are not only real [65] but also inexpensive ($22) [70]. Furthermore, as wired QR code readers lacking RF capabilities dominate the market [64], the generalizability issue associated with RF-based techniques cannot be overlooked (**C4**: ✗).

Distance-bounding protocols [11], designed to establish an upper bound on the distance between devices, have the potential to counter radio relay attacks [21]. Active research is underway to study their security aspects [17,44], while new attack methods continue to emerge [5, 7] (**C1**: **?**). The protocols are sensitive to even minor processing latency and thus require specialized hardware that is not yet widely available (**C2**: ✗). Moreover, due to the absence of standards, compatibility issues between devices of different vendors hinder the widespread adoption of the protocols (**C4**: ✗).

Motion-based authentication. Human action-based authentication has sparked numerous methods in different domains, spanning from smart homes [37, 53, 59] to drones [61, 71]. While a comprehensive review of all these methods exceeds the scope of this paper, we focus on approaches employing camera-IMU signal correlation for authentication. These methods compare motions estimated from camera data and recorded by IMUs. UniverSense [53] and PosePair++ [59] require users to move an IoT device equipped with an IMU in front of a camera, and IMU readings and acceleration data

estimated from images are used for pairing.[2] G2Auth [71] conducts authentication between drones and users by having users wave a smartphone in front of a drone's camera.

These methods translate 2D images captured by cameras into 2D acceleration data and compare it with IMU readings. In contrast, our work converts 2D images into fine-grained 3D pose information and incorporates it for authentication. IDIoT [58] estimates a plane of possible orientations based on the locations of human body joints in 2D images. However, the orientations cannot be uniquely determined from the joint locations in 2D images. Thus, as admitted by the authors, it cannot recover fine-grained orientation information. Furthermore, it assumes human bodies can be captured by cameras, while during payment a scanner mainly captures a smartphone displaying a QR code.

We introduce a mathematical model to estimate fine-grained 3D poses of smartphone from 2D images. Additionally, we propose a method to establish correlation between the estimated poses and IMU readings. Notably, PQRAUTH stands out as the *first* correlation-based authentication approach that utilizes fine-grained 3D pose data as a distinctive authentication factor.

3 Background

Two main QR code payment schemes have been proposed for different payment scenarios [43].

Consumer-presented QR code mode. To check out, a consumer opens a digital wallet app, e. g., PayPal, generates a unique one-time payment QR code with the app, which is then scanned. The scanner decodes the QR code and sends the decoded data to the payment server. The cashier receives a notification once the payment is verified and prints the sales receipt. Alternatively, in a self-service checkout system, consumers present their payment QR codes to the scanners themselves. The consumer-presented QR code payment procedure is similar to paying with a credit card, where the QR code functions as a one-time credit card.

To scan consumer-presented QR codes for transactions, merchants typically need to apply dedicated scanners and obtain necessary permissions from a Point of Sale (POS) provider [66]. Payment QR codes are not functional with unauthorized scanners.

For convenience, most digital wallet apps, such as Paypal and Venmo, do *not* require consumers to confirm transactions after presenting the payment QR codes to scanners. Some digital wallet apps do *not* need confirmation for transactions below a predefined amount. For example, no password or security verification is required by WeChat Pay for single transactions under RMB 1000 (approximately USD 140) [69]. In other apps, like Alipay [3], consumers have an option to set up a transaction limit, below which no confirmation is required. Despite the great usability (i.e., confirmation is not mandated), the payment is vulnerable to replay attacks, where an attacker replays the QR code presented by a consumer to another authorized scanner.

Merchant-presented QR code mode. In contrast to the consumer-presented QR code mode, upon checking out, the cashier, rather than the consumer, generates a dynamic QR code which contains the bill. The consumer launches the digital wallet app, scans the QR code, and confirms the transaction in the app. Alternatively, the merchant generates a static QR code containing their ID, and the consumer enters the bill after scanning the QR code and confirms the purchase on their smartphone. In this case, the merchant's static QR code can be printed on a portable paper, which is usually adopted by small businesses, such as street food vendors. In the merchant-presented QR code payment scheme, explicit confirmation is *mandatory* for each transaction [2].

In the merchant-presented QR code mode, the QR code obtained by an attacker cannot be exploited for illicit financial gains. Additionally, the security of this mode is strengthened by the mandatory consumer confirmation. In contrast, the consumer-presented QR code payment scheme is vulnerable to replay attacks, as demonstrated in previous research [8, 39, 52, 74, 80]. Therefore, we focus on consumer-presented QR code mode.

4 Threat Model and Overview

4.1 Threat Model

QR code replay attacks. The attacker can obtain the consumer's QR code in several ways. For example, they may physically get in proximity to a victim, and sneakingly record the victim's QR code with a smartphone. Note that the acquired QR code can be sent to a remote attacker to conduct a fraudulent transaction. Alternatively, an attacker may deploy cameras in the environment and take a sneak shot of the victim's QR code remotely [52]. Given that individuals typically have their payment QR codes displayed on their phone screens tens of seconds prior to cashiers scanning them [52], attackers could exploit this window to acquire the victim's QR code and use it before the legitimate scanning process takes place. Such attacks are also described in prior work [39, 52, 74]. Moreover, a variant of replay attacks, called *Synchronized Token Lifting and Spending* [8], describes a variety of means to disrupt a legitimate transaction, while the attacker can acquire and use the QR code.

Mimicry attacks. An attacker who knows the scheme of PQRAUTH may launch mimicry attacks. Note that the QR code generated by the victim contains the victim's account ID. A server only compares the poses of the smartphone being scanned with the sensor data reported by that account owner's

[2] UniverSense and PosePair++ are designed for pairing, but it is straightforward to adapt them to authentication.

smartphone. Consequently, an attacker must accurately replicate the real-time poses of the victim's smartphone, striving to achieve the highest possible resemblance.

Similar to acquiring the victim's QR code, the attacker can employ a camera to observe the poses of the victim's smartphone and mimic the poses simultaneously. However, it is important to note that the average human reaction time exceeds 200ms [26,31,45]. Therefore, it is unlikely for attackers to replicate the poses of the victim's smartphone in real time, and such time difference can be detected by our algorithm. We also assume that attackers have the capability to predict the victim's behaviors through various side-channels, such as leveraging auditory cues like the distinct beep sound produced by a successful QR code scan. This allows them to estimate the timing of the victim's scanning completion and adjust their own smartphone accordingly. However, research reveals that individuals tend to overestimate acute angles and underestimate obtuse angles when reproducing angles, even without time constraints [14,27]. Therefore, even if the attacker predicts the timing of the victim's smartphone movement, it is unlikely that they can accurately replicate the poses.

Perspective distortion attacks. An attacker, who knows the scheme of PQRAUTH and the difficulties of impersonating a user's operations in real time, may choose to perform perspective distortion on the replayed QR code. Specifically, the attacker employs computer vision techniques to analyze the poses of the victim's smartphone and meanwhile distorts the replayed QR code, rendering a visual effect that the replayed QR code's poses correlate with the poses of the victim's smartphone. However, the perspective distortion attacks require utilizing specialized algorithms and ample computing resources to lively infer poses of the victim's smartphone and distort the QR code, which make it less practical in real world. More importantly, the perspective distortion attacks can be easily detected, as the boundaries of the distorted QR code are not parallel to those of the smartphone screen.

A variant of the attack is to record a video or generate a fake video, e.g., using AI, which includes a smartphone that shows the victim's QR code and the poses of the victim's smartphone. Then, a large screen is used to show the video to the scanner. However, with this attack, the phone is not live but rendered using a screen. Either of the two distinct types of techniques can detect such attacks: (1) techniques that detect AI-created videos [40], and (2) techniques that detect whether the part showing phone boundaries belongs to a screen based on, e.g., moire patterns [52] and flickering [39].

Assumptions. Similar to prior work [39,52,74], we have the following assumptions. We assume that the attacker cannot physically get and unlock the victim's smartphone. We also assume a malicious app, if installed on the victim's smartphone, does not manipulate the sensor data, since the current smartphone's sensor security model allows only *read* access to sensitive sensors. We assume that those authorized scanners are not compromised, as retailers usually have strict polices regarding software installed in scanners.

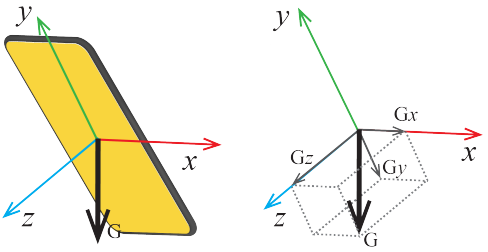

Figure 2: A smartphone's pose is represented as the orientation of the smartphone, which is indicated by the gravitational forces acting along the smartphone reference axes.

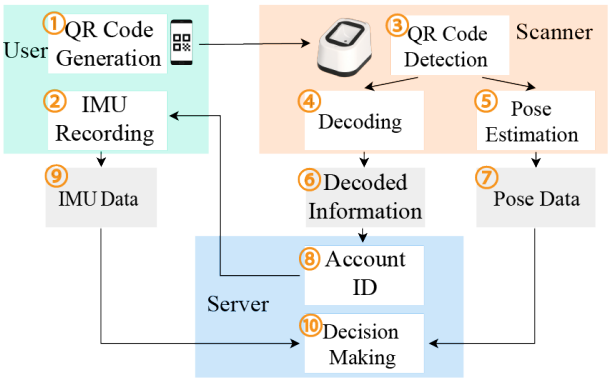

Figure 3: System architecture.

4.2 Overview

Our objective is to enhance the security of QR code payment without altering users' habits. In PQRAUTH, users follow a typical QR code payment process, while a factor of authentication based on poses is added *implicitly*. As shown in Figure 2, a smartphone's *pose* is represented as the orientation of the smartphone, which is reflected by the gravitational forces acting along the smartphone reference axes. The readings from the gravity sensor along the device reference axes, i. e., G_x, G_y, and G_z, represent the projections of gravity, which in turn indicate the orientation of the smartphone.

Figure 3 illustrates the system architecture, consisting of three entities: a smartphone owned by a user, a scanner used by a merchant, and a server that provides authentication services. A representative procedure of PQRAUTH is as follows; note that specific details may vary based on the implementation and payment scenarios.

1. After a bill is generated, the user unlocks the smartphone and launches the payment app to generate a payment QR code (①), and the smartphone starts recording its IMU data (②). The user shows the code to the scanner.

2. Once the code is detected by the scanner (③), a beep alert is emitted to indicate a successful scan, and the user may then put away the smartphone.

3. The scanner decodes the payment code (④) and estimates the poses of the smartphone displaying the code (⑤). The scanner sends the decoded information (⑥) and estimated poses to the back-end server (⑦).

4. Once the account ID is decrypted (⑧), the server fetches the IMU data from the app logged in with that ID (⑨).

5. The server makes a decision by comparing the IMU data with the pose data estimated by the scanner, and sends the payment result to the scanner and the smartphone (⑩). If the pose information estimated by the scanner matches with that recorded by the consumer's smartphone, the payment is authorized; otherwise, it is rejected, and the user is notified to re-generate a payment code and repeat the authentication procedure until the maximum number of attempts is reached.

It is worth clarifying that a payment QR code encodes the consumer's account ID. Thus, the server only compares the scanner-observed pose data with IMU data fetched from the payment app logged in with that account ID. In other words, the decision-making process involves a one-to-one verification problem rather than a one-to-many identification problem, meaning that its accuracy does not decline as the number of users increases.

5 System Design

On the smartphone side, we utilize IMU sensor data to determine the smartphone's poses. On the scanner side, we perform smartphone pose estimation (Section 5.1) from the recorded video and apply data pre-processing to eliminate noise and outliers (Section 5.2). After receiving the pose data from the scanner and the smartphone, the server determines their correlation (Section 5.3). For scanners without an IMU, we perform scanner orientation calibration, which is a one-time effort (Section 5.4).

5.1 Smartphone Pose Estimation

To determine the poses of the smartphone from the recorded video, we perform QR code detection to locate the QR code in the video frame. Within the QR code, three square *position markers* are situated at its top-left, top-right, and bottom-left corners. These markers facilitate the process of locating and orienting the QR code, enabling a QR code reader to identify it accurately.

After locating the QR code, we estimate the pose of the smartphone in the world coordinate system. When a QR code

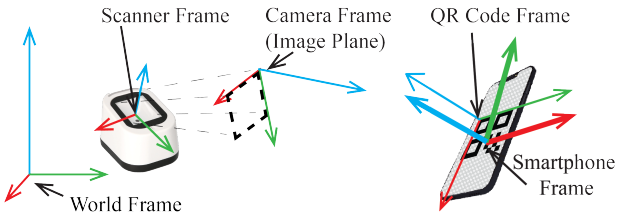

Figure 4: Transformation between coordinates. X-axis: red; Y-axis: green; Z-axis: blue.

is detected by the scanner, the rotation of the smartphone can be obtained by the following equation:

$$R_{World}^{Phone} = R_{World}^{Cam} \cdot R_{Cam}^{QR} \cdot R_{QR}^{Phone} \tag{1}$$

where R_{World}^{Phone} represents the rotation matrix from the world coordinate system to the smartphone coordinate system.

The matrix R_{World}^{Cam} denotes the rotation from the world coordinate system to the scanner camera coordinate system. It can be calculated by Equation 2:

$$R_{World}^{Cam} = R_{World}^{Scanner} \cdot R_{Scanner}^{Cam} \tag{2}$$

where $R_{World}^{Scanner}$ is the rotation matrix from the world frame to the scanner frame, and $R_{Scanner}^{Cam}$ is the rotation matrix from the scanner frame to the camera frame. For scanners with IMU integrated, the scanner frame is defined as their sensor coordinate system. $R_{World}^{Scanner}$ can be obtained from the IMU sensor built in the scanner. For instance, Android provides the `getRotationMatrix()` method, which uses the gravity sensor and the geomagnetic field sensor to get the rotation matrix for a device. Since the camera is fixed in the scanner, the pose of the camera is stable relative to the scanner, and the transformation $R_{Scanner}^{Cam}$ is constant and can be predetermined based on their relative poses. For example, in the case of a smartphone scanner, the camera frame can be obtained by rotating the smartphone's IMU coordinate system by 180 degrees along its x-axis. In summary, R_{World}^{Cam} can be calculated based on the scanner's IMU data. For scanners without IMU integrated, such as a hands-free scanner shown in Figure 4, we propose to perform scanner orientation calibration, which is discussed in Section 5.4.

The rotation matrix R_{Cam}^{QR} represents the rotation of the QR code with respect to the camera frame. We employ a Perspective-n-Point (PnP) based method [35], which minimizes the reprojection error from 3D-2D point correspondences, to estimate R_{Cam}^{QR}. Specifically, a matrix T_{Cam}^{QR} is defined to denote the homogeneous transformation from the camera coordinate system to the QR code coordinate system, as shown in Equation 3. It consists of the 3×3 rotation matrix R_{Cam}^{QR}, and a 3×1 position vector P_{Cam}^{QR}.

$$T_{Cam}^{QR} = \begin{bmatrix} R_{Cam}^{QR} & P_{Cam}^{QR} \\ 0_{1\times 3} & 1 \end{bmatrix} \tag{3}$$

With the transformation matrix T_{Cam}^{QR}, the coordinates of the four corners of a QR code within the image plane can be described by Equation 4, as outlined in accordance with the pinhole camera model [78]:

$$\begin{bmatrix} U_i \\ V_i \\ 1 \end{bmatrix} = \begin{bmatrix} f_x & 0 & c_x & 0 \\ 0 & f_y & c_y & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \cdot T_{Cam}^{QR} \cdot \begin{bmatrix} X_i \\ Y_i \\ Z_i \\ 1 \end{bmatrix} \tag{4}$$

where $[X_i\ Y_i\ Z_i]$ represents the 3D position vector of the i-th corner of the QR code, and $[U_i\ V_i]$ denotes the corresponding 2D position vector in the image frame captured by the camera. To simplify and without sacrificing generality, we designate the QR code frame's origin as the origin of the world frame. Given that the four corners of a QR code lie in the same plane, their z-axis coordinates Z_i within the QR code frame are uniformly set to zero. In Equation 4, f_x and f_y are the focal lengths expressed in pixel units, while (c_x, c_y) is the principal point which is at the image center. f_x, f_y, c_x, and c_y are intrinsic parameters of a camera and can be obtained via one-time preliminary camera calibration [78].

By localizing the four corners within the image plane and providing their corresponding 3D coordinates, the transformation matrix T_{Cam}^{QR} can be deduced utilizing Equation 4. The rotation matrix R_{Cam}^{QR} is then used to estimate the smartphone's orientation in the world coordinate system, as illustrated in Equation 1.

The matrix R_{QR}^{Phone} is defined as rotation from the QR code coordinate system to the smartphone's coordinate system. We use the smartphone's sensor frame to represent the smartphone's coordinate system since the sensor data are leveraged for authentication. As illustrated in Figure 4, the QR code coordinate system is a right-handed coordinate system with the corner of the middle position marker as the origin, while the x-axis and y-axis are represented by two margins. The sensor coordinate system is defined relative to the smartphone's screen, and its x-axis points to the right, y-axis points up, and z-axis points toward the outside of the screen. Since the coordinate systems of the QR code and the smartphone are predefined, the matrix R_{QR}^{Phone} is predetermined.

We have the following equation that describes the relationship between the gravity measured in the world frame and in the smartphone's frame:

$$\begin{bmatrix} 0 \\ 0 \\ g \end{bmatrix} = R_{World}^{Phone} \cdot \mathbf{gravity} = R_{World}^{Phone} \cdot \begin{bmatrix} G_x \\ G_y \\ G_z \end{bmatrix} \tag{5}$$

where g is the constant value of gravity, and $[G_x\ \ G_y\ \ G_z]$ represents the gravity values measured by the smartphone along its three axes.

To compare the rotation information estimated by a scanner with the sensor data recorded by a smartphone, we calculate the gravity values estimated by the scanner with the formula adapted from Equation 5:

$$\begin{bmatrix} G_x \\ G_y \\ G_z \end{bmatrix} = {R_{World}^{Phone}}^{-1} \cdot \begin{bmatrix} 0 \\ 0 \\ g \end{bmatrix} = {R_{World}^{Phone}}^{\intercal} \cdot \begin{bmatrix} 0 \\ 0 \\ g \end{bmatrix} \tag{6}$$

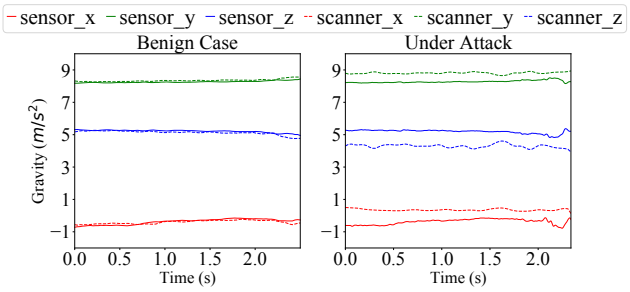

Figure 5: Poses, represented as gravity data, after pre-processing. Solid line: pose data collected by a smartphone sensor; Dashed line: pose data inferred by a scanner. In non-malicious scenarios, there is a robust correlation between the pose data derived from the scanner and that collected from the smartphone. Conversely, in instances of replay attacks, this correlation tends to deteriorate significantly.

We perform smartphone pose estimation for each frame captured by the scanner, resulting in a sequence of data points representing the smartphone's poses during the presentation of the QR code. Each data point in the sequence corresponds to the gravity values along the three axes of the smartphone's sensor coordinate system ($[G_x\ \ G_y\ \ G_z]$). This sequence is then sent to the server for correlation determination.

5.2 Data Pre-processing

Obtaining the smartphone's pose data inferred by the scanner and the user ID in the QR code, the server acquires the IMU data from the user's smartphone for comparison. The pose data determined by the scanner and collected by the smartphone's IMU may both fluctuate and contain noises. Therefore, we perform pre-processing operations on this data.

We use linear interpolation to fill gaps in the data that arise due to uneven sampling. IMU data may contain high frequency noises caused by environmental vibrations, such as sounds [30, 34], we apply a low-pass filter to filter out noises with high frequencies [60]. As the vibration caused by human mobility is mostly less than 10 Hz [15], we select a low-pass Butterworth filter with a cut-off frequency of 10Hz. We apply a median filter to remove outliers and smooth the data [25].

In this manner, two sequences of gravity data are obtained, denoted as: $G_S = \{G_S^{(1)}, G_S^{(2)}, \ldots, G_S^{(n)}\}$ estimated by the scanner, and $G_P = \{G_P^{(1)}, G_P^{(2)}, \ldots, G_P^{(n)}\}$ collected by the smartphone's IMU. Note that each data point in the gravity sequence contains three elements, each measures the force of

gravity that is applied to the smartphone on one of the sensor coordinate system's axes. The gravity data, as inferred by a camera and collected by a smartphone's IMU after pre-processing, is depicted in Figure 5.

5.3 Correlation Determination

After pre-processing, we obtain sequences of gravity data, G_S and G_P. Note that each data point in the gravity sequences contains three elements, each representing the gravity projections along the respective sensor axis.. To determine the correlation between the data sequences obtained from the camera and smartphone, we calculate the Euclidean distances for each attribute in the sequences separately. To account for variations in the length of data n each time a user presents a QR code, we obtain the average distances by dividing the Euclidean distances of each attribute by n. The resulting averaged Euclidean distances are used as features for training a classification model.

The IMU has demonstrated its reliability as an instrument for evaluating various ranges of motion, as noted in previous research studies [9, 18, 51]. Even low-cost IMUs can offer remarkable precision, with a maximum error of approximately 0.5 degrees [33]. Particularly for short time intervals, the influence of IMU drift resulting from integration errors, sensor bias, and sensor noise is minimal [51]. However, the accuracy of smartphone sensors can vary across different devices. To further strengthen the resilience of our system and account for potential inaccuracies in IMU measurements, we propose utilizing correlation to assess the similarity of the **shape** between data sequences. This approach is based on the observation that despite the inherent inaccuracies and drift in IMU sensor data, the overall trend, whether increasing or decreasing, tends to be reliable. Specifically, we employ the Pearson correlation coefficient (PCC) [16], which is a widely used algorithm for quantifying the correlation between two time series. The PCC is calculated as the covariance of two data sequences divided by the product of their standard deviations. The resulting PCC value ranges from -1 to 1. A PCC value of 1 indicates a perfect positive linear relationship between the sequences, while a value of -1 suggests a perfect negative linear relationship. A PCC value of 0 indicates the absence of a linear relationship between the sequences.

In addition to utilizing the Euclidean distances and PCC scores, we also leverage the following features regarding the differences between data sequences: *minimum*, *maximum*, *difference between minimum and maximum*, *average*, *standard deviation*, *median absolute deviation*, *and median*.

We further calculate the fisher score to select fundamental features. The normalized fisher scores are shown in Table 2. Features with a normalized fisher score above 0.1 are selected.

Table 2: Normalized fisher scores of features.

Feature	Pose		
	X-axis	Y-axis	Z-axis
Euclidean	**1.00**	**0.24**	**0.39**
PCC	**0.36**	**0.26**	**0.21**
Minimum	**0.20**	0.10	**0.12**
Maximum	**0.92**	**0.23**	**0.44**
Max-Min Diff	**0.41**	**0.19**	**0.35**
Average	**0.99**	**0.27**	**0.38**
Std	**0.39**	**0.15**	**0.27**
MAD	**0.24**	0.08	**0.24**
Median	**0.79**	**0.26**	**0.79**

5.4 Scanner Orientation Calibration

The smartphone orientation estimation from the recorded video requires the knowledge of the scanner's orientation. (1) Scanners that are equipped with IMU, such as smartphones, can obtain $R_{World}^{Scanner}$ from the sensor data, as described in Section 5.1. (2) For scanners without IMU, we propose to do scanner orientation calibration with the help of an off-the-shelf smartphone, which is a one-time effort. Specifically, a cashier shows a smartphone displaying a QR code to a scanner to be calibrated; meanwhile, the scanner estimates the rotation of the smartphone and the smartphone records its rotation with built-in sensors. Note that the calibration we perform is for extrinsic parameters corresponding to the scanner's orientation. The intrinsic parameters, which are solely determined by the scanner's camera and remain constant after the factory calibration, are not affected. It is also worth noting that recalibration is unnecessary as long as the pose of the scanner remains constant, meaning that $R_{World}^{Scanner}$ remains unchanged, even if the scanner is relocated. For example, on a flat checkout counter, the scanner can be moved without necessitating recalibration.

Based on Equation 1, Equation 2, and Equation 5, we can derive the following:

$$\begin{aligned}\begin{bmatrix}0\\0\\g\end{bmatrix} &= R_{World}^{Scanner}\cdot R_{Scanner}^{Cam}\cdot R_{Cam}^{QR}\cdot R_{QR}^{Phone}\cdot\begin{bmatrix}G_x\\G_y\\G_z\end{bmatrix}\\ &= R_{World}^{Scanner}\cdot Q\end{aligned} \tag{7}$$

where $R_{World}^{Scanner}$ represents the rotation matrix from the world coordinate system to the scanner frame and Q is the multiplication of multiple matrices and vectors that are known. As a rotation matrix has only three rotational degrees of freedom, $R_{World}^{Scanner}$ can be determined with a one-time calibration procedure, even though multiple operations can enhance accuracy.

To evaluate the effectiveness of the proposed scanner orientation calibration, we use a smartphone placed on a holder to serve as a scanner, mimicking the calibration process for hands-free QR code scanners widely adopted by retailers and

Figure 6: Four pairs of smartphones. Each pair contains two identical phones.

merchants. During this process, we consider the IMU sensor data of the scanner as ground truth and compare the calibration results with the IMU sensor data. Our results indicate that, with the one-time calibration, the average angular error along three axes is 0.04 radian (2.3 degrees), demonstrating the effectiveness of the proposed calibration method. Additionally, we evaluate the authentication accuracy of PQRAUTH based on the calibration results. PQRAUTH achieves an equal error rate (EER) of only 0.01 with the one-time calibration, a performance level similar to using the scanner's IMU data for orientation determination. These findings underscore the accuracy and efficiency of the proposed calibration method.

6 Datasets

To evaluate how PQRAUTH performs in determining the correlation between two sequences of pose data, we conduct experiments and build two datasets. Dataet I is collected for normal cases, i. e., without attacks, while Dataset II is collected with mimicry attackers. We recruited 20 participants, including 10 males and 10 females aged range from 18 to 63. It is worth noting that PQRAUTH tackles a verification problem where each individual is matched to a unique identity, rather than an identification problem where one individual is matched against multiple identities. Thus, the accuracy of PQRAUTH remains consistent even as the user base expands. All the participants have prior experience with QR code payment services. The experiments are performed with the approval of an Institutional Review Board (IRB).

6.1 Devices

Without loss of generality, we generate a version-2 (25×25) QR code as the payment code. We employ smartphones as scanners, a strategy consistent with previous work [39, 52, 74, 80]. These smartphones also serve as consumer owned devices for displaying QR codes. To ensure that the attacker's scanner has the same orientation as the victim's scanner, we use two identical smartphone holders with fixed tilt angles. Figure 6 illustrates the smartphones used in our experiments, including Nexus 5X, Pixel 3A, Pixel 4, and Pixel 6.

6.2 Dataset I

To build Dataset I, we instruct the participants to present the payment code to a scanner (Pixel 6) individually. The scanner is positioned on a smartphone holder to emulate a hands-free QR code scanner. The participants are requested to present a QR code with a smartphone (Pixel 3A) to the scanner in the same manner they normally use a QR code payment service. They are allowed to hold the smartphone with any hand and in any way they feel most comfortable. After each successful QR code scan, a notification sound is produced by the scanner to indicate a success, and participants are then free to put away the smartphone. Each participant performs 50 times of authentication operations.

6.3 Dataset II

For the construction of Dataset II, participants are randomly paired, where each pair consists of one individual acting as the victim and the other as the attacker. These roles are later interchanged between them. We ensure that the attacker participant uses identical devices as the victim participant. Specifically, two Pixel 6 smartphones are positioned on two identical holders to serve as scanners. These holders are placed parallel to each other at the same height, with a 70-centimeter distance between them. This distance is selected to ensure that the attacker participant can closely observe the victim participant's authentication actions without interfering with their operations. The victim participant, using a Pixel 3A, is told to perform transactions in the same manner as they would typically do at a retail store. The attacker participant, also using a Pixel 3A, is instructed to imitate the victim's actions as closely as possible. Both scanners provide feedback in the form of beeps if they detect a QR code.

The experimental settings inherently favor attackers, as they can closely and clearly observe the victim's behaviors in real time. By contrast, in real-world scenarios where attacks are launched remotely to maintain stealth, attackers need to use cameras to spy on the victim and then observe the victim in a screen. This introduces additional delays and also results in less clear observation of the victim's actions. Moreover, even if attacks are conducted at the same location, it is unlikely that attackers would have such a clear view, as checkout counters are typically obstructed with boards.

7 Evaluation

7.1 Accuracy

Metrics. We use the *False Acceptance Rate* (FAR) and the *False Rejection Rate* (FRR) as two of the metrics to evaluate the accuracy of PQRAUTH. FAR denotes the percentage of instances where attacks are incorrectly authenticated and a lower FAR indicates higher security. FRR shows the percent-

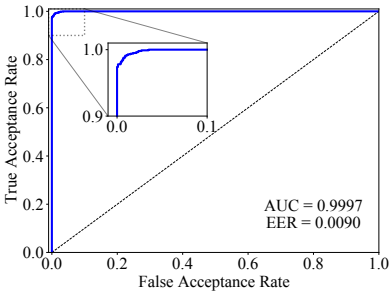

Figure 7: ROC curve, AUC, and EER.

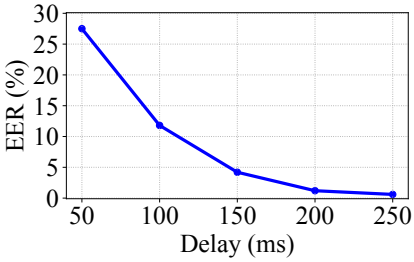

Figure 8: Robotic mimicry attacks with delays.

age of legitimate authentication instances are rejected and a lower FRR shows better usability. We also report *Equal Error Rate* (EER) which corresponds to the point at which the FRR is equal to the FAR. A lower EER indicates a higher accuracy (1-EER) of a system. We also use a *Receiver Operating Characteristics* (ROC) curve to show the accuracy of our system across all possible thresholds and report the *Area Under the Curve* (AUC) of the ROC curve.

Human Mimicry Attacks. From Dataset I, we form the data sequence uploaded by the scanner and the sensor data collected by the smartphone for each authentication as a positive data pair, and label it as 1. From Dataset II, we form the data sequence uploaded by the scanner which scans the attacker-presented QR code and the sensor data collected by the victim's smartphone for each authentication as a negative data pair, and label it as 0. We adopt a strict mechanism, Leave-One-Subject-Out (LOSO), to train an SVM model and evaluate PQRAUTH without user bias. That is, we iteratively choose the data of one subject for testing and use the data of the other 19 subjects to train the system, and report the average performance of these systems.

We compare PQRAUTH with a **baseline** approach that utilizes camera-IMU signal correlation for authentication. UniverSense [53] and G2Auth [71] confine user motions to a 2D plane parallel to the camera, and PosePair++ [59] projects user's motions onto a 2D plane parallel to the camera's image plane to estimate the acceleration data. As the baseline, we also project the smartphone's positions onto a 2D plane parallel to the scanner's image plane to estimate the smartphone's 2D acceleration. The 3D pose data is not used in the baseline. The results of the baseline show that the EER is 0.244.

The results of PQRAUTH are shown in Figure 7. The average EER is 0.009, and the AUC is 0.9997. The low EER indicates that PQRAUTH achieves a high accuracy of 0.991 in distinguishing benign users and attackers. Thus, our approach significantly outperforms the baseline, highlighting the importance of 3D pose data for accurate authentication.

Robotic Mimicry Attacks. To delve deeper into PQRAUTH's vulnerabilities, we also explore how a robot could potentially attack the system. We assume a humanoid robot which can mimic consumer's behaviors perfectly. However, the physical responses of a robot always suffer from delays imposed by physics, and these delays cannot be reduced beyond a fundamental limit [62]. For instance, even leading humanoid robots like NAO, which has a high cost of $9,000, require 200ms to execute a motion command [22]. Another work gives a detailed analysis of the delay and considers the minimum delay as 180 ms (including 80 ms of mechanical delay) in their evaluation [79]. But note the delay does not include the computer vision analysis. One study shows the end-to-end delay from human-waving to robot-waving can take up to 1.72 seconds [13]. Thus, we consider a perfect robot but with a reasonable delay.

To evaluate how resilient PQRAUTH is to robotic mimicry attacks, we construct negative data pairs by shifting the sensor data in Dataset I, and label them as 0. Suppose a robot has a delay of 50 ms, then the sensor data is shifted by the same amount. With the positive data pairs and negative data pairs from Dataset I, we train an SVM model to evaluate the accuracy of PQRAUTH. Figure 8 shows the EERs of PQRAUTH under robotic mimicry attacks with different delays. For mimicry robots with delays greater than 200 ms, PQRAUTH achieves EERs less than 0.012, demonstrating its resilience to robotic mimicry attacks.

7.2 Entropy

Entropy is a widely accepted metric for assessing the security strength of authentication methods, such as passwords [32] and PINs [68]. In the context of PQRAUTH, we employ **entropy** to evaluate the randomness of the poses. This randomness directly reflects the difficulty faced by attackers attempting to guess these poses. The formula for calculating the entropy of a variable x, given the distribution $P(x)$, is expressed as $E = -\sum_{x \in X} P(x) \log P(x)$. To assess the entropy of individual users, we analyze the pose distributions gathered from our dataset. Note that each data point comprises gravity along the three axes of the smartphone sensor coordinate system (see Section 5.2). The gravitational forces along the three axes exhibit totally two degrees of freedom [36]. To quantify the overall entropy, we first compute the average entropy of the gravitational force along each axis and then double it to take into account the degrees of freedom. The resulting average entropy, calculated across all individuals, amounts to

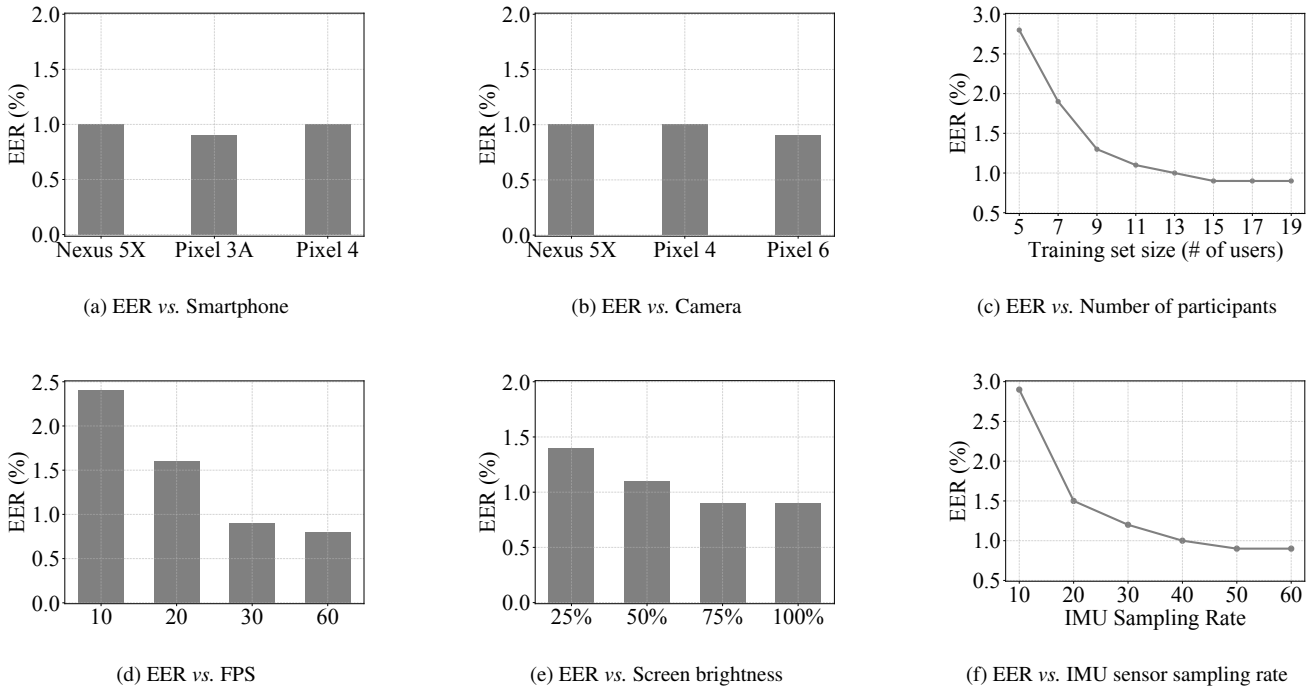
14.4 bits. For comparison, human-chosen passwords typically have an entropy ranging from 14 to 30 bits [32]. Authentication mechanisms based on four-digit PINs exhibit an entropy of 8.4 bits, while those employing six-digit PINs have an entropy of 13.2 bits [68]. These findings underscore the substantial uncertainty due to PQRAUTH, further establishing its potential as a promising biometric authentication factor.

PQRAUTH not only evaluates a single pose presented by a user but also considers the dynamic poses within the authentication process. Consequently, attackers must guess not only the victim's static pose but also a sequence of poses. To measure the unpredictability of the dynamic poses, we employ **approximate entropy** (ApEn), which a metric utilized to quantify the level of randomness and unpredictability within time series data [57]. In essence, given a time series of length N, $ApEn(m,r,N)$ is approximately equal to the negative average logarithm of the conditional probability that two subseries of length m, which are similar within a tolerance specified by $\pm r$ times the standard deviation of the time series, will remain similar for subseries of length $m+1$. ApEn generates a unitless value that falls within the range of 0 to 2, where 0 corresponds to a perfectly regular time series (e. g., a periodic signal), while 2 signifies a completely random time series (e. g., Gaussian noise) [47]. Some prior work has also employed ApEn to gauge the unpredictability of various authentication methods. For instance, For EEG signals, ApEn is 0.25 bits [48], for ECG signals it is under 0.21 bits [29], and for gait at a comfortable speed it is 0.53 [63]. To calculate the total ApEn of PQRAUTH, we first compute the average ApEn for the gravitational force along each axis and then double it. Based on our datasets, the ApEn is calculated to be 0.52 bits. This indicates that the dynamic poses during a QR code payment is more unpredictable compared to EEG [48] and ECG [29], and comparable to gait [63].

7.3 Parameter Study

QR Code Reader. We employ a variety of cutting-edge QR code readers that are publicly available, including ZBar [77], ZXing [81], BoofCV [10], OpenCV [49], and WeChat [50]. The results of our evaluation, which reveal EER_{ZBar}=0.011, EER_{ZXing}=0.012, EER_{BoofCV}=0.010, EER_{OpenCV}=0.010, and EER_{WeChat}=0.009, indicate that there are negligible differences in accuracies across all the QR code readers. PQRAUTH performs effectively regardless of the specific QR code reader employed, demonstrating its robustness.

Classifier. We employ three different classifiers, SVM, kNN, and Random Forest, to train the model. We examine different kernels for SVM, including linear, polynomial, and radial basis function (RBF), and find RBF to be the most effective. We use grid search to determine the optimal hyperparameters for SVM, setting c to 10 and γ to 0.01. We also experiment with different values of k for kNN, ranging from 1 to 20, and find that 5 is the optimal value. We test different numbers of trees for Random Forest, ranging from 50 to 200, and find that 80 is the optimal value. The results, which show EER_{SVM}=0.009, EER_{RF}=0.012, and EER_{kNN}=0.013, indicate that SVM has the lowest EER.



Smartphones. In this study, we investigate the impact of smartphones on PQRAUTH. We utilize smartphones of different sizes and weights, including the Nexus 5X, Pixel 3A, and Pixel 4. Victim participants choose one of the smartphones, and attacker participants are instructed to use smartphones of the same model as those used by the victims to launch mimicry attacks. The results, depicted in Figure 9a, demonstrate no significant performance difference among the smartphones. Therefore, we conclude that regardless of the smartphone used, the accuracy of PQRAUTH keeps high.

Cameras. This study aims to determine if PQRAUTH works equally well on different scanners. To do this, we use three different smartphones, namely the Nexus 5X, Pixel 4, and Pixel 6, as scanners. Both the victim and attacker participants use the Pixel 3A smartphones to display the QR code. The results, shown in Figure 9b, indicate that there is no significant difference in performance between the three cameras. Therefore, we conclude that cameras have little impact on the performance of PQRAUTH.

Training Dataset Size. We evaluate the impact of training dataset size on the system performance. The training dataset size is defined as *the number of participants* for training. We train PQRAUTH with data from 5 to 19 participants, and test the accuracy of PQRAUTH with data of the reset of participants. The results in Figure 9c shows that the accuracy converges when the number of participants in the training dataset reaches 15. It indicates that PQRAUTH only needs a few data samples in the training phase to determine the threshold.

Camera FPS. We study the impact of camera FPS by varying its frame rate while fixing the camera resolution to 1080P. We have the smartphone's camera to record videos at 10, 20, 30, and 60 FPS, separately. As shown in Figure 9d, the higher FPS, the higher accuracy of PQRAUTH. Especially, a significant improvement can be observed when the FPS is increased from 10 to 20. Considering a higher FPS requires more resources, and the improvement from 30 to 60 FPS is less significant, we set the FPS as 30, which is also the default frame rate of most smartphones.

Camera Resolution. We study the impact that camera resolution has on PQRAUTH, by setting the smartphone's camera to different resolutions. We set the smartphone's resolution to the most popular resolutions supported by mobile devices, including 480P (720×480), 720P (1280×720), and 1080P (1920×1080). The results show that increasing the camera resolution leads to higher accuracy, as evidenced by EER_{480P}=0.016, EER_{720P}=0.011, and EER_{1080P}=0.009. Notably, even at 480P resolution, PQRAUTH still achieves acceptable accuracy, indicating that high-resolution scanners are

(a) EER *vs.* Smartphone

(b) EER *vs.* Camera

(c) EER *vs.* Number of participants

(d) EER *vs.* FPS

(e) EER *vs.* Screen brightness

(f) EER *vs.* IMU sensor sampling rate

Figure 9: Impact of different parameters.

not necessary for its deployment, making it an economically viable solution.

Screen Brightness. We evaluate the performance of PQRAUTH in four screen brightness levels, i. e., the brightness on the consumer side is set to 25%, 50%, 75%, and 100% of the highest level. On the attacker side, the brightness level is set 100% to favor the attacker. Figure 9e shows the corresponding results. The accuracy of PQRAUTH remains consistent under different brightness levels. However, the brighter the screen is, the easier it is to capture the QR code, resulting in less time required for authentication. We thus recommend that smartphones set their screen brightness to the highest level when presenting QR codes. It should be noticed that the recommendation is not specific for PQRAUTH, most mobile payment apps, such as AliPay, PayPal, and Venmo, adjust the screen brightness to the highest level automatically when generating a payment code.

IMU Sensor Sampling Rate. Increasing the sampling rate of the IMU sensor data in smartphones can capture more subtle characteristics, but it also comes with higher burdens such as data collection and power consumption. To determine the optimal sampling rate, we conducted a study by down-sampling the original sensor data and analyzing the performance at different sampling rates. We vary the sampling rate from 10Hz to 60Hz in steps of 10Hz. The results, shown in Figure 9f, indicate that the performance significantly improves when the sampling rate increases from 10Hz to 20Hz, and it stabilizes when the sampling rate reaches 50Hz. Therefore, we choose the sampling rate of 50Hz, which is well within the capabilities of most IMU sensors.

Environmental Brightness. To study the impact of environmental brightness, we use dimmable LED bulbs and adjust their illuminance levels. The recommended lighting levels for retail stores, where mobile payments are frequently happen, range from 200 to 500 lux [6]. We thus change the environmental brightness level from 200 to 500 lux in steps of 100 lux. The results show that the environmental brightness has a very small impact on the system performance and PQRAUTH can work in a wide range of illuminance levels. This is because the smartphone screens are bright enough to clearly show the QR code, under various illuminance levels in buildings.

Real World Retail Stores. We evaluate how PQRAUTH performs in various real world retail stores, including McDonald's, ALDI, CVS, Walmart, and Costco. McDonald's is a fast-food restaurant, ALDI is a grocery store, CVS is a pharmacy, Walmart is a supermarket, and Costco is a warehouse club. PQRAUTH consistently attains a remarkable accuracy rate exceeding 99% across diverse retail stores. There is no discernible variance in PQRAUTH's performance between controlled laboratory environments and real-world retail establishments, underscoring its robustness.

Table 3: Authentication time. Our experiments show that the authentication decision is consistently made before the user operation is complete. Thus, compared to standard QR code payment, the latency overhead of PQRAUTH is zero.

Part	Average Time (ms)	Std (ms)
User Operation	3573	722
Data Transmission	66	8
Data Processing and Decision Making	55	8

7.4 Authentication Time

We measure the time needed for a QR code payment enhanced with PQRAUTH, which starts when the user launches the app and ends when the authentication decision is made or the user operation is complete, whichever is later. The user operation of presenting a QR code is complete when the user hears the beep alert and thus puts away her smartphone (i.e., naturally holding it). Our experiments show that the authentication decision is consistently made before the user operation is complete. In other words, during the time the user puts away her smartphone, the data transmission, processing and decision making are conducted.[3] The breakdown of authentication time is detailed in Table 3. Note that the user operations remain consistent, with or without PQRAUTH. Therefore, PQRAUTH incurs a latency=0, compared to standard QR code payment.

8 User Study

8.1 Recruitment and Design

We recruit 40 participants aged from 18 to 68, including 20 females and 20 males. The participants come from a variety of occupational backgrounds, such as students, lecturers, public servants, university staff, and retirees. Out of the 40 participants, 35 are familiar with the standard QR code payment method, and 32 have used it before. To avoid social desirability bias, we do not make the participants aware of the fact that PQRAUTH is designed by us. Instead, the participants are told to evaluate the usability of different QR code payment methods. We develop a customized app capable of using both the standard QR code and PQRAUTH scheme. The usability study is conducted under an IRB approval and each subject is asked to sign a consent form.

The evaluation procedure consists of three steps: the pre-study instruction, the experiment, and the post-study questionnaire. We first introduce the two authentication methods to the participants by playing a pre-recorded instructional video. We explain the rationale and operations of the two QR code payment systems and tell them the goal of this study is to compare their usability. Each participant is given a smartphone and use our customized app to perform 5 attempts, i. e., showing a QR code to a scanner, for each of the payment methods. Participants are free to ask questions regarding these authentication methods.

In the experiment step, each subject performs another 10 attempts using each payment method. The orders of using each payment method is counterbalanced, i. e., with half of the tasks beginning with standard QR code payment and the other half PQRAUTH. The measurement of the time needed for a QR code payment is described in Section 7.4.

At the end of the study, each subject fills in a questionnaire and judges the two mobile payment methods by answering six questions, which are adapted from the widely-used SUS [12]. The six questions are about usability scales of the two systems. Specifically, the six questions assess (Q1) *if the payment method is easy to learn*, (Q2) *if the payment method is easy to use*, (Q3) *if the payment method is efficient in time*, (Q4) *if they feel the system is secure enough*, (Q5) *if they feel comfortable to use the payment method*, and (Q6) *if they are willing to adopt the payment method*. The scores for each question range from 1 to 5, where 1 indicates strongly disagree and 5 strongly agree. Thus, higher scores indicate better usability. Participants are also encouraged to leave suggestions and comments in the questionnaire.

Table 4: User study results.

	Standard QR Code	PQRAUTH	p-value
Q1	4.95 ± 0.21	4.90 ± 0.30	0.33
Q2	4.85 ± 0.35	4.85 ± 0.35	1.00
Q3	4.70 ± 0.56	4.65 ± 0.33	0.72
Q4	2.15 ± 1.15	4.65 ± 0.57	0.00
Q5	3.05 ± 0.86	4.75 ± 0.70	0.00

8.2 Usability Study Results

We use paired *t-tests* to check for differences in the opinions towards each payment method. The p-value of the tests indicates the statistical significance of the results. If the p-value is less than 0.05, we reject the null hypothesis that there is no difference between the means and thus conclude that a significant difference *does* exist. If the p-value is larger than 0.05, a significant difference does *not* exist. Table 4 shows the scores for the standard QR code payment and PQRAUTH.

Participants find PQRAUTH easy to learn and use, and they are satisfied with the payment speed. User perception regarding ease of learning, ease of use, and efficiency in time does not significantly differ between the two payment methods. Participants agree that PQRAUTH is more secure, according to the average score (4.65) towards Q4, which is significantly greater than that (2.15) achieved by the standard QR code payment method ($p = 0.00$). Participants express

[3] It is worth highlighting that, on the scanner side, the frame collection, QR code detection and pose estimation are processed in a *pipeline*, rather than batch-processing the frames after they are all collected. Thus, the computations in the scanner and the user operation are parallel.

(a) Hands-free

(b) Hand-held

Figure 10: Various mainstream scanners.

that they are more comfortable to use PQRAUTH (Q5: 4.75) than a standard QR code (Q5: 3.05). Also, they are more willing to adopt PQRAUTH. The standard QR code payment method achieves 3.85 towards Q6, while PQRAUTH achieves 4.75. In total, PQRAUTH achieves significant higher scores (28.55) than the standard QR code payment method (23.55) due to its perceived higher security.

In summary, users perceive PQRAUTH to be easy-to-learn, easy-to-use, efficient in time, secure, and comfortable, and they are willing to adopt PQRAUTH for mobile payment.

9 Discussion

Can PQRAUTH be widely used? To estimate the rotation of a smartphone from the video recorded by a scanner, we need to know the scanner's orientation. Mainstream scanners in the market can be categorized into two groups: hands-free scanners and hand-held scanners, as shown in Figure 10. We admit this limitation: if a store only provides hand-held scanners, PQRAUTH cannot work (unless the scanners are modified to carry an IMU sensor). We conduct an extensive survey of various retail stores in our city, encompassing fast-food restaurants (such as McDonald's and Subway), grocery stores (such as ALDI and Love's), pharmacies (such as CVS and Walgreens), supermarkets (such as Walmart and Target), and warehouse stores. Among the 25 stores equipped with QR code scanners, all provide hands-free scanners, meaning that PQRAUTH can be used in all the stores. Detailed information can be found in Appendix A.

For other applications that use QR codes, such as gate access control in buildings and ticketing services for subways, they typically provide hands-free scanners, as shown in the leftmost photo in Figure 10. Thus, PQRAUTH can be readily applied. For applications that use smartphones as scanners, such as social media apps, PQRAUTH works as well, since smartphones have built in IMU sensors [37].

In addition, if the hands-free scanner is not placed on a flat counter, it needs to be re-calibrated every time the scanner is moved (Section 5.4).

Is network required for the smartphone? Some mobile payment apps, such as Alipay, WeChat, PayPal, and Venmo, support offline payments. To enable PQRAUTH to operate independently of network connections, we put forth a simple yet effective approach. We propose to have the user's smartphone display encrypted IMU data together with the payment QR code on its screen. Alternatively, the encrypted IMU data can be embedded into the payment QR code, simplifying the process for the scanner, which only needs to detect the QR code. The primary idea is to employ the visual channel, rather than the network connection, to transmit the IMU data from the smartphone to the scanner for verification.

The fundamental process for authentication is outlined below. The scanner decodes the QR code and sends the information to the server. The server extracts the consumer's account ID from the received information and deciphers the IMU data using the key unique for each account. It then compares the decrypted IMU data with the poses captured by the scanner.

Repeated attacks. To increase the success rate of mimicry attacks, an adversary could learn a user's motion pattern by forcing the user to present QR code repeatedly. For instance, the attacker might deploy a malicious reader to intentionally fail in reading the QR code, prompting the user to repeatedly display it. As a result, the attacker could observe and learn the user's motion pattern before conducting the replay attack. However, as highlighted in Robotic Mimicry Attacks (Section 7.1), the timing is important. If an adversary shows poses too early or late, the attack will still fail. Thus, one possible countermeasure is to add a random but short delay before a new QR code is generated, such that the mimicry attacker cannot predict the timing of the user's next payment attempt.

10 Conclusion

QR codes have been widely adopted for mobile payment, making their authentication an important problem. We presented PQRAUTH, a highly usable implicit authentication method to enhance the security of QR code payment. It is the first correlation-based approach to enhancing QR code security. PQRAUTH leverages the unclonable, real-time poses when a consumer presents a QR code. Authentication proceeds only if the poses inferred by a scanner match the poses of the consumer's smartphone. Our method attains an accuracy of 0.991 in the real-world scenario where mimicry attacks are launched with zero latency overhead. Extensive experiments demonstrate its accuracy, security, and robustness. PQRAUTH has potential applications to other scenarios that use QR codes, such as gate access control and ticketing services.

A Scanners Used by Various Retailers

PQRAUTH can work with hands-free scanners (and hand-held scanners with built-in IMU, such as smartphones). We thus survey the scanners used by various retail stores in our city, including fast-food restaurants, convenience stores, pharmacies, supermarkets, and warehouse stores. Table 5 shows the results. Among the 25 stores equipped with QR code scanners, all provide hands-free scanners, meaning that PQRAUTH can be used in all the stores.

Simulated Stress: A Case Study of the Effects of a Simulated Phishing Campaign on Employees' Perception, Stress and Self-Efficacy

Markus Schöps

Abstract

Many organizations are concerned about being attacked by phishing emails and buy Simulated Phishing Campaigns (SPC) to measure and reduce their employees' susceptibility to these attacks. Whilst some prior studies reported reduced click rates after SPCs, others have raised concerns that it may have undesirable side effects: causing some employees stress, and/or reducing their self-efficacy. This would be counterproductive, since stress and self-efficacy play a key role in learning and behavior change. We report the first study in which stress and self-efficacy were measured with $n = 408$ employees immediately after they *clicked* on or *reported* a simulated phishing email they received as part of an SPC in a large organization. To obtain richer data how employees experienced the SPC, we conducted semi-structured interviews with $n = 21$ employees. We find that participants who *clicked* on and *reported* simulated phishing emails generally perceived SPCs as positive and effective, even though recent research casts doubt on this effectiveness. We further find that participants who *clicked* on simulated phishing emails had significantly higher stress levels and significantly lower phishing self-efficacy than participants who *reported* them. We further discuss the impact of our findings and conclude that the effect of SPCs on the perceived stress of employees is an important relationship that needs to be investigated in future studies.

1 Introduction

Phishing is still a prominent threat in the corporate context [76]. Companies are interested in reducing the risk of falling victim to phishing attacks, so billions of dollars are spent every year by companies on security awareness measures with the aim of countering risk and meeting security regulations [26]. One of the most propagated countermeasures of the industry are so-called simulated phishing campaigns (SPC). Phishing emails are sent to the company's own employees on behalf of the company in order to measure the employees' ability to recognize phishing emails and to sensitize and train employees. In most cases, a phishing training is embedded for those who fall for the phishing simulation to improve their phishing detection. However, according to recent findings, embedded training as part of SPCs is not effective [44]. Still, there has been no empirical evaluation of how employees who *click* on or *report* simulated phishing emails perceive those campaigns, how this affects their *self-efficacy*, and how it affects their perceived *stress*. It has been shown that stress in the workplace has a negative impact on employee performance and their well-being [24,32,52,79,85], and that, overall, "daily stressors" can have similar negative effects [29]. These stressors, even if moderate, can accumulate over time and induce many negative effects on physical and mental health [9,58,82]. Furthermore, it has been shown that employees' self-efficacy in executing a security-relevant task is essential for successful secure behavior [21,22]. Since the experience of "failing" can induce stress [39], it can be assumed that the experience of failing to successfully recognize a simulated phishing email (by clicking on it) can also induce stress. Additionally, since the experience of failure can reduce perceived self-efficacy [71], we hypothesize that failing to recognize a simulated phishing email negatively affects self-efficacy.

It is therefore crucial to investigate SPCs not only based on click rates and performance results but also to consider the individual perspective of employees who *click* on or *report* simulated phishing emails, as well as their perceived stress and self-efficacy. We focus on the following questions:

RQ1: How do employees who interact with simulated phishing emails (*click* on, or *report* them) perceive simulated phishing campaigns?

RQ2: Do employees who *click* on a simulated phishing email report different levels of stress from those who *report* it?

RQ3: Do employees who *click* on simulated phishing emails assess their self-efficacy in dealing with future phishing emails differently from those who *report* them?

Regarding **RQ2** and **RQ3**, we generated two hypotheses for the statistical analysis: **(H1)** Employees that *clicked* on the simulated phishing email rate higher *stress* levels than employees that *reported* the email; **(H2)** Employees that *clicked* on the simulated phishing email rate lower *self-efficacy* levels than employees that *reported* the email.

Methodology and Findings We cooperated with a large-scale manufacturing company employing over 16,000 employees. As part of an SPC, we embedded a questionnaire and specifically recruited those employees who either *clicked* on (4,520) or *reported* (3,034) the simulated phishing email. Our final sample consisted of 408 employees, 5,4% of the total of employees who either *clicked* or *reported*. We further recruited 21 employees for qualitative interviews. We wanted to gain a better understanding of participants' perceived stress, self-efficacy, and perception of the campaign. We found that participants who fell for the simulated phishing email reported higher levels of stress and lower levels of phishing self-efficacy. Furthermore, the campaign was perceived as effective by most participants, although various negative emotions related to the campaign were reported.

Contribution (I) We are the first to investigate the effects on stress and self-efficacy in the context of SPCs. (II) Furthermore, we contribute to the thin literature on the effects of SPCs by investigating the perception of participants who *clicked* on a phishing email and those who successfully *reported* one. (III) Finally, we discuss our results, present recommendations for industry, and highlight open challenges for researchers.

2 Related Work & Background

Here we describe previous research on SPCs (2.1), stress and emotions (2.2), and self-efficacy (2.3).

2.1 Simulated Phishing Campaigns

Simulated phishing campaigns are a common industry practice [26, 44]. During these SPCs, organizations send employees simulated, authorized phishing emails for the purpose of evaluating or improving employees' detection ability via embedded training or awareness information [62]. Even though previous studies suggest the effectiveness of SPCs in reducing *click rates* [42, 43, 80], other studies show that these campaigns have no positive effect [15, 28]. Adding to this, Lain et al. [44] conducted a large-scale and long-term study in an organization and found that embedded training was not effective in making employees more resilient to phishing. On the contrary, it made employees more susceptible. Additionally, they reported negative side effects like a false sense of security. Some researchers further hypothesize negative effects on trust relationships of employees and organizations, and question the meaningfulness of *click rates* as an IT security measurement [78]. The effort and cost of running SPCs may also be much higher than organizations think [13], contradicting the idea of these campaigns being cheap and effective solutions to improve IT security.

2.2 Stress and Emotions

Stress arises, according to Lazarus' and Folkman's transactional model [46], when a situation is evaluated as a danger to one's well-being and makes excessive demands on one's resources. This creates an imbalance between external demands and one's own coping strategies [27]. The results are cognitive, emotional, behavioral, and physiological responses [17]. When this imbalance occurs in a work-related environment, we speak of work stress [23]. The list of work stress causes is long and includes role ambiguity, lack of resources, workload, and unsound organizational policies [14]. Consequences of work stress can be the detriment of the well-being of employees, with cognitive, behavioral, emotional, and physical consequences [14], and the decline in their job performance [87]. Regarding the severity of the perceived stress, even moderate stress can have negative consequences, especially over time [9, 58, 82], and "daily stress" can lead to additive, independent effects on physical and mental health [29, 82].

When it comes to learning and memory, an integral part of training in general, stress can have different influences: For one, stress before or during learning can block the retrieval of memories [69, 84]. Although there is evidence that stress before learning improves memory formation [33], this seems to be mostly the case with emotionally arousing, specially negative, memory elements, and at the cost of neutral elements [83]. When stress is induced during learning, the formation of both neutral and emotional memory elements seems to be impaired [70]. Similarly, stress seems to impair the updating of memories with new information, leading to an inflexible, routine-like behavior [77]. Regarding IT security, the term "information security stress" (ISS) describes the stress that results from enhanced security requirements [47], which can lead to employee violation of information security policies [1, 18]. This violation behavior can also be reinforced by feelings of frustration [20]. Furthermore, findings suggest a relation between high email load, stress and susceptibility to phishing emails [65], and a relation between high workload and the likelihood of employees clicking on a phishing link [38]. A low level of job stress is also associated with higher levels of information security awareness [54]. When it comes to emotions, findings show that positive emotions positively influence protection-motivated behaviors [88], and negative emotions are frequently viewed as detrimental to motivation, performance and learning [64] In the last decades, work stress has increased rapidly [24, 61], and with this, the amount of absenteeism and sick leave caused by stress-related

illnesses [24, 79, 85]. The outcome of this are great losses of productivity and high healthcare costs [32, 52, 85].

2.3 Self-Efficacy

The concept of self-efficacy, first explored by Bandura [3, 7], defines a person's belief in their capability to successfully perform a particular task. This perceived subjective belief can have a variety of effects on cognition and affect [6] and is positively related to the implementation of behavioral change [5]. This means that, in a work context, employees are more likely to try a new behavior if they believe that they can perform it successfully [67]. The creation and development of self-efficacy beliefs can have different sources: *Mastery Experience* (experiences of success), *Vicarious Experience* (seeing others perform successfully), *Verbal Persuasion* (giving feedback and encouragement), and *Affective State* (the influence of physiological and emotional situations on the estimation of the own capacities) [4]. One of these states, *stress*, can negatively influence self-efficacy [48, 74], while the increase of self-efficacy itself can act as a buffer against the negative impact of stress [51, 68]. Additionally, the experience of failure can reduce individuals' self-efficacy [71]. Regarding IT security, an ENISA meta-review of 2019 identified self-efficacy as the only human characteristic that could be linked to "correct" cyber security behaviors [22]. Self-efficacy also shows positive effects on threat avoidance behavior [2], preventive behavior [59, 63], on the likelihood of performing phishing attack prevention behavior [21], and on securing smart homes [12]. Furthermore, the development of self-efficacy has positive effects on learning [36] and help-seeking behavior [10]. When it comes to the effects of SPCs on self-efficacy, it has been hypothesized that these campaigns reduce self-efficacy by giving employees negative, unsuccessful experiences when falling for a phishing email [78].

2.4 Research Gap

To the best of our knowledge, no previous studies have investigated the effect of SPCs on perceived *stress* or *self-efficacy* of employees who click on or report simulated phishing emails. Lastly, although one study found side effects of an SPC on the sense of security of employees [44], no other research has specifically examined the general perception that employees who interact with simulated phishing emails (by *clicking* on or *reporting*) have about SPCs.

3 Methodology

Here we describe the context of the organization and the SPC 3.1, the recruitment process and data collection procedure 3.2, and how the questionnaire and the interview guide were created 3.3. Lastly, the analysis of the data 3.4, limitations 3.5, as well as ethics and data privacy 3.6 are discussed. An overview of the study procedure is presented in Figure 1.

3.1 Organization and SPC

The data collection for the study took place in a manufacturing company headquartered in a German-speaking country but employing more than 16,000 employees globally. We specifically collected data from employees who *clicked* on (4,520 in total) or *reported* (3,034 in total) the simulated phishing email. Our final sample consisted of 408 employees, 5,4% of the 7,554 employees who either *clicked* on or *reported* the simulated phishing email. The company executives and security specialists had decided to run an SPC as part of their security awareness measures. One researcher (R3) was involved in the organization and acted as a pivot point between the company and the research team. This researcher collected the data for our study after receiving approval from the company leaders, security experts, and the work council. The platform for the SPC was provided by an external security-awareness-training company. The campaign itself consisted of three different simulated phishing emails, of which every employee received one randomly. The emails were sent out globally to over 16,000 employees in January of 2023 over the course of three days. All three emails were in English and contained spelling mistakes in the sender's address, two of which were intended to look like coming from the company and one from Microsoft Support. When an employee clicked on the link in the email, a page was shown in which the phishing simulation was revealed and a short training was displayed. The employees could *report* the phishing email by clicking on the "Report Phishing" button that was recently implemented in the company. This button is an add-on for the Outlook email client which creates a one-click solution for users to report emails. After clicking on the button the email is sent to a tool where software and humans define the emails as clean, spam, or threat. Other ways of reporting the email (e.g. informing the security team) were not counted in our study. The campaign was not announced beforehand by the company.

3.2 Recruitment and Procedure

We specifically recruited employees who *clicked* on (4,520 in total) or *reported* (3,034 in total) the simulated phishing email. For the questionnaire, participants were recruited directly after either *clicking* on the link in the email or *reporting* the email. Employees who *clicked* on the link of the simulated phishing email were shown a message on the subsequent web page that invited them to give feedback about how the campaign affected them, as well as a link to the questionnaire. Due to technical restrictions, a direct email response to the employees who *reported* the email was not possible. Instead, a pop-up window was implemented that appeared once the

phishing email was *reported* via the "Report Phishing" button. The pop-up window contained a congratulations message for successfully reporting the email as well as the same invitation to fill out the questionnaire to give feedback. A scannable QR code and a link, which possible participants could copy and paste into their browser, were implemented to access the questionnaire. Participants were not compensated and there were no selection criteria. The questionnaire was presented in German for German-speaking countries and in English for all other countries and offered a clear opt-out. Employees who did not interact with the simulated phishing email, either by ignoring it or not seeing it, were not part of our sample. The final sample consisted of 408 employees.

For the interviews, participants were recruited through a message that invited them to give more extensive feedback in a 30-minute interview. The message was displayed after the questionnaire and in a post on the internal social media. Participants were also asked to share the invitation with other colleagues. The interviews were done either remotely or in person, and, in all cases, the audio was recorded to later be transcribed.

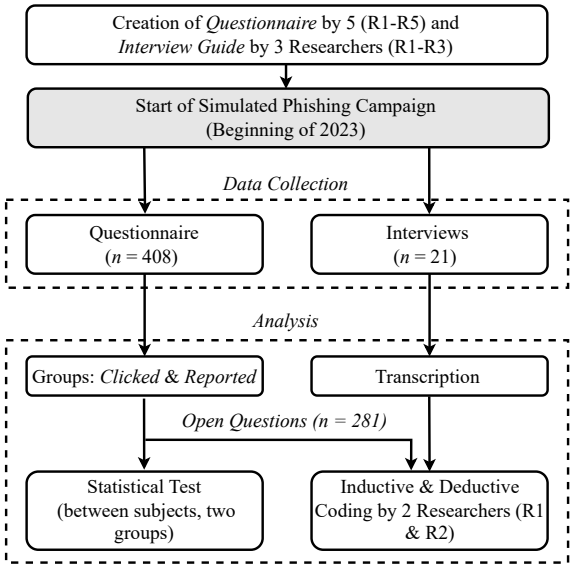

Figure 1: Overview of Study Procedure

3.3 Instrument Development

For the development of both the questionnaire and the interview guide, we were guided by our three research questions and divided both instruments accordingly. The full questionnaire, as well as the interview guide, can be found in the Appendix (see B and C).

3.3.1 Questionnaire Development

The questionnaire consisted of three parts: *Stress Measurements, Self-Efficacy Measurement, General Perception Measurements*. At the beginning of the questionnaire, participants were given the privacy statement and were informed that the questionnaire was voluntary, that no data was collected that could be traced back to them, and that the survey could be terminated at any time. Together with the company, we decided not to capture demographic data within the survey. On the one hand, the length of the questionnaire was severely limited and, on the other, we were concerned that collecting personal data would increase the drop-out rate or might have amplified a bias in our study. The length of the questionnaire was also kept short because we did not want to create any "survey fatigue".

Part I: Stress Measurements The first stress measurement that was used was the question "How stressed do you feel right now?". The question could be answered on a scale from 1 to 10 (from *Not at all* to *Fully*) and was meant to measure the direct stress after interacting with the phishing email. The second stress question was "How stressed do you feel on an average working day?", which could be answered on the same scale as the first question. This question was used to control for the possibility of one of the two groups (*Clicked* or *Reported*) being significantly more stressed on average than the other. Both of these questions were modeled after simple stress measurements like the Visual Analogue Scale (VAS) [49, 50], which shows to be as discriminating as a questionnaire when comparing the stress levels between two groups [50]. Regarding the contextualization of the stress results, Dutheil et al. [19] propose that VAS values from 5.0 to 8.2 represent an at-risk population, while a value above 8.2 represents a population in need of intervention. Other authors, like Barré et al. [8], classify values under 4.0 as low, values between 4.0 and 7.5 as moderate, and values above 7.5 as high stress. The last question was "Compared to before you clicked or reported the phishing email, how much more stressed do you feel right now?". This question could be answered on a scale from 1 to 5 (from *Significantly less stressed than before* to *Significantly more stressed than before*). Since we did not have the possibility to measure the stress before and after the interaction with the phishing email, this question was used to investigate the influence of the interaction on the perceived stress of the participants. Even though stress can be measured objectively (without self-reporting) via, for example, cortisol [57] or eye-tracking [86], these measurements present many difficulties when used in real-world contexts [31, 45, 73]. Because of this and the high number of participants, we decided to measure stress with the validated Visual Analogue Scale [49, 50].

Part II: Self-Efficacy Measurement Self-Efficacy scales should be tailored to the specific activity domain that is being investigated [6]. Because of this, we used the questionnaire developed by Ehizibue [21], which specifically measures participants' perceived self-efficacy regarding phishing, and which showed good construct reliability and validity in the past [21]. The questionnaire consisted of 4 questions (e.g. *I am confident of recognizing a phishing email*) that could be answered on a scale from 1 to 5 (from *Strongly disagree* to *Strongly agree*). This questionnaire was used to compare the self-efficacy between the two groups (*Clicked* and *Reported*). In Ehizibue's sample [21], the mean self-efficacy value was 4.51.

Part III: General Perception Measurements In this part of the questionnaire, participants were first asked to rate the *perceived importance* of the following topics: *IT security in general*, *Your role when it comes to IT security in general*, *Your role when it comes to preventing phishing attacks*, and *IT security training*. These four questions could be answered on a scale from 1 to 5 (from *Not important at all* to *Extremely important*). After this, participants were asked about their *perceived effectiveness* of the following measures to prevent clicking on phishing emails: *online phishing training*, *simulated phishing emails sent from the company*, and *technical measures (eg. email filters)*. These questions, too, could be answered on a scale from 1 to 5 (from *Not effective at all* to *Extremely effective*). Lastly, two open questions were asked: *Why do you think simulated phishing emails sent by the company are effective or not?* and *What changes would you like to see regarding the anti-phishing campaign?*. In summary, the questions in this part of the questionnaire aimed at investigating participants' perceptions of IT security measures, the phishing campaign, and their effectiveness, and how these answers differed between the two groups (*Clicked* and *Reported*).

3.3.2 Interview Guide Development

The interview guide was developed by three researchers (R1-R3) following the steps recommended by Kallio et al.'s [40] framework for developing semi-structured interview guides. The first step was to decide whether this method was appropriate to answer the research questions. Since we wanted to get a deeper understanding of the employee's diverse perceptions and possibly emotional opinions [40], we deemed this method suitable. After this, we reviewed related literature (see section 2) and developed the interview guide, which consisted of three themes related to our research questions: *General Perception*, *Stress and Emotions*, and *Self-Efficacy*. We arranged these themes and their questions in such a way, as to protect the logic and fluency of the conversation, adding follow-up questions where necessary. Next, we piloted the interview guide, which happened once with a member of our university and three times with employees of the company. The interview guide was improved after the first interview, but since no changes emerged from the three other pilotings, pilot interviews 2, 3 and 4 were included in the dataset and analysis.

The interviews themselves started with a short onboarding, in which the participants were informed about the purpose of the study, the process of data collection and storage, and the possibility of terminating the interview or skipping questions at any time. Participants then gave informed consent to record the interview. After this, a question block pertaining to the *General Perception* theme asked about how they perceived the campaign and how it was communicated. Next followed several questions asking about the *Stress and Emotions* of the participants regarding the SPC. Participants were asked to put themselves back into the situation when they first heard about the campaign and received a simulated phishing email, adding questions about what they thought, if they were stressed, and if they felt other emotions. Following this, a series of questions about the *Self-Efficacy* of the participants regarding phishing detection were asked. These questions were partly based on the sources of self-efficacy by Bandura [4] and asked, among other questions, if they had successfully *reported* a phishing email (Mastery Experience), if they had seen others successfully recognize phishing emails (Vicarious Experience), and if the company gave them feedback and encouragement (Social Persuasion). The fourth source, Affective State, was answered by the questions in the *Stress and Emotions* part of the questionnaire. Lastly, participants were once again inquired about their *General Perception* of the campaign, asking how it affected their work routine, their personal opinion about it and its effectiveness, and what other measures or changes they would like to see. Finally, we asked participants whether they would like to add anything, which has not been covered and offered a debriefing.

3.4 Analysis

The data analysis consisted of the statistical analysis of the quantitative questionnaire responses 3.4.1, and the qualitative content analysis of the interviews and the open-ended questions of the questionnaire 3.4.2.

3.4.1 Statistical Analysis

Statistical data analysis was performed using the statistical software *R* [60] and *RStudio* [66]. We used the Mann-Whitney U test to compare the means between the two groups *Clicked* and *Reported* to look for significant differences. The Mann-Whitney U test is a non-parametric test for two independent samples, that requires an ordinally or continuously scaled y-variable and doesn't require a normally distributed y-variable within the groups [55]. The Mann-Whitney U test was also

performed for the continuous data of the Self-Efficacy scale since a Shapiro-Wilk-Test showed no normal distribution of the data. We used Bonferroni-Holm corrections to correct for multiple testing and calculated effect sizes for significant comparisons, regarding a 0.1 to 0.3 as a small effect, 0.3 to 0.5 as a medium effect, and > 0.5 as a strong effect [16]. The significance level was uniformly set at < 0.05. An a priori power analysis was conducted using G*Power version 3.1.9.7 [53] to determine the minimum sample size required to test the study hypotheses. Results indicated the required sample size to achieve 95% power for detecting a medium effect, at a significance level of .05, was $n = 176$ for the Mann-Whitney U test. Thus, the obtained sample size of $n = 408$ is adequate to test the study hypotheses.

3.4.2 Qualitative Analysis

Qualitative analysis was performed using MAXQDA [75]. We used Kuckartz's qualitative content analysis [41] to evaluate the data by building categories and coding deductively and inductively. The coding of both the interviews and the open questions from the questionnaire was done by two experienced coders (R1 & R2) and was performed in multiple steps: **(I)** R1 and R2 developed preliminary codebooks deductively (one for the *Interviews* and one for the *Open Questions*) based on the research questions and the interview guide. **(II)** R1 coded all 21 interviews and 281 open questions once, in order to derive relevant themes, adding new categories inductively to the codebook. **(III)** R1 and R2 discussed the emerged codes and underlying themes, differentiating main- and sub-categories and improving the codebook with these newly created codes. **(IV)** R1 and R2 coded 11 Interviews and all Open Questions together in joint sessions, in order to further improve the codebook, refining code categories and definitions until saturation was achieved. **(V)** Using the codebook R1 and R2 coded then all previously coded and remaining *Interviews* and *Open Questions* together in joint sessions, resolving conflicts by discussion as they emerged.

Because of this method of resolving all coding issues between the coders as they appeared (which is a usual approach in our field of study [30, 35, 37, 81]) it is possible to reach a hypothetical *full* final agreement. To improve data exploration and facilitate the continuity of the process [11] memos were used and discussed during all steps of the analysis process.

3.5 Limitations

As with most studies, our study presents several limitations. First and foremost, our sample only consisted of participants who *clicked* on or *reported* the simulated phishing email via the "Report Phishing" button. Employees who did not interact with the email (either by consciously ignoring it or not seeing it) or who reported the email in other ways were not investigated in this study. Additionally, our final sample (those who answered the questionnaire, 408 in total) consisted of a small percentage (5,4%) of the number of employees we recruited from (those who either *clicked* on or *reported* the email, 7,554 in total), which limits claims about representativity. The case study was performed in one company, so the results may vary in other contexts. Additionally, we only measured the direct effects of the simulated phishing email on participants, and did not measure long-term effects of continuous exposure to these emails. The quantitative design posed challenges, since a before and after measurement was not possible. This could have led to the fact that the differences in some variables could not be attributed completely to the effect of the campaign. Due to the nature of qualitative research, the findings belonging to the interviews cannot be generalized. Also, social desirability may have influenced the answers of participants, especially when it comes to the perception of the campaign. The presentation of the questionnaire after the phishing email interaction could have led to participants thinking that this was still part of the "test", and, therefore, not responding.

3.6 Ethics & Data Privacy

Our institution did not have an institutional review board nor an ethics review board at the time of conducting the study. We adhered to the EU data privacy guidelines (GDPR) and informed all participants about their rights prior to participation. All participants gave their consent. The questionnaire collected no personal information and was, therefore, completely anonymous. The interviews were treated with confidentiality and, during transcription, all words that could identify participants or the company were removed. After transcribing the interviews, the audio files were deleted. We closely collaborated with the working council and the head of the security department to address ethical concerns. The study was then approved by the work council and the data protection teams of the countries in which the company is active. The company only received anonymized data from the study.

4 Results

Here we report the quantitative results of the questionnaire 4.1, the qualitative results of the questionnaire (open questions) 4.2, and the qualitative results of the interviews 4.3. Regarding the results of the SPC itself, 4,520 employees (26,8%) *clicked* and 3,034 (18,0%) *reported* the email. The rest did not interact with the email that they received.

4.1 Quantitative Questionnaire Results

In total, $n = 408$ participants completed the questionnaire. Of these, $n_1 = 99$ reported the phishing email (here called *reported*), and $n_2 = 309$ clicked on the link in the phishing email (here called *clicked*). On average, participants took 6.3

minutes to fill out the questionnaire. Cronbach-Alpha values showed very good reliability for the Self-Efficacy Scale (4 items; $\alpha = .86$) [72]. All reported p values are after applying Bonferroni-Holm corrections. Table 1 shows the results of the group comparisons, for which the abbreviations are written in quotes in the text below. Figure 2 in the appendix shows Boxplots for the results of the three stress measurements and the self-efficacy scale.

Table 1: Scale Response Ranges, Mean scores and p values from the group comparisons (*Clicked* and *Reported*) using Mann-Whitney U tests with Bonferroni-Holm corrections.

Variable (Scale Response Range)	Group Mean		p
	Clicked (n=309)	*Reported* (n=99)	
Stress Now (1-10)	5.40	3.39	<.001 ***
Stress Average (1-10)	5.50	4.81	.050
Stress Compared (1-5)	0.25	-0.23	<.001 ***
Self-Efficacy (Phishing) (1-5)	3.56	4.1	<.001 ***
Perceived Importance of... (all 1-5)			
ITS in General	4.56	4.7	.261
Role ITS	4.13	4.1	1.00
Role Phishing	4.3	4.39	.948
ITS Training	4.26	3.96	.015 *
Perceived Effectivity of... (all 1-5)			
Online Phishing Trainings	3.8	3.84	1.00
Phishing Campaigns	3.93	4.22	.019 *
Technical ITS Measures	4.3	4.21	1.00

Note: p = significance value, *p < .05., **p < .01., ***p < .001.

Stress-related Results The Mann-Whitney U test showed that, directly after either *clicking* on or *reporting* the simulated phishing email, the participants who *clicked* (M=5.40) had a significantly higher level of perceived stress ("Stress Now") than participants who *reported* the email (M=3.39)(U=9007.5; z=-5.824; p<.001; r=0.288). This effect was small. Regarding participants' level of stress on an average working day ("Stress Average"), there was no significant difference between the groups *clicked* (M=5.50) and *reported* (M=4.81) (U=12633; z=-1.959; p=.050). When comparing their own perceived level of stress to before clicking or reporting ("Stress Compared"), participants who *clicked* (M=0.25) indicated feeling more stressed, while participants who *reported* (M=-0.23) indicated feeling less stressed. This difference was significant (U=10771; z=-4.156; p<.001; r=0.206) with a small effect.

Self-Efficacy Results Mann-Whitney U results showed that, regarding participants' self-efficacy for detecting phishing ("Self-Efficacy (Phishing)"), participants who *clicked* (M=3.56) had a significantly lower level than participants who *reported* the email (M=4.1)(U=21810; z=-6.099; p<.001; r=0.302). This effect was medium.

General Perception Results Regarding their perceived importance of IT security in general ("ITS in General"), there were no significant differences between participants who clicked, and those who did not *click* (M=4.56) and *reported* (M=4.7) (U=16968; z=-1.124; p=.261). The same applied to participants' perceived importance of their own role regarding IT security in general ("Role ITS") (M *clicked*=4.13, M *reported*=4.1; U=15036; z=0; p=1.00) and the perceived importance of their own role regarding the prevention of phishing attacks ("Role Phishing") (M *clicked*=4.3, M *reported*=4.39; U=16391; z=-0.064; p=.948). Regarding the perceived importance of IT security training ("ITS Training"), however, participants who *clicked* (M=4.26) showed significantly higher scores than participants who *reported* (M=3.96) (U=12366; z=-2.437; p=.015; r=0.121). This effect was small. When asked about their perceived effectiveness of online phishing training, the two groups showed no significant difference (M *clicked*=3.8, M *reported*=3.84; U=15828; z=0; p=1.00). The perceived effectiveness of SPCs differed significantly between the groups, with participants who *clicked* (M=3.93) showing lower scores than participants who *reported* (M=4.22)(U=18176; z=-2.354; p=.019; r=0.117). This effect was small. The group differences regarding the perceived effectiveness of technical It measures were not significant (M *clicked*=4.3, M *reported*=4.21; U=14539; z=0; p=1.0).

Summary Participants who *clicked* reported significantly higher levels of perceived stress and lower phishing self-efficacy than participants who *reported*. Also, participants who *clicked* considered IT security training more important but SPCs less important.

4.2 Qualitative Questionnaire Results

In total, $n = 281$ participants answered at least one of the open questions from the questionnaire. Of these, $n = 13$ were excluded (if the meaning of the response could not be deciphered), resulting in a final count of $n = 268$. Of this count, $n = 196$ *clicked* and $n = 72$ *reported* the phishing email. We report counts (n_C meaning the counts of participants who *clicked*, and n_R those who *reported*), as well as what percentage of employees of the relevant group (*clicked* or *reported*) reported this. Some participants gave more than one answer, resulting in multiple codes, and some participants only answered one of the two questions. The final codebook can be found in the replication package.

4.2.1 Perception of Campaign Effectiveness

In general, $n = 224$ participants (83,6%) rated the campaign as being effective. Of the participants who *clicked* on the email, $n = 161$ (82,1%) rated the campaign as being *effective*, and of the participants who *reported* the email, $n = 63$ (87,5%). The most frequent reason given for perceiving it as effective was, in both groups, that it improved employees'

awareness (n_C = 87; *44,4%* / n_R = 38; *52,8%*). The fact that they were good *training or learning* (n_C = 25; *12,8%* / n_R = 12; *16,7%*), *real practice* (n_C = 16; *8,2%* / n_R = 15; *20,8%*), and a good *measurement* (n_C = 10; *5,1%* / n_R = 8; *11,1%*) was mentioned by participants of both groups. Next, the fact that it was a *surprise or shock* was also mentioned by participants of both groups (n_C = 9; *4,6%* / n_R = 3; *4,2%*). Additionally, some of the participants of the group that *clicked* mentioned *feedback* ($n = 4$; *2,0%*) and the *protection of the company or themselves* ($n = 10$; *5,10%*) as reasons, while some participants of the group that *reported* mentioned the feeling of *success* ($n = 2$; *2,8%*), *shame* ($n = 2$; *2,8%*), and the *communication about the topic* ($n = 2$; *2,8%*) as reasons. On the other hand, $n = 20$ participants (7,5%) rated the campaign as *not effective*. Of these, $n = 15$ (7,7%) belonged to the participants who *clicked*, and $n = 5$ (6,9%) to the participants who *reported*. Four participants mentioned the emails being *too specific* as reasons for the campaign not being effective (n_C = 3; *1,5%* / n_R = 1; *1,4%*) *"I believe phishing emails keep evolving. No way to simulate all possibilities."* – [C196], and three that they were no real *learning* (n_C = 2; *1,0%* / n_R = 1; *1,4%*). Additionally, two participants who *clicked* mentioned the creation of *mistrust* ($n = 2$; *1,0%*). Two participants who *reported* mentioned that the emails were *too easy* ($n = 2$; *2,8%*) and also two that *people talked about it* ($n = 2$; *2,8%*) *"[...] the first one informs the others, who then don't have to be "alert" anymore."* – [C196]. Three participants who *clicked*, ($n = 3$; 1,5%) mentioned reasons for and against the effectiveness of SPCs, as did three ($n = 3$; 4,2%) participants who *reported*.

4.2.2 Changes and Other Measures

Participants suggested a number of changes that they would like to see related to the SPC. The most frequently suggested change by participants who *clicked* was the wish for *more training* ($n = 24$; *12,2%*) , while only one participant who *reported* mentioned this ($n = 1$; *1,4%*). Other changes that were mentioned were that the SPCs should occur *more frequently* (n_C = 18; *9,2%* / n_R = 11; *15,3%*), that there is a need for *more information* regarding the campaign and phishing in general (n_C = 13; *6,6%* / n_R = 7; *9,7%*), the need for *technical measures* to protect against phishing (n_C = 4; *2,0%* / n_R = 7; *9,7%*) and the need for *more feedback* (n_C = 3; *1,5%* / n_R = 1; *1,4%*). Additionally, three participants who *clicked* mentioned *easier emails* ($n = 3$; *1,5%*) and two mentioned *more communication* ($n = 2$; *1,0%*) as changes, while four participants who *reported* mentioned *more difficult emails* ($n = 4$; *5,6%*) and one mentioned an *adaptation of the difficulty* to the success of the participants ($n = 1$; *1,4%*). Furthermore, one participant of each group mentioned the *termination* of the campaign as a change (n_C = 1; *0,5%* / n_R = 1; *1,4%*). Lastly, some participants mentioned that they wished for no changes (n_C = 39; *19,9%* / n_R = 11; *15,3%*).

4.2.3 Stress, Emotions and Self-Efficacy

In addition to the direct answers to the two open questions, participants also mentioned effects of the SPC on *Stress and Emotions* and *Self-Efficacy*. *Stress* was not mentioned much in either group (n_C = 3; *1,5%* / n_R = 1; *1,4%*), even though one participant who *clicked* voiced a strong negative reaction: *"[...] I now feel worthless within the company and it has now reduced me to a very negative approach to my work where i now need to switch off and calm down before i become ill."* – [C69]. *Annoyance* about the campaign was mentioned by participants in both groups (n_C = 8; *4,1%* / n_R = 2; *2,8%*): *"People who are not interested are annoyed by this and feel harassed, patronized or perhaps even deceived."* – [C191]. Two participants who *clicked* mentioned feeling *confused* ($n = 2$; *1,0%*) and also two mentioned feeling *angry* ($n = 2$; *1,0%*), while two participants who *reported* mentioned feeling *happy* ($n = 2$; *2,8%*). The negative effect on *Self-Efficacy* was only observed in statements by participants who belonged to the group that *clicked* ($n = 18$; *9,2%*): *"Before I clicked this link, I was sure I recognized phishing emails. The fact that I clicked the link showed that this is not the case."* – [C100].

Summary Most participants perceived the SPC as effective, but some wished for more training. A small number of participants mentioned negative emotions and stress, and mostly participants who *clicked* mentioned a decrease in self-efficacy because of the SPC.

4.3 Qualitative Interview Results

We first present results about the *General Perception* of the SPC 4.3.1. Next, we present results about the *Perceived Stress and other Emotions* 4.3.2, as well as the effect on participants' *Self-Efficacy* 4.3.3. Table 2 in the appendix shows the most relevant codes and their occurrences by participant. The interviews lasted between 20 and 30 minutes.

4.3.1 General Perception

Perception of Campaign All 21 participants perceived the campaign as something positive and many described that their colleagues also perceived it as something positive (P2,3,6-10,13-16,20). Regarding the reasons why they perceived it as positive, some participants stated that it was good because they had *witnessed other incidents* in the past (P1,3,8,10,14,20): *"You see in the news how many companies or authorities are shut down for weeks."* – [P14]. Others mentioned the *protection of the company* as a reason (P7,13,14,16,20,21): *"So that people deal with it, because in the end it also protects the company, if the employees pay attention to such things [...]"* – [P20]. Next, five participants mentioned that it was good because it showed them that the *organization cared about IT security* (P6,8,12,14,20). Additionally, five participants liked the *challenge* idea behind it (P3,6,7,9,20): *"Yeah, more like that, like a*

challenge, like, "I want to detect every phishing email and always report it in a timely manner."" – [P6]. Also, three participants stated that it was something that was also *useful in private* (P3,4,15), and also three that it offered a *safe space to practice* without repercussions (P1,10,12).

Perception of Campaign Effectiveness All interviewed participants perceived the campaign to be effective in some ways, mostly because they thought it increased *awareness* (P1,2,4-10,12-15,17-21). Seven participants stated that it was effective because it was *real practice* (P2,6,10,12,13,16,20): *"It trains, it's just like a little training camp [...] for reality."* – [P6]. Five participants mentioned the *shock* that it created for participants who clicked as a reason for it being effective (P2,4,7,13,21). Two participants described that the campaign was effective because it *lowered the confidence* of people who clicked (P6,11): *"[...] I personally think that you should approach such things with a not-too-strong self-confidence [...]"* – [P13]. One participant mentioned *fear* of consequences for employees who clicked as an effective characteristic of the campaign (P13): *"And maybe also, this is maybe a little bit mean, but maybe also worry that that might get to the boss, and be a little bit more careful in the future."* – [P13]. Some interviewed participants also perceived the campaign as ineffective in some ways (P7,16-19,21). Six participants (P7,8,16,18,19,21) explained that the training effect was *forgotten quickly*

Communication Most interviewed participants stated that they communicated in some way with other employees about the campaign (P1-3,6-11,14,15,17,16,21), even though half of them said that it was just briefly discussed (P2,3,6,8,11,14,15): *"I do, but not often, maybe, maybe kind of briefly mentioned in conversation or something."* – [P11]. One-third of the participants stated that they did not really communicate about the campaign (P1,4,5,12,13,16,19). Interestingly, many participants stated that there should be *no communication about the campaign* during the campaign (P3,5,8-10,13,14,18), because it could reduce the effectiveness: *"We should do it in such a way that we do not communicate it to colleagues, because then the awareness is a bit gone."* – [P3]. Only two participants said that it was positive communicating about the campaign (P2,6). Regarding the *announcement of the campaign*, four participants (P2,4,7,13) noticed that there would be a SPC, but were told about it unofficially by colleagues. The rest of the intrviewed (P3,5,6,8-21) participants stated that they noticed the campaign either after interacting with one of the emails or reading about it in the company's social media.

Changes and Other Measures More than half of the interviewed participants wished that the *frequency* of the simulated phishing emails would be increased (P1,3,6,8,10,13,14,16,18-20), even though two participants mentioned that the emails should not be sent out too often (P3,10): *"Well, I wouldn't do it too often, because then people are annoyed and then it really leads to said stress."* – [P10]. On the other hand, one participant even stated that it would be good to send out many emails in a short period of time to stress employees (P14): *"[...]that you get two or three in a week. In order to simply...then to trigger stress."* – [P14]. Many participants also mentioned that they would like more *information* about the outcome of the campaign (P1,4,7,8,13,14,16-18), which included evaluations and feedback, while others mentioned wanting more *training* (P4,6,8,11,14,18,20): *"[...] a more intensive training, maybe presence training or so."* – [P18]. Some participants described the need for more *awareness* in the company (P6,8,10,13-15,18). Regarding the *difficulty* of the emails, four participants were in favor of a higher difficulty (P5,11,17,21), while two participants wanted them to be adapted to the ability of the employees (P3,15): *"I would harass them with a different quality of phishing emails."* – [P3]. Lastly, one participant wanted the possibility to give *feedback* (P1), one more *gamification*-inspired measures (P3), and one extending the simulated-phishing to *other mediums* (P15): *"[...] like a phone social engineering campaign [...]"* – [P15].

4.3.2 Stress and Emotions

Five interviewed participants mentioned being stressed in some form or other because of the SPC (P1,2,13,15,17). Of these, one participant mentioned being stressed after receiving the email (P1): *"[...] that gut feeling: "Something's wrong, isn't it?" And that puts you in a bit of stress"* – [P1]. Three participants reported being stressed after clicking on the phishing email (P2,13,17): *"I already had a guilty conscience and the pulse was a bit higher. Because at first you don't know "Wait, was that really spam or was that a training campaign?" There was also a screen that [said that] it was a training campaign. Ehm. But that did increase my stress level significantly."* – [P17]. Two participants also mentioned being stressed because of the campaign in general (P13,15): *"Because the feeling of stress that came up for me was the fear that I work in IT and have relatively large and extensive access to some IT systems in our company. I'm always relatively quickly worried that [...] I'm the starting point of some ransomware attack or something."* – [P13]. No participant mentioned being stressed after *reporting* the email, but four participants stated seeing other colleagues being stressed after *clicking* on the email (P4,6,10,11).

When it comes to the effect of the SPC on the emotions of the participants, four interviewed participants mentioned feeling *angry* after clicking on the email (P3,12,13,20): *"The second one, I fell for it, the third one I fell for it too, and that angered me massively."* – [P3]. One participant stated feeling angry because of the timing of the campaign (P4): *"I [had a] beautiful Christmas, New Year, [...] a few days off and then you come around the corner with such a phishing campaign. On the first day, I didn't think that was quite fair."* – [P4]. One participant described feeling *shame* for *clicking* (P17), and two participants described

that other colleagues felt ashamed for *clicking* on the email (P9,10). Six participants mentioned feeling *confused* after receiving the simulated phishing email (P1,4,8,10,13,16): *"I was confused, I was very confused the moment I got that email."* – [P10]. Also, two participants experienced other colleagues being confused (P9,11). The feeling of *curiosity* was also reported by four participants (P7,8,11,18), especially when it came to how they or others performed: *"[...] curiosity. That's because I'm always interested in such topics. And I'm interested in how colleagues implement them."* – [P8]. Two participants also mentioned that they felt *relief* after *reporting* (P14,17), and two even after *clicking* (P2,13): *"I felt relief after realizing that it was just a phishing campaign and so nothing else is going on."* – [P2]. Also, three participants stated that they felt relief when they noticed that the emails, in general, were simulated and no real attack on the organization (P8,9,14): *"Being relieved, it was just a test, right? It was not a real attack on [company] now."* – [P14]. On a more positive note, eight participants described feeling happy after *reporting* the email (P1,6,7,12,14,17,19,20): *"I was rather pleased that I recognized it and also reported it, yes."* – [P6].

4.3.3 Self-Efficacy

Regarding their *Mastery Experience* (the experience of success), all but one interviewed participant stated that they successfully detected at least one simulated phishing email (P1,3-21). Of these, two participants consciously ignored the email (P10,21), while the others *reported* it (P1,3-9,11-20). Seven participants mentioned that they *clicked* on at least one simulated phishing email (P1-3,12,13,17,20). The fact that some participants mentioned both *clicking* and *reporting* is due to them recalling older SPCs. Participants also experienced the success of others (*Vicarious Experience*), with one-third of participants stating that their colleagues detected at least one of the simulated phishing emails (P2,3,5,7,8,11,13). Other participants mentioned that they experienced colleagues falling for the simulated phishing email (P6-10,14,18): *"[...] and I know that from some colleagues, that they did click twice on the links and then also felt totally insecure that moment"* – [P9]. Many participants mentioned that they did not know if other colleagues *reported* or *clicked* (P1,4,12,15-17,19-20). When it comes to the third source of self-efficacy, *Social Persuasion*, participants were asked about them getting *feedback* and *encouragement*. When asked about *feedback*, many participants mentioned the SPC itself (P1,2,4,6-8,10,12,13,16,19,21), meaning the automated email that was sent out after interacting with the simulated phishing email: *"[...] and if you do it right and press the button, then you get a pat on the back, you get a virtual one [...]"* – [P1]. The other type of feedback that was mentioned by the interviewed participants was the internal media of the company (P1,3,5,6,8,10,12,13,15,17-21), which mainly consisted of click rates reported in the internal social network or the company's intranet: *"Yes, there is always...there is always something in the intranet again afterward."* – [P3]. Three participants stated that they did not perceive receiving any kind of feedback (P9,11,14). When asked about how the company *encouraged* the participants to be successful in detecting phishing emails, many interviewed participants mentioned sources that did not come directly from the company. Many participants mentioned the motivation to *protect the company* from an incident as encouragement (P1,2,4,6,8,10,12,14,15,18): *"Because I know that if something goes wrong, the costs are immense. In the worst case, the business can't continue."* – [P15]. Others mentioned *protecting themselves* as encouragement (P1,6,8-10,14,15,20): *"[...] what motivates me is just having the fear of being the one, so being the reason [...] So to open the doors for, yes, attacks."* – [P9]. Four participants felt encouraged by the automated response after *reporting* the simulated phishing email (P6,11,18,20): *"[...] when you get this feedback: "Yes, thank you very much for reporting it, and it really was the right thing to do." I think that motivates people to remain vigilant."* – [P6]. Three participants mentioned not feeling encouraged at all (P5,17,19).

Lastly, interviewed participants were asked about their self-efficacy regarding phishing detection and the influence that the SPC had on it. Most of the participants reported that they felt somehow secure when it came to handling phishing emails (P1-7,9-16,18-21), even though some stated that being completely secure was not possible (P4,7,8,11,14,16,18,21): *"Yes, as I mentioned, so I don't think anybody is immune from that."* – [P18]. Two participants did not feel as secure (P8,17), either because of the aforementioned reason that there is no complete security, or because of failing the SPC: *"Well, I would have actually assessed myself as competent, but then I clicked on the email. That's why I wouldn't say that anymore."* – [P17]. This possible negative *influence* of the campaign on the self-efficacy regarding phishing detection was reported by four participants in total (P2,9,13,17). Eight participants stated that it *increased* their self-efficacy (P1,3,6,8,16,18,20,21): *"I would say very secure. Because I haven't misjudged any of them yet."* – [P5]. The remaining interviewed participants (P4,5,7,10-12,14-16,18-21) reported that the campaign had no real influence on them. This *increase* and *reduction* of self-efficacy as a result of the campaign is also described in Table 2 in the appendix.

Summary All interviewed participants rated the SPC as positive and effective, but some mentioned restricted communication because of it and the need for more training. Some participants mentioned feeling stressed and having their self-efficacy reduced because of the SPC. This was especially the case for participants who *clicked*.

5 Discussion

In this section, we discuss the results of the study. First, we answer our first research question (**RQ1**), by reporting that the campaign is mostly perceived as positive and effective by

participants who *clicked* on and *reported* the simulated phishing email 5.1, that participants want more training 5.2, and that the campaign, according to them, restricts communication about phishing 5.3. Next, we discuss our second research question **RQ2**, describing how the campaign increases *stress* for participants who fall for it, and confirm our first hypothesis (**H1**) that stress is higher for participants who *clicked* than those who *reported* 5.4. After that, we answer our third research question (**RQ3**), discussing the negative effect that the campaign has on the *self-efficacy* of participants who fall for it, and confirm our second hypothesis (**H2**), that participants who *clicked* on the email have lower self-efficacy than those who *reported* it 5.5. Lastly, we present *recommendations for practicioners* 5.6 and *recommendations for researchers* 5.7.

5.1 Perceived as Good and Effective

Most participants have a positive perception of the campaign (see 4.3.1 and 4.2.1). The main reasons they cited are the witnessing of other incidents and wanting to protect the company from them - which suggests that the awareness of our participants was high. Similarly, the results from the questionnaire and the interviews show that participants are motivated and care about the protection of the company, and respond positively when the company introduces ways to promote this protection 4.3.1. They perceive IT security in general, and their role regarding IT security and phishing as relatively high, with no difference between participants who *clicked* and *reported*. It seems clear that they see themselves as the main protectors of the company, as one participant stated: *"Because the human factor is one of the biggest adjusting screws that can be influenced positively or negatively. That's why it's an important topic, and it could be made even more prominent because IT security is something you can't take lightly."* – [P8].

Even though this view belongs to a sample which only represents a small percentage of the company's employees who interacted with the simulated phishing email, research shows that this view is often propagated in industry [56]: the human factor is seen as the main way to improve IT security. A possible reason for the participants' perceived effectiveness of the campaign could be that this industry view affected the company's view and this, in turn, may have "trickled down" and affected the participants' perception: that it is effective, mainly because it improves awareness. The "real practice" that participants mentioned is, in theory, a good way to establish positive IT security behavior, by promoting *mastery experience*. But this is mostly the case for participants who detect and *report* phishing emails (see section 5.5). Other reasons for the effectiveness of the campaign were that it "shocked" participants, "lowered confidence" or transmitted "fear of consequences", which can be compared to the "teachable moment" with which awareness companies think that they can transmit IT security knowledge and behavior [25], even though it is doubtful if they work [78]. This may be an explanation for why the stress that the campaign may cause is also seen as something positive by the majority of participants, even though it has mostly negative effects (see 5.4). Still, there were also doubts about the effectiveness of the campaign (see 5.2 and 5.4). Furthermore, results show that participants who *clicked* perceived the campaign as significantly less effective than participants who *reported* 4.1. This is not surprising, considering that participants who clicked "failed" the campaign. It is not clear how more frequent campaigns might influence this mostly positive perception that the participants have when the "teachable moments" also become more frequent. Besides, the fact that participants may feel the need to talk positively about their company's measures is a bias that should also be considered.

5.2 More Training and Feedback Desired

Continuing with the positive perception of the campaign, many participants wished that the emails were sent out more often, which was mostly the case for participants who *reported*. For participants who *clicked*, we can see a preference for more *training* 4.2.2 and a higher perceived effectiveness of IT security training 4.1. The perceived need for more training by the participants may be a result of the critical appraisal of their skills after failing the "test", and wanting to improve them, with the motivation to protect themselves or the company 4.3.1. More training, though, may also mean that the simulated phishing emails are not seen as enough to improve participants' IT security skills. Lastly, some participants wished for more *information* about the campaign, meaning getting feedback and seeing an evaluation of the campaign in general. Apparently, these participants wish to know the outcome of their efforts, a motivation that may be related to the "challenge" aspect of the campaign, which some participants described as positive 4.3.1. Two ways how the organization informs about the SPC and gives feedback is via click rate reporting in the internal media and short, automated feedback from the emails itself. Apparently, some participants think that this form of giving information about the SPC is too restrictive.

5.3 Restricted Communication

Restricted communication was also reported in the behavior of employees. Some participants reported that, even though communication about the campaign takes place, it is often brief. One explanation for this may be that some participants believe that there should be no communication at all 4.3.1. The "selling points" of SPCs are the "teachable moments" [25], which cannot occur when employees are forewarned. Participants who think that there should be no communication about it might have heard about these "teachable moments" and believe that talking about it is forbidden. Even though our sample is not representative of the whole organization, it

is questionable that these participants "learn" not to communicate, when communicating and warning about phishing attacks constitutes an important protection mechanism. Adding to this, since the SPC was not officially announced by the company, employees may not know that the email before them is simulated. In the worst case, employees might encounter a real phishing email but think that it's simulated, leading to them not warning their colleagues and the company.

5.4 Increased Stress when Clicked

The quantitative results showed that participants who *clicked* on the simulated phishing email reported significantly higher stress levels than those who *reported* 4.1. Therefore, we consider our first hypothesis (**H1**) confirmed. Furthermore, participants who *clicked* rated higher stress levels than before the simulated phishing email, while participants who *reported* rated lower stress levels than before. These results, which were significant, speak for the effect of the simulated phishing email on the increase/decrease of stress. The stress on an average day of both groups did not differ significantly, which supports the claim that the effect was caused by the SPC experience which immediately preceded the measurement. Stress was also reported in the qualitative results of the interviews 4.3.2. Here, especially participants who *clicked* on a simulated phishing email reported stress. Lastly, even though there were extreme reactions, stress was hardly reported in the qualitative results of the open questions 4.2.3.

When looking at the research about stress 2.2, it shows a possible explanation for why participants who *clicked* on simulated phishing reported higher stress levels: the external demands from the company to successfully detect the phishing email can be seen as too high, their own resources evaluated as too low [27, 46]. The fear of having "done something wrong" and potentially put themselves and the company in danger, may be another reason for the increased stress. Some participants mentioned feeling confused, and not only participants who *reported* the email mentioned feeling relieved, but also participants who *clicked* 4.3.2. It is possible that participants who *clicked* on simulated phishing emails thought at that moment that the attack was real, felt stressed because of it, and were relieved after knowing that they caused no harm. As mentioned in 5.1, the positive attitude regarding the phishing simulation despite the increased stress levels might be because campaigns are not done frequently, that participants think that this stress is "necessary" for the teachable moment, or that participants felt the need to talk positively about their employer.

The perceived stress level of the participants who clicked (5.40) can be categorized differently by different researchers: some categorize it as "at-risk" [19], others as "moderate" [8]. As mentioned in 2.2, stress can have negative effects on IT security behavior [1, 18, 54], and negative emotions, like the reported *anger*, 4.3.2 can reduce motivation [64, 88]. Furthermore, other findings suggest a relation between high email load, stress, and susceptibility to phishing emails [65]. This increased susceptibility is reported by Lain et al. as a side effect of SPCs [44]. It may be that stress plays a critical role in this relationship. Lastly, one important aspect of stress that needs to be mentioned is its negative effect on learning [70, 83]. Even though our results can not be generalized to the whole organization, some participants reported an increase in stress after *clicking* on the simulated phishing email. Thus, their learning of the information in the embedded training might be impaired. This effect of stress on learning could be an explanation for the low effectiveness of embedded training in SPCs that Lain et al. reported [44].

5.5 Decreased Self-Efficacy when Clicked

The results from the statistical tests showed that the participants who *clicked* on the simulated phishing email reported significantly lower phishing self-efficacy levels than participants who *reported* 4.1. Therefore, we consider our second hypothesis (**H2**) confirmed. Since we were not able to conduct a before and after test, it is not clear from the quantitative results if the lower self-efficacy regarding phishing of participants who *clicked* stems from the campaign, or if it was the reason for why these participants clicked in the first place [21]. Still, qualitative analysis shows that some participants (specially of those who *clicked*) report an effect on their phishing self-efficacy: results from the open questions show that some participants mentioned this negative effect 4.2.3, as did some participants in the interviews 4.3.3. In contrast, qualitative results from the open questions show that no participants who *reported* mentioned a decrease in phishing self-efficacy because of the campaign, while results from the interviews show that mostly participants who had never falsely clicked on a simulated phishing email mentioned an increase in phishing self-efficacy. These differences in the qualitative results are not generalizable to the whole population of employees who *clicked* or *reported*, especially because of the small sample, but they still offer a hint regarding the possible direction of the effect of simulated phishing emails on self-efficacy.

If we try to rationalize this possible decrease and increase of phishing self-efficacy, we can derive reasons from the *sources* of self-efficacy [4]: Individuals who fall for the simulated phishing email experience no success (*mastery experience*), while individuals who detect it do [71, 78]. It is not clear how often employees see the success of others (*vicarious experience*), which can foster the development of self-efficacy, in the investigated organization. Looking at the qualitative results of the interviews, two-thirds of the participants mentioned that they either saw other colleagues fail, or that they did not know how they performed 4.3.3. Furthermore, it is not clear how employees experience *social persuasion* to act successfully regarding phishing in the organization. Most participants mentioned in the interviews that *feedback* mostly

stems from the automated response of the simulated phishing email that was *clicked* on or *reported*, or by click rates reported in the internal media 4.3.3. Regarding *encouragement*, most participants mentioned other, internal sources than the company: the motivation to protect themselves or the company. Only participants who *reported* mentioned feeling encouraged by the automated response of the simulated phishing email. Lastly, participants who *clicked* might have been subjected to a negative *affective state* caused by an increase in stress [48, 74] that they reported 4.1. Concluding, there is a significant difference regarding phishing self-efficacy between participants who *clicked* on and *reported*. Even though the qualitative results from this study hint at it, it needs to be confirmed in future studies whether this difference is caused by falling for the simulated phishing email. Regardless, low self-efficacy can have negative effects not only on phishing detection [21], but also on "correct" IT security behavior [22], threat avoidance [2], and preventive behavior [59, 63].

5.6 Recommendations for Industry

Most participants in our sample believed that SPCs were effective, and other studies showed that CISOs like SPCs because they allow them to report "numbers" (*click rates*) [34]. However, this form of measurement and reporting may not be meaningful [78], and studies showed that SPCs are not an effective way of training employees [15, 28, 44]. Furthermore, the costs of implementing SPCs can be higher than anticipated [13]. We advise organizations to view these campaigns and the promises from awareness companies critically.

Our study showed that the implemented SPC significantly increased the perceived stress of participants who *clicked* on a simulated phishing email and that there is a significant difference regarding the phishing self-efficacy between participants who *clicked* on and *reported* a simulated phishing email (see Sec. 4.1, 4.3 and 4.2.3). Because of the limited representativity of our results, claims about how organizations should react to these results are limited: employees who ignored the simulated phishing email were not investigated, and their perceived stress and self-efficacy may or may not have been affected by the SPC. The perceived stress and self-efficacy of those employees who did not see the simulated phishing email were likely not affected by the SPC. Future studies are needed to further investigate these effects on stress and self-efficacy (see 5.7). Still, looking at studies which have shown negative effects of stress [70, 83] and positive effects of self-efficacy [36] on learning, we would advise organizations for any training taking place in calm situations and showing people that they can be successful.

5.7 Recommendations for Researchers

Our study showed that participants who *clicked* on a simulated phishing email felt significantly more stressed than those who *reported* it. Still, there are many opportunities for future studies to investigate stress in the context of SPCs. First, our study only gathered data from 5,4% of employees who *clicked* on or *reported* the simulated phishing email, which presents the need to investigate a larger, representative sample of participants who interact with simulated phishing emails in an organization. Second, there is a group which was not investigated in the present study: employees who did not interact with the SPC. Employees who either ignored the simulated phishing email or simply did not see it should be investigated in future studies to see how SPCs affect the perceived stress of all employees who are subjected to such campaigns. Furthermore, the perceived stress of employees should be measured long-term to see how an increased frequency of campaigns influences this stress. Moderate stress, despite its independent negative effects, can also "add up" over time, leading to negative effects on physical and mental health [9, 29, 58, 82], so it remains to be seen how repeated clicking on simulated phishing emails affects individuals.

Regarding self-efficacy, it is not clear if the significant difference between participants who *clicked* and those who *reported* was caused by the simulated phishing email itself. Future studies can confirm, via before and after measures and with a large, representative sample, if the *clicking* on a simulated phishing email negatively affects self-efficacy, as hinted at in the interviews 4.3.3. Additionally, other studies can investigate how the presence and absence of sources of self-efficacy in an organization affect the self-efficacy of employees. Measuring, with a large and representative sample, how the organization gives feedback and encouragement regarding phishing (*social persuasion*) and how employees see others being successful or not in identifying phishing emails (*vicarious experience*) can lead to valuable insights into how organizations can influence this important concept.

6 Conclusion

Our study was the first that specifically investigated stress and phishing self-efficacy as part of a real-world simulated phishing campaign of an organization. Furthermore, we investigated how participants perceived the campaign, and what emotional reactions were triggered. We specifically compared a small sample of participants who *clicked* on the campaign's phishing email and those who successfully *reported* it. We found that those who *clicked* reported a higher level of perceived stress and a lower level of phishing self-efficacy. Our findings show that SPCs can *increase stress* for individuals who click on simulated phishing emails. A possible explanation for recent research claiming that training interventions embedded in SPCs are not effective is the negative effect that stress has on learning. Future studies should investigate this effect with a representative sample and other employee groups (those who ignored or did not see the simulated phishing email).

A Replication Package

To make our study reproducible and allow for easy access for meta-research, we publish a replication package[1] containing the following documents:

1. **The full code books**, created as part of the analysis described in Section 3.4.2.
2. **The Questionnaire and Interview Guide**, created as part of the instrument development described in Sections 3.3.1 and 3.3.2 .
3. **Figures and Tables**, created as part of the results described in Sections 4.1 and 4.3

B Questionnaire

A.1 How stressed do you feel right now?

1 2 3 4 5 6 7 8 9 10
□ □ □ □ □ □ □ □ □ □
Not at all *Fully*

A.2 How stressed do you feel on an average working day?

1 2 3 4 5 6 7 8 9 10
□ □ □ □ □ □ □ □ □ □
Not at all *Fully*

A.3 Compared to before you clicked or reported the phishing mail, how much more stressed do you feel right now?

○ Significantly more stressed than before
○ Slightly more stressed than before
○ Just as stressed as before
○ Slightly less stressed than before
○ Significantly less stressed than before

A.4 Here you will find a list of statements on possible attitudes of employees towards phishing emails. Please indicate to what extent you agree with the following statements

- I am confident of recognizing a phishing email.
- I can recognize a phishing email even if there was no one around to help me.
- I can recognize a malicious URL from a legitimate URL.
- I am sure of the steps to follow to recognize a phishing email.

○ Strongly agree
○ Agree

[1] https://doi.org/10.6084/m9.figshare.25990963

○ Neither agree nor disagree
○ Disagree
○ Strongly disagree

A.5 How important do you consider...

- IT security in general.
- Your role when it comes to IT security in general.
- Your role when it comes to preventing phishing attacks.
- IT security training.

○ Extremely important
○ Very important
○ Moderately important
○ Slightly important
○ Not important at all

A.6 How effective do you consider...

- Online phishing trainings to prevent clicking on real phishing mails.
- Simulated phishing mails sent by the company to prevent clicking on real phishing mails.
- Technical measures (email filter, etc.) to prevent clicking on real phishing mails.

○ Extremely effective
○ Very effective
○ Moderately effective
○ Slightly effective
○ Not effective at all

A.7 Why do you think simulated phishing emails sent by the company are effective or not?

A.8 What changes would you like to see regarding the anti-phishing campaign?

C Interview Guide

B.1 General Perception (1/2)

- Can you tell me what you heard about the campaign and how it went?
  - How did you first hear about the campaign?
  - Was the campaign communicated to you in any other way?
  - Did you have any questions or uncertainties?

B.2 Stress and Emotions

- Please put yourself back into the situation in which you first learned about the campaign.
  - What were you thinking at that moment?
  - Did this situation stress you? Why?
  - Did this situation trigger any other emotions in you?
  - Did this situation bother you even longer afterwards?

B.3 Self-Efficacy

- How confident do you feel about dealing with phishing emails?
  - What influence did the campaign have on this?
  - *If not mentioned:* Have you ever successfully reported a simulated phishing email?

- Do you get to see if colleagues recognize phishing emails?
  - How do they view the campaign? Why?

- In what form does the company give you feedback on the results of the campaign?

- In what way does the company encourage you to be successful in the campaign?

B.4 General Perception (2/2)

- Do you exchange information about the campaign with anyone?
  - With whom? About what?
  - *Additional stress question:* Were the others stressed?

- At this point, what would you do if you were confronted with a potential phishing email?

- More generally, what is your personal opinion of the phishing campaign?

- Do you think that the campaign will help employees click on phishing emails less often in the future? What about you?

- Would you like to see other measures to help you click on phishing emails less often?
  - What changes would you like to see regarding the anti-phishing campaign?

D Figures & Tables

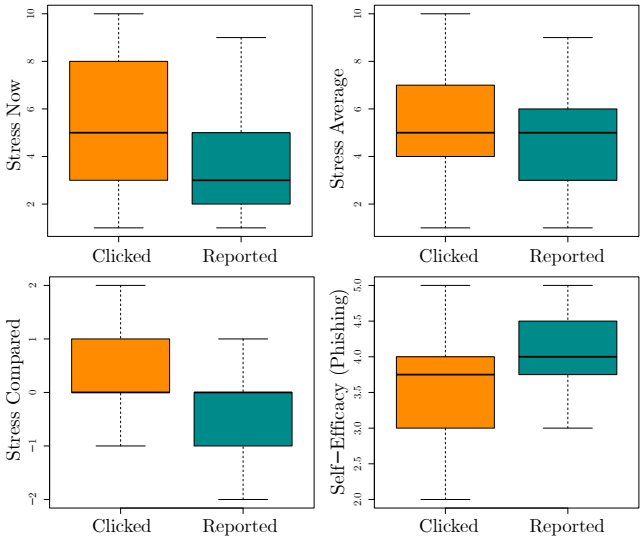

Figure 2: Boxplots of perceived stress directly after clicking/reporting ("Stress Now"), average stress, stress compared to before clicking/reporting ("Stress Compared") and phishing self-efficacy for the two Groups *Clicked* and *Reported*.

Table 2: Occurences of the most relevant codes by participants.

Arcanum: Detecting and Evaluating the Privacy Risks of Browser Extensions on Web Pages and Web Content

Qinge Xie
Georgia Institute of Technology

Manoj Vignesh Kasi Murali
Georgia Institute of Technology

Paul Pearce
Georgia Institute of Technology

Frank Li
Georgia Institute of Technology

Abstract

Modern web browsers support rich extension ecosystems that provide users with customized and flexible browsing experiences. Unfortunately, the flexibility of extensions also introduces the potential for abuse, as an extension with sufficient permissions can access and surreptitiously leak sensitive and private browsing data to the extension's authors or third parties. Prior work has explored such extension behavior, but has been limited largely to meta-data about browsing rather than the contents of web pages, and is also based on older versions of browsers, web standards, and APIs, precluding its use for analysis in a modern setting.

In this work, we develop Arcanum, a dynamic taint tracking system for modern Chrome extensions designed to monitor the flow of user content from web pages. Arcanum defines a variety of taint sources and sinks, allowing researchers to taint specific parts of pages at runtime via JavaScript, and works on modern extension APIs, JavaScript APIs, and versions of Chromium. We deploy Arcanum to test all functional extensions currently in the Chrome Web Store for the automated exfiltration of user data across seven sensitive websites: Amazon, Facebook, Gmail, Instagram, LinkedIn, Outlook, and PayPal. We observe significant privacy risks across thousands of extensions, including hundreds of extensions automatically extracting user content from within web pages, impacting millions of users. Our findings demonstrate the importance of user content within web pages, and the need for stricter privacy controls on extensions.

1 Introduction

Web browsers manage some of the most sensitive user data. From emails, to banking information, to medical records, to social media, web pages display private information and users rely on web browsers to ensure information remains secure within their devices, and available only to the correct parties.

At the same time, browser extensions serve a fundamental role in the web ecosystem. Used by millions of users, extensions enhance browser functionality with expressive, powerful features. Google's Chrome Web Store hosts over 100K extensions with billions of total installs [11].

Unfortunately, the same access and capabilities that extensions rely on to enrich the web browsing experience can also be abused to harm user privacy; extensions can collect sensitive user data at scale, potentially without users' knowledge or explicit consent. Even in cases where data collection is benign and necessary for legitimate extension functionality, it introduces privacy risks as sensitive user data can be transmitted and stored by a third party, which may further share the data or possibly leak the data during a data breach.

The intersection of the sensitive nature of some websites and the powerful nature of extensions creates a core privacy conflict: how can we secure *some* websites and types of content when third-party code has significant access to that information. One mechanism deployed by browsers requires extension developers to explicitly document what kinds of content can be accessed, and on what sites. Unfortunately, these permissions are coarse-grained; a simple extension that changes page colors requires the ability to interact with all content on the page. Such construction still affords abuse.

This avenue of privacy problems has not gone unnoticed. Prior work such as Mystique [4] sought to develop an analysis framework for Chromium—the most popular browser platform, underpinning more than 68% of all users' browsing [58]—to explore how extensions access some kinds of user information such as URLs and passwords. Unfortunately, the architecture of modern browsers, the expressiveness of extension APIs, and the web itself have advanced since such tools were developed, making them incapable of operating in a modern context. Orthogonal to prior work, another remaining question is the role that extensions play in the collection of web page *content*, and once they access that information, how it is processed, stored, and potentially exfiltrated.

To address these limitations, we present Arcanum, a dynamic taint tracking system for Chromium designed to track sensitive user content on modern web pages and extensions. The key distinctions of Arcanum from prior systems are its

ability to track user data from within web pages, operate on the modern browser architecture, and support taint propagation across a more comprehensive set of browser, web, and JavaScript (JS) APIs used by extensions (including new APIs as well as important ones not previously accounted for, such as the Fetch network request, and data encoding/encryption).

Arcanum understands a diverse set of data sources ranging from meta-data, to content DOM elements, location information, history data, and cookies. From these sources, Arcanum is able to track data flow to a variety of exit sinks, including all forms of web requests and storage APIs. Arcanum does this by instrumenting both the Blink browser engine and the V8 JS engine to mark taint for sensitive data objects (including those returned by sensitive APIs) and comprehensively propagate taint across data manipulation functions. A key feature of Arcanum is allowing researchers to instrument *specific* web page elements as tainted at runtime via JS DOM annotations. This allows Arcanum to not only track how extensions use, manipulate, store, or exfiltrate *specific* data objects, but also reduce flagging of non-sensitive data, such as page colors.

We deploy Arcanum at scale to study all 113,099 functional extensions in the Chrome Web Store. We test each extension against seven privacy-critical sites covering a diverse set of categories: Amazon, Facebook, Gmail, Instagram, LinkedIn, Outlook, and PayPal.

We observe that the automated collection of potentially private data is pervasive; we uncover 3,028 extensions collecting sensitive user data, impacting up to 144M users. Of these, the super majority exfiltrate the data, with a minority storing it locally. We also observe the collection of sensitive user data from within web page *content* by 202 extensions, potentially affecting up to 300K+ users, which has not been previously investigated. The collected information includes the contents of emails, private social media profiles and activity, banking information, and professional networks. Further, all sites tested are impacted by thousands of extensions.

In summary, our contributions include:

- Identifying that more than 58% of today's extensions cannot be analyzed by the existing extension analysis system [4].
- Designing and implementing Arcanum, a dynamic taint tracking system driven by runtime annotations, for modern Chromium browsers.
- Performing a study of *all* functional extensions from the Chrome Web Store, across 7 popular and privacy-critical sites covering email, banking, and social media. We present analysis across extensions, sites, taint sources, and sinks.
- Finding 3,028 extensions automatically collect private user data across sites, impacting up to 144M users; the super majority of these extensions exfiltrate the data off-device.
- Uncovering 202 extensions collected detailed user *content* from web pages, impacting as many as 300K+ users.

We open-source Arcanum at https://github.com/BEESLab/Arcanum/ to support future research. We have also shared our results with Google and the affected sites.

2 Background and Motivation

In this section, we provide background on Chrome browser extensions. We also discuss related prior work and their limitations, motivating our system and study.

2.1 Chrome Browser Extensions

Extensions expand upon browser features and functionality. Chrome extensions are composed of several core components.

Manifest File. Every extension has a `manifest.json` file specifying an extension's metadata and configuration, such as the permissions required by the extension. In December 2020 [12], Chrome 88 rolled out a new version of its extension platform, called Manifest Version 3 (MV3) [10]. Compared to the previous version MV2, MV3 includes new features and functionality, as well as changes to existing ones. The Chrome Web Store no longer accepts new MV2 extensions. While existing MV2 extensions remain in the Web Store, Google will begin disabling MV2 extensions in pre-stable versions of Chrome in June 2024 [21]. To migrate to MV3, extensions must at a minimum update their manifest file.

Background Scripts. Background scripts (or service workers in MV3) provide the long-term state and functionality of an extension, independent of browser windows/tabs. Background scripts can use Extension APIs (e.g., `chrome.history`) if the necessary permissions are granted to the extension (e.g., the "`history`" permission).

Content Scripts. Background scripts cannot directly access web pages in browser windows/tabs. Instead, extensions can inject content scripts into a window/tab, which runs within the page's context and thus can access the page's DOM interface. In order to inject into a page, extensions must define host permissions in the manifest file (or request it via the "`activeTab`" permission). Content scripts can be injected by an extension either through declarations or programmatic methods:

- Extension manifest files can statically declare content scripts to always inject into web pages with URLs that match specified patterns (including wildcard patterns). Starting with Chrome 96, content scripts can also be dynamically declared, registering content scripts using the `chrome.scripting.registerContentScripts` API and determining injection at runtime.
- Extensions can also programmatically inject a content script through `chrome.tabs.executeScript` (MV2) or `chrome.scripting.executeScript` (MV3).

Content scripts can communicate with the extension background script through message passing APIs, such as using `tabs.sendMessage` and `runtime.postMessage`.

2.2 Prior Browser Extension Privacy Work

The security and privacy research community has broadly investigated browser extensions, such as by assessing exten-

sion fingerprinting [23, 28, 33] and discovering vulnerable data flows in extensions [20, 31]. In this work, we specifically focus on studying privacy leakage via browser extension behaviors, which prior work has investigated through differing methods. The types of user information investigated by prior work include those provided by browser or web API calls [3, 4, 17, 20, 32, 67, 68], Document properties (e.g., cookies) [4, 17], and specific HTML element types (e.g., password-typed fields in HTML forms) [4, 22]. Note that these information sources are generically available across all sites, affording straightforward evaluation at scale. However, prior work has not investigated sensitive user data from *within* web pages themselves, such as account profiles, user emails and posts, and personal images. In our work, we seek to expand beyond the user information considered by prior work and account for the wealth of user data within web pages.

To evaluate extension privacy leakage, some works [32, 67] have applied network monitoring and analysis, searching for user data within network requests generated by extensions. The network vantage point is ultimately limited though, as it struggles to identify encoded, encrypted, or otherwise obfuscated user data, and provides limited visibility into how the data is collected and exfiltrated. To provide deeper visibility into extension activity, both static analysis [20, 22] and dynamic taint tracking [4, 17] approaches have been used. Extension static analysis by itself cannot comprehensively identify data leakage flows though, as extension behavior is often heavily dependent on dynamic values that can only be determined at runtime on real-world sites. Thus, in this study, we adopt the dynamic taint tracking approach, of instrumenting a browser to trace how sensitive tainted data may eventually reach exfiltration points. Most similar to our approach is Dhawan et al. [17], who implemented taint tracking for Firefox, and Chen and Kapravelos [4], who developed taint tracking for Chromium. However, in our work, we develop a new browser taint system, Arcanum, to overcome critical limitations with these prior systems, as detailed next.

2.3 Motivation for Arcanum

Our study focuses on extensions for Chromium, the most popular browser platform [58]. While prior work [4] developed extension taint tracking for Chromium, we identified critical limitations necessitating a new system for modern Chromium.

Mystique [4] was developed in 2018, built upon Chromium version 54 released in November 2016. Modern Chromium has significantly evolved since this browser version though. Beyond supporting additional features and APIs, the internal browser architecture has been been substantially updated, including redesigning the JS engine. As a consequence, modern websites and extensions do not function correctly on such an outdated version of Chromium. The browser changes have also been significant enough that Mystique cannot be easily ported to the new version of Chromium. We identify the following browser changes that drive the need for a new system:

Changes to the V8 JS Engine. Chromium uses the V8 JS engine, which in 2017 migrated to an entirely new JS execution pipeline (from Full-codegen/Crankshaft to Ignition/TurboFan) [64]. V8 has further updated its internal implementation, such as optimizing its garbage collection in 2018 [59, 60] and applying pointer compression to reduce memory consumption in 2020 [62]. As a consequence, Mystique's design cannot be directly ported to modern Chromium versions, as the JS engine architecture is distinct. Instead, a Chromium taint tracking system specific to the modern V8 architecture is needed.

Native Code Data Flow. Prior versions of Chromium implemented core browser functionality in JS, including built-in functions and the extension bindings system that supports extension APIs [14]. These features provide both potential taint sources as well as methods that could propagate tainted user data. However, modern Chromium has migrated these functionalities to native C++ for security and performance reasons, as discussed in Section 3.2.3. Thus, taint tracking on current Chromium requires tracking taint through both JS and native code, necessitating an updated taint tracking system.

Manifest Version 3. As described in Section 2.1, Chrome released a new version of the extension platform, MV3, in 2020. MV3 introduces new APIs and features; MV3 extensions cannot operate on older browser versions that do not support it. Mystique, built upon Chromium 54, cannot run MV3 extensions.

To identify the extent of this limitation, we downloaded all extensions in the Chrome Web Store (leveraging the Store sitemap [7]) in both August 2022 and August 2023. In 2022 we observed 20.65% of extensions (out of 118,655) utilized MV3, while in 2023, the prevalence of MV3 had increased to 58.89% of extensions (out of 114,714). Thus, any attempt to utilize prior taint tracking systems on modern extensions precludes an ever-increasing majority of extensions. It is vital that a taint tracking system supports MV3, especially given that the Web Store no longer accepts new MV2 extensions.

Broken Websites. Since Chromium 54 (which Mystique used), numerous new JS expressions and operators have been added to Chromium. Many of these features have been adopted by websites. For example, the LinkedIn website automatically loads a JS snippet that uses the Nullish coalescing operator, a feature only supported in Chrome 80+. Furthermore, the Spread syntax in object literals is widely used today [1], a feature only supported in Chrome 60+. We identified early in our study that many websites displayed fatal errors when visited in an older browser (e.g., LinkedIn cannot load in Chromium 54, as its core JS scripts relied on missing operators and errored). Thus, not only will an outdated browser impact taint tracking, it inhibits the analysis of modern websites.

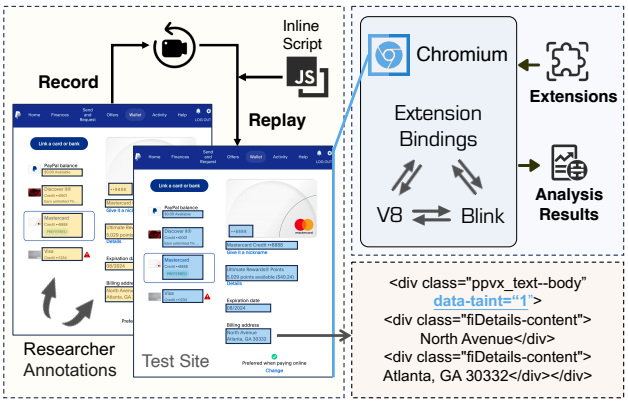

Figure 1: Overview of Arcanum. Researchers identify target sites and annotate privacy-sensitive data on web pages. Arcanum then replays content across all extensions in a given dataset, using its instrumented version of Chromium, producing detailed taint source and sink logs per extension and site.

3 System Design

We now present Arcanum, a browser framework that utilizes dynamic taint tracking to detect and analyze the usage of privacy-sensitive data by browser extensions. Figure 1 shows an overview of Arcanum's architecture.

Arcanum allows researchers to understand if specific elements of a web page's content or meta-data are processed, stored, or exfiltrated by extensions. Arcanum provides a variety of privacy-sensitive taint sources (Section 3.1) and sinks (Section 3.3), and monitors the flow of tainted data through its taint propagation engine (Section 3.2), including in the extension's context. Unique to Arcanum is its support for tainting sensitive user data within web pages, through researcher-provided annotations. To evaluate extensions at scale, Arcanum records and replays annotated webpages across all browser extensions (Section 3.5), revealing how data is processed and flows.

3.1 Taint Sources

To ensure the comprehensiveness of Arcanum in tracking data flows containing sensitive information, we surveyed all Chrome Extension APIs [6] and Web APIs [19], and list taint sources supported by Arcanum in Table 1. Note that there are other Chrome Extension/Web APIs supported by Arcanum in the taint propagation process but are not taint sources, such as Web Crypto APIs, which will be discussed in Section 3.2. Overall, our sources can be categorized into three groups:

- Chrome APIs: Extensions can utilize Chrome Extension APIs to directly query for privacy-sensitive information (e.g., `Chrome.history.getVisits`) or dispatch events to notify the extension when specific browser actions are triggered and subsequently return privacy-sensitive data (e.g., `Chrome.tabs.onUpdate`). Arcanum includes the `Chrome.cookies` API as a taint source that can query websites' cookies, which was not considered in prior work. Arcanum also supports information fields that only exist in newer Chrome versions (e.g., "PendingUrl", "initiator", and "ip"). We also further consider the "title" field for the history and tabs API, which can include sensitive information.
- Web APIs: While prior work [4] did not recognize any Web APIs as taint sources, extensions can leverage Web APIs to retrieve privacy-sensitive information. Arcanum thus supports the History, Geolocation and User-Agent APIs.
- DOM Elements: Extensions can access users' private information through the DOM interface. For example, the DOM property `document.title` gives the title of the page, which is supported by Arcanum. Notably, Arcanum allows researchers to mark custom DOM elements that contain sensitive information as taint sources (discussed subsequently).

Notably, while prior work focused on browser APIs as taint sources [3, 4, 68], Arcanum expands beyond prior work to also encapsulate webpage-specific taint sources. Arcanum is designed to also be easily extensible, should additional taint sources be desired in the future (e.g., new browser APIs or other site-specific tainted data). This is accomplished by Arcanum separately handling native data flows in Chrome's extension bindings system (Section 3.2).

DOM Tainting. Arcanum allows researchers to generate custom annotations to taint specific DOM elements on a per-web page basis, enabling investigation of exactly what information is consumed by extensions. This flexibility allows researchers to focus on the parts of the web page that are sensitive, and ignore portions that are not, e.g., we can taint the content of emails, while ignoring colors or themes (common extension behaviors). This custom annotation method is a trade-off; each web page we are interested in must be annotated, but in exchange we get fine-grained information about extension behavior, and reduced false positives of privacy concerns.

For each target web page, researchers identify DOM elements that include sensitive information and label them as taint sources via adding a "`data-taint`" attribute. The HTML `data-*` attribute [18] can be used to store custom data private to the page or application. We designate these element nodes as *labeled* nodes. We modified Blink so that when the "`data-taint`" attribute of an element node is set, Blink traverses all of its descendant nodes, marking the content of all text and CDATA nodes as tainted.

We briefly note that our taint annotation strategy is resistant to evasion. Once an element is tainted (i.e., by a researcher's annotations), its taint status is maintained by the browser internals and cannot be modified via JavaScript (i.e., extension content scripts), even if removing the "`data-taint`" attribute later on. In Section 3.4, we discuss our method for tainting elements prior to extension content script execution.

Accessing Tainted DOM Elements. Extensions can use different HTML element properties to retrieve the data content of

Category	Taint Source	Permission
DOM custom elements	**innerText/outerText, innerHTML/outerHTML, textContent, wholeText, nodeValue, jQuery text(), etc.**	Content script injection
DOM location	Href, Protocol, Host, Hostname, Pathname, Search, Origin, Hash	Content script injection
DOM property	**URL**, **Domain**, **Title**, Cookie	Content script injection
DOM Input Element	<input type="password">	Content script injection
Chrome.history API	URL, **Title**	"history" permission
Chrome.tabs API	URL, **PendingUrl**, **Title**	"tabs" permission
Chrome.cookies API	**Domain, Path, Name, Value**	"cookies" permission
Chrome.webNavigation API	URL	"webNavigation" permission
Chrome.webRequest API	URL, **Initiator**, **IP address**, Cookies in request/response headers	"webRequest" permission
History Web API	**URL**	-
Geolocation Web API	**Position**	-
User-Agent Client Hints	**Brands, Platform, Architecture, Model, PlatformVersion, UaFullVersion**	-

Table 1: Taint sources supported by Arcanum. Sources in bold have not been considered by prior work [4].

a node within the DOM, such as "innerText", "innerHTML" and "NodeValue". As the innerText/outerText property recursively collects text nodes from all child elements within the specified element, we flag the resulting value as tainted if any of the recursively retrieved text nodes are tainted. A similar rule applies to innerHTML/outerHTML; we also mark the return value of innerHTML/outerHTML as tainted if any descendant nodes or ancestor nodes of the retrieved node have the "data-taint" attribute. Arcanum handles the wholeText and TextContent properties in the same way as innerText/outerText. The nodeValue property (used by the common jQuery text() method) returns the content of a text node (or content of the CDATA section of a CDATA node), and is tainted if the text node is tainted. We also separately taint the value property of HTMLTextAreaElement and the text property of HTMLTitleElement. We further notice that Blink uses the StringBuilder class to aggregate texts within various HTML elements, such as the <img> title attribute and the text attribute of HTMLOptionElement. Thus, we modify the StringBuilder class so that whenever a tainted string is appended to a StringBuilder object, we mark the aggregated return values as tainted (i.e., the return value of the StringBuilder.ToString() function).

3.2 Taint Propagation Engine

To track the flow of tainted information across the extension's JS execution, Arcanum instruments the V8 engine that Chromium uses to parse and execute JS. V8 parses JS source code into an abstract syntax tree (AST). Arcanum first marks AST nodes as tainted when the corresponding concrete runtime objects (e.g., string objects) are tainted. Then for each individual JS function that is in the Extension context (discussed below), a data flow graph (DFG) is constructed from the AST to process taint propagation that starts from the tainted AST nodes. When this propagation occurs, the corresponding runtime objects linked to these tainted AST nodes are also marked as tainted. This method is consistent with prior work [4], although implemented on the modern Chromium V8 engine. To our knowledge, there are currently no plans for major architectural changes to the V8 engine, indicating that Arcanum should be applicable for the foreseeable future.

3.2.1 Tracking Extension Context

Arcanum exclusively monitors JS execution within the Extension context, which distinguishes it from scripts initiated by the website page itself. V8 uses a Context object to represent a JS execution environment, enabling concurrent execution of distinct JS applications within a single V8 instance. For MV2 extensions, this Context object can be used to identify JS code that is from the extension's content script or background page. We use this Context object to identify and restrict taint propagation to JS code that belongs to an extension, similar to prior work [4, 17].

However, this strategy does not fully translate to MV3, where service workers replace extension background pages. While the Context of content scripts and background scripts in extensions are initiated by Blink, service workers are managed by Chrome's extension bindings system. For each extension, the bindings system installs extension API bindings before a service worker starts evaluating its top-level script. Arcanum modifies the installation function to mark the service worker Context before any service worker starts execution, allowing us to also identify service worker JS code.

3.2.2 JavaScript Data Flows

We first discuss how Arcanum tracks the flow of tainted data purely within JS execution.

Explicit Flows. While the previous Full-codegen compiler in V8 directly generated unoptimized machine code, the Ignition interpreter generates V8 bytecode from the AST. These bytecode instructions are then interpreted by the TurboFan compiler to generate optimized machine code. Arcanum modifies the Ignition interpreter in V8 to construct the DFG and propagate taint status for AST nodes and runtime objects. The V8 bytecode instructions can be broadly categorized into three categories: 1) assignment operations, 2) arithmetic and logic operations, and 3) control dependencies. Arcanum handles assignment operations by tainting the left-hand side (LHS) if the right-hand side (RHS) of the assignment is tainted. Additionally, when the RHS contains arithmetic and logic operations, Arcanum considers the expression results as tainted if any of the arguments within the expression are tainted. Lastly, in the context of control dependencies (such as `switch-case`, `if-else`, and `do-while` loops), if any arguments within the conditional expression of a control structure are tainted, the LHS in every assignment operation contained within the control structure is also tainted [4,17,65]. Note that Arcanum supports all current JS operators, including those introduced after prior Chromium-based tainting systems [4] (e.g., `await`).
