the handled lock of this call from the lockset. To collect locking relations, when encountering a variable-access instruction, for each lock l in the lockset, our method checks whether the accessed variable v and the lock are different fields but in the same data structure, by checking whether the nodes representing v and l have a common ancestor (representing a common higher-layer structure) in the field graph. If so, our method records a locking relation $<AP_v, AP_l>$, where AP_v means the access path from the common higher-layer structure to the variable v, and AP_l means the access path from the common higher-layer structure to the lock l.

Figure 5 shows the process of collecting locking relations. It creates a locking relation set *LR_set*, which stores all locking relations. Each element in the set is a triple [*lr*, *type*, *cp*], where *lr* is the constructed locking relation, *type* is how the data field involving in the locking relation is accessed (either a write or a read) and, *cp* is the code path of the locking relation. Like existing approaches [6, 51], this process starts from each function that has no explicit caller function in kernel code. Note that this process performs inter-procedural analysis, by combining the code paths of the callee and caller functions to get complete code path. Given a code path of the analyzed function, for each instruction in the code path, this process performs lockset analysis, updates field graph or constructs locking relations according to different types of the instruction (Lines 5–22). Specifically, for a lock-acquire/release function call, this process updates the lockset (Line 7). For an arrow operation, this process updates the field graph according to the handled instruction (Line 9). For a variable-access instruction, this process first gets the accessed variable and the access type (Lines 11–12). Then, for each lock in the lockset, this process traverses the field graph to find a common ancestor of the accessed variable and the lock (Line 14). If a common ancestor is found (Line 15), this process gets the access paths from the ancestor to the accessed variable and the lock (Lines 16–17), and records them as a locking relation (Line 18). Besides, the access type and the code path are also recorded for subsequent locking rule mining.

Example. Figure 6 illustrates how our method constructs locking relations for the example code in Figure 4. In Figure 6(a), in the code path 1468→1486→1487→1491 (denote as `CP1`), the lock `fimc->lock` is acquired at Line 1484, and thus it is added into the lockset. Then, the code accesses five fields including `fmt->pad`, `mf->width`, `mf->height`, `ff->width` and `ff->height`. However, in Figure 6(b), only the two nodes representing the data fields `ff->width` and `ff->height` (n_7 and n_8), and the node representing the lock field `fimc->lock` (n_4) have a common ancestor (n_2). Take `ff->width` and `fimc->lock` as an example, the access paths from the common ancestor to the nodes representing them are `fimc_dev...width` and `fimc_dev.lock`, and the access is a read. Thus, our method inserts [<`fimc_dev...width`, `fimc_dev.lock`>, `read`, `CP1`] into the locking relation set. Similarly, our method also inserts [<`fimc_dev...height`, `fimc_dev.lock`>, `read`, `CP1`] into the locking relation set for the access to `fimc_dev...height`.

S2: Locking rule mining. After collecting locking relations, for each data field involved in them, our method statistically calculates the proportion of the accesses to this data field protected by each involved lock field among all the accesses to this data field, to mine locking rules. We observe different functions can have quite different numbers of code paths. Thus, distinguishing locking relations by code paths may be unfair for diverse functions, which can reduce the accuracy of locking rule mining. To address this problem, our method distinguishes locking relations by calling contexts, like existing approaches [42, 58]. Specifically, given a data field AP_v and a lock field AP_l, our method first counts the number $num_{protected}$ of calling contexts containing the locking relation $<AP_v, AP_l>$

Figure 7: Example of mining locking rules.

from the locking relation set returned by *CollectLockingRelation()* in Figure 5, and then counts the number num_{all} of all the calling contexts containing accesses to AP_v using a dataflow analysis. If the proportion of $num_{protected}$ among num_{all} is larger than a threshold T (set to 0.7 in this paper, as described in Section 5.1), and at least one of all the access is a write, our method mines a locking rule <AP_v, AP_l> that the data field AP_v should be protected by the lock field AP_l.

Example. In Figure 7, our method collects four accesses (num_{all}) to `fimc_dev...width`, including one write and three reads, three ($num_{protected}$) of which are protected by the lock `fimc_dev.lock`. Thus, the proportion of $num_{protected}$ among num_{all} is 0.75. As the proportion is large, our method infers the data field `fimc_dev...width` should be protected by the lock field `fimc_dev.lock`, and mines a locking rule <`fimc_dev...width`, `fimc_dev.lock`>. Similarly, our method mines another locking rule <`fimc_dev...height`, `fimc_dev.lock`> for accesses to `fimc_dev...height`.

3.2 Alias-Aware Race Checking

Method design. Due to heavy use of pointers and data structures in large-scale kernel code, static race detection can be inaccurate and time-consuming. Inspired by DLOS [7] that detects kernel deadlocks, we use function summaries to reduce the time of inter-procedural analysis. However, DLOS uses an intra-procedural and flow-insensitive alias analysis, which can introduce much inaccuracy. To improve accuracy and efficiency, we propose an alias-aware checking detection based on field graph (in Section 3.1). It uses a flow/field-sensitive intra-procedural analysis to construct field graphs representing alias relationships, detect races in single function and create a function summary containing alias relationships. When detecting races across functions, it performs a context-sensitive inter-procedural analysis with such summaries.

Representation of aliased variables. Our method focuses on alias relationships involving locks and accessed variables, based on their field graphs. Specifically, in a field graph, the aliased variables are represented by different access paths ending with the same node. However, for lockset analysis involving alias relationships, it is necessary to use one common access path to represent multiple aliased variables. Indeed, the locks and accessed variables shared by different threads often come from function arguments [5,64]. Thus, our method selects one access path starting from the node representing function argument, to represent these aliased variables.

Intra-procedural analysis. Based on the above representation of aliased variables, our method performs lockset analysis and race detection by handling the following instructions:

- For each lock-acquire/release function call, our method first extracts the access path AP_l of the handled lock l, and then performs lockset analysis with AP_l for this call.
- For each variable-access instruction, our method first extracts the access path AP_v of the handled variable v. Then, for each locking rule <AP_v, AP_{lx}> mined in Section 3.1, our method checks whether AP_{lx} is in the lockset. If not, a rule violation is reported as a possible race.

After analyzing a function, our method creates and maintains a function summary for inter-procedural analysis. This function summary records the access paths and related instructions for all the lock-acquire/release function calls and variable accesses in the analyzed function. Formally, a function summary can be defined as a set of pairs <*inst*, AP_v>, where *inst* is an instruction of lock-acquire/release function call or variable access, and AP_v is the access path of the variable handled by *inst*.

Inter-procedural analysis. When encountering a function call, our method first looks for the summary of the called function. If not found, our method performs intra-procedural analysis of the called function and creates its function summary. Then, our method instantiates the function summary by replacing each formal argument with actual argument. Finally, the instantiated summary of the called function is spliced to the call site of the caller function and stored as a part of the summary of the caller function.

During inter-procedural analysis, our method uses lockset analysis and detects the violations of the mined locking rules as possible races, like intra-procedural analysis.

Example. Figure 8 illustrates how our method detects races across multiple functions, using the mined locking rule in Figure 7. This figure shows three functions and their partial instructions. Suppose that the analysis order of our method is `set_frame_crop` → `__fimc_capture_set_format` → `fimc_subdev_set_fmt`. After analyzing `set_frame_crop`,

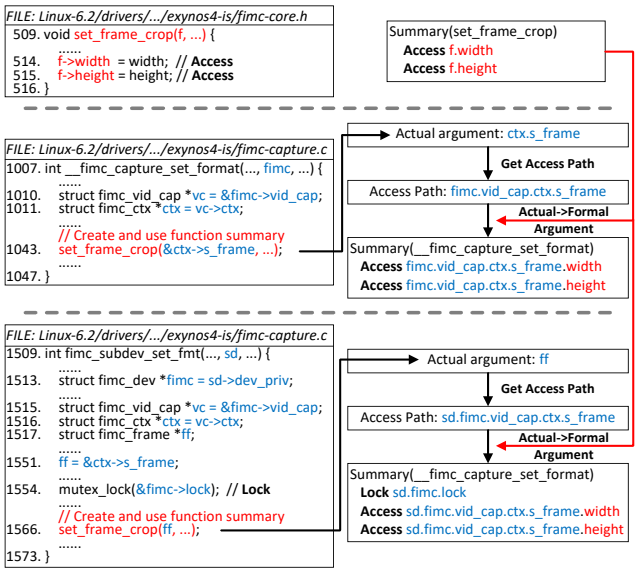

Figure 8: Example of alias-aware race checking.

our method records two variable accesses at Lines 514 and 515 in its function summary. When analyzing the function call to `set_frame_crop` at Line 1043 in the function `__fimc_capture_set_format`, our method first calculates the access path of the actual argument `ctx->s_frame`, namely `fimc.vid_cap.ctx.s_frame`, and then replaces the formal argument `f` in the function summary of `set_frame_crop` with the calculated access path to instantiate variable accesses in the summary. Finally, our method splices the instantiated variable accesses to the function summary of the caller function `__fimc_capture_set_format`, and then checks whether the instantiated accesses violate the minded locking rules. In this example, the two accesses to the fields `fimc_dev...width` and `fimc_dev...height` are not protected by the lock `fimc_dev.lock`, which violates the mined locking rules in Figure 7. Thus, our method reports two possible races here. When analyzing the function call at Line 1566 in `fimc_subdev_set_fmt`, the function summary of `set_frame_crop` is reused to avoid repeated analysis of the definition of `set_frame_crop`, which can reduce the time usage of race detection. In `fimc_subdev_set_fmt`, the accesses are all protected by the lock `fimc_dev.lock` acquired at Line 1554, and thus our method reports no race here.

3.3 Pattern-Based Harmfulness Estimation

Method design. Inspired by Portend [44] that reproduces and identifies harmful races, we estimate the security impact of the found races by analyzing code information. Different from Portend that executes the tested program to analyze trace information, we aim to statically analyze source code for security estimation without program execution. For this purpose, we propose a pattern-based estimation strategy that performs propagation analysis of the racy variables, according to some representative patterns that can cause security problems. Overall, our strategy has two main steps:

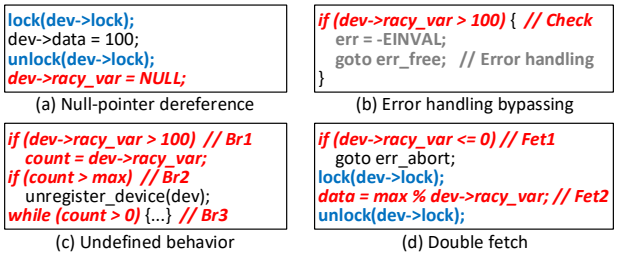

Figure 9: Four patterns of identifying harmful races.

S1: Identifying racy-variable accesses. The alias-aware checking method in Section 3.2 reports the variable-access instruction of each found race. If this instruction is a read, this step just passes this access into the next step. If this instruction is a write, namely other reads of the racy variable can be affected due to the uncertain value caused by this write, this step identifies the racy variable, and uses a field-based analysis [6, 37] of the kernel code to identify other accesses that possibly read the racy variable. These accesses are all handled in the next step.

S2: Checking usage patterns from racy-variable accesses. For each racy-variable access identified by *S1*, this step performs a flow/field/context-sensitive inter-procedural analysis starting from the access, to analyze the propagation of the racy variable and check its usage. The found race is considered to be harmful, if the racy variable's usage satisfies one of the following patterns:

P1) Null-pointer dereference (NPD): affecting NULL assignment or check. When the racy variable is a pointer that is assigned or checked by NULL, the concurrent access of this pointer may cause a null-pointer dereference. We select this pattern because many reported kernel vulnerabilities (like CVE-2023-31081 [26] and CVE-2023-46862 [27]) are caused by this pattern, and they can lead to DoS attacks. Figure 9(a) shows an example of this pattern.

P2) Error handling bypassing (EHB): affecting error check. When the racy variable affects a branch check of error handling, the race can make the kernel abnormally bypass error checks to access the resources already released by other threads due to error occurrence. We select this pattern because error handling are necessary but error-prone in OS kernels [41, 57], and error handling bugs can lead to DoS attacks, memory corruption and other security problems. Figure 9(b) shows an example of this pattern.

P3) Undefined behavior (UB): affecting multiple branches. When the racy variable affects multiple ($\geq$3) branches, the race can cause kernel control flow to be non-deterministic at runtime, which may lead to undefined behaviors. We select this pattern because some existing fuzzing approaches [42, 79] for kernel race detection reveal the security impact of such races. Figure 9(c) shows an example of this pattern.

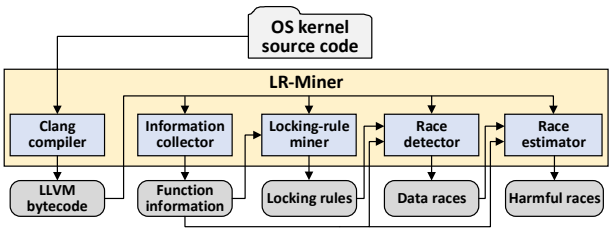

Figure 10: LR-Miner architecture.

P4) Double fetch (DF): affecting variable check and usage without a common lock. When the racy variable is checked before being used, but this check and use are not protected by a common lock, the race can cause a double fetch issue where the checked value and used values are inconsistent. We select this pattern because many double fetch issues in OS kernels are caused by code concurrency, and they can cause DoS attacks, restriction bypassing and other security problems [75, 80]. Figure 9(d) shows an example of this pattern.

These four bug types are selected, as many approaches [8, 38, 42, 51, 79, 81] have proven their harmfulness and use different ways to detect them. However, these approaches focus on static analysis of sequential code [8, 38, 51, 81] or dynamic analysis [42, 79] with limited coverage. In comparison, our strategy focuses on static analysis of concurrent code, and thus has significant difference from these approaches.

4 LR-Miner Approach

Based on the three key techniques introduced in Section 3, we design a new static analysis approach named LR-Miner, to effectively detect data races in OS kernels by mining locking rules from kernel code. We have implemented LR-Miner with the Clang compiler [18] to perform static analysis on the LLVM bytecode of OS kernels. Figure 10 shows the architecture of LR-Miner, which has four phases:

Phase1: Code compilation. First, the *Clang compiler* compiles the kernel source code into LLVM bytecode. During the compilation, the operators "." and "->" are all compiled to LLVM getelementptr (GEP) instructions. Then, the *information collector* scans each LLVM bytecode file to record the information about each function (including function name and function definition position) in a database. The information is used in the subsequent phases for inter-procedural analysis across source files.

Phase2: Locking-rule mining. The *locking-rule miner* uses our field-aware mining method to mine locking rules from kernel code. The mined locking rules are recorded in a readable form, to help detect races and understand the restriction of kernel concurrency.

Phase3: Race detection. The *race detector* uses our alias-aware checking method to detect the violations of the mined locking rules as data races. Note that for a given race, there may be multiple code paths from the entry function to its problematic instruction, and thus many repeated races can be reported. To drop repeated results, for a new possible race, the detector checks whether its problematic instruction is identical to any existing race. If so, this possible race is considered to be repeated and dropped.

Phase4: Harmfulness estimation. The *race estimator* uses our pattern-based estimation strategy to estimate the security impact of the found races and identify harmful ones. Note that a race can simultaneously satisfy two or more patterns presented in Section 3.3, so the estimator matches it with the most suitable pattern according to the usage of racy variable.

Global variable handling. In kernel code, some global locks are used to protect global variables, and they are unrelated to function arguments. To handle such situations, LR-Miner specifically introduces a virtual node in the field graph, and this node is the ancestor of all global variables and locks. In this way, the accessed global variable and the global protection lock have a common ancestor, and thus they can be normally handled during locking rule mining and race detection.

Atomic access handling. To ensure the atomicity of variable accesses in concurrent execution, some special functions and macros (like `atomic_inc` and `READ_ONCE` in the Linux kernel) are used. If such a function or macro is encountered during static analysis, LR-Miner neglects the related variable accesses in race detection.

False positive dropping. On the one hand, similar to existing approaches of kernel bug detection [7, 8, 51], LR-Miner uses an SMT solver Z3 [84] to validate code-path feasibility during static analysis, which can drop false races caused by infeasible code paths. Specifically, for each possible race, LR-Miner translates instructions in the related code path into constraints using the Z3 grammars, and then checks whether these constraints can be satisfied. If not, LR-Miner regards the possible race as a false positive and thus drops it. On the other hand, similar to existing approaches of kernel race detection [29, 64, 74], LR-Miner drops the races occurring in the functions for kernel-module initialization and removal, by matching function names with keywords like "init" and "remove", as such functions are expected to have no concurrency during module execution.

5 Evaluation

We evaluate LR-Miner on the two OS kernels including Linux (version 6.2) and FreeBSD (version 14.0), and their versions are the latest minor releases as of our evaluation. Table 1 shows their information, and source code lines are counted by CLOC [19]. For the Linux kernel, we use the kernel configuration *allyesconfig* to enable all kernel code for the x86-64 architecture. For the FreeBSD kernel, we use the *GENERIC* configure file for the x86-64 architecture. We run the evaluation on a regular x86-64 desktop with sixteen Intel i7-10700 CPU@2.90GHz processors and 64GB physical memory.

OS	Version	Source files (*.c)	LOC
Linux	6.2	28.3K	14.2M
FreeBSD	14.0	19.6K	9.2M

Table 1: Information about the two checked OS kernels.

Description		Linux	FreeBSD
Code analysis	Source files (analyzed/all)	22.5K/28.3K	4.2K/19.6K
	Source code lines (analyzed/all)	13.9M/14.2M	3.3M/9.2M
Locking-rule mining	Identified locking relations	52.1M	16.8M
	Mined locking rules	1.6K	1.1K
Race detection	Times of handling called functions	57.1M	12.8M
	Times of reusing function summaries	53.3M	12.7M
	Dropped false races (path/concurrency)	4.4K/1.2K	4.5K/1K
	Found races (real/all)	273/341	33/41
Harmfulness estimation	Handled racy-variable accesses	1,381K	127K
	Identified harmful races	173	27
	Harmful patterns (NPD/EHB/UB/DF)	26/59/50/38	11/6/10/0
Time usage	Locking-rule mining	1h33m	56m
	Race detection	10h43m	4h3m
	Harmfulness estimation	7h26m	3h35m
	Total time	21h48m	9h32m

Table 2: Analysis results of the two OS kernels.

5.1 Bug Detection

We run LR-Miner to automatically mine locking rules, detect kernel races and estimate their harmfulness. The proportion threshold T used by our field-aware mining method is set to 0.7 in the evaluation. We select this value as it can help LR-Miner achieve good accuracy of race detection, according to our experience of kernel development and detection results of small-scale code bases. The user can conveniently change this threshold as needed. Then, we manually check all the races found by LR-Miner. Table 2 summarizes the results, and we make the following observations:

Code analysis. LR-Miner in total analyzes 17.2M lines of code in 26.7K source files, within 32 hours. The remaining 6.2M lines of code in 21.2K source files are not analyzed, because they are not enabled by the configurations for the x86-64 architecture. We believe that LR-Miner can find more kernel races, if these source files can be compiled with proper configurations for other architectures.

Locking-rule mining. LR-Miner identifies 68.9M locking relations from the code of the two kernels. By analyzing these locking relations and the related variable accesses, LR-Miner mines 2.7K locking rules (including 1.6K in Linux and 1.1K in FreeBSD) indicating which data field should be protected by which lock field. Besides race detection, we believe that these locking rules can also help to improve the documents about kernel concurrency and benefit the secure development of new kernel code.

Race detection. Based on the mined locking rules, LR-Miner finds 382 kernel races, including 341 in Linux and 41 in FreeBSD. 11.1K false races are dropped, because their code paths are infeasible (8.9K) or their caller functions have no concurrency (2.2K). We spent 18 hours on checking these races, and identified 306 of them (including 273 in Linux and 33 in FreeBSD) to be real. Thus, LR-Miner achieves a false positive rate of 19.9%, which is lower than many existing static approaches of kernel race detection [3, 29, 64, 73, 74].

Part	Filesystem	Network	Driver				Others
			All	*Network*	*SCSI*	*Others*	
Races	29 (9%)	36 (12%)	198 (65%)	43	42	113	43 (14%)
Harmful	19 (10%)	29 (15%)	126 (63%)	28	27	71	26 (13%)

Table 3: Distribution of the found races.

Efficiency improvement. During race detection, LR-Miner uses function summaries to avoid repeated analysis of the same functions. Specifically, to perform inter-procedural analysis, LR-Miner handles called functions for 69.9M times, 66M (94%) of which are handled by reusing function summaries, without the need of analyzing function definitions again. Thus, race-detection efficiency is largely improved.

Harmfulness estimation. For the 306 real races, LR-Miner first identifies 1,508K accesses to the racy variables in kernel code, and then estimates the security impact of these races by analyzing the identified accesses according to four patterns introduced in Section 3.3. LR-Miner identifies 200 harmful races (173 in Linux and 27 in FreeBSD). Specifically, 37 can cause null-pointer dereferences (NPD), 65 can cause error handling bypassing (EHB), 60 can cause undefined behaviors (UB), and 38 can cause double fetch (DF) issues.

Race distribution. We classify all the real and harmful races found by LR-Miner, according to the category of the kernel part containing the race. Table 3 shows the distribution results of the real and harmful races. We find that drivers have over 60% of the real and harmful races, indicating that drivers are more error-prone than other kernel parts and thus deserve more attention in race detection. We also classify the driver races by driver class, and show the result in Table 3. We find that network and SCSI drivers together have over 40% of the real and harmful races in all drivers, possibly because these drivers have more concurrent code than other driver classes.

Harmful race reporting. We reported all the 200 harmful races to kernel developers, and 61 of them (including 51 in Linux and 10 in FreeBSD) have been confirmed. We are still waiting for the response of the remaining ones. Moreover, 10 harmful races have been assigned with CVE IDs. Some kernel developers also expressed their interests of integrating LR-Miner in their continuous integration (CI) testing systems to help detect races during kernel development.

Security impact of the found harmful races. We manually check these races and find that: 37 NPD races can cause null-pointer dereferences, leading to DoS attacks; 65 EHB races can bypass error handing to cause use-after-free vulnerabilities due to accessing the resources released by other threads, leading to memory corruption; 60 UB races can make kernel control flow non-deterministic to cause undefined behaviors, leading to DoS attacks; 38 DF races can cause double fetch issues where the checked value and used value are inconsistent, leading to restriction bypassing and memory corruption.

5.2 False Positives and Negatives

False positives. LR-Miner reports 76 false races in the two kernels, for four main reasons:

R1) LR-Miner mines some false locking rules due to over lock protection of the data field that should not be protected. In a data structure, if a lock field is often used to protect many other fields, LR-Miner will mine the related locking rules. But in fact, only one specific field should be protected while the other fields are not, and thus some mined locking rules are actually false, causing 53 false races to be reported.

We infer that over lock protection is introduced, as the related developers fail to identify which data fields should be protected by a given lock field, and thus just blindly add lock protection for extra fields together. Although over lock protection hardly causes security bugs, it can reduce kernel concurrency and degrade OS performance. Thus, it is meaningful to detect over lock protection in kernel code.

R2) In order to reduce memory overhead and accelerate data passing across different functions, an integer can be divided into several bit vectors to represent different data structure fields in kernel code. However, in the LLVM bytecode, the accesses to these vectors are divided into a load and several bit operations. At present, LR-Miner cannot correctly distinguish the accesses to different structure fields in this case, causing 14 false races to be reported.

R3) In some kernel functions, special assertions are used at the entry of these functions, to guarantee that the required lock is held. However, LR-Miner does not specially handle these assertions, and thus maintains incorrect locksets during analysis, causing 6 false races to be reported.

R4) LR-Miner still errs when handling some complicated cases, like checking the accesses to array elements via non-constant indexes and validating path feasibility related to complex arithmetic conditions. This reason causes 3 false races.

False negatives. LR-Miner may still miss some real races for three main reasons:

R1) LR-Miner maintains and checks locksets by analyzing the arguments of lock-acquire/release function calls, but some lock-acquire/release functions (such as `rcu_read_lock` and `rcu_read_unlock` in the Linux kernel) have no argument in the calls to them. Thus, LR-Miner neglects the calls to these functions during locking-rule mining and race detection, which may miss the related real races.

R2) Some locks are represented as array elements that are used via non-constant indexes (such as `dev->locks[i]`) in kernel code, and analyzing these locks is error-prone. Thus, LR-Miner neglects such locks during lockset analysis to reduce false positives, but may miss the related real races.

R3) Some locks are customized in special forms like reference counts and condition variables, instead of calling lock-acquire/release functions. Thus, LR-Miner cannot handle such locks, which may miss the related real races.

5.3 Case Studies of the Found Harmful Races

Figure 11 shows four harmful races found by LR-Miner in Linux and FreeBSD. All of these races have been confirmed.

NPD race in the FreeBSD firewire driver. In Figure 11(a), the pointer field `ir->stproc` is dereferenced without holding lock in the function `fw_read` at Line 363. However, in many other functions, this pointer field is accessed with the lock acquired by calling `FW_GLOCK`, like Line 471 in the function `fw_write` (note that `it->stproc` in this function and `ir->stproc` in `fw_read` are actually identical). Thus, there is a race at Line 363. Moreover, `it->stproc` is checked with NULL at Line 417, namely it can be NULL, and thus `ir->stproc` can be also NULL at Line 363, causing a null-pointer dereference. The attacker can exploit this harmful race to crash the kernel and perform DoS attacks.

EHB race in the Linux media driver. In Figure 11(b), the data field `dmxdev->exit` is checked for error handling without holding lock in the function `dvb_dvr_read` at Line 271. However, in many other functions, this data field is accessed with the lock `dmxdev->mutex`, like Line 1456 in the function `dvb_dmxdev_release`. Thus, there is a race at Line 271. Meanwhile, we observe that in the function `dvb_dmxdev_release`, after `dmxdev->exit` is set to 1 at Line 1456, `dvb_unregister_device` is called at Line 1470 to release the data buffer used in the driver; in the function `dvb_dmxdev_release`, if `dmxdev->exit` is 0 in the error check at Line 271, `dvb_dmxdev_buffer_read` is subsequently called at Line 273 to read the data buffer. Thus, in a special execution order in form of Lines 1455 $\rightarrow$ 271 $\rightarrow$ 1456 $\rightarrow$ 1457 $\rightarrow$ 1470 $\rightarrow$ 273, the race can bypass the error check at Line 271 and cause that `dvb_dmxdev_buffer_read` is executed after `dvb_unregister_device`, namely the data buffer is read after being released, leading to a use-after-free vulnerability. The attacker can exploit this harmful race to corrupt the memory of data buffer and inject malicious data.

UB race in the Linux SCSI driver. In Figure 11(c), the data field `phba->fcf.fcf_flag` is written without holding lock in the function `lpfc_unregister_fcf_rescan` at Line 6979. However, in many other functions, this data field is accessed with the lock `phba->hbalock`, like Lines 6791, 6797, 6834 and 6942 in the function `lpfc_sli4_async_fip_evt`. Thus, there is a race at Line 6979. Moreover, in the function `lpfc_sli4_async_fip_evt`, there are at least four branches are directly affected by `phba->fcf.fcf_flag`, and thus this race can disorder the code execution to cause undefined behavior of the driver. The attacker can exploit this harmful race to interfere driver execution and perform DoS attacks.

DF race in the Linux sound subsystem. In Figure 11(d), the data field `card->total_pcm_alloc_bytes` is checked without holding lock in the function `do_alloc_pages` at Line 41. However, in many other functions, this data field is accessed with the lock `card->memory_mutex`, like Lines 62 and 63 in the function `do_free_pages`. Thus, there is a

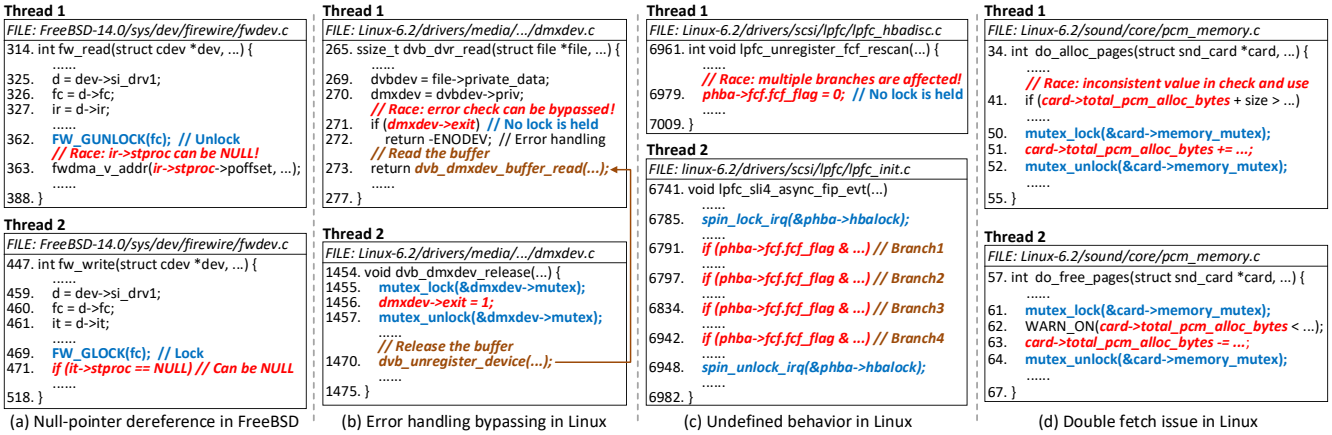

Figure 11: Four example harmful races found by LR-Miner.

race at Line 41. Moreover, in the function `do_alloc_pages`, `card->total_pcm_alloc_bytes` is used with the lock at Line 51, after being checked at Line 41, so the checked and used values of this field can be inconsistent. Note that this field is used to represent the total size of the PCM (Pulse Code Modulation) buffers in sound subsystem, so this race can cause buffer overflow when the value is changed after the check. The attacker can exploit this harmful race to corrupt the memory of PCM buffers and inject malicious sound data.

5.4 Comparison Experiment

We aim to compare with existing static approaches of kernel race detection, including Relay [74], RacerX [29], CPALockator [3], Goblint [73], Locksmith [64] and Lockpick [14]. We select Linux 5.17 to check, as many of them can only check old Linux kernel versions including 5.17 but excluding 6.2.

As for Relay, we build it from its source code [65] with minor modification to parse Linux 5.17 code. As for RacerX, its source code is not available, so we tried our best to implement a RacerX-like tool referring to its paper. As for CPALockator, we build it from its source code [21] based on the race detection part of CPAchecker [20]. As for Goblint and LockSmith, we downloaded their source code from their repositories [35, 55], but encountered too many error when parsing Linux 5.17 code. We tried our best to solve these errors but failed. We contacted the authors of these approaches, and they also had no solution of these errors. As for Lockpick, it is not publicly available. Thus, we make a methodology comparison with Goblint, LockSmith and Lockpick.

Note that LR-Miner uses our field-aware mining method and alias-aware checking method to improve the accuracy of kernel race detection, as well as the function summary to improve the efficiency of data race detection. To validate the value of these three key techniques, we implement three tools by modifying LR-Miner: (1) LR-Miner$_{FieldBased}$ that uses a field-based analysis when mining locking rules, without using field graph to check whether the data field and lock field are in the same structure; (2) LR-Miner$_{NonAlias}$ that neglects alias relationships when detecting races with the locking rules mined by LR-Miner; (3) LR-Miner$_{NonSum}$ that performs inter-procedural analysis without using function summaries.

We run the three existing static approaches and three implemented tools to check Linux 5.17 with a timeout of 7 days (168h), and summarize the results in Table 4. We have the following observations from the table:

(1) LR-Miner finds all the real and harmful races found by Relay, RacerX-like and CPALockator, and it also finds more real and harmful races missed by these approaches, with a lower false positive rate. Note that Relay and RacerX-like report too many races (12,291 and 20,457) that require much manual work to check, so we randomly select 300 of them to check. We analyze the methodology of the three existing approaches according to their papers, and summarize the following reasons why LR-Miner produces better results:

Relay uses classical lockset analysis [69] to detect races by checking the intersection of locksets in different code paths, without using locking rules about kernel concurrency. Moreover, it uses flow/field-insensitive alias analysis when maintaining locksets, and neglects code-path feasibility during analysis. In comparison, LR-Miner accurately mines locking rules and detects races, with flow/field-sensitive alias analysis and SMT-based path-feasibility validation.

RacerX uses imprecise dataflow analysis that can statistically identify simple locking rules from kernel code, without checking whether the data field and lock field are in the same structure. Moreover, RacerX neglects alias relationships and code-path feasibility during analysis. Thus, RacerX produces many incorrect locking rules and false races. In comparison, LR-Miner uses field graph and considers alias relationships to more accurately mine locking rules and detect races.

CPALockator combines imprecise but fast classical lockset analysis and precise but slow model checking, without using locking rules. However, classical lockset analysis assumes that all the functions can be concurrently executed, which is actually incorrect during kernel execution [6]. More-

Description	Relay	RacerX-like	CPALockator	LR-Miner$_{FieldBased}$	LR-Miner$_{NonAlias}$	LR-Miner$_{NonSum}$	LR-Miner
Found races	12,291	20,457	782	3,171	742	N/A	385
Real races	8 in 300	6 in 300	21	185	51	N/A	274
Harmful races	4 in 300	3 in 300	9	154	40	N/A	188
Time usage	1h7m	4h38m	126h15m	5h25m	5h32m	>168h	5h51m

Table 4: Comparison results of Linux 5.17.

over, to accelerate model checking for concurrency analysis, CPALockator sacrifices analysis accuracy by pruning many code paths, simplifying path constraints, etc. In comparison, LR-Miner mines accurate locking rules from kernel code, without using the incorrect assumption used by CPALockator; and then it uses alias relationships and function summaries to improve both accuracy and efficiency of race detection.

(2) LR-Miner spends more time than Relay and RacerX-like, as it has more complicated analyses of building field graphs, computing accurate alias relationships, etc. LR-Miner spends less time than CPALockator, as CPALockator heavily suffers from concurrency state explosion of model checking, despite achieving some acceleration by sacrificing accuracy.

(3) LR-Miner produces fewer false positives and negatives than LR-Miner$_{FieldBased}$ and LR-Miner$_{NonAlias}$, indicating our field-aware mining method and alias-aware checking method can indeed help improve the accuracy of race detection. LR-Miner$_{NonSum}$ cannot finish analysis within the timeout in our evaluation, indicating that summary-based analysis is very important to improving the efficiency of race detection.

Goblint, Locksmith and Lockpick. We make methodology comparison with them, according to their papers. Goblint analyzes just driver code in the Linux kernel, by assuming all driver interface functions can be concurrently executed. However, this assumption is actually incorrect during kernel execution [6], causing many false results. Locksmith checks the intersection of locksets in different code paths, but using the user's annotations. However, the annotations can be wrong provided by the inexperienced user, affecting the accuracy of concurrency analysis. Lockpick requires the user to provide lock specifications, to detect lock misuses including some kinds of races. However, the user can provide wrong lock specifications due to misunderstanding code logics, which can cause many false results. By contrast, LR-Miner detects races by mining locking rules that reflect kernel concurrency conventions, without concurrency assumption, user annotation or locking specifications, so it can achieve better accuracy.

6 Discussion

Field graph. LR-Miner exploits field graph to conveniently describe the relation between each data field and lock field in structures. Compared to existing field-based analysis [12, 31, 68] that uses just structure type and field name to identify aliased structure fields, LR-Miner can achieve better accuracy in lockset analysis by using field graph.

Exploitability of the found harmful races. After knowing the locations of these harmful races, the attacker can intentionally trigger them by preparing the related concurrency workloads, and then can transform them into deterministic vulnerabilities like null-pointer dereferences and use-after-free issues, which can be exploited to perform DoS attacks, privilege escalation, etc. Several works [49, 82, 86] have explored the vulnerability exploitation of such harmful races.

Detecting other concurrency issues. Besides races, we believe LR-Miner can be extended to detecting other concurrency issues in OS kernels, like atomicity violations, deadlocks and concurrency use-after-free issues. For example, LR-Miner can mine lock-order rules like that *lock A should be acquired before lock B when the two locks need to be held together*, and such rules can be used to detect kernel deadlocks caused by ABBA locking cycles. Besides, LR-Miner can also identify concurrency use-after-free by checking whether a racy variable is freed by the kernel.

Limitations and future works. First, LR-Miner still reports some false results due to neglecting bit vectors in structures, omitting special assertions about locks, etc. Thus, we plan to handle these cases in LR-Miner to further reduce false positives. Second, LR-Miner fails to handle special locks, like RCU and customized locks (including reference counts, condition variables, etc), so it may miss some races involving these locks. Thus, we plan to study the usage of these special locks, and improve LR-Miner to detect the related races. Third, LR-Miner detects races caused by missing lock protection at present, and fails to detect races involving non-lock concurrency mechanisms like wait queue and completion mechanisms. Thus, we plan to improve LR-Miner to support the analysis of these mechanisms and detect the related races. Fourth, LR-Miner just considers the sequential propagation of racy variables in harmful estimation, without checking their concurrent propagation across different functions, and thus may introduce some inaccuracy. To solve this problem, we plan to analyze possible thread interleavings and check the related concurrent propagation, to improve the accuracy of harmful estimation. Finally, besides races, we plan to extend LR-Miner to detect other concurrency issues in OS kernels.

7 Related Work

Dynamic race detection. Many dynamic approaches detect races based on address watchpoint [30, 40, 46], lockset analysis [4, 16, 66, 69, 87], happens-before relation [11, 13, 33, 50, 83],

or hybrid of them [28, 47, 48, 72, 78]. However, these approaches require the tested program to actually cover different thread interleavings for deep race detection. To solve this problem, several dynamic approaches [15, 36, 39, 42, 79] introduce coverage-guided fuzzing into race detection. These approaches automatically control thread scheduling or inject random delays, guided by new concurrency metrics that reflect the covered thread interleavings during program execution. Despite using concurrency fuzzing, these approaches still miss some program code and infrequent thread interleavings, due to limited test cases and testing time, causing many real races to be missed.

Different from the above approaches, LockDoc [54] first analyzes kernel execution traces to identify locking rules, and then detects the violations of these rules as kernel races. However, identical to the above approaches, LockDoc also suffers from limited code coverage of kernel execution, and thus it misses many execution situations for the analyzed traces, which affects the accuracy of the mined locking rules.

Different from LockDoc, LR-Miner statically analyzes kernel source code, to conveniently handle many more possible execution situations, without actual kernel execution. Due to higher analysis coverage, LR-Miner can achieve better accuracy of locking-rule mining to benefit race detection and detect more kernel races.

Static race detection. Many static approaches [1, 2, 10, 31, 32, 43, 52, 61, 70] focus on race detection in user-level applications. Indeed, different from applications actively executing code, kernel code is often passively executed via system calls invoked by upper-level applications [9, 67]. Thus, kernel concurrency is actually caused by application concurrency in many cases, without having explicit operations of thread creation and termination like applications do. However, these approaches require such thread operations to perform concurrency analysis, and thus they cannot effectively check kernel code to perform static race detection.

A few static approaches [3, 14, 29, 64, 73, 74] can detect kernel races, based on the assumption that all the functions can be concurrently executed or using the user's annotations about code concurrency. As this assumption is actually incorrect during kernel execution and the inexperienced user can provide wrong annotations, these approaches can report many false races. Moreover, some of these approaches [29, 64, 74] use inaccurate lockset analysis that neglects field information about accessed variables and protected locks, which can produce many false results. Besides, these approaches fail to estimate the security impact of the found races. In comparison, LR-Miner mines locking rules and detects races with precise field information and alias relationships, without concurrency assumption or user annotation, so it can achieve better accuracy in race detection. Besides, LR-Miner identifies harmful races, according to representative patterns that can cause security problems.

8 Conclusion

We design a novel static analysis approach named LR-Miner, to detect races in OS kernels by mining locking rules from kernel code. Among the found races, it can identify harmful ones, according to representative patterns that can cause security problems. In the evaluation on Linux and FreeBSD, LR-Miner finds 306 real races, 200 of which are estimated to be harmful. 61 of the harmful races have been confirmed. In experimental comparison to existing approaches, LR-Miner finds more real races with better accuracy. LR-Miner is available on https://sites.google.com/view/LR-Miner/.

When Threads Meet Interrupts: Effective Static Detection of Interrupt-Based Deadlocks in Linux

Chengfeng Ye Yuandao Cai Charles Zhang

Abstract

Deadlocking is an unresponsive state of software that arises when threads hold locks while trying to acquire other locks that are already held by other threads, resulting in a circular lock dependency. Interrupt-based deadlocks, a specific and prevalent type of deadlocks that occur within the OS kernel due to interrupt preemption, pose significant risks to system functionality, performance, and security. However, existing static analysis tools focus on resource-based deadlocks without characterizing the interrupt preemption. In this paper, we introduce Archerfish, the first static analysis approach for effectively identifying interrupt-based deadlocks in the large-scale Linux kernel. At its core, Archerfish utilizes an Interrupt-Aware Lock Graph (ILG) to capture both regular and interrupt-related lock dependencies, reducing the deadlock detection problem to graph cycle discovery and refinement. Furthermore, Archerfish incorporates four effective analysis components to construct ILG and refine the deadlock cycles, addressing three core challenges, including the extensive interrupt-involving concurrency space, identifying potential interrupt handlers, and validating the feasibility of deadlock cycles. Our experimental results show that Archerfish can precisely analyze the Linux kernel (19.8 MLoC) in approximately one hour. At the time of writing, we have discovered 76 previously unknown deadlocks, with 53 bugs confirmed, 46 bugs already fixed by the Linux community, and 2 CVE IDs assigned. Notably, those found deadlocks are long-latent, hiding for an average of 9.9 years.

1 Introduction

Deadlocking [7, 15, 21, 33] commonly refers to an unresponsive condition caused by circular lock dependencies, in which, each thread within a group of threads holds a lock while also attempting to acquire another lock that is already held by other threads. In the OS kernel, the interrupt preemption [68] can cause additional lock dependencies, when preempted threads, which have already acquired locks, attempt to acquire additional locks within the interrupt handling procedure [4]. In this paper, we refer to the circular lock dependencies related to the interrupt preemption as *interrupt-based deadlocks*.

There is abundant evidence that deadlocks can significantly hurt the functionality, performance [5], and even security of modern software [50–55]. Furthermore, the interrupt-based deadlocks within the OS kernel can pose a more severe danger as they occur within the interrupt context [43], potentially leading to the entire unresponsive CPU core and even a whole system breakdown [70]. Unfortunately, there are no effective tools for identifying interrupt-based deadlocks, as both the previous static and dynamic approaches have certain limitations.

First, existing static approaches [7, 10, 14, 15, 18, 20–22, 34, 63] primarily focus on detecting resource-based deadlocks [15] caused by thread interleaving, thus overlooking interrupt-based deadlocks. Specifically, most past static analysis tools [14, 15, 18, 34, 35] target deadlock detection in userland software without considering interrupt preemption, a unique feature of the OS kernel. Also, although a few tools [7] aim to detect deadlocks in OS kernel, they still use traditional thread interleaving models by directly treating interrupts as threads, missing lock dependencies caused by interrupt preemption.

Second, dynamic approaches [11, 13, 17, 30, 31, 40, 57, 84, 85] often suffer from low coverage and reliance on the runtime execution environment such as external devices. Specifically, although dynamic fuzzing can detect such deadlocks with the assistance of Lockdep [73], the built-in Linux kernel lock validator, they require high-quality seed inputs or configurations to guide the execution towards a faulty path. Besides, the interrupt preemption [68] significantly enlarges the exploration space of dynamic concurrent execution, degrading the effectiveness. Moreover, the dynamic triggering of interrupts heavily depends on signals generated by hardware devices, which sometimes are hard to be properly estab-

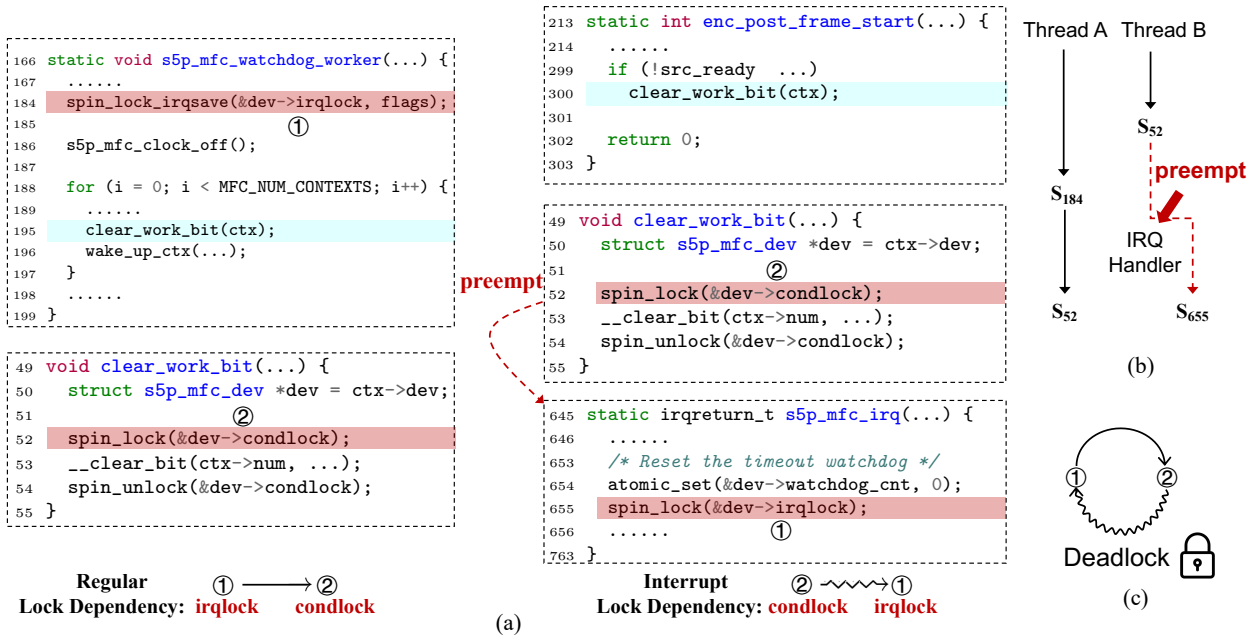

Figure 1: An eleven-year-old deadlock detected by Archerfish in Linux media subsystem (*s* denotes a statement).

lished or available [60].

We use an example shown in Figure 1(a), which was introduced in Linux kernel [74] v3.7-rc1 eleven years ago [41] and discovered by us. The example shows an interrupt-based deadlock caused by circular lock dependencies between two threads, Thread A and Thread B. First, in the left-hand side of Figure 1(a), Thread A acquires `&dev->irqlock` ① at Line 184 and then calls the function `clear_work_bit()` at Line 195, which further acquires `&dev->condlock` ② at Line 52. This *regular execution flow*, establishes a **regular lock dependency** from `&dev->irqlock` ① to `&dev->condlock` ②. Second, on the right-hand side of Figure 1(a), Thread B, in the callback function `enc_post_frame_start()`, also calls `clear_work_bit()` at Line 300 and acquires `&dev->condlock` ②. Since the interrupt handler `s5p_mfs_irq()` is not disabled at that moment, there is a possibility of preemption by the interrupt handler between Line 52 and Line 54. If the interrupt handler acquires `&dev->irqlock` ① during this preemption, it creates an **interrupt lock dependency** from `&dev->condlock` ② to `&dev->irqlock` ①. Note that this interrupt lock dependency cannot be captured by existing static methods [7,14,15] without characterizing interrupt preemption. Consequently, in certain concurrent scheduling, an interrupt-based deadlock may occur, as depicted in Figure 1(b), resulting in a system halt.

Our Approach. In this work, we present Archerfish, the first static analysis approach to characterize the interrupt preemption to detect the interrupt-based deadlocks in the Linux kernel. At the core, Archerfish is empowered by the extended notion of an Interrupt-Aware Lock Graph (ILG), which captures both kinds of lock dependencies in the Linux kernel, *namely regular lock dependencies and interrupt lock dependencies*, caused by regular execution flow of threads and interrupt preemption, respectively. By effectively constructing the ILG, Archerfish can reduce the detection of interrupt-based deadlocks to the discovery and validation of dependence cycles. For example, the deadlock in Figure 1(a) can be detected by finding the cycle shown in Figure 1(c).

However, there are three core challenges of effectively analyzing the Linux kernel to identify the lock dependencies and refine deadlock cycles. **(1)** First, identifying the *Interrupt Service Routines (ISRs)* is challenging without domain-specific knowledge, as different subsystems in the Linux kernel often have their own unique APIs and callback interfaces for registering ISRs [71]. **(2)** Second, the interrupt preemption enlarges the concurrency reasoning space of static analysis. As each interrupt-enabled program location can be potentially interrupted [68], it is necessary to consider preemption at each statement to capture all possible interrupt-induced lock dependencies. However, the large concurrency reasoning space can significantly degrade the effectiveness of static analysis. **(3)** Third, it is crucial to identify feasible lock dependencies, taking into account the feasibility of *both interrupts and program paths*. However, for example, directly validating the path-feasibility of numerous lock dependencies using SMT solving [82] may cause low efficiency.

To address the three challenges, we design four stages shown in Figure 2 with several tailored techniques.

- First, to address the first challenge, Archerfish

harnesses the power of Large Language Models (LLMs) to generate interrupt specifications that complement manually modeled ones for identifying interrupts. This is because LLMs have been trained on a vast amount of online textual data, including information related to the Linux kernel [61].

- Second, we employ a summary-based data-flow analysis to compute the lockset [32,81] and the state of interrupt enabling or disabling at relevant statements. To tackle the second challenge of the vast reasoning space of the interrupt preemption, we introduce the notion of *a preemption unit*, clustering all statements within a critical section. Our key idea is that a critical section [78] shares the same lockset so that any interrupts occurring within the region hold the same set of locks. Thus, separately computing each individual program point within the region is unnecessary during lockset analysis.
- Third, using the computed data-flow facts, Archerfish constructs the ILG and captures both kinds of lock dependencies as graph edges. In particular, it identifies dependency cycles within the ILG, each representing an interrupt-based deadlock.
- Fourth, to overcome the third challenge of expensive deadlock feasibility checking, our key idea is that not all lock dependencies are related to deadlock detection. Thus, we lazily check the feasibility of *both interrupts and paths*, deferring the costly validation for each discovered cycle instead of early validating each edge during ILG construction.

We have implemented the Archerfish prototype based on the LLVM framework [36] and evaluated it on the Linux kernel v6.4. Archerfish can analyze the Linux kernel (19.8 MLoC) in about one hour with a relatively low positive (49.7%). More excitingly, we have found 76 new and long-latent interrupt-based deadlocks in the Linux kernel and reported all of them to the Linux community. In total, 53 bugs have been confirmed by developers, and 46 of them have already been fixed in the mainstream Linux kernel with 2 CVE IDs assigned.

Contribution. We make the following contributions.

- We propose the notion of the Interrupt-Aware Lock Graph (ILG), which captures both kinds of regular and interrupt-related lock dependencies as edges, enabling the reduction of *interrupt-based deadlock* detection via graph cycle discovery and refinement.
- We present Archerfish, the first static interrupt-based deadlock detection for the Linux kernel, addressing three specific challenges of effectively constructing ILG and refining cycles.
- We evaluate Archerfish on Linux kernel v6.4, where it revealed 76 new interrupt-based deadlocks that across various subsystems in the Linux kernel.

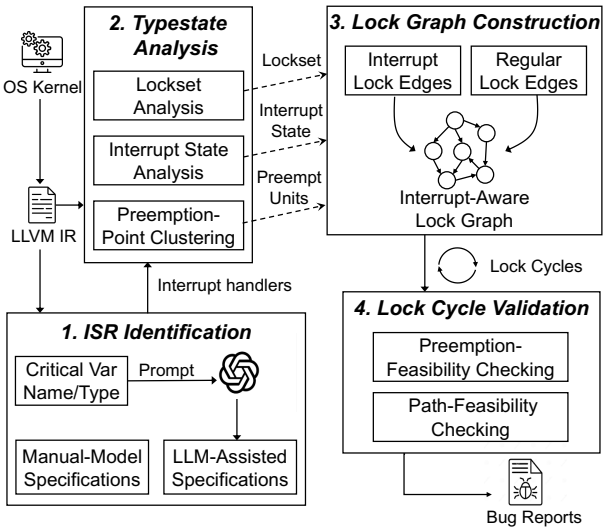

Figure 2: The design of Archerfish framework.

2 Background

We present the interrupts' concept, the interrupt-based deadlocks, the limitations of existing works, and the threat model in § 2.1, § 2.2, § 2.3, and § 2.4, respectively.

2.1 Interrupts in Linux kernel

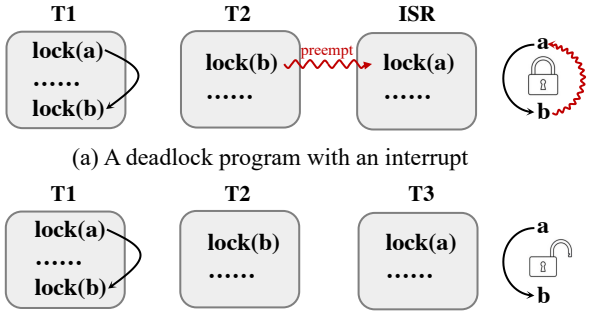
Interrupt Handling. An interrupt [43] in the Linux kernel is a special event that alters the regular execution flow of a program, and such action is also called *interrupt preemption* [68]. In contrast, the action that one thread switches to another thread is called *thread preemption* [72]. Their major difference is that interrupt preemption is *asymmetric*, indicating that interrupt runs in higher priority and cannot switch back to the previously preempted execution flow until the interrupt finishes its execution [43]. Thus, interrupt preemption could introduce new lock dependencies and cause deadlocks [2].

Interrupt Priority. Interrupts in the Linux kernel have two categories: hardware interrupts [42] and software interrupts [44], also known as *hardirqs* and *softirqs*, respectively. Hardirqs are triggered by interrupt signals from hardware devices and execute under the context called the *hardirq context*. In recent Linux kernel, local interrupt is disabled inside *hardirq context* by default, so hardirqs normally run with the highest priority and cannot be preempted by any other execution units, including other hardirqs [43].

Because hardirqs should execute quickly in response to hardware signals, time-consuming tasks would be deferred to softirqs [44]. Softirqs run in the execution context called the *softirq context* with lower priority than the hardirq context and can be preempted by hardirqs [44]. Nevertheless, both the hardirqs and softirqs belong to

```
struct net_device_ops ks_wlan_netdev_ops = {
    .ndo_start_xmit = ks_wlan_start_xmit,
    .ndo_open = ks_wlan_open,
    .ndo_stop = ks_wlan_close,
    .ndo_do_ioctl = ks_wlan_netdev_ioctl
    ……
}
```

ISR



(a) Registered via a structure field interface

```
request_irq(IO_INTERRUPT, do_cio_interrupt, 0,
"I/O", NULL);
```

ISR

(b) Registered via an API call

Figure 3: Examples of ISR registration in Linux.

(b) The thread model missing interrupt preemption

Figure 4: (a) shows a deadlock program while (b) shows its previous thread modeling with one lock edge missed.

interrupts and have higher priority than normal kernel threads executing under the *process context* [23]. The priority-based preemption relationship leads to the specific concurrency model in the Linux kernel. Therefore, any static analyzer that aims to reason about interrupt preemption should consider this relationship.

Interrupt Service Routine (ISR) Registration. An ISR [3] is a function in response to interrupt signals from hardware devices or software interrupt. In the Linux kernel, an ISR is typically registered in two ways. First, an ISR can be registered by being assigned to a structure field. In Figure 3(a), function `ks_wlan_start_xmit()` is registered as a softirq ISR by being assigned to the `net_device_ops.ndo_start_xmit` structure field, a callback interface responsible for handling network packet transmission [71]. Second, an ISR can be registered by being passed as an argument to a specific API call. For example, as shown in Figure 3(b), the function `do_cio_interrupt()` is registered as a hardirq ISR for the interrupt line `IO_INTERRUPT` using the standard API `request_irq()` [3]. The large codebase of Linux contains diverse subsystems, each with its own interfaces or APIs for ISR registration. The variation presents a challenge for identifying ISRs and capturing interrupt preemption in static deadlock detection.

2.2 Interrupt-Based Deadlocks

Distinguishing interrupt-based deadlocks from other types of deadlocks [14, 15] is the presence of lock dependencies introduced by *interrupt preemption* [68]. Specifically, interrupt preemption is an asymmetric process [43], in which a preempted thread is required to wait until the ISR completes before it can proceed. Consequently, any locks held by the preempted thread cannot be released until the ISR finishes its execution. When the ISR itself attempts to acquire locks, it can give rise to lock dependencies, potentially resulting in cyclic lock acquisitions.

For example, consider Figure 4(a), in which lock b is held by thread $T2$ and the thread is preempted by an ISR that acquires another lock a. In this scenario, the interrupt lock dependency $b \rightsquigarrow a$ appears, as $T2$ cannot release lock b until the ISR finishes. When considering the regular lock dependency $a \rightarrow b$ introduced by $T1$ together, an interrupt-based deadlock could happen under the specific thread and the interrupt interleaving.

Note that the thread switching cannot introduce the lock dependencies (e.g., $b \rightsquigarrow a$) as interrupt preemption. This is because if a thread is holding a lock and is switched out, it could be switched back at any time to release the lock it acquired. This paper refers to the lock dependencies introduced by interrupt preemption as *interrupt lock dependencies* and deadlocks that involve interrupt lock dependencies as *interrupt-based deadlocks*.

2.3 Limitations of Existing Static Detectors

Existing static deadlock detection techniques [7, 14, 15, 18, 34, 35] do not consider the interrupt lock dependencies and model interrupts in the same way as threads. As a result, they cannot detect interrupt-based deadlocks. Consider the example program in Figure 4(b), where the interrupt in Figure 4(a) is modeled as thread $T3$ by the existing deadlock detectors and then the interrupt preemption is not captured to identify the lock dependency $b \rightsquigarrow a$. Consequently, the existing static deadlock detectors, which model interrupts as threads, are unable to detect deadlock situations that arise from interrupts.

Some works [38, 75] detect other specific interrupt-related concurrency bugs like data race [46, 75, 80] or atomicity violation [28, 38]. However, the challenges associated with modeling and detecting these types of bugs differ from those encountered in deadlock detection. Therefore, their approaches cannot be directly applied to identify interrupt-based deadlocks effectively.

2.4 Security Impacts of Interrupt-Based Deadlocks in the Linux Kernel

Threat Model. We characterize the deadlock vulnerability as potential lock acquisitions that can be exploited by local or remote adversaries. These adversaries have the capability to trigger specific deadlock-introducing ISRs through various means, such as remote network packets, local system call execution, or physical hardware access, manipulating the control flow. When these deadlock-introducing ISRs in the system are periodically activated and happen to preempt the execution of code involving vulnerable and cyclic lock acquisitions, a deadlock situation can arise. Once this deadlock is exploited, the corresponding ISRs can seize CPU cores, causing them to remain indefinitely stuck [2, 4, 5] and leading to issues like lockup [70] or system crashes. A concrete instance of the deadlock (CVE-2023-0160) [56] was reported in the BPF subsystem, allowing low-privileged local attackers to exploit the deadlock and crash the system.

Conventional deadlocks primarily impact blocked threads, allowing other threads to continue execution [7, 15]. In contrast, interrupt-based deadlocks pose a more severe impact by monopolizing the CPU with deadlock-introducing ISRs, resulting in a complete blockage of the entire system's execution and halting further progress.

3 Archerfish in a Nutshell

We present the problem formulation, the challenges, and our solutions to interrupt-based deadlock detection.

3.1 Problem Formulation and Challenges

In essence, interrupt-based deadlocks are cyclic lock dependencies that occur due to interrupt preemption. To identify and address these deadlocks, we introduce ILG by extending the conventional notion of lock graphs [15, 33], which incorporate both interrupt lock dependencies and regular lock dependencies as lock edges. As a result, the problem of interrupt-based deadlock detection is formulated as the construction of ILG and the discovery of feasible deadlock cycles within the graph. However, three challenges hinder the precise and efficient ILG construction and deadlock cycle validation.

C1: Lack of ISR Registration Specifications. Various methods exist to register interrupt handlers in Linux, a complex and feature-rich OS kernel containing many subsystems [74]. As shown in Figure 3 (a), without any domain-specific knowledge, it is difficult to identify that `net_device_ops.ndo_start_xmit` is a callback interface executed under the softirq context. However, identifying functions executed under interrupt contexts is the prerequisite for capturing interrupt preemption and interrupt lock dependencies. Thus, lacking domain-specific knowledge about ISR registration poses a significant challenge for interrupt-based deadlock detection.

C2: Large Interrupt-Involving Reasoning Space. The concurrency reasoning space of thread interleaving already grows exponentially with the number of statements [19, 65], and this complexity is further amplified by the presence of interrupt preemption. In particular, efficiently and precisely capturing lock dependencies becomes challenging when considering the interrupt enabling/disabling state at each statement, and the state could vary under different calling contexts, which require expensive context-sensitive analysis [79]. For example, in the Figure 1(a), `clear_work_bit()` could be preempted by the ISR `s5p_mfs_irq()` when called by function `enc_post_frame_start()`, but not when called by function `s5p_mfc_watchdog_worker()` because hardirq is already disabled by `spin_lock_irqsave()` at Line 184. Worse still, the large codebase of the Linux kernel also further complicates the interruption-involving concurrency reasoning space.

C3: Validation of Feasible Lock Dependencies. Finally, not all lock dependencies are feasible during runtime execution. First, the interrupt preemption leading to some lock dependencies may be infeasible as the preemption cannot happen before the corresponding ISR is registered [3]. Second, the path conditions of certain lock dependencies could also be infeasible. However, the large number of lock dependencies to validate and the high overhead (e.g., SMT solving [82]) of feasibility checking make efficient validation challenging.

3.2 Four Core Stages in Archerfish

The architecture of Archerfish is shown in Figure 2, consisting of four main stages to address these challenges.

S1: Interrupt Service Routine Identification (§5.1). Public LLMs like ChatGPT-4.0 are trained with vast online textual data, including those of Linux kernel [61]. Thus, we can consider LLMs as Linux *experts* and extract domain-specific knowledge about subsystem ISR registration from them. The subsystem specifications generated by LLMs would complement a set of standard ISR registration specifications modeled by humans.

S2: Lockset and Interrupt-State Analysis (§5.2). To effectively reason about the interrupt preemption and capture interrupt lock dependencies, our basic idea is that statements inside the same critical section share the same lockset. Consequently, instead of enumerating the possibility of interrupt preemption at each program location, we treat all statements in a critical section as a *preemption unit*, calculating a unified state of interrupts for the unit and reducing the preemption reasoning space. Furthermore, we propose a compositional and summary-

based data-flow analysis to compute the lockset and interrupt state at interesting statements.

S3: ILG Construction (§5.3). By inspecting the computed data-flow facts, both *Interrupt Lock Edge (ILE)* and *Regular Lock Edge (RLE)* are captured to construct an ILG. Specifically, we capture RLEs by examining the lockset on statements of interest, while we capture ILEs by pairwise checking between several precomputed summaries on preempted threads and ISRs. After constructing ILG, a standard cycle detection algorithm [29] is run to identify potential deadlock cycles.

S4: Deadlock Cycle Validation (§5.4). Instead of performing heavyweight feasibility checking on each identified lock dependency edge, we delay the analysis by only performing feasibility checking on those forming a deadlock cycle. At this stage, Archerfish performs happen-before analysis [45,83] regarding ISR registration to examine the preemption feasibility and path-feasibility checking on each potential deadlock-leading dependency edge. Finally, deadlock reports are generated on validated interrupt-based deadlock cycles.

4 Preliminary

In this section, we introduce the definitions used in the paper and formulate the problem we aim to solve.

Abstract Domain. Figure 5 shows the basic abstract domain, where the symbol $s \in \mathbb{S}$ represents each statement in a standard LLVM-like language. Specifically, lock- and interrupt-related API call sites are modeled during static analysis. The symbol $o \in \mathbb{O}$ represents each lock object, and a cyclic dependency among them forms a deadlock. The symbol $t \in \mathbb{T}$ represents a kernel thread executing under the process context, while $isr \in \mathbb{R}$ represents an ISR [3] executing under the interrupt context, including both hardirq and softirq. Note that identification of ISRs is important for Archerfish to capture interrupt lock dependencies and perform deadlock detection. We give more details of ISR identification in § 5.1.

The $\mathbb{LS}$ and $\mathbb{RS}$ represent the lockset and the interrupt states computed by typestate analysis. Lockset $\mathbb{LS}$ maintains whether a specific lock $o \in \mathbb{O}$ is **A**cquired, **R**eleased or its state is Unknown ($\bot$). Interrupt state $\mathbb{RS}$ maintains whether a specific $isr \in \mathbb{R}$ is **E**nabled, **D**isabled or its state is Unknown ($\bot$). To reach flow-sensitivity, we compute a unique lockset $\mathbb{LS}$ and interrupt state $\mathbb{RS}$ at each statement $s \in \mathbb{S}$. For example, at Line 186 of the program in Figure 1(a), we identify that $\mathbb{LS} = (irqlock, \mathbf{A})$ and $\mathbb{RS} = (s5p\_mfc\_irq(), \mathbf{D})$, indicating *irqlock* is **A**cquired and $s5p\_mfc\_irq()$ is **D**isabled. Both $\mathbb{LS}$ and $\mathbb{RS}$ are derived from a compositional typestate analysis described in § 5.2, forming the foundation of deadlock detection.

Next, we formally define the notion of ILG.

Statements	$s \in \mathbb{S}$	Locks	$o \in \mathbb{O}$
Threads	$t \in \mathbb{T}$	Interrupt Handlers	$isr \in \mathbb{R}$
Lockset	$\mathbb{LS} := \mathbb{S} \to (\mathbb{O}, TY)$,		
	where $TY = \{\underline{\mathbf{A}}cquired, \underline{\mathbf{R}}eleased, \bot\}$		
Interrupt State	$\mathbb{RS} := \mathbb{S} \to (\mathbb{R}, ST)$,		
	where $ST = \{\underline{\mathbf{E}}nabled, \underline{\mathbf{D}}isabled, \bot\}$		

Figure 5: Basic abstract domain.

Definition 1. The Interrupt-Aware Lock Graph (ILG) is defined as a three-tuple, $G = (N, E_S, E_I)$.

- N denotes the set of vertices in ILG, where each vertex represents a unique lock object o.
- E_S represents a set of regular lock edges with the form $o_1 \to o_2$, indicating that during thread or ISR execution, lock o_2 could be acquired with o_1 held.
- E_I represents a set of interrupt lock edges with the form $o_1 \rightsquigarrow o_2$, indicating that at certain program points, lock o_1 is held while an ISR preempts the execution and subsequently acquires o_2.

At a high level, interrupt lock edges are constructed by pairwise matching between preemption units and summaries of lock acquisition inside ISRs, both of which are constructed in § 5.2. We give more details of ILG construction in § 5.3. With the definition of ILG, we further define the concept of Interrupt-Based Lock Cycle (ILC).

Definition 2. An Interrupt-Based Lock Cycle (ILC) is a cycle on ILG where at least one of the edges on the cycle belongs to E_I, representing a potential deadlock introduced by interrupt preemption.

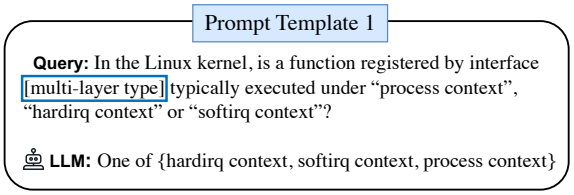

Figure 1(c) shows an example of ILC constituting an interrupt lock edge ②⇝① and a regular lock edge ①→②. Note that an ILC does not necessarily represent a real interrupt-based deadlock in practice, so further validation is required to reduce false positives. We give a detailed illustration in § 5.4. In addition, this paper focuses on detecting interrupt-based deadlocks, despite Archerfish being capable of detecting conventional deadlocks.

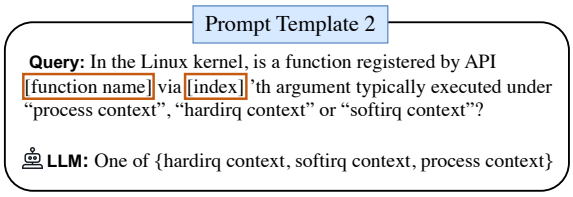
5 The Approach of Archerfish



In this section, we detail each core stage in Archerfish.

5.1 ISR Identification

Prompt queries with LLMs allow us to automatically extract ISR registration specifications in Linux subsystems, which supplement manually modeled standard specifications with a complete list shown in appendix A.3.

(a) Prompt template for ISR registration interface

(b) Prompt template for ISR registration API

Figure 6: Prompt templates for LLM-assisted specs.

To construct a prompt query [66], Archerfish performs static analysis to trace each address-taken function along its def-use chain until reaching one of the two cases:

- **Registration Interface:** If the function pointer $fptr$ is used as $*p = fptr$, we take the struct $type$ of p as a potential ISR registration interface. The $type$ would be used to construct a prompt query via the example template shown in Figure 6(a) to determine under which context the interface is executed.
- **Registration API:** If the function pointer $fptr$ is used as $call\ bar(..., fptr, ...)$, we extract the callee function name and its argument index, treating them as a potential ISR registration API. Similarly, these information would be used to construct a prompt query via the template in Figure 6(b).

LLMs can act as a classifier for the execution context of queried APIs or interfaces. With such specifications, we can identify whether a function is an ISR or a kernel thread by inspecting whether it is passed to these APIs or interfaces. Specifically, if an address-taken function is classified as *hardirq* or $softirq$, it would be identified as an $isr \in \mathbb{R}$, otherwise it would be identified as $t \in \mathbb{T}$.

Example 5.1. To determine whether the function `ks_wlan_start_xmit()` in Figure 3(a) is an ISR or a thread, Archerfish traces its def-use chain and reaches the structure field `net_device_ops.ndo_start_xmit`. This structure field is an interface commonly used by Linux network developers for `NET_TX_SOFTIRQ` softirq registration. In our experiment, LLM can correctly recognize that it is executed under the $softirq$ context.

5.2 Lockset and Interrupt-State Analysis

Next, we perform a flow- and context-sensitive typestate analysis for computing lockset and interrupt states. Specifically, Archerfish runs forward data-flow analyses

$$\frac{\texttt{s:lock(o)}}{\mathbb{LS}(s) \cup \{o \mapsto \mathbf{A}\}}\ (1) \qquad \frac{\texttt{s:unlock(o)}}{\mathbb{LS}(s) \cup \{o \mapsto \mathbf{R}\}}\ (2)$$

$$\frac{\texttt{s:disable\_irq(isr)}}{\mathbb{RS}(s) \cup \{isr \mapsto \mathbf{D}\}}\ (3) \qquad \frac{\texttt{s:enable\_irq(isr)}}{\mathbb{RS}(s) \cup \{isr \mapsto \mathbf{E}\}}\ (4)$$

$$\frac{\begin{array}{c}\texttt{s:merge}(\texttt{s}_1,\texttt{s}_2) \\ (o \mapsto ty_1) \in \mathbb{LS}(s_1),\ \ (o \mapsto ty_2) \in \mathbb{LS}(s_2) \\ (isr \mapsto st_1) \in \mathbb{RS}(s_1),\ \ (isr \mapsto st_2) \in \mathbb{RS}(s_2)\end{array}}{\begin{array}{l}\mathbb{LS}(s) \cup \{o \mapsto LS_{merge}(ty_1,\ ty_2)\} \\ \mathbb{RS}(s) \cup \{isr \mapsto RS_{merge}(st_1,\ st_2)\}\end{array}}\ (5)$$

$$LS_{merge}(ty_1, ty_2) = \begin{cases} \mathbf{A} & \texttt{if } ty_1 = \mathbf{A} \texttt{ or } ty_2 = \mathbf{A} \\ \mathbf{R} & \texttt{if } ty_1 = \mathbf{R} \texttt{ and } ty_2 = \mathbf{R} \\ \bot & \texttt{other cases} \end{cases}$$

$$RS_{merge}(st_1,\ st_2) = \begin{cases} \mathbf{E} & \texttt{if } st_1 = \mathbf{E} \texttt{ or } st_2 = \mathbf{E} \\ \mathbf{D} & \texttt{if } st_1 = \mathbf{D} \texttt{ and } st_2 = \mathbf{D} \\ \bot & \texttt{other cases} \end{cases}$$

Figure 7: Intra-procedural abstract operations

for each function following the reverse topological order on Call Graph (CG) [12, 16] and computes function summaries. These summaries can be inlined by callers to achieve efficient inter-procedural context-sensitive analysis and to be used for efficient ILG construction.

5.2.1 Intra-Procedural Data-Flow Analysis

At the entry of an analyzed function, the state of each lock o and isr are initialized as $\bot$. Next, Archerfish proceeds forward along the control flow graph to analyze each instruction sequentially until the function returns. The state at each instruction is initialized as a merge of states at its predecessors, and then the corresponding abstract operation shown in Figure 7 is used. A concrete list of modeled APIs can be found in appendix A.2.

Next, we provide a detailed illustration of the abstract operations. Note that the strong update [25], denoted by the $\mapsto$ operator, is applied to achieve flow-sensitivity.

- **Lock Acquisition and Release**: At each lock-acquisition API call $lock(o)$, Archerfish applies (1) $o \mapsto \mathbf{A}$ on the current lockset, indicating the state of lock o is updated as **A**cquired. A similar operation (2) is applied at each lock-release API call $unlock(o)$.
- **Interrupt Disabling and Enabling**: At each ISR-disabling API call $disable\_irq(isr)$, Archerfish performs the operation (3) $isr \mapsto \mathbf{D}$ on the current interrupt state to mark isr as **D**isable. The opposite operation (4) is performed at ISR-enabling API calls.
- **Merging.** The (5) merge operation first retrieves the lockset and interrupt states at predecessor in-

Preempt Summary	$\mathbb{M}_1 := (\mathbb{O}, \mathbb{S}) \rightarrow (\mathbb{R}, ST)$, *where* $ST = \{\mathbf{E}, \mathbf{D}\}$
Locking Summary	$\mathbb{M}_2 := (\mathbb{O}, \mathbb{S}) \rightarrow \mathbb{O}$
Return Summary	$\mathbb{M}_3 := (\mathbb{RS}, \mathbb{LS})$

Figure 8: Three function summaries

structions, and then performs LS_{merge} and RS_{merge} to conservatively merge these states. Specifically, *may* analysis is used to determine whether a lock o could be **A**cquired or whether an *isr* could be **E**nabled.

Example 5.2. If the typestate from one incoming branch is $\{(o, \mathbf{A}),\ (isr, \perp)\}$ and that from the opposite branch is $\{(o, \mathbf{R}),\ (isr, \mathbf{E})\}$, the merged results would be $\{(o, \mathbf{A}),\ (isr, \mathbf{E})\}$, indicating lock o could be acquired and *isr* could be enabled at the branches confluence.

5.2.2 Function Summary Construction

Figure 8 shows the definition of three function summaries constructed along the data-flow analysis.

- **Preemption Unit Summary ($\mathbb{M}_1$)**: This summary forms the units of interrupt preemption. Each summary item represents a critical section, denoted by a lock object and a lock statement $(o,\ s)$. The item also maintains a set of conservative interrupt states, representing the set of ISRs that could preempt this critical section. To do so, we record *must*-**D**isabled and *may*-**E**abled state of each already analyzed ISR.
- **Lock Acquisition Summary ($\mathbb{M}_2$)**: This summary represents lock acquisitions inside a function. Each summary item is also denoted by a lock object and a lock statement $(o,\ s)$. Different from $\mathbb{M}_1$, the item in $\mathbb{M}_2$ records a set of locks that *must* have been **R**eleased before this lock acquisition.
- **Return State Summary ($\mathbb{M}_3$)**: This summary caches the lockset and interrupt states at the end of a function, which can be inlined by caller functions to update the typestate at call sites.

Summary Construction. Algorithm 1 shows how to construct the three summaries. First, for each encountered lock-acquisition API call $s : lock(o)$, we construct a new item of $\mathbb{M}_1$, recording the set of ISRs that *must* have been **D**isabled and cannot preempt the current critical section (Line 3). Similarly, we construct a new item of $\mathbb{M}_2$, recording the set of locks *must* have been **R**eleased before lock o is acquired (Line 4). Second, for each ISR-enabling API call $s : enable\_irq(isr)$ (including those inlined from callee's summary), we first retrieve the set of locks $(o,\ s')$ guarding s, and update corresponding items of $\mathbb{M}_1$ to mark that *isr may* be **E**nabled inside the critical sections (Lines 5-7). Finally, at the function return,

Algorithm 1: Function Summary Construction

```
1 Function SummaryConstruction(s):
2     case s : lock(o) do
3         M1[(o, s)] := {(isr, D) : (isr, D) ∈ RS[s]};
4         M2[(o, s)] := {o' : (o', R) ∈ LS[s]};
5     case s : enable_irq(isr) do
6         foreach o : (o, A) ∈ LS[s], acquired at s' do
7             M1[(o, s')] ∪ (isr, E)
8     case s : return do
9         M3 := (RS[s], LS[s])
```

Algorithm 2: Function Summary Inlining

```
1 Function SummaryInlining(s : call bar()):
2     Retrieve M1', M2' and M3' from bar
3     foreach isr : (isr, D) ∈ RS[s] do
4         foreach (o', s') : (isr, E) ∉ M1'[(o', s')] do
5             M1'[(o', s')] ∪ (isr, D)
6     foreach o : (o, R) ∈ LS[s], (o', s') ∈ M2' do
7         M2'[(o', s')] ∪ {o}
8     Append M1', M2' to M1, M2
9     Update RS, LS by M3'
```

$\mathbb{LS}$ and $\mathbb{RS}$ would be cached as $\mathbb{M}_3$ (Lines 8-9), used by callers to update typestates at call sites.

5.2.3 Function Summary Inlining.

At a call site of an already analyzed function, constructed summaries inside the callee function can be inlined by the caller for context-sensitive inter-procedural analysis. Algorithm 2 shows the detail of the inlining process.

Summary Inlining. Archerfish first retrieves the three summaries $\mathbb{M}_1'$, $\mathbb{M}_2'$ and $\mathbb{M}_3'$ constructed in callee function (Line 2). Before inlining the summary, we take two steps. First, if some ISRs have already been disabled at the call site and are not enabled inside the callee's preempt unit, Archerfish will update the summary item in $\mathbb{M}_1'$ by marking the state as **D**isabled. (Lines 3-5). Second, some locks have already been **R**eleased before the call site, so Archerfish needs to insert these released locks into each item of callee's $\mathbb{M}_2'$ (Lines 6-7). After these, callee's $\mathbb{M}_1'$ and $\mathbb{M}_2'$ would be inlined (Line 8), and the current lockset and interrupt states are updated by callee's Return State Summary $\mathbb{M}_3'$ (Line 9).

Example 5.3. Figure 9 shows partial analysis results of Figure 1. Once `clear_work_bit()` is analyzed, its summary $\mathbb{M}_1$ contains a preemption unit $\{(\texttt{condlock}, s_{52}) : \{\}\}$, indicating that the critical section $(\texttt{condlock}, s_{52})$ does not execute with any ISR explicitly enabled or disabled. Next, the summary is inlined by two caller

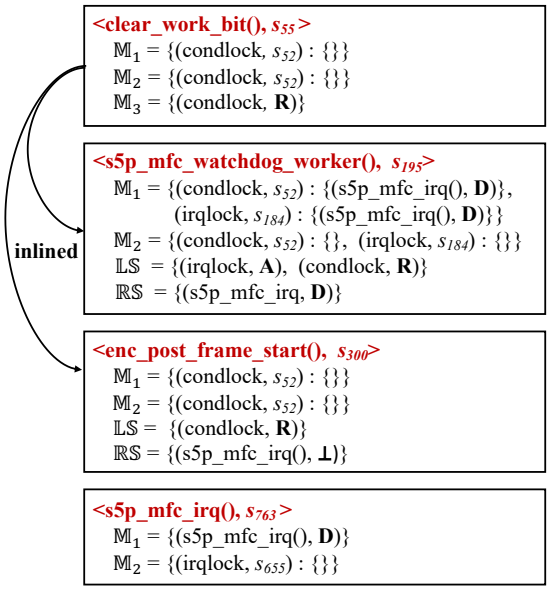


Figure 9: The analysis result for code in Figure 1.

functions. For caller `s5p_mfc_watchdog_worker()`, since the hardware ISR `s5p_mfc_irq()` is already disabled at Line 184, the summary $\mathbb{M}_1$ is updated to $\{(\texttt{condlock}, s_{52}) : \{(\texttt{s5p\_mfc\_irq()}, \mathbf{D})\}\}$, indicating that all statements inside the critical section cannot be preempted by `s5p_mfc_irq()`. On the contrary, no ISR is explicitly disabled or enabled inside the caller `enc_post_frame_start()`, so the summary item $\{(\texttt{condlock}, s_{52}) : \{\}\}$ is inlined without being updated.

5.3 Interrupt Lock Graph Construction

In this stage, Archerfish proceeds to perform ILG construction. The core algorithm is shown in Algorithm 3.

Interrupt Lock Edge Construction. Interrupt lock dependencies are captured as interrupt lock edges ($\mathbf{E_I}$). As shown in `InterruptLockEdgeAnalysis()`, pairwise matching is run between each preemption unit ($\mathbb{M}_1$) of lock o inside a function f and each higher priority *isr* (Lines 2-5). If the *isr* is not disabled inside the preemption unit, for each lock acquisition ($\mathbb{M}_2$) of o' inside *isr*, an interrupt lock edge $o \rightsquigarrow o'$ is constructed (Lines 6-10).

Regular Lock Edge Construction. Regular lock dependencies are captured as regular lock edges ($\mathbf{E_S}$). As shown in `RegularLockEdgeAnalysis()`, for a *lock* statement on lock o and each already acquired lock o', a regular lock edge $o' \rightarrow o$ is constructed (Lines 12-14) ; while for a *call* statement, Archerfish performs pairwise matching between each already acquired lock o and each acquisition of lock o' inside the callee function. If o is not released before o' is acquired inside the callee, a regular lock edge $o \rightarrow o'$ is constructed (Lines 15-20).

Once ILG is constructed, we use a standard cycle-detection algorithm [29] to identify an initial set of ILCs.

Algorithm 3: ILG Construction

```
1  Function InterruptLockEdgeAnalysis():
2      foreach f ∈ 𝕋 ∪ ℝ, isr ∈ ℝ do
3          if isr has higher priority than f then
4              Retrieve 𝕄1 from f;
5              foreach (o, s) ∈ 𝕄1 do
6                  if (isr, D) ∈ 𝕄1[(o, s)] then
7                      continue;
8                  Retrieve 𝕄2′ from isr;
9                  foreach (o′, s′) ∈ 𝕄2′ do
10                     add o ⇝ o′
11 Function RegularLockEdgeAnalysis(s):
12     case s : lock(o) do
13         foreach (o′, A) ∈ 𝕃𝕊[s] do
14             add o′ → o ;
15     case s : call bar() do
16         Retrieve 𝕄2 from bar;
17         foreach o : (o, A) ∈ 𝕃𝕊[s] do
18             foreach (o′, s′) ∈ 𝕄2 do
19                 if o ∉ 𝕄2[(o′, s′)] then
20                     add o → o′
```

Example 5.4. In Figure 9, by running pairwise matching between summaries $\mathbb{M}_1$ of `enc_post_frame_start()` and $\mathbb{M}_2$ of `s5p_mfc_irq()`, we can construct an interrupt lock edge *condlock* $\rightsquigarrow$ *irqlock*. By performing pairwise matching between $\mathbb{M}_2$ of `clear_work_bit()` and $\mathbb{LS}$ of `s5p_mfc_watchdog_worker()` at s_{195}, we can construct a regular lock edge *irqlock* $\rightarrow$ *condlock*. As a result, the two lock edges form an ILC, as shown in Figure 1(c).

5.4 Lazy Deadlock Cycle Validation

Finally, each detected ILC is validated in terms of both the happen-before relationship and path feasibility.

5.4.1 Interrupt Happen-Before Validation

Synchronization between threads and ISRs should be characterized to ensure a true deadlock. Specifically, since interrupt preemption cannot happen before it is registered, all statements before ISR registration cannot be preempted. To this end, we perform a static happen-before analysis to validate the feasibility of an interrupt lock edge $o \rightsquigarrow o'$ in terms of ISR registration. Specifically, we perform a forward search from the last statement of the preemption unit of o, following the context-sensitive control flow graph. Once the registration statement of the ISR acquiring o' is found during the graph traversal, the interrupt lock edge is considered invalid.

$$\Phi(\circ) = \bigwedge_{e \in E_S} \Phi_S(e) \wedge \bigwedge_{e' \in E_I} \Phi_I(e')$$

$$\Phi_S(e) = \underbrace{\bigvee_{p \in P(T_{entry},\, s)} \Phi(p)}_{(1)} \wedge \underbrace{\bigvee_{p' \in P(s,\, s')} \Phi(p')}_{(2)}$$

$$\Phi_I(e) = \underbrace{\forall s \in S_p, \bigvee_{p \in P(T_{entry},\, s)} \Phi(p)}_{(3)} \wedge \underbrace{\bigvee_{p' \in P(R_{entry},\, s')} \Phi(p')}_{(4)}$$

Figure 10: Path-feasibility constraints of an ILC

5.4.2 Interrupt Path-Feasibility Validation

Figure 10 shows the path constraints $\Phi(\circ)$ of an ILC (denoted by $\circ$), which consist of two parts: path constraints on regular lock edges, denoted as $\Phi_S(e)$ and the path constraints on interrupt lock edges, denoted as $\Phi_I(e')$. The Z3 SMT solver is used to determine path feasibility.

Regular Lock Edge. At a high level, the path constraints $\Phi_S(e)$ of a regular lock edge represent that at least one path starting from the entry point could lead to lock dependency $o \rightarrow o'$. To do so, we first collect the disjunctive path conditions of each path from the entry to the first lock acquisition site s of o, as shown in Figure 10 (1). Second, we collect the disjunctive path conditions of each path from s to the second lock acquisition site s' of o', as shown in Figure 10 (2).

Interrupt Lock Edge. The path condition $\Phi_I(e)$ of an interrupt locking edge $o \rightsquigarrow o'$ is more complicated, as the preemption at each statement inside the preemption unit with target ISR enabled (denoted by S_p) should be considered. Consequently, the disjunctive path conditions of each path from entry to each statement s in S_p are encoded, as shown in Figure 10 (3). Finally, the disjunctive path conditions of each path from ISR entry to lock acquisition site s' are encoded, as shown in Figure 10 (4).

Example 5.5. Figure 11 depicts the path conditions on the interrupt lock edge *s_lock* $\rightsquigarrow$ *r_lock* when the critical section of `s_lock` in the `vq_alloc()` function is preempted by the `vq_heartbeat()` ISR. With two valid preemption points within the critical section, the first part constraint (Figure 10 (3)) is formulated as the disjunctive conditions of these two preemption points (① $\vee$ ②). The second part constraint (Figure 10 (4)) consists of the disjunctive conditions on program paths from the entry of `vq_heartbeat()` to the lock acquisition site of `r_lock` (③). By evaluating the conjunction of these two parts using an SMT solver, the constraints are satisfied, as the second preemption point ② is feasible along the path.

```
void vq_thread(...) {
    dev->vq = nullptr;
    ...
    spin_lock(dev->s_lock);          ①
    dev->vq = kmalloc(...);          ②
    spin_unlock(dev->s_lock)
    ...                                  preempt
}
void vq_heartbeat(...) {
    ...
    if (!dev->vq)
      return;
    spin_lock(dev->r_lock);          ③
    ...
}
```

① ② ③

$(dev\text{->}vq = 0 \vee dev\text{->}vq = new\_o) \wedge (dev\text{->}vq \neq 0)$

Figure 11: An example of path-feasibility validation. The symbol *new_o* is the return value of `kmalloc()`.

6 Implementation

Archerfish is implemented on LLVM [36] (4,034 Loc) and uses Z3 [82] as its path condition solver. Several Python scripts (354 Loc) are implemented to perform network interaction with the OpenAI RESTful API [49]. For the pointer aliasing information, we use a standard pointer analysis, following the previous work [21, 48].

Lockset and Interrupt-State Analysis. Archerfish performs analysis by modeling a set of locking and interrupt-related APIs in the Linux kernel. Appendix A.2 shows the whole set of these APIs. To avoid these APIs being inlined during compilation, we attach `__attribute__((noinline))` attribute on these functions before compilation. We model several heavily used lock types in the Linux kernel, such as `spin_lock` and `rw_lock` [69], and model both the hardware and software interrupts (e.g., timer and tasklet [44]).

LLM-Assisted Specification Generation. The program data for constructing prompt queries, including the struct types [47] and function names, are extracted from compiled LLVM IR. Since the LLVM type system does not contain the name of the structure field types, we compile the Linux kernel with the "-g" option and parse LLVM metadata to extract such information. To construct prompt queries, we use RESTful APIs provided by Azure OpenAI Service and ChatGPT-4.0 model [49].

Path Conditions Solving. Path feasibility is validated with Z3 SMT solver, where each variable in the LLVM IR is modeled as a bit vector, on top of which arithmetic computation and guarded constraints can be modeled and solved. Following existing works [7, 14], the conditions solving is under-constrained, losing the bounds of external values (e.g., those derived from hardware IO operations or input arguments of root functions). As a result, false positives are possible due to the presence of under-constrained values.

7 Evaluation

This section presents the evaluation results of Archerfish, through investigating the following research questions:

- **RQ1:** How effective is Archerfish in detecting interrupt-based deadlocks? (§ 7.1)
- **RQ2:** How do the stages contribute to enhancing the effectiveness of Archerfish? (§ 7.2)

We also discuss other points, such as the false negatives and generalizability of our approach in § 7.3.

Experiment Setup. We built the source code of Linux to LLVM IR using clang-12 and evaluated the latest version Linux (v6.4) at the time of the experiment. Following the conventional setup, we used the built-in `allyesconfig` setting during compilation. To generate subsystem specifications, Archerfish relies on the Azure OpenAI Service APIs [49] and uses the ChatGPT-4.0 model for evaluation. While performing the prompting, we set the temperature as 0.1 and set Top-p as 0.2, to achieve relatively stable and accurate results. All experiments were conducted on an Ubuntu server with two 20-core Intel(R) Xeon CPU@2.20GHz and 256GB of physical memory.

Note that Archerfish is the first static tool for detecting interrupt-based deadlocks in Linux kernel. To the best of our knowledge, no other open-source tools are available that can serve as a basis for comparison. Crucially, Archerfish is specific to detect interrupt-based deadlocks that previous static methods have overlooked.

7.1 Effectiveness on Bug Detection

The Archerfish's effectiveness in detecting interrupt-based deadlocks is evaluated and summarized in Table 1.

Performance. Archerfish finished analysis of Linux v6.4 in 68.6 minutes with a peak memory of 38.3G. We inspected the time consumption of each step and found that the specification generation (Stage I), the data-flow analysis (Stage II), ILG construction (Stage III), and ILCs validation (Stage IV) consumes 31.0 mins, 28.4 mins, 1.3 mins, and 7.9 mins, respectively. The high proportion of time consumption in Stage I is mainly due to network communication with OpenAI, and the generated specifications can be reused for later analysis. These results demonstrate that Archerfish can scale up to large software like Linux within an acceptable timeframe.

False Positive Analysis. Archerfish reported 151 bugs with 75 false warnings, resulting in a 49.7% false positive rate. Specifically, we spent roughly 10 - 60 minutes examining each bug report, which depends on the complexity of the bug report and the corresponding source code. Two key reasons lead to false positives. First, the misidentification of ISRs or threads causes 34 of the false alarms. Specifically, out of these 34 false alarms, 21 are due to the case that an ISR cannot be identified and is misclassified as a kernel thread. Such misclassification leads to infeasible preemption scenarios, where the misclassified ISR is deemed able to be preempted by other ISRs. In the remaining 13 cases, a kernel thread is misidentified as an ISR due to incorrect specifications generated by LLMs, also leading to infeasible preemption scenarios. The high proportion of false alarms in this category indicates that correctly identifying ISRs is important to interrupt-based deadlock detection. Second, complex path conditions involving under-constrained values cause 25 false alarms. For example, Archerfish reports a false alarm on the function `gmc_v10_0_process_interrupt()`, which could be executed under both interrupt context and process context, depending on an under-constrained hardware status value received from IO operators. Since the actual execution path is directly controlled by the hardware status, such path constraints cannot be identified by static analysis. The remaining cases are associated with false alias relationships, which are inherent static analysis problems.

Table 1: Analysis results on the Linux kernel v6.4

	Description	Results
Linux kernel statistics	Lines of source code	19.8M
	Number of functions	798.3K
Performance	Peak memory	38.3G
	Time spend on Stage I (Spec. generation)	31.0 mins
	Time spend on Stage II (Data-flow analysis)	28.4 mins
	Time spend on Stage III (ILG construction)	1.3 mins
	Time spend on Stage IV (ILC validation)	7.9 mins
	Total time (Stages I - IV)	68.6 mins
Precision	Validated ILCs **(detected bugs)**	151
	Real interrupt-based deadlocks **(real bugs)**	76
ISR and thread identification	Kernel threads	136,207
	Softirq ISRs by manual-model specifications	689
	Hardirq ISRs by manual-model specifications	1,226
	Softirq ISRs by LLM-assisted specifications	578
	Hardirq ISRs by LLM-assisted specifications	1,151
	Total tokens used for prompt query	752,666
ILG construction	Preempt units	309,821
	Preempt units with ISRs enabled	234,547
	Total ISRs	3,644
	ISRs containing lock acquisitions	1,449
	Lock acquisition inside ISRs	5,957
	Regular lock edges	1,507,760
	Interrupt lock edges	3,962,932
Interrupt-based deadlocks detection	Detected ILCs	353
	Invalid ILCs	202
	ILCs pruned by happen-before analysis	67
	ILCs pruned by path-feasibility validation	135
	Validated ILCs brought by hardirq preemption	52
	Validated ILCs brought by softirq preemption	99

Real-World Impacts. We manually reviewed all the detected interrupt-based deadlocks and identified 76 of them as genuine and new bugs. These interrupt-based deadlocks are difficult to detect, as they have remained hidden for an average of 9.9 years. We wrote 37 patches to fix these bugs and sent the patches to the corresponding Linux kernel subsystem developers. Currently, 53 of these bugs have been confirmed by the Linux kernel developers, and most of the bug-fixing patches have al-

Table 2: Accuracy of LLM-Assisted Specifications

Hardirq		Softirq	
Precision	Recall	Precision	Recall
78.6	87.3	80.6	88.0

ready been merged into the mainstream Linux kernel or corresponding subsystem development branch, resulting in 46 bugs already fixed.

The detected interrupt-based deadlocks cover numerous subsystems of Linux kernel, including various device drivers, network stack, and filesystems. Linux kernel developers highly appreciated our bug-reporting and patch-submitting efforts and demonstrated high interest in our tool with comments like *"Will this tool be available for general use? It's obviously quite handy."*, *"Your experimental tool looks really promising."*, *"Interesting."*. Furthermore, two bugs inside the SCTP and TIPC network subsystems are assigned 2 CVEs. Details of these detected bugs can be found in appendix A.4.

7.2 Effectiveness on Each Stage

Next, we investigate the key stages of Archerfish.

7.2.1 ISR Identification

We study how LLMs address the first challenge by inferring subsystem ISR registration specifications automatically. As shown in Table 1, among all the 3,644 ISRs identified by Archerfish, 1,729 (47.1%) are derived from the LLM-assisted subsystem specifications. During the process, Archerfish spent 752,666 tokens in prompting with the GPT-4 model, with 1,292 APIs and 19,172 interfaces collected and used in prompting.

Out of all the identified ISRs, 1,267 are softirq ISRs, while 2,377 are hardirq ISRs. ISRs only account for a small portion (2.6%) of all routines, compared to a large number of kernel threads (136,207). Despite their relatively small number, ISRs play a crucial role and lead to many interrupt-based deadlocks.

Accuracy of LLM-Assisted Specifications. To examine the precision of the LLM-assisted specifications, we randomly sampled 150 hardirq and 150 softirq ISRs from the generated specifications and manually inspected their correctness. Additionally, to examine the recall, we collected 150 real hardirq and 150 real softirq ISRs (the ground truth) from subsystem API documentation, code comments, or manual code reviewing, and checked whether they are covered by the LLM-assisted specifications. Table 2 shows that the overall precision and recall are 79.6% and 87.6%, respectively.

Ablation Study 1: LLM-Assisted Specifications. We further performed end-to-end ablation evaluation to examine the direct effect of LLM-assisted subsystem specifications on bug detection. As shown in Figure 12, with the LLM-assisted specifications, Archerfish detects 41 new bugs and misses 27 originally detected bugs, compared to Archerfish without the help of LLMs.

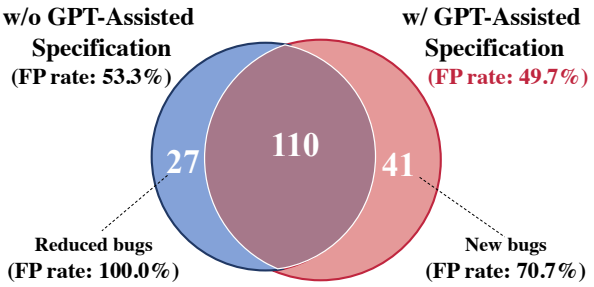

Figure 12: Bug reports of Archerfish with (denoted as $w/$) or without (denoted as w/o) the assistance of GPT.

We manually examined all the 27 missed bugs and confirmed they are false warnings. The false warnings arise from situations of infeasible preemption, where an ISR is not correctly identified and mistakenly classified as a kernel thread, thus allowing the ISR to be preempted by other ISRs incorrectly. With the LLM-assisted subsystem specifications, more real ISRs can be identified, thus reducing such infeasible preemptions.

Out of the 41 additionally reported bugs with the help of LLM-assisted specifications, 12 are true positives. The false positive rate of these additionally reported bugs is a bit higher (70.7% vs 53.3%) because the LLM-assisted specifications contain some fake ISRs. When considering together the 27 reduced bugs brought by infeasible preemption, the overall false positive rate remains similar (49.7% vs 53.3%). In conclusion, the specifications help Archerfish capture new preemption and reduce infeasible preemption with high precision, resulting in 12 more real bugs detected while remaining comparable FP rate shown in our evaluation. A case study of a real bug can be found in appendix A.1. To sum up, the effect of LLM-assisted specifications in Stage I of Archerfish is highly effective.

7.2.2 Lockset and Interrupt-State Analysis

We first present some statistical data in data-flow analysis (Stage II). During typestate analysis, 309,821 preempt units are constructed, and 234,547 among them have at least one ISR enabled. On the other hand, 5,957 lock acquisition summaries are constructed inside 1,449 ISRs. These lock acquisitions and preempt units can introduce interrupt lock dependencies, represented by interrupt lock edges on the ILG. Specifically, a total of 3,962,932 (72.4%) interrupt lock edges and 1,507,760 (27.6%) regular lock edges are constructed. This result indirectly indicates that, despite the number of ISRs be-

ing much smaller than kernel threads, interrupt preemption is a noteworthy source of deadlocks in the Linux kernel that existing deadlock detection tools have ignored.

Ablation Study 2: Preemption Unit. Next, we study the effectiveness of the interrupt preemption unit to address the large concurrency reasoning space. Importantly, the preemption unit can significantly reduce the time costs for interrupt preemption analysis, as only critical sections need to be checked instead of all statements. To demonstrate the importance of this design, we created an ablation group called Archerfish$^-$, where each statement is considered a unique preemption point, and executed Archerfish$^-$ with the same experiment setup. Our evaluation results indicate that Archerfish$^-$ takes 166.7 minutes to complete the analysis, resulting in a time overhead that is 2.43 times greater than before. The peak memory usage is also up to 130.2G (3.39x), as we require more memory resources to maintain enormous summaries for each statement during typestate analysis. In summary, using the preemption unit can significantly reduce the overhead regarding both time and memory.

7.2.3 Lazy Circular Lock Dependency Validation

We first demonstrate the effectiveness of deadlock cycle validation (Stage IV) to reduce false positives. By performing cycle detection on the ILG, we initially detected 353 ILCs. In total, 202 (57.2%) ILCs are pruned away during validation. Specifically, 67 ILCs are pruned by the interrupt happen-before validation, and 135 ILCs are dropped due to infeasible paths.

Ablation Study 3: Lazy Validation. We next explore the effectiveness of the lazy validation strategy in improving efficiency. As shown in Table 1, the number of lock edges (5,470,692) significantly exceeds the number of finally detected ILCs (353). Consequently, it is inefficient to validate the feasibility of every edge, highlighting the need for the lazy validation strategy.

7.3 Discussion

False Negative Study. We collected the past interrupt-based deadlocks and examined whether Archerfish can find them. Specifically, we searched the commit history of the Linux kernel using keywords, including "interrupt" and "deadlock", and examined each relevant commit message. We then identified 16 existing interrupt-based deadlocks in the past five years. These deadlocks were detected by Lockdep [73] or manual code review, 14 of which can be initially detected by Archerfish in their corresponding historical versions. We manually checked the two missed bugs and found that their critical ISRs cannot be identified with LLMs, resulting in the missed corresponding interrupt lock dependencies. By manually modeling those ISRs, Archerfish can finally detect those two bugs without inducing false negatives.

Generalizability. Archerfish aims to detect interrupt-based deadlocks on `spin_lock` and `rwlock` [69] inside the Linux kernel. However, the lockset analysis, ILG construction, and cycle validation are general to model various locks. We believe that, with further engineering effort, Archerfish can be extended to model other locking mechanisms (e.g., completion variables and waiting queues) or detect interrupt-aware deadlocks in other OS kernels [1]. We leave the extension as our future work.

8 Related Work

Concurrency bug detection in the OS Kernel is an important problem [6,8,9,24,27,80]. Among the diverse types of concurrency errors [15, 26, 37, 38, 67, 75], including data races [46, 75, 80], atomicity violation [28, 38] and deadlocks [7, 14], we focus on presenting the previous deadlock detection work in this section.

Static Deadlock Detection. Archerfish is specialized for detecting interrupt-based deadlocks and is orthogonal to existing works [7,14,15,21,34], which generally focus on deadlocks under thread interleaving and do not consider interrupt preemption. Recently, a few works were proposed for deadlock detection in specialized domains. For example, DeadWait [63] focuses on detecting deadlocks in asynchronous C# programs. Also, the work [58] proposes approaches for static communication deadlock detection in Go programs. Recently, DLOS [7] proposes a deadlock detection tool for OS kernel; however, their algorithm still does not consider interrupt preemption.

Dynamic Deadlock Detection. Dynamic tools like Lockdep [73] and ThreadSanitizer [64] can perform program instrumentation and monitor the runtime locking behaviors for deadlock detection. However, dynamic and static approaches have been separate realms for bug finding, having different merits. For thoroughly interrupt-based deadlocks detection with higher code coverage, a static bug detector has its advantages since there is no reliance on test cases or runtime environment like concurrency fuzzing [8, 11, 17, 27, 80] or controlled concurrency testing [57, 77]. As an illustration of its effectiveness, Archerfish has uncovered 76 previously unknown and long-latent interrupt-based deadlocks in the Linux kernel despite subjecting the system to stress testing and extensive fuzzing.

Finally, we are the first to use LLMs to infer interrupt specifications. Using LLMs for dynamic or static program analysis is an interesting recent trend [39,59,62,76] on it. We believe that using LLMs for specification generation would bring new inspiration for combining LLMs into security analysis and solving practical problems.

9 Conclusion

We have presented Archerfish, a static and effective approach for interrupt-based deadlock detection in the Linux kernel. Evaluation shows that Archerfish effectively analyzes the Linux kernel in around one hour, uncovering 76 previously unknown interrupt-based deadlocks, with 53 confirmed and mostly fixed (with two assigned CVE IDs), demonstrating its real-world impact.

A Appendix

A.1 Case Study of a Real Bug Detected with LLM-Assisted Specification

```
42  static int timbgpio_update_bit(...) {
43    struct timbgpio *tgpio = ...
44    ...
45
46    spin_lock(&tgpio->lock);
47    ......
48  }                    preempt

101 static void timbgpio_irq_disable(...) {
102   ...
103   unsigned long flags;
104
105   spin_lock_irqsave(&tgpio->lock, flags);
106 }
107
207 static struct irq_chip timbgpio_irqchip = {
208   .name  = "GPIO",
209   .irq_enable    = timbgpio_irq_enable,
210   .irq_disable   = timbgpio_irq_disable,
211   .irq_set_type =  timbgpio_irq_type,
212 };
```

Figure 13: A new interrupt-based deadlock detected after applying LLM-assisted specification.

Figure 13 shows one of the newly detected bugs after applying LLM-assisted specification. Since the function `timbgpio_update_bit()` acquires `tgpio→lock` under process context at Line 46, `timbgpio_irq_disable()` could preempt the execution and acquire the lock again under interrupt context at Line 105. In such a scenario, the CPU would spin on the lock infinitely, resulting in a system hang. The

key to detecting this bug is the expert knowledge that `timbgpio_irq_diable()` could be executed under the interrupt context, which is ignored by manual modeling. As `timbgpio_irq_diable()` is registered via the interface `irq_chip→irq_disable`, ChatGPT-4.0 can infer that this callback interface is executed during interrupt handling, enabling Archerfish to detect this self-cyclic interrupt-based deadlock.

A.2 Details of APIs used in Static Lockset and Interrupt-State analysis

Table 3 shows the list of APIs modeled for the lockset and interrupt-state analysis. Next, we illustrate some details of the implementation to model these APIs.

- **Lock/Unlock:** We model three kinds of commonly used locks inside the interrupt context, including `spin_lock`, `read_lock`, and `write_lock`. One special case in modeling is that read_lock operations allow concurrent accesses, whereas write_lock operations require exclusive accesses. As a result, two read_lock acquisitions do not introduce lock dependency, and we model these special cases in our tool.
- **Hardirq Enable/Disable:** There are several special cases in the API modeling. First, different APIs could disable/enable different sets of ISRs. The APIs `*_lock/unlock_irq()` and `*_local_irq_disable/enable()` operate on all the hardirq ISRs in the system, while APIs `enable/disable_irq()` only operate on a designated hardirq specified by an irq line number. As a result, we perform different operations on different APIs to model these differences. Second, APIs end with `_irqsave()` or `_irqrestore()` suffix would store/load the interrupt state into/from a local flag variable. Thus, we perform a local data-flow analysis to track the interrupt state stored inside the flag variable.
- **Softirq Enable/Disable:** Compared with hardirq, the modeling for softirq is relatively simple. Specifically, each one of these APIs would disable/enable all the softirq ISRs in the system.

A.3 Details of Manually Modeled ISR Registration APIs in the Linux Kernel

Table 4 shows some standard APIs used by all the subsystems in Linux. Since there are well-defined documentations [42, 44], we can manually model them in the implementation.

- **Hardirq:** Standard APIs such as request_irq() are used for hardware interrupt handler registration, and they are well-defined in the documentation of Linux Kernel [42]. Thus, we can manually model these commonly used hardware ISR registration APIs.
- **Softirq:** The timer, tasklet, and polling are well-known types of software interrupt handlers in the Linux kernel, and corresponding registration APIs are well-defined in the Linux Kernel documentation [44]. We also manually model the corresponding APIs.

For subsystem APIs or interfaces that are not well-defined, we resort to LLM-assisted specifications.

Table 3: List of manually modeled APIs for the lockset and interrupt-state analysis.

Category	APIs
Lock	spin/read/write_lock() spin/read/write_lock_irq() spin/read/write_lock_irqsave() spin/read/write_lock_bh()
Unlock	spin/read/write_unlock() spin/read/write_unlock_irq() spin/read/write_unlock_irqrestore() spin/read/write_unlock_bh()
Hardirq Enable	spin/read/write_unlock_irq() spin/read/write_unlock_irqrestore() enable_irq_nosync() local_irq_enable(), enable_irq()
Hardirq Disable	spin/read/write_lock_irq() spin/read/write_lock_irqsave() disable_irq_nosync() local_irq_disable(), disable_irq()
Softirq Enable	spin/read/write_unlock_bh() local_bh_enable()
Softirq Disable	spin/read/write_lock_bh() local_bh_disable()

Table 4: Manually modeled APIs for ISR registration.

Category	APIs
Hardirq Registration	devm_request_irq() devm_request_threaded_irq() request_irq(), request_threaded_irq() request_percpu_irq()
Softirq Registration	tasklet_init(), timer_setupt() irq_poll_init(), open_softirq()

A.4 Detected Deadlocks

Table 5 presents a list of all the bugs detected. Two bugs detected inside SCTP and TIPC subsystems are assigned CVE-2024-0639 and CVE-2024-0641, respectively.

Table 5: List of 76 interrupt-based deadlocks detected by Archerfish on Linux kernel v6.4. Each row displays the subsystem name, the preempted function that introduces the deadlock, whether the bug is detected with the help of LLM-assisted specifications, and the status of the bug. ● denotes the corresponding bug-fixing patch is already merged into Linux, ◐ denotes developers already confirmed the bug by adding "Acked-by" or "Reviewed-by" tags under the patch and prepared to accept the patch, and ○ denotes the patch is still under review.

Abstract

Race conditions arise when multiple threads attempt to access a shared resource without proper synchronization, often leading to vulnerabilities such as concurrent use-after-free. To mitigate their occurrence, operating systems rely on synchronization primitives such as mutexes, spinlocks, etc.

In this paper, we present GhostRace, the first security analysis of these primitives on *speculatively executed* code paths. Our key finding is that *all* the common synchronization primitives can be microarchitecturally bypassed on speculative paths, turning *all* architecturally race-free critical regions into *Speculative Race Conditions (SRCs)*. To study the severity of SRCs, we focus on Speculative Concurrent Use-After-Free (SCUAF) and uncover 1,283 potentially exploitable gadgets in the Linux kernel. Moreover, we demonstrate that SCUAF information disclosure attacks against the kernel are not only practical, but that their reliability can closely match that of traditional Spectre attacks, with our proof of concept leaking kernel memory at 12 KB/s. Crucially, we develop a new technique to create an unbounded race window, accommodating an *arbitrary* number of SCUAF invocations required by an end-to-end attack in a *single* race window. To address the new attack surface, we also propose a generic SRC mitigation to harden all the affected synchronization primitives on Linux. Our mitigation requires minimal kernel changes and incurs only ≈5% geomean performance overhead on LMBench.

"There's security, and then there's just being ridiculous."
– Linus Torvalds, on Speculative Race Conditions

1 Introduction

Since the discovery of Spectre [45], security researchers have been scrambling to locate all the exploitable snippets or *gadgets* in victim software. Particularly insidious is the first Spectre variant (exploiting conditional branch misprediction [45]), since any victim code path guarded by a source `if` statement may result in a gadget. To identify practical Spectre-v1 gadgets, previous research has focused on speculative memory safety vulnerabilities [42,45,53], use-after-free [41], and type confusion [41]. However, much less attention has been devoted to other classes of (normally architectural) software bugs, such as *concurrency bugs*.

To avoid (or at least reduce) concurrency bugs, modern operating systems allow threads to safely access shared memory by means of synchronization primitives, such as mutexes and spinlocks. In the absence of such primitives, e.g., due to a software bug, *critical regions* would not be properly guarded to enforce mutual exclusion and *race conditions* would arise. While much prior work has focused on characterizing and facilitating the architectural exploitation of race conditions [49], very little is known about their prevalence on transiently executed code paths. To shed light on the matter, in this paper we ask the following research questions:

"*How do synchronization primitives behave during speculative execution? And what are the security implications for modern operating systems?*"

To answer these questions, we analyze the implementation of common synchronization primitives in the Linux kernel. Our key finding is that *all* the common (write-side) primitives (i) lack explicit serialization and (ii) guard the critical region with a conditional branch. As a result, in an adversarial speculative execution environment, i.e., with a Spectre attacker mistraining the conditional branch, these primitives essentially behave like a *no-op*. The security implications are significant, as an attacker can speculatively execute *all* the critical regions in victim software with *no* synchronization.

Building on this finding, we present GhostRace, the first systematic analysis of Speculative Race Conditions (SRCs), a new class of speculative execution vulnerabilities affecting all common synchronization primitives. SRCs are pervasive, as an attacker can turn arbitrary (architecturally) race-free code into race conditions exploitable on a speculative path—

[*]This work was partially done at IBM Research, Zurich, Switzerland

in fact, one originating from the synchronization primitives' conditional branch itself. While the effects of SRCs are not visible at the architectural level (e.g., no crashes or deadlocks), due to the transient nature of speculative execution, a Spectre attacker can still observe their microarchitectural effects via side channels. As result, any SRC breaking security invariants can ultimately lead to Spectre gadgets disclosing victim data to the attacker. To investigate the practical security impact of SRCs, we focus on Speculative Concurrent Use-After-Free (SCUAF), a subclass of speculative race conditions which concerns all critical regions which, once speculatively executed, can expose Use-After-Free (UAF) vulnerabilities.

To investigate the resulting attack surface, we first present new techniques to exploit SCUAF in practice. SCUAF exploitation carries with it all the exploitation challenges of Spectre as well as those of architectural race conditions. The latter alone is far from trivial, as reliable exploitation relies on *controlling* and *stretching* the race window to fit the exploit [49]. Nonetheless, architectural exploits are typically *one-shot*, i.e., with a single iteration of a (e.g., UAF) primitive and thus a single (successful) race window. Spectre exploits, in turn, typically require thousands or millions of iterations to scan memory looking for the secret to leak [27]. As such, with existing race window-stretching techniques [49], we would need to win the race an overwhelming number of times, hindering practical exploitation. To address this challenge, we propose a new (architectural or speculative) UAF race window-massaging technique to (i) surgically interrupt the victim thread at the "*right time*" and (ii) create an *unbounded* window. Our technique builds on and extends existing timer interrupt-based techniques [81] to not only make SCUAF attacks realistic, but accommodate a full end-to-end speculative information disclosure attack in a *single* race window.

Second, to investigate the extent of the problem, we present a SCUAF gadget scanner and apply it to the Linux kernel to find 1,283 potentially vulnerable gadgets. By manually reaching one of our identified (device-specific) gadgets, we implement a Proof of Concept (PoC) which triggers a concurrent UAF on a speculative path to hijack the control flow to disclosure gadget in the kernel, allowing an unprivileged attacker to leak arbitrary kernel memory at the rate of 12 KB/s.

Finally, we present a mitigation to serialize the execution of all the vulnerable synchronization primitives. Our mitigation has general applicability and can completely close the attack surface of not only SCUAF but SRC in general. Moreover, it requires minimal kernel changes and incurs low performance overhead (≈5% geomean on LMBench).

Contributions. We make the following contributions:

1. We present a new exploitation technique to precisely interrupt any (kernel) thread and create an architecturally unbounded UAF exploitation window (Section 4.1).
2. We present Speculative Race Conditions (SRCs), a new class of speculative execution vulnerabilities affecting all common synchronization primitives (Section 4.2).
3. We study the security implications of SRCs on architecturally race-free critical regions in the Linux kernel, demonstrating a Proof of Concept exploiting a Speculative Concurrent UAF (SCUAF) and leaking arbitrary kernel memory at a rate of 12 KB/s (Section 4.3).
4. We propose a gadget scanner to find 1,283 potentially vulnerable SCUAF gadgets in the kernel (Section 5).
5. We propose a generic mitigation to harden synchronization primitives against SRC, with a ≈5% geomean performance overhead on LMBench (Section 6).

The PoC code, the gadget scanner, and additional information are publicly available at https://www.vusec.net/projects/ghostrace.

2 Background

2.1 Transient Execution

```
if (x < array1_size){
    y = array2[ array1[x] * 0x1000 ];
}
```

Figure 1: An example of Spectre bounds check bypass. The conditional branch (in red) with the attacker-controlled `x` speculatively bypassing the comparison with `array1_size`, the first speculative load reading a secret byte at address `(array1 + x)` (in blue), and the second speculative load referencing the CPU cache with a secret-dependent address (in orange).

Since 2018, after the discovery of Spectre [45] and Meltdown [50], transient execution attacks have become an intensively studied area of research. Whenever a modern CPU implements speculative optimizations (e.g., branch prediction), it speculatively executes a sequence of instructions. The two possible outcome for these instructions are that either they are committed and made visible to the architectural level or they are squashed due to mispeculation (e.g., misprediction)—leading to transient execution. When the instructions are squashed, the CPU rollbacks the state. Despite the rollback, some microarchitectural side effects are left and can be observed through one of the many side channels available (e.g., data cache [21,29,76,77], branch target buffer [52], port contention [12], etc.) to leak sensitive information.

Spectre-PHT, also known as Spectre-v1, is the first known attack of this kind, targeting the pattern history table and exploiting a code pattern such as the one shown in Figure 1. As shown in the figure, the code checks for x to be in-bound

before performing a double array access. For exploitation purposes, the attacker can ensure *x* is out-of-bound and *array1_size* is not present in the cache. In this scenario, instead of waiting for *array1_size* to be loaded from main memory to perform the comparison, the CPU speculates and starts to transiently execute the instructions beyond the comparison. If the comparison has been executed several times before with *x* in-bound, the CPU is prone to speculate that *x* is once again in-bound, hence transiently performing the out-of-bound access of *array1*. When the not cached *array2* is accessed using the byte retrieved from the out-of-bound access of *array1*, the specific accessed location is loaded into the cache. The attacker can complete the 1 byte leak by testing which location of *array2* can be accessed faster than the others. Its position within the buffer reveals the secret byte value.

Notably, Spectre-PHT remains unmitigated in hardware. Software developers remain responsible to harden potentially vulnerable branches with mitigations (e.g., fencing to prevent speculation), but the extent to which all the "*right*" branches have been adequately hardened in large high-value codebases such as the Linux kernel remains an open question.

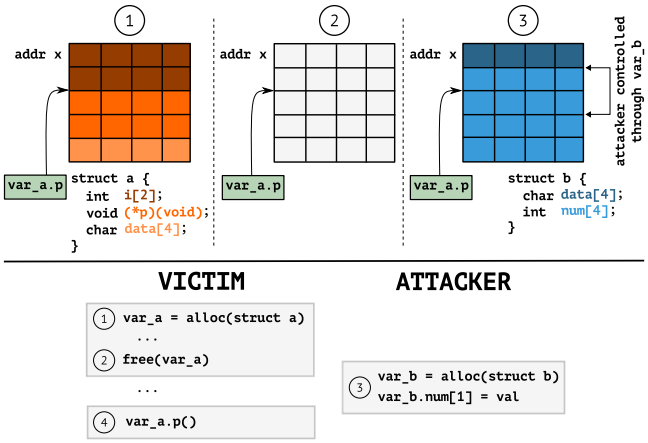

Figure 2: Object reallocation in a UAF attack. First, the victim allocates a heap object which is subsequently freed (steps *1* and *2*). Then, the attacker forces the allocation of an object (*var_b*) reusing memory slot of the victim's object, taking control of the data referenced by the dangling pointer (step *3*). Finally, the dangling pointer is dereferenced, ultimately allowing the attacker to hijack control flow (step *4*).

2.2 Concurrency Bugs

Concurrency bugs are a category of bugs which affect multithreaded programs and occur due to the absence or the incorrect use of synchronization primitives. Due to their nondeterministic behavior, concurrency bugs are one of the most elusive and difficult to triage classes of bugs. Under certain conditions, concurrency bugs can also lead to memory error vulnerabilities. In modern operating systems such as the Linux kernel, one of the most common memory error vulnerability caused by concurrency bugs is Use-After-Free (UAF).

In a UAF attack, the first step is generally to free a memory object. This operation invalidates all the pointers to that object, which become *dangling*. The second step generally involves forcing the allocator to reuse the memory slot of the free object for the allocation of a new object. This step reinitialize the previously freed memory slot. The final step of the attack is generally to force the victim to use one of the dangling pointers, which now points to the newly allocated object. A read from or write to such pointer to controlled data can be used to exploit the bug in a variety of ways. An example illustrated in Figure 2 is for instance to mount a control-flow hijacking attack via a dangling function pointer.

When this attack is performed in concurrency settings, and the free step and the use step are executed by distinct threads sharing the underlying object. Such concurrent use-after-free vulnerability is harder to exploit than the single-threaded UAF case, since exploitation depends on thread interleaving and the availability of a sufficient *race window* [49]. While the community has invested significant effort in investigating traditional concurrency bugs and concurrent UAF—e.g., studies demonstrating that more than 40% of the UAF vulnerabilities patched in Linux kernel drivers are concurrent UAF [9]—their microarchitectural properties have largely been neglected. In this paper, we study such properties and their security implications for the first time, uncovering a new class of speculative execution vulnerabilities in the process.

3 Definitions and Threat Model

3.1 Definitions

A traditional *data race* entails two threads accessing the same memory location, with one thread performing a write and no synchronization primitive protecting the shared accesses. The data race is referred to as a *race condition* when it impacts the correctness of the program. We define that a *Speculative Race Condition* (SRC) occurs when two threads access the same memory location, with one thread performing an architectural write operation and another a transient access, with an impact on the correctness of the speculatively executed program. Intuitively, the synchronization primitive, such as exclusive locking, can be bypassed by one of the two threads due to speculative execution. Due to their security impact, we specifically focus on *Speculative Concurrent Use-After-Free* (SCUAF), the SRC equivalent of traditional concurrent use-after-free [49]. Intuitively, because concurrent use-after-frees are often escalated to control-flow hijacking [49], SCUAFs are also likely to be escalated to speculatively control-flow hijacking, a powerful speculative execution primitive [45].

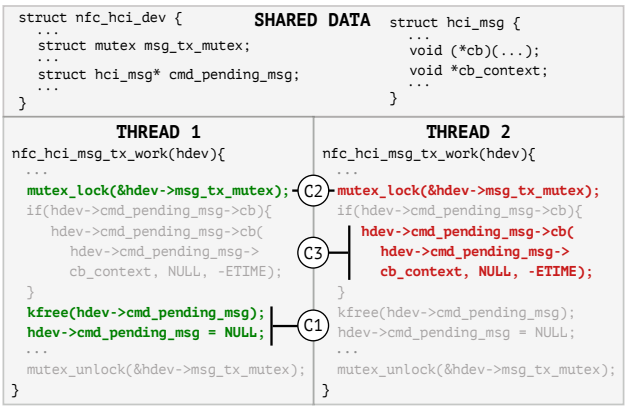

Figure 3: The NFC gadget (`net/nfc/hci/core.c:78`) found by our scanner and the three main challenges to mount an end-to-end GhostRace attack.

3.2 Threat Model

We consider a typical cross-domain Spectre threat model, with a local unprivileged attacker able to issue system calls to the victim kernel. The attacker seeks to leak arbitrary kernel data by exploiting a speculative race condition in an otherwise architecturally-race-free critical region in the kernel. We assume state-of-the-art mitigations against transient execution attacks are all enabled and other classes of (e.g., software) bugs are out of scope—for instance, subject to orthogonal mitigations. Hereafter, without loss of generality, we specifically focus on the Linux kernel running on Intel x86-64.

4 GhostRace Attacks

The goal of a GhostRace attack is to disclose arbitrary kernel data by exploiting a speculative race condition in an otherwise architecturally race-free critical region. To illustrate the workings of an attack, we use one of the gadgets found in Linux kernel v5.15.83 by our gadget scanner (`net/nfc/hci/core.c:78`) as a running example. Figure 3 depicts two threads both executing the gadget, at the core of the `nfc_hci_msg_tx_work` function. Such function serves as part of the implementation of the Host Controller Interface (HCI) layer of the Near Field Communication (NFC) driver core of the Linux kernel and processes pending messages to the NFC device. As we do not have the required NFC hardware to natively execute this function, we added a system call to reach this code path during our analysis. The function contains a critical region (i.e., our gadget) operating on the `nfc_hci_dev hdev` device and performing the following operations. *First*, it locks the `msg_tx_mutex` mutex to gain exclusive access to the device and enter the critical region. *Second*, it checks whether the pending `hci_msg hdev->cmd_pending_msg` command message to process has a callback set. If so, the callback is invoked via the `hdev->cmd_pending_msg->cb` function pointer. *Third*, it frees the memory backing the command message and sets the now-dangling `hdev->cmd_pending_msg` pointer to `NULL`. *Lastly*, it exits the critical region by releasing the mutex.

Since the critical region can be concurrently accessed by different user processes/threads sharing the NFC device, it is crucial for the mutex to guard the region, enforcing mutually exclusive access to the device and ruling out any race conditions. Indeed, absent the mutex, the code in question would be vulnerable to a concurrent Use-After-Free (UAF) vulnerability: as *Thread 1* executes *Free* code (in bold green), between the `kfree` of the `hdev->cmd_pending_msg` pointer and the `NULL` update of the pointer, *Thread 2* may execute the *Use* code (in bold red) and invoke the `hdev->cmd_pending_msg->cb` callback of the pending message which was just freed. An attacker able to control memory reuse can then trigger the *Use* with a controlled callback value and escalate the vulnerability to control-flow hijacking. Luckily, thanks to mutexes and other synchronization primitives offered by modern operating systems such as the Linux kernel (spin locks, RW locks, etc.), architectural exploitation of such race-free code is infeasible.

Unfortunately, as we will show, the same does not apply in the speculative domain, where architecturally race-free execution can still be (microarchitecturally) subject to SRCs. Specifically, in our GhostRace attack, we exploit the NFC gadget to craft a SCUAF primitive and ultimately disclose data, with *Thread 1* architecturally executing its critical region, i.e., architectural *Free*, and *Thread 2* concurrently being speculatively executed i.e., speculative *Use*. Moreover, we need to ensure that *Thread 1* is interrupted immediately after the *Free*, with a sufficiently large *race window* (or UAF exploitation window) for practical exploitation. Finally, we need to effect our SCUAF primitive several times to mount end-to-end speculative information disclosure attacks.

In other words, to mount GhostRace attacks, we need to address the following challenges highlighted in Figure 3:

- (C1) Create a large, ideally unbounded, architectural UAF exploitation window between `kfree` and the `NULL` `hdev->cmd_pending_msg` pointer update to accommodate as many SCUAF primitive invocations as possible.
- (C2) Turn our architecturally race-free gadget into a speculative race condition, crafting a SCUAF primitive speculatively dereferencing the (dangling) `hdev->cmd_pending_msg->cb` function pointer.
- (C3) Use the building blocks above to mount end-to-end information disclosure attacks against the kernel.

4.1 Creating an Unbounded UAF Window

To address (C1), we need a strategy to interrupt an arbitrary thread in the Linux kernel for a large and ideally unbounded

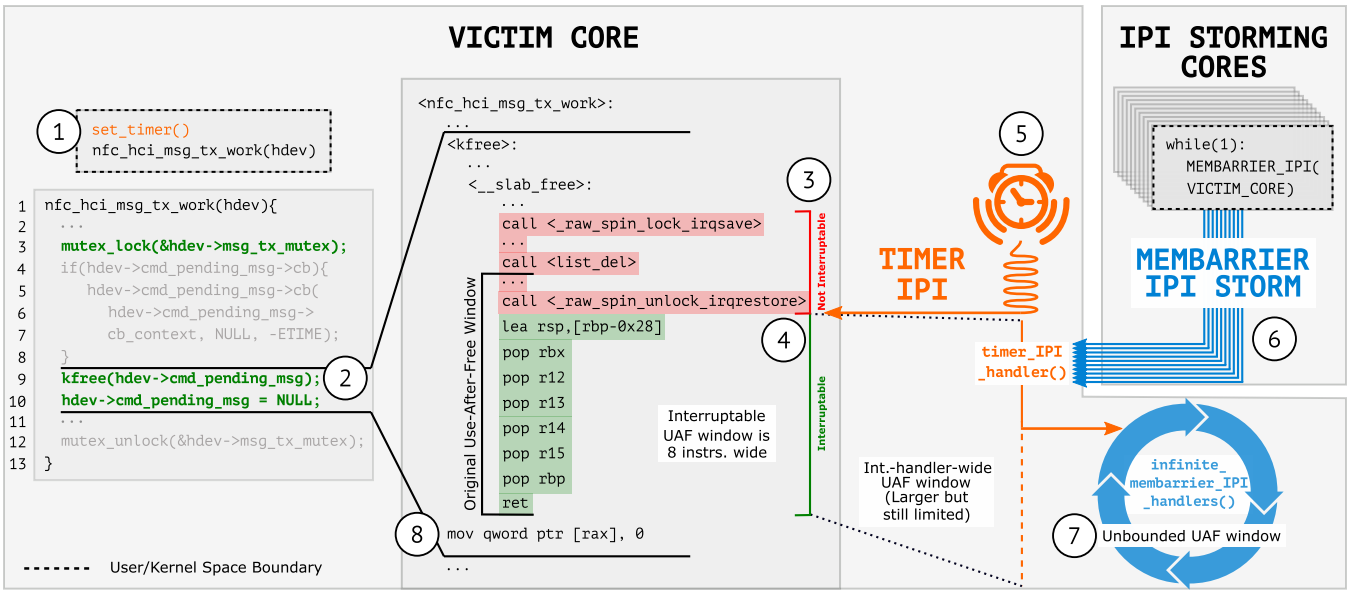

Figure 4: From eight instructions-wide to **unbounded** architectural Use-After-Free exploitation window. Steps 1 and 6 run in user mode, issuing syscalls to trigger the relevant kernel code. The other steps run in kernel mode.

period of time. We can then use this strategy to create an architectural unbounded UAF window in the *victim Thread 1* for the *attacker Thread 2* to exploit. Our case study is particularly challenging as the "original" UAF exploitation window is very small: the attacker must be able to use the `hdev->cmd_pending_msg` pointer (at line 5 in *Thread 2*) after the `hci_msg` memory object is freed (line 9 in *Thread 1*) and before the pointer is nullified (line 10 in *Thread 1*). In other words, the time between `kfree` freeing the object and the `NULL` update of the `hdev->cmd_pending_msg` pointer is the only span *Thread 2* could exploit to craft a UAF primitive.

A Tiny Window. To precisely quantify the original UAF exploitation window, one can inspect the implementation of `kfree`. As shown in Figure 4, under the hood, the default (`__slab_free`) implementation frees the object (`list_del`) and then releases an interrupt-safe spinlock (`_raw_spin_unlock_irqrestore`) immediately before returning control to the caller. Since such spinlock runs with interrupts disabled (i.e., the CPU cannot be interrupted), the original (interruptible) UAF exploitation window is as tiny as *eight instructions*—accounting for the time between spinlock release and the `NULL` pointer update at line 10. To stretch such a tiny window, we can build on existing interrupt-driven techniques [49, 81]. Nonetheless, this is challenging as such techniques were not designed to produce race windows that would reliably accommodate several UAF invocations. Moreover, other techniques relying on a high-priority user thread to preempt the victim kernel execution [34] are not applicable to stock kernels, which run with preemption off by default (i.e., `CONFIG_PREEMPT` unset).

From Tiny to Unbounded. To address these issues, we propose a new strategy based on a combination of techniques. First, drawing from the *timerfd*-based technique proposed in [81], we rely on *high-precision hardware timers* [26] to interrupt the victim thread at the right time and slightly amplify the original UAF window. Note that, in our setting, the original *timerfd*-based technique [81] becomes more effective, since we can exploit the interrupt-disabled behavior of `kfree` to more precisely interrupt the victim thread at the right time. Second, we rely on user interfaces to trigger an (interprocessor) interrupt (*IPI*) *storm* to (less precisely) interrupt the victim thread in the *amplified window* and stretch such window indefinitely. This is possible since the victim CPU is stuck handling IPIs until the attacker so wishes. Figure 4 illustrates the steps of our strategy.

As shown in the figure, the attack starts with ① the attacker scheduling a high-precision hardware timer [26] on a victim core. The attacker calibrates the timer to expire at some point in the future, at nanosecond resolution. Next, ② the attacker starts a victim (i.e., *Free*) thread on the same core, which issues a system call to reach the target gadget and thus the victim `kfree` invocation. Next, ③ `kfree` acquires the interrupt-safe spinlock and completes the freeing of the victim memory object within uninterruptible execution. Next, ④ `kfree` releases the spinlock and resumes interruptible execution. At this point, as long as the timer already expired during uninterruptible execution, ⑤ the victim gets immediately interrupted at the start of the interruptible UAF window. Indeed, when the timer expires, the hardware raises an interrupt, but its actual delivery gets delayed until interrupts are enabled again (i.e., upon spinlock release). In other words,

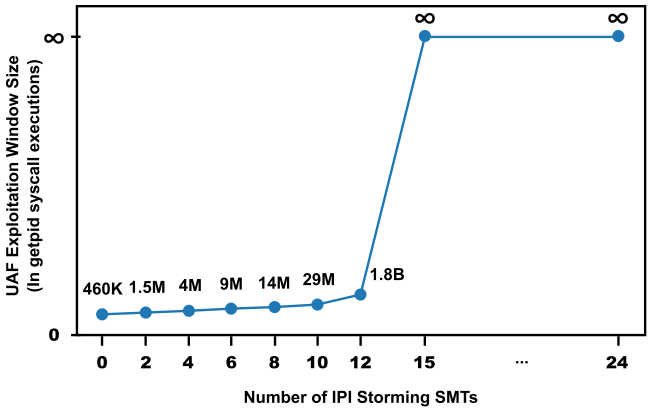

Figure 5: Size of the UAF exploitation window vs. number of IPI storming cores targeting the victim core. The size of the exploitation window is measured in number of `getpid` syscalls (a standard benchmark to evaluate generic round trips to the kernel [11]) that attackers can run before the victim core handles all incoming `membarrier` IPIs and updates the dangling `hdev->cmd_pending_msg` pointer to `NULL`. The experiment is performed on a commodity client Intel 12th-generation i9-12900K CPU, which has 16 cores and 24 Simultaneous Multithreads (SMTs). We observe that only 15 SMTs are sufficient to obtain an unbounded UAF exploitation window. We also observe that the location of the IPI storming cores matters [23, 57], as the physically closer a storming core is to the victim core, the higher the IPI throughput due to the lower latency on the interconnect. This explains the big increase from 10 to 12 and from 12 to 15 SMTs as the storming cores added in both experiments were physically the closest to the victim core among all available cores.

even with imprecise timer calibration or jitter, the attacker has significant chances to interrupt the victim at precisely the right time. It is, in fact, sufficient to cause the timer to expire *any time* within the core (uninterruptible) execution of `kfree`, rather than in the original tiny eight-instruction UAF window. Put differently, the interrupt-disabled behavior of `kfree` ultimately *helps* rather than hinders the attack.

When the timer interrupt gets delivered, kernel execution switches from the victim thread to the timer interrupt handler. The latter normally is short-lived, but one can amplify the window by registering several timer observers, e.g., via `timerfd` support. Still, while this strategy can interrupt the victim thread at the right time and amplify the original UAF window, the latter is still insufficient to accommodate many SCUAF primitive invocations. However, the amplified window *is* sufficient for the attacker to interrupt the timer interrupt handler with a more jittery Inter-Processor Interrupt (IPI) sent by another core. Building on this intuition, ⑥ the attacker schedules on the remaining cores *storming* threads that constantly send IPIs to the victim core. For this purpose, the `membarrier` system call

```
1 void mutex_lock(struct mutex *lock){
2   ...
3   if (!__mutex_trylock_fast(lock))
4     if (atomic_long_try_cmpxchg_acquire(&lock, ...))
5       return true;
6   ...
7 }

  Call Stack:
  atomic_long_try_cmpxchg_acquire(&lock, ...)
   └arch_atomic_long_try_cmpxchg_acquire(&lock, , ...)
     └arch_atomic_try_cmpxchg_acquire(&lock, , ...)
       └arch_atomic_try_cmpxchg(&lock, , ...)
         └arch_try_cmpxchg((&lock, , ...)
           └__raw_try_cmpxchg(ptr, ...)({
               asm volatile(
                    "lock cmpxchgq %2, %1"
                    : "=a" (ret), "+m" (*ptr)
                    : "r" (new), "0" (old)
                    : "memory"
                    );
           })
```

Figure 6: Top part: The core implementation of the `mutex_lock` synchronization primitive, with the conditional branch which can be abused to craft SRCs in red. Bottom part: The branch ultimately checks the outcome of the `lock cmpxchgq` instruction which does not serialize the execution.

`MEMBARRIER_CMD_PRIVATE_EXPEDITED_RSEQ` IPI is ideal, since, unlike other IPIs used by previous work [49], its delivery can be triggered via a low-latency system call targeting a single (victim) core. The resulting IPI storm not only causes the timer interrupt handler to be interrupted, but completely overwhelms the victim core. Figure 5 relates the size of the UAF exploitation window to an increasing number of storming cores on our test platform, with 15 SMTs being sufficient to overwhelm the victim. Indeed, ⑦ the victim core is forced to constantly handle an indefinite number of `MEMBARRIER` IPIs, effectively creating an architectural unbounded UAF exploitation window to mount an arbitrarily long end-to-end attack. Finally, once the attack completes, the attacker terminates the storming threads, ⑧ victim thread execution resumes, and only then the dangling `hdev->cmd_pending_msg` pointer is updated to `NULL`. Note that, between steps ⑦ and ⑧, the attacker may execute a speculative execution attack as many times as they wish, given the unbounded window. This means the steps ① to ⑧ here for creating the unbounded exploitation window only need to succeed once for the attacker to be able to leak as many bytes as desired.

4.2 Crafting Speculative Race Conditions

To address **C2** and craft speculative race conditions, we turn to the implementation of common synchronization primitives (e.g., *mutex*, *spinlock*, etc.). At the architectural level, these primitives guarantee mutual exclusion of critical regions and this is no different for our gadget. However, they offer no

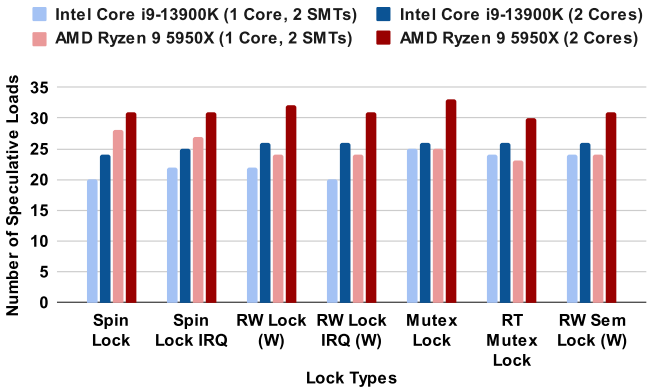

Figure 7: Transient window size for different write-side synchronization mechanisms, i.e., number of speculative loads that leave an observable microarchitectural trace.

microarchitectural guarantees and their behavior is subject to their implementation. To understand their behavior, we investigated the implementation of common synchronization primitives in the Linux kernel. The core implementation of the `mutex_lock` primitive (Figure 6 top) serves to illustrate.

As shown in the figure, line 4 includes a conditional branch that ultimately checks the outcome of the `lock cmpxchgq` instruction. Such instruction atomically compares the current value of the mutex `ptr` with its old one `old`, and, if identical, it means that the mutex can be locked—setting the mutex to the new value `new` and granting access to the guarded critical region. Likewise, if the comparison fails, it means that the mutex has been locked by another thread, therefore the code falls through after failing to acquire the mutex.

Although the comparison is done atomically, the instruction (as we experimentally verified) does not serialize the execution stream. As a result, we can mistrain the conditional branch at line 4 (e.g., simply by acquiring the mutex multiple times) to be taken and consistently trick speculative execution into acquiring a mutex and entering the guarded critical region. Since this is the case regardless of the current (architectural) state of the mutex, we can speculatively acquire a mutex already held by another thread. In other words, the mutex becomes a no-op on the speculative path, leading to a *speculative race condition* and opening the door to arbitrary concurrency vulnerabilities at the microarchitectural level.

Generalizing, our analysis shows *all* the other common write-side synchronization primitives in the Linux kernel are ultimately implemented through a conditional branch and are therefore vulnerable to speculative race conditions. To experimentally confirm this intuition, we tested all such synchronization primitives under speculative execution after mistraining the vulnerable branch. In all cases, we confirmed transient execution of the guarded critical region despite another victim thread already architecturally executing in the region. To determine the transient window size, we measured the maximum number of speculative load instructions we could speculatively execute inside the critical region.

Figure 7 presents our results for two microarchitectures (Intel Core i9-13900K and AMD Ryzen 9 5950X) and two configurations: (i) attacker and victim thread co-located on the same core; (ii) attacker and victim thread running on different cores. As shown in the figure, the transient window size is significant across settings (20+ loads). Moreover, the window is usually larger when the two threads are running across cores, evidencing that the cache coherency protocol plays a crucial role in propagating the lock architectural state across cores before speculation aborts. Finally, our results show some variations across microarchitectures. For instance, the AMD processor has a longer speculation window than the Intel one, matching trends from prior work [61]. Overall, our results show an attacker can speculatively bypass all the common (write-side) synchronization primitives and craft speculative race conditions, turning every (architecturally race-free) critical region into a potential generic Spectre gadget.

To conclude, we note that not all the vulnerable synchronization primitives we analyzed are equally exploitable. For instance, uninterruptible primitives (e.g., irq-safe spinlocks) are not amenable to the interrupt-driven techniques we detail in the next section, preventing the attacker from stretching the race window. Moreover, our analysis focuses on the kernel, excluding primitives that normally apply only to user execution (e.g., Intel TSX-based primitives, also uninterruptible without aborting the underlying memory transactions).

4.3 Exploiting Speculative Race Conditions

To address (C3), we need to mount end-to-end information disclosure attacks. To this end, armed with knowledge of speculative race conditions (SRCs), we can now bypass synchronization primitives (e.g., mutex) on a speculative path and turn safe architectural *uses* into a speculative concurrent *use-after-free* (SCUAF). Next, armed with control over memory reuse, we can escalate our SCUAF primitive to first speculative control-flow hijacking and then speculative information disclosure of some target kernel data. Finally, armed with an unbounded UAF window, we can repeatedly effect our primitives, disclose arbitrary kernel data, and mount end-to-end attacks leaking some target secret in kernel memory. Figure 8 details the steps of an attack based on our NFC gadget.

Initialization. To kickstart the attack, ① the attacker starts executing on a given (attacker) core and triggers the allocation of `hdev` and `hdev->cmd_pending_msg`. Next, ② the attacker mistrains the victim mutex's conditional branch by executing the gadget and acquiring the mutex architecturally many times. Next, ③ the attacker starts the victim thread and the storming threads on the corresponding cores.

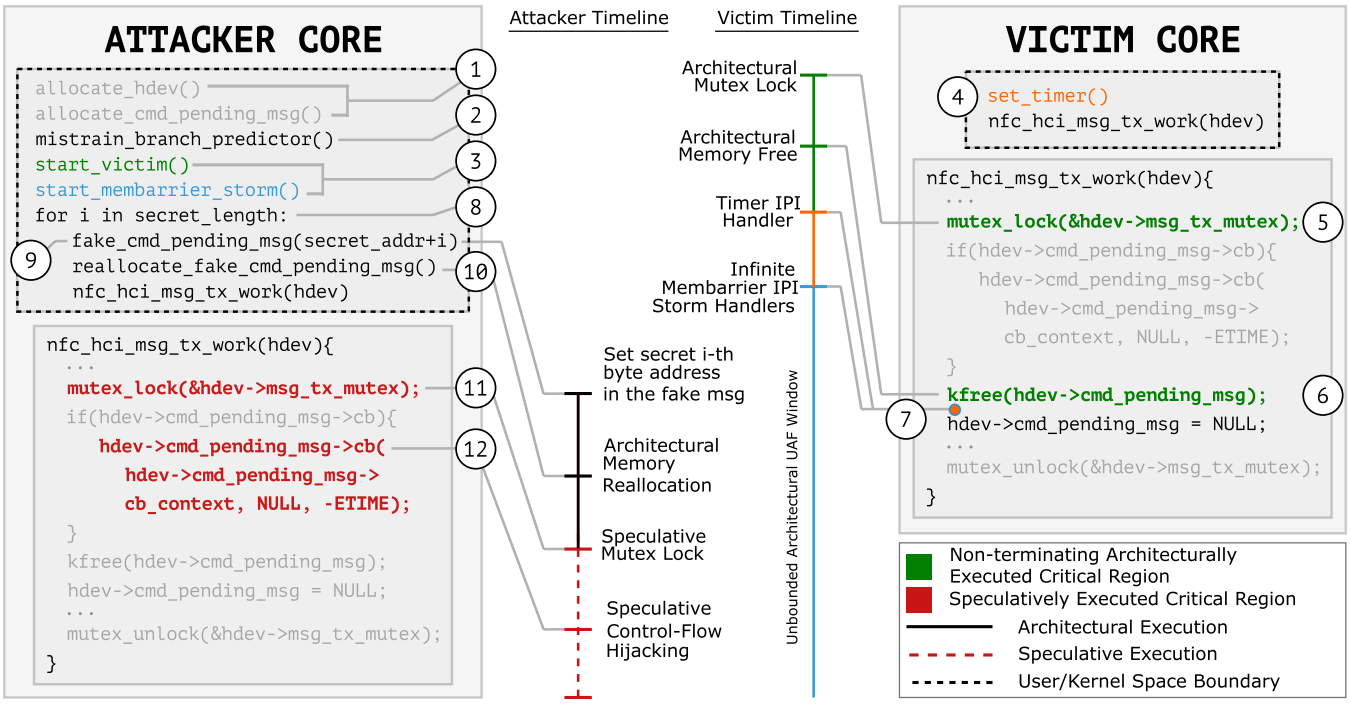

Figure 8: Speculative information disclosure attack exploiting a speculative race condition. Steps 1-4 and 8-10 run in user mode, issuing syscalls to trigger the relevant kernel code. The other steps run in kernel mode. The `nfc_hci_msg_tx_work` gadget code is shown only to explain how the speculative race condition is created.

Unbounded UAF Window. To create an unbounded UAF window, ④ the attacker schedules a high-precision timer on the victim core. Next, ⑤ the attacker causes the victim thread to trigger the execution of the NFC gadget, architecturally locking the mutex and entering the guarded critical region. Next, ⑥ the NFC gadget calls `kfree` on the `hdev->cmd_pending_msg` pointer. Next, ⑦ the high-precision timer expires, interrupting the victim thread when the `hdev->cmd_pending_msg` pointer is still dangling. Shortly after, the attacker signals the storming threads to target the victim core with a storm of `MEMBARRIER` IPIs, preventing the victim thread to resume execution until the attacker signals again the storming threads to terminate.

Speculative Control-Flow Hijacking. ⑧ For each kernel address to leak in order to disclose the target secret, the attacker first crafts a speculative control-flow hijacking (SCFH) primitive. To this end, the attacker needs to allocate a controlled object reusing the memory slot `kfreed` earlier via slab massaging. With SLUB (default slab implementation), the attacker can exploit same-CPU, same-size-class slab cache collision techniques [48] to achieve memory reuse. Specifically, ⑨ the attacker first creates a malicious `struct msgbuf` message, casts it to `struct hci_msg`, and sets: (i) the `hci_msg.cb` callback to the speculative SCFH *target*, (ii) the `hci_msg.cb_context` first callback argument to the SCFH *argument*. Next, ⑩ the attacker calls the `msgsnd` system call with the malicious `msgbuf` message, which ultimately gets allocated in the same slot as the freed `hdev->cmd_pending_msg`. Next, ⑪ the attacker triggers the execution of the gadget. Due to the mistrained branch, the CPU speculatively enters the critical region despite the mutex being architecturally held by the victim thread. Next, ⑫ the gadget speculatively dereferences the dangling pointer, hijacking control flow to the attacker-controlled callback target.

Speculative Information Disclosure. To craft a speculative information disclosure primitive, the attacker needs to first break KALSR using existing techniques [2]. Next, the attacker needs to trigger the SCFH primitive with the callback target set to a kernel disclosure gadget using the controlled first callback argument (`rdi`) as input. For this purpose, we use the `vp_del_vqs` Spectre gadget in Figure 9, also exploited in older kernel versions in prior work [27]. As shown in the figure, the controlled memory referenced by `rdi` is referenced by the gadget to compute the secret address (`r12`+0x28) and the base address of an array (`rax`)—which we can use as the reload buffer of a classic FLUSH+RELOAD Spectre covert channel [45]. The gadget reads the secret in the `rdx` register, then used to index the reload buffer with stride `8` at line 22. To handle the small stride and the high secret entropy, we can use sliding techniques, as done in prior work [27, 73]. Ultimately,

```
1  ffffffff817a1a20 <vp_del_vqs>:
2        ...            // Function Prologue

Figure 10: Simplified Cocci scripts (left *Free* and right *Use*) scanning for SCUAF gadgets in the Linux kernel.

this translates to 3 gadget repetitions needed to leak one byte from a known prefix [73]. Finally, to break the entropy of the kernel (direct map) address referencing the (user) reload buffer, we can repeatedly probe for known secret data, guess the kernel reload buffer address, and check for a cache signal in the (user) reload buffer until successful.

4.4 Proof-of-Concept Exploit

We implemented a Proof-of-Concept exploit (PoC) based on the end-to-end attack workflow described earlier. To exploit our NFC gadget (not easily reachable on commodity platforms), we simulated an attacker-controlled service interacting with the NFC function via a dedicated system call. We evaluated our PoC an Intel 12th-generation i9-12900K Alder Lake processor. We ran our PoC on Linux kernel v5.15.83, using the default kernel configuration while enabling all transient execution mitigations. Using only 15 SMTs (out of 24 available on the i9-12900K CPU), we experimentally confirmed our PoC exploit can reliably create an unbounded UAF exploitation window after a single attempt. We also observed an average of 13 attempts to achieve successful memory reuse. This confirms that, despite the entropy of slab massaging and that of having to interrupt the victim thread at precisely the right time, our proposed techniques are successful in making exploitation reliable and almost deterministic. Note that *some* nondeterminism is acceptable and has marginal impact on the attack. Indeed, our PoC can detect unsuccessful memory reuse (i.e., lack of signal) and simply terminate the UAF exploitation window and start over. Once memory reuse is successful, we keep the window open and effect as many (fully reliable) speculative information disclosure iterations as needed to complete the attack. When instructing our PoC to leak 10 MB of kernel memory (after breaking the kernel reload buffer address entropy in milliseconds), we observed a leakage rate of 12 KB/s with an error rate of 1% on average (of 100 repetitions). To put things in perspective, on our idle system running Ubuntu with 8 GB of RAM, this translates to an end-to-end attack time of around 35 seconds (all in a single race window) to leak the root password hash from Linux kernel memory—a common target in previous user-to-kernel Spectre exploits [27, 66, 73].

5 Gadget Scanner

The Linux kernel, as a linchpin of open-source software, is susceptible to security vulnerabilities, among which UAFs represent one of the most frequently recurring class of vulnerabilities [48]. Concurrent programming exacerbates the detection and resolution of UAF vulnerabilities due to the intricacies of shared resource management [9].

Existing solutions focus on gadget scanning for the kernel [8, 10, 31, 41, 63, 64, 72, 73], however, none of them target SCUAF gadgets. Therefore, we systematically explore the attack surface for speculative concurrent UAF gadgets in Linux kernel, specifically focusing on (speculative) control-flow hijacking primitives based on UAF. To this end, we rely on the

Coccinelle static code-pattern matching engine [58, 59] to automate the detection of SCUAF vulnerabilities, which arise from the intricate interplay of concurrent UAF patterns and the effect of speculation-unsafe synchronization primitives in critical regions. We immediately note that, since we focus on SCUAF for control-flow hijacking, our SRC analysis is not exhaustive. Moreover, the accuracy of the results is subject to the precision of static pattern matching. Nonetheless, our analysis helps estimate the extent of the problem.

5.1 SCUAF Coccinelle Scripts

Coccinelle is an advanced program matching and transformation engine. Its effectiveness lies in the utilization of the Semantic Patch Language (SmPL) for expressing semantic patches. SmPL enables developers to define intricate code patterns and transformations in a human-readable manner. It is widely used by Linux kernel developers to identify undesirable code patterns across the kernel code base, including misuse of APIs or vulnerabilities such as UAFs.

Coccinelle facilitates the automated identification of UAF vulnerabilities, as an attacker can easily articulate complex patterns indicative of SCUAF vulnerabilities using Coccinelle's pattern definition capabilities.

Figure 10 presents the Cocci scripts used to detect hundreds of SCUAF gadgets, including the `nfc_hci_msg_tx_work` gadget discussed in Section 4. On the left is the script scanning for the *Free* part of the SCUAF vulnerability. Specifically, the script scans for functions with synchronization primitives guarding critical regions and the latter containing calls to (slab) free functions (e.g., kfree) over a nested data structure pointer followed by the `NULL` update of the pointer. On the right of the Figure 10 is the *Use* Cocci script. The script scans for functions with synchronization primitives guarding critical regions with a nested function pointer-based call. Highlighted in orange is the synchronizing pointer in shared memory (i.e., mutex, lock, etc.). The latter has to match between the *Free* and *Use* for the architecturally exclusive execution of the corresponding critical regions to be guaranteed (i.e., architecturally race-free invariant). In green is the pointer to the data structure being freed and in red the pointer to the function pointer being used. In blue is the matching data type of the freed structure and the one containing the function pointer.

Our gadget scanner can find different *variants* of potential SCUAF gadgets, namely, as illustrated in Figure 11:

Ⓐ *Free*: Guarded *free*

Ⓑ *Free*: Guarded *free* + *list_del*

Ⓒ *Free*: Guarded *free* + *NULL*

Ⓓ *Free*: Guarded *free* + pointer update

Ⓔ *Use*: Guarded pointer dereference + function pointer call

Figure 11: Simplified Cocci scripts used to scan the Linux kernel for different variants of guarded *Free* gadgets (left) and guarded *Use* (right). Any combination of these *Free* and *Use* variants results into a potential SCUAF vulnerability.

Ⓕ *Use*: Guarded function pointer *copy* + function pointer copy call

In the case of the `nfc_hci_msg_tx_work` gadget, both the *Free* and *Use* happen to be in the same function (hence the reason we used this gadget as our compact running example), but generally this is not the case as shared resources are more likely to be used in different contexts and functions. We also scan for different levels of nested pointers both for *Free* and *Use*. Our results show that the deepest (i.e., most nested) function pointer in the Linux kernel is 3 chained pointer dereferences away e.g., `ptr1->ptr2->ptr3->fptr(...)`, which our scanner can identify. It can also automatically extract the type of the data structure for each pointer in the chain and match it with any *Free* gadget operating on the same data type, resulting in a potential SCUAF gadget.

Table 1: Gadgets per lock type.

Sync Primitives	Gadgets Found
Mutex	887
Spin Lock	301
Spin Lock IRQ	95
Total	**1283**

Table 2: Gadgets variants vs. nesting levels.

Gadget Variants	Nesting Levels 0	1	2	3
Ⓐ	757	71	1	0
Ⓑ	80	8	0	0
Ⓒ	78	39	0	0
Ⓓ	87	42	0	0
Ⓔ	1387	565	71	2
Ⓕ	9	1	0	0

5.2 Evaluation

We ran our gadget scanner on the source code of Linux kernel v5.15.83. Table 1 presents our results. As shown in the table, our scanner found a total of unique 1,283 gadgets, with 69% (887) of the gadget pairs guarded by *Mutex*, 23% (301) guarded by *Spin Lock*, and 7% (95) guarded by *Spin Lock IRQ*. Almost 78% of the identified gadgets are in device drivers and 15% is located in kernel code serving (device) specific implementations of kernel services (e.g., the NFC HCI core in Figure 3). Table 2 reports the distribution of the nesting levels of the different gadgets variants for both *Free* and *Use* variants. As shown in the table, < 2 nesting levels are the most common and so are variants Ⓐ and Ⓔ. Overall, our static analysis confirms these gadgets are prevalent in modern operating system code bases such as the Linux kernel.

Limitations. Generally, false positives and negatives are possible because we rely on types to match objects that are freed before their uses. False positives occur when, despite having the same type, the objects referenced in the code are different. False negatives occur when a reference to an object may be cast to one of a different type and our analysis fails to account for it. Moreover, despite its widespread use, Coccinelle does exhibit one significant limitation in the exploration of SCUAF gadgets in the Linux kernel. Specifically, Coccinelle provides no inter-procedural analysis capabilities. Inter-procedural analysis involves examining the interactions and dependencies between different functions or procedures within a program. In the case of the Linux kernel, which is characterized by a multitude of interconnected functions, Coccinelle's inability to perform inter-procedural analysis may result in incomplete vulnerability detection in general and for SCUAF in particular. Indeed, SCUAF vulnerabilities often span multiple functions and complex execution paths, thus the lack of inter-procedural analysis may result in false negatives. Moreover, additional imprecision may originate from static pattern matching's inability to capture arbitrarily complex patterns, potentially leading to additional false negatives.

Finally, concerning false positives, our static analysis-based approach cannot guarantee that the identified gadgets can be realistically reachable in a practical attack. Indeed, reachability verification is a hard problem for SCUAF and concurrent UAF in general, as many concurrent UAF vulnerabilities plague device-specific code—as also reported in previous work [9]—and reachability is subject to device availability. For instance, we could not easily reach the `nfc_hci_msg_tx_work` gadget we used in our attack. Since the gadget is in an NFC driver, we contacted the maintainers to ask which devices use this code but never received an answer. We tried 3 NFC devices and development platforms, but none of them used the gadget code. Therefore, we implemented a system call extension making use of the exact same code as the NFC driver, to simulate it being exercised as realistically as possible. Nonetheless, while precise gadget and reachability analysis are crucial for gadget-specific mitigations (e.g., hardening seemingly dangerous *Use* patterns against attacks), we found these properties to be less important for SCUAF since a generic and efficient gadget-agnostic mitigation not just for SCUAFs but for SRCs overall is at reach. We present such mitigation in the next section.

6 Mitigation

To mitigate the SRC class of vulnerabilities, we implement and evaluate the simplest, most robust, and generic one: introducing a serializing instruction in every affected synchronization primitive before it grants access to the guarded critical region, thus terminating the speculative path. This provides a baseline to evaluate any future mitigations, and, as mentioned, mitigates not only the SCUAF vulnerabilities presented in the paper, but all other potential SRC vulnerabilities.

6.1 Mitigation via Serialization

Our approach to mitigate Speculative Race Conditions (SRCs) is to place a serializing instruction such as `lfence` after the `lock cmpxchg` instruction (i.e., bottom instruction in Figure 6) in each of the affected synchronization primitives. We have implemented such a mitigation in just a few lines of code by patching the `arch/x86/include/asm/cmpxchg.h` Linux kernel source file. Specifically, our patch adds a `lfence` instruction in both the `__raw_cmpxchg` and `__raw_try_cmpxchg` assembly macros, which are used to implement all (write-side) synchronization primitives.

6.2 Evaluation

To evaluate the performance impact of our mitigation on the Linux kernel, we ran two benchmarks, i.e., the standard LMBench [54] since: (i) it is a system call benchmark commonly used by the security and Linux community to evaluate Linux kernel performance; (ii) it allows one to compare mitigation overheads against other solutions; (iii) it includes parallel benchmarks that stress synchronization primitives and thus uncover the overhead of our mitigation unlike other benchmarks we tried. To further evaluate our mitigation overhead, we also included our own microbenchmark to stress-test the synchronization primitives.

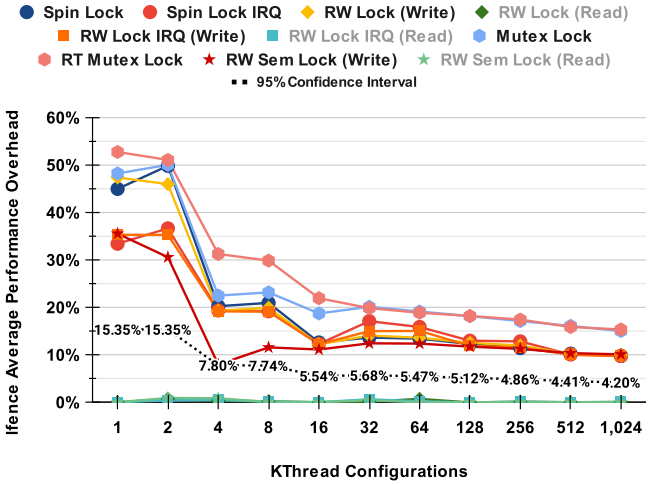

Figure 12: Average performance overhead of our mitigation across different kernel thread configurations and synchronization primitives. The branchless read-side synchronization primitives (in grey) experience no performance overhead.

LMBench. Table 3 presents the results of the LMBench benchmark for over 30 independent runs on our test platform (Section 4). In the default Linux kernel configuration, we measured an overall geomean performance overhead of 5.13%. We believe such a performance overhead is well within the range of a practical mitigation, especially when compared to the 95% LMBench geomean overhead of the default transient attack mitigations enabled on Ubuntu [32].

Microbenchmark. We designed a stress-test microbenchmark which consists of a kernel module measuring the time it takes to simultaneously run N kthreads equally distributed over all CPU cores, with each kthread acquiring and releasing the same synchronization primitive for one million iterations.

Figure 12 presents the average (over 30 independent runs on our test platform) performance overhead caused by our mitigation, serializing the execution of each synchronization primitive across the different kthreads configurations.

As shown in the figure, read-side synchronization primitives (in grey), which contain no conditional branch, are unaffected by the mitigation and thus experience no performance overhead. On the write side, we observe the highest overhead in a synthetic single-kthread configuration, ranging between 33% for *Spin Lock IRQ* to 53% for *RT Mutex Lock*. The overhead decreases to 10% for 1,024 kthreads. This trend suggests that, with an increasing number of kthreads contending the same synchronization "lock", the performance overhead of our mitigation is increasingly masked by lock contention overhead. Overall, our results confirm the overhead of our mitigation is isolated in synchronization-heavy scenarios and even then may be aggressively masked by lock contention.

7 Related Work

7.1 UAF Detection

Most of the work on detecting UAF is focused on sequential bugs. Solutions like UAFChecker [78] and Hua et al. [75] apply static analysis to find problematic code sequences, while others [55, 70] rely on fuzzing. Another technique to detect UAF bugs is to observe memory accesses at runtime [14, 46, 82]. To detect concurrency UAF vulnerabilities, UFO [36] uses execution traces and applies model checking to infer thread causality. Alternatively, DCUAF [9] relies and extends lockset analysis to verify whenever a concurrency UAF is present. ConVul [15] is also based on execution traces and can detect concurrency UAF by identifying exchangeable events. Finally, DDRace [80] specifically targets UAFs in Linux drivers by implementing new heuristics and metrics to simplify the work of the directed fuzzer in targeted locations. Given that they do not analyze transient execution, none of these solutions can find SCUAFs.

7.2 Fuzzing

Fuzzing is a popular technique to find vulnerabilities in software. By feeding crafted input to a program, a fuzzer looks for instances that make the program crash. In this section, we briefly survey existing work on directed fuzzing and then specifically focus on fuzzing to find race conditions. None of the existing work described in this section can find SCUAFs.

Directed Fuzzing. Directed fuzzing techniques aim to reach specific targets within the code [13, 18, 22, 47, 79]. For instance, to reach its targets, AFLGo [13] attempt to minimize the average distance of the basic blocks found in execution traces that link an input to the fuzzing targets. Work like FuzzGuard [82] and Beacon [35] instead apply techniques like deep learning and static analysis to filter inputs that cannot reach the fuzzing targets. Related to UAF fuzzing, CAFL [47] uses a constraint-distance metric that is able to prioritize the inputs towards the goal. The constraints are expressed as a combination of a target site and data conditions which can be used to find UAFs. However, CAFL is only focused on sequential UAFs.

Fuzzing for Concurrency Bugs. Fuzzing techniques have also been extended to concurrent programs to find specific vulnerabilities such as data race bugs. In this area, solutions like RAZZER [38], ConAFL [51], RaceFuzzer [62], and others [28, 39, 44, 67] statically identify potential race situations and then dynamically test the interleavings using generic fuzzing. The program is executed with run-time instrumentation or in a virtualized environment where the race is checked. DDRace [80] works in a similar fashion but employs directed fuzzing instead of traditional fuzzing, reducing the input space and improving performance. Given that data race bugs present themselves in different settings, Conzzer [40], Muzz [17], and KRace [74] design ad-hoc coverage metrics that are thread- and context-aware.

7.3 Gadget Scanning

The ultimate goal of gadget scanning is to find code patterns of interest in a target program, either for offensive or defensive purposes. In the context of transient execution attacks, the majority of scanners, with the exception of [41, 43], are designed to detect bounds check bypass patterns, like the one in Figure 1. Two types of scanners exist, that is based on *static* or *dynamic* analyzers, described in the following. None of the existing work described in this section can find SCUAFs.

Static Analyzers. Existing static gadget analyzers use a plethora of different techniques to scan either source or binary code. For instance, Smatch and Respectre [16, 37] rely on pattern matching against the program's source code while others [19] operate on binary code. oo7 [69] uses static taint analysis while Spectector [30] and KLEESpectre [68] use symbolic execution to detect valid Spectre gadgets. Gadget scanners based on static analysis techniques often lead to a high number of false positives, while those based on symbolic execution tend to suffer from path explosion issues, hindering their scalability.

Dynamic Analyzers. Dynamic analysis techniques like fuzzing and dynamic taint analysis (DTA) can also be used to detect vulnerable patterns. SpecFuzz [56] relies on fuzzing and sanitizers to detect bounds check bypass violations. SpecTaint [60] relies on DTA to link the memory accesses and the leakage points. Finally, Kasper [41] is also based on DTA and sanitizers but its the detection capabilities go beyond the simple bounds check bypass gadget case. Dynamic analysis techniques for Spectre gadgets, like static analysis, also suffer from false positives. Moreover, they also suffer from false negatives due to lack of coverage. Indeed, the analysis is limited to the code executed during the analysis. Reaching high coverage is particularly challenging for large code bases such as the Linux kernel.

7.4 Intel SGX

The techniques we use to control the race window are comparable to those used in various SGX controlled-channel attacks. AsyncShock [71] shows how controlled-channel attacks can be used to exploit concurrency bugs in SGX enclaves. Similar to the use of the non-interruptible *kfree* in our work, SGX-Step [65] uses a coarse-grained APIC timer interrupt to reliably interrupt enclave execution at instruction granularity. AEX-Notify [20] proposes a defense against such attacks.

8 Discussion

SRC Beyond SCUAF. In this paper, we mainly analyze SCUAFs, because architectural UAF vulnerabilities represent one of the most frequent class of memory error vulnerabilities [5–7], thus it is very likely that SCUAF gadgets have the recurrence. Nevertheless, other classes of exploitable SRCs may exist. For example, an SRC where one thread may update a shared, lock-protected index, into an array architecturally, and another thread, speculatively bypassing the corresponding lock and writing attacker-controlled data at that index (See Appendix). Such a speculative buffer overflow type of SRC is likely exploitable, however we have not found kernel coding patterns likely to lead to such a condition in practice in the Linux kernel. More generally, we deem that any SRC may lead to leaking secret data as soon as the speculative thread is susceptible to a speculative control-flow hijack, through any traditional concurrent memory corruption pattern. Nonetheless, finding such gadgets in practice requires significant work as we show in Section 5, and we leave to future work to develop novel approaches to find such gadgets, for example by extending a speculative vulnerability fuzzer [41, 56] to a concurrent fuzzing setting. Note that the mitigation we propose in Section 6 prevents all potential attacks in the generalized SRC class, not merely SCUAFs.

SRC with Speculative Writing (*Free*) Thread. We recall that, by definition, a traditional race condition requires at least one writing thread. Our definition of SRCs in Section 3.1 is worded such that the architectural thread is the writing (*Free*) thread, and the speculative thread is the reading (*Use*) thread. This is because, on existing microarchitectures, writes are only visible to other threads once they are committed, therefore the writing thread cannot bypass the synchronization mechanism. However, CPU architectures where writes may become visible to other threads during speculation, via Store-To-Load (STL) forwarding [33] across simultaneously executing microarchitectural threads, have been discussed in the literature [24, 25]. Such a microarchitecture, if implemented in practice, would unlock additional gadgets.

Beyond x86 and Linux. While we have explicitly focused on x86 and Linux in the paper, SRCs affect other hardware and software targets as well. On the hardware front, we have verified that all the major hardware vendors are affected by SRCs since, regardless of the particular compare-and-exchange instruction implementation, the conditional branch that follows is subject to branch (mis)prediction. In other words, all the microarchitectures affected by Spectre-v1 are also affected by SRCs. On the software front, any target relying on conditional branches to determine whether to enter critical regions—a common design pattern that extends well beyond Linux—is vulnerable to SRCs. In summary, any OS, hypervisor, etc. implementing synchronization primitives through conditional branches and running on any microarchitecture (e.g., x86, ARM, RISC-V, etc.) which allows conditional branches to be speculatively executed without any serializing instruction on that path, is vulnerable to SRCs.

9 Conclusion

In this paper, we presented Speculative Race Conditions (SRCs), a new class of speculative execution vulnerabilities. SRCs stem from all the common synchronization primitives using a conditional branch as a building block (Section 4.2). Such an implementation allows attackers to mistrain the branch prediction unit and speculatively enter a critical region already concurrently accessed by another thread. This enables attackers to bypass these synchronization primitives (Section 4.2) in *all* critical regions, reintroducing many (otherwise architecturally-mitigated) security issues such as Use-After-Free (UAF) and control-flow hijacking.

To study the security impact of SRCs, we focused on Speculative Concurrent Use-After-Frees (Section 4.3), a subclass of SRCs which speculatively exploits a concurrent UAF vulnerability. We demonstrated the practicality of SCUAF attacks by developing a Proof of Concept (PoC) which allows an attacker to speculatively disclose arbitrary kernel memory at a leakage rate of 12 KB/s (Section 4.4). To mount an end-to-end speculative disclosure attack with a tiny UAF exploitation window, we presented a novel race window-massaging technique which allows an attacker to (i) precisely interrupt any kernel thread at any point during its execution and (ii) create an unbounded architectural UAF window (Section 4.1). While our technique is also applicable to the (already challenging) exploitation of architectural race conditions, it is particularly powerful in the context of SRCs, allowing the attacker to mount end-to-end attacks within a *single* race window. Furthermore, to explore the SCUAF attack surface, we developed a gadget scanner which identified 1,283 potentially vulnerable SCUAF gadgets in the Linux kernel (Section 5). Finally, we proposed and evaluated a new mitigation which tackles the root cause of SRCs by placing a serializing instruction at the vulnerable conditional branch, thus terminating the speculative path. Our proposed mitigation incurs a ≈5% geomean performance overhead on LMBench (Section 6).

10 Disclosure

We disclosed Speculative Race Conditions to the major hardware vendors (Intel, AMD, ARM, IBM) and the Linux kernel in late 2023. Hardware vendors have further notified other affected software (OS / hypervisors) vendors and all parties have acknowledged the reported issue (CVE-2024-2193 [1]). Specifically, AMD responded with an explicit impact statement (i.e., "existing [Spectre-v1] mitigations apply"), pointing to the attacks relying on conditional branch mis-speculation,

like Spectre-v1. The Linux kernel developers have no immediate plans to implement serialization of synchronization primitives due to performance concerns. However, they confirmed the IPI storming issue (CVE-2024-26602 [3]) and implemented an IPI rate limiting feature to address the CPU saturation issue by adding a synchronization mutex on the path of `sys_membarrier` and avoiding its concurrent execution on multiple cores [4]. Unfortunately, as our experiments show (Figure 5), hindering IPI storming primitives (i.e., 0 storming cores) is insufficient to completely close the attack surface.

Acknowledgments

We would like to thank the anonymous reviewers for their feedback, Andrew Cooper for his early comments on the paper, Julia Lawall for the Coccinelle clarifications, and Alessandro Sorniotti for the early discussions about the project. This work was partially supported by Intel Corporation through the "Allocamelus" project, by the Dutch Research Council (NWO) through project "INTERSECT", and by the European Union's Horizon Europe program under grant agreement No. 101120962 ("Rescale").

A Additional SRC Code Patterns

We discuss SRC code patterns other than SCUAFs that are potentially exploitable. In principle, any data race pattern that may lead to a memory error could be vulnerable, but they must also exhibit a Spectre-like transmitter pattern as shown in the examples below.

A data race may lead for example to an out-of-bounds access. We show in Listing 1 a code pattern where Thread 1, which is the architecturally executing thread, performs an update on a shared index variable. We can also assume that the offset value can be attacker-controlled. Such a pattern could occur for example when using a circular buffer. The transiently executed thread performs a speculative write, which can be out-of-bounds. Assuming that array elements are the same size as pointers, this scenario would lead to the ability to control the function pointer. Note that a speculative control flow hijack is not necessary, and any known Spectre transmitter pattern could also suffice, as shown in Listing 2. This case immediately leads to an arbitrary read primitive, without the need for additional gadgets.

Listing 1: OOB access SRC

```
//Thread 1 (architectural, interrupted):
mutex_lock (&m);
shared_idx += offset; // interrupt here
if (shared_idx > ARRAY_SIZE)
    shared_idx = 0;
mutex_unlock (&m);

//Thread 2 (transient):
mutex_lock (&m);

// spec. OOB write
array[shared_idx] = val;

// control flow hijack
fptr();
mutex_unlock (&m);
```

Listing 2: Other transmitter

```
//Thread 2 (transient):
mutex_lock (&m);

// access secret
byte = array[shared_idx];

// transmit
val = probe_array[4096*byte];
mutex_unlock (&m);
```

Other patterns are highly likely to exist. We expect future work to further study their prevalence and exploitability.

CARDSHARK: Understanding and Stablizing Linux Kernel Concurrency Bugs Against the Odds

Tianshuo Han, Xiaorui Gong, Jian Liu*

School of Cyber Security, University of Chinese Academy of Sciences
{hantianshuo, gongxiaorui, liujian6}@iie.ac.cn

Abstract

Concurrency bugs in the Linux kernel are notoriously difficult to reproduce and debug due to their non-deterministic nature. While they bring constant headaches to Linux kernel developers, the reasons behind the non-determinism and how to improve the efficiency in triggering concurrency bugs to ease the debugging process still need to be studied.

This work aims to fill the gap. We comprehensively study the concurrency bug stability problem in the Linux kernel, dissect the factors behind the non-determinism, and systematize the insights into a model to explain the non-deterministic nature of concurrency bugs.

Based on insights derived from the model, we identify an under-studied factor, named *misalignment*, which plays a vital role in triggering concurrency bugs. By controlling this factor, we significantly reduce the randomness in the concurrency bug-triggering process.

Inspired by this insight, we design a novel technique, named CARDSHARK, that can significantly improve the efficiency in triggering concurrency bugs when kernel instrumentation is possible. A variant of CARDSHARK, named BLINDSHARK, enables developers to improve efficiency in triggering concurrency bugs without knowing their root causes, making the use of CARDSHARK practical.

In our evaluation of 12 real-world concurrency bugs, CARDSHARK and BLINDSHARK significantly reduce the needed time and the number of attempts to trigger concurrency bugs in the Linux kernel. Notably, CARDSHARK can deterministically trigger 10 out of the 12 concurrency bugs with a single attempt. Our evaluation shows that CARDSHARK significantly outperforms existing works in stabilizing concurrency bugs, making it a potential great help to developers in analyzing and fixing concurrency bugs.

1 Introduction

Concurrency significantly enhances the Linux kernel by enabling efficient resource utilization, rapid response to user actions, and greater scalability, thus solidifying its role as the backbone of modern computing infrastructure. However, it also introduces unprecedented complexity, leading to a class of bugs known as concurrency bugs. These bugs arise from unexpected thread interleaving orders that developers often do not anticipate, potentially causing severe damage to the kernel's stability and security.

In addition to undermining the kernel's stability and leading to kernel panics, concurrency bugs are also known to open doors to memory corruption vulnerabilities [4–6], such as out-of-bound access, use-after-free, and double-free, which can be exploited to compromise the whole system. Its severity has been demonstrated by many successful concurrency bug-based exploits [1–3] that bypass the latest Linux kernel protections and achieve local privilege escalation on real-world devices in the past.

The non-deterministic nature of concurrency bugs poses significant challenges in their analysis and fixing. Coupled with the rapid evolution of fuzzing techniques, there are more bugs than developers can handle. In Linux kernel drivers, which is known to be a significant source of vulnerabilities [41, 50], 19% of their bugs are concurrency bugs, which leads to a substantial number of concurrency bugs [50]. This overwhelming amount of hard-to-analyze concurrency bugs leads to the delay in fixing severe concurrency bugs [18], threatening the security and privacy of billions of Linux users.

In response to these challenges, it is imperative to develop new methods to efficiently trigger and debug concurrency bugs. Despite extensive research on detecting, reproducing, and exploiting these bugs [11–14, 22–24, 49, 51–53], little has been done to understand the underlying factors contributing to their non-deterministic nature and systematize how concurrency bugs manifest. The latest related study, EXPRACE [26], suggests that increasing the time window size could improve the success rate in triggering concurrency bugs. However,

our experiments indicate that, despite a larger time window, the triggering of concurrency bugs still suffers from significant non-determinism (§ 6.2), suggesting a more complex underlying nature.

In light of the need, we embarked on a comprehensive analysis of the manifestation process of concurrency bugs in the Linux kernel. We manually analyzed 12 real-world concurrency bugs and systematized our insights into a model, which we term as the Concurrency Bug Reproduction Model. This model highlights *misalignment*—the deviation in execution timing from the ideal timing required to trigger a bug—as a vital yet unstudied factor. By manipulating the elements that cause *misalignment*, we can improve the triggerability of concurrency bugs.

Armed with these findings, we developed an intuitive yet powerful technique, named CARDSHARK, that can substantially increase the success rate of triggering concurrency bugs by manipulating system call timing to minimize the *misalignment*. As shown in Table 2, CARDSHARK significantly reduces the time and number of attempts required to trigger concurrency bugs. Notably, CARDSHARK enables deterministic triggering of 10 out of 12 concurrency bugs in our dataset with a single attempt.

We further explored the potential of CARDSHARK and implemented a downstream application, named BLINDSHARK, that can be seamlessly incorporated into proof-of-concept programs of concurrency bugs to make them more efficient without knowing the root causes. The method employs a two-step approach: it first identifies an approximate *align time* and then compensates for the *misalignment* with it, thereby increasing the likelihood of achieving the desired execution interleaving. As shown in Table 3, BLINDSHARK significantly reduces the time and number of attempts needed to trigger concurrency bugs without knowing their root causes.

We believe that our work is a solid step toward understanding the intricacies of concurrency bug manifestation and demystifying its non-deterministic nature. In summary, our paper makes the following contributions:

- We comprehensively studied concurrency bugs and proposed the Concurrency Bug Reproduction Model to explain the manifestation process of concurrency bugs.
- Based on the model, we pointed out the importance of *misalignment* in the manifestation of concurrency bugs and designed the CARDSHARK to improve the efficiency of triggering concurrency bugs by manipulating it.
- We developed BLINDSHARK, a downstream application of CARDSHARK that can substantially increase the efficiency in triggering concurrency bugs without knowing vulnerability root causes or instrumenting the kernel.

We release the implementations and the experiment dataset at https://github.com/keymaker-arch/CARDSHARK. We believe these artifacts will benefit the community by helping with the evaluation of future concurrency bug stabilization techniques and potentially providing new insights.

2 Background

2.1 Concurrency Bug in the Linux Kernel

Concurrency bugs in the Linux kernel, a significant security concern, arise from the parallel execution of kernel functions [8]. Unlike non-concurrency bugs, which are triggered by reaching specific code paths, concurrency bugs require particular interleavings of multiple execution paths, needing events to occur in a precise sequence to manifest.

Typically, these bugs involve two paths: the *racee*, which consists of two events, and the *racer*, with a single event, as illustrated in Figure 1. A concurrency bug is triggered when the racer's event happens within the time window defined by the racee's events. While some concurrency bugs present more intricate scenarios involving additional execution paths or events, it is noteworthy that over half of these bugs involve just two racing execution paths, with a total of three events [26, 40]. This pattern underscores a typical structure in the manifestation of concurrency bugs.

The triggering of a concurrency bug often results in adverse outcomes like memory corruption, posing significant security risks. Attackers can exploit such vulnerabilities to conduct malicious attacks on the kernel, such as local privilege escalation (LPE) [1–3], underlining the critical need for a comprehensive understanding and effective management of these bugs.

2.2 Concurrency Bug Stability Issue

The triggering of concurrency bugs is inherently non-deterministic [9,12,23,26,49,51,53]. Unlike non-concurrency bugs, their activation relies on a precise chronological sequence of events that is unpredictable and cannot be directly controlled, making their occurrence random and difficult to analyze or fix [15, 16].

Although inherently non-deterministic, the triggerability of concurrency bugs varies. Some bugs can be easily triggered, requiring fewer race attempts for successful manifestation. The time window size is a recognized factor affecting this triggerability - larger time windows typically mean higher chances of bug occurrence. However, the exact reasons behind this non-deterministic nature and the factors influencing triggerability beyond the size of the time window remain largely unknown.

3 Overview

Problem Statement. Our research centers on enhancing the stability of triggering concurrency bugs in the Linux kernel. We aim to delve into this non-deterministic nature of concurrency bugs, dissect its causes, and subsequently improve concurrency bug-triggering stability.

Problem Scope. This study dissects the underlying causes of non-determinism in concurrency bugs. It develops user-level techniques to trigger these bugs more effectively without requiring modification of the kernel source code. We assume that an initial, though unstable, reproducer for the concurrency bugs is available. Moreover, our scope does not cover concurrency bugs involving more complex scenarios, such as multiple (more than two) execution paths or numerous (more than three) racing events, as these represent a minority according to existing studies [26, 40] and present distinct challenges.

4 Concurrency Bug Reproduction

The triggering of concurrency bugs is known to be inherently non-deterministic. While the time window size is a critical factor in this process, as highlighted in EXPRACE [26], it is not the sole determinant. This is exemplified by cases such as CVE-2022-1729 [47], where even a substantial time window does not guarantee deterministic triggering, as evidenced in Section 6.2. Often, hundreds of attempts are required to trigger such vulnerabilities once successfully, indicating that additional factors contribute to their non-deterministic nature.

In this section, we delve into the mechanics of concurrency bug reproduction and unravel the factors contributing to their non-determinism.

4.1 Concurrency Bug In The Vacuum

Triggering of a concurrency bug hinges on a specific interleaving during the parallel execution of kernel functions. This section delves into an idealized scenario, wherein this interleaving is reliably reproducible, to discern the critical elements for deterministic concurrency bug triggering.

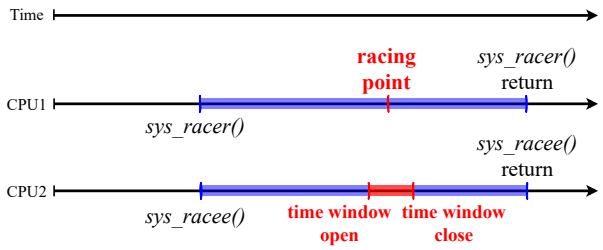

Figure 1: In an ideal environment where the racing point always falls into the middle of the time window, concurrency bugs can reproduce consistently.

Figure 1 depicts a typical concurrency bug pattern, characterized by two racing system calls, termed *sys_racer* and *sys_racee*. The bug is triggered when these system calls execute simultaneously, with the *racing point* of *sys_racer* aligning chronologically within *sys_racee*'s time window.

A *race attempt* is defined as a concurrent execution of *sys_racer* and *sys_racee*. In each *race attempt*, two threads (or processes) are spawned, each invoking a respective system call. Under ideal conditions, these two system calls commence synchronously, ensuring the *racing point* falls within the time window, as depicted in Figure 1. In such an ideal scenario, every *race attempt* leads to the specific execution interleaving necessary to trigger the concurrency bug, thereby enabling consistent bug triggering.

The inference drawn from this scenario is clear: deterministic triggering of a concurrency bug hinges on the *racing point* occurring within the time window for each *race attempt* consistently. However, this synchronicity of events remains a theoretical construct in this idealized setup and only sometimes translates to real-world situations. The following section will explore the challenges of reproducing concurrency bugs in real-world scenarios and why this idealized assumption often fails to materialize.

4.2 Concurrency Bug in Practice

In real-world scenarios, the *racing point* seldom consistently aligns within the time window in every race attempt. This non-determinism arises from the fact that user space programs have no precise control over the commence timing of racing point and the time window in real-world conditions. As a result, the *racing point* may randomly fall within or outside the time window in one race attempt. This issue is rooted in several functional aspects of the Linux kernel.

When a system call is invoked, it transitions the execution flow from user space to kernel space. The kernel then requires a certain duration to process the call. This indicates a fact that there is a time span from the invocation of *sys_racer* to the execution of *racing point*, and similarly, from the invocation of *sys_racee* to the time window midpoint. We term this duration as the *path time* of a system call.

The *path time* of a system call is an inherent property of that call. Thus, for any combination of *sys_racer* and *sys_racee*, their *path times* are inherently unequal. This difference in *path time* is referred to as *path disparity*. As the specific *sys_racer* and *sys_racee* differ in each concurrency bug context, *path disparity* becomes a unique characteristic of each bug. In real-world scenarios, the existence of *path disparity* often leads to the *racing point* not aligning with the time window, as illustrated in Figure 2.

Moreover, *invocation disparity* also plays a significant role in this context. This disparity emerges because parallel invocation of racing system calls typically requires the creation of two distinct threads (or processes). However, due to the

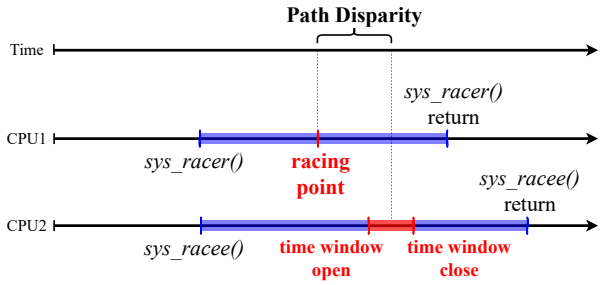

Figure 2: In reality, path disparity is one of the reasons why racing point does not always fall into the time window.

nature of the Linux kernel's scheduling policy, new threads do not start executing immediately after spawned [27]. An unpredictable delay between thread spawning and the commencement of execution is expected. Hence, when spawning two threads for racing system calls, a random disparity in their actual invocation timings is inevitable. This can lead to the *racing point* being misaligned with the time window, as shown in Figure 3.

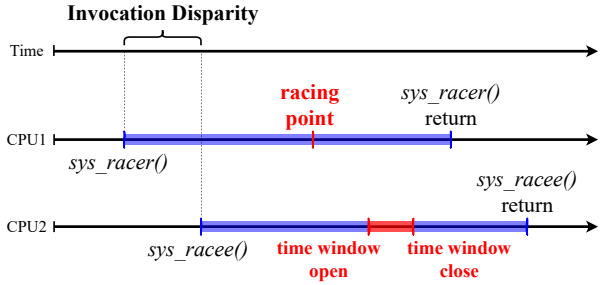

Figure 3: Random invocation disparity also introduces randomness to the concurrency bug reproduction process.

In summary, the existence of *path disparity* along with *invocation disparity* can lead to a timing difference between the racing point and the time window in a race attempt. Specifically, we define the timing difference between the *racing point* and the midpoint of the time window as *race timing misalignment*, or simply *misalignment*, as demonstrated in Figure 4.

4.3 Concurrency Bug Reproduction Model

Refining our understanding from previous sections, it is evident that *racing point* does not consistently align within the time window in real-world scenarios due to *misalignment*, a consequence of both *path disparity* and *invocation disparity*. While *path disparity* and the size of the time window (T_{win}) are intrinsic characteristics of a concurrency bug, *invocation disparity* introduces a variable element, manifesting as a random value in each race attempt.

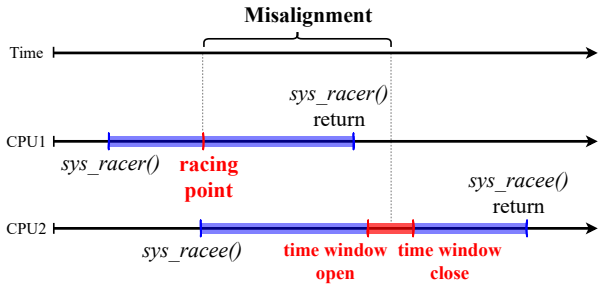

Figure 4: We define *misalignment* as the time difference between the racing point and the midpoint of the time window.

We formalize these concepts in this section. We represent the *misalignment* in a single race attempt as M, the *path disparity* as P, and the *invocation disparity* as E. The relationship between these factors is mathematically represented as:

$$M = E + P$$

As we define it, *misalignment* measures the time distance between the racing point and the *midpoint* of the time window. Specifically, *misalignment* takes a positive value when the racing point occurs before the midpoint of the time window and a negative value otherwise. As detailed in Section 4.1, a race bug is triggered when the *racing point* is positioned within the time window, meaning the distance between the racing point and the time window's midpoint does not exceed half of the time window's span. This condition can be formally expressed through the following inequality:

$$|M| < \frac{T_{win}}{2}$$

This inequality serves as the success criterion for a race attempt. It implies that a race attempt will successfully trigger the bug if the *misalignment* is not substantial enough to displace the *racing point* outside the time window. Essentially, this criterion serves as a quantifiable measure, guiding us in evaluating the likelihood of a race attempt to successfully trigger a concurrency bug, taking into account the interplay between *misalignment* and the time window.

This criterion succinctly delineates the difference between the idealized and practical scenarios, as detailed in Sections 4.1 and 4.2, respectively, and sits at the core of our Concurrency Bug Reproduction Model.

In the idealized setup of Section 4.1, we postulate synchronous execution of racing system calls ($E = 0$) and a consistent alignment of the *racing point* at the midpoint of the time window ($P = 0$). This scenario leads to a consistently null *misalignment* ($M = 0$), ensuring the criterion is perpetually satisfied. Consequently, each race attempt reliably triggers the concurrency bug.

In contrast, real-world conditions yield non-zero *path disparity* and *invocation disparity*. The stochastic nature of *invocation disparity* bestows an element of randomness upon the

misalignment. Given the fixed time window length intrinsic to the bug, this criterion is only sometimes achievable. Hence, a race attempt triggers the bug in real-world conditions only when a fortuitous *invocation disparity* incidentally satisfies the success criterion.

The criterion also clarifies why bugs with larger time windows (T_{win}) are more prone to triggering yet lack deterministic certainty. A more extensive T_{win} increases the likelihood of a *misalignment* aligning with the criterion. This principle underpins techniques like EXPRACE [26], which extends T_{win} by injecting interrupts, enhancing the chance of criterion fulfillment. However, due to the inherent randomness of *misalignment*, even an enlarged T_{win} does not guarantee consistent bug triggering.

As will be demonstrated in Section 6.1, the ability to derive observable and verifiable properties evidence the correctness of the Concurrency Bug Reproduction Model.

5 CARDSHARK

In light of the Concurrency Bug Reproduction Model (§ 4.3), there are two ways to increase the likelihood of triggering a concurrency bug: 1) enlarging the size of the time window, and 2) decreasing the *misalignment*. While the existing concurrency bug stabilizing technique EXPRACE [26] focuses on enlarging the time window, we explore the possibility of stabilizing concurrency bugs by controlling *misalignment*.

5.1 Technique Overview

As previously discussed in Section 4.2, *misalignment* is contributed by two factors: *invocation disparity* and *path disparity*. Controlling *misalignment* therefore involves addressing both its contributing factors.

The *invocation disparity* stems from the timing variance in the invocations of the racing system calls. This is because a newly created thread (or processes) does not commence execution immediately after it is spawned, and a random timing disparity appears when we create two threads to invoke the racing system calls in parallel. Thus, *invocation disparity* can be nullified by precisely synchronizing the invocation timing of racing system calls in parallel threads.

We synchronize two system calls by inserting an execution barrier before them, ensuring the precisely synchronized invocation timing. The detailed implementation can be found in the Appendix 11.1.

Addressing the *path disparity* presents a more intricate challenge. As an intrinsic property of system calls, *path time* can not be directly altered by user space programs. Nonetheless, we can strategically manipulate the invocation timing of the racing system call precisely in user space to compensate for its influence. Specifically, as shown in Figure 5, we insert a precise delay before the invocation *sys_racer* to ensure that the racing point will fall into the time window. Conversely, we insert a delay before *sys_racee* in case racing point falls behind the time window.

Theoretically, if this delay precisely equals the *path disaprtiy*, it can offset the racing point within the time window and achieve consistent concurrency bug triggering. We refer to this delay as *align time*. However, in reality, *path disparity* cannot be precisely measured without knowing the root cause of the concurrency bugs. As a result, we can only significantly increase the chance of triggering concurrency bugs but not reproduce them consistently in practice.

To summarize, our control over *misalignment* consists of two steps:

1. Precisely synchronizing the invocation timing of racing system calls to eliminate random *invocation disparity*.
2. Injecting a delay equal to the *path disparity* into the system call invocation process to compensate for the *path time dispartiy*.

We have termed this method of manipulating *misalignment* as CARDSHARK. Implementing CARDSHARK theoretically nullifies *misalignment*, leading to consistent alignment of the racing point within the time window, as illustrated in Figure 5.

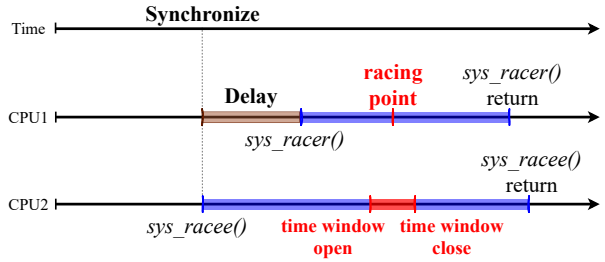

Figure 5: CARDSHARK injects a delay to racing system calls to increase the chance of racing point falling into the time window, thus triggering concurrency bugs.

5.2 Algorithmic Implementation of CARDSHARK With Presumed Align Time

For clarity in this section, we assume that the *align time* has already been accurately determined, allowing us to focus on the principle of CARDSHARK. In the following section, we will demonstrate the efficacy of CARDSHARK without this assumption.

As established before, CARDSHARK controls *misalignment* by addressing its two contributors. This is achieved by meticulously manipulating the invocation timings of the racing system calls. The specific steps of this approach are detailed in Algorithm 1.

CARDSHARK operates by precisely controlling the invocation timing of system calls to manipulate *misalignment*

Algorithm 1 CARDSHARK Algorithm

```
1:  Global Variable: delay_racee, delay_racer
2:  function THR_RACEE
3:      SYNCHRONIZE
4:      DELAY(delay_racee)
5:      SYS_RACEE
6:  end function
7:  function THR_RACER
8:      SYNCHRONIZE
9:      DELAY(delay_racer)
10:     SYS_RACER
11: end function
12: function RACE_ATTEMPT(delay1, delay2)
13:     PIN_CPU(0)
14:     THREAD_CREATE(thr_racee)
15:     PIN_CPU(1)
16:     THREAD_CREATE(thr_racer)
17:     PIN_CPU(2)
18:     THREAD_JOIN
19: end function
20: function CARDSHARK(align_time)
21:     delay_racee ← 0
22:     delay_racer ← 0
23:     if align_time > 0 then
24:         delay_racer ← align_time
25:     else
26:         delay_racee ← -align_time
27:     end if
28:     RACE_ATTEMPT
29: end function
```

using a predetermined *align time*, as outlined in Algorithm 1. If *misalignment* is positive, the *align time* is applied when invoking *sys_racer*; if negative, it is applied to *sys_racee* (lines 21 to 27).

At its core, CARDSHARK relies on the *RACE_ATTEMPT* function (lines 12 to 19) to launch two threads for the racing system calls. The main thread sets its CPU affinity with the *PIN_CPU* primitive before creating the two threads to ensure that they commence execution in parallel (lines 12 to 19). The threads, executing *thr_racer* and *thr_racee* functions, synchronize using the *SYNCHRONIZE* primitive for coordinated execution. Following synchronization, one thread waits for the *align time* before calling its system call, while the other executes its call immediately.

This algorithm's prototype, including the implicated primitives, is presented in pseudo-C code in the appendix11.1.

The efficacy of CARDSHARK under this assumption is assessed in Section 6.2. To overcome this assumption and enhance CARDSHARK's practical applicability, the following section outlines the methodology for identifying a feasible *align time*.

5.3 BLINDSHARK: CARDSHARK with Approximated Align Time

The practical application of CARDSHARK hinges on a viable *align time*. This section explores methodologies for determining this parameter for a concurrency bug.

A straightforward approach to identify *align time* involves calculating the *path time* difference between the racing system calls. This method necessitates measuring the *path time* of each racing system call and the time window, achievable through kernel instrumentation. For *sys_racer*, the *path time* is determined by the interval between its invocation and the racing point, both pinpointed via instrumentation. Likewise, the *path time* and the time window for *sys_racee* are ascertained through similar kernel instrumentations.

While this direct measurement approach to determine *align time* is conceptually straightforward, its real-world application faces complexities. It involves complex steps, including understanding the root cause of the concurrency bug to identify the racing point and the time window, which defeats the purpose of stabilizing the triggering of concurrency bugs for analysis and fixing.

We propose a brute-force BLINDSHARK method as an alternative, which obviates the need for deep insights into the concurrency bug's root cause or kernel code instrumentation. This approach is premised on the fact that the *range* of *align time* can be determined quickly, and it is feasible to test for all possible *align time* to determine a viable one.

The principle behind BLINDSHARK is that *path time* does not surpass the total execution time of the racing system calls since racing point and the time window are integral to the execution path. Consequently, the difference in *path times*, or *misalignment*, will not exceed the bounds of the execution time of the system calls.

BLINDSHARK methodically determines *align time* by iterating through all possible values. Initially, it measures the execution times of *sys_racer* and *sys_racee*, then introduces incremental delays to each, monitoring for kernel crashes. By testing every potential *align time*, a kernel crash at a specific *align time* indicates a viable candidate. The algorithm of BLINDSHARK, as shown in Algorithm 2, efficiently navigates through all possible *align times*, leveraging kernel crashes as indicators for a feasible *align time*.

BLINDSHARK begins by measuring the execution times of racing system calls with the *MEASURE* function (defined in lines 1 to 6). The *READTIME* primitive reads high-resolution timers like time stamp counters [20, 26, 35] or HPET devices [37]. Next, from lines 10 to 21, BLINDSHARK systematically explores potential *align times* by incrementally applying them to *sys_racee* and *sys_racer* during race attempts, utilizing the *CARDSHARK* function (Algorithm 1). Appendix 11.2 provides a prototype implementation in pseudo-C code.

It is worth mentioning that the feasible *align time* is not a single, fixed value; rather, it encompasses a range. An *align*

Algorithm 2 BLINDSHARK Algorithm

```
1:  function MEASURE(syscall)
2:      start ← READTIME
3:      SYSCALL
4:      end ← READTIME
5:      return end - start
6:  end function
7:  function BLINDSHARK
8:      T_racer ← MEASURE(sys_racer)
9:      T_racee ← MEASURE(sys_racee)
10:     for t in [0, T_racer] do
11:         CARDSHARK(-t)
12:         if CRASH then
13:             return -t
14:         end if
15:     end for
16:     for t in [0, T_racee] do
17:         CARDSHARK(t)
18:         if CRASH then
19:             return t
20:         end if
21:     end for
22: end function
```

time is considered suitable if it adjusts the racing point to fall within the defined time window. Due to the inherent non-deterministic elements of CARDSHARK, as will be elaborated in Section 5.4, the ideal *align time* would place the racing point at the midpoint of the time window. However, BLINDSHARK does not explicitly aim to locate this exact *align time*. It terminates its search upon the occurrence of the first kernel crash, offering the associated *align time* as the output. This resulting *align time* can shift the racing point to a position within the time window but does not necessarily align it with the window's center unless the *path disparity* for the concurrency bug is zero.

To sum up, we do not claim that the viable *align time* obtained by Algorithm 2 is the optimal *align time*. Instead, it finds a viable or approximated *align time* that can improve stability in triggering concurrency bugs. Nonetheless, as evidenced in Section 6.3, the approximated *align time* determined by BLINDSHARK proves to be significantly effective in increasing the stability of triggering concurrency bugs.

5.4 Non-determinism Factors in CARDSHARK

While CARDSHARK is conceptually capable of eliminating *misalignment* to deterministically trigger concurrency bugs, achieving this in practical scenarios is hampered by inherent non-determinism factors. This section delves into these factors and assesses their impact on deploying CARDSHARK in real-world settings.

As delineated in Section 5, CARDSHARK endeavors to control *misalignment* by meticulously addressing its two contributors. The first contributor, *invocation disparity*, arises due to the variable timing of racing system call invocations in user space. Since this disparity originates within user space, it can be effectively eliminated with precise synchronization primitives implemented in user space.

However, addressing the second contributor, *path disparity*, is not as straightforward. This disparity arises due to variations in *path time* of the racing system calls. Since *path time* is inherent to the system call and can not be directly altered by user space programs, the resulting *path disparity* can not be directly manipulated or seamlessly eliminated.

In CARDSHARK, *path disparity* is not eliminated directly; instead, its influence on the concurrency bug triggering is mitigated by strategically introducing a delay in the user space. This indirect approach to managing *path disparity* unfortunately adds a layer of non-determinism to CARDSHARK, primarily due to the inherent variability of *path times* for racing system calls in real-world scenarios.

By definition, *path time* refers to the duration from invoking a system call in user space to the execution of a specific point in kernel space (for *sys_racer*, this point is the *race point*, and for *sys_racee*, it is the midpoint of the time window). This duration encompasses the transition from user to kernel state and the execution of specific kernel functions. During any given race attempt, the *path time* may extend due to non-deterministic occurrences such as interrupts [26] or scheduling processes [25, 27]. These events necessitate additional handling by the kernel, thereby prolonging the *path time*.

Despite the absence of non-deterministic events, *path time* remains variable. Various factors can influence its duration. Notably, hardware characteristics such as memory cache and CPU frequency scaling significantly impact the execution time of instructions. For instance, the time to execute a given set of instructions increases if a memory cache miss occurs or when the CPU operates at a lower frequency [19, 34, 38]. Furthermore, kernel utilities, like memory allocators and locking mechanisms, exhibit variability in their execution times. For example, the SLUB memory allocator demands more time to allocate a memory chunk when it needs to request a new page from the buddy system [25, 55]. Similarly, the duration for acquiring locks within the kernel can also vary.

As such, the actual *path disparity* in race attempts under real-world conditions is inconsistent. Consequently, pinpointing an exact *align time* that ensures the complete mitigation of its effects proves challenging. Nonetheless, the strategy of diminishing its impact by injecting a delay, as implemented in CARDSHARK, effectively addresses its influence on the triggering of concurrency bugs. As will be demonstrated in Section 6.2, CARDSHARK can adeptly manage *misalignment* and enhances the stability of concurrency bug triggerings, even when the *path disparity* is inconsistent.

Vulnerability	Race Attempts	Racee Path	Racer Path	Path Disparity	Time Window
CVE-2017-2636 [43]	262	6824	1120	5704	11398

Table 1: Precise timing evaluation of 12 real-world concurrency bugs. The time unit in the table is TSC. The *path disparity* in the table are absolute values for simplicity. The result shows that the time window size is not the only factor contributing to the randomness of the concurrency bug reproduction process.

6 Evaluation

In this section, we evaluate the effectiveness of CARDSHARK technique by answering the following research questions:

RQ1: Is it true that the larger the race time window is, the more stable concurrency bugs can be reproduced? Moreover, is it the only factor behind the non-determinism of concurrency bug reproduction?

RQ2: How much improvement does CARDSHARK offer in enhancing the efficiency of triggering concurrency bugs by manipulating *misalignment*?

RQ3: Without a thorough analysis of the root causes of concurrency bugs (hence, without knowing the ideal alignment time), is BLINDSHARK capable of determining an effective *align time* and successfully stabilizing concurrency bugs?

RQ4: How does the performance of CARDSHARK compare with the existing concurrency bug stabilizing technique EXPRACE [26]?

To address these questions empirically, we devised a set of experiments focusing on real-world concurrency bugs.

Experimental Setup. Our experiment framework was established on a machine with an Intel i5-8700 CPU and 32GB of memory.

Instead of running the experiments in virtual machines, we ran all the experiments on the *physical machine* to avoid unexpected influence introduced by virtual machines. We use a separate Raspberry Pi 4B+ to automate the experiment process by enabling serial console communication between the physical test machine and the Raspberry Pi controller. The controller sends commands to the physical machine to boot into target kernels, run exploits, and restore the physical machine's state when exploits succeed (causing kernel panic) or fail (after more than 10,000 race attempts).

In each experiment, a concurrency bug that succeeds in triggering or fails to trigger is run 50 times to ensure the statistical significance of the result.

Dataset. We diligently collected concurrency bug reproducers from existing works [26, 49, 55], syzbot [7], and Linux kernel commits [36]. Note that EXPRACE is another work in stabilizing concurrency bugs, and their work was evaluated on 10 real-world bugs. We contacted the authors for bug reproducers used in their evaluation but did not obtain the complete set of functional reproducers. Eventually, we obtained 12 real-world concurrency bugs for our evaluation.

Among the concurrency bugs, some had publicly available reproducers. These existing reproducers merely attempt to invoke the racing system calls repetitively without any form of stabilization. We use them as the baseline in our evaluation. For bugs lacking a public reproducer, we conducted root cause analysis and developed the corresponding reproducers by ourselves.

To ensure the triggerability of real-world concurrency bugs and minimize the influence of extraneous kernel features, we compiled the last known vulnerable kernel version for each concurrency bug based on default configurations (*defconfig*) for the experiment.

6.1 Empirical Verification of the Model

We first designed an experiment to empirically verify the correctness of the Concurrency Bug Reproduction Model to

Vulnerability	Time To Reproduce		Race Attempts	
	Baseline	CARDSHARK	Baseline	CARDSHARK
CVE-2017-2636 [43]	0.1	0.1	262	1
CVE-2017-7533 [45]	0.1	0.1	147	1
CVE-2021-26708 [44]	0.1	0.1	17	1
CVE-2021-32606 [46]	61.1	0.1	>10000	1
CVE-2022-1729 [47]	1.1	0.1	379	1
CVE-2023-31083 [48]	10.2	0.1	>10000	1

4ccf11c4e8 [32]	0.2	0.2	481	1

Table 2: The time cost (in second) and race attempts for CARDSHARK and baseline approach to trigger concurrency bugs. CARDSHARK significantly reduces the number of needed race attempts to trigger concurrency bugs by manipulating *misalignment*, indicating the correctness of the Concurrency Bug Reproduction Model.

answer RQ1.

In this experiment, we analyzed the root causes of all the concurrency bugs in our dataset and instrumented the kernels at the racing point and the time window to record the exact execution timing of the baseline bug reproducer (the ones with no stabilization techniques) to verify our model. We use time stamp counter (TSC) [20, 35] as a precise time measurement, which is also used in existing research works needing precise timing control [55].

The results in Table 1 indicate that reproducing concurrency bugs becomes challenging with significantly small racing time windows. This finding aligns with prior research suggesting that larger time windows increase the likelihood of bug reproduction [26]. Nonetheless, this pattern does not hold universally to all cases, suggesting that time window size is not the sole determinant of concurrency bug non-determinism.

6.2 CARDSHARK Efficacy

We structured another experiment to evaluate if controlling *misalignment* enhances the efficiency of triggering concurrency bugs, directly addressing RQ2.

The experiment consists of two distinct phases. In the first phase, we reused the kernel instrumentation infrastructure from the last experiment and used the measured *path disparity* as the precise *align time* to be used in CARDSHARK. In the second phase, we apply the precise *align time* delay to trigger the concurrency bug, launching CARDSHARK technique. Here, we inject the precise *DELAY* by injecting a busy loop before the system call invocation and constantly monitoring the elapse of time by constantly reading TSC, similar to what is used in the Context Conservation technique in existing works [55].

In this experiment, we modified the baseline exploits by incorporating invocation synchronization and *align time* injection to create CARDSHARK reproducers. Each version, whether baseline or CARDSHARK, was tested 50 times on a physical machine to determine success or failure. Specifically, for some bugs like CVE-2021-32606 [46], the baseline group required an exceptionally high number of attempts to trigger the bugs. For simplicity, we capped the maximum number of attempts at 10,000 for these baseline experiments.

The results are detailed in Table 2. As shown in the table, CARDSHARK significantly reduces the average time and number of attempts required to trigger concurrency bugs. This substantial improvement strongly suggests that *misalignment* is a key factor contributing to the non-determinism of concurrency bugs.

Notably, CARDSHARK enables deterministic triggering of 10 out of the 12 bugs in our dataset with just one attempt. However, CVE-2017-15265 [42] and 20f2e4c228 [28] are not deterministically triggered by CARDSHARK. As Table 1 shows, these two bugs have very narrow time windows combined with relatively large *path time*, indicating that the non-deterministic factors, which are not addressed by CARDSHARK as discussed in Section 5.4, still significantly influence the triggering of some concurrency bugs. This is particularly evident in cases like CVE-2017-15265 and 20f2e4c228, where a large *path time* are more likely to be influenced by the non-deterministic factors that can offset

Vulnerability	Time To Reproduce		Race Attempts

the racing point outside of the narrow time window. Future improvements in CARDSHARK should aim to handle these non-determinism factors, as will be discussed in Section 7.4. Nonetheless, the overall efficacy of CARDSHARK supports the validity of our Concurrency Bug Reproduction Model.

6.3 BLINDSHARK Efficacy

In this section, we assess BLINDSHARK's ability to identify an approximated *align time* without prior knowledge of the concurrency bug's root causes or kernel instrumentation, addressing RQ3.

The experiment utilizes the same set of concurrency bugs as in Section 6.2 but with a realistic setting. Specifically, here, BLINDSHARK determines the *align time* without kernel instrumentation or knowing the root cause, and it uses this approximated *align time* for bug triggering. The experimental setup remains consistent as before.

We detail the evaluation result in Table 3. As shown in the table, even without knowing the root causes or kernel instrumentation, BLINDSHARK can still significantly reduce the time and number of attempts required to trigger the concurrency bugs.

BLINDSHARK's performance improvement over the baseline is less pronounced compared to CARDSHARK's. This is attributed to the less accurate approximation of *align time*, stemming from the absence of precise kernel instrumentation. Nonetheless, BLINDSHARK offers a practical solution for developers to reproduce, analyze, and fix concurrency bugs in real-world scenarios.

6.4 Evaluation Against Existing Work

In this section, we evaluate the performance of our technique against the existing concurrency bug stabilization technique EXPRACE [26] on our dataset to answer RQ4. As discussed in Section 4, EXPRACE is primarily designed for non-inclusive multi-variable data races, but its underlying principles apply to the concurrency bugs analyzed in this paper.

EXPRACE offers four distinct variant implementations: *reschedule*, *membarrier*, *TLB-shootdown*, and *HW-interrupt*. According to EXPRACE's evaluation, the *HW-interrupt* variant, which extends the time window by receiving network packets, is the most performant one over all variants in stabilizing non-inclusive data races. However, the performance of *HW-interrupt* variant significantly depends on the network latency, yet the information is not available in the paper. Consequently, we implemented the *membarrier* variant, which operates by sending memory barrier signals from user space to the local CPU, and should thus provide relatively consistent and good performance across different experimental settings. While we do not claim these values precisely represent EXPRACE's performance, they are our best effort to reproduce their results.

Results are presented in Table 4. The result illustrates that while *membarrier* reproducers can improve the reproducibility of concurrency bugs, the improvement does not apply to all bugs. In other cases, *membarrier* achieves comparable performances with the baseline reproducers. This observation conforms with what they reported in the original EXPRACE paper. EXPRACE's limitation arises because the success of

Vulnerability	Time To Reproduce			Race Attempts		
	Baseline	Membarrier	BLINDSHARK	Baseline	Membarrier	BLINDSHARK
CVE-2017-2636 [43]	0.1	0.1	0.1	262	10	10
CVE-2017-7533 [45]	0.1	0.1	0.1	174	5	5
CVE-2021-26708 [44]	0.1	0.1	0.1	17	10	10
CVE-2021-32606 [46]	61.1	39.3	0.1	>10000	>10000	22
CVE-2022-1729 [47]	1.1	0.4	0.1	379	331	9
CVE-2023-31083 [48]	10.2	58.7	0.1	>10000	>10000	37
CVE-2017-15265 [42]	5.2	2.1	0.3	>10000	>10000	3037
3c4f8333b5 [29]	0.1	0.1	0.1	2	2	1
423ecfea77 [30]	0.1	0.1	0.1	47	32	2
20f2e4c228 [28]	26.8	9.2	1.2	>10000	>10000	7963
458c15dfbc [31]	0.1	0.1	0.1	967	1077	4
4ccf11c4e8 [32]	0.2	0.2	0.2	481	494	2

Table 4: The time cost (in second) and the attempt number for each tool to trigger concurrency bugs. BLINDSHARK performs the best in reproducing concurrency bugs compared to baseline and EXPRACE's *membarrier* variant.

triggering concurrency bugs depends on both *misalignment* and the size of the time window. While injecting *membarrier* into reproducers can probabilistically increase the size of the time window, it does not eliminate the impact of *misalignment*.

On the other hand, while working on the same condition (not knowing the root cause and no instrumentation), BLINDSHARK can significantly stabilize *all* concurrency bugs, which further outlines the accuracy of the Concurrency Bug Reproduction Model compared to EXPRACE's time-window-centric model.

7 Discussion

7.1 Limitation of CARDSHARK

While CARDSHARK offers a robust solution, its effectiveness is not uniform across all concurrency bugs. This section explores the limitations of CARDSHARK and identifies scenarios where its application may be less effective or impractical, explaining the reasons behind these constraints.

For certain concurrency bugs in the Linux kernel, one (or even both) of the racing execution paths may not be initiated via a system call in the user space. For instance, the concurrency bug fd3d91ab1c [33] emerges from the concurrent execution of a system call in user space and a process triggered by the physical detachment of a USB device. The strength of CARDSHARK lies in its ability to meticulously manage the initiation timing of system calls from user space. Consequently, it becomes inapplicable for concurrency bugs where a racing path is not initiated by a user-space system call.

Moreover, CARDSHARK's reliability diminishes in scenarios involving complex concurrency bugs with more than three interdependent events and in non-inclusive data races, as described in some existing studies [26,40]. While applying the CARDSHARK in these situations is technically feasible, the outcome is uncertain. CARDSHARK allows for the satisfaction of some, but not necessarily all, interleaving constraints. Fully enforcing all the interleaving is challenging due to the inherently random nature of the interleaving between the two execution flows.

In essence, the comprehensive applicability and effectiveness of CARDSHARK for addressing all types of concurrency bugs in the Linux kernel remain unclear, and its performance on certain bugs has not yet been thoroughly evaluated.

7.2 Mitigation

Although CARDSHARK and BLINDSHARK are designed to facilitate analysis and debugging of concurrency bugs, they could theoretically be incorporated into concurrency bug exploitations and improve their success rate. To mitigate this exploitation risk, two approaches are proposed: (1) detecting abnormal frequencies of system call invocations, and (2) restricting non-root users from directly accessing high-resolution timers.

The first approach involves monitoring system call invocations at the kernel level, as exploiting concurrency bugs requires frequent system calls with identical parameters. By introducing small random delays to these system calls, the kernel can disrupt the precise timing control required by CARD-

SHARK and BLINDSHARK, impairing their functionality.

The second approach restricts access to high-resolution timers, which CARDSHARK and BLINDSHARK rely on to inject precise delays and mitigate *misalignment*. Limiting access would straightforwardly render these tools ineffective. However, on some specific hardware platforms, there are high-resolution timers provided at the hardware level (such as the Time Stamp Counter on modern x86 platforms). Restricting these timers may require corresponding hardware-specific patches.

7.3 Combination of EXPRACE and CARDSHARK

As suggested by the Concurrency Bug Reproduction Model, we can further improve CARDSHARK's ability to stabilize concurrency bugs because CARDSHARK focuses on reducing *misalignment* while EXPRACE tries to increase the race time window.

However, unfortunately, these two techniques are not compatible. This is because EXPRACE treats interrupt injections as random occurrences, not ensuring deterministic injection within the time window. Even if CARDSHARK injects a precise *align time* to synchronize the system call invocation and compensate for the *path disparity*, EXPRACE can still inject an interrupt before the *racing event* or *time window*, destroy the precise timing control.

7.4 Future Work

Enhancing CARDSHARK's Capabilities: Section 5.4 points out that CARDSHARK does not resolve all non-determinism factors in concurrency bugs, making deterministic triggering a complex challenge. Identifying and managing these non-deterministic factors is a critical direction for future research.

Furthermore, as Section 7.1 discusses, the effectiveness of CARDSHARK varies when applied to specific types of concurrency bugs. A detailed evaluation of CARDSHARK's applicability and potential refinements for specific bug categories is a priority for future investigations.

Additionally, it is worth noting that CARDSHARK currently represents a basic application of our Concurrency Bug Reproduction Model. The model's broader capabilities still need to be explored. We plan to develop and introduce more refined techniques based on a deeper understanding of it.

Enhancing *align time* Search Algorithm: As discussed in Section 5.3, BLINDSHARK can determine a viable *align time*, not the optimal one. We plan to improve the algorithm of BLINDSHARK to automatically determine the optimal *align time* in the future.

Integration with Syzkaller: Syzkaller [17] is the state-of-the-art kernel fuzzer aiming to discover kernel bugs, including concurrency bugs. However, many concurrency bugs uncovered by Syzkaller are not reproducible. Many of these bugs cause a kernel crash during the fuzzing process and never reproduce [15, 16]. Analyzing the root cause of such concurrency bugs without a reproducer is highly challenging, leaving many concurrency bugs delayed in fixing or even unfixed.

As an open-source project, we examined Syzkaller's bug reproduction mechanism. We noted its approach to reproducing concurrency bugs: it repetitively and blindly makes race attempts, similar to the baseline settings in our evaluation experiments (see Section 6.2). Given that CARDSHARK can be fully automated with the *align time* determined by BLINDSHARK, we propose that CARDSHARK can be integrated into Syzkaller to enhance its ability to generate concurrency bug reproducers.

Expanding CARDSHARK to Other Systems: While CARDSHARK is primarily designed for addressing concurrency bugs in the Linux kernel, its underlying principles are not exclusive to this context. The core foundation of CARDSHARK, the Concurrency Bug Reproduction Model, is versatile and not inherently limited to the context of the Linux kernel. Consequently, we plan to broaden the scope of CARDSHARK, applying it to other operating systems and user space programs in the future.

8 Related Works

Concurrency Bug Triggering. The latest work in this field, EXPRACE [26], focuses on enhancing the triggerability of non-exclusive data races by utilizing interrupts. EXPRACE initially noted that certain data race bugs are difficult to trigger due to a smaller time window for the racee compared to the racer. It categorized these as non-exclusive data races. EXPRACE's findings suggest that without expanding the racee's time window, these non-exclusive data races remain untriggerable. To address this, EXPRACE increases the racee's time window by introducing interrupts.

While EXPRACE is designed for non-exclusive data races, its principles apply to broader concurrency bug contexts. The approach highlighted the significant influence of time window size on triggering concurrency bugs. EXPRACE's model correlates the success rate of triggering non-exclusive data races with the ratio of the time window sizes. However, as analyzed in our study, the triggering of concurrency bugs depends on the interplay between *misalignment* and time window size. This implies that EXPRACE presupposes a constant alignment of time windows between the racer and racee (*misalignment* equals zero). According to our analysis in Section 4.2, this assumption is not a natural occurrence.

In essence, while EXPRACE's method of invoking interrupts can increase the triggerability of non-exclusive concurrency bugs, it does not fully address the fundamental aspect of *misalignment*. This oversight limits their understanding of the root causes behind the observed improvements in

bug triggerability.

Concurrency Bug Discovering. Many research efforts have been dedicated to identifying concurrency bugs in the Linux kernel, employing diverse methodologies ranging from static to dynamic analysis. Works like those by Erickson et al. [14], Engler and Ashcraft [13], Vojdani et al. [51], Ryan et al. [49], Deligiannis et al. [12], Voung et al. [52], and Xu et al. [53] adopt static analysis approaches. These methods scrutinize the code without executing it, aiming to pinpoint potential concurrency issues. In contrast, dynamic analysis techniques, as used in works like SEGFUZZ [23], Razzer [22], PACER [11], and DRDDR [24], involve analyzing the code during its execution to uncover bugs that manifest at runtime.

Among these contributions, Ryan et al. [49] introduced the innovative Probabilistic Lockset Analysis (PLA), which utilizes memory access patterns to predict and rank the likelihood of kernel races. This approach adds a probabilistic dimension to race detection, offering insights into race conditions' potential severity and frequency. Deadline [53] brings a different perspective by precisely defining and pinpointing double-fetch bugs in OS kernels. It employs symbolic checking, systematically identifying and detecting vulnerabilities involving multiple reads, enhancing the reliability of kernel operations.

On the dynamic analysis front, SEGFUZZ [23] dissect thread interleavings into manageable segments, paving the way for exploring new interleavings and identifying potential race conditions. Razzer [22] merges static analysis with deterministic thread interleaving, effectively locating and triggering data races that might otherwise remain undetected.

Additionally, Syzkaller [17] holds a unique position as it not only detects concurrency bugs in the Linux kernel but also automates the generation of reproducers. This feature is particularly valuable as it aids in subsequent bug verification and analysis steps.

Concurrency Bug Diagnosing. Diagnosing concurrency bugs is challenging due to the complex thread interleavings. RAProducer [54] addresses this by dissecting the execution trace of a concurrency bug's Proof of Concept (PoC), providing insightful backtracing. ConCrash [10] efficiently navigates the vast space of test codes using advanced search pruning strategies, pinpointing failure-inducing codes. AITIA [21] clarifies kernel race issues by defining and tracing causality chains, illuminating the root causes of concurrency bugs. ERACE [39] combines dynamic and static analysis to streamline the exploration and exploitation of kernel race vulnerabilities, offering a comprehensive approach to diagnosing these complex issues.

9 Conclusion

In our research, we spotlighted *misalignment*, a critical but previously underappreciated factor influencing the triggering of Linux kernel concurrency bugs. This insight reshapes our understanding of concurrency bug triggering, revealing that the intricate interplay between the time window and *misalignment* dictates bug triggering. We encapsulated this concept in the Concurrency Bug Reproduction Model, a predictive tool for assessing the success probability of a race attempt in triggering a bug. Leveraging this model, we introduced CARDSHARK, a strategy to enhance the probability of triggering concurrency bugs by manipulating *misalignment*. We believe that our insights into the concurrency bug-triggering process represent a significant step toward unraveling the unpredictable nature of concurrency bugs. Furthermore, the introduction of CARDSHARK could significantly improve the stability of concurrency bug triggering to ease concurrency bug fixing and analyzing.

11 APPENDIX

11.1 CARDSHARK

The demonstration of CARDSHARK is provided below in pseudo-C code. The *SYNCHRONIZE* primitive refered in Algorithm 1 is achieved by busy waiting on global variables. The *DELAY* primitive relies on continuously checking the time stamp counter within an infinite loop for timing delays. Finally, the *PIN_CPU* functionality is achieved through the *sched_setaffinity* system call to bind a thread to a specific CPU.

```
unsigned long long racer_delay, racee_delay;
unsigned char flag1, flag2, flag3;

static void delay(unsigned long long interval)
{
  unsigned long long end;

  end = rdtsc() + interval;
  while (1) {
    if (rdtsc() > end)
      return;
  }
}

static void pin_cpu(int cpu)
{
  cpu_set_t cset;

  CPU_ZERO(&cset);
  CPU_SET(cpu, &cset);
}

void* thr_racee(void* arg)
{
    flag1 = 1;
    while(!flag3);
    delay(racee_delay);
    sys_racee();
}

void* thr_racer(void* arg)
{
    flag2 = 1;
    while(!flag3);
    delay(racer_delay);
    sys_racer();
}

void race_attempt(void)
{
    pthread_t thrs[2];

    pin_cpu(0);
    pthread_create(&thrs[0], NULL, thr_racee, NULL);
    pin_cpu(1);
    pthread_create(&thrs[1], NULL, thr_racer, NULL);
    pin_cpu(2);
    while (!flag1 || !flag2);
    flag3 = 1;

    pthread_join(thrs[0], NULL);
    pthread_join(thrs[1], NULL);
}

void cardshark(long long align_time)
{
    if (align_time > 0)
        racer_delay = align_time;
    else
        racee_delay = -align_time;

    race_attempt();
}
```

11.2 BLINDSHARK

Below is a sample implementation of BLINDSHARK in pseudo-C code. The *MEASURE* primitive measures execution time by reading the time stamp counter immediately before and after the system call invocation.

```
unsigned long long measure(void (*syscall)())
{
    unsigned long long start, end;
    start = rdtsc();
    syscall();
    end = rdtsc();

    return end-start;
}

void blindshark(void)
{
    unsigned long long racer_len, racee_len;
    long long i;

    racer_len = measure(sys_racer);
    racee_len = measure(sys_racee);

    for (i=0; i<racer_len; i+=100) {
        cardshark(-i);
    }

    for (i=0; i<racee_len; i+=100) {
        cardshark(i);
    }
}
```

zkCross: A Novel Architecture for Cross-Chain Privacy-Preserving Auditing

Abstract

One of the key areas of focus in blockchain research is how to realize privacy-preserving auditing without sacrificing the system's security and trustworthiness. However, simultaneously achieving auditing and privacy protection, two seemingly contradictory objectives, is challenging because an auditing system would require transparency and accountability which might create privacy and security vulnerabilities. This becomes worse in cross-chain scenarios, where the information silos from multiple chains further complicate the problem. In this paper, we identify three important challenges in cross-chain privacy-preserving auditing, namely Cross-chain Linkability Exposure (CLE), Incompatibility of Privacy and Auditing (IPA), and Full Auditing Inefficiency (FAI). To overcome these challenges, we propose zkCross, which is a novel two-layer cross-chain architecture equipped with three cross-chain protocols to achieve privacy-preserving cross-chain auditing. Among these three protocols, two are privacy-preserving cross-chain protocols for transfer and exchange, respectively; the third one is an efficient cross-chain auditing protocol. These protocols are built on solid cross-chain schemes to guarantee privacy protection and audit efficiency. We implement zkCross on both local and cloud servers and perform comprehensive tests to validate that zkCross is well-suited for processing large-scale privacy-preserving auditing tasks. We evaluate the performance of the proposed protocols in terms of run time, latency, throughput, gas consumption, audit time, and proof size to demonstrate their practicality.

1 Introduction

Cross-chain technology [2] has been considered to be one of the effective ways to enhance communications and interoperability among separate blockchain systems. Users located at different blockchains can realize cross-chain transfer and exchange through cross-chain protocols. Many cross-chain protocols have arisen recently [15, 30, 36, 40], with their primary focuses residing on various aspects such as universality, security, and efficiency, largely neglecting privacy and auditing challenges. This omission may impede the widespread adoption of cross-chain mechanisms and result in significant security vulnerabilities, privacy risks, and even the loss of trust and credibility.

Privacy protection and auditing are two vital requirements in cross-chain operations. As the awareness of the worth of data grows, so does the desire for privacy protection [23, 38]. Nevertheless, privacy considerations in cross-chain need to protect not only the confidentiality of information being transferred across different blockchains but also the interactions among users across multiple chains. Disclosure of the relationship of cross-chain interactions can lead to a number of privacy risks, including the possibility of tracing the transfer of funds between chains or identifying parties involved in a specific transaction. This can potentially undermine the overall security of cross-chain systems [6]. Additionally, auditing plays an important role in cross-chain scenarios. For instance, auditing is needed to ensure the proper functioning of the interactions between two parties that need to collaborate but may potentially have conflicts of interest [22].

However, privacy protection and auditing in blockchain systems are two conflicting goals, as the former demands maintaining data confidentiality and minimizing data exposure, while the latter requires transparency and access to data. Therefore juggling the issues of privacy protection and auditing is difficult, which has long been an important research topic for single blockchains [4, 7, 9, 34, 37]. This problem becomes even more challenging in cross-chain. Specifically, the design premise of a single chain assumes that the auditors, serving as blockchain nodes, can access information within the chain. However, a multi-chain scenario breaks this premise as auditors of one chain cannot obtain all information from another chain. Intuitively, auditors can register accounts on all chains, but this is extremely resource-intensive and impractical for real-world applications, particularly in large-scale cross-chain scenarios. For instance, the ledger sizes of

*Corresponding author

Bitcoin and Ethereum have reached 500 and 700 GB, respectively, and they continue to grow over time [17]. This implies that when auditing Bitcoin and Ethereum, an auditor requires at least terabyte-level storage space, and as the number of blockchains in the network grows, this demand also increases. This poses a significant barrier for auditors. As a result, it is hard for single-chain solutions to be inherited in cross-chain.

This paper aims to make a contribution by first identifying three key challenges faced by cross-chain privacy protection and auditing, then presenting feasible solutions. The first challenge is *the Cross-chain Linkability Exposure* problem (CLE), which enables adversaries to obtain linkability between the two parties involved in cross-chain interactions, thereby exposing privacy. Addressing this issue requires designing corresponding cross-chain privacy-aware protocols for different cross-chain activities. These protocols must not permit the involvement of a third party that could compromise the security of the entire blockchain system. Second, we need to implement an audit protocol based on publicly available information, and this protocol should not contradict the protocol aimed at addressing the CLE problem. Therefore the bottleneck of cross-chain privacy protection with auditing, namely *the Incompatibility of Privacy and Auditing (IPA)*, needs to be overcome. The third challenge is termed *Full Auditing Inefficiency (FAI) problem*, which is caused by the presence of multiple heterogeneous chains that may lead to extremely low auditing efficiency. These challenges are detailed in Section 3.2.

In this paper, we propose zkCross to effectively address these three challenges. Specifically, we first present a two-layer cross-chain architecture, with the lower layer including multiple blockchains that can interact with each other, and the upper layer being a blockchain consisting of auditors. Then, in the pursuit of addressing the CLE problem, we propose two different cross-chain privacy protection protocols based on zero-knowledge proofs for two cross-chain activities (namely cross-chain transfer and cross-chain exchange), which preserve privacy without requiring any trusted third party. Finally, in an effort to address the IPA and FAI problems, we present a cross-chain auditing protocol, which compresses the auditing processes and transaction verification process into a new circuit. Such a design ensures that all auditors do not need to obtain the entire transaction content to guarantee the correctness of auditing tasks, and they can audit a linearly growing number of transactions within a constant time.

zkCross is developed for general blockchain systems with cross-chain interoperability requirements. That is, it is applicable to both permissionless and permissioned blockchains (introduced in Section 2). For convenience, we highlight our contributions as follows:

1. zkCross is the first cross-chain scheme that considers both privacy protection and auditing for cross-chain activities. To the best of our knowledge, solutions that simultaneously consider both privacy protection and auditing only exist in single-chain systems while it is hardly possible to adopt them for cross-chain operations.

2. A two-layer cross-chain architecture is designed to support the realization of simultaneous privacy protection and auditing. This architecture is auditor-friendly. It allows the decoupling of itself with the cross-chain interaction protocols, making the design of the latter more flexible.

3. Two cross-chain privacy-preserving protocols are proposed in this paper, which can guarantee the unlinkability of the interacting parties, ensure the atomicity of cross-chain interactions, and further solve the CLE problem without introducing any trusted third party.

4. We design a cross-chain auditing protocol, that can effectively address the challenges of IPA and FAI. This protocol can enhance the auditing efficiency of the upper layer, without causing conflicts with addressing the CLE issue.

5. To verify the performance of zkCross, we conduct extensive experiments over a 200-node blockchain network, and the results validate the effectiveness and efficiency of our design.

The remainder of this paper is structured as follows. In Section 2, we provide the background of our work. Section 3 provides an overview of the most relevant literature and proposes the three cross-chain challenges. The models of our proposed scheme, along with a brief introduction to the necessary preliminary knowledge, are described in Section 4. The technical details of our zkCross scheme and the related security analysis are presented in Section 5 and Section 6, respectively. The performance of zkCross is reported in Section 7. Finally, Section 8 offers conclusive remarks and directions for future research.

2 Background

This section provides the necessary background to understand our work, including blockchain and cross-chain activities.

2.1 Blockchain

Blockchain [32] is a shared, distributed ledger that records all transactions and is maintained by peer nodes in a decentralized network. Each transaction is stored in a block and linked together in a chronological chain, hence the name blockchain. One of the key features of blockchain is its immutability, meaning once a transaction is recorded, it cannot be altered. Immutability ensures the integrity of the data stored on the blockchain, making it secure and resistant to unauthorized modifications. Additionally, blockchain eliminates the need for intermediaries in transactions, solving the problem of a

single point of failure. Transparency in blockchain denotes the ability to access all transactions. This is in contrast to traditional banks and service providers, which do not grant users access to their complete ledgers. Originally developed for Bitcoin [32], blockchain has since evolved to be applied in various industries beyond cryptocurrency, such as finance, the Internet of Things, smart grids, and supply chain management [45]. To accommodate various scenarios, blockchain has gradually diverged into two types: permissionless and permissioned blockchains [38]. Permissionless blockchains are decentralized networks where anyone can join, participate, and validate transactions without needing approval. Permissioned blockchains are centralized or semi-centralized networks where access and participation are restricted to approved entities.

2.2 Cross-chain Activities

Cross-chain technology facilitates the interaction between two independent blockchains [2]. Depending on the type of cross-chain activities, cross-chain interactions can be divided into cross-chain transfers and cross-chain exchanges. Cross-chain transfers refer to the movement of assets between two blockchains, which involve the process of burning assets on one blockchain and minting them on another blockchain. Cross-chain exchanges, conceptually, involve a two-way process of cross-chain transfers. They refer to the swapping of assets between two distinct blockchains. Both participating blockchains individually lock the assets intended for exchange and subsequently unlock them to receive the corresponding assets from the other blockchain.

While the concept of these two activities may appear similar, the specific technical and operational aspects of cross-chain asset transfer and exchange protocols are different and require distinct approaches and solutions. For instance, various cross-chain exchange protocols, such as HTLC and the works in [6, 18, 30], do not support asset transfer. While other schemes such as the notary scheme and relay chains (introduced in Section 3), have the capability to facilitate both cross-chain asset transfer and exchange, albeit often requiring the involvement of third-party entities possessing significant authority, thereby introducing centralized security risks.

3 Related Work and Motivations

In this section, we first briefly introduce the most related work for cross-chain interactions, then present the motivations and implications of our design by detailing the three cross-chain challenges that have largely been overlooked by the related research.

3.1 Related Work

State-of-the-art cross-chain schemes can be divided into two categories: either chain-based or bridge-based. Chain-based schemes, such as side chains [28] and hashed timelock contract (HTLC) [31], refer to those that rely on the inherent mechanisms of a chain, without the requirement for additional entities. A side chain is a separate blockchain that operates in conjunction with a parent blockchain. ZeroCross [21] is a privacy-preserving side chain solution based on the Monero platform, and Zedoo [10], which implements auditing based on the zk-SNARK technology. Baldimtsi *et al.* [1] proposed a scheme to connect anonymous chains. HTLC utilizes a combination of a hash lock and a time lock to support the cross-chain exchange activity XCLAIM [41] alleviates some of the stringent assumptions inherent in the original HTLC framework, such as the necessity for the concurrent online presence; Deshpande *et al.* [6] added privacy protection features to HTLC based on the Schnorr signatures; MAD-HTLC [31] effectively counters the incentive manipulation attack utilizing a blockchain-based incentive mechanism; Cross-Channel [15] increases the throughput of a cross-chain system based on HTLC; Thyagarajan *et al.* [30] employed verifiable timed signatures instead of time locks.

Bridge-based solutions, such as notary schemes [40] and relay chains [2], need the implementation of a third component to facilitate the interactions among chains. In the context of a notary scheme, a trusted third-party entity, referred to as a notary, performs the duties of validating the authenticity of cross-chain transactions. The design of a notary scheme is straightforward; however, it poses a potential single point of failure risk. Yin *et al.* [40] adopted secure hardware and cryptographic techniques to enhance the security of notary platforms. As for a relay chain scheme, a dedicated blockchain network, referred to as the relay chain, serves the purpose of enabling the transfer of assets between participating chains. zkBridge [36] proposed deVirgo to enhance the verification efficiency of cross-chain bridges. Wang *et al.* [33] proposed the concept of governing the chain by chain while BeDCV [44] employs a supervision chain for decentralized auditing, utilizing technologies such as homomorphic encryption. Note that, bridge-based schemes introduce trusted mechanisms such as notaries and relay chains, which enable the simultaneous consideration of both cross-chain transfers and cross-chain exchanges. Moreover, the bridge-based scheme is a type of star-shaped architecture, making it suitable for auditing tasks. However, it carries the risk of a single point of failure.

3.2 Challenges of Cross-Chain Privacy Protection & Auditing

Despite the availability of several well-conceived cross-chain solutions, significant challenges persist in the areas of cross-chain privacy preservation and auditing, including the Cross-

chain Linkability Exposure problem (CLE), the Incompatibility issue of Privacy and Auditing (IPA), and the Full Auditing Inefficiency problem (FAI). The details of these three challenges are presented below.

Challenge 1: CLE. Some solutions have been proposed to address cross-chain privacy concerns. Specifically, the schemes in [39, 43] are highly tied to the application scenarios. The privacy protection in [1, 21] benefits from its underlying blockchain platform, such as Monero and Zcash, which makes it incompatible with other blockchain systems. The mechanism in [6] provides a solution for cross-chain exchange but requires both parties to trust the same secret as a prerequisite, which creates challenges for two individuals who lack trust in one another to reach an agreement. Based on the above analysis, it is evident that the current research on cross-chain privacy protection is insufficient, and there also exist concerns regarding their generality and security risks. Additionally, existing works overlook the significant differences between cross-chain transfer and cross-chain exchange, attempting to use a single protocol to support both activities, which needs third-party entities and thereby poses security risks (such as the bridge-based scheme). One can see that the difficulty in addressing the CLE problem lies in comprehending and differentiating the activities and characteristics of blockchain interactions while using more adaptable techniques to obscure the relations between the participants. More importantly, the entire process cannot introduce third parties to disrupt the security of the system.

Challenge 2: IPA. The demands for both privacy protection and auditing often exist concurrently in a system and these two requirements have conflicting ultimate goals. To the best of our knowledge, no existing cross-chain work can solve this conflict. Current cross-chain privacy-preserving solutions [1, 6, 21, 39, 43] are not initially designed with auditing support in mind. Their primary focus is directed towards simultaneously minimizing the disclosure of information and ensuring the integrity of the protocols, disregarding considerations for information verifiability. Moreover, considering that in permissioned blockchains, auditors are external to a blockchain, they may not have access to the transaction information. For example, in a multi-chain system comprising several companies, internal nodes engage in frequent interactions, while third-party entities, such as banks and insurance companies, assume the role of auditors. The privacy of internal data, including receipts and employee information, cannot be disclosed to external entities. However, this restriction prevents banks from conducting audits, consequently impeding their ability to perform operations such as lending. To effectively address the above issues, it becomes crucial to enable the validation of private information by leveraging publicly accessible data.

Challenge 3: FAI. Current auditing works can be further broken down into two distinct subcategories: incentive-based and relay-based. The former, such as the fisherman in Polkadot [35], utilizes an incentive mechanism in which auditors selectively verify a subset of transactions to get the corresponding reward. The latter employs a relay mechanism, such as an entity or a network, to facilitate the thorough examination of all transactions in order to mitigate the risks of malicious activities [33, 44]. In general, a relay-based auditing scheme offers better security as it audits all transactions (full auditing), however, it may be less efficient than an incentive-based audit scheme. Specifically, assuming k blockchains and an average of n transactions processed per chain in a unit of time, the workload responsibility of each audit node in a relay-based scheme can be estimated as $O(\mathsf{k} \times \mathsf{n})$. This poses a high computational demand for auditors and leads to issues with inefficient verification. More seriously, as the number of blockchains continues to grow, the limitations of both methods in terms of auditing efficiency pose a challenge to their adoption in real-world settings. To address this issue, it is crucial to design an auditor-friendly scheme that guarantees security and efficiency while providing full auditing.

Motivations and Implications. Motivated by the above observations, we propose zkCross consisting of a novel architecture with three protocols. Compared to bridge-based schemes (introduced in Section 3), the architecture in zkCross adopts a tree-shaped structure. This design takes into consideration the requirements of both privacy protection and auditing, mitigating the centralization risks posed by auditing in cross-chain interactions. In the design of privacy-preserving protocols, zkCross utilizes SPV (Simplified Payment Verification) [32] and HTLC (Hashed Timelock Contracts) [31], two fundamental techniques supporting decentralized cross-chain interactions, to facilitate cross-chain transfers and exchanges. zkCross adopts zk-SNARKs, hash functions, and denomination mechanisms to address all factors that compromise the unlinkability, including receiver addresses, preimages, and transaction amounts. For the design of auditing protocols, zkCross leverages the succinctness of zk-SNARKs and offloads complex computational tasks to off-chain, thereby enhancing on-chain auditing efficiency.

4 The Model and Preliminaries

In this section, we first define our network and threat models. Then, we present the zk-Rollup, hashed timelock contracts, and simplified payment verification, which are the basic building blocks of zkCross.

4.1 Models

Network Model. zkCross is a two-layer cross-chain architecture equipped with three protocols. All entities in zkCross refer to real-world users who own blockchain accounts and can engage in off-chain and on-chain operations. Furthermore, each entity can possess multiple accounts, with each account equivalent to a node on the blockchain.

In zkCross, the lower layer has multiple independent blockchains (which we refer to as ordinary chains), where there are cross-chain transactions between a sender ($\mathcal{S}$) and a receiver ($\mathcal{R}$). Each node in an ordinary chain can serve as a committer ($\mathcal{C}_\mathcal{T}$), facilitating the aggregation of chain-related data. We assume that there is at least one honest committer in each ordinary blockchain [36]. The ordinary chain can be either permissionless or permissioned blockchains. In permissionless blockchains, all entities can register accounts and access transactions. In permissioned blockchains, external nodes, such as auditors in the upper layer, cannot access transactions as freely as in permissionless chains. Consequently, we assume that auditors may only gain access to block headers of permissioned blockchains through auxiliary means, such as Gateways [25] or blockchain explorers, to facilitate auditing procedures while preserving transaction privacy.

The upper layer comprises an audit chain, including nodes with two roles: committers and auditors. To upload the collected chain-related data to the audit chain and earn rewards, the lower-layer committer needs to register an account and become an upper-layer committer on the audit chain. Auditors, represented by $\mathcal{A}_\mathcal{D}$, are responsible for auditing the data submitted by upper-layer committers. Based on the incentive mechanism of blockchains, honest upper-layer committers are duly rewarded. The audit chain is a permissionless blockchain because it allows all entities to register committer nodes on the audit chain.

Threat Model. Nodes are running in polynomial time and might exhibit Byzantine behaviors within the blockchain network. However, their voting power cannot exceed predetermined thresholds to maintain the security of the blockchain consensus [15, 30, 31, 36]. For example, in PBFT (Practical Byzantine Fault Tolerance), the number of Byzantine nodes must be below one-third of the total, and in PoW (Proof of Work), malicious nodes cannot control more than 50% of the network's computing power.

Design Goals. zkCross aims to achieve the following goals to answer the challenges in Section 3.2.

- Privacy: Let $\mathcal{S}^{\mathsf{I}}$ and $\mathcal{R}^{\mathsf{II}}$ be two accounts involved in a cross-chain transfer or exchange. zkCross aims to ensure the unlinkability (formally defined in Definition 1) between $\mathcal{S}^{\mathsf{I}}$ and $\mathcal{R}^{\mathsf{II}}$.

- Efficiency: If a cross-chain network has k ordinary chains, where each chain has an average of m blocks, and each block contains an average of n transactions, then zkCross has an $O(\mathsf{k}\times\mathsf{m})$ complexity in auditing efficiency, comparing to $O(\mathsf{k}\times\mathsf{m}\times\mathsf{n})$ for the traditional full auditing approaches.

Definition 1 (Unlinkability [3, 11, 24])**.** *An adversary is unable to link the receiver's account from the transactions initiated by the sender, or conversely.*

In the rest of this section, we will introduce the three key technologies that we adopt in zkCross to help achieve these goals.

4.2 zk-Rollup Based on zk-SNARKs

zk-Rollup [38] is a scaling solution for blockchain networks, in which the "zk" stands for "zero-knowledge". zk-SNARK [13] is a type of zero-knowledge proof technology that is widely employed in blockchain. In the following, we provide the definition of zk-Rollup based on zk-SNARK. Note that, depending on a specific use case, alternative zero-knowledge proof schemes such as deVirgo [36], can be selected to replace zk-SNARK in the construction of zk-Rollup.

Definition 2 (zk-Rollup Based on zk-SNARK)**.** *zk-SNARK requires the implementation of an $\mathbb{F}$-arithmetic circuit Λ, which enforces constraints on the computational relationships between the public input $\vec{\mathsf{x}}$ and the private input (witness) $\vec{\mathsf{w}}$. The complete process of zk-Rollup based on zk-SNARK can be formally expressed as a three-tuple of polynomial time algorithms $\Pi \stackrel{def}{=} (\mathsf{Setup}, \mathsf{Prove}, \mathsf{Verify})$.*

- $\mathsf{crs} \leftarrow \mathtt{Setup}(1^\lambda, \Lambda)$. In zk-SNARK, the algorithm takes a security parameter 1^λ and a circuit Λ as inputs to derive the common reference string (crs), which is comprised of the proving and verification keys $(\mathsf{pk}, \mathsf{vk})$ used in subsequent proof generation and verification processes; while in zk-Rollup, the computational logic embedded within the circuit entails the verification of both the correctness of all transaction signatures and of state transitions resulting from the executed transactions.
- $\pi \leftarrow \mathtt{Prove}(\mathsf{pk}, \vec{\mathsf{x}}, \vec{\mathsf{w}})$. In zk-SNARK, the algorithm takes the proving key pk, the public inputs $\vec{\mathsf{x}}$, and the private inputs $\vec{\mathsf{w}}$, to generate a succinct zero-knowledge proof π; while in the process of implementing zk-Rollup, the public inputs $\vec{\mathsf{x}}$ include more details such as transfer amounts and address information, and the private inputs $\vec{\mathsf{w}}$ consist of the data such as transaction signatures.
- $1/0 \leftarrow \mathtt{Verify}(\mathsf{vk}, \vec{\mathsf{x}}, \pi)$. In both zk-SNARK and zk-Rollup, the algorithm performs a verification process of the proof π using the verification key vk and public inputs $\vec{\mathsf{x}}$. Its output is a binary value, with 1 indicating a successful verification and 0 the opposite.

Note that, the three-tuple of the polynomial time algorithms (Setup, Prove, Verify) represented by Π, can be adapted to various specific application scenarios by adjusting the relevant parameters, i.e., Λ, $\vec{\mathsf{x}}$, and $\vec{\mathsf{w}}$.

4.3 Hashed Timelock Contracts

HTLC (Hashed TimeLock Contract) is a critical technology that powers the Lightning Network. It has broad applications, especially for cross-chain exchanges [31].

Definition 3 (HTLC in Cross-chain Scenarios)**.** *The HTLC protocol necessitates that both parties involved in a transaction, represented by $\mathcal{S}$ and $\mathcal{R}$, possess accounts in each blockchain. For better elaboration, these accounts are denoted as $\mathcal{S}^{\mathsf{I}}$ and $\mathcal{R}^{\mathsf{I}}$ for* Chain I*, and $\mathcal{S}^{\mathsf{II}}$ and $\mathcal{R}^{\mathsf{II}}$ for* Chain II*, for $\mathcal{S}$ and $\mathcal{R}$, respectively. The protocol consists of three distinct stages:* Lock*,* Unlock*, and* Refund*.*

• Lock : $\mathcal{S}^{\mathsf{I}}$ selects a random key, such as a 256-bit integer, as the preimage pre, which is then hashed to produce the corresponding hash value $\mathsf{h}(\mathsf{pre})$. $\mathcal{S}^{\mathsf{I}}$ then employs $\mathsf{h}(\mathsf{pre})$ to lock the asset to be sent to $\mathcal{R}^{\mathsf{I}}$ in the smart contract ξ^{I} of Chain I, and sets a timer T_1. Then, $\mathcal{R}^{\mathsf{II}}$ locks its asset being sent to $\mathcal{S}^{\mathsf{II}}$ in the smart contract ξ^{II} of Chain II using the same $\mathsf{h}(\mathsf{pre})$, and sets a timer T_2 with $\mathsf{T}_1 > \mathsf{T}_2$.
• Unlock : Within the time limit T_2, $\mathcal{S}^{\mathsf{II}}$ presents the preimage pre to the smart contract ξ^{II} in order to unlock the asset sent by $\mathcal{R}^{\mathsf{II}}$. Once $\mathcal{R}^{\mathsf{II}}$ receives the preimage, $\mathcal{R}^{\mathsf{I}}$ provides pre to the smart contract ξ^{I} within the time limit T_1, which unlocks the asset sent by $\mathcal{S}^{\mathsf{I}}$.
• Refund : If $\mathcal{S}^{\mathsf{II}}$ fails to provide pre within the allotted time frame T_2, the locked asset in ξ^{II} would be refunded to $\mathcal{R}^{\mathsf{II}}$. As a result, $\mathcal{R}^{\mathsf{I}}$ cannot unlock the asset it should receive from $\mathcal{S}^{\mathsf{I}}$ since it does not possess the necessary pre information, which only $\mathcal{S}$ possesses. Consequently, in the event of T_1 timing-out, the locked asset would be refunded to $\mathcal{S}^{\mathsf{I}}$.

Note that, certain blockchain systems, including Bitcoin, do not have native support for smart contracts. As an alternative, HTLC can be implemented using other mechanisms such as scripting [32]. For simplicity, this paper uses the term smart contract to refer to a true smart contract or an implementation technique such as scripting when discussing HTLC.

4.4 Simplified Payment Verification

SPV (Simplified Payment Verification) was proposed by Satoshi Nakamoto [32] in 2008 and has been widely adopted by various blockchain systems such as Ethereum since its birth. It aims to enable lightweight clients to participate in a blockchain network without having to store the entire on-chain data by making use of a Merkle proof, a crucial component that allows a light node to verify the inclusion of a transaction in a block without downloading the entire block. Specifically, the Merkle proof of a transaction is the combination of the Merkle path of that transaction and the root node of the entire Merkle tree. The Merkle path of a node is the siblings of all nodes along the path from the node to the root of the Merkle tree.

5 The zkCross

In this section, we first present an overview of zkCross and its advantages, then elaborate on three protocols designed for the purpose of privacy-preserving auditing.

5.1 Overview

zkCross addresses the aforementioned challenges of CLE, IPA, and FAI. Figure 1 depicts its two-layer architecture and three key protocols.

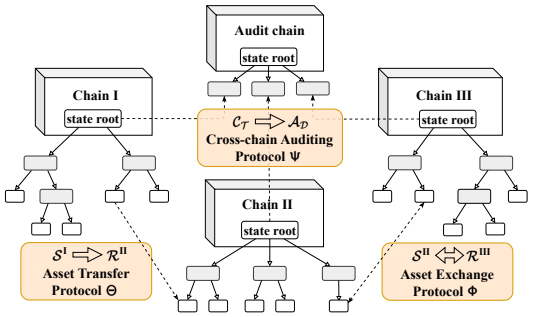

Figure 1: Illustration of zkCross: upper-layer: the audit chain; lower-layer: multiple ordinary chains; and the three protocols shown in the orange boxes.

The lower layer is comprised of multiple ordinary chains, three in Figure 1 marked as Chain I, Chain II, and Chain III, respectively. The upper layer encompasses an audit chain that regulates the activities of the ordinary chains in the lower layer. Within this architecture, each blockchain maintains a state tree, which is essentially a binary Merkle tree. In an ordinary chain, each leaf in its state tree represents the hash result of an account state, encompassing public keys and balances. For the audit chain, its state tree stores the state tree roots of ordinary chains as leaves, establishing hierarchical links between ordinary and audit chains.

zkCross includes two privacy protection protocols (Θ and Φ), tailored for the two distinct cross-chain interaction activities: transfers and exchanges, respectively. Users participating in these protocols are nodes at different ordinary chains. For instance, a sender $\mathcal{S}^{\mathsf{I}}$ in Chain I, can employ protocol Θ to secretly transfer cross-chain assets to a receiver $\mathcal{R}^{\mathsf{II}}$ in Chain II, while a sender $\mathcal{S}^{\mathsf{II}}$ in Chain II can conduct a cross-chain exchange with a receiver $\mathcal{R}^{\mathsf{III}}$ in Chain III through the privacy-preserving protocol Φ. Both Θ and Φ can protect the privacy of the relationship between the interacting parties. Entities in the audit chain primarily consist of auditors and committers. Under the cross-chain auditing protocol Ψ, a committer is responsible for packaging the transactions in an ordinary chain and uploading them to the auditors to complete the auditing process.

The two-layer architecture is capable of supporting the interactions between various entities, such as cross-chain interacting entities and auditing entities, thereby facilitating the design of privacy-preserving cross-chain protocols and efficient auditing protocols. Note that the proposed architecture decouples auditing from cross-chain protocols (such as Θ and Φ) among ordinary chains. This implies that the two-layer architecture is not restricted to privacy-preserving auditing,

it can support other protocols developed according to the specific application scenarios. On the other hand, the cross-chain protocols designed in this paper are not restricted to the two-layer architecture only, they are implemented with popular cross-chain technologies, such as SPV and HTLC, and hence can be adopted directly or with modifications for other multiple-chain architectures. The audit content of the auditing protocol can be tailored to specific requirements, encompassing tasks such as verifying transaction amounts within a predefined range and checking if a transaction address is blacklisted. The protocol Ψ can conduct audits without exposing the information of the lower-layer transactions.

In the remainder of this section, we elaborate on the two privacy-preserving cross-chain protocols and the efficient auditing protocol.

5.2 Privacy-preserving Cross-chain Protocols

In this subsection, we present two different privacy-preserving protocols to address the CLE problem.

5.2.1 An Cross-chain Transfer Protocol with Privacy Preservation

In the process of cross-chain transfer based on SPV, the receiver address and the transfer amount of a transaction are two important factors that can expose the correlation between the parties involved in the interaction. Obviously, one needs to hide the destination address of a transfer. Concealing the transfer amount is necessary too, as the process of a cross-chain transfer involves the burning of funds on one chain and the minting of an equivalent amount on another chain. For example, consider a situation where the public exchange rate between Bitcoin and Ether is 1:10. During a cross-chain transfer, a fund in the form of one Bitcoin is burned on its original chain, and as a result, 10 Ether of equivalent value is minted on the destination Ethereum. Therefore, if the transfer amount is public, adversaries can deduce the correlation between the parties by examining the burning and minting transactions on the two chains. Nevertheless, if the above two privacy-sensitive information are both hidden, they would cause SPV authentication to fail and disrupt the atomicity of the cross-chain interaction.

Based on the above analysis, we design a privacy-preserving cross-chain transfer protocol Θ (shown in Figure 2) to address the privacy concerns arising from the receiver's address and the transfer amount. We choose to hide the receiver's address via zk-SNARK but conceal the transfer amount by setting a fixed denomination [12, 16, 29]. For example, on an Ethereum chain, if the basic denomination is set to 2 Ether when $\mathcal{S}$ intends to transfer 6 Ether to $\mathcal{R}$, $\mathcal{S}$ needs to make separate transfers of 3 2-Ether transfers. Such a design makes use of more transactions to protect the privacy of the transfer value. The whole protocol Θ is presented as follows.

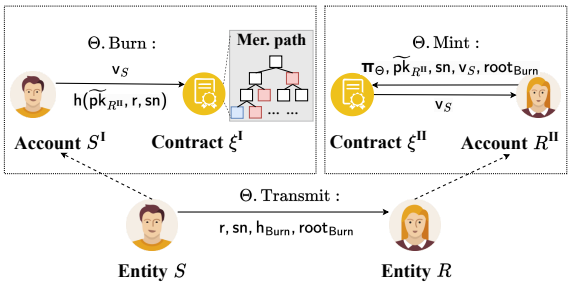

Figure 2: Process of the cross-chain transfer protocol Θ. The blue block depicts the hash digest of the transaction $\mathsf{Tx}_{\mathsf{Burn}}$ and the red block represents the Merkle proof information, i.e.,$\mathsf{h}_{\mathsf{Burn}}$ and $\mathsf{root}_{\mathsf{Burn}}$.

Assume that $\mathcal{S}^{\mathsf{I}}$ in Chain I sends amount $\mathsf{v}_{\mathcal{S}}$ to $\mathcal{R}^{\mathsf{II}}$ in Chain II, where $\mathsf{v}_{\mathcal{S}}$ is a standard value. The entire protocol consists of four steps: **Burn, Transmit, Mint, and Redeem**. Note that in a cross-chain transfer, the **Mint** and **Redeem** steps can only have one of them executed. If **Mint** is executed, it signifies a successful transfer; if **Redeem** is executed, it means the transferred amount has been returned to the sender.

Θ.Burn. In this step, $\mathcal{S}^{\mathsf{I}}$ sends the transaction $\mathsf{Tx}_{\mathsf{Burn}}$ to the smart contract ξ^{I} (or a dedicated burn-account) to burn $\mathsf{v}_{\mathcal{S}}$. The transaction $\mathsf{Tx}_{\mathsf{Burn}}$ contains the transfer amount $\mathsf{v}_{\mathcal{S}}$, and the hash digest $\mathsf{h}(\widetilde{\mathsf{pk}}_{\mathcal{R}^{\mathsf{II}}}, \mathsf{r}, \mathsf{sn})$ calculated by hashing the receiver's public key $\widetilde{\mathsf{pk}}_{\mathcal{R}^{\mathsf{II}}}$, and two random numbers r and sn. Using both r and sn in a hash function implementation can enhance the randomness of the hash result, hiding the receiver information $\widetilde{\mathsf{pk}}_{\mathcal{R}^{\mathsf{II}}}$ and preventing brute force attacks [19]. Note that r and sn can be generated by utilizing a Pseudo-Random Function (PRF) [20]. Also, note that sn serves as a unique identifier (like the serial number in currency) for each cross-chain transfer activity. Once $\mathsf{v}_{\mathcal{S}}$ is claimed, the corresponding sn is publicly revealed to prevent double-spending attacks [42]. The smart contract ensures the legality of $\mathsf{Tx}_{\mathsf{Burn}}$, locks the asset $\mathsf{v}_{\mathcal{S}}$ after verifying the correctness of the sender's signature and whether or not the account balance is sufficient, and then sets a time lock T_3.

$$\mathsf{Tx}_{\mathsf{Burn}} \stackrel{\text{def}}{=} (\mathsf{From}: \mathcal{S}; \mathsf{To}: \xi; \mathsf{v}_{\mathcal{S}}, \mathsf{h}(\widetilde{\mathsf{pk}}_{\mathcal{R}}, \mathsf{r}, \mathsf{sn})).$$

The above design ensures that an adversary can only get that a node sent the transaction $\mathsf{Tx}_{\mathsf{Burn}}$, without knowledge of its receiver.

Θ.Transmit. After reaching consensus, the hash digest of the transaction $\mathsf{Tx}_{\mathsf{Burn}}$ would be included as a leaf node in a block of Chain I. For simplicity, we omit non-essential data, such as the Nonce and block number, when describing the transaction hash. The hash digest of $\mathsf{Tx}_{\mathsf{Burn}}$ is defined as:

$$\mathsf{h}(\mathsf{Tx}_{\mathsf{Burn}}) \stackrel{\text{def}}{=} \mathsf{hash}(\widetilde{\mathsf{pk}}_{\mathcal{S}}, \mathsf{addr}_{\xi}, \mathsf{v}_{\mathcal{S}}, \mathsf{h}(\widetilde{\mathsf{pk}}_{\mathcal{R}}, \mathsf{r}, \mathsf{sn})).$$

Through off-chain communication, $\mathcal{S}$ sends to $\mathcal{R}$ the following parameters: random number r, random serial number sn,

and the Merkle proof of $\mathsf{Tx}_{\mathsf{Burn}}$ consisting of a set of hashes, denoted by $\mathsf{h}_{\mathsf{Burn}}$, that includes the Merkle root $\mathsf{root}_{\mathsf{Burn}}$ and the Merkle path of $\mathsf{Tx}_{\mathsf{Burn}}$.

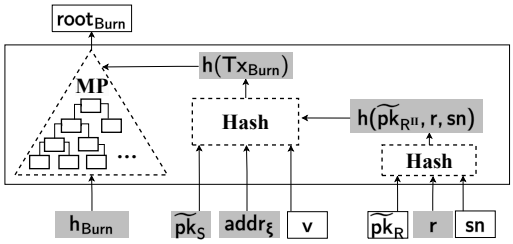

Figure 3: The circuit logic diagram for the privacy-preserving cross-chain transfer protocol. The parameters with a gray background are private ones protected with zk-SNARK.

Θ.Mint. After the off-chain communication, $\mathcal{R}^{\mathsf{II}}$ selects a security parameter and constructs a new circuit Λ_Θ (shown in Figure 3). The entire circuit includes two types of functions (represented by dashed boxes): Hash and MP, where Hash is used to calculate the hash value of the input data, while MP implements the Merkle proof functionality to prove that a transaction exists in a block. $\mathcal{R}^{\mathsf{II}}$ employs the algorithm $\Pi.\mathsf{Setup}$ (introduced in Section 4.2) to get the key pair $(\mathsf{pk}_\Theta, \mathsf{vk}_\Theta)$. Then, it adopts the algorithm $\Pi.\mathsf{Prove}$ to generate a proof π_Θ, with the public inputs $(\widetilde{\mathsf{pk}}_{\mathcal{R}^{\mathsf{II}}}, \mathsf{sn}, \mathsf{v}_{\mathcal{S}}, \mathsf{root}_{\mathsf{Burn}})$ and the private inputs $(\widetilde{\mathsf{pk}}_{\mathcal{S}^{\mathsf{I}}}, \mathsf{addr}_{\xi^{\mathsf{I}}}, \mathsf{r}, \mathsf{h}_{\mathsf{Burn}})$. Note that in this transaction, $\widetilde{\mathsf{pk}}_{\mathcal{R}^{\mathsf{II}}}$ is public as the transaction is sent from $\mathcal{R}^{\mathsf{II}}$ to ξ^{II}. Next, $\mathcal{R}^{\mathsf{II}}$ packages π_Θ with the public inputs into the transaction $\mathsf{Tx}_{\mathsf{Mint}}$, and sends it to the smart contract ξ^{II} (or a dedicated mint-account) to acquire the assets of equal value to $\mathsf{v}_{\mathcal{S}}$. Finally, the smart contract ξ^{II} verifies the validity of π_Θ through algorithm $\Pi.\mathsf{Verify}$ and sends the asset to $\mathcal{R}^{\mathsf{II}}$.

$$\mathsf{Tx}_{\mathsf{Mint}} \stackrel{\text{def}}{=} (\mathsf{From}:\mathcal{R}; \mathsf{To}:\xi; \pi, \widetilde{\mathsf{pk}}_{\mathcal{R}}, \mathsf{sn}, \mathsf{v}, \mathsf{root}_{\mathsf{Burn}}).$$

Θ.Redeem. If $\mathcal{R}^{\mathsf{II}}$ fails to complete the step Θ.Mint before T_3, $\mathcal{S}^{\mathsf{I}}$ can request to redeem $\mathsf{v}_{\mathcal{S}}$ from the smart contract ξ^{I}. $\mathcal{S}^{\mathsf{I}}$ needs to create a proof as $\mathcal{R}^{\mathsf{II}}$ does in step Θ.Mint, with the only difference being that $\widetilde{\mathsf{pk}}_{\mathcal{S}^{\mathsf{I}}}$ and $\widetilde{\mathsf{pk}}_{\mathcal{R}^{\mathsf{II}}}$ must be changed to public and private inputs, respectively, in the circuit design. Upon completion of the proof, $\mathcal{S}^{\mathsf{I}}$ sends $\mathsf{Tx}_{\mathsf{Redeem}}$ to ξ^{I} and receives $\mathsf{v}_{\mathcal{S}}$ after a successful validation.

$$\mathsf{Tx}_{\mathsf{Redeem}} \stackrel{\text{def}}{=} (\mathsf{From}:\mathcal{S}; \mathsf{To}:\xi; \pi, \widetilde{\mathsf{pk}}_{\mathcal{S}}, \mathsf{sn}, \mathsf{v}, \mathsf{root}_{\mathsf{Burn}}).$$

5.2.2 An Cross-chain Exchange Protocol with Privacy Preservation

We employ HTLC to develop an exchange protocol. According to the definition of HTLC in Section 4.3, it is evident that because HTLC.Unlock requires both parties in cross-chain interactions to use the same preimage to unlock the exchanged assets, attackers can easily identify the correlation between the two parties. Therefore our design challenge for privacy protection is to obscure the preimage while ensuring the atomicity of the HTLC protocol. Note that we also need to protect the privacy of the exchanged values. For this purpose, we take the same idea as that for the cross-chain transfer by setting the fundamental denominations to eliminate the risk of exposing privacy through exchanged amounts.

To address the privacy challenges posed by the preimage in HTLC, we develop a privacy-preserving protocol Φ based on zk-SNARK (introduced in Section 4.2). The protocol consists of four steps: **Prepare, Lock, Unlock, and Refund**. According to the requirement of HTLC (shown in Section 4.3), Φ necessitates the existence of accounts for $\mathcal{S}$ and $\mathcal{R}$ on both Chain I (i.e., $\mathcal{S}^{\mathsf{I}}$, $\mathcal{R}^{\mathsf{I}}$) and Chain II (i.e., $\mathcal{S}^{\mathsf{II}}$, $\mathcal{R}^{\mathsf{II}}$). Note that in a cross-chain exchange, only one of the **Unlock** and **Refund** steps can be executed. The execution of **Unlock** indicates a successful exchange, while the execution of **Refund** implies that the exchanged amount has been returned to the sender.

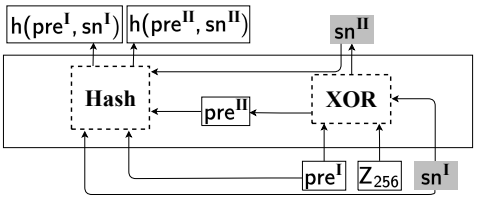

Figure 4: The circuit logic diagram used for Φ.Prepare. The parameters with a gray background are private ones protected with zk-SNARK.

Φ.Prepare. During this process, $\mathcal{S}$ is required to generate a security parameter and then employs it, along with a circuit $\Lambda_\Phi^{\mathsf{off}}$ illustrated in Figure 4, to derive the key pair $(\mathsf{pk}_\Phi^{\mathsf{off}}, \mathsf{vk}_\Phi^{\mathsf{off}})$ based on the setup algorithm $\Pi.\mathsf{Setup}$. The circuit $\Lambda_\Phi^{\mathsf{off}}$ comprises of two functions (indicated by dashed lines), namely a hash function denoted as Hash and an exclusive OR operation denoted as XOR. Specifically, $\mathcal{S}$ generates two preimages ($\mathsf{pre}^{\mathsf{I}}$ and $\mathsf{pre}^{\mathsf{II}}$), two random serial number (sn^{I} and $\mathsf{sn}^{\mathsf{II}}$), and a 256-bit integer Z_{256}, where sn^{I} and Z_{256} are combined with XOR to derive $\mathsf{sn}^{\mathsf{II}}$. These random serial numbers are kept as private inputs, while preimages and Z_{256} are used as public inputs. Making use of the Hash function, $\mathsf{h}(\mathsf{pre}^{\mathsf{I}}, \mathsf{sn}^{\mathsf{I}})$ and $\mathsf{h}(\mathsf{pre}^{\mathsf{II}}, \mathsf{sn}^{\mathsf{II}})$ are calculated by taking ($\mathsf{pre}^{\mathsf{I}}$, sn^{I}), and ($\mathsf{pre}^{\mathsf{II}}$, $\mathsf{sn}^{\mathsf{II}}$) as inputs, respectively. Then, by employing the protocol $\Pi.\mathsf{Prove}$, $\mathcal{S}$ generates a proof π_Φ^{off}. The proof along with the public inputs, such as the hash results ($\mathsf{h}(\mathsf{pre}^{\mathsf{I}}, \mathsf{sn}^{\mathsf{I}})$, $\mathsf{h}(\mathsf{pre}^{\mathsf{II}}, \mathsf{sn}^{\mathsf{II}})$), preimages ($\mathsf{pre}^{\mathsf{I}}$, $\mathsf{pre}^{\mathsf{II}}$), and the integer Z_{256}, are sent to $\mathcal{R}$ by $\mathcal{S}$ through off-chain communications. This off-chain process can achieve the following goals: first, it allows $\mathcal{S}$ to prove the relationship between sn^{I} and $\mathsf{sn}^{\mathsf{II}}$ without disclosing sn^{I}; second, it enables $\mathcal{R}$ to easily derive sn^{I} from $\mathsf{sn}^{\mathsf{II}}$ through a reverse operation.

Φ.Lock. After off-chain communications, based on $\mathsf{Tx}_{\mathsf{Lock}}$,

$\mathcal{S}^{\mathrm{I}}$ uses $\mathsf{h}(\mathsf{pre}^{\mathrm{I}}, \mathsf{sn}^{\mathrm{I}})$ to lock the asset $\mathsf{v}_{\mathcal{S}}$ in the smart contract ξ^{I}. After $\mathcal{R}^{\mathrm{I}}$ verifies the correctness of $\mathsf{Tx}_{\mathsf{Lock}}$ sent by $\mathcal{S}^{\mathrm{I}}$, $\mathcal{R}^{\mathrm{II}}$ sends $\mathsf{Tx}_{\mathsf{Lock}}$ with $\mathsf{h}(\mathsf{pre}^{\mathrm{II}}, \mathsf{sn}^{\mathrm{II}})$ to lock the amount $\mathsf{v}_{\mathcal{R}}$ in the smart contract ξ^{II}. The time lock operation involved is consistent with the step HTLC.Lock (introduced in Section 4.3), where both parties set time locks T_1 and T_2 on smart contracts, with $\mathsf{T}_1 > \mathsf{T}_2$.

$$\mathsf{Tx}_{\mathsf{Lock}} \stackrel{\text{def}}{=} (\mathsf{From}: \mathcal{S}/\mathcal{R}; \mathsf{To}: \xi; \mathsf{v}, \mathsf{h}(\mathsf{pre}, \mathsf{sn}, \mathsf{v})).$$

After reaching consensus, $\mathsf{Tx}_{\mathsf{Lock}}$ would be included as a leaf node in a block and the hash digest of $\mathsf{Tx}_{\mathsf{Lock}}$ is defined as:

$$\mathsf{h}(\mathsf{Tx}_{\mathsf{Lock}}) \stackrel{\text{def}}{=} \mathsf{hash}(\widetilde{\mathsf{pk}}, \mathsf{addr}_{\xi}, \mathsf{v}, \mathsf{h}(\mathsf{pre}, \mathsf{sn})).$$

Φ.Unlock. Within T_2, $\mathcal{S}^{\mathrm{II}}$ first generates a circuit $\Lambda_{\Phi}^{\mathsf{on}}$ that has similar logic to Λ_{Θ} (shown in Figure 3) but requires modifying its inputs (shown in Figure 5). Specifically, the public inputs include the serial number $\mathsf{sn}^{\mathrm{II}}$, the amount $\mathsf{v}_{\mathcal{R}}$, and the Merkle root $\mathsf{root}^{\mathrm{II}}_{\mathsf{Lock}}$. The private inputs consist of the $\mathcal{R}^{\mathrm{II}}$'s public key $\widetilde{\mathsf{pk}}_{\mathcal{R}^{\mathrm{II}}}$, the address of the smart contract $\mathsf{addr}_{\xi^{\mathrm{II}}}$, the preimage $\mathsf{pre}^{\mathrm{II}}$, the Merkle proof of $\mathsf{Tx}_{\mathsf{Lock}}$ (denoted by $\mathsf{h}^{\mathrm{II}}_{\mathsf{Lock}}$), the transaction hash $\mathsf{h}^{\mathrm{II}}(\mathsf{Tx}_{\mathsf{Lock}})$, and the hash lock $\mathsf{h}(\mathsf{pre}^{\mathrm{II}}, \mathsf{sn}^{\mathrm{II}})$. Similar to Θ.Mint, $\mathcal{S}^{\mathrm{II}}$ generates a proof π^{II}_{Φ} based on the above circuit. Then, $\mathcal{S}^{\mathrm{II}}$ sends π^{II}_{Φ} along with the public inputs to the smart contract ξ^{II} through $\mathsf{Tx}_{\mathsf{Unlock}}$ to unlock $\mathsf{v}_{\mathcal{R}}$. After that, $\mathcal{R}^{\mathrm{II}}$ learns $\mathsf{sn}^{\mathrm{II}}$ and uses the XOR operation with Z_{256} to obtain sn^{I}. Following the same steps as $\mathcal{S}^{\mathrm{II}}$, $\mathcal{R}^{\mathrm{I}}$ generates a proof π^{I}_{Φ} with public inputs $(\mathsf{sn}^{\mathrm{I}}, \mathsf{v}_{\mathcal{S}}, \mathsf{root}^{\mathrm{I}}_{\mathsf{Lock}})$ and private inputs $(\widetilde{\mathsf{pk}}_{\mathcal{S}^{\mathrm{I}}}, \mathsf{addr}_{\xi^{\mathrm{I}}}, \mathsf{pre}^{\mathrm{I}}, \mathsf{h}^{\mathrm{I}}_{\mathsf{Lock}}, \mathsf{h}^{\mathrm{I}}(\mathsf{Tx}_{\mathsf{Lock}}), \mathsf{h}(\mathsf{pre}^{\mathrm{I}}, \mathsf{sn}^{\mathrm{I}}))$, then sends $\mathsf{Tx}_{\mathsf{Unlock}}$ to get $\mathsf{v}_{\mathcal{S}}$.

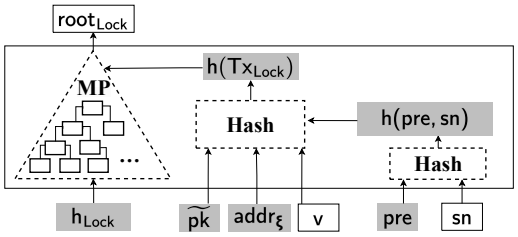

Figure 5: The circuit logic diagram used for Φ.Unlock. The parameters with a gray background are private ones protected with zk-SNARK.

$$\mathsf{Tx}_{\mathsf{Unlock}} \stackrel{\text{def}}{=} (\mathsf{From}: \mathcal{S}/\mathcal{R}; \mathsf{To}: \xi; \pi, \mathsf{sn}, \mathsf{v}, \mathsf{root}_{\mathsf{Lock}}).$$

Φ.Refund. As in HTLC.Refund (introduced in Section 4.3), if $\mathcal{S}^{\mathrm{II}}$ fails to send $\mathsf{Tx}_{\mathsf{Unlock}}$ within T_2, $\mathcal{R}^{\mathrm{II}}$ would be unable to calculate sn^{I}. Therefore, the smart contracts on both chains would return the locked assets after the timeout.

For the convenience of the readers' understanding, we summarize the process of the exchange between $\mathcal{S}$ and $\mathcal{R}$ using protocol Φ in Figure 6.

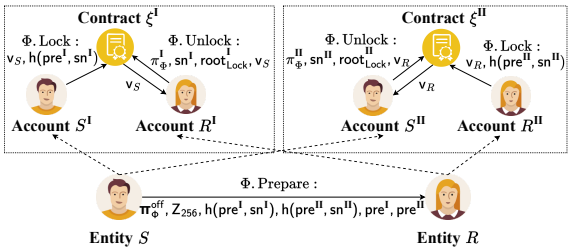

Figure 6: Process of the cross-chain exchange based on protocol Φ.

5.2.3 Discussion

When contingencies are in place for parties not following the protocols (Θ or Φ) explicitly, the protocol also guarantees the correctness of the amount settlement.

The protocol Θ ensures that the interaction results in either $\mathcal{R}$ receiving $\mathsf{v}_{\mathcal{S}}$ or $\mathcal{S}$ revoking $\mathsf{v}_{\mathcal{S}}$. Specifically, after $\mathcal{S}$ completes Θ.Burn, if $\mathcal{S}$ fails to execute Θ.Transmit, $\mathcal{R}$ cannot perform Θ.Mint. To prevent the deadlock of the amount $\mathsf{v}_{\mathcal{S}}$, $\mathcal{S}$ can execute Θ.Redeem to reclaim $\mathsf{v}_{\mathcal{S}}$ after a timeout if $\mathcal{R}$ does not execute Θ.Mint.

The protocol Φ ensures that the interaction results in both $\mathcal{S}$ and $\mathcal{R}$ receiving each other's funds or both parties refunding their respective funds. In Φ.Lock, if party $\mathcal{S}$ executes the lock operation but party $\mathcal{R}$ does not, $\mathcal{S}$ would reject executing Φ.Unlock and $\mathsf{sn}^{\mathrm{II}}$ remain undisclosed. In this case, $\mathcal{R}$ cannot calculate sn^{I} and thus cannot execute Φ.Unlock. Consequently, during Φ.Refund, both parties would refund their respective funds. Once $\mathcal{S}$ executes Φ.Unlock, $\mathcal{R}$ can receive $\mathsf{sn}^{\mathrm{II}}$ and calculate sn^{I} to complete the unlock operation. In this case, both parties can obtain the amount of the other party.

5.3 Cross-chain Auditing Protocol

To solve the FAI issue, we develop an auditing protocol Ψ, which enhances the efficiency of cross-chain auditing. Moreover, Ψ can be compatible with privacy protection protocols (introduced in Section 5.2), thereby addressing the IPA problem.

In our scheme, the purpose of auditing is to check whether transactions within blocks of the lower-layer blockchain meet the auditing requirements established by the auditors. Depending on specific requirements, auditing tasks can be categorized into basic tasks or complex tasks. The former involves auditing individual transactions, while the latter involves auditing multiple transactions collectively. zkCross can be used for both types of auditing tasks: basic tasks, such as verifying the legitimacy of transaction amounts and addresses, and complex tasks, such as confirming the legitimacy of total amounts sent by each node over a specified time period. The core of the protocol Ψ lies in a newly proposed circuit (shown in Figure 8) that simultaneously considers transaction auditing

and aggregation. The aggregation process is implemented in an approach that is similar to zk-Rollup (introduced in Section 4.2), except that our solution can further reduce the on-chain storage cost and hide the transaction content. The original intention of zk-Rollup is to handle off-chain transactions that have not undergone consensus. In zkCross, the focus of the audit is on transactions that have been validated by consensus in the lower-layer blockchains. As a result, in certain auditing tasks, there is no need to disclose transaction amounts and the associated addresses, as done in zk-Rollup, to prevent malicious tampering of the off-chain transactions.

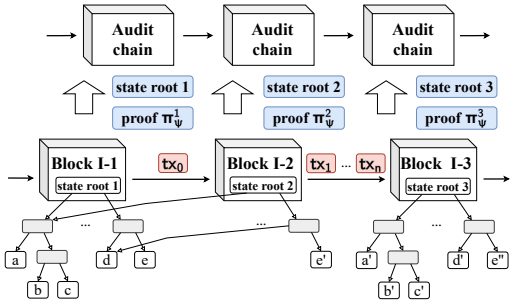

Figure 7: An example interaction between the audit chain and Chain I based on the cross-chain auditing protocol.

To aid in comprehension, we expound on the details of protocol Ψ through the example depicted in Figure 7. This example displays three blocks (identified as Block I-1–Block I-3) of Chain I, and the states of Chain I are denoted as a–e in the first block. Whenever miners create a new block, such as Block I-2 that contains a transaction tx_0, which modifies the account state from e to e′, the corresponding state root changes from root 1 to root 2. The majority of blockchain systems involve many transactions and alterations in the states of multiple accounts, such as the transition from Block I-2 to Block I-3. Upon discovering a new block, the committer updates the new state root of Chain I, i.e., state root 3, on the audit chain. Simultaneously, to demonstrate the correctness of the state transition to the auditors, the committer generates a zero-knowledge proof, such as the proof π_Ψ^3 shown in Figure 7. The entire process of protocol Ψ can be divided into three steps: **Initialize, Commit, and Audit**.

Ψ.Initialize. To initiate the protocol Ψ based on algorithm Π.Setup, the committer $\mathcal{C}_\mathcal{T}$ is required to generate a security parameter, denoted as 1^λ, and subsequently utilizes 1^λ along with a circuit Λ_Ψ illustrated in Figure 8 to derive the key pair (pk_Ψ, vk_Ψ). One can observe that circuit Λ_Ψ consists of four functions (indicated by dashed lines), i.e., the Auditing Function AF, the Signature Verification Function SVF, the State Transition Function STF, and the Root Verification Function RVF. In this example, the auditing focus is on validating the legitimacy of the sender's address within Chain I. Therefore, AF audits transactions by checking if the address is present in the blacklist, thus completing transaction auditing. SVF is designed to demonstrate the correctness of the transaction signatures; STF ensures the correctness of the transition from the old state $\mathsf{State}^{\mathsf{old}}$ to the new state $\mathsf{State}^{\mathsf{new}}$ after the transaction takes place; and RVF guarantees the consistency of $\mathsf{State}^{\mathsf{old}}$ and $\mathsf{State}^{\mathsf{new}}$ with the states recorded in the blocks of Chain I by recomputing the state root. For example, in Figure 7, the state of Block I-2 ($\mathsf{State}^{\mathsf{old}} = \mathsf{a}, \mathsf{b}, \mathsf{c}, \mathsf{d}, \mathsf{e}'$) transitions to the state of Block I-3 ($\mathsf{State}^{\mathsf{new}} = \mathsf{a}', \mathsf{b}', \mathsf{c}', \mathsf{d}', \mathsf{e}''$) after n transactions. Note that, one can compress transactions from multiple blocks and modify the logic of the circuit Λ_Ψ according to the auditing task.

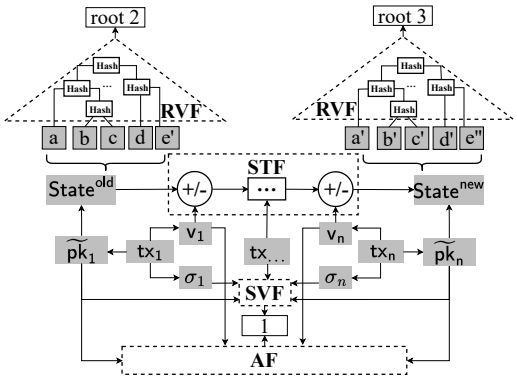

Figure 8: The logic diagram of the circuit used for the cross-chain auditing protocol Ψ. The specific values of the parameters are derived from the state transition process between Block I-2 to Block I-3, as illustrated in Figure 7. Private inputs are indicated by a gray background.

Ψ.Commit. In this step, the committer $\mathcal{C}_\mathcal{T}$ requires information to set specific private and public inputs for the algorithm Π.Prove. We continue to use Block I-3 as an example, as depicted in Figure 7. Specifically, $\mathcal{C}_\mathcal{T}$ gathers a set of transactions (tx_1–tx_n) and sets the account state information ($\mathsf{State}^{\mathsf{old}}, \mathsf{State}^{\mathsf{new}}$) with transaction content (such as transfer amount v, public key $\widetilde{pk}$, and signature σ) as the private input $\vec{w}$, while the public input $\vec{x}$ includes the initial root (root 2), and the final state root (root 3). Note that, the blacklist can be directly written into the circuit as a constant, thereby reducing the number of circuit inputs. Subsequently, $\mathcal{C}_\mathcal{T}$ invokes Π.Prove based on the aforementioned data $(\vec{x}; \vec{w})$ and the proving key pk generated by Ψ.Initialize to produce the proof π_Ψ^3 for the corresponding state transition. Finally, $\mathcal{C}_\mathcal{T}$ registers as a light node in the audit chain and packages public inputs $\vec{x}$ with π_Ψ^3 into a new transaction $\mathsf{Tx}_{\mathsf{Commit}}$ to the audit chain.

$$\mathsf{Tx}_{\mathsf{Commit}} \stackrel{\text{def}}{=} (\mathsf{From} : \mathcal{C}_\mathcal{T}; \mathsf{To} : \xi; \vec{x}, \pi).$$

Ψ.Audit. After receiving the transaction $\mathsf{Tx}_{\mathsf{Commit}}$, auditors would call Π.Verify based on parameters vk, $\vec{x}$, and π_Ψ^3 to verify and reach a consensus on the proof. Upon a successful consensus, the latest uploaded state root (root 3) would be

stored as a leaf in the state tree of the audit chain. Of course, this step can also be written into the smart contract of the audit chain to reduce the security risks caused by human errors. Note that, auditors can collect multiple proofs for verification and auditing, enabling them to conduct certain complex auditing tasks, such as auditing the total amount of transactions sent by a node across multiple blocks.

6 Security Analysis

In this section, we analyze that zkCross can achieve the goals of privacy and efficiency (as outlined in Section 4.1).

Lemma 1 (Properties of zk-SNARK [13,15])**.** *zk-SNARK has the property of succinctness, where the complexity of verifying a proof remains constant at $O(1)$ regardless of the complexity of the proving process. Moreover, the proof size remains fixed. Additionally, zk-SNARK is a non-interactive zero-knowledge proof technique that satisfies completeness, soundness, and zero-knowledge requirements.*

Theorem 1 (Unlinkability)**.** *A sender $\mathcal{S}$ interacts with a receiver $\mathcal{R}$ via protocol Θ or Φ. Given the assurance of security offered by the collision-resistant hash function and the zero-knowledge proof system, within an anonymity set, the adversary cannot link $\mathcal{R}$ based on the information initiated by $\mathcal{S}$, nor vice versa.*

Proof. zkCross considers all factors that may compromise the unlinkability, including receiver addresses, preimages, and transaction amounts. Specifically, each transaction in blockchains records the addresses of both sender and receiver, providing adversaries with information to link both parties. Additionally, in HTLCs, both parties use the same preimage to generate hash locks, facilitating adversaries in linking their accounts. Moreover, the variation in the amount of each transaction allows adversaries to link the accounts of both sender and receiver with the same state changes. Within an anonymity set, we use the following experiment to define the unlinkability: Given two transactions sent by $\mathcal{S}$, one (denoted as tx) to $\mathcal{R}$, and the other (denoted as tx') to $\mathcal{R}'$, the adversary $\mathcal{A}$ is guessing whether the transaction tx or tx' is sent for $\mathcal{R}$. Note that tx and tx' are two transactions of the same type, for example, both are $\mathsf{Tx}_{\mathsf{Burn}}$. The probability of $\mathcal{A}$'s success is defined as $\Pr[\mathbf{Exp}^{\mathsf{Unlinkability}}_{\mathcal{A},\mathsf{zkCross}}(\lambda)=1]$, where λ is the security parameter. zkCross satisfies the unlinkability if, for all adversaries, it holds that $|\Pr[\mathbf{Exp}^{\mathsf{Unlinkability}}_{\mathcal{A},\mathsf{zkCross}}(\lambda)=1]-\frac{1}{2}|\leq \mathsf{negl}(\lambda)$.

We denote $\mathbb{U}$ as an anonymity set consisting of the receivers whose states change during a period, among whom the actual receiver of a transaction is concealed. The size of an anonymity set is denoted as $|\mathbb{U}|$. If adversaries know a sender's address and intend to compromise unlinkability, they must link it to the corresponding receiver's address from an anonymity set $\mathbb{U}$. If $|\mathbb{U}|$ is 1, there is only one active pair of $\mathcal{S}$ and $\mathcal{R}$. Therefore, concealing the relation between $\mathcal{S}$ and $\mathcal{R}$ is impossible in our context through the utilization of any privacy-preserving solutions [8, 12, 26, 27, 29]. Therefore, in the following context, we only consider an anonymity set $\mathbb{U}$ with $|\mathbb{U}|>1$, zkCross employs methods such as hiding receiver addresses, utilizing independent preimages, and adding transactions with same amounts, thereby guaranteeing that the probability of adversaries compromising unlinkability is negligible.

[Hide receiver address] zkCross employs hashing and zk-SNARK to hide the receiver's address.

Specifically, in Θ.Burn, zkCross employs $\mathsf{h}(\widetilde{\mathsf{pk}_{\mathcal{R}}},\mathsf{r},\mathsf{sn})$ to hide the receiver's address $\widetilde{\mathsf{pk}_{\mathcal{R}}}$. To obtain $\widetilde{\mathsf{pk}_{\mathcal{R}}}$, an adversary must get sn and r, where sn is revealed at the end of the protocol, and r is a private input protected by the zk-SNARK. According to Lemma 1, zk-SNARK has the property of zero-knowledge, meaning that the probability of $\mathcal{A}$ can derive the private input r is negligible. Moreover, due to the security of the hash function, the probability that $\mathcal{A}$ obtains $\widetilde{\mathsf{pk}_{\mathcal{R}}}$ from $\mathsf{h}(\widetilde{\mathsf{pk}_{\mathcal{R}}},\mathsf{r},\mathsf{sn})$ without knowing r is negligible. During Θ.Mint, $\mathcal{R}^{\mathsf{II}}$ takes $\widetilde{\mathsf{pk}_{\mathcal{S}}}$ as the private input for the zk-SNARK to hide $\mathcal{S}^{\mathsf{I}}$'s address. Similarly, in Θ.Redeem, $\mathcal{S}^{\mathsf{I}}$ takes $\widetilde{\mathsf{pk}_{\mathcal{R}}}$ as the private input to hide $\mathcal{R}^{\mathsf{II}}$'s address, which indicates that $\mathcal{A}$ should break the zero-knowledge property of the zk-SNARK and this probability is negligible.

During cross-chain exchanges, the protocol Φ adopts HTLC, which does not involve interaction between $\mathcal{S}^{\mathsf{I}}$ and $\mathcal{R}^{\mathsf{II}}$. HTLC involves only the transfer of funds between accounts within the same chain, such as between $\mathcal{S}^{\mathsf{I}}$ and $\mathcal{R}^{\mathsf{I}}$, or between $\mathcal{S}^{\mathsf{II}}$ and $\mathcal{R}^{\mathsf{II}}$. Φ first adopts a similar approach to the protocol Θ in hiding the receiver's address, preventing adversaries from linking the addresses of both interacting parties within the same chain (such as $\mathcal{S}^{\mathsf{I}}$ and $\mathcal{R}^{\mathsf{I}}$). Moreover, since the accounts of the same entity on different chains are independent, adversaries cannot link between $\mathcal{S}^{\mathsf{I}}$ and $\mathcal{S}^{\mathsf{II}}$, or between $\mathcal{R}^{\mathsf{I}}$ and $\mathcal{R}^{\mathsf{II}}$. Similar to the analysis for protocol Θ, based on the security of zk-SNARKs and hash functions, the probability of $\mathcal{A}$ deducing the receiver address is negligible. Based on the above design, in $\mathbf{Exp}^{\mathsf{Unlinkability}}_{\mathcal{A},\mathsf{zkCross}}(\lambda)=1$, the probability of the adversary $\mathcal{A}$ linking $\mathcal{S}$ and $\mathcal{R}$ based on the receiver address is $\frac{1}{2}+\mathsf{negl}(\lambda)$.

[Use independent preimages] In HTLCs, when $\mathcal{S}$ interacts with $\mathcal{R}$, this interaction involves two same hash locks generated by a preimage. $\mathcal{A}$ can link $\mathcal{S}$ and $\mathcal{R}$ based on the same hash locks. The interacting parties in zkCross use independent preimages to generate hash locks and adopt zk-SNARK to ensure the correctness of preimages.

Specifically, in step Φ.Lock, $\mathcal{S}^{\mathsf{I}}$ and $\mathcal{R}^{\mathsf{II}}$ use independent hash locks to lock the exchange amounts. However, using independent preimages may compromise the security of the protocol, for example, $\mathcal{R}$ cannot verify whether the preimage provided by $\mathcal{S}$ is correct. The design challenge lies in the entity $\mathcal{S}$ needing to convince $\mathcal{R}$ of the correctness of the hash lock and ensuring that $\mathcal{R}^{\mathsf{I}}$ executes the unlock operation

only after $\mathcal{S}^{\mathsf{II}}$ has executed the unlock operation. To solve the above challenge, we design a novel circuit shown in Figure 4. Based on this circuit, $\mathcal{S}$ can generate a proof to convince $\mathcal{R}$ of the correctness of the hash lock, thereby eliminating the assumption that both parties need to share the same secret [6]. Since the unlocking information sn is hidden, $\mathcal{R}^{\mathsf{I}}$ can only execute the unlock operation after $\mathcal{S}^{\mathsf{II}}$ has executed the unlock operation (reveal sn). Based on the above design, given two hash locks generated by two independent preimages, the probability that the adversary breaks the collision resistance of the hash function to link two hash locks is negligible. Therefore, in $\mathbf{Exp}^{\mathsf{Unlinkability}}_{\mathcal{A},\mathsf{zkCross}}(\lambda) = 1$, the probability that the adversary links $\mathcal{S}$ and $\mathcal{R}$ based on preimages is $\frac{1}{2} + \mathsf{negl}(\lambda)$.

[Add transactions with same amounts] We establish fundamental denominations to divide a transfer amount into multiple sub-amounts, thereby increasing the number of transactions with the same amounts within the network. Similar to works [12, 16, 29], the sub-amount is a fixed value that can be set according to specific scenarios. The above design means that one can always find two transactions with the same amount from the network, ensuring that $|\mathbb{U}| > 1$.

Based on the above analysis, one can conclude that in the experiment $\mathbf{Exp}^{\mathsf{Unlinkability}}_{\mathcal{A},\mathsf{zkCross}}(\lambda) = 1$, the probability that an adversary compromises unlinkability, even when collecting all factors that may compromise unlinkability such as receiver addresses, preimages, and transaction amounts, is $\frac{1}{2} + \mathsf{negl}(\lambda)$. Therefore, $|\Pr[\mathbf{Exp}^{\mathsf{Unlinkability}}_{\mathcal{A},\mathsf{zkCross}}(\lambda) = 1] - \frac{1}{2}| \leq \mathsf{negl}(\lambda)$, indicating that zkCross satisfies unlinkability.

□

Theorem 2 (Efficiency)**.** *In a network consisting of* k *ordinary blockchains, each blockchain has an average block production rate of* m *new blocks per second and processes an average of* n *transactions per block.* zkCross *can increase the audit efficiency by nearly* n *times.*

Proof. We consider two auditing methods: auditors examining each transaction individually (referred to as the full auditing method) with an average audit time of t_1 per transaction, or relying on protocol Ψ for auditing with an average verification time of t_2 per proof. Based on Lemma 1, zk-SNARK exhibits succinctness, ensuring that t_1 and t_2 remain constant at $O(1)$. The first approach would require $\mathsf{t}_1 \times \mathsf{k} \times \mathsf{m} \times \mathsf{n}$ to audit the entire network, while the second one would demand $\mathsf{t}_2 \times \mathsf{k} \times \mathsf{m}$. The ratio between the two methods is $\frac{\mathsf{t}_1 \times \mathsf{n}}{\mathsf{t}_2}$. Notably, as the number of transactions processed within a block increases linearly, the time growth of verifying proofs in the Ψ.Audit step remains constant. Consequently, zkCross is nearly n times faster in audit time compared to the full auditing scheme for the same task. □

7 Performance Evaluation

In this section, we implement zkCross systems with both local and cloud servers and conduct comprehensive tests to evaluate the performance of the three protocols in terms of run time, latency, throughput, gas consumption, audit time, and proof size. Our code repository is open-sourced on Github[1].

7.1 Implementation

zkCross has three protocols, i.e., the two privacy-preserving cross-chain protocols (Θ, Φ) and the cross-chain auditing protocol Ψ, with each including two critical components: the off-chain zk-SNARK and the on-chain transaction. For the off-chain zk-SNARK, we use xjsnark[2] to obtain the circuits in each protocol, which are implemented with 1,500+ lines of code. Then, we utilize the Groth16 algorithm [13] to realize the Setup (initialization), Prove (generation), and Verify (verification) of zk-SNARK. The Groth16 algorithm is well-known and has been established as a reliable paradigm in blockchain [14]. For the on-chain component, each node runs go-ethereum[3] (an official implementation of the Ethereum protocol using Golang) to build the blockchain, and we employ Solidity[4] to write smart contracts and implement the transactions with 500+ lines of Solidity. To address the limitation of go-ethereum and Solidity of not supporting the verification of zk-SNARK, we make modifications to the source code of go-ethereum and Solidity, adding a function to smart contracts for proof verification, and setting the gas required to invoke this function at 440,000 gas (equivalent to Groth16 [36]).

We test the performance of zkCross on both local and cloud servers. The local servers are equipped with an Intel® Xeon(R) Silver 4214R CPU @ 2.40 GHz * 48 and 98.3 GB RAM running 64-bit Ubuntu 20.04.2 LTS. As for the experiment on cloud servers, we use 50 ecs.g6.3xlarge instances, with each running the Ubuntu 20.04 system Intel Xeon (Cascade Lake) Platinum 8269CY processor and having 12 vCPUs of frequency 3.2 GHz and 48 GB RAM. We start 4 docker nodes in each instance to form multiple blockchains based on the Proof-of-Work consensus algorithm, and the number of transactions at each blockchain reaches up to 10,000. More details of the setup of each experiment will be presented before reporting the performance evaluation results.

7.2 Experimental Results

7.2.1 Cross-Chain Transfer and Exchange

We build two blockchains on cloud servers, varying the number of nodes and transactions in each blockchain based on the

[1] https://github.com/Anonymous-Authors-zkCross/zkCross
[2] https://github.com/akosba/xjsnark
[3] https://github.com/ethereum/go-ethereum
[4] https://github.com/ethereum/solidity

test requirements.

We first test the performance of zk-SNARK, including the time consumption in three steps: Setup, Prove, and Verify. The performance of zk-SNARK varies based on the circuit used. In protocols Θ and Φ, there are a total of three circuits. Circuit Λ_Θ (as depicted in Figure 3) is used for protocol Θ, while circuits $\Lambda_\Phi^{\text{off}}$ (as depicted in Figure 4) and Λ_Φ^{on} (as depicted in Figure 5) are used for protocol Φ. The size of Λ_Θ and Λ_Φ^{on} is related to the inputs of the MP function, which corresponds to the number of transactions included within a given block, i.e., the block size. For instance, a block containing 16 transactions (block size = 16) can construct a full binary tree with a height of 4, requiring MP to consist of 4 hash values with corresponding 4 hash operations.

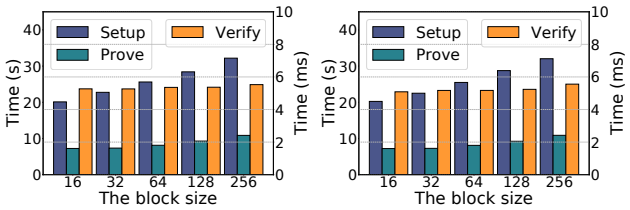

Figure 9: Run time for the initialization (Setup), generation (Prove), and verification (Verify) of proofs with different block sizes. Left: Λ_Θ; right: Λ_Φ^{on}.

In Figure 9, we test the time consumption of zk-SNARK related to circuits Λ_Θ and Λ_Φ^{on}, and change the block size from 16 to 256. As the block size increases, the time consumption of Setup and Prove increases linearly, while Verify remains nearly unchanged. While Setup and Prove take more time when compared to the millisecond-level Verify, they do not require additional on-chain resources as they run off-chain. Table 1 shows the average time consumption of Setup, Prove, and Verify related to $\Lambda_\Phi^{\text{off}}$, with values of 6.96 seconds, 1.91 seconds, and 5.16 milliseconds, respectively.

Table 1: Run time of the three steps based on $\Lambda_\Phi^{\text{off}}$.

Setup (s)	Prove (s)	Verify (ms)
6.96	1.91	5.16

Then, we test the latency of transactions and system throughput at different node scales. The protocol Θ encompasses transactions Tx_{Burn} and Tx_{Mint}, and $\text{Tx}_{\text{Redeem}}$ ($\text{Tx}_{\text{Redeem}}$ exhibiting the same performance as Tx_{Mint}), while the protocol Φ integrates transactions Tx_{Lock} and $\text{Tx}_{\text{Unlock}}$. Note that the transaction delay refers to the duration between the time a transaction is sent to the blockchain and the time it is confirmed by miners. The unit utilized to measure the throughput is TPS, which refers to the number of transactions a scheme can process per second. For more accurate tests, we establish two blockchains and vary the number of on-chain nodes to simulate cross-chain environments. As shown in Figures 10, the maximum number of nodes for each blockchain is 100. The number of transactions in the network is related to the number of nodes, that is, the more nodes, the more transactions in the network. We stipulate that the number of transactions is equal to 10 times that of the nodes, i.e., there are 1,000 pending transactions in a network of 100 nodes.

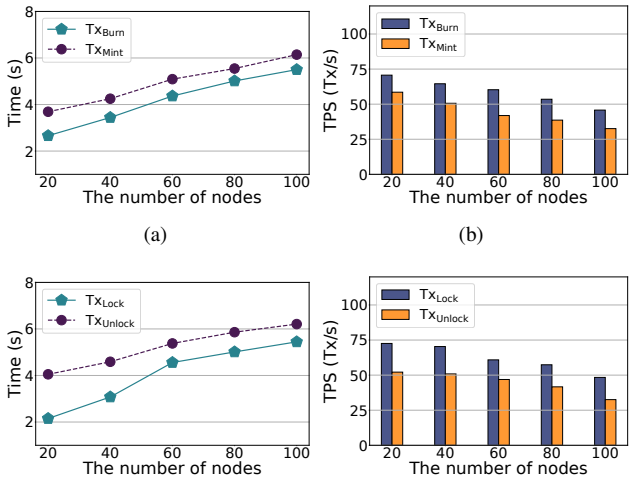

Figure 10: Network latency (left) and throughput (right) of the cross-chain transfer protocol Θ (top) and exchange protocol Φ (bottom).

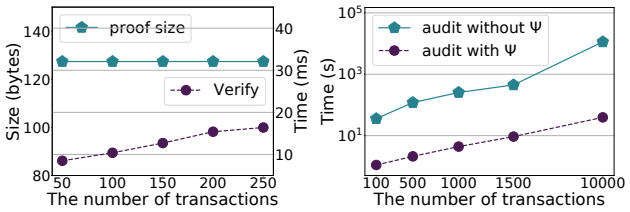
Specifically, Figures 10 ((a), (b)) and ((c), (d)) respectively show the performance of protocols Θ and Φ. As the number of nodes in the network increases, the latency of the four types of transactions slightly increases, leading to a slight decrease in the corresponding network throughput. When there are 100 nodes in the network, the delay of the transaction Tx_{Burn} is about 5.50 seconds, and that of transaction Tx_{Mint} is approximately 6.14 seconds in protocol Θ, as demonstrated in Figure 10 (a). The corresponding network throughput for Tx_{Burn} and Tx_{Mint} are 45.78 and 32.58, respectively, as shown in Figure 10 (b). In protocol Φ (shown in Figures 10 (c), (d)), the transaction Tx_{Lock} takes around 5.44 seconds to complete, while the transaction $\text{Tx}_{\text{Unlock}}$ takes around 6.21 seconds. The corresponding network TPS values for Tx_{Lock} and $\text{Tx}_{\text{Unlock}}$ are 48.38 and 32.55, respectively. The increasing number of nodes and transactions is responsible for this trend because the communication time between the nodes and the number of transactions waiting in the queue simultaneously increase, leading to longer transaction delays and decreased network throughput. To mitigate this problem, it is recommended to implement layer-2 scaling solutions [15] to lower the transaction delay and enhance the system throughput.

Finally, we simulate the gas consumption of each protocol in two 20-node blockchains. As shown in Table 2, the protocol

Table 2: Gas consumption of each protocol.



Protocol	Gas	ETH	USD*
Θ	494,000	0.000494	1.72
Φ	901,472	0.000901	3.13

* Gasprice = 1 Gwei, 1 Ether = 10^9 Gwei, and 1 Ether = 3,470.71 USD.

Θ consumes 494,000 gas (equivalent to around 1.72 dollars), while the protocol Φ requires 901,472 gas (about 3.13 dollars). The gas consumption of Θ is mainly due to proof verification, whereas the gas consumption Φ mainly arises from the proof verification and multiple interactions with smart contracts.

7.2.2 Cross-Chain Auditing

In this experiment, we build a 20-node audit chain, to audit whether whether all senders of transactions are included in the blacklist of the audit chain. The experimental results are reported in Figures 11 (a), (b). Specifically, in Figure 11 (a),

(a) (b)

Figure 11: The proof size, proof verification time (left), and audit time (right) of the cross-chain auditing protocol Ψ vary with the number of transactions.

we initially evaluate the impact of the number of aggregated transactions within circuit Λ_Ψ (shown in Figure 8) on both the audit time and the size of a proof. We vary the number of transactions from 50 to 250 and observe an increase in the time required for auditing (proof verification) from 8.52 milliseconds to 16.43 milliseconds, while the proof size remains 127.38 bytes. One can see that, owing to the succinctness of zk-SNARK, the growing number of transactions aggregated within a single proof leads to only a slight increase in verification time, with no change in the size of the proof.

Subsequently, in Figure 11 (b), we conduct a comparative experiment on the audit efficiency with protocol Ψ and full auditing without Ψ. We vary the transaction quantity in the range of 100 to 10,000, which corresponds to the number of ordinary chains ranging from 1 to 100, each being assigned to processing 100 transactions. One can see that the audit time without Ψ is about 35.66 seconds, while with Ψ, it is only 1.10 seconds. However, when the number of transactions is increased to 10,000, the network congestion among the 20 nodes causes the audit time to be around 3.15 hours without Ψ. In contrast, with Ψ, the audit time is decreased to about 40 seconds under the same condition, which demonstrates a significant improvement in efficiency.

Table 3: Gas consumption of the protocol Ψ.

Protocol	Gas	ETH	USD*
Ψ	466,520	0.000467	1.62

* Gasprice = 1 Gwei, 1 Ether = 10^9 Gwei, and 1 Ether = 3,470.71 USD.

Then, based on the experimental setup of gas outlined in Section 7.2.1, we conduct tests to determine the gas consumption required for the auditing protocol Ψ, where each proof contains 50 transactions. As shown in Table 3, the gas required for executing Ψ is 466,520. Note that, as mentioned in Section 5.3, proof verification can be implemented without the use of smart contracts, thus reducing gas consumption.

Table 4: Storage cost of zk-Rollup and our scheme.

Solution	Constraints	Pubic inputs (KB)	Veri. key (KB)
zk-Rollup	11,466,073	10.21	12.20
Our work	11,763,593	**6.83**	**0.24**

Finally, we simulate the storage cost of zk-Rollup (introduced in Section 4.2) and our protocol Ψ, with both circuits containing 100 transactions. As shown in Table 4, Ψ adds circuit constraints but reduces the size of data, i.e., public inputs and verification keys, to be uploaded to the audit chain, thereby reducing the storage cost for auditors. Based on Ethereum's storage cost, storing 256 bits of data costs 20,000 units of gas [5]. Therefore, verifying 100 transactions can conserve approximately 16 KB of space and save about 10 million units of gas. This saving is significant for blockchain networks with billions of transactions.

8 Conclusion

In this paper, we propose zkCross, a cross-chain scheme that supports privacy protection and efficient auditing. zkCross employs a novel auditing architecture with three protocols to address the Cross-chain Linkability Exposure (CLE) problem, the Incompatibility of Privacy and Auditing (IPA), and the Full Auditing Inefficiency (FAI) problem. We conduct a thorough security analysis and carry out comprehensive simulation studies, and our results indicate that zkCross can bring higher audit efficiency while preserving privacy. In our future research, we will focus on enhancing the system's resilience against attacks while maintaining privacy. Moreover, we will extend zkCross to support multi-layer (more than 2) auditing, thereby expanding its application scenarios and further optimizing the audit efficiency.

Pixel+ and Pixel++: Compact and Efficient Forward-Secure Multi-Signatures for PoS Blockchain Consensus

Abstract

Multi-signature schemes have attracted considerable attention in recent years due to their popular applications in PoS blockchains. However, the use of general multi-signature schemes poses a critical threat to the security of PoS blockchains once signing keys get corrupted. That is, after an adversary obtains enough signing keys, it can break the immutable nature of PoS blockchains by forking the chain and modifying the history from some point in the past. Forward-secure multi-signature (FS-MS) schemes can overcome this issue by periodically updating signing keys. The only FS-MS construction currently available is Drijvers et al's Pixel, which builds on pairing groups and only achieves forward security at the time period level.

In this work, we present new FS-MS constructions that either are free from pairing or capture forward security at the individual message level (i.e., fine-grained forward security). Our first construction Pixel+ works for a maximum number of time periods T. Pixel+ signatures consist of only one group element, and can be verified using two exponentiations. It is the first FS-MS from RSA assumption, and has 3.5x and 22.8x faster signing and verification than Pixel, respectively. Our second FS-MS construction Pixel++ is a pairing-based one. It immediately revokes the signing key's capacity of re-signing the message after creating a signature on this message, rather than at the end of the current time period. Thus, it provides more practical forward security than Pixel. On the other hand, Pixel++ is almost as efficient as Pixel in terms of signing and verification. Both Pixel+ and Pixel++ allow for non-interactive aggregation of signatures from independent signers and are proven to be secure in the random oracle model. In addition, they also support the aggregation of public keys, significantly reducing the storage overhead on PoS blockchains.

We demonstrate how to integrate Pixel+ and Pixel++ into PoS blockchains. As a proof-of-concept, we provide implementations of Pixel+ and Pixel++, and conduct several representative experiments to show that Pixel+ and Pixel++ have good concrete efficiency and are practical.

1 Introduction

The proof-of-stake (PoS) consensus protocol achieves the decentralization and immutability of blockchain in an energy-efficient way, and has been widely studied both in the industry (e.g., DFINITY and Algorand[1]) and academia [16, 31, 54]. In most PoS-based blockchain consensus protocols, all selected block proposers need to check the validity of block proposals and state their own agreement by generating digital signatures on acceptable block proposals. When the number of received signatures on the same block proposal reaches a pre-specified threshold, a participant appends the block proposal to the local blockchain. Due to the large number of protocol participants, improving the efficiency of the underlying signature scheme becomes extremely important to the usability of PoS blockchain consensus protocols.

Multi-signature schemes [13, 63] allow multiple signers to jointly generate a space and time-efficient signature on a single message so that a verifier can be convinced that all participants signed this message. Although this cryptographic primitive has been introduced and studied for decades, it has recently been drawing new attention due to it perfectly fulfilling the requirements of the above scenario. Specifically, given n participants indexed by their own public/secret key pairs $\{(pk_i, sk_i)\}_{i=1}^{n}$, each participant i computes a signature σ_i on a message m using sk_i. Then, a third party (e.g., a miner) can compress these signatures $\{\sigma_i\}_{i=1}^{n}$ into a short multi-signature σ. Consequently, a verifier can determine whether every participant approved the message m by just checking the correctness of σ. This significantly reduces not only the time to check that a consensus on the next block has been reached, but also the corresponding block storage.

Despite the obvious advantages of applying multi-signature to PoS blockchain settings, they are vulnerable to long-range attacks (a.k.a. posterior corruptions and costless simulation) [26, 42] due to the leakage of signing keys. More concretely, if the stake ownership is shown through the possession of the corresponding signing key, then an adversary can fork

[1] https://dfinity.org/, https://algorand.com/.

the chain and modify the history from some point in the past when he obtained substantial signing keys. On the other hand, from a practical point of view, those users with relatively small stakes may not protect their accounts well compared to active users. Moreover, after users sell their stakes, they may also no longer need to maintain their signing keys. These realistic human factors further exacerbate this attack.

A well-studied approach to mitigating the damage of signing key exposure is to use forward-secure signatures [3, 25]. Roughly, in the setting of such a cryptographic primitive, the user's signing key evolves unidirectionally over time periods, and each signature is associated with the corresponding time period in which the user generated it. As a consequence, given the exposed current signing key, the adversary cannot use it to forge signatures from previous time periods. Focusing on the scenario of PoS blockchains, this means that an adversary will fail to create any forks in the past of the blockchain, even if he has controlled a total stake above a certain threshold.

To date, we are aware of only one forward-secure multi-signature (FS-MS) scheme Pixel due to Drijvers et al. [35]. By using a new manner of encoding time periods, Pixel achieves substantial savings in bandwidth and verification effort. On the other hand, as in previous forward-secure signatures, it still follows the key delegation mechanism of hierarchical identity-based encryption (HIBE) [20], and thus inevitably has logarithmic cost. In addition, as demonstrated by Green and Miers [45], this traditional forward security is coarse-grained, that is, an adversary can still utilize the corrupted signing key to create signatures during the current time period. Conversely, fine-grained forward security is more desirable since it allows a user to individually revoke the signing key's capacity of re-signing a message, without waiting for a time period to elapse. Moreover, Pixel builds its security on a non-standard q-type complexity assumption over bilinear groups, and involves computation-heavy pairing operations.

1.1 Our Results

Given the significant advantage of the primitive of *forward-secure multi-signatures* to efficiently remedy long-range attacks in PoS blockchains, it is desirable to study different FS-MS constructions that provide various performance and security trade-offs, giving users application-specific choices.

In this work, we propose two new FS-MS constructions under different cryptographic assumptions. Our first construction Pixel+ is based on the RSA assumption, and achieves more efficient signing and verification than Pixel. In more detail, Pixel+ works for a bounded number of time periods T, which is specified in the system setup phase. The main technical challenge is how to come up with an efficient solution for an T value large enough to be practical. For example, under the demand that a PoS blockchain needs to be maintained for fifty years and the time to generate a block is ten seconds, then we need to assign $T = 2^{28}$. To this end, we use the RSA sequencer [51] as the core building block, which is an abstraction of pebbling techniques of Itkis and Reyzin [53] and provides a trade-off between computation cost and storage overhead. Specifically, in the scenario of T time periods and n participants, a multi-signature of Pixel+ comprises just one group element, and the verification algorithm only requires two hash operations and two exponentiations, and the size of both public parameters and signing key scales with $\log T$.

Our second construction, Pixel++, is designed to achieve more practical (i.e., fine-grained) forward security and efficient key evolution. In more detail, inspired by Green and Miers' [45] elegant work of puncturable encryption, we introduce the notion of puncturable multi-signature scheme[2], where a signing key is updated by repeatedly and sequentially puncturing it with tags associated with signed messages. As a consequence, the updated (or punctured) signing key cannot be used to create valid signatures on previous pairs of tags and messages. Pixel++ builds on bilinear groups, and uses the probabilistic data structure Bloom filter to maintain signing keys. A multi-signature of Pixel++ is comprised of two group elements and an integer, the verification requires four pairings and two exponentiations. Particularly, the key update only needs a few deletion operations, and thus is very efficient. This comes at the cost of additional storage overhead and a non-negligible probability of failing to sign.

We prove the security of Pixel+ and Pixel++ in random oracle models under the RSA assumption and a q-type assumption, respectively. Our forward-secure multi-signature constructions provide attractive solutions to the problem of long-range attacks in PoS blockchain consensus protocols. As depicted in Table 1, Pixel+ is the only one that builds on the RSA assumption. Its signing and verification algorithms require one and two exponentiations respectively, and are more efficient than Pixel. Similar to Pixel, our second construction, Pixel++, also builds on bilinear groups. But it provides more practical forward security and more efficient key update. Compared with multi-signature schemes based on discrete logarithm assumptions [60, 61], ours eliminate the interaction among independent signers.

We provide implementations of Pixel+ and Pixel++ using Python. We conduct representative experiments that evaluate their computation cost and storage/communication overhead under different usage scenarios, and compare their performance with previous forward-secure multi-signature schemes. The experimental results indicate that Pixel+ and Pixel++ are efficient for practical applications. For instance, in the setting of 100 signers and $T = 2^{32}$ time periods, the signature sizes of Pixel+ and Pixel++ are 0.90 KB and 0.92 KB, respectively. At the same time, the signing time of Pixel+ and Pixel++ are 0.07 s and 0.2 s respectively, and the verification time is 0.13 s and 2.91 s respectively. We also demonstrate how to integrate them into PoS blockchain to resist long-range attacks.

[2] We consider puncturable multi-signature schemes as FS-MS schemes.

Table 1: The comparison of existing FS-MS schemes with ours. Here, $|\mathbb{G}_i|$ $(i = 1,2)$ and $|\mathbb{Z}_N|$ denote the sizes of an element of the bilinear group and RSA group. $\mathbb{G}$ is a group of order p. E and P are the computation cost of one exponentiation and one pairing. We omit lightweight operations like addition, multiplication and hash. T refers to the maximum number of time periods. ℓ denotes the parameter of a Bloom filter. FS-I and FS-II represent traditional forward security and fine-grained forward security.

1.2.1 Multi-signature Schemes

The notion of multi-signatures was first put forth by Itakura and Nakamura [52] 40 years ago, and has received renewed attention in recent years, mainly motivated by novel real-world applications like blockchains and cryptocurrencies. We can acquire a trivial multi-signature scheme from any signature by just concatenating each signer's individual signature. Therefore, a multi-signature only makes sense if its length is independent of the number of signers.

To produce compact multi-signatures, most of available multi-signature schemes build on Schnorr signature. Bellare and Neven [12] proposed the first multi-signature with provable security in the plain public-key model, where each signer is required to generate a proof of possession of the secret key [66], so as to resist rogue public-key attacks. The signing algorithm of their scheme needs three rounds of interaction among signers. After that, many two-round multi-signature schemes were proposed [8, 58, 74]. However, Drijvers et al. [34] found that these schemes suffer from concurrent attacks, and put forth a secure scheme based on Bagherzandi et al.'s multi-signature scheme [8]. In recent years, a larger number of two-round multi-signature schemes against concurrent attacks have been proposed, such as MulSig-DN [62], HMBS [10], MuSig2 [61] and MuSig2-H [75]. To further compress the storage overhead of multi-signatures, Maxwell et al. [60] proposed a Schnorr-based multi-signature scheme that supports public key aggregation.

Although computationally expensive, pairing-based multi-signatures avoid the requirement of communication among signers, and thus are more suitable for the setting of PoS blockchains. Based on Boneh-Lynn-Shacham (BLS) signature [23], Boldyreva [18] constructed a multi-signature scheme in gap Diffie-Hellman groups. Ristenpart and Yilek [66] extended Boldyreva's scheme to be free from rogue public-key attacks. Boneh et al. [21] introduced a BLS-based multi-signature scheme with public-key aggregation for blockchains. Another important research line of eliminating signing interactions is to restrict the signing setting to be synchronized [5, 43, 50]. That is, all signers share a global value each time they sign, such as the current time period.

All of the above multi-signature schemes (including our proposed schemes) are built upon traditional complexity assumptions, e.g., discrete logarithm assumptions, RSA assumptions, and pairings-based assumptions, and thus are vulnerable to quantum attacks [70]. Lattice-based cryptography is considered to be resilient against quantum attacks, and there has been a spark of interest in building multi-signature schemes from lattice in recent years. Those early lattice-based multi-signature schemes [9, 40, 41] follow the idea of Bellare and Neven's [12] multi-signature, and have three rounds of signing interaction. Damgård et al. [30] employed the structure of Drijvers et al.'s [34] scheme, and proposed a two-round lattice-based multi-signature. Boschini et al. [24] proposed a lattice-based multi-signature MuSig-L with single-round online phase and key aggregation. Chen [28] further put forward a lattice-based two-round multi-signature with smaller public keys and signatures than MuSig-L. Fleischhacker et al. [37, 38] constructed synchronized multi-signature schemes from lattices. We note that none of the above lattice-based multi-signature schemes consider forward security. By combining our techniques with the approach of achieving forward security in the setting of lattices [4, 36], it might be possible to extend them to be forward secure.

1.2.2 Forward-secure Signature Schemes

Anderson [6] first introduced the notion of forward security, which was originally studied in the context of key exchange, into the setting of digital signature, so as to mitigate the damage of signing key compromise. Bellare and Miner [11] later formally defined the primitive of forward-secure digital signature and presented the first concrete construction based on the hardness of factoring. Numerous subsequently proposed forward-secure signature schemes [3, 25, 53] optimize the previous one in terms of security and efficiency.

Given a maximum number T of total time periods, in order to reduce the computation cost or storage/communication overhead to $O(\log T)$, these constructions either follow the binary tree structure of hierarchical identity-based encryption [20], or use the pebbling techniques due to Itkis and Reyzin [53]. The idea of forward-secure signatures has been extended in several aspects, e.g., forward-secure signatures in untrusted update environments [57], tightly forward-secure signature [1], forward-secure threshold signature schemes [2], forward-secure identity/attribute-based signatures [80, 81], forward-secure aggregate signature schemes [59, 68, 79].

Early FS-MS schemes [59,72] either have $O(T)$-size public key or require an interactive signing protocol, and thus are not suitable for PoS blockchain consensus protocols. Drijvers et al. [35] recently presented a pairing-based forward-secure multi-signature scheme Pixel, which is specially optimized for use in PoS blockchains and achieves significant savings in terms of bandwidth overhead and verification cost. On the other hand, although combing tree-based forward-secure signature schemes [3, 11] with multi-signature schemes [19, 21] might also yield forward-secure multi-signature schemes, their bandwidth cost would scale linearly with T.

Green and Miers [45] pointed out that the original notion of forward security in the literature of public-key encryption is relatively blunt, and thus introduced the notion of puncturable public-key encryption that provides fine-grained forward security. Their work motivates various new constructions and extensions of puncturable public-key encryption [32, 71, 76, 77], and also has found many interesting applications in the design of other cryptographic primitives [33, 47, 78]. In the setting of digital signature, Bellare et al. [14] introduced the concept of puncturable signature, and provided a construction based on iO and one-way function. Halevi et al . [48] defined a puncturable signature scheme that needs to update signers' public keys repeatedly. Li et al. [56] put forth a puncturable signature scheme based on the idea of bloom filter encryption.

2 Technical Overview

This paper aims to build forward-secure multi-signature schemes under assumptions different from previous ones. Our first construction Pixel+ is based on the RSA assumption, and uses the RSA sequencer [51] to maintain a user's signing key. Our second construction Pixel++ is a paring-based one, and employs the bloom filter data structure to achieve efficient key update and fine-grained forward security.

Overview of Pixel+. The starting point of Pixel+ is Itkis and Reyzin [53]'s pebbling technique for constructing forward-secure signature schemes with fast signing. Specifically, given a maximum number T of time periods and an RSA modulus N, this technique enables a signer to successively compute the e_i-th root U^{1/e_i} of a group element $U \in \mathbb{Z}_N$ for $i = 1, \ldots, T$, and captures the forward security by erasing U^{1/e_i} at the end of the i-th time period. One of its major limitations is that the computation cost of generating a user's signing key is linear in T. The RSA sequencer [51], as the abstraction of the pebbling technique, overcomes this issue by additionally storing roots of a user's public key U of size $\log T$, and can immediately provide U^{1/e_i} at the time period i.

In more detail, given an RSA sequencer comprised of algorithms $(\mathsf{Setup}, \mathsf{Update}, \mathsf{Current}, \mathsf{Shift}, \mathsf{Program})$, we perform the Setup algorithm to produce an initial state $\mathsf{state}_{\mathsf{pp}}$ that contains a global public parameter $U = g^{\prod_{i \in [T]} e_i}$, where $g \in \mathbb{Z}_N$, $e_i = \mathsf{H}_{\mathsf{Primes}}(i)$ and $\mathsf{H}_{\mathsf{Primes}}(\cdot)$ is a hash function that maps an integer to a prime with a fixed size. Then, from $\mathsf{state}_{\mathsf{pp}}$ and a random integer $x \in \mathbb{Z}_N^*$, a user can run the Shift algorithm to efficiently compute his initial signing key sk_1 consisting of group elements of size $\log T$ and public key $pk = U^x$. In fact, sk_i, the secret key for the i-th time period, already contains the e_i-th root u_i of U^x that is used as the actual signing key throughout the time period i. Thus, the $\mathsf{Current}$ algorithm directly reads it from sk_i. To achieve forward security, the Update algorithm evolves sk_i to sk_{i+1} by erasing those auxiliary group elements that can be used to compute u_i, while generating new auxiliary group elements for computing subsequent roots.

The structure of RSA sequencer yields general forward-secure signature schemes. However, in the setting of multi-signature, it becomes challenging since we need to aggregate multiple signatures on the same message m into one. Luckily for us, we observe that signatures from different signers are generated at the same time period t. Therefore, our setting is similar to the synchronized setting of multi-signature [38, 50]. This enables us to derive a shared random number from the same message m and time period t. Roughly, for n signers indexed by public keys $\{pk_1, \ldots, pk_n\}$ and current signing keys $\{sk_{1,t}, \ldots, sk_{n,t}\}$, each signer first obtains the e_i-th root $u_{i,t}$ of pk_i, and then creates the signature $\sigma_{i,t} = u_{i,t}^{r \cdot a_{i,t}}$, where $a_{i,t} = \mathsf{H}_\lambda(pk_i, pk_1, \ldots, pk_n)$ and $r = \mathsf{H}_\lambda(m,t)$ that are computed using a hash function $\mathsf{H}_\lambda(\cdot)$. The shared r makes it possible to aggregate $\{\sigma_{1,t}, \ldots, \sigma_{n,t}\}$ into $\sigma_t = \prod_{i=1}^n \sigma_{i,t}$. The aggregated signature can be verified through checking $\sigma_t^{e_t} = apk^r$, where $apk = \prod_{i=1}^n pk_i^{\mathsf{H}_\lambda(pk_i, pk_1, \ldots, pk_n)}$ is the aggregated public key.

Note that Pixel+ only allows a user to sign once using the signing key of each time period. Such a restriction can be removed by combining the above construction with a general signature scheme [51]. However, it seems unnecessary in the context of PoS blockchain consensus, since each user only uses the current signing key to sign the block to be packaged, and then updates the secret key for the next block.

Overview of Pixel++. Our second construction Pixel++ aims to achieve more efficient key update and fine-grained forward security. To this end, we adopt the idea of Bloom filter encryption due to Deler et al. [32], and introduce the notion of puncturable multi-signature. Pixel++ builds upon

the BLS signature scheme in the setting of bilinear groups $(\mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, g_1, g_2, p, e)$, and uses a Bloom filter to manage all signing key materials.

A Bloom filter provides a succinct representation T of a set S, and can answer membership queries with a non-negligible false positive probability f. That is, for a membership query about an element s, if $s \in S$, it always answers "yes", and if $s \notin S$, it might also answer "yes" with probability f. Initially, the representation is assigned as $T = 0^\ell$. Adding an element s to the set S requires to compute k hash functions $\{H_j\}_{j\in[k]}$ on input s, and set corresponding positions of T to $T[H_j(s)] = 1$. Then, when querying the Bloom filter on an element, it outputs "yes" if it holds $T[H_j(s)] = 1$ for all $j \in [k]$.

In the construction of Pixel++, we associate each position l of T with a key component sk_l that binds the position l and a common secret key x. When a user intends to create a signature on a message m, he first chooses a valid key component $sk_{l'}$ from $\{sk_l | l \in \{H_j(m)\}_{j\in[k]}\}$, and then uses it to produce a BLS-style signature. After that, the signer adds m to Bloom filter, and also assigns $sk_l = \perp$ for each $l \in \{H_j(m)\}_{j\in[k]}$. As a result, even if the current signing key gets exposed, it cannot be used to create signatures for the previous message m. This captures the desirable forward security. The aggregation nature of BLS signature enables us to aggregate signatures on the same message from different users to one.

Since the key update (or puncture) in Pixel++ only involves erasure operations, it achieves more efficient key update than Pixel and Pixel+, which scale with $\log T$. Moreover, it evolves the signing key at the level of individual messages (vs. time periods in both Pixel and Pixel+), and thus also provides more practical forward security. Of course, these merits come at the cost of more storage overhead and signing error probability. As we discuss in Section 6.1, they are tolerated in the context of PoS blockchain consensus protocols.

3 Preliminaries

3.1 Hashing to Primes

In Pixel+, we need a hash function that maps an integer to a random prime with fixed size $\lambda+1$. We make use of the hash function $\mathsf{H}_{\mathsf{Primes}} : [T] \to \{0,1\}^{\lambda+1}$ introduced in [49].

Specifically, $\mathsf{H}_{\mathsf{Primes}}$ maps an integer $x \in [T]$ to a random prime of size $\lambda+1$ by rejection sampling. In more detail, it first chooses a PRF function $F : [T] \times [\lambda \cdot (\lambda^2+\lambda)] \to \{0,1\}^\lambda$, and randomly picks a key k' for F. Then, it selects a random string $c \in \{0,1\}^\lambda$ and a default prime $e_{\text{default}} \in [2^\lambda, 2^{\lambda+1}]$, and assigns $k \leftarrow (k', c, e_{\text{default}})$. After that, an integer $x \in [T]$ is mapped to a prime as follows. For $i = 1$ to $\lambda \cdot (\lambda^2+\lambda)$, compute $y_i = c \oplus F_{k'}(x, i)$. If $2^\lambda + y_i$ is a prime, then return it. Otherwise, increment i and repeat the above procedure. Eventually, if there does not exist an integer $i \in [\lambda \cdot (\lambda^2+\lambda)]$ such that $2^\lambda + y_i$ is a prime, then return e_{default}. For each $x \in [T]$, we denote by $e_x = \mathsf{H}_{\mathsf{Primes}}(x)$.

3.2 RSA Sequencer

The notion of RSA sequencers was recently introduced by Hohenberger and Waters [51], as an abstraction of the pebbling technique. Informally, the goal of an RSA sequencer is to maintain and manage roots of a public key $U \in \mathbb{Z}_N$ such that given a specific integer t, it can immediately provide U^{1/e_t}, where $e_t = H(t)$ is an RSA exponent computed from t via a certain function $H(\cdot)$. It is formally defined as follows:

Definition 1 (RSA Sequencer [51])**.** *An RSA sequencer* RSASeq *is comprised of a 5-tuple of deterministic algorithms* $(\mathsf{Setup}, \mathsf{Update}, \mathsf{Current}, \mathsf{Shift}, \mathsf{Program})$ *that are specified as follows:*

- $\mathsf{Setup}(N, T, H(\cdot), \ell, (v_1, \ldots, v_\ell))$*: This algorithm takes as input an integer* $N \in \mathbb{Z}$*, a maximum number of allowed tags* T*, a function* $H(\cdot) : [T] \to \mathbb{Z}$*, an integer* $\ell \in \mathbb{Z}$ *and a* ℓ*-length vector* $(v_1, \ldots, v_\ell)$ *sampled from* $\mathbb{Z}_N^\ell$*. It outputs a state value* state*.*
- $\mathsf{Update}(\mathsf{state}, t)$*: This algorithm takes as input a state value* state *and an integer* $t \in [T]$*, and outputs an updated state value* state$'$*.*
- $\mathsf{Current}(\mathsf{state})$*: This algorithm takes as input a state value* state*, and outputs a* ℓ*-length vector* $(s_1, \ldots, s_\ell) \in \mathbb{Z}_N^\ell$*.*
- $\mathsf{Shift}(\mathsf{state}, (z_1, \ldots, z_\ell))$*: This algorithm takes as input a state value* state *and a vector* $(z_1, \ldots, z_\ell) \in \mathbb{Z}^\ell$*. It outputs another state value* state$'$*.*
- $\mathsf{Program}(N, T, H(\cdot), \ell, (v'_1, \ldots, v'_\ell), \mathsf{start})$*: On input of an integer* $N \in \mathbb{Z}$*, a maximum number of allowed tags* T*, a function* $H(\cdot) : [T] \to \mathbb{Z}$*, an integer* $\ell \in \mathbb{Z}$*, a* ℓ*-length vector* $(v_1, \ldots, v_\ell) \in \mathbb{Z}_N^\ell$ *and an integer* start $\in [T]$*, this algorithm outputs a state value* state*.*

Update/Output Correctness. For arbitrarily selected parameters $N, T, \ell \in \mathbb{Z}, (v_1, \ldots, v_\ell) \in \mathbb{Z}_N^\ell$ and $H(\cdot) : [T] \to \mathbb{Z}$, assign $\mathsf{state}_1 = \mathsf{Setup}(N, T, H(\cdot), \ell, (v_1, \ldots, v_\ell))$ and $\mathsf{state}_t = \mathsf{Update}(\mathsf{state}_{t-1})$ for all $t \in [2, T]$. Then, for any $t \in [T]$, it must hold that

$$\mathsf{Current}(\mathsf{state}_t) = \left(v_1^{\prod_{i\in[T]\setminus\{t\}} e_i}, \ldots, v_\ell^{\prod_{i\in[T]\setminus\{t\}} e_i}\right),$$

where $e_t = H(t)$, and the arithmetic is conducted in $\mathbb{Z}_N$.

Shift Correctness. Let $\mathsf{state} = \mathsf{Setup}(N, T, H(\cdot), \ell, (v_1, \ldots, v_\ell))$ and $\mathsf{state}' = \mathsf{Setup}(N, T, H(\cdot), \ell, (v'_1, \ldots, v'_\ell))$, where $v'_j = v_j^{z_j}$ for $j \in [\ell]$. Then, it must hold that

$$\mathsf{state}' = \mathsf{Shift}(\mathsf{state}, (z_1, \ldots, z_\ell)).$$

Program Correctness. Let $\mathsf{state}_1 = \mathsf{Setup}(N, T, H(\cdot), \ell, (v_1, \ldots, v_\ell))$ and $\mathsf{state}_t = \mathsf{Update}(\mathsf{state}_{t-1})$ for $t \in [2, \mathsf{start}]$

and $\mathsf{start} \in [T+1]$. Furthermore, let $v_j^{\prod_{i\in[T]\setminus\{t\}} e_i}$ for $j \in [\ell]$, and $\mathsf{state}' = \mathsf{Program}(N, T, H(\cdot), \ell, (v'_1, \ldots, v'_\ell), \mathsf{start})$. Then, it must hold that $\mathsf{state}_{\mathsf{start}} = \mathsf{state}'$.

3.3 Bloom Filter

The Bloom filter (BF) [17] is a widely used probabilistic data structure that supports membership query. Denote by $S = \{x_1, \ldots, x_c\}$ a set of c elements from a universal set U (i.e., $S \subseteq U$). BF succinctly represents the set S using a ℓ-length binary string T, which is initialized as $T = 0^\ell$. To insert an element x, a group of k hash functions $\{H_j\}_{j\in[k]}$ are employed to randomly map x to k positions $\{H_j(x) \in [\ell]\}_{j\in[k]}$ of T. Then, the bits in these positions are all assigned to 1. Conversely, an element y is assumed to be a member of S if $T[H_j(y)] = 1$ holds for all $j \in [k]$. Formally, a Bloom filter is defined by the following algorithms.

Definition 2 (Bloom filter)**.** *A Bloom filter* BF *for a universal set* U *is comprised of three algorithms* $\mathsf{BF} = (\mathsf{Gen}, \mathsf{Update}, \mathsf{Check})$*, which are specified as follows.*

- $\mathsf{Gen}(\ell, k)$*: The generation algorithm takes as input two parameters* $\ell, k \in \mathbb{Z}$*. It first selects* k *independent hash functions* $\{H_j\}_{j\in[k]}$*, where* $H_j : U \to [\ell]$*. Then, it initializes* $T = 0^\ell$*, and output* $(\{H_j\}_{j\in[k]}, T)$*.*

- $\mathsf{Update}(\{H_j\}_{j\in[k]}, T, x)$*: The update algorithm takes as input the current state of the bloom filter* $(\{H_j\}_{j\in[k]}, T)$ *and an element* $x \in U$*. It first assigns* $T' \leftarrow T$*, and then sets* $T'[H_j(x)] = 1$ *for all* $j \in [k]$*. Finally, it returns* T'*.*

- $\mathsf{Check}(\{H_j\}_{j\in[k]}, T, y)$*: The check algorithm takes as input the current state of the bloom filter* $(\{H_j\}_{j\in[k]}, T)$ *and an element* $y \in U$*. If* $T[H_j(y)] = 1$ *holds for all* $j \in [k]$*, then it outputs 1 indicating that* y *has been inserted into* BF*, and 0 otherwise.*

The membership query based on the Bloom filter may suffer from false positive errors, that is, outputting 1 for an element y that has not been inserted into the Bloom filter. Given the maximum number c of elements allowed to be inserted into the set S, the false positive probability f can be arbitrarily tuned by adequately choosing the parameters ℓ and k. More precisely, the value of f can be calculated as $f \approx \left(1 - e^{-\frac{k \cdot c}{\ell}}\right)^k$.

4 Forward-Secure Multi-Signature from RSA

We first formally define the syntax and security notion of forward-secure multi-signature schemes, and then present the concrete construction of Pixel+, a forward-secure multi-signature scheme from RSA assumption.

4.1 Syntax and Security Definitions

We follow the syntax and security notion of forward-secure multi-signature scheme due to Drijvers et al. [35]. Formally, a forward-secure multi-signature scheme consists of the following algorithms:

$\mathsf{Setup}(1^\lambda, T) \to \mathsf{pp}$: Given a security parameter λ and the maximum number of time periods T, a third party runs the setup algorithm to generate the public parameter pp for all signers.

$\mathsf{KeyGen}(\mathsf{pp}) \to (pk, sk_1)$: Each signer performs the key generation algorithm on input the public parameter pp to produce a public verification key pk and an initial secret signing key sk_1.

$\mathsf{Update}(\mathsf{pp}, sk_t)$: At the end of each time period t, by running the key update algorithm, each signer updates its current secret key sk_t to sk_{t+1} used throughout the next time period $t+1$. After that, the previous secret key $sk_{i,t}$ is immediately erased.

$\mathsf{KeyAgg}(\mathsf{pp}, \{pk_1, \ldots, pk_n\}) \to apk$: Given a set of public keys $\{pk_1, \ldots, pk_n\}$, the key aggregation algorithm returns a single aggregate public key apk.

$\mathsf{Sign}(\mathsf{pp}, sk_t, \{pk_1, \ldots, pk_n\}, m) \to \sigma_t$: All signers can independently sign a message m by each invoking the signing algorithm on input its current secret key sk_t and the set of all signers' pubic verification keys $\{pk_1, \ldots, pk_n\}$.

$\mathsf{SigAgg}(\sigma_{1,t}, \ldots, \sigma_{n,t}) \to \sigma_t$: Given signatures $\sigma_{1,t}, \ldots, \sigma_{n,t}$ from different signers on the same message m and for the same time period t, anyone can run the signature aggregation algorithm to aggregate them into a single one σ_t.

$\mathsf{Verify}(\mathsf{pp}, apk, \sigma_t, m, t) \to b$: A verifier can check the validity of an aggregate signature σ_t on a message m and a time period t under an aggregate public key apk by calling the verification algorithm, which outputs 1 or 0 indicating that the signature is valid or invalid, respectively.

Correctness. The correctness of a forward-secure multi-signature scheme requires that, for any integer $n \in \mathbb{Z}$, for any message m and for any time period $t \in [T]$, if we have $(pk_i, sk_{i,1}) \leftarrow \mathsf{KeyGen}(pp)$ for $i \in [n]$, $apk \leftarrow \mathsf{KeyAgg}(\mathsf{pp}, \{pk_1, \ldots, pk_n\})$, $sk_{i,j} \leftarrow \mathsf{Update}(\mathsf{pp}, sk_{i,j-1})$ for $i \in [n]$ and $j = 2, \ldots, t$, $\sigma_{i,t} \leftarrow \mathsf{Sign}(\mathsf{pp}, sk_{i,t}, m)$ for $i \in [n]$ and $\sigma_t \leftarrow \mathsf{SigAgg}(\sigma_{1,t}, \ldots, \sigma_{n,t})$, then it holds that

$$\Pr[\mathsf{Verify}(\mathsf{pp}, apk, \sigma_t, m, t) = 1] = 1.$$

Security. The unforgeability under chosen message attacks for a forward-secure multi-signature scheme is defined through the following security game consisting of three stages.

Setup. The challenger $\mathcal{C}$ first generates the public parameter $\mathsf{pp} \leftarrow \mathsf{Setup}(1^\lambda, T)$ and a public/secret key pair $(pk^*, sk_1^*) \leftarrow \mathsf{KeyGen}(\mathsf{pp})$, then sends pp and pk^* to the adversary $\mathcal{A}$.

Queries. The adversary $\mathcal{A}$ is allowed to adaptively issue the following queries.

- Secret key update: For such a query, when the current secret signing key is sk_t^* ($t < T$), the challenger $\mathcal{C}$ updates it to sk_{t+1}^* for the next time period $t+1$.
- Signing: Given any message m and any set of public keys $\mathcal{PK} = \{pk_1, \ldots, pk_n\}$ with $pk^* \in \mathcal{PK}$, the challenger $\mathcal{C}$ uses the current secret key sk_t^* to generate a signature σ_t with respect to $(m, t, \mathcal{PK})$, and returns σ_t to $\mathcal{A}$.
- Corruption: At some point, the adversary $\mathcal{A}$ can issue a corruption query to obtain the current secret key sk_t^* held by the challenger $\mathcal{C}$. After this query, the adversary $\mathcal{A}$ is not allowed to issue any other queries. Here we record the corruption time as $\hat{t} \leftarrow t$.

Output. Finally, the adversary $\mathcal{A}$ outputs a multi-signature forgery tuple $(t^*, m^*, \sigma_{t^*}, \mathcal{PK}^*)$. The adversary $\mathcal{A}$ wins the security game provided that the following conditions are fulfilled:

- The adversary $\mathcal{A}$ made no signing queries on m^* during the time period t^*.
- $pk^* \in \mathcal{PK}^*$.
- $\hat{t} > t^*$.
- $\mathsf{Verify}(\mathsf{pp}, \mathsf{KeyAgg}(\mathsf{pp}, \mathcal{PK}^*), \sigma_{t^*}, m^*, t^*) = 1$.

Definition 3. *Denote by* $\mathsf{Adv}_{\mathcal{A}}^{\text{fu-cma}}(\lambda)$ *the probability of* $\mathcal{A}$ *winning the above security game. A forward-secure multi-signature scheme is said to be unforgeable under chosen message attacks provided that for any PPT adversary* $\mathcal{A}$, $\mathsf{Adv}_{\mathcal{A}}^{\text{fu-cma}}(\lambda)$ *is negligible in the security parameter* λ.

4.2 The Pixel+ Construction

Pixel+ follows the framework of GQ signature [46], and builds on a particular instance of RSA sequencer that only produces one global RSA group. Given such an RSA sequencer $\mathsf{RSASeq} = (\mathsf{Setup}, \mathsf{Update}, \mathsf{Current}, \mathsf{Shift}, \mathsf{Program})$, Pixel+ works as follows.

$\mathsf{Setup}(1^\lambda, T)$: The setup algorithm takes as input a security parameter λ and the total number $T = 2^{\ell+1} - 2$ of time periods. It first chooses two safe primes $p = 2p' + 1$ and $q = 2q' + 1$, and assigns the RSA modulus $N = p \cdot q$ such that $2^\lambda < \varphi(N) < 2^{\lambda+1}$. Denote by QR_N the group of quadratic residues, and let g be its generator with order $p'q'$. Next, this algorithm defines two independent hash functions $\mathsf{H}_\lambda : \{0,1\}^* \to [0, 2^\lambda - 1]$ and $\mathsf{H}_{\mathsf{Primes}} : [T] \to \mathsf{Primes}(\lambda)$. Furthermore, it generates an initial state of the RSA sequencer $\mathsf{state}_{\mathsf{pp}} \leftarrow \mathsf{RSASeq.Setup}(N, T, \mathsf{H}_{\mathsf{Primes}}, g)$, and computes $U = g^{\prod_{i \in [T]} e_i} \mod N$, where $e_i = \mathsf{H}_{\mathsf{Primes}}(i)$. Finally, it outputs the public parameter as $\mathsf{pp} = \{T, N, U, \mathsf{H}_{\mathsf{Primes}}, \mathsf{H}_\lambda, \mathsf{state}_{\mathsf{pp}}\}$.

$\mathsf{KeyGen}(\mathsf{pp})$: Given the public parameter pp, each signer performs the key generation algorithm to produce his/her own public and secret key pair. For the i-th signer, this algorithm first picks a random integer $s_i \in [N]$, and then computes $\mathsf{state}_{i,1} \leftarrow \mathsf{RSASeq.Shift}(\mathsf{state}_{\mathsf{pp}}, s_i)$. Next, it publishes the public key as $pk_i = U^{s_i} \mod N$, and assigns the initial secret key as $sk_{i,1} = \{\mathsf{state}_{i,1}, e_1, 1\}$, where $e_1 = \mathsf{H}_{\mathsf{Primes}}(1)$.

$\mathsf{Update}(\mathsf{pp}, sk_{i,t}, t+1)$: For the i-th signer, the secret key update algorithm takes as input the public parameter pp, the current secret key $sk_{i,t}$ of the form $\{\mathsf{state}_{i,t}, e_t, t\}$ and the next time period $t+1$. It computes $\mathsf{state}_{i,t+1} \leftarrow \mathsf{RSASeq.Update}(\mathsf{state}_{i,t})$ and $e_{t+1} = \mathsf{H}_{\mathsf{Primes}}(t+1)$. It outputs the secret key for the next time period $t+1$ as $sk_{i,t+1} = \{\mathsf{state}_{i,t+1}, e_{t+1}, t+1\}$. At the same time, the previous secret key $sk_{i,t}$ is erased.

$\mathsf{KeyAgg}(\mathsf{pp}, \{pk_1, \ldots, pk_n\})$: Given the public parameter pp and public keys $pk_1, \ldots, pk_n$, the public key aggregation algorithm outputs the aggregated public key

$$apk = \prod_{i=1}^{n} pk_i^{\mathsf{H}_\lambda(pk_i, pk_1, \ldots, pk_n)} \mod N.$$

$\mathsf{Sign}(\mathsf{pp}, sk_{i,t}, \{pk_1, \ldots, pk_n\}, m)$: For the i-th signer, the signing algorithm takes as input the public parameter pp, the current secret key $sk_{i,t} = \{\mathsf{state}_{i,t}, e_t, t\}$, all signers' public keys $\{pk_1, \ldots, pk_n\}$ and the message m to be signed. It first lets $u_{i,t} \leftarrow \mathsf{RSASeq.Current}(\mathsf{state}_{i,t})$, and then computes $a_{i,t} = \mathsf{H}_\lambda(pk_i, pk_1, \ldots, pk_n)$ as well as $r = \mathsf{H}_\lambda(m, t)$. Next, it outputs the corresponding signature $\sigma_{i,t} = (u_{i,t})^{r \cdot a_{i,t}} \mod N$. Finally, it sends $\sigma_{i,t}$ to a designated combiner.

$\mathsf{SigAgg}(\sigma_{1,t}, \ldots, \sigma_{n,t})$: Given signatures $\sigma_{1,t}, \ldots, \sigma_{n,t}$ on the message m and time period t, the signature aggregation algorithm, which is run by the designated combiner, outputs the aggregated signature $\sigma_t = \prod_{i=1}^{n} \sigma_{i,t}$.

$\mathsf{Verify}(\mathsf{pp}, apk, \sigma_t, m, t)$: The verification algorithm takes as input the public parameter pp, the aggregated public key apk, the aggregated signature σ_t and the corresponding message m as well as time period t. It first computes the hash prime $e_t = \mathsf{H}_{\mathsf{Primes}}(t)$ and $r = \mathsf{H}_\lambda(m, t)$. Then, it outputs 1 to accept if

$$\sigma_t^{e_t} = apk^r,$$

and returns 0 otherwise.

Correctness. Given the initial state $\mathsf{state}_{\mathsf{pp}}$ of the RSA sequencer, we have that the i-th signer's initial secret key $sk_{i,1}$ is the same as the output of $\mathsf{RSASeq.Setup}(N, T, \mathsf{H}_{\mathsf{Primes}}, g^{s_i})$, due to the shift correctness of the RSA sequencer. Accordingly, his/her public key is assigned as

$$pk_i = U^{s_i} = g^{s_i \cdot \prod_{i \in [T]} e_i} \mod N.$$

After $t-1$ secret key updates, the i-th signer's secret key on the time period t is $sk_{i,t} = \{\mathsf{state}_{i,t}, e_t, t\}$, and it holds that

$$\mathsf{RSASeq.Current}(\mathsf{state}_t) = u_{i,t} = U^{s_i/e_t} = pk_i^{1/e_t} \mod N,$$

due to the output correctness of the RSA sequencer. Thus, for the message m and the time period t, the signature from the i-th signer is computed as

$$\sigma_{i,t} = (u_{i,t})^{r \cdot a_{i,t}} = pk_i^{\mathsf{H}_{\mathsf{Primes}}(m,t) \cdot \mathsf{H}_\lambda(pk_i, pk_1, \ldots, pk_n)/e_t} \mod N.$$

Furthermore, the aggregated signature is formed as

$$\sigma_t = \prod_{i=1}^{n} \sigma_{i,t} = \Big(\prod_{i=1}^{n} pk_i^{\mathsf{H}_\lambda(pk_i, pk_1, \ldots, pk_n)}\Big)^{\mathsf{H}_{\mathsf{Primes}}(m,t)/e_t}.$$

Consequently, during the verification procedure, we have that

$$\sigma_t^{e_t} = \Big(\prod_{i=1}^{n} pk_i^{\mathsf{H}_\lambda(pk_i, pk_1, \ldots, pk_n)}\Big)^{\mathsf{H}_{\mathsf{Primes}}(m,t)} = apk^r.$$

Security. The security of Pixel+ is guaranteed by the following theorem.

Theorem 1. *If F is a secure pseudorandom function and the RSA assumption holds, then the proposed forward-secure multi-signature scheme Pixel+ is unforgeable under chose message attacks in the random oracle model.*

The security proof uses the general forking lemma [8], and also is similar to that of Hohenberger and Waters' signature scheme. Due to space constraints, we refer the readers to the full version of this work for the proof.

Discussions. Note that, in the above construction, we need a trusted third party to run the global setup algorithm to generate a secure RSA modulus. In the case that the third party is untrusted, we can use the distributed manner of securely producing RSA modulus [27,29,39]. On the other hand, if the third party is believed to be fully trusted, then it also knows $\varphi(N)$. This enables it to compute $E = \prod_{i \in [T]} e_i \mod \varphi(N)$ and $U = g^E \mod N$, significantly reducing the computation cost of the setup algorithm. Moreover, observe that Pixel+ allows to sign only once during each time period, since the shared random r is completely determined by the corresponding message m and time period t. We can transform it to support multiple signatures per time period by using a common idea in the literature. That is, we use Pixel+ to sign a public key of a standard signature scheme.

5 Puncturable Multi-Signature from Pairing

We first formally define the syntax and security notion of puncturable multi-signature schemes, and then present our second construction Pixel++, a pairing-based forward-secure multi-signature scheme.

5.1 Syntax and Security Definitions

We follow the models of Ristenpart-Yilek's multi-signature scheme [66] and Derler et al.'s Bloom filter encryption scheme [32] to define the syntax and security notion of puncturable multi-signature. By using proofs of possession of secret keys, this combination prevents the puncturable multi-signature scheme from being vulnerable to the rogue public-key attack. Specifically, a puncturable multi-signature scheme consists of the following algorithms.

$\mathsf{Setup}(1^\lambda)$: On input a security parameter λ, the setup algorithm generates the global public parameter pp. This algorithm may be run by a trusted third party through a distributed protocol. We assume that all the algorithms described below implicitly take pp as input.

$\mathsf{KeyGen}(\ell, k)$: On input parameters $\ell, k \in \mathbb{N}$ for the Bloom filter, each signer runs this key generation algorithm to generate a public key pk and a secret key sk as well as a proof of possession π.

$\mathsf{KeyVerify}(pk, \pi)$: On input a public key pk and the corresponding proof of possession π, the public key verification algorithm outputs 1 if pk is valid under the proof π and 0 otherwise.

$\mathsf{Punc}(sk, m)$: On input a secret key sk and a message m, the secret key puncturing algorithm outputs an updated (a.k.a. punctured) secret key sk'. After that, we also say that sk' has been punctured with m.

$\mathsf{Sign}(sk, m)$: On input a secret key sk and a message m, a signer runs this signing algorithm to output a signature σ, and further sends it to a designated combiner.

$\mathsf{KeyAgg}(\mathcal{PK})$: On input a set of public keys $\mathcal{PK} = \{pk_1, \ldots, pk_n\}$, the public key aggregation algorithm outputs an aggregate public key apk, or $\perp$ to indicate a fail of aggregating these public keys.

$\mathsf{SigAgg}(\sigma_1, \ldots, \sigma_n)$: On input signatures $\sigma_1, \ldots, \sigma_n$ on the same message m from different signers, the designated combiner runs this signature aggregation algorithm to output an aggregate signature σ.

$\mathsf{Verify}(apk, \sigma, m)$: On input an aggregate public key apk, an aggregate signature σ and a message m, the verification algorithm outputs 1 to indicate that all singers in apk correctly signed the message m, and 0 otherwise.

Correctness. Intuitively, the correctness of puncturable multi-signature scheme requires that, if the secret key has not been punctured with a message m, then the probability of correctly signing m is bounded by some non-negligible function $\mu(\ell,k)$ in parameters ℓ,k of the Bloom filter. On the other hand, if the secret key has been punctured with a message m, then the signing would definitely fail. Formally, for any $\lambda,\ell,k,n\in\mathbb{N}$, any message m, any $(pk_i,\pi_i,sk_i)\leftarrow\mathsf{KeyGen}(\ell,k)$ and any signature $\sigma_i\leftarrow\mathsf{Sign}(sk_i',m)$, it holds that

$$\Pr[\mathsf{KeyVerify}(pk_i,\pi_i)=1]=1,\Pr[\mathsf{Verify}(apk,\sigma,m)=1]=1,$$

where $i\in[n]$ and $apk=\mathsf{KeyAgg}(\{pk_1,\ldots,pk_n\})$ as well as $\sigma=\mathsf{SigAgg}(\sigma_1,\ldots,\sigma_n)$. Moreover, for any arbitrary interleaved sequence of invocations of $sk_i'\leftarrow\mathsf{Punc}(sk_i,m')$ for $m'\neq m$, it holds that

$$\Pr[\mathsf{Verify}(apk,\sigma,m)=1]\geq 1-\mu(\ell,k).$$

Remark 1. *As suggested by Li et al. [56], we can split the message into several blocks $m=m_1||\ldots||m_b$, and choose to run the puncturing algorithm on any block m_i according to the concrete scenarios of specific applications. For example, in the setting of PoS blockchains, we can think of the block number as part of a block message and conduct a puncture operation on the block number. This enables the signer to create signatures on the same block message at different blocks while capturing fine-grained forward security.*

Security. The definition of unforgeability under chosen message attacks (fu-cma) for a puncturable multi-signature scheme is similar to that described in Section 4.1. Here we emphasize that the fu-cma definition implicitly includes forward security. Essentially, this is achieved by allowing the adversary to obtain the signing key that has been punctured with the challenge message m^*. Specifically, it is captured through the following security experiment consisting of three stages.

Setup. The challenger $\mathcal{C}$ first generates the global public parameter $\mathsf{pp}\leftarrow\mathsf{Setup}(1^\lambda)$. Then, it runs the key generation algorithm $\mathsf{KeyGen}(\ell,l)\rightarrow(pk^*,\pi^*,sk^*)$, and initializes two sets $\mathcal{S}\leftarrow\emptyset$ and $\mathcal{P}\leftarrow\emptyset$. Finally, it forwards the public parameter pp and the public key pk^* as well as the proof of possession π^* to the adversary $\mathcal{A}$.

Queries. The adversary $\mathcal{A}$ is allowed to adaptively issue the following queries.

- Secrete key puncturing: Given a message m, the challenger $\mathcal{C}$ punctures the secret key sk^* by running the algorithm $\mathsf{Punc}(sk^*,m)\rightarrow sk^{*\prime}$. After that, the challenger $\mathcal{C}$ updates the set $\mathcal{P}\leftarrow\mathcal{P}\cup\{m\}$.
- Signing: Given a message m, the challenger $\mathcal{C}$ runs the algorithm $\mathsf{Sign}(sk^*,m)\rightarrow\sigma$, and returns σ to the adversary $\mathcal{A}$. It also updates the set $\mathcal{S}\leftarrow\mathcal{S}\cup\{m\}$.
- Corruption: At some point, the adversary $\mathcal{A}$ can issue a corruption query to obtain the current secret key sk^* held by the challenger $\mathcal{C}$. After this query, the adversary $\mathcal{A}$ is not allowed to issue any other queries.

Output. Finally, the adversary $\mathcal{A}$ outputs a multi-signature forgery tuple $(m^*,\sigma^*,\mathcal{PK}^*)$ such that $pk^*\in\mathcal{PK}^*$. Denote by $\mathcal{PK}^*=\{pk_1,\ldots,pk_n\}$, and let the corresponding proofs of possession be $\{\pi_1,\ldots,\pi_n\}$. The adversary $\mathcal{A}$ wins the security game provided that the following conditions are fulfilled:

- For each $i\in[n]$, $\mathsf{KeyVerify}(pk_i,\pi_i)=1$.
- $\mathcal{A}$ made no signing queries on m^*, i.e., $m^*\notin\mathcal{S}$.
- If $\mathcal{A}$ made the corruption query, then it must be $m^*\in\mathcal{P}$.
- $\mathsf{Verify}(\mathsf{KeyAgg}(\mathcal{PK}^*),\sigma^*,m^*)=1$.

Definition 4. *Denote by $\mathsf{Adv}^{\text{fu-cma}}_{\mathsf{PMS},\mathcal{A}}(\lambda)$ the probability of $\mathcal{A}$ winning the above security experiment. A puncturable multi-signature scheme is said to be unforgeable under chosen message attacks provided that for any PPT adversary $\mathcal{A}$, $\mathsf{Adv}^{\text{fu-cma}}_{\mathsf{PMS},\mathcal{A}}(\lambda)$ is negligible in the security parameter λ.*

5.2 The Pixel++ Construction

We build Pixel++ upon the BLS signature scheme, and employ a Bloom filter to maintain signing key components. Given a bloom filter $\mathsf{BF}=(\mathsf{Gen},\mathsf{Update},\mathsf{Check})$, the details of Pixel++ are specified as follows.

$\mathsf{Setup}(1^\lambda)$: This algorithm first generates Type-3 bilinear groups $(\mathbb{G}_1,\mathbb{G}_2,\mathbb{G}_T,g_1,g_2,p,e)\leftarrow\mathsf{BilGen}(\lambda)$, and then picks three independent hash functions $\mathsf{H}_1:\mathbb{N}\rightarrow\mathbb{Z}_p^*$, $\mathsf{H}_2:\{0,1\}^*\rightarrow\mathbb{G}_1$ and $\mathsf{H}_3:\{0,1\}^*\rightarrow\mathbb{Z}_p^*$. Furthermore, it chooses random group elements $h,h_0,h_1,h_2\in\mathbb{G}_1$. We assume that all the algorithms described below implicitly take the above global public parameters as input.

$\mathsf{KeyGen}(\ell,k)$: For the i-th user, this algorithm first initializes a Bloom filter instance $(\{H_j\}_{j\in[k]},T)\leftarrow\mathsf{BF.Gen}(\ell,k)$. Then, it picks a random integers $x_i\in\mathbb{Z}_p^*$, and assigns the public key as $pk_i=g_2^{x_i}$. Furthermore, for each $l\in[\ell]$, it chooses a random integer $r_{i,l}\in\mathbb{Z}_p$, and computes the secret key $sk_i=\{T,\{(sk_{i,l,0},sk_{i,l,1},sk_{i,l,2})\}_{l\in[\ell]}\}$, where

$$sk_{i,l,0}=g_2^{r_{i,l}},\ sk_{i,l,1}=h_2^{r_{i,l}},$$
$$sk_{i,l,2}=h^{x_i}\cdot\left(h_0\cdot h_1^{a_l}\right)^{r_{i,l}},\ a_l=\mathsf{H}_1(l).$$

In addition, this algorithm computes a proof of possession $\pi_i=\mathsf{H}_2(pk_i)^{x_i}$.

$\mathsf{KeyVerify}(pk_i,\pi_i)$: This algorithm outputs 1 validating the proof of possession if it holds that

$$e(\mathsf{H}_2(pk_i),pk_i)=e(\pi_i,g_2).$$

$\mathsf{Punc}(sk_i, m)$: Given a message m and a secret key $sk_i = \{T, \{(sk_{i,l,0}, sk_{i,l,1}, sk_{i,l,2})\}_{l\in[\ell]}\}$, this algorithm first computes an array $T' = \mathsf{BF.Update}(\{H_j\}_{j\in[k]}, T, m)$. Then, for each $l \in [\ell]$, it defines

$$(sk'_{i,l,0}, sk'_{i,l,0}, sk'_{i,l,2}) = \begin{cases} (sk_{i,l,0}, sk_{i,l,1}, sk_{i,l,2}), & T'[l] = 0 \\ \perp, & T'[l] = 1 \end{cases}$$

where $T'[l]$ is the l-th bit of T'. Finally, this algorithm outputs $sk'_i = \{T, \{(sk'_{i,l,0}, sk'_{i,l,0}, sk'_{i,l,2})\}_{l\in[\ell]}\}$.

$\mathsf{Sign}(sk_i, m)$: Given a message m with the prefix m' and a secret key $sk_i = \{T, \{(sk_{i,l,0}, sk_{i,l,0}, sk_{i,l,2})\}_{l\in[\ell]}\}$, this algorithm first checks whether $\mathsf{BF.Check}(\{H_j\}_{j\in[k]}, T, m) = 1$ and outputs $\perp$ in this case. Otherwise, it picks the smallest index $l' \in [\ell]$ such that $(sk_{i,l',0}, sk_{i,l',0}, sk_{i,l',2}) \neq \perp$. Then, it chooses a random integer $r'_i \in \mathbb{Z}_p$, and computes

$$\sigma_{i,1} = sk_{i,l',2} \cdot (sk_{i,l',1})^{\mathsf{H}_3(m)} \cdot (h_0 h_1^{a_{l'}} h_2^{\mathsf{H}_3(m)})^{r'_i},$$
$$\sigma_{i,2} = sk_{i,l',0} \cdot g_2^{r'_i},$$

where $a_{l'} = \mathsf{H}_1(l')$. Finally, it sends $(\sigma_{i,1}, \sigma_{i,2}, l')$ to a designated combiner[3].

$\mathsf{KeyAgg}(\mathcal{PK})$: Given a set of public keys $\mathcal{PK} = \{pk_1, \ldots, pk_n\}$, if $\mathsf{KeyVerify}(pk_i, \pi_i) = 1$ for each index $i \in [n]$, then this algorithm outputs an aggregate public key $apk = \prod_{i=1}^{n} pk_i$. Otherwise, it outputs $\perp$.

$\mathsf{SigAgg}(\sigma_1, \ldots, \sigma_n)$: Given n signatures $\sigma_1 = (\sigma_{1,1}, \sigma_{1,2}, l')$, $\ldots$, $\sigma_n = (\sigma_{n,1}, \sigma_{n,2}, l')$ on the same message m from independent signers, this algorithm computes the aggregate signature $\sigma = (\sigma_1, \sigma_2, l')$, where

$$\sigma_1 = \prod_{i=1}^{n} \sigma_{i,1}, \quad \sigma_2 = \prod_{i=1}^{n} \sigma_{i,2}.$$

$\mathsf{Verify}(apk, \sigma, m)$: Given the aggregate public key and signature $\sigma = (\sigma_1, \sigma_2, l')$ on the message m, this algorithm outputs 1 if and only if $apk \neq \perp$ and

$$e(\sigma_1, g_2) = e(h, apk) \cdot e(h_0 \cdot h_1^{\mathsf{H}_1(l')} \cdot h_2^{\mathsf{H}_3(m)}, \sigma_2).$$

Correctness. Given public keys $\mathcal{PK} = \{pk_1, \ldots, pk_n\}$ and signatures $\sigma_1 = (\sigma_{1,1}, \sigma_{1,2}, l'), \ldots, \sigma_n = (\sigma_{n,1}, \sigma_{n,2}, l')$ on the same message m under these public keys, the aggregate public key apk and $\sigma = (\sigma_1, \sigma_2, l')$ are the forms of

$$apk = \prod_{i=1}^{n} pk_i = \prod_{i=1}^{n} g_2^{x_i} = g_2^{\sum_{i=1}^{n} x_i},$$
$$\sigma_1 = \prod_{i=1}^{n} \sigma_{i,1} = \prod_{i=1}^{n} sk_{i,l',2} \cdot (sk_{i,l',1})^{\mathsf{H}_3(m)} \cdot (h_0 h_1^{a_{l'}} h_2^{\mathsf{H}_3(m)})^{r'_i}$$
$$= h^{\sum_{i=1}^{n} x_i} \cdot (h_0 \cdot h_1^{a_{l'}} \cdot h_2^{\mathsf{H}_3(m)})^{\sum_{i=1}^{n}(r_{i,l'} + r'_i)},$$
$$\sigma_2 = \prod_{i=1}^{n} \sigma_{i,2} = \prod_{i=1}^{n} sk_{i,l',0} \cdot g_2^{r'_i} = g_2^{\sum_{i=1}^{n}(r_{i,l'} + r'_i)},$$

where $a_{l'} = \mathsf{H}_1(l')$.

Then, the left-hand of the verification equation holds

$$e(\sigma_1, g_2) = e\left(h^{\sum_{i=1}^{n} x_i} \cdot (h_0 \cdot h_1^{a_{l'}} \cdot h_2^{\mathsf{H}_3(m)})^{\sum_{i=1}^{n}(r_{i,l'} + r'_i)}, g_2\right)$$
$$= e\left(h^{\sum_{i=1}^{n} x_i}, g_2\right) \cdot e\left((h_0 \cdot h_1^{a_{l'}} \cdot h_2^{\mathsf{H}_3(m)})^{\sum_{i=1}^{n}(r_{i,l'} + r'_i)}, g_2\right)$$
$$= e\left(h, g_2^{\sum_{i=1}^{n} x_i}\right) \cdot e\left(h_0 \cdot h_1^{a_{l'}} \cdot h_2^{\mathsf{H}_3(m)}, g_2^{\sum_{i=1}^{n}(r_{i,l'} + r'_i)}\right)$$
$$= e(h, apk) \cdot e(h_0 \cdot h_1^{a_{l'}} \cdot h_2^{\mathsf{H}_3(m)}, \sigma_2).$$

During the above signature verification process, we assume that the message m has not been punctured. This means that the secret key component $sk_{i,l'}$ has not been deleted, and enables the signer to correctly generate the signature σ_i. On the other hand, if $\mathsf{BF.Check}(\{H_j\}_{j\in[k]}, T, m) = 1$, then signing the message m fails.

Security. The security of Pixel++ is guaranteed by the following theorem.

Theorem 2. *If the 2-BDHE$_3^*$ assumption holds, then the proposed puncturable multi-signature scheme is unforgeable under chosen message attacks. Formally, given an adversary $\mathcal{A}$ against the unforgeability of the proposed puncturable multi-signature scheme, we can construct an algorithm $\mathcal{C}$ against the 2-BDHE$_3^*$ problem such that*

$$\mathsf{Adv}_{\mathcal{C}}^{\text{2-BDHE}_3^*}(\lambda) \geq \frac{1}{\ell \cdot q_{\mathsf{H}_3}} \cdot \mathsf{Adv}_{\mathsf{PMS},\mathcal{A}}^{\text{fu-cma}}(\lambda),$$

where q_{H_3} is the number of $\mathcal{A}$'s queries to random oracle H_3, and ℓ is the length of the binary string in the Bloom filter.

Due to space constraints, we refer interested readers to the full version of this work for the proof.

Discussions. The key update procedure in Pixel++ only involves deletion operations, and thus is much more efficient than Pixel and Pixel+. The cost of this gain is that the signing may fail with a non-negligible probability. However, as we discuss in the next section, this is tolerable for PoS blockchain consensus protocols. Moreover, when the number of puncture operations reaches the upper bound of the Bloom filter's capacity, the false-positive probability (i.e., the probability of failing to sign) would exceed an acceptable bound. At

[3] To ensure l' is the same for all signers, we require every user to puncture his key after generating a new block, even if he does not participate in the packaging process.

this point, to maintain such a bound, we have to generate a new pair of public and secret keys. As suggested by Gree and Miers [45] and Derler et al. [32], we can avoid this by combining puncturable multi-signature with traditional FS-MS (e.g., Pixel). More precisely, we split the lifetime of the system into time periods, during each of which we can conduct puncture operations as in Pixel++. At the end of each time period, we can update the current secret key to a new unpunctured one for the next time period, as in Pixel. This ensures the signing error probability never exceeds the acceptable bound, while avoiding the requirement of generating new public keys.

6 Applications

In this section, we mainly demonstrate how to apply Pixel+ and Pixel++ to the setting of PoS blockchains that use forward-secure signature schemes to mitigate the damage of posterior corruptions. Of course, we can also use our schemes to improve the performance and security of those systems based on multi-signature schemes, such as improving the scalability of Bitcoin [60] and distributed randomness protocols [73].

6.1 Background on PoS Blockchains

How to securely and efficiently achieve a consensus is a basic design goal of blockchain systems. In PoS blockchains [15, 16, 44, 54, 55], each user (a.k.a stakeholder) possesses a certain amount of stakes or tokens that determine his/her voting power in the consensus procedure. In general, this is measured via the fraction of the user's stakes out of the total ones. The time is divided into a sequence of units called slots $\{sl_1, sl_2, \ldots, sl_n\}$. In each slot, all users have a probability approximately proportional to their relative stakes to be assigned as a leader. Such leaders, organized as a committee, are permitted to collectively generate a new block.

A block generated at a slot sl_j is structured in the form of $B_j = (sl_j, st_j, d_j, \sigma_j)$, where $st_j \in \{0,1\}^\lambda$ is the state of the previous block B_{j-1}, $d_j \in \{0,1\}^*$ is the packaged transaction data, and σ_j is a signature on (sl_j, st_j, d_j) produced by the committee. Then, the final blockchain is organized as a sequence of blocks $\{B_1, B_2, \ldots, B_n\}$, which strictly corresponds to the increasing sequence of slots $\{sl_1, sl_2, \ldots, sl_n\}$. During the generation of a block in each slot, most PoS protocols run a Byzantine fault-tolerant sub-protocol to tolerate malicious users. It is usually assumed that the majority (greater than $2/3$) of stakes involved in each consensus process is held by honest users. We say that each block is valid provided that a majority of committee members approved it.

6.2 Applications to PoS blockchains

. As we have discussed earlier, most of the existing PoS protocols suffer from the issue of posterior corruptions. In PoS protocols Ouroboros Praos [31] and Ouroboros Genesis [7] as well as Thunderella [64], to resist posterior corruption attacks, the signature on each block is generated with traditional forward-secure signature schemes, which mainly build on hierarchical identity-based encryption. We can apply Piexl+ or Piexl++ in these PoS protocols to achieve the same security goal, while possibly reducing the storage overhead and communication cost in some special scenarios where many users broadcast a large number of signatures on the same message. In addition, there are a few PoS protocols like Snow White [16] and Ouroboros [54] that use ordinary signature schemes to sign each block. Therefore, Piexl+ and Piexl++ can also be deployed in these PoS protocols to enable them to resist posterior corruption attacks. Below we provide the details of integrating our proposals into general PoS blockchains.

Registering public keys. When a user intends to participate in the consensus, he needs to register the public key of his voting keys. To this end, a user runs the Setup algorithm of Pixel+ or Pixel++ to generate a key pair. Then, the user issues a key registration transaction that includes the public key and the corresponding proof of possession. Furthermore, those verifiers participating in the Byzantine fault-tolerant protocol check the validity of both the key registration transaction and the proof of possession. If the check passes, the newly generated voting keys are added to the user's account. After this, if the user is eligible to participate in the consensus protocol, he employs either Pixel+ or Pixel++ to sign blocks.

Voting on blocks. The stake ownership is generally shown through the possession of corresponding signing keys. So, the number of signing keys is proportional to the stake. Each committee member participating in the consensus is required to vote on a new block B_j to be generated. This is conducted by letting participants sign blocks with their voting keys and propagating signatures to the blockchain network. The voting details are slightly different when we use Pixel+ or Pixel++, respectively.

In the case of Pixel+, we treat the block number j as the current time period. Thus, participants first need to update their secret keys to the current time period by repeatedly invoking the update algorithm in sequence. Then, using the current voting keys, they independently perform the signing algorithm to produce corresponding signatures on the same block B_j. As in Pixel+, the block number j is necessary for checking B_j's validity.

Recall that in Pixel++, each user can produce a correct signature on a message only if the secret key has not been punctured with this message. Therefore, when we use Pixel++ to authenticate the voting, each participant should make sure that his voting key has not been punctured with the block to be signed. Furthermore, during the voting process, each participant freely chooses a key component corresponding to a position l of the Bloom filter's string T such that $T[l] = 0$, and then directly runs the signing algorithm to generate a vote on the block B_j.

Particularly, Pixel++ has a non-negligible probability of signing failure due to the use of the Bloom filter. That is, it might be possible that even if the user's secret key has not been punctured with the block to be signed, signing the block still yields a failure symbol $\perp$. This failure probability can be as small as possible by adjusting the parameters of the Bloom filter, which implies a trade-off between the failure probability and the cost of generating and storing the signing key. Moreover, for those committee-based PoS consensus protocols, we can exclude participants who fail to sign. In fact, in exchange for the vast efficiency gain, most PoS blockchain protocols like Ouroboros and Snow White tolerate a non-negligible signing error.

Propagating and aggregating signatures. After the voting is done, the corresponding signature $\sigma_{i,j}$ on the block B_j from the i-th committee member would be broadcast through the blockchain network. When a designated aggregation node receives N signatures $\{\sigma_{1,j},\ldots,\sigma_{N,j}\}$ on the same block B_j, where N is a predefined threshold, it terminates the propagation, and invokes the aggregation algorithm to aggregate all signatures into a single multi-signature σ_j. Then, after σ_j is verified to be correct, B_j is written into the blockchain.

Note that the aggregation process in both Pixel+ and Pixel++ is non-interactive and incremental. This means that, on the one hand, those signatures propagated through the network can be aggregated by any party without interacting with the corresponding committee members (i.e., those original signers). On the other hand, it allows propagating nodes to just broadcast the aggregation result of several committee members' signatures, since adding a new signature to the current multi-signature immediately yields a new multi-signature. These two features bring huge communication overhead benefits.

Updating or puncturing secret keys. To achieve forward security, the voting key should be immediately updated or punctured after each new block is signed. In more detail, when we use Pixel+ in PoS blockchains, its entire lifetime is divided into T time periods, each of which corresponds to a block number in a natural order. During each time period t, the i-th participant's voting key $sk_{i,t}$ can only be used to sign the corresponding block B_t once. Although this is an inherent limitation of Pixel+, it just fits the actual application scenario of the blockchain. After that, the current voting key $sk_{i,t}$ is updated to the next time period $sk_{i,t+1}$, while $sk_{i,t}$ is erased securely [65]. For those users who have not participated in the consensus, they should first update their keys to the current time period before voting on a new block.

In the case of using Pixel++ in PoS blockchains, the forward security is captured by letting each participant puncture his voting key with the signed block. Since Pixel++ enables a user to conduct puncture operations on any position of a message, and each block B_j is uniquely identified by the corresponding slot number sl_j, so we can succinctly run the puncture algorithm with the slot number, instead of the entire block. Pixel++ allows a user to participate in the consensus on-the-fly. That is, he can directly participate in a new consensus without updating his voting key, even if he has not been elected to the committee for a long time.

7 Performance Evaluation

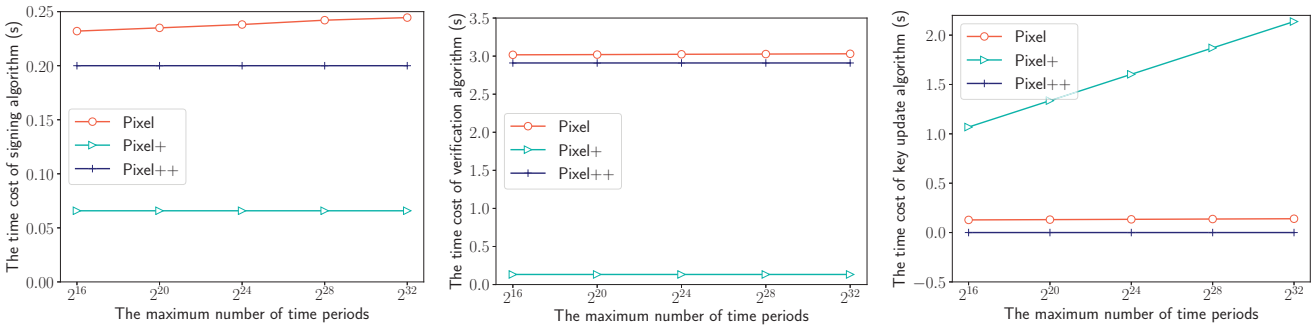
As a proof-of-concept, we implement Pixel+ and Pixel++ using Python[4], and conduct several representative experiments.

Experimental setup. For Pixel+, we use a 3072-bit RSA modulus N that provides 128-bit security. The hash function $\mathsf{H}_{\mathsf{Primes}}(\cdot)$ maps an integer to a 128-bit prime, and is implemented with SHA256 and Rabin-Miller primality test. We consider the maximum number of time periods for $T \in \{2^{16},2^{20},2^{20},2^{24},2^{28},2^{32}\}$. As an exemplary scenario, for $T = 2^{28}$, if the generation of each block takes 10 seconds, then the lifetime of the public key is around 85 years.

For Pixel++, we use the BLS12-381 curve that also provides 128-bit security, and builds its implementation upon Python implementation of BLS12-381[5]. The underlying Bloom filter is implemented with Python package `pybloom`, and takes into account three false positive probability $f \in \{0.1,0.01,0.001\}$ and capacity $c \in \{100,1000,10000\}$. The assignments of f and c also determine the length ℓ of the binary string of the Bloom filter and the number k of hash functions.

When comparing Pixel+ and Pixel++ with Pixel [35], we use Pixel's Python implementation [6]. All experiments are conducted on a PC with 3.00GHz Intel Core i7-9700 CPU and 40.0 GB DDR3 memory.

Table 2: Comparison of the cost of generating and aggregating public key and signature.



Scheme	Sig. size	pk size	SigAgg	KeyAgg
Pixel [35]	0.92 KB	0.62 KB	47.41 ms	42.25 ms
Pixel+ (Section 4.2)	0.90 KB	0.90 KB	0.42 ms	523.42 ms
Pixel++ (Section 5.2)	0.92 KB	0.62 KB	46.84 ms	41.46 ms

Storage cost. We evaluate the space complexity of these schemes in terms of the sizes of signature, public key and secret key, and obtain their specific values by storing the corresponding data in a text file. From Table 2 we can see that our constructions are almost as efficient as previous schemes from the perspective of blockchain data storage overhead. Figure 2 indicates that Pixel+ has smaller space complexity on the user side than Pixel. In the setting of $T = 2^{32}$, it is less than 60 KB. As indicated in Table 3, at the cost of achieving fine-grained forward security and more efficient key update,

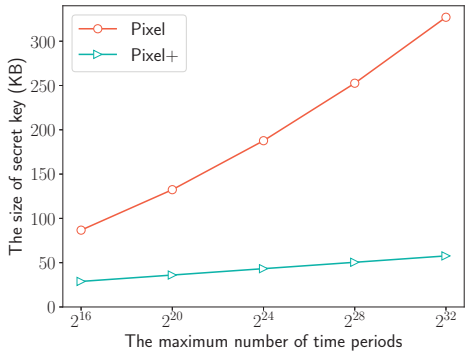
(a) Sign algorithm (b) Verify algorithm (c) Key update/puncture algorithm

Figure 1: The time cost of main algorithms in Pixel [35] and our Pixel+ and Pixel++ under different numbers of time periods.



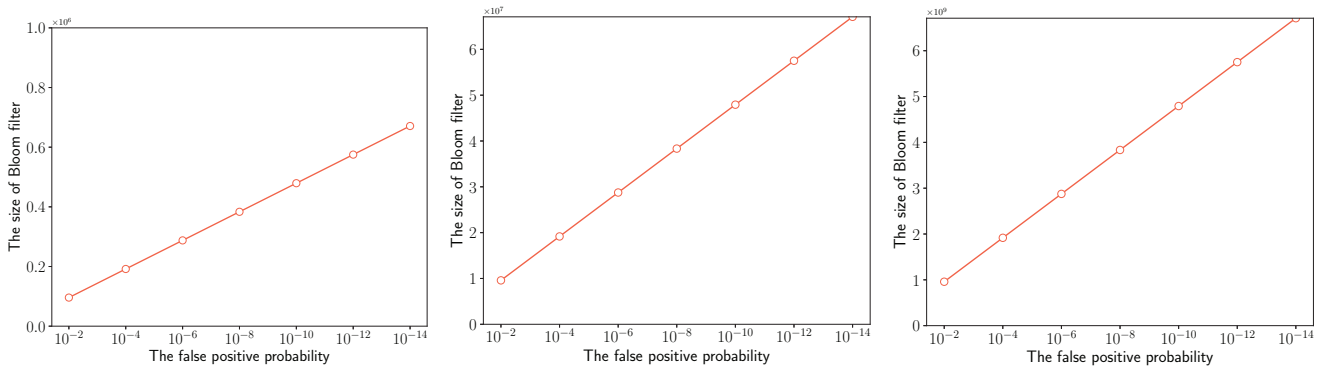


Figure 2: The secret key size under different maximum numbers of time periods.

the secret key size of Pixel++ is several orders of magnitude more expensive than the other two schemes.

Computation cost. In Figure 1 we provide the timing results of main algorithms (in the case of a single signer or verifier) in Pixel and Pixel+ as well as Pixel++. Observe that the signing and verification algorithms of Pixel+ are more efficient than that of the other two, and only take 0.07 s and 0.13 s, respectively. Pixel++ achieves the most efficient key update, and only takes 0.05 ms which is 1000x faster than Pixel. Also, note that the time cost of these three algorithms in Pixel time cost is slightly dependent on the maximum number of time periods. Moreover, as shown in Table 2, Pixel++ and Pixel are almost as efficient in generating and aggregating public keys and signatures.

Signing capacity of Pixel+ and Pixel++. The parameters T and c state the maximum number of messages that can be signed with Pixel+ and Pixel++, respectively. In our experiments, we use a practical assignment of $T = 2^{32}$ and assign the largest $c = 10000$ that is much less than T. This is mainly because the cost of KeyGen in Pixel++ is roughly linear in c, while Pixel+'s cost is logarithmic in T. As shown in Table 3, given $f = 0.001$ and $n = 1000$, the running time of KeyGen is roughly 17 hours. Thus, setting $c = 2^{32}$ is unpractical. On the other hand, a small c is indeed not practical. Fortunately, as suggested by Green and Miers [45] and Derler et al. [32], we can increase Pixel++'s signing capacity by combining it with a traditional FS-MS scheme, without sacrificing fine-grained forward security. Of course, this will additionally bring logarithmic computation cost and storage overhead.

The impact of Bloom filter parameters on Pixel++. The performance of Pixel++ partially depends on the parameters of the underlying Bloom filter. More precisely, the failure probability of signing (i.e., false positive probability) can be roughly computed as $f \approx \left(1 - e^{-\frac{kn}{\ell}}\right)^k$, where ℓ is the size

(a) The capacity $c = 10^4$ (b) The capacity $c = 10^6$ (c) The capacity $c = 10^8$

Figure 3: The relationship between the false-positive probability and the size of Bloom filter.

of the bloom filter, k is the number of hash functions, c is the maximum number of elements that tolerates the failure probability of signing f. As indicated in Table 1 and Table 3, the parameters (f, c, ℓ, k) of the Bloom filter *do not* affect Pixel++'s signature size, public-key size and the computation cost of signing, verification, key aggregation and puncturing. On the other hand, the smaller f is, the better, and c are larger. As demonstrated in Figure 3, for such desirable assignments of f and c, we need to increase the size ℓ of the Bloom filter, which brings more cost of generating and storing the signing key. This is a trade-off between usability and performance.

8 Conclusion

In this work, we presented Pixel+ and Pixel++, two forward-secure multi-signature schemes from RSA and pairing, respectively. Pixel+ is based on the GQ signature and uses the RSA sequencer to maintain signing keys. It outperforms previous FS-MS constructions in terms of signing and verification efficiency. Pixel++ provides more practical forward security (i.e., fine-grained forward security) and more efficient key update by using the Bloom filter, but at the cost of a non-negligible probability of signing failure. We proved the security of Pixel+ and Pixel++ in the random oracle model, and demonstrated how to integrate them into PoS blockchains. We also implemented our proposals, and conducted several representative experiments that show its practicability.

A Complexity Assumptions

A.1 Number Theoretic Assumptions

The security of our first FS-MS construction Pixel+ is built upon the following RSA assumption.

Definition 5 (RSA Assumption [67])**.** *Given a security parameter λ, let $p = 2p'+1$ and $q = 2q'+1$ be two safe primes of size λ, and $N = p \cdot q$. Denote by e a prime randomly sampled from $[2^{\lambda}, 2^{\lambda+1}-1]$ and QR_N the $p'q'$-order group of quadratic residues in $\mathbb{Z}_N^*$. Randomly select $x \in QR_N$ and assign $y \equiv x^e \bmod N$. Then, given (N,e,y), the RSA problem is required to compute x such that $y \equiv x^e \bmod N$. We define the advantage of an algorithm $\mathcal{B}$ solving this problem as*

$$\mathsf{Adv}_{\mathcal{B}}^{\mathsf{RSA}}(\lambda) = \Pr[x \leftarrow \mathcal{B}(N,e,y) : y \equiv x^e \bmod N].$$

We say that the RSA assumption holds provided that for any PPT algorithm $\mathcal{B}$, its advantage $\mathsf{Adv}_{\mathcal{B}}^{\mathsf{RSA}}(\lambda)$ is negligible in the security parameter λ.

We will also use the following lemma in the security proof of Pixel+ and another theorem about the number of primes.

Lemma 1 (Shamir's Trick [69])**.** *Given $x, y \in \mathbb{Z}_N$ and $a, b \in \mathbb{Z}$ that satisfy $\gcd(a,b) = 1$ and $x^a \equiv y^b \bmod N$, then there exists an algorithm of efficiently computing $z \in \mathbb{Z}_N$ such that $z^a \equiv y \bmod N$.*

Theorem 3 (Prime Number Theorem)**.** *Let $\pi(x)$ be the number of primes less than x. Then, for $x > 1$, we have that*

$$\frac{7}{8} \cdot \frac{x}{\ln x} < \pi(x) < \frac{9}{8} \cdot \frac{x}{\ln x}.$$

A.2 Bilinear Groups and q-BDHE Assumption

Let $\mathbb{G}_1$ and $\mathbb{G}_2$ be two groups of prime order p with a non-degenerate bilinear map pairing $e : \mathbb{G}_1 \times \mathbb{G}_2 \to \mathbb{G}_T$. Let g_1 and g_2 be generators of $\mathbb{G}_1$ and $\mathbb{G}_2$, respectively. For simplicity, we assume that there exists an efficient algorithm BilGen that can generate bilinear groups for the given security parameter λ, i.e., $(\mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, g_1, g_2, p, e) \leftarrow \mathsf{BilGen}(\lambda)$. In this paper, we use the Type-3 pairing. That is, it holds that $\mathbb{G}_1 \neq \mathbb{G}_2$, and there exists a public and efficient isomorphism $\psi : \mathbb{G}_2 \to \mathbb{G}_1$ such that $\psi(g_2^x) = g_1^x$ for any $x \in \mathbb{Z}_p$.

The security of our second forward-secure multi-signature construction Pixel++ is built upon the weak q-bilinear Diffie-Hellman exponent (q-BDHE)[7] assumption [22], which was originally defined in the setting of Type-1 pairing. We utilize its variant for Type-3 pairing (denoted by ℓ-BDHE$_3^*$), and define it as follows.

Definition 6. *Given bilinear groups $(\mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, g_1, g_2, p, e) \leftarrow \mathsf{BilGen}(\lambda)$, let $\{g_i^{\alpha}, \ldots, g_i^{\alpha^q}, g_i^{\alpha^{q+2}}, \ldots, g_i^{\alpha^{2q}}, g_i^{\gamma}\}_{i=1,2}$ be random group elements, where $\alpha, \gamma \in \mathbb{Z}_p$ are random integers. Let $\mathsf{Adv}_{\mathcal{A}}^{q\text{-BDHE}_3^*}(\lambda)$ be the probability (a.k.a advantage) of an algorithm $\mathcal{A}$ successfully outputting $e(g_1,g_2)^{\alpha^{q+1}\gamma}$. We say ℓ-BDHE$_3^*$ assumption holds if for any PPT algorithm $\mathcal{A}$, its advantage $\mathsf{Adv}_{\mathcal{A}}^{q\text{-BDHE}_3^*}(\lambda)$ is negligible in the security parameter λ.*

[7] We use a specific case of this assumption in our scheme, i.e., $q = 2$.

Max Attestation Matters: Making Honest Parties Lose Their Incentives in Ethereum PoS

Abstract

We present staircase attack, the first attack on the incentive mechanism of the Proof-of-Stake (PoS) protocol used in the Ethereum 2.0 beacon chain. Our attack targets the penalty of the incentive mechanism that penalizes inactive participation. Our attack can make honest validators suffer from penalties, even if they strictly follow the specifications of the protocol. We show both theoretically and experimentally that if the adversary controls 29.6% stake in a moderate-size system, the attack can be launched continuously, so eventually *all* honest validators will lose their incentives. In contrast, the adversarial validators can still receive incentives, and the stake owned by the adversary can eventually exceed the one-third threshold (system assumption), posing a threat to the security properties of the system.

In practice, the attack feasibility is directly related to two parameters: the number of validators and the parameter MAX_ATTESTATIONS, the maximum number of attestations (i.e., votes) that can be included in each block. We further modify our attack such that, with the current system setup (900,000 validators and MAX_ATTESTATIONS =128), our attack can be launched continuously with a probability of 80.25%. As a result, the incentives any honest validator receives are only 28.9% of its fair share.

1 Introduction

Ethereum [49], one of the most popular blockchain systems, upgraded to 2.0 in Sep 2022. The system now uses a Proof-of-Stake (PoS) protocol called Gasper as its core consensus scheme [12], a Byzantine fault-tolerant (BFT) protocol that tolerates Byzantine failures (i.e., arbitrary failures). Different from conventional BFT protocols [13, 16–18, 24, 46, 52, 53] that assume the adversary does not control over one-third of nodes (also called validators) or Nakamoto consensus (the consensus protocol of Bitcoin and Ethereum 1.0) that assumes the adversary does not control over 50% computational power, PoS assumes that the adversary does not control more than one-third of the total stake. Here, the stake in general refers to the account balance of the validators.

The PoS protocol of Ethereum assumes a partially synchronous network [19], where there exists an unknown upper bound for message processing and transmission. The protocol is a combination of Casper friendly finality gadget (FFG) [11] and a variant of the GHOST fork-choice rule [43] called Hybrid Latest Message Driven Greedy Heaviest-Observed Sub-Tree (HLMD GHOST). The protocol is epoch-based, and there are many slots in each epoch, divided by physical clocks. In each epoch, HLMD GHOST selects the *canonical chain* based on the received block proposals. Informally speaking, an honest block proposer will extend the canonical chain when creating a new block, and an honest validator only votes for blocks on the canonical chain (so the system is somewhat *live*). Additionally, Casper is a gadget that essentially counts the number of votes (also called attestations) so eventually some blocks are finalized and honest validators will finalize the same chain (and the system is *safe*).

Almost all PoS protocols [12, 23, 26] make an implicit assumption similar to conventional BFT: all honest validators are always online, and the system cannot support an unknown number of validators that may go to sleep [35]. This is in sharp contrast to the Nakamoto consensus. While some academic efforts have been made to study PoS in the sleepy model [5, 30], Ethereum utilizes the *incentive* mechanism to encourage validators to stay online. The incentive mechanism for attestations consists of *rewards* and *penalties*. In particular, validators whose attestations are finalized on-chain will receive rewards, and validators whose attestations are not finalized on-chain for a sufficiently long period of time will suffer from penalties (see §3.4 for details). The incentive mechanism has been very successful in practice. According to the report provided by *rated.network*[1], the participation

† Sisi is also with Zhongguancun Laboratory, Shandong Institute of Blockchains, and Beijing National Research Center for Information Science and Technology

[1] Data source (accessed in Feb 2024): https://www.rated.network/

rate of Ethereum has reached 99.6%. Indeed, validators are incentivized to make the system both safe and live so they can continue gaining rewards from the blockchain.

An attack on the attestation incentive mechanism. For the first time, we present an attack on the incentive mechanism of Ethereum PoS, and we call it *staircase attack* (mainly because the branches the adversary constructs in the attack look like a staircase). Our work focuses on the rewards and penalties for attestations only, so we call them *attestation incentives* in this paper. Our attack can be launched even if the network is synchronous, i.e., there exists a known upper bound for message transmission and processing. The goal of our attack is to force honest validators to be penalized, even if they strictly follow the specifications of the protocol. We begin with a warm-up attack where a single Byzantine validator, upon some *opportune epoch*, is able to make some honest validators suffer from penalties without any cost. We then extend the attack to a scenario where Byzantine validators controlling 29.6% of the total stake may collude. After an opportune epoch, the Byzantine validators can make half of the honest validators suffer from penalties in *every* epoch. Eventually *all* honest validators will lose their incentives. Meanwhile, none of the Byzantine validators suffer from any penalties at all. The consequence of our attack is thus the same as *discouragement attack* [10]: the fraction of the stake controlled by the adversary may continue to increase, posing safety threats. However, [10] only briefly mentions the concept and does not provide the attack strategies. Therefore, we consider our attack the first concrete instantiation of a discouragement attack.

Our attack utilizes a parameter used in both HLMD GHOST and Casper called the *last justified checkpoint LJ*. In Ethereum PoS, Casper updates the *LJ* parameter, and HLMD GHOST determines the canonical chain based on the *LJ* parameter. The design of Ethereum PoS identifies the *LJ* parameter as a *frozen* parameter that is not supposed to change within an epoch. However, as Byzantine validators may withhold their blocks (and attestations) and release them at any time, an honest validator might update *LJ* in the middle of an epoch. We show that by deliberately packing the attestations from *all* Byzantine validators into one block and withholding such a block, the honest validators always change their *LJ* in the middle of an epoch. As a result, the canonical chain (output by HLMD GHOST) may switch from an old branch to a new one. Thus, attestations from honest validators included in the old branch will be discarded and the corresponding honest validators will be penalized.

Evaluation of the attack. We implement our attack using an Ethereum implementation *Prysm (Capella version)* and conduct experiments using 1,000 validators. Our experimental results match our theoretical analysis: if the adversary controls 29.6% stake, *all* honest validators lose their incentives. As the fraction of stake controlled by the adversary grows, honest validators may suffer from stake loss. For instance, if the adversary controls 33.3% stake, all honest validators are expected to suffer from a 20% stake loss compared to their fair share.

Attack feasibility and insights. Ethereum has over 900,000 validators as of Feb 2024. When demonstrating the feasibility of our attack in such a large-scale system, we find a somewhat surprising result. Specifically, the feasibility of our attack is related to two parameters: the number of validators and the number of attestations each block can carry, i.e., the MAX_ATTESTATIONS parameter. Based on the system setup of Ethereum, if we fix the MAX_ATTESTATIONS parameter, our attack can be launched continuously for a system with fewer than 16,384 validators. If we fix the system size of 900,000 validators, the attack can be launched if the MAX_ATTESTATIONS parameter is increased from 128 to 2,048.

We further modify our attack to *accommodate* the system parameters of today's Ethereum system. With the modification, our attack can be continued in each epoch with a probability of 80.25%, given that the adversary controls 33% of the total stake. As a result, the attestation incentives of an honest validator become only 28.9% of the fair share. As reported by *rated.network*, the largest mining pool today already controls 32.66% of the total stake. Therefore, our attack can cause discouragement to honest validators.

It is also worth mentioning that our warm-up attack is additionally affected by the *honest reorg* mechanism [45]. To successfully launch the warm-up attack, the adversary needs to carefully release a block *late* enough and the timing is highly related to the network condition.

Responsible disclosure. For ethical reasons, we disclosed our findings to the Ethereum Foundation in April 2023, and the development team has taken measures since then to mitigate the attack. With the mitigation, the probability of continuing the attack in each epoch is significantly reduced. The mitigation is already effective after the Deneb upgrade in March 2024. The communication and the mitigation can be found at https://github.com/ethereum/consensus-specs/pull/3339#issuecomment-1637117341.

Our attack and analysis show some interesting insights that may lead to future research directions. First, the incentive mechanism is usually considered an economic factor in a system and has never been considered in the design of Byzantine-fault tolerant consensus protocols [12]. However, the attacks on the incentive mechanism may make the PoS protocol violate the security goals. Indeed, the stake of the adversary may exceed one-third of the total stake so eventually the safety and liveness of the system might be violated. Therefore, it is interesting to learn whether the incentive mechanism should be part of the security properties in the design of the consensus protocols. Second, the number of attestations that can be included in each block is closely related to both the incentives of validators and the security goals of the

system. Such a counter-intuitive finding shows that the value of the MAX_ATTESTATIONS parameter (and its closely related parameters) should be set up carefully.

Our contributions. We make the following contributions.

- We propose staircase attack on the attestation incentive mechanism of Ethereum's PoS protocol. We show that when the adversary controls at least 29.6% of the total stake, the attack can be launched continuously and eventually make *all* honest validators lose their incentives.
- We implement the attack using 1,000 validators. By conducting each experiment for one day (225 epochs), we show that an adversary controlling 29.6% stake makes *all* honest validators lose their incentives; if an adversary controls 33% stake, all honest validators are expected to suffer from a 20% of stake loss compared to their fair share.
- Our feasibility analysis shows that the number of validators and the MAX_ATTESTATIONS parameter have a direct impact on whether the attack can be continuously launched. Based on today's system setup of Ethereum, our attack can be launched under the following two conditions: the system has no more than 16,384 validators; the MAX_ATTESTATIONS parameter is increased from 128 to 2,048. We further modify our attack such that with a probability of 80.25%, the attack can be continued in the next epoch and the expected attestation incentives of honest validators become only 28.9% of their fair share.

2 Related Work

Identified attacks against Ethereum PoS only. Many efforts have been made to analyze Ethereum PoS since Ethereum announced its plans to upgrade to 2.0, as summarized in Table 1.

Balancing attack. A balancing attack aims to split honest validators into two parts, forcing them to vote for two conflicting branches with the same weight. Consequently, neither chain can be finalized and the system suffers from liveness issues [30, 42]. Ethereum fixed the balancing attack [9] using a *proposal boosting* mechanism [39]. In short, proposal boosting is a "temporary" weight assigned to the block in the current slot. As the two branches do not have the same weight anymore, the situation created in the balancing attack will not last forever. Later, it was shown that the balancing attack can be revised to bypass the proposal boosting mechanism [31]. In the balancing attack, the cost of the adversary is that at least one Byzantine validator will suffer from the slashing condition. According to the specification of Ethereum, slashed validators will suffer from stake loss and eventually be removed from the system.

Bouncing Attack. In a bouncing attack, checkpoints from two branches are *justified* one after the other. Therefore, the canonical chain jumps from one chain to another and neither branch can be finalized, causing a liveness issue [29, 36]. Ethereum's upgrade in March 2023 fixed all known bouncing attacks [22]. Our attacks are designed based on the latest specifications.

Reorg Attack. In reorg attacks [33, 41, 42], the adversary reorganizes the chain to increase the fraction of the blocks from Byzantine validators on the canonical chain. The goal is to gain more profit [25,50,55], decrease the *chain quality* [34], or lower the performance of the system. There are two types of reorg attacks: short reorg attacks (SRA) and long reorg attacks (LRA) [41]. In SRA, the attacker makes the adversarial branch heavier than the honest branch so the honest branch becomes orphaned [33, 42]. An interesting fact is that the SRA in [33, 42] are fixed by the proposal boosting mechanism [9]. It was later mentioned informally that the proposal boosting mechanism does not fully address the issue and a revised SRA called *sandwich attack* is proposed [15].

Meanwhile, in LRA, the attacker forces the honest branch to be pruned and the number of blocks affected is usually larger than that in SRA [2, 37, 40]. Two types of LRA have been found: unrealized justification attacks [2] and justification withholding attacks [37, 40]. In unrealized justification attacks, the validator in the first slot of an epoch needs to be Byzantine. The Byzantine validator creates a fork by proposing a block that extends an older block so the canonical chain is re-organized. In justification withholding attacks, the validators in the last few slots of an epoch need to be Byzantine and the Byzantine validators withhold their blocks. In the middle of the subsequent epoch, the withheld blocks are released so the *LJ* of honest validators is updated and the honest branch is pruned. A patch is provided recently to prevent all LRA known so far in which branches with *enough* attestations are not pruned [2, 38].

Our staircase attack can be viewed as a long reorg attack, specifically a justification withholding attack. Different from existing attack that requires validators in consecutive slots to be Byzantine, our attack only requires the last Byzantine validator in an epoch to withhold the attestations and the block. Therefore, our attack is much easier to launch. Besides, the patch for the LRA does not affect our attack.

Identified attacks against PoS. We summarize some identified attacks against PoS in general, some of which are applicable to Ethereum PoS as well.

Nothing-at-stake attack. A nothing-at-stake attack refers to the attack where an adversary is willing to contribute to multiple forks at no cost (as the validators in PoS do not have to compete to propose or vote) [8, 26, 27]. The goal of nothing-at-stake attacks is usually the liveness and the performance of the system. The *avalanche attack* is one example of PoS GHOST [31]. In the attack, it was shown that by deliberately working on multiple forks at the same time, the canonical chain consists of blocks only from the adversary, so the system may not be live. Note that Ethereum does not suffer from nothing-at-stake attack, as a validator that equivocates (e.g., it votes for two conflicting blocks) will be slashed.

Table 1: Comparison of known attacks against Ethereum PoS. **Slashed* denotes whether at least one Byzantine validator will be slashed. According to the specification of Ethereum, slashed validators will suffer from stake loss and eventually be removed from the system. *After the recent upgrade, our attack can still be launched but the impact has been significantly reduced.

Long-range attack. In a long-range attack, the adversary first acquires the secret keys of some validators after they withdraw their stake (and leave the system). The adversary then revises the blocks proposed previously and rewrites the history of the blockchain. Many protocols are designed to prevent the attack [3, 4, 26, 48, 51]. The Casper protocol [11] used in Ethereum is a solution to the long-range attack.

Grinding attack. Most PoS protocols use pseudorandom functions (e.g., verifiable random functions (VRF) [28]) to select block proposers. The way the randomness is generated usually depends on the blocks in the canonical chain [47]. In practice, the roles of the nodes might be learned in advance [6] so the randomness (and the validators eligible to propose subsequently) can be manipulated [1, 8]. The goal is to improve the adversary's chances of being selected as a block proposer (to gain extra profits or decrease the chain quality).

Selfish mining. Selfish mining is an attack first known in Proof-of-Work (PoW) [20]. In selfish mining, a mining pool (with a number of validators) may collude [54] and gain more revenue than the fair share. Selfish mining attack was later found to be feasible in some PoS protocols as well [6, 8, 21, 32]. To the best of our knowledge, selfish mining attack has not been identified in Ethereum 2.0 yet.

3 Review of Ethereum Proof-of-Stake

Our notations in this section largely follow the specifications by Ethereum foundation [44].

3.1 System Model

Nodes that participate in the PoS protocol are called *validators*. To become a validator, one must deposit at least 32 ETH as an initial stake in its account. Each validator's voting power is weighted by its stake. There are N validators $\{v_1, v_2, \cdots, v_N\}$, where N may change over time as validators join and leave the system. Each validator holds a private/public key pair. Validators may be Byzantine and arbitrarily deviate from the protocol. Non-faulty validators are called honest validators. Ethereum PoS assumes that the stake controlled by Byzantine validators is less than one-third of the total stake.

To facilitate the description of our attack and without loss of generality, we assume that N does not change and each validator is assumed to hold at least 32 ETH. In this way, we normalize each validator's balance to *1 unit* [12]. This enables us to tally the number of attestations instead of taking into consideration the fractions of the validators' balance. Accordingly, let f be the number of Byzantine validators, we assume $f < N/3$. We believe this assumption is reasonable as according to the data from *beaconcha.in*, the average actual balance of the validators is 32.08 ETH[2].

Ethereum PoS assumes that the network is partially synchronous [19], i.e., there exists an unknown upper bound Δ for message propagation and processing delay. However, our attack can be launched even if the network is synchronous, i.e., the value of Δ is known to every validator.

3.2 Terminology and Notation

Ethereum PoS proceeds in epochs, and each epoch consists of 32 slots. Given a slot number t, every validator is able to obtain the epoch number $e \leftarrow \lfloor \frac{t}{32} \rfloor$. Each slot lasts for 12 seconds in the current production system. Within a slot, only a single block can be proposed. A *block* b consists of the slot number, a hash pointer to the parent block, a batch

[2]Data source (accessed in Feb 2024): https://www.beaconcha.in/charts/average_balance

of transactions, and a set of attestations (i.e., votes, to be described shortly). Given a block b, the *branch* led by b is the path from b to the *genesis block* (the first block of the blockchain history). Each validator maintains a *block tree* $\mathcal{T}$ about the blocks proposed by the validators. Additionally, a *checkpoint* is a special block b. By default, the checkpoint is the first block proposed in each epoch. If such a block does not exist, the most recent preceding block becomes the checkpoint. A checkpoint is denoted as a pair (b,e), where b is the block and e is an epoch number. For simplicity, we use the block instead. We use $\mathsf{ep}(b) \leftarrow \lfloor \frac{t}{32} \rfloor$ to denote the epoch number of block b proposed in slot t.

Ethereum PoS consists of Hybrid Latest Message Driven Greedy Heaviest-Observed Sub-Tree (HLMD GHOST) and Casper FFG [12]. HLMD GHOST is a fork-choice rule that recursively chooses the root of the *heaviest subtree* and outputs the leaf block as *head*. The chain led by head is also called the *canonical chain*. Each honest validator will only vote for the head of the canonical chain it is aware of or create a new block by extending the canonical chain. Additionally, Casper FFG helps finalize the checkpoints, and once a checkpoint is finalized, all the blocks on the chain led by the checkpoint are finalized. As attestations are contained in blocks, we can also say that the attestations are finalized on-chain.

Attestor and proposer. In each epoch, N validators are randomly and evenly divided into 32 validator sets (determined by the RANDAO protocol[3]). Each validator set is allocated for one slot of the epoch and validators (also called *attestors*) in this set are allowed to vote. Additionally, in each slot, one validator is randomly selected as the *proposer*, also according to RANDAO. The proposer is the only validator that is allowed to propose a block in the slot. Our work simply assumes RANDAO is a pseudorandom function that randomly determines the roles of the validators, i.e., the expected number of honest attestors in each slot is $(N-f)/32$. Every validator is able to determine its role one epoch in advance and also verify the roles of other validators. A message from validator v_i is considered invalid if v_i's role is not verified.

Attestation. In Ethereum, a vote is also called an *attestation*. An attestation (*att*) by validator v_i consists of a slot number, two checkpoints (*source* and *target*), and the hash of a block b. We say *att* is an attestation for block b. By default, *source* is v_i's *last justified checkpoint* (i.e., *LJ*, to be described shortly). The *target* field is the checkpoint block of the current epoch in v_i's canonical chain. Both *source* and *target* are needed to identify the chain each attestor votes for. In an attestation, the *source* or the *target* field is denoted as the hash of a checkpoint block b and the epoch number. In this paper, we omit the epoch number for ease of understanding. Notably, the block b is the output of the HLMD GHOST.

Justification and finalization. The justification and finalization rules are defined in Casper for checkpoints only. Specifically, if attestations from more than two-thirds validators with the same *source* and *target* are received, the *target* checkpoint is *justified*. Additionally, if the descendant checkpoint of a checkpoint cp is justified, cp becomes *finalized*. If cp is finalized, all the blocks on the chain led by cp are finalized and the order of the finalized blocks will never be reversed.

Given a branch c in v_i's block tree $\mathcal{T}$, we use $V(c)$, $J(c)$, and $C(c)$ to denote the number of attestations included in chain c, the last justified checkpoint based on $V(c)$, and checkpoint block of the current epoch in c, respectively. Given a block b and a branch c led by b's parent block, if the slot numbers of b and b's parent block indicate that b is from a new epoch, *LJ* is updated to $J(c)$. Ideally, *LJ* is updated at the beginning of an epoch and is not changed during the epoch. In contrast, $J(c)$ is updated whenever $V(c)$ is updated.

Fork choice rule. The fork choice rule HLMD GHOST defines the canonical chain and HLMD GHOST outputs the head of the canonical chain. In particular, the block each attestor votes for is the head of its canonical chain. Meanwhile, a block proposer will extend the head of the canonical chain when creating a new block b, i.e., by setting the hash pointer of b as the hash of the head. Given a block tree $\mathcal{T}$, the canonical chain is defined as follows (an example is provided in Figure. 1):

1. Prune any branch $c \in \mathcal{T}$ such that $J(c)$ is lower than *LJ*. Then calculate the *weight* of each block in the chain. Here, weight is determined by the attestations. In particular, if there exists an attestation for block b, the weight of b is incremented by one.
2. Recursively calculate the sum of weights of each subbranch. The branch with the largest accumulative weight is considered *the heaviest subtree* and becomes the canonical chain.

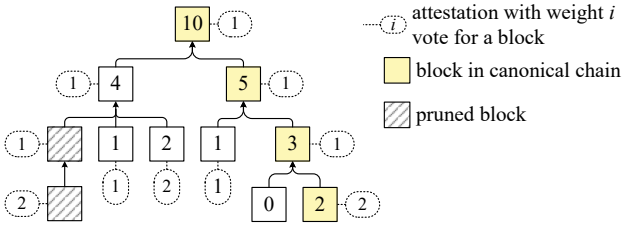

Figure 1: Example of the fork choice rule HLMD GHOST. Attestations are represented in dashed rounded rectangles and blocks are represented in solid rectangles. The number shown in each attestation denotes the weight of the attestation and the number shown in each block denotes the weight of the subtree. The leftmost branch c is pruned (because $J(c)$ is lower than *LJ*), and its weight is not calculated. The rightmost branch is the canonical chain.

3.3 Workflow of Ethereum PoS

We summarize the workflow of Ethereum PoS in Figure. 2. Each validator maintains three local parameters: the last justified checkpoint LJ, a set of received attestations $Atts$, and the block tree $\mathcal{T}$.

In slot t, if v_i is the proposer, it broadcasts a $(\text{PROPOSE}, t, v_i, H(head), newatts, txs)$ message to all validators (lines 1-10). Here, *head* is the output of HLMD GHOST and $H(head)$ is the hash of *head*, serving as a hash pointer of the parent block. The *newatts* field consists of a set of attestations v_i has received. Given the canonical chain c, any attestation that satisfies the following two requirements will be included in *newatts*: 1) the attestation has not been included in c so far; 2) the *source* is the same as LJ and the *target* is the same as $C(c)$. If v_i is an attestor, it waits until 1/3 time of slot t has elapsed (i.e., four seconds) and updates its LJ. Then, v_i prepares an attestation message $(\text{ATTEST}, t, v_i, H(head), LJ, C(c))$ and sends it to all validators, where LJ is the *source*, and the checkpoint of current epoch $C(c)$ is the *target* (lines 11-19).

Upon receiving a block b from the proposer v_j of slot t', v_i checks: 1) whether the epoch number of b is higher than the epoch number of b's parent block; 2) whether the epoch number of $J(c)$ is higher than LJ, where c is the branch led by b (line 24). If so, v_i updates LJ to $J(c)$. Validator v_i then processes the attestations included in b and updates its block tree $\mathcal{T}$, i.e., for each branch $c \in \mathcal{T}$, update $J(c)$, $V(c)$, and $C(c)$ (lines 27-31). Last, if b is a block from the prior epoch and $\mathsf{ep}(J(c)) > \mathsf{ep}(LJ)$, v_i also updates its LJ (lines 33&34).

It is worth mentioning that a validator v_i updates LJ in three cases. First, v_i receives the first block in some epoch e such that $J(c)$ is higher than its LJ (lines 23-25). Second, before v_i prepares an attestation, it updates its LJ according to the messages it receives (lines 14-16). Last, although v_i already enters epoch e, it has received a sufficiently large number of attestations for an epoch lower than e (e.g., included in the blocks withheld in previous epoch(s) and released in epoch e[4]) such that $J(c)$ is higher than its LJ (lines 32-34). Before epoch e begins, the epoch number of LJ of any honest validator is at most $e-2$.

3.4 The Attestation Incentive Mechanism

The incentive mechanism consists of *rewards* that encourage active participation and *penalties* that discourage inactive behavior [12, 44]. Validators with attestations finalized on-chain will receive rewards, and validators who do not have their attestation finalized on-chain (after a sufficiently large number of slots) will get penalties. Note that penalties differ from the *slashing conditions* [12]: slashing conditions penalize behaviors such as equivocation, while penalties only act on inactive behavior. The slashing condition is also part of the incentive mechanism of the system. We thus use attestation incentives to denote rewards and penalties in this paper.

Generally speaking, the rewards and penalties of each validator depend on its own stake, the total amount of stake, and the corresponding attestation. For each validator v_i, a *base reward* I_{base} is first decided, which is an equation of v_i's stake

[4] Note that according to the design of the system, a block tagged with epoch e' where $e' < e$ can still be accepted by validator v_i even if v_i already enters epoch e.

and stake of all validators. Both rewards and penalties are then calculated based on I_{base}. The reward is $R \times W_r I_{base}$. Here, R is the *rewards scale with participation*, which is related to v_i's stake and the total stake of attestors who have their attestations finalized on-chain. W_r is the weight determined by the *source*, *target*, and block in the attestation. Additionally, the penalty is $W_p I_{base}$, where W_p is the weight determined by the *source* and *target* of the attestation v_i is supposed to send. If a validator submits an attestation in an epoch e and the attestation is finalized on-chain, the validator receives a $R \times W_r I_{base}$ reward. On the contrary, if the attestation is not finalized on-chain, the validator gets a penalty with amount $W_p I_{base}$ and no reward for epoch e.

4 An Attack on the Incentive Mechanism

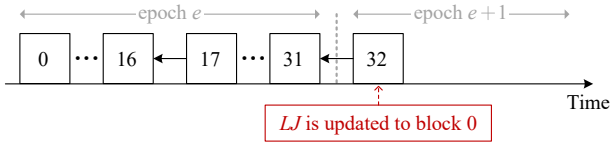
In this section, we present staircase attack, an attack on the incentive mechanism of the Ethereum PoS protocol. The goal of this attack is to make honest validators suffer from penalties, even if the network is synchronous and honest validators strictly follow the specification of the PoS protocol.

We begin with a warm-up attack where a single Byzantine validator can manipulate the *target* of attestations from honest validators and make $(N-f)/32$ honest validators suffer from penalties. We then show that if Byzantine validators (owning 29.6% of the total stake) collude, the colluding validators can manipulate both the *source* and *target* of attestations from half of the honest validators. After the attack is started, it can be launched in *every* epoch. Eventually, *all* honest validators will lose their incentives. In contrast, Byzantine validators do not suffer from any penalties. The only cost is that the incentives Byzantine validators can obtain during the attack are slightly lower than their fair share.

We show in Figure. 3 the meaning of legends used in the figures of this paper.

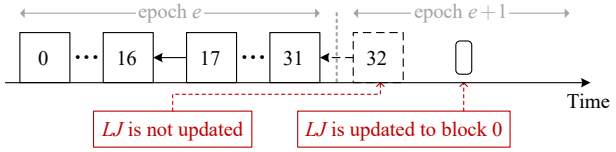
Legend	Meaning
	attestations from honest validators with *source* lower than the checkpoint block of the previous epoch
	attestations from honest validators with *source* as the checkpoint block of the previous epoch
	attestations from Byzantine validators with *source* as the checkpoint block of the previous epoch
	discarded attestations
	a block proposed by an honest validator that includes
	a block proposed by an honest validator that includes
	a block proposed by a Byzantine validator that includes
	a pruned block
t	a block that will be received at time t
	a withheld and released block
	attestations included in the block

Figure 3: The meaning of legends used in the figures of this paper. Figures in this paper are best viewed in color.



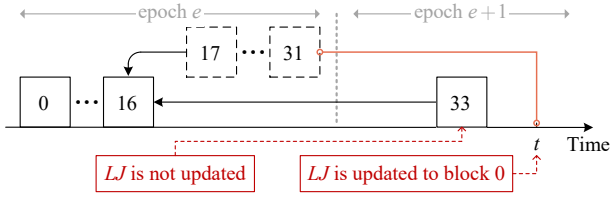
4.1 Overview of the Attack Methodology

Our attack exploits the fact that *LJ* and the latest checkpoint might be changed in the middle of an epoch, as mentioned in §3.3. For ease of understanding, we illustrate three examples in Figure. 4 to show three possible cases. Before epoch e, *LJ* is set as cp, and attestations by all honest validators in epoch e have *target* set as block 0.



- **Case 1: *LJ* is updated upon receiving the first block of an epoch.** As shown in Figure. 4a, in epoch e, v_1 receives block 0 to block 31. The attestations of all honest validators are included in the blocks. As attestations from all honest validators are received, the condition $V(c)[0] > 2N/3$ is satisfied and $J(c)$ is updated to block 0. In epoch $e+1$, v_1 receives block 32 in the first slot. As the epoch number of $J(c)$ is greater than *LJ*, *LJ* is set as block 0 (line 24 in Figure. 2). Honest attestors all use block 0 as *source* and block 32 as *target* in their attestations i n epoch e.
- **Case 2: *LJ* is updated before preparing an attestation.** As shown in Figure. 4b, v_2 receives block 0 to block 31, but no blocks have been received in epoch $e+1$. *LJ* is not updated to block 0 until v_2 becomes an attestor (line 14 in Figure. 2). Before v_2 prepares its attestation, it updates its *source* as block 0 and *target* as block 31.
- **Case 3: *LJ* is updated in the middle of an epoch.** As shown in Figure. 4c, validator v_3 has received block 0 to block 16 in epoch e. In epoch $e+1$, v_3 receives block 33, the parent of which is block 16. As blocks 17-31 are withheld or delayed, v_3 has not received $2N/3$ attestations and $J(c)$ is still cp, where c is the chain led by block 33. The attestation from v_3 has cp as *source* and block 16 as *target*. Later, in slot t of epoch $e+1$, v_3 receives blocks 17 to 31, blocks created in epoch e but received in slot t of epoch $e+1$. Now, the blocks on the branch led by block 31 include enough attestations in epoch e. Therefore, $J(c)$ and *LJ* are updated to block 0 (line 33 in Figure. 2).

It is worth mentioning that after *LJ* is updated, any branch c such that $J(c)$ is lower than *LJ* will be pruned in the block tree, and HLMD GHOST will not output a block from a pruned branch. Take the case for validator v_3 as an example, we show the block tree of v_3 after v_3 receives blocks 17-31 in Figure. 5. In this example, before v_3 receives blocks 17-31, branch c_2 is the canonical chain. After *LJ* is updated to block 0, branch c_1 led by block 31 becomes the canonical chain. Branch c_2 led by block 33 will then be pruned as $J(c_2) = cp$, lower than *LJ* (block 0).



Our attack utilizes this fact to *force* honest validators to prune a branch led by a block from an honest validator, so the attestations on the pruned branch are discarded, e.g., the attestations included in block 33 in Figure. 5 with cp as *source* and block 16 as *target* are discarded. Moreover, these attestations will never be finalized on-chain, as their *source* is lower than *LJ* (lines 5-7 in Figure. 2) and the corresponding validators will be penalized. In the following, we show that one Byzan-

(a) v_1 receives block 32, the first block in epoch $e+1$. v_1 updates its *LJ* to block 0.

(b) v_2 has not received any blocks in epoch $e+1$ yet and does not update its *LJ* until it prepares an attestation. Before v_2 prepares its attestation, it updates its *source* as block 0 and *target* as block 31.

(c) v_3 receives block 33 and the chain led by block 33 does not include $2N/3$ attestations. v_3 does not update its *LJ*. When v_3 later receives blocks 17-31, the chain led by block 31 includes $2N/3$ attestations with *target* as block 0. v_3 updates *LJ* to block 0.

Figure 4: Examples of updating *LJ*.

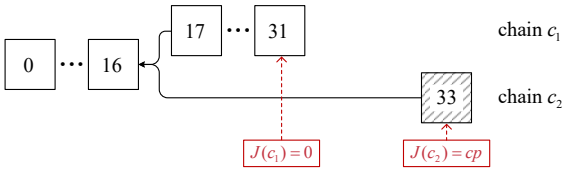


Figure 5: Validator v_3's block tree.

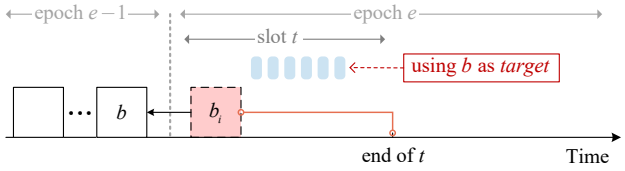
tine validator is able to make the attestations from $(N-f)/32$ honest validator be discarded. We then show that if all Byzantine validators collude, they can utilize the re-organization of the chain to make *half* honest validators suffer from penalties in every epoch.

4.2 The Warm-up Attack

In our warm-up attack, a single adversarial validator v_i can launch the attack and $(N-f)/32$ honest validators are expected to be penalized. To kick-start the attack, v_i waits for an *opportune epoch*. An epoch e is deemed opportune if v_i is eligible to propose in the first slot of epoch e (let the slot number be t).

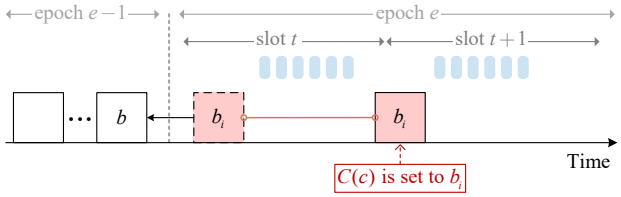
Before epoch e, honest validators maintain a consistent view of the canonical chain, and *LJ* of all honest validators is the same checkpoint. According to the discussion in §3, we know that before epoch e begins, the epoch number of *LJ* is $e-2$, and we use cp_{e-2} to denote the *LJ* of all validators. We use cp_{e-1} to denote the checkpoint block proposed in the first slot of epoch $e-1$ and b to denote the last block proposed in epoch $e-1$. We assume that all validators receive cp_{e-1} and b in epoch $e-1$. Given such an opportune epoch e, the attack strategies of v_i are summarized below.

(1) (Figure. 6a) Validator v_i first creates a block b_i that extends block b and withholds b_i. As none of the validators has received the first block in epoch e yet, case 2 mentioned in §4.1 is satisfied: *LJ* is updated to cp_{e-1} when attestors in slot t prepare their attestations. Thus, attestors in slot t then send attestations using cp_{e-1} as *source* and b as *target*.



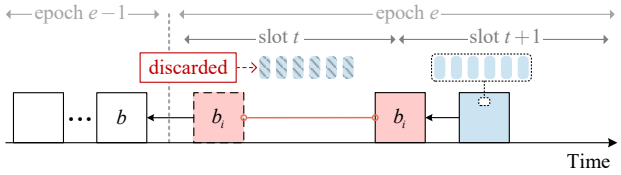
(2) (Figure. 6b) At the end of slot t, validator v_i sends b_i to all validators. Here, b_i becomes the head of the canonical chain, and all honest validators set their checkpoint block as b_i. Additionally, the chain c led by b consists of the attestations from all validators in epoch $e-1$, so $J(c)$ is already set as cp_{e-1}. As the first block of epoch e is received, case 1 in §4.1 is satisfied and all honest validators update their *LJ* to cp_{e-1} (lines 23-25 in Figure. 2).

(3) (Figure. 6c) After slot t, any attestations created by honest attestors in slot t will be discarded by all honest validators. To see why, given any attestation *att* mentioned in step (1), the *target* field of *att* is b. However, the checkpoint of epoch e for all honest validators is b_i. When any proposer creates a new block, *att* will be filtered (lines 6-7 in Figure. 2). Therefore, all honest attestors in slot t will be penalized. According to our discussion in §3.2, the expected number of honest attestors penalized is thus $(N-f)/32$.



4.3 The Staircase Attack

We are now ready to present our staircase attack, in which Byzantine validators collude to launch the attack. Here, we assume the adversary controls a set of Byzantine validators to launch the attack and later discuss the number of Byzantine validators the adversary needs to control. Recall that our warm-up attack manipulates the *target* of attestations from honest validators. Our full staircase attack relies on the warm-up attack to kick-start the attack. After that, the staircase attack manipulates the *source* of honest validators instead. The idea is to let half of the honest validators use an outdated *LJ* as *source* and eventually be penalized. To do so, all Byzantine validators withhold their attestations and blocks, making *LJ* *non-frozen* and updated in the middle of an epoch. After that, the attestations released before *LJ* is updated are not included in the canonical chain, resulting in penalties for the corresponding honest validators.



Notations. We define several notations to assist the explanation of our attack. We divide each epoch e into two periods: the first period consists of slots before *LJ* is updated; the sec-

(a) Step 1: v_i withholds block b_i. Honest attestors in slot t create attestation with b as *target*.

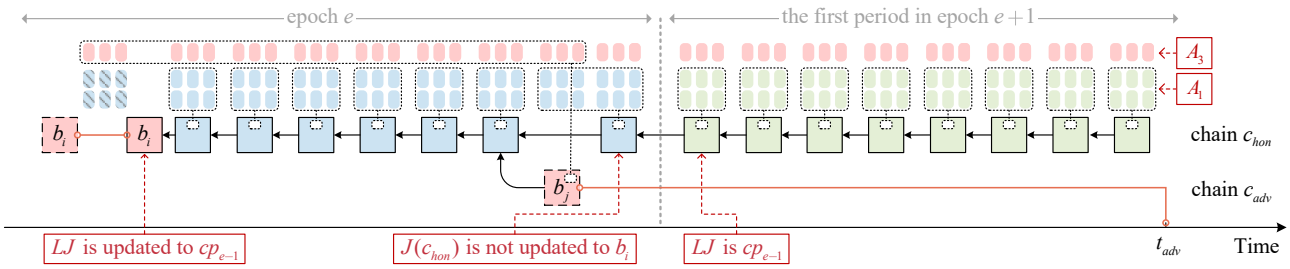
(b) Step 2: v_i releases b_i and all honest validators update their checkpoint block to b_i (i.e., $C(c)$).

(c) Step 3: Attestations with *target* different from b_i will be discarded and honest attestors in slot t will eventually be penalized.

Figure 6: Warm-up attack where v_i is the Byzantine validator. Before epoch e begins, all validators receive the last block b in epoch $e-1$.

ond period consists of the rest of the slots in epoch e. Honest attestors in the first period create attestations with some checkpoint cp as the *source*, while honest attestors in the second period create attestations with cp' as the *source*, where cp' is higher than cp. We partition attestations from all validators into three sets: A_1 denotes the attestations from honest attestors in the first period; A_2 denotes the attestations from honest attestors in the second period; A_3 denotes the attestations from all Byzantine attestors in epoch e. Our goal is to make the attestations in A_2 and A_3 share the same *source* and *target*, and the number of attestations in $A_2 \cup A_3$ is greater than $2N/3$, so the canonical chain can be *manipulated* by the adversary and attestations in A_1 will be discarded. As illustrated in Figure. 3, we use green, blue, and red rounded rectangles to represent the attestations in A_1, A_2, and A_3, respectively.

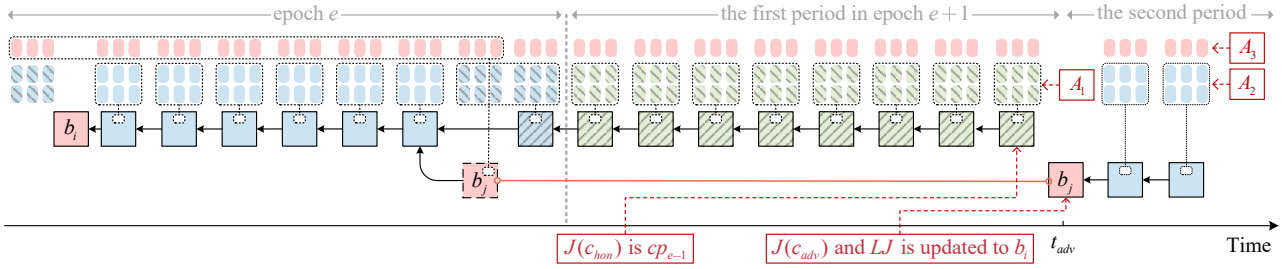
We use c_{adv} to denote the branch withheld by Byzantine validators. In our attack, after c_{adv} is released, *LJ* is updated by all honest validators. Similarly, c_{hon} is the branch seen by honest validators before c_{adv} is released.



The (one-time) attack. To kick-start a staircase attack, Byzantine validators also need to wait for an opportune epoch, the condition of which is exactly the same as our warm-up attack: the proposer v_i of the first slot t in epoch e is Byzantine. Similar to our warm-up attack, we use cp_{e-2} to denote the *LJ* of all validators and cp_{e-1} to denote the checkpoint block proposed in the first slot of epoch $e-1$. The strategies of our staircase attack are summarized below.

(1) (Figure. 7a) In slot t of epoch e, v_i replays the warm-up attack: v_i withholds its block b_i and releases b_i at the end of slot t, after which all honest validators set their checkpoint of epoch e as b_i. In epoch e, the Byzantine validators have two strategies. First, *all* Byzantine validators in epoch e withhold their attestations with cp_{e-1} as *source* and b_i as *target* (i.e., A_3), regardless of which slot each validator is the designated attestor. Second, the *last* Byzantine proposer v_j in slot t_j (all proposers in the rest of epoch e are honest[5]) in epoch e includes the attestations from the Byzantine validators in its block b_j and withholds b_j. Note that not *all* the attestations from Byzantine validators are included in b_j (as according to the protocol, a block in some slot cannot include attestations with a higher slot number). In this case, the attestations not included in b_j can simply be included in blocks proposed in epoch $e+1$ and the corresponding validators will still receive their rewards.
At the end of epoch e, the chain c seen by all honest validators consists of the attestations from all honest attestors from slot $t+1$ to $t+31$ (the last slot in epoch e) where *source* of these attestations is cp_{e-1}. The expected number of attestations on chain c is then $31(N-f)/32$, equal to the number of honest attestors from slot $t+1$ to $t+31$. Note that even if the attestations from honest attestors in slot $t+31$ are received by all honest validators and the proposer of the first block in epoch $e+1$ includes these attestations, the maximum number of attestations with b_i as *target* is still $31(N-f)/32$. Namely, as we assume $f = N/3$, the number of attestations is $\frac{31}{32} \times \frac{2N}{3} < \frac{2N}{3}$, the requirement for validators to update their $J(c)$. Therefore, at the end of epoch e, *LJ* and $J(c)$ of *all* honest validators is cp_{e-1}.

(2) (Figure. 7b) In epoch $e+1$, we divide the epoch into two periods. Let t' be the first slot in epoch $e+1$, i.e., $t' = t+32$. For now, we assume the first period ends at the end of slot $t_{adv}-1$ and discuss the value of t_{adv} later. There are two forks of the chain, branch c_{hon} seen by honest validators and branch c_{adv} withheld by Byzantine validators. The adversary's strategy in the first period is to prepare attestations with b_i as *source* and b_j as *target* and withhold their attestations. The branch c_{hon} thus consists of blocks from honest proposers for slots $[t', t_{adv}-1]$. The attestations included in c_{hon} will all have *source* as cp_{e-1}, and we let the set of attestations be A_1.



(3) (Figure. 7c) At the beginning of slot t_{adv} (i.e., the second period), the adversary releases the withheld chain c_{adv} and our goal here is for all honest validators to update their *LJ* to b_i and make c_{adv} become the canonical chain. Here, we need to dive into the attestations in c_{adv}. According to the discussion in step (1), the branch from b_i to b_j consists

[5] According to the RANDAO protocol, the roles of each validator in epoch e can be predicted before epoch e begins.

(a) Step 1: In epoch e, the first Byzantine proposer v_i replays the warm-up attack. All Byzantine validators withhold their attestations. The last Byzantine proposer v_j includes the attestations from the Byzantine validators in its block b_j and withholds b_j. LJ and $J(c)$ of all honest validators are cp_{e-1}.

(b) Step 2: In the first period of epoch $e+1$ (before slot t_{adv} begins), branch c_{hon} is seen by honest validators and branch c_{adv} is withheld by Byzantine validators. LJ is not updated and is still cp_{e-1} during this period. The attestations A_1 included in c_{hon} have cp_{e-1} as the *source*.

(c) Step 3: At the beginning of slot t_{adv}, Byzantine validators release c_{adv}. As c_{adv} includes a sufficiently large fraction of attestations with *target* as b_i, LJ is updated to b_i. In the second period, c_{hon} is pruned and c_{adv} becomes the canonical chain. Attestations A_1 included in c_{hon} are discarded and the corresponding validators will be penalized.

Figure 7: One-time staircase attack where all Byzantine validators collude. We assume that before epoch e begins, the LJ of all validators is cp_{e-2} and the (checkpoint) block proposed in the first slot of epoch $e-1$ is cp_{e-1}.

of the attestations (with *source* as cp_{e-1} and *target* as b_i) from *all* attestors (Byzantine and honest) between slot t and t_j (the slot of b_j). If the number of the attestations is greater than $2N/3$ (i.e., $V(c_{adv})[b_i] > 2N/3$), all honest validators will set their $J(c_{adv})$ as b_i. Therefore, we know that if $\frac{t_j-t-1}{32} > \frac{2}{3}$, the condition $V(c_{adv})[b_i] > 2N/3$ will be satisfied. We show in Lemma 1 that if the adversary controls $f = N/3$ validators, this happens with a probability of 98.84%.

As $J(c_{adv})$ is updated to b_i after c_{adv} is released, it is not difficult to see that LJ will be updated to b_i in the middle of an epoch! Moreover, as $J(c_{hon})$ is still cp_{e-1} in the second period of epoch $e+1$, the branch c_{hon} (up to b_i) will be pruned and c_{adv} becomes the canonical chain. Any attestations in A_1 will be discarded since the *source* field in A_1 is different from LJ of validators in the second period. Thus, the corresponding attestors will be penalized.

Value of t_{adv} in one-time attack. As discussed in step (1), $J(c_{hon})$ will never be updated to b_i in our attack. Therefore, the branch c_{hon} (up to b_i) will be pruned. To maximize the number of honest attestors that will be penalized (i.e., $|A_1|$), we can set up t_{adv} as large as possible. If t_{adv} is the last slot in epoch $e+1$, almost *all* honest validators will be penalized.

Lemma 1. *Assuming that slot t is the first slot of epoch e and $f = N/3$. Given the last slot t_j of epoch e in which the proposer v_i is Byzantine (all proposers in the rest of epoch e are honest), the probability that $\frac{t_j-t-1}{32} \geq 2/3$ is at least* 98.84%.

Proof. According to the definition, $\frac{t_j-t-1}{32} < 2/3$ happens only if any proposer in slot t_j+1 to slot $t+31$ is honest, i.e., $\lfloor \frac{32}{3} \rfloor = 11$. We now calculate the probability that the proposers in the last 11 slots in epoch e are all honest. As the proposer of each slot is selected pseudorandomly according to RANDAO, the probability of the above situation is:

$$(\frac{N-f}{N})^{11} \approx 1.16\%.$$

The probability that there is at least one Byzantine proposer in one of the last 11 slots is thus:

$$P_{succ} = 1 - (\frac{N-f}{N})^{11} \approx 98.84\%.$$

□

Repeating the attack for *every* epoch. Our attack above can in fact be continued in *every* epoch after $e+1$. This is

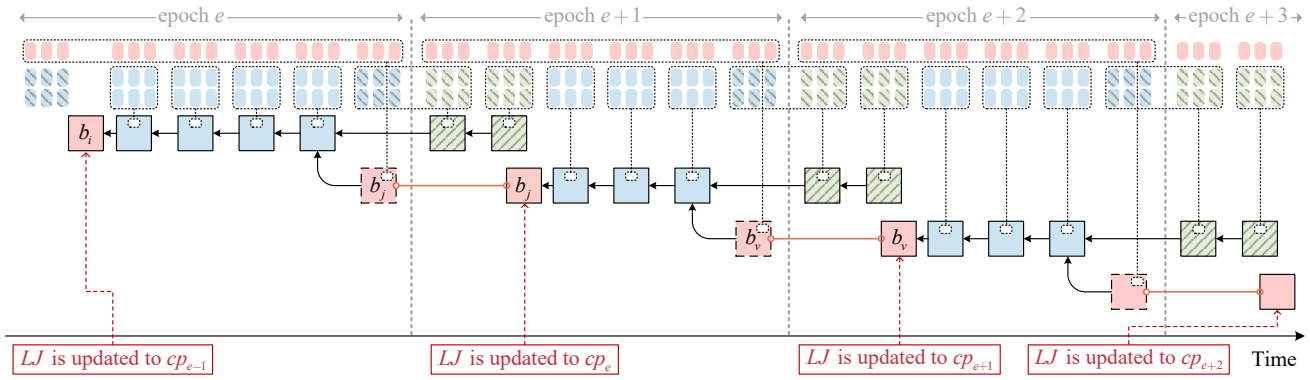


Figure 8: Staircase attack where the attack is repeated in every epoch. The figure is best viewed in color. The green, blue, and red rounded rectangles represent attestations in A_1, A_2, and A_3 respectively.

achieved by simply having the last Byzantine validator in *each* epoch e' withhold its block just as v_j does and then repeat steps (2) and (3) in epoch $e'+1$. For instance, in epoch $e+1$ of the (one-time) attack, the last Byzantine validator v_k in slot t_k starts to withhold its block b_k and all Byzantine attestors in the rest of epoch $e+1$ withhold their attestations. In epoch $e+2$, branch c_{hon}^{e+2} that extends the canonical chain is seen by all honest validators and Byzantine validators withhold a branch c_{adv}^{e+2} led by b_k. After the end of the first period of $e+2$, the withheld branch is released, in the hope that $J(c_{adv}^{e+2})$ and LJ is updated to the first block in epoch $e+1$ (denoted as cp_{e+1}) and $J(c_{hon}^{e+2})$ is still b_i (the first block in epoch e). After LJ of honest validators is updated to cp_{e+1}, c_{hon}^{e+2} will be discarded.

Value of t_{adv} in staircase attack. Notably, same as our one-time attack, only the attestations in A_2 and A_3 can be included in c_{adv}^{e+2}. Therefore, we need to ensure that $J(c_{adv}^{e+2})$ can be updated to cp_{e+1} (and also every epoch after $e+2$). Now it becomes clear why we additionally need to define A_2 and A_3 in addition to A_1. We already know that the set of attestations from Byzantine validators is A_3 and $|A_3| = f < N/3$. To ensure that the branch c_{adv}^{e+2} consists of $2N/3$ attestations, set A_2 must consist of more than $2N/3 - f$ attestations. To satisfy this condition, we can set A_1 to A_3 with roughly the same size and set t_{adv} as the middle of an epoch e', i.e., $t_{adv} = 16 + t'$, where t' is the first slot in e'.

Lemma 2. *In our staircase attack, honest attestors that create attestations in A_1 will be penalized and $|A_1| \leq N/3$, regardless of the fraction of f in N.*

Proof. Let $|A_3|$ be f. $|A_2|$ must be greater than $2N/3 - f$ for the branch by the adversary to become the canonical chain, following the discussion above. Therefore, the size of A_1 must no more than than $N - |A_2 \cup A_3| = N/3$. □

Theorem 1. *According to the configuration in Ethereum where $W_r \leq 27W_p/20$ (see Appendix A for more details), the expected incentive of any honest validators becomes lower than 0 when $f \geq 8N/27 \approx 29.6\%N$.*

Proof. The attestation incentive each validator receives is the difference between the rewards and the penalties. According to our attack, attestors that create attestations in A_2 will receive rewards and attestors that create attestations in A_1 will suffer from penalties. To lower the expected incentives received by honest validators, we can simply let $|A_1| = N/3$ according to Lemma 2. According to our discussion §3.4, to determine the concrete amount, we also need to calculate R, the rewards scale with participation. As attestations in A_2 and A_3 are included in the canonical chain, $R = |A_2 \cup A_3|/N \approx 2/3$. Therefore, the reward received by each honest validator is $R \times W_r I_{base} = \frac{2}{3} W_r I_{base}$ and the penalty of each validator is $W_p I_{base}$. Accordingly, the incentives received by all honest validators are $(\frac{2}{3}|A_2|W_r - |A_1|W_p)I_{base}$. Our goal is to learn the expected incentives received by any honest validator. As the number of honest validators is $|A_1 \cup A_2|$, the expected incentives of each validator becomes:

$$I_{hon} = (\frac{2}{3}|A_2|W_r - |A_1|W_p)\frac{I_{base}}{|A_1 \cup A_2|}.$$

As $|A_1| = N/3$ and $|A_1 \cup A_2| = N - f$, we have:

$$I_{hon} = (\frac{4}{15}N - \frac{9}{10}f)\frac{W_p I_{base}}{N - f} \leq 0.$$

We can simply set $\frac{4}{15}N - \frac{9}{10}f \leq 0$ to satisfy the equation above, so $f \geq 8N/27$. □

On the contrary, Byzantine validators do not suffer from penalties. However, the rewards they receive will be decreased. Following the discussion in Theorem 1, the reward each Byzantine validator receives is $I_{adv} = \frac{2}{3} W_r I_{base}$ in each epoch, about 33% lower than the fair share.

5 Implementation and Evaluation

Implementation. We implement our attack using *Prysm*[6], one of the most widely adopted Ethereum 2.0 beacon chain implementations written in Golang. The Prysm version is in Capella[7], the latest version at the time of writing. We modify the codes in the Prysm as specified in Figure. 9, where changes we make on top of the PoS protocol are highlighted in red and the files we modify are included as comments. Our implementation has exactly the same effect as the attack mentioned in §4.3 while the actual implementation is slightly different. We have made the scripts for our attacks and the logs of our experiments available[8].

The Workflow of a Byzantine Validator v_k

Figure 9: The workflow of a Byzantine validator v_k. The main changes made on top of Figure. 2 are highlighted in red. The source code files we revised are highlighted in gray.

Experiment configuration. We establish a local *testnet* with 1,000 validators connected through a P2P LAN network and vary the fraction of Byzantine validators to understand the impact of our attack. We choose the LAN network as the communication delay is negligible, demonstrating that our attack can be launched even in a fully synchronous network.

We vary the number of Byzantine validators using $f = 296$ (i.e., $f \approx 8N/27$), $f = 310$, $f = 320$, and $f = 333$ and assess the incentives received by the validators. In each experiment, we fix the identities of f Byzantine validators, run our testnet for one day (225 epochs), and collect the attestation incentive of each honest validator from their logs. As a comparison, we also run the testnet for one day without launching the attack and collect the incentives of all validators, the value of which is also known as the *fair share*.

Evaluation results. We evaluate the *incentive loss rate* of honest validators and report the result in Figure. 10. Here, the incentive loss rate is calculated as follows. We first calculate the incentive loss of an honest validator as the difference between its fair share and the incentives it receives during the attack. The incentive loss rate is then calculated as the percentage of incentive loss in the fair share. The incentive loss rate can be interpreted as follows. If the attack is not launched, the incentive loss rate is supposed to be 0%. If the incentive loss rate is close to 100%, *all* honest validators will lose their incentives.

Our results show a notable trend: as the attack is being launched, the incentive loss rate of each honest validator increases significantly and then stabilizes. For $f = 296$, the loss rate eventually stabilizes at 100%, matching our results in Theorem 1. For $f = 310$, $f = 320$, and $f = 333$, the incentive loss rate exceeds 100% and all the honest validators are expected to suffer from stake loss. For instance, when $f = 333$, the incentive loss rate is close to 120%, i.e., honest validators suffer from a 20% stake loss compared to their fair share.

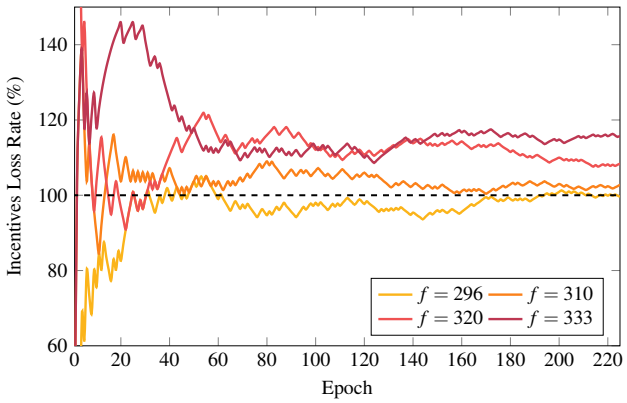

Figure 10: The incentives loss rate of an honest validator for experiments with 1,000 validators and f Byzantine validators. Each experiment is launched for one day (225 epochs).

6 Attack Feasibility and Analysis

In this section, we analyze the feasibility of our attacks in the current Ethereum system considering the production-level implementation details. So far, we have presented three attacks on the incentive mechanism of Ethereum: a warm-up attack where a single Byzantine validator can launch the attack and make some honest validators suffer from penalties; a one-time attack where Byzantine validators collude to make all honest validators suffer from penalties; and the staircase attack where

[6]Prysm: https://github.com/prysmaticlabs/prysm
[7]Capella: https://github.com/ethereum/consensus-specs/tree/dev/specs/capella
[8]Scripts of our attacks and logs of the experiments: https://github.com/tsinghua-cel/Staircase-Attack

Byzantine validators continuously launch the attack in every epoch and all honest validators lose their incentives.

Feasibility of warm-up attack. Recall that in our warm-up attack, the Byzantine validator v_i only needs to delay its block b_i. In practice, the feasibility is related to *honest reorg* currently implemented in Ethereum. *Honest reorg* is a mechanism that prevents intentionally withheld blocks. In particular, a block proposed in slot t with fewer than 20% attestations from attestors in slot t is considered invalid. If v_i releases its block at the end of slot t, the block will be re-organized and our warm-up attack may fail. To prevent b_i from being considered invalid due to honest reorg, v_i can carefully release a block *late* enough to ensure that at least 20% attestors (but not all) receive b_i. In this way, the warm-up attack can still succeed and around 80% honest attestors in the slot will be penalized (i.e., approximately $(N-f)/40$). Note that in practice, the concrete release time is highly related to the actual network condition in the Ethereum network. We leave the analysis as future work.

Feasibility of one-time attack and staircase attack. We have validated the feasibility of our attacks in the current Ethereum system beyond 1,000 validators. Indeed, Ethereum has more than 900,000 validators as of today[9], we thus analyze whether our attacks can be launched in such a large-scale system. Our analysis reveals a somewhat surprising result: the feasibility of the attacks is directly related to the number of validators and the maximum number of attestations in each block (i.e., MAX_ATTESTATIONS in Ethereum (MaxAtt for short)).

Ethereum currently employs a committee-based scheme to aggregate the attestations using the BLS signature [7]. Recall that every slot has $N/32$ validators randomly selected by RANDAO. The validators in each slot are further divided into several committees [44]. In every slot, matching attestations (same *target*, *source*, and *head*) in the same committee are aggregated into one aggregated attestation. We use N_c to denote the number of committees in each epoch and N_a to represent the number of aggregated signatures in every block.

In the most recent configuration of Ethereum, N_a is limited by MaxAtt [44]. The value of N_c is determined as follows (also as shown in Figure. 11), where MaxCom is the maximum number of committees in a slot (the actual parameter name is MAX_COMMITTEES_PER_SLOT [44]):

$$N_c = \begin{cases} N/128, & \text{if } N \leq 4096 \times \mathsf{MaxCom}; \\ 32 \times \mathsf{MaxCom}, & \text{otherwise.} \end{cases} \quad (1)$$

Currently, the parameter MaxAtt is 128 and the parameter MaxCom is 64. Thus we have $N_a = \mathsf{MaxAtt} = 128$, $N_c = 32 \times \mathsf{MaxCom} = 2048$, and $N_c = 16N_a$.

Lemma 3. *To launch staircase attack, $N_a \geq N_c$.*

[9]Data source (accessed in Feb 2024): https://www.beaconcha.in/charts/validators

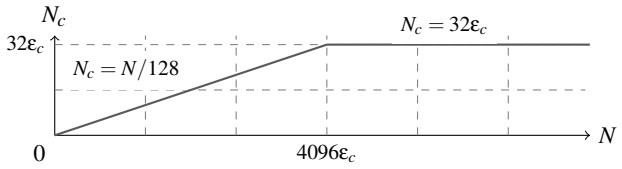

Figure 11: The value of N_c as N grows. We use ε_c to denote MaxCom.

Proof. In our staircase attack, the block proposed by the last Byzantine validator in an epoch includes attestations from all Byzantine validators. Therefore, N_a is no less than the number of aggregated attestations from Byzantine validators.

According to the RANDAO protocol, Byzantine attestors are randomly distributed among N_c committees. Since attestations across committees cannot be aggregated, the number of aggregated attestations from Byzantine validators is no less than N_c, i.e., $N_a \geq N_c$. □

Based on Lemma 3, we now analyze the impacts of system parameters and the number of validators to our attack. We also provide a modified attack to make our attack feasible in today's Ethereum system.

Impacts of the maximum number of attestations to our attack. To satisfy the condition $N_a \geq N_c$ specified in Lemma 3, we need either a larger N_a or a smaller N_c. We have the following observations:

- If the MaxAtt parameter increases from 128 to 2,048, a block can include aggregated attestations from *all* Byzantine validators. This is mainly because $N_c = 16N_a$ in the current system, and a 16-fold increase in MaxAtt would make $N_a = N_c$. Alternatively, we can also set MaxCom to MaxCom/16 to achieve the same result (as N_c depends on MaxCom), i.e., by decreasing MaxCom from 64 to 4.
- There are many alternative ways for $N_a = N_c$ to be satisfied. For instance, if the parameter MaxAtt increases from 128 to 512 and the parameter MaxCom decreases from 64 to 16, the condition $N_a \geq N_c$ is also satisfied.

Such a counter-intuitive finding shows that the values of system parameters such as MaxAtt and MaxCom are not an easy engineering decision and should be set up carefully.

Impacts of the number of the number of validators to our attack. If we fix the MaxAtt and MaxCom parameters, our attack can be launched with fewer than 16,384 validators. This is because when we fix the value of parameters, we need to set $N_c \leq N_a = 128$ according to Lemma 3. According to equation (1), setting N_c as $32 \times \mathsf{MaxCom}$ will never make $N_c \leq 128$. As a result, we can set $N_c = N/128$ for $N_c \leq N_a = 128$ to hold. Accordingly,

$$N \leq 128 \times 128 = 16384.$$

Namely, if we do not change the system parameters, Ethereum

becomes vulnerable to our attack when the number of validators is below 16,384.

A modified attack on the current system. We can modify our attack to be feasible in the current Ethereum system. The main reason why our attack might fail in the current system is that a block cannot include attestations from all Byzantine validators. Indeed, based on the current system parameters, a block can include attestations from 128 committees (i.e., MaxAtt =128), and there are 64 committees (i.e., MaxCom =64) in each slot. Since the Byzantine attestors are distributed in every committee and attestations across committees cannot be aggregated, a block can include attestations of Byzantine attestors from at most two slots. Our modified attack thus requires more Byzantine validators to release the withheld attestations. In particular, the attestations from Byzantine validators in the first 28 slots are directly sent to all validators in the system. Only the attestations from Byzantine validators in the last four slots are withheld. Among them, attestations in two slots are included in the block proposed by the last Byzantine proposer. Therefore, we require the slot of the last Byzantine proposer to be one of the last four slots. Under the assumption of $f = 0.33N$, the probability of repeating the attack is:

$$P_{succ} = 1 - \left(\frac{N-f}{N}\right)^4 \approx 80.25\%.$$

We provide the details of the modified attack in Appendix B. If the attack cannot be repeated in the next epoch, the adversary can wait for another opportune epoch to restart the attack. Recall that our attack can be started if the proposer of the first slot of an epoch is Byzantine. The probability of starting an attack is thus 33%.

Combining the discussion above, we show the attestation incentives of honest validators in Theorem 2 in Appendix B. Specifically, if the adversary controls 33% of the total stake, the attestation incentives of an honest validator become only 28.9% of the fair share.

7 Discussion

Mitigation. We show two possible solutions as mitigation of the attack. One solution is to modify the tree pruning rules in HLMD GHOST. In the current fork choice rule (see §3.2), the branch that does not include the latest justification information will be pruned. Our attack takes advantage of this to force honest validators to be penalized. Relaxing the pruning rules and still keeping the honest branch in the HLMD GHOST tree can mitigate our attack. Alternatively, adjusting the concrete amount of rewards and penalties can also mitigate our attack. Currently, the amount of penalties and rewards are almost identical. If the penalties in the attestation incentive mechanism are lowered, our attack can be mitigated accordingly.

Note that Ethereum is taking the first approach as mentioned in our responsible disclosure. In particular, chain c will not be pruned if the difference between $\mathsf{ep}(J(c))$ and the current epoch is no more than two epochs. This solution can mitigate our attack but cannot fully prevent our staircase attack from happening. In particular, the Byzantine validators can delay the attestations for a longer period of time and the honest chain will still be pruned.

Situations observed in practice. Situations similar to our warm-up attack are in fact quite common in practice. According to beaconcha.in, at least one validator in each epoch is penalized because of *incorrect* attestations. Such events are often caused by natural network delay such that honest attestors do not receive the first block in an epoch before sending their attestations.

Extension of our attack. As mentioned in §2, our staircase attack is one kind of reorg attack. Although we focus on attestation incentives in this paper, our attack can be extended to cause other effects, given its nature as a reorg attack. For example, the adversary can manipulate the order of the transactions and obtain more MEV (Maximal Extractable Value) [14]. Besides, strategically choosing the parent block for the withheld blocks allows the adversary to reorg more blocks from the honest validators. This may lower the chain quality and pose a liveness threat to the system.

Future directions. Our counter-intuitive finding about MAX_ATTESTATIONS parameter setting may lead to future research directions. Indeed, having a larger MAX_ATTESTATIONS will enhance the performance of the system as more attestations are aggregated. In fact, the parameter is even related to the liveness of the system. However, our attack shows that a larger MAX_ATTESTATIONS might make honest validators suffer from higher incentive loss. Therefore, it is interesting to learn whether there exists some sweet spot for the MAX_ATTESTATIONS parameter and how the MAX_ATTESTATIONS, N, and the incentives are correlated. Furthermore, it would be useful to consider security properties related to incentives when designing consensus protocols.

8 Conclusion

We present staircase attack, the first attack on the incentive mechanism of the Ethereum Proof-of-Stake (PoS) protocol. Without considering the constraints of system parameters such as the number of validators, we show that an adversary that controls 29.6% stake can launch the attack and eventually *all* honest validators lose their attestation incentives. As the fraction of stake controlled by the adversary increases, honest validators may even suffer from stake loss. Moreover, considering the values of system parameters, the feasibility of our attack is closely related to two parameters: the number of validators and MAX_ATTESTATIONS, the maximum number of attestations included in each block. With the current Ethereum

setup (900,000 validators and MAX_ATTESTATIONS =128), we show that an adversary that controls 33% stake can make honest validators suffer from no incentives with a probability of 80.25%. Our attack shows that in addition to the safety and liveness properties considered in conventional consensus protocols, properties regarding the incentives might also be worth investigating in today's blockchain systems.

A Rewards and Penalties in Ethereum

In this section, we provide more details on attestation rewards and penalties [44]. The reward weight of a validator W_r is set to 54 if the corresponding attestation is finalized on-chain and the *head* field in the attestation is correct (i.e., the block matches the head of the canonical chain). If the attestation is finalized on-chain but the *head* in the attestation is incorrect, the reward weight W_r is set to 40. Finally, if the corresponding attestation is not finalized on-chain[10], the penalty weight of a validator W_p is set to 40.

As mentioned in §4, the attestations in A_2 are finalized on-chain, so the reward weights of the corresponding attestors W_r are at most 54. Meanwhile, the attestations in A_1 are discarded, so the penalty weight of the corresponding attestors W_p is 40. Thus, we have $W_r \leq 27W_p/20$.

B Modified Staircase Attack

In this section, we show the modified staircase attack. The modified attack can be launched based on the latest system configuration of Ethereum. We show the workflow of the modified attack in Figure. 12. Compared to the attack presented in §4.3, we make three major changes. First, as shown in Figure. 13, there are now three statuses for each Byzantine validator: idle, repeat, and stop. The status is *idle* if the attack is not being launched. The status is *repeat* if the attack is being launched and can be repeated to the next epoch. The status is *stop* if the attack cannot be repeated and will be stopped at the end of the epoch. Here, the last epoch of the attack becomes similar to that in our one-time staircase attack. Second, the attestations from Byzantine validators in the first

37         send att to all validators
37       else
38         send att to the last Byzantine proposer in I
39   if t is the last slot in epoch e then
40     status_cr ← status_nxt
41 function judge(epoch e)
42   obtain a set I of Byzantine proposers in epoch e
43   if there is a Byzantine proposer in the last four slots then
44     return 1
45   return 0
```

Figure 12: The workflow of a Byzantine validator v_k.

28 slots are not withheld. Instead, they are directly sent to all validators in the system. The attestations from the Byzantine attestors in the last four slots are sent to the last Byzantine proposer v_j. Third, to continuously launch the attack, slot t_{adv} (when the last Byzantine proposer v_j releases the block b_j) is not set to the middle of an epoch. Instead, it is set to the beginning of the 14-th slot of an epoch.

We also introduce a function called *judge* (lines 41-45). Briefly speaking, given an epoch e, the *judge* function returns 1 if the attack can be repeated in the next epoch and 0 otherwise.

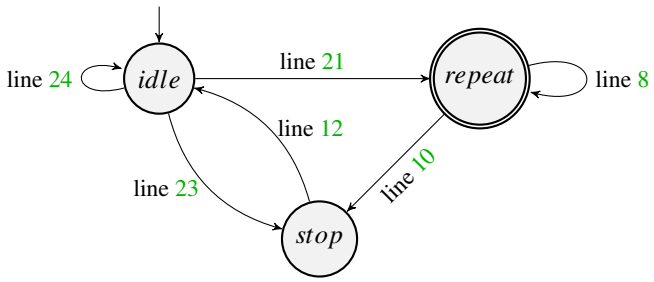

Figure 13: The status of the attack. Line numbers refer to those in Figure. 12.

Lemma 4. *In the modified attack, the number of attestations included in the canonical chain can not exceed* $2N/3$ *at the end of an epoch.*

Proof. After the attack is launched, none of the honest validators update their *LJ* before the last Byzantine validator releases the withheld block. If the status is *repeat*, the attestations from the honest validators in the first 13 slots are discarded and attestations from the honest validators in the last slot are not included. On the contrary, Byzantine validators use the new *LJ* as *source* of their attestation. Therefore, the number of attestations included in the canonical chain is smaller than $18(N-f)/32+28(N-f)/32 = 2N/3$. For the *stop* status, the proof is conducted in the same manner. After the warm-up attack is launched, none of the honest validators update their *LJ* before the 28-th slot. On the contrary, Byzantine validators use the new *LJ* as *source* of their attestation. Thus, the number of attestations is lower than $2N/3$ and the checkpoint is not set correctly. □

Lemma 5. *If the adversary controls 33% of the total stake and the attack is being launched, all honest validators lose their incentives or even suffer from stake loss.*

Proof. We consider the attestations from honest validators in epoch e while the attack is being launched. The attestations from honest validators in the first period of epoch e are included in the branch c^e_{hon}. The attestations from honest validators in the last four slots are included in the branch c^{e+1}_{hon}. The rest attestations from honest validators are included in the branch c^e_{adv} and c^{e+1}_{adv}. We thus consider the following three cases.

(1) The branch c^e_{hon} in the first 13 slots is pruned in epoch e. Attestations from the honest attestations in the first 13 slots are thus discarded.

(2) The branch c^{e+1}_{hon} in the last four slots is pruned in epoch $e+1$. Block b_j can include attestations with a number roughly equal to the number of attestations in most two slots. Therefore, the attestations from honest attestations in the last two slots are discarded.

(3) The branches c^e_{adv} and c^{e+1}_{adv} are not pruned, and the attestations from the honest validators in c^e_{adv} and c^{e+1}_{adv} are finalized on-chain.

Thus, the fraction of discarded attestations from honest validators in total attestations is $R_{hon} = (13+2)/32$. The expected incentives of an honest validator is then I_{hon} is

$$(((1-R_{hon})\frac{N-f}{N}+\frac{f}{N})(1-R_{hon})W_r - R_{hon}W_p)\times I_{base}.$$

Let $f = 0.33N$ and $W_r = 27W_p/20$, we have the incentive $I_{hon} \approx -0.0382 \times W_r I_{base} < 0$, where $W_r I_{base}$ is the fair share of an honest validator. □

Theorem 2. *If the adversary controls 33% of the total stake, our modified attack makes the incentives of an honest validator decrease to 28.9% of its fair share.*

Proof. The incentive of an honest validator in each epoch can be modeled as a discrete-time Markov chain. In particular, there are three states of the attack: the *idle* status (staircase attack is not launched), the *repeat* status (staircase attack is launched and being repeated in every epoch), and the *stop* state (staircase attack can not be repeated and conduct a one-time attack to penalize all honest validators). In each state, the incentives of honest validators are $W_r I_{base}$, I_{hon}, and $-W_p I_{base}$, respectively. Meanwhile, the transition matrix is shown as follows:

$$\mathbf{P} = \begin{pmatrix} 2/3 & P_{succ}/3 & (1-P_{succ})/3 \\ 0 & P_{succ} & 1-P_{succ} \\ 1 & 0 & 0 \end{pmatrix}.$$

By applying the matrix to a n-epoch transition, we have matrix $\mathbf{P^{(n)}} = \mathbf{P^n}$. The $\mathbf{P^{(n)}}$ becomes stable after $n = 27$, we have

$$\mathbf{P^{(n)}} \approx \begin{pmatrix} 0.372 & 0.504 & 0.124 \\ 0.372 & 0.504 & 0.124 \\ 0.372 & 0.504 & 0.124 \end{pmatrix},$$

for $n \geq 27$. Thus, the incentive of an honest validator is equal to any entry in the matrix $\mathbf{P^{(n)}}$ multiplied by $(W_r I_{base}, I_{hon}, -W_p I_{base})^{\mathrm{T}}$, which is approximately $0.289 \times W_r I_{base}$.

Fan Zhang
Yale University

Abstract

Cryptocurrencies and decentralized platforms have been rapidly gaining traction since Nakamoto's discovery of Bitcoin's blockchain protocol. Prominent systems use Proof of Work (PoW) to achieve unprecedented security for digital assets. However, the significant carbon footprint due to the manufacturing and operation of PoW mining hardware is leading policymakers to consider stark measures against them and various systems to explore alternatives. But these alternatives imply stepping away from key security aspects of PoW.

We present Sprints, a blockchain protocol that achieves almost the same security guarantees as PoW blockchains, but with an order-of-magnitude lower carbon footprint while increasing the number of mining rigs by a factor 1.27x. Our conservative estimate of environmental footprint uses common metrics, taking into account both power and hardware. To achieve this reduction, Sprints forces miners to mine intermittently. It interleaves Proof of Delay (PoD, e.g., using a Verifiable Delay Function) and PoW, where only the latter bears a significant resource expenditure. We prove that in Sprints the attacker's success probability is the same as that of legacy PoW. To evaluate practical performance, we analyze the effect of shortened PoW duration, showing a minor reduction in resilience (49% instead of 50%). We confirm the results with a full implementation using 100 patched Bitcoin clients in an emulated network.

1 Introduction

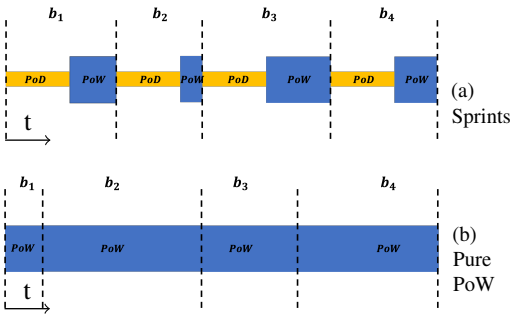
Proof of Work (PoW) cryptocurrencies offer a decentralized form of money, with monetary policy dictated by code. Participants can acquire coins and perform transactions without needing permission from other parties or centralized exchanges. PoW cryptocurrencies, starting with Nakamoto's Bitcoin [1], have gained significant success with market capitalization in the hundreds of billions [2] and attract the attention of major financial institutions [3, 4]. But PoW cryptocurrencies consume significant resources, with Bitcoin's electricity consumption surpassing Argentina's in 2022 [5]. Environmental concerns are leading to policy changes, including bans [6, 7]. Nevertheless, the stable valuation of the PoW Bitcoin, despite the proliferation of non-PoW alternatives, demonstrates the demand for PoW guarantees. It implies the need for a protocol that provides such guarantees with lower carbon footprint.

Indeed, both theoretical work and operational systems address this issue. Previous work (§2), showed [8] that resource expenditure cannot be reduced by tuning the protocol parameters. Proof of Storage [9] requires participants to dedicate storage resources instead of computation but is about 50% cheaper to attack [10]. Proof of Stake (PoS) protocols (e.g., [11–16]) take a different approach: Instead of physical resource expenditure, PoS uses on-chain deposits, thus the likelihood of a miner being able to create a new block and add it to the blockchain is determined by the amount of cryptocurrency they have *staked*, i.e., held in their account. With this approach, no physical resource is expended. But PoS protocols require stronger assumptions, such as long-term connectivity and availability [17–19].

***Sprints*.** We introduce *Sprints* (§4), a blockchain protocol that maintains the advantages of PoW but with significantly lower resource consumption. The key idea is to force miners to perform PoW intermittently, i.e., to insert periods of time during which miners pause mining. Like Bitcoin, *Sprints* miners collect transactions (e.g., payment orders) from users and batch them into *blocks* that they broadcast. Each block contains a hash reference to its predecessor, so the blocks together form a tree with an agreed-upon root. The system state is thus obtained by processing the transactions in the longest path in the tree, called the *longest chain*.

In addition to PoW — statistical proofs that the miner expended computational effort, *Sprints* also requires PoD, proving the miner waited for a certain time before the PoW computation. Unlike PoW, PoD computation does not require significant computational resources. Thus, a miner alternates between producing PoD with nominal power expenditure and PoW with high power expenditure – Figure 1 illustrates this process. The PoD primitive shares similarities with a Verifiable Delay Function (VDF) [20–24]. The distinction lies in the uniform delay period enforced across all miners, a feature not

generally guaranteed by VDFs. Uniform delay periods are crucial for the protocol's security (§6.5), while a perfect PoD architecture is currently theoretical, near-ideal PoD solutions are attainable with a reliable hardware setup assumption [25, 26].



Like PoW systems where participation is profitable only for miners with efficient hardware [27–29], *Sprints* is profitable only for miners with efficient PoD hardware. We thus assume all miners have similar, efficient, PoD hardware; others with weaker hardware would not participate.

Security. At first glance, it might seem that an attacker has an advantage compared to a *pure PoW* system like Bitcoin: She does not have to stop calculating PoW while performing the PoD calculation, whereas honest miners will. We prove (§5) that such behavior specifically is futile, and that in general there is no sacrifice of security compared to a pure PoW system. Due to the distinct characteristics of *Sprints*, previous proof techniques [10, 30, 31] are not applicable. Specifically, the PoD puzzle delay eliminates the memorylessness of pure PoW systems and prevents the use of the common Markov chain analysis. Consequently, we are compelled to devise a novel proof approach.

The key step is showing that in a race where the attacker competes with the honest miners, the attacker has to solve PoW and PoD puzzles sequentially, thus, parallel mining would not benefit her. Intuitively, the only race between the honest chain and that of the attacker is the PoW puzzles, as both spend the same amount of time-solving PoD puzzles for the same number of blocks. The implication is that the attacker's probability of winning the race is the same as in a pure PoW blockchain. We use this result to show that if we consider a race where the honest miners and the adversary are building two chains that extend the same block and the adversary controls less than half of the PoW computational power, then her probability of building a chain that is at least r blocks deep and is longer than the honest chain is bounded by $2^{-\Omega(r)}$. Finally, we utilize this result to show that if the propagation delay is negligible, *Sprints* provides the same guarantees as pure PoW.

Implementation and evaluation. If we compare Sprints to a pure PoW system with the same block interval, since part of the block generation is computing PoD, PoW duration in Sprints is shorter. Our theoretical analysis shows that with shorter PoW average duration it is more likely for honest miners to generate blocks with the same parent, forming *forks*. The implication is that the longest chain extension is slower and the threshold attacker size is smaller.

Figure 1: Pure PoW and *Sprints* over time.

To confirm this analysis, we implemented *Sprints* by patching the standard Bitcoin client [32] and measured the frequency of forks as a function of both the network propagation delay and the PoW duration. With system parameters similar to those of the operational Bitcoin system [33], when using only 5% of block interval for PoW, the threshold attacker size is 49%, compared to Bitcoin's 50%.

Implementing *Sprints* involves addressing several practical challenges (§6). To address spam prevention while maintaining efficient propagation, we lazily validate PoDs, i.e. nodes do not wait for the PoD validation to complete before propagating the block, allowing for the same propagation delay as a pure PoW system without sacrificing spam prevention [34]. Additionally, we adjust the difficulty of both PoW and PoD to maintain constant block intervals as hardware for PoW and PoD improves. We do this by estimating parameters using the second moments of the interval probability distribution.

Enviromental footprint. The analysis *Sprints*'s enviromental footprint (§7) is more involved than comparing the ratio of PoW per block. We show that *Sprints* miners use their budget to purchase more mining equipment compared to pure PoW, for the short duration where they PoW-mine. In other words, *Sprints* shifts a portion of the *operating expenses* (*OPEX*) to *capital expenditure* (*CAPEX*), which we show to have a lower carbon footprint by comparing the emissions from the hardware lifecycle to the emissions from electricity consumption. On the other hand, the increase in the number of mining rigs implies a potential increase in rare metal depletion. While raw materials like rare-earth have an environmental impact (e.g., they are difficult to recycle), we show that the increase is significantly smaller than the factor by which the carbon footprint decreases. We use the CO2e (carbon dioxide equivalent) metric [35] to compare systems, which allows us to quantify the emissions resulting from electricity consumption and the hardware lifecycle (manufacturing, transportation, and disposal). Importantly, the assumptions made in our analysis err on the side of conservatism, suggesting that the actual reduction in carbon footprint could be greater than our estimates indicate.

Combining the security and emission analyses, Figure 2 shows how the attack threshold and emission reduction ratio change with the PoW time ratio when using Bitcoin-like parameters (100ms network delay, 600s block interval [33]). At 5% of the block interval the CO2e is 9.2% that of Bitcoin. At the same time, the total number of mining rigs in *Sprints* increases by 27%, implying an increase in rare metal depletion by a factor of 1.27.

In summary, our main contributions are:

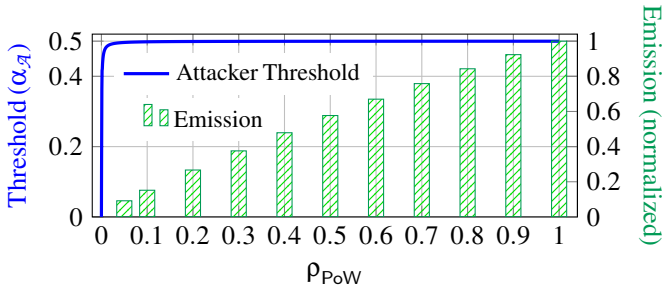


Figure 2: Attack threshold and normalized emission under as a function of portion of PoW time out of block interval

- *Sprints*, a novel blockchain protocol that introduces intermittent mining, alternating between PoD and PoW;
- proof that the security threshold is the same as in PoW;
- tuning of both PoD and PoW based on block interval;
- evaluation with full implementation over an emulated network demonstrating effective difficulty adjustment and close-to-optimal (49%) attack threshold values; and
- carbon footprint analysis showing over 10x CO2e reduction.

2 Related Work

We review energy-efficient alternatives to PoW and their trade-offs.

The most well-established energy-efficient alternative to PoW is Proof of Stake (PoS) [11–16]. Instead of solving hash puzzles, PoS miners participate in a mining lottery with a winning probability proportional to their token holding in the system. However, these protocols require stronger assumptions than PoW protocols regarding network connectivity, validator behavior, or the availability of a randomness oracle [17–19]. Additionally, in PoS protocols new nodes need cooperation from existing nodes to join the network [36], in contrast to *Sprints*, where new nodes can join the network by mining blocks using external computations.

Several protocols take advantage of Verifiable Delay Functions (VDFs). Verifiable Delay Functions (VDFs) [20–24] are a class of functions that cannot be accelerated by a parallel computation and can be verified efficiently. Long and Wei [37] propose a PoS protocol that incorporates a variation of Verifiable Delay Functions (VDFs) that has a random delay. However, the threshold for a successful private attack is less than 27% compared to almost 50% in *Sprints*. PoSAT [38] has a similar construction. PoSAT is vulnerable to nothing-at-stake attacks, where an attacker can mine on multiple forks for no additional cost. The authors, therefore, divide the rounds into epochs which prevents new players from joining the network during an epoch. The system has a threshold of 50% for a private attack only when the epochs are infinitely long, which turns it into a permissioned system. Thus, PoSAT has a tradeoff between decentralization and security.

HEB [39] also utilizes on-chain resources uses mechanism design to reduce electricity consumption by 50%, but reduces resilience to malicious attacks by 2, while *Sprints* has almost the same threshold as pure PoW with an 8x reduction in electricity consumption.

Several approaches reduce expenditure with particular types of PoW. REM [40] and PoET [41] use trusted hardware to reduce resource expenditure. As the protocols are based on trusted hardware, they rely on a trusted party to guarantee the hardware's integrity. *Sprints* makes no such assumptions.

Chia [9] shifts the costs of miners from electricity to hardware by combining Proof-of-Space (PoS) and Proof-of-Time (PoT). It reduces electricity consumption by replacing much of the mining costs with storage costs. However, it is resilient to attackers with under 30% of the network storage resources [10], which is significantly lower than the almost 50% threshold of *Sprints*.

Another approach to deal with this challenge is to use permissioned protocols [42–44], which are a class of protocols that require pre-authorization of nodes to participate in the protocol. However, permissioned protocols are not decentralized and require a trusted third party to authorize new nodes.

As for the analysis of PoW protocols, Dembo et al. [10] analyze the security of blockchain systems by showing that a so-called *private attack* is the worst-case attack. They define the notion of Nakamoto blocks and use their existence to prove that the system is secure. We use a different approach, where we avoid the notion of Nakamoto blocks and instead describe a single race between the attacker and the honest miners. We use this race to prove directly that the security requirements hold.

3 Model

The system consists of a set of participants called *miners*. Each miner maintains a tree data structure whose vertices are called *blocks*. Each block contains *transactions*, commands issued by system users, which are the *payload* of the block. All miners start with the same block, called *genesis*, that serves as the root of the tree. In addition to the payload, each block contains metadata. The metadata of all blocks (except the genesis block) includes a hash that points to its *parent* block; we say that a block *extends* the pointed-to block. A path with the most blocks in the tree is called a *longest chain*. There may be several longest chains and one of them, chosen by a deterministic arbitrary algorithm, is called the *main chain*. The *height*[1] of a block b is the number of blocks in the path from the genesis to b.

Time progresses in discrete steps $t = 0,1,\ldots$ (as in, e.g., [45]). In each step, miners can *work* on two types of *puzzles*. The first type is *Proof-of-Delay (PoD)*, a function that maps an arbitrarily sized input and difficulty parameter to a small

[1] Called depth in graph-theory literature.

output. Given a random input, a PoD requires a deterministic number of steps, called *delay period* and denoted by Δ_{PoD}. In each step, a miner can choose to mine on multiple PoD puzzles. After working on a particular PoD puzzle in Δ_{PoD} distinct steps, a miner has its solution, which cannot be guessed except with negligible probability. The formal specification of a PoD is the same as that of a VDF [20] with the added requirement that all the players have the same delay period. This assumption is reasonable since miners who cannot solve the PoD puzzle in the given delay period will not be able to compete in the protocol, and thus will be forced to leave the system.

The second puzzle type is *Proof-of-Work*, a probabilistic puzzle that has an independent probability of being solved in any given step. In each step, a miner can choose to mine on a PoW puzzle. Miner p has a probability $P_w(p)$ of solving it in each step independent of previous attempts. The number of steps until success thus has a Geometric distribution with parameter $P_w(p)$.

Combining metadata M, payload D and puzzle solutions Z, a block is the tuple (M,D,Z).

The miners communicate over a Δ-synchronous broadcast network [10, 30]: If a miner sends a message in step t, then all miners receive it by step $t+\Delta$. We assume that $\Delta < \Delta_{PoD}$.

Thus, at the beginning of every step, a miner receives messages sent in previous steps. The miner can then perform local computations, i.e., work on one PoW and multiple[2] puzzles. Then the environment notifies the miners if they found solutions. Finally, the miner can broadcast blocks.

There are a total of $n+1$ miners in the system, where n are *honest*, i.e., miners that follow a predefined protocol, and a single miner is controlled by an *adversary* $\mathcal{A}$ and acts arbitrarily.

Note that the adversary can only work on a single PoW puzzle in a single step in our model. However, working on multiple PoW puzzles in parallel can be approximated by frequent puzzle changes.

The adversary controls the message delay, constrained by the bound Δ.

Next, we define a predicate that validates the correctness of a block and its puzzles. A *validity function* $V(b)$ returns *true* if some predefined conditions on the block contents are met and *false* otherwise. A block b is *valid* if $V(b) = true$. Invalid blocks with either invalid payloads or proofs are simply ignored.

An *execution* is a series of states of the system that develops based on the miners' algorithms and the environment's coin flips, i.e., the outcome of PoW puzzle-solving attempts. Each execution has a certain probability of occurring. Let Σ denote the set of all executions. Given step t_0, denote by π the t_0-*prefix* that is the collection of all executions in Σ that agree on the state of the system at step t_0. Given an execution σ, denote by $\mathcal{T}^\sigma(t)$ the tree that corresponds to the execution in step t, called a *mother tree* [10]. The mother tree consists of all valid blocks in the system (published or not) until step t. Note that $\mathcal{T}^\sigma(t)$ represents the state of the tree at the beginning of the step. Denote the depth of a valid block b by $d(b)$. Given a execution σ, denote the depth of the longest chain(s) in $\mathcal{T}^\sigma(t)$ by $d^\sigma(t)$. Each player p has a local copy of the mother tree, which is updated according to the blocks she receives, it is denoted by $\mathcal{T}_p^\sigma(t)$.

Given an execution σ, the execution view of miner p is denoted by σ_p. It includes all the information she received and the results of her local computations.

In each step, each honest miner performs an *action* that comprises the mining target for PoW and PoD and the blocks a miner publishes. The action is defined by the *mining function* $q(\sigma_p)$, given a view σ_p of miner p. The vector $Q_H^\sigma(t)$ includes the honest miners' actions in step t defined by the mining function. We denote by $Q_{\mathcal{A}}^\sigma(t)$ the action of the adversary at step t and execution σ. The adversarial action is decided based on a predefined *strategy* A, which is a map from step t and a state of execution at step $t-1$ to a vector that represents the mining targets for PoW and PoD, the blocks being published and the delay the adversary imposes on messages.

A longest chain protocol is thus defined by a validity function and a mining function, $(V(\cdot),q(\cdot))$. For each node, the sequence of payloads along the main chain, excluding the payloads of the last r blocks (for some r), is called a *ledger*. We use the notions of *persistence* and *progress*[3], similar to the definitions in previous work [10, 30, 31]. Given a block b, we denote by $d_b^\sigma(t,p)$ the depth of the longest chain in the view of miner p in step t that contains b and by $d_{\neg b}^\sigma(t,p)$ the depth of the longest chain in the view of miner p in step t that does not contain b.

Definition 1. *A protocol $(V(\cdot),q(\cdot))$ implements a ledger if it satisfies the following two conditions:*

Persistence *Given $\varepsilon > 0$ and step t_f, there exists $r \in \mathbb{N}$ such that for all adversarial strategy A given a randomly drawn execution $\sigma \leftarrow \Sigma_A$, for every step $t \le t_f$ and every block $b \in \sigma$, if b is at depth i of the main chain and $d_b^\sigma(t-\Delta,p) > d_{\neg b}^\sigma(t-\Delta,p)+r$ for an honest miner p, then for every $t' > t$ it holds that b is in depth i in the main chain of the view of all other honest miners with probability at least $1-\varepsilon$.*

Progress[3] *Given $\varepsilon > 0$ and t_f, there exists $\delta \in \mathbb{N}$, s.t. for all steps $t_0 \le t_f$ and adversarial strategy A the probability that a random execution $\sigma \in \Sigma_A$ does not include a block that was mined in $[t_0,t_0+\delta]$ in the main chain of all honest miners for some step $t' > t_0+\delta$ is smaller than ε.*

4 *Sprints*

We now present the *Sprints* protocol, which implements a ledger, by defining a mining function $q(\sigma_p)$ for a player p and a validity function $V(b)$.

A valid block in *Sprints* contains two puzzle solutions: a proof of delay b^{PoD} that enforces serial computation, and a

[2] The number of puzzles is polynomial in a system security parameter; we omit these details to simplify the presentation.

[3] Our Progress is called Liveness in some prior work [10, 30, 31] although it is a safety property [46].

proof of work b^{PoW}. The mining function chooses the deepest block, partial or full, in the view of the miner and returns the puzzle required. If the deepest block is a full block, then the mining function works on the PoD of the next block, as follows: Given a metadata M that contains the previous block's hash, the mining function returns the action to take a step in the PoD puzzle of M. If the deepest block is partial, i.e., the PoD puzzle of the new block was already solved, then the mining function works on the PoW puzzle, as follows: Given the PoD puzzle solution of the metadata, b^{PoD}, and the payload of the new block, D, the mining function returns the action to take a step in the PoW puzzle of $b^{PoD}||D$. If the PoW step is successful and the miner obtains a solution b^{PoW}, then the miner publishes the new block: $b = (M, D, (b^{PoD}, b^{PoW}))$.

The validity function $V(b)$ validates a block b by checking that the PoD and PoW puzzles are valid, using the validity functions $V_{PoD}(\cdot)$ and $V_{PoW}(\cdot)$, respectively:

$$V(b) := V_{PoD}(b^{PoD}, M) \wedge V_{PoW}(b^{PoW}, b^{PoD}||D).$$

Note that the PoD does not require the payload of the block, while the PoW requires the payload of the block.

If a node learns of a chain longer than the block it is currently working on, it discards its work and begins generating a block extending the new chain.

The pseudocode of the protocol is in the full version of this paper [47].

5 Security

We prove that *Sprints* achieves both persistence and progress. To do so, we tackle two main challenges:

1. **Persistence:** we aim to prove that a block in the main chain will almost surely stay there. We assess the risk of an attacker removing a block by breaking the problem into smaller "mini-games," each focused on a block at a specific depth. We then sum up the probabilities of the attacker winning these mini-games using a union bound, giving us an overall likelihood of a persistence violation.
2. **Progress:** we show that, given a sufficiently long duration, at least one honestly-mined block within that period will remain in the main chain forever with high probability. This is decomposed into:
   (a) Establishing that given $r > 0$, honest miners will discover r blocks within a long enough period.
   (b) And showing that the probability of an adversary forming a tree deeper than the tree in each honest miner's view by at least r blocks is bounded by $2^{-\Omega(r)}$.

Both proofs employ a reduction to a *simple game*. In this game the adversary and honest miners initially mine their respective block trees, stemming from a shared genesis block. The adversary's goal is to reach or surpass the length of the honest miners' tree once both trees have reached a length of at least r blocks. Subsequently, we examine an infinite set of games where the adversary achieves victory when both trees have lengths of at least $r, r+1, r+2, \ldots$, and so forth. We prove that the sum of the probabilities of the adversary winning each game is bounded by $2^{-\Omega(r)}$. To do this we find the attack that is most likely to succeed and bound the probability of its success; we say this attacker is the *worst attacker*. In particular, we should find which PoW and which PoD the worst attacker should calculate at each step. For PoD, we assume that the adversary mines all possible PoD blocks in parallel. This assumption makes the adversary stronger since any other adversary can be emulated by the one described above. Subsequently, we prove that the optimal strategy, defined as the one that maximizes the length of the adversary's subtree while minimizing the honest subtree for any given step, is the strategy that PoW mines on the deepest block in the adversary's subtree as long as no PoW solution exists of the same depth, i.e., a complete PoW puzzle does not yet extend this PoD puzzle. In the latter scenario, the adversary halts PoW until a PoD puzzle is found.

After showing that we only need to consider this worst attack, we find that when adversary and honest subtrees are of equal length, they contain the same number of PoD blocks. This reduces the competition to just PoW computations, paving the way for an easy conclusion to the proof using standard tools, namely random walk analysis.

Before detailing the proof, we present some terminology and notation (§5.1). We then discuss optimal strategies for the adversary (§5.2) and the honest miners (§5.3) subtrees. Next, we use these strategies to analyze the simple game (§5.4). Finally, we prove persistence and progress and the security of *Sprints* (§5.5).

5.1 Terminology and Notation

We define a race between the honest miners and an adversary with strategy A. We assume that the adversary always chooses to PoD-mine on all possible blocks in parallel, as every strategy A_1 that PoD-mines only some blocks creates the same tree as the one created by a strategy A_2 that is identical to A_1 but PoD-mines everywhere. Therefore, for succinctness, we define a mining action at step t as the block that the adversary chooses to PoW mine on; if there is no such block, the adversary's action is $\perp$, i.e., empty action. The adversary chooses a delay for each block b and honest miner p. To simplify the analysis, we assume that the attacker can delay the block even for the miner who found it. This assumption only strengthens the adversary, allowing us to bound the adversary's success probability.

Given a depth i, execution σ and honest block b at depth i, we define two *sub-trees* (portrayed in Figure 3): for all steps t, $\mathcal{T}_H^{\sigma}(t)$ is the sub-tree of $\mathcal{T}^{\sigma}(t)$ that includes b, its descendants that are known by all honest miners and its

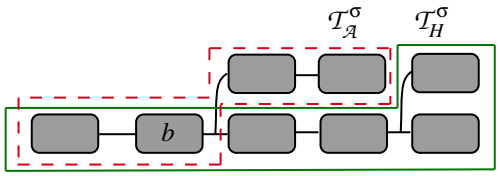

Figure 3: Scheme of $\mathcal{T}_{\mathcal{A}}^{\sigma}$ and $\mathcal{T}_{H}^{\sigma}$ depending on b.

ancestors; tree $\mathcal{T}_{\mathcal{A}}^{\sigma}(t)$ is the sub-tree of $\mathcal{T}^{\sigma}(t)$ that includes b and its private adversarial descendants and ancestors. Note that $\mathcal{T}^{\sigma}(t)$ can include adversarial blocks.

A block data structure containing only the PoD puzzle, $(M,D,(b^{PoW},\perp))$, is called a *partial block* and a valid block with all proofs is called a *full block*. Denote the depth of a partial block b by $\tilde{d}(b)$. Given an execution σ, we define the *PoD depth* of a tree as the deepest block in the mother tree that has a completed PoD puzzle on the subtree, it is denoted by $\tilde{d}_b^{\sigma}(t)$ for $\mathcal{T}_{\mathcal{A}}^{\sigma}(t)$ and by $\tilde{d}_{\neg b}^{\sigma}(t)$ for $\mathcal{T}_{H}^{\sigma}(t)$. For some π, denote by $\Sigma_A^{\pi_i}$ the subset of Σ^{π}, where the adversary follows a strategy A.

Next, we define the optimality of an adversarial strategy. We look separately at $\mathcal{T}_{H}^{\sigma}(t)$ and $\mathcal{T}_{\mathcal{A}}^{\sigma}(t)$ and find a single strategy that minimizes the depth of the former and maximizes the depth of the latter for all steps.

5.2 Adversary tree

We focus on the optimal strategy of the adversary on her private tree $\mathcal{T}_{\mathcal{A}}^{\sigma}(t)$.

Given a prefix π of length t_0 and an execution $\sigma \in \pi$, we start by considering only the actions of an adversary targeting the subtree $\mathcal{T}_{\mathcal{A}}^{\sigma}(t)$. At first, we assume that given some step $t_f > t_0$, the adversary aims to maximize the depth of $\mathcal{T}_{\mathcal{A}}^{\sigma}(t_f)$. Later we generalize this to a strategy that aims to maximize the depth of $\mathcal{T}_{\mathcal{A}}^{\sigma}(t)$ for all $t > t_0$.

We define the notion of an *optimal strategy*. As a first step, we define a (t_f,ℓ)-optimal strategy that maximizes the probability that at step t_f the depth of $\mathcal{T}_{\mathcal{A}}^{\sigma}$ is at least ℓ. For a set of executions Σ_A^{π}, denote by $\Pr_{\Sigma_A^{\pi}}[\cdot]$ the conditional probability $\Pr[\cdot|\sigma \in \Sigma_A^{\pi}]$.

Definition 2. *An attacker strategy A is* (t_f,ℓ)-optimal *if, for all prefixes π of length $t_0 < t_f$ and strategies A', it holds that* $\Pr_{\Sigma_A^{\pi}}[d_{\neg b}^{\sigma}(t_f) \geq \ell] \geq \Pr_{\Sigma_{A'}^{\pi}}[d_{\neg b}^{\sigma}(t_f) \geq \ell]$. *Strategy A is* optimal *if it is (t_f,ℓ)-optimal for all t_f and ℓ.*

For execution σ, denote by $B_{max}(\mathcal{T}_{\mathcal{A}}^{\sigma}(t))$ the *tips of the chain* the set of deepest partial blocks in step t whose PoD puzzle is completed locally for player p. Denote their depth by $\tilde{d}_{\neg b}^{\sigma}(t)$.

Definition 3 (longest-chain mining)**.** *Given an execution σ, an attacker strategy that chooses a block in $B_{max}(\mathcal{T}_{\mathcal{A}}^{\sigma}(t))$ for $t \geq t_0$ is* longest-chain mining *(*LCM*).*

We show that any longest-chain mining strategy is (t_f,ℓ)-optimal.

Lemma 1. *For all prefixes π of length t_0, ℓ and steps t_f, an LCM strategy A played from step t_0 is (t_f,ℓ)-optimal.*

Before proving Lemma 1, we introduce another lemma, which will also be useful later. We show that given two execution sets where the first has higher partial depth at step t_0 and Δ_{PoD} steps later, it has a higher probability to be deeper at step $t_f > t_0$ if the attacker follows a (t_f,ℓ)-optimal strategy.

Lemma 2. *Let there be two prefixes π_1 and π_2 of length t_0, given t_f and ℓ, and a (t_f,ℓ)-optimal strategy A. Consider two sets of executions, Σ_1 and Σ_2, such that $\Sigma_i = \Sigma_A^{\pi_i}$. We assume that for π_1 and π_2, in step t_0 no PoD puzzle is being calculated so that at some point in the future, an execution from Σ_2 will be deeper than any execution from Σ_2 due to this puzzle. Formally:*

$$\forall \sigma_1 \in \Sigma_1, \sigma_2 \in \Sigma_2, t \in [t_0, t_0+\Delta_{PoD}] : \tilde{d}_{\neg b}^{\sigma_1}(t) \geq \tilde{d}_{\neg b}^{\sigma_2}(t).$$

Then it holds that

$$\Pr_{\Sigma_1}[d_{\neg b}^{\sigma}(t_f) \geq \ell] \geq \Pr_{\Sigma_2}[d_{\neg b}^{\sigma}(t_f) \geq \ell].$$

The full proof of Lemma 1 and Lemma 2 is given in the full version of this paper [47]. The main idea is that we prove both lemmas by double induction starting from t_f. We run the induction for decreasing step period and prove both lemmas together at each step of the induction. We first show that the base of the induction holds for $t_0 \in [q_0, t_f - 1]$ for both lemmas Next, we assume that both lemmas hold for $t_0 \in [q_0 - n, t_f - 1]$ for some n. We then prove the induction step for Lemma 2 for $t_0 = t_f - n - 1$ using the assumption. Finally, we prove the induction step for Lemma 1 for $t_0 = t_f - n - 1$ using the result we just proved for Lemma 2 for $t_0 = t_f - n - 1$. This concludes the proof of both lemmas.

After showing that LCM is a (t_f,ℓ)-optimal strategy, we show that there is no benefit for the adversary from PoW mining while she calculates the deepest block's PoD puzzle. For this purpose, we first define useless actions we call *backward mining*, where the adversary mines a PoW puzzle that would not extend the depth of the chain:

Definition 4. *Given an execution σ, an action $Q_{\mathcal{A}}^{\sigma}(t) = b_{PoD}$ at step t is* backward mining *if the adversary already computed a partial block b'_{PoD} that extends a block in $\mathcal{T}_H^{\sigma}$, such that $\tilde{d}(b_{PoD}) < \tilde{d}(b'_{PoD})$ or if there is a full block b such that $\tilde{d}(b_{PoD}) = d(b)$.*

Next, we define an upgrade of the LCM strategy without useless backward mining actions.

Definition 5. *A strategy is* (t_f,ℓ)-intermittent LCM *if it is (t_f,ℓ)-optimal and does not perform backward mining actions.*

It remains to show that every LCM can be transformed to (t_f,ℓ)-intermittent LCM without affecting its optimality.

Lemma 3. *For all t_f, ℓ and an LCM strategy A, the intermittent LCM strategy A' that is identical to A, except that every backward mining action is replaced with $\perp$, is (t_f,ℓ)-optimal.*

Proof. Given a prefix π of length t_0, We look at two sets of executions. (1) Σ_A^π for a (t_f,ℓ)-optimal strategy A that for some $\sigma \in \Sigma_A^\pi$ chooses some backward mining action $Q_{\mathcal{A}}^\sigma(t_0) = b$. and (2) $\Sigma_{A'}^\pi$, where the strategy A' chooses $\perp$ at step t_0 but for $t > t_0$ it is identical to A. As before, the probability to find a block exactly at t_0 is $P_w(\mathcal{A})$. Note that this probability is not relevant for $\Sigma_{A'}^\pi$. Denoted the subset of Σ_A^π where no block is found at step t_0, by Σ_1. For all $\sigma_1 \in \Sigma_1$, there exists a unique $\sigma_2 \in \Sigma_{A'}^\pi$ such that $\mathcal{T}_b^{\sigma_1} \equiv \mathcal{T}_b^{\sigma_2}$ and vice versa. σ_1 and σ_2 agree on all random coins from t_0+1. If a block is found at step t_0, the tree depth of both executions is still equal, therefore:

$$\Pr_{\Sigma_1}[d_{\neg b}^\sigma(t_f) \geq \ell]) = \Pr_{\Sigma_{A'}^\pi}[d_{\neg b}^\sigma(t_f) \geq \ell]. \tag{1}$$

The block that is found in step t_0 for all $\sigma_1 \in \Sigma_A^\pi \setminus \Sigma_1$ does not extends the depth of $\mathcal{T}_b^{\sigma_1}$. Therefore, for all $\sigma_2 \in \Sigma_{A'}^\pi$, it holds that $\tilde{d}_b^{\sigma_1}(t) \leq \tilde{d}_b^{\sigma_2}(t)$ for $t \in [t_0+1, t_0+\Delta_{PoD}+1]$. The conditions of Lemma 2 thus hold, so:

$$\Pr_{\Sigma_A^\pi \setminus \Sigma_1}[d_{\neg b}^\sigma(t_f) \geq \ell] \leq \Pr_{\Sigma_{A'}^\pi}[d_{\neg b}^\sigma(t_f) \geq \ell]. \tag{2}$$

Using complete probability:

$$\begin{aligned}
&\Pr_{\Sigma_A^\pi}[d_{\neg b}^\sigma(t_f) \geq \ell] = \\
&\quad P_w(\mathcal{A}) \cdot \Pr_{\Sigma_A^\pi \setminus \Sigma_1}[d_{\neg b}^\sigma(t_f) \geq \ell] + \\
&\quad (1 - P_w(\mathcal{A})) \cdot \Pr_{\Sigma_1}[d_{\neg b}^\sigma(t_f) \geq \ell]) \\
&\qquad \textit{Equation (1) and Equation (2)} \\
&\qquad \leq \\
&\quad P_w(\mathcal{A}) \cdot \Pr_{\Sigma_{A'}^\pi}[d_{\neg b}^\sigma(t_f) \geq \ell] + \\
&\quad (1 - P_w(\mathcal{A})) \cdot \Pr_{\Sigma_{A'}^\pi}[d_{\neg b}^\sigma(t_f) \geq \ell] = \\
&\qquad \Pr_{\Sigma_{A'}^\pi}[d_{\neg b}^\sigma(t_f) \geq \ell].
\end{aligned}$$

Note that although $P_w(\mathcal{A})$ has no meaning in the context of $\Sigma_{A'}^\pi$, we used a simple algebraic trick to disassemble $\Pr_{\Sigma_{A'}^\pi}[d_{\neg b}^\sigma(t_f) \geq \ell]$ to two parts.

We apply the described process recursively, each time eliminating a single backward mining action. We end with a new (t_f,ℓ)-optimal intermittent LCM strategy as required by the lemma. □

We can now conclude that any intermittent LCM strategy is an optimal strategy.

Corollary 1. *Intermittent LCM is an optimal strategy.*

Proof. By Lemma 3, for all ℓ and t_f any intermittent LCM strategy is (t_f,ℓ)-optimal, so it is an optimal strategy. □

5.3 Honest tree

We now focus on the subtree $\mathcal{T}_H^\sigma(t)$. We look for a strategy that minimizes the depth of the tree.

Definition 6 (Maliciously optimal strategy)**.** *A strategy A is* (t_f,ℓ)-maliciously optimal *if, for all prefixes π of length $t_0 < t_f$ with block b, and for all strategies A', it holds that*

$$\Pr_{\Sigma_A^\pi}[d_b^\sigma(t_f) \geq \ell] \leq \Pr_{\Sigma_{A'}^\pi}[d_b^\sigma(t_f) \geq \ell].$$

We call A a maliciously optimal *if it is (t_f,ℓ)-maliciously optimal for all $t_f > t_0$ and for all ℓ.*

We consider a strategy where the attacker does not mine new blocks on $\mathcal{T}_H^\sigma(t)$ and delays any honest block by Δ, which is the maximal delay she can impose.

Definition 7. *Given a prefix π, a strategy A is a* Maximum Delay and No Mining strategy (MDNM) *if the adversary chooses to mine no blocks and to maximize the delay for the arrival of all honest blocks to be Δ for all miners.*

Denote the hash rate of the honest miners that received the block that is a tip of the chain in execution σ at step t by $\lambda^\sigma(t)$. Similarly, denote by $\lambda_m^\sigma(t)$ the total hash rate of miners that heard of blocks of depth at least m.

We show that an MDNM strategy maintains some advantages.

Lemma 4. *Given two prefixes π_1 and π_2 of length t_0, ℓ, and a MDNM strategy A, such that for all $\sigma_1 \in \Sigma_A^{\pi_1}$, $\sigma_2 \in \Sigma_A^{\pi_2}$ it holds that*

$$\forall t \in [t_0, t_0+\Delta_{PoD}] : d_b^{\sigma_1}(t) \geq d_b^{\sigma_2}(t)$$

and

$$\forall t \in [t_0, t_0+\Delta+\Delta_{PoD}] : \lambda_{d_b^{\sigma_2}(t)}^{\sigma_1}(t) \geq \lambda^{\sigma_2}(t),$$

it holds that for all $\ell > 0$ and step t_f:

$$\Pr_{\Sigma_A^{\pi_1}}[d_b^\sigma(t_f) > \ell] \geq \Pr_{\Sigma_A^{\pi_2}}[d_b^\sigma(t_f) > \ell].$$

We overview the proof with the details deferred to the full version of this paper [47].

Proof sketch. The goal is to demonstrate that a prefix with greater depth and miner engagement is more likely to maintain its lead. We prove by reverse induction.

Basis For the initial time frame $t_0 \in [t_f - \Delta_{PoD}, t_f]$, the lemma trivially holds. A deeper prefix with more miners retains its advantage in this brief period, where at most one full block can be found.

Assumption We assume the statement holds for all $t_0 \in [t_f - \Delta_{PoD} - n, t_f]$.

Induction Step Extending to the previous step $t_f - \Delta_{PoD} - n - 1$, we consider two cases: if a new block is found in the step and if not. In both cases, the leading prefix maintains its lead due to higher probabilities of block addition and mining power. □

Next, we use Lemma 4 to prove the following with the details deferred to the full version of this paper [47].

Lemma 5. *An MDNM strategy is maliciously optimal.*

Proof sketch. The goal is to show that an MDNM strategy is maliciously optimal. We prove this too by reverse induction.

Basis For $t_0 \in [t_f - \Delta_{PoD}, t_f]$, MDNM is optimal since the blockchain can grow by at most one block in this period, and MDNM is not worse than any other strategy.

Assumption We assume the lemma holds for all $t_0 \in [t_f - \Delta_{PoD} - n, t_f]$.

Induction Step Extending the proof to $t_f - \Delta_{PoD} - n - 1$, we consider two scenarios: one where an honest miner finds a new block and another where no new block is found. In both cases, MDNM retains its optimality. We apply Lemma 4 to compare the probabilities of extending the blockchain depth under MDNM and alternative strategies, confirming that MDNM is optimal. □

5.4 Basic race

We now introduce a two-epoch race where the adversary tries to fork a chain of blocks. We then find an upper bound on the probability that the adversary succeeds in the attack. From now on, we assume that $\Delta = 0$.

Given an adversarial strategy A and execution σ, we define a block $b_s^\sigma(q)$ as the first published depth-q block in σ.

We consider a race where the adversary mines a secret tree denoted by $\mathcal{T}_\mathcal{A}^\sigma(t,q)$, whose root is $b_s^\sigma(q)$ and it is a function of step t and depth q of $b_s^\sigma(q)$. We assume that the adversary did not mine any blocks before a block at depth q is published. The adversary never sends blocks from $\mathcal{T}_\mathcal{A}^\sigma(t,q)$ to the honest miners until the end of the race and they stay secret. We also consider a public subtree $\mathcal{T}_H^\sigma(t,q)$ whose blocks are public and has $b_s^\sigma(q)$ as its root. All blocks that have $b_s^\sigma(q)$ as an ancestor and are not in $\mathcal{T}_\mathcal{A}^\sigma(t,q)$ are in $\mathcal{T}_H^\sigma(t,q)$. The attacker can mine on $\mathcal{T}_H^\sigma(t,q)$ and publish the blocks at any time. Given an integer $r > 0$, we say that the adversary has won the race if, at some step t, it holds that $d(\mathcal{T}_\mathcal{A}^\sigma(t,q)) \geq q + r$ and $d(\mathcal{T}_\mathcal{A}^\sigma(t,q)) \geq d(\mathcal{T}_H^\sigma(t,q))$. Note that in this race the adversary cannot mine before a block of depth q is published by miners. Therefore, we conclude that the probability that the adversary wins the race does not depend on q.

Given a random execution $\sigma \in \Sigma_A$, we denote the probability that the adversary wins the race by $\chi(A,r)$ and the respective event by $e_\chi(A,r,q)$.

With foresight, we define the sum

$$S(r) = \max_A \sum_{i=0}^{\infty} \chi(A, r+i) \tag{3}$$

and show that $S(r) = 2^{-\Omega(r)}$. We later use this result to prove persistence and progress.

Lemma 6. *For a minority attacker ($\alpha_\mathcal{A} < \alpha_H$) and $\Delta = 0$ it holds that $S(r) = 2^{-\Omega(r)}$.*

Proof. First we bound $\chi(A,m)$.

For a block $b_s^\sigma(q)$ of depth q, we break the race into two epochs. The first epoch ends when the honest miners find m blocks and the second epoch ends when the adversary wins the race. Denote by $d_\mathcal{A}$ the number of blocks that the adversary has at the beginning of the first epoch and by $\Pr[d_\mathcal{A} = k]$ the probability of a given k.

Next, to simplify the calculations we observe that different values of Δ_{PoD} do not affect the probability that the adversary wins the race. We prove that the attacker has the same probability to win for $\Delta_{PoD} > 0$ and for $\Delta_{PoD} = 0$. Intuitively, the introduction of PoD affects both the honest and the adversary miners equally, so that we can cancel it out. This is only true for strategies that mine blocks sequentially, such as LCM mining with interruption. In this case, the number of PoD blocks is the same for both $\mathcal{T}_\mathcal{A}^\sigma(t,q)$ and $\mathcal{T}_H^\sigma(t,q)$.

We observe that given an intermittent LCM strategy A there is a strategy A' where the adversary stops mining after she finds m blocks earlier than the honest miners find their first m blocks. Note that in this scenario whether the adversary stops mining or not, she already won the race. Strategy A' has the same probability to win the race as A, as they are different only when the adversary has found m blocks, and won the race. For strategy A', the race always ends when both $\mathcal{T}_H^\sigma$ and $\mathcal{T}_\mathcal{A}^\sigma$ have identical depth. Therefore, because both the honest and the adversary trees have an identical number of PoD blocks at the end of the race, we can cancel out the effect of PoD blocks on both trees. In other words, for the strategy A' every execution where the adversary wins for $\Delta_{PoD} > 0$ has a parallel execution for $\Delta_{PoD} = 0$ with the same probability to happen. Therefore, the probability of winning for $\Delta_{PoD} > 0$ is the same as for $\Delta_{PoD} = 0$.

Denote by $P_w(k)$ the probability that the attacker wins the race in the second epoch for a given k. The probability of the attacker winning is:

$$\chi(A,m) \leq \max_A \chi(A,m) = \sum_{k=0}^{m-1} P_w(k) \cdot \Pr[d_\mathcal{A} = k] + \sum_{k=m}^{\infty} \Pr[d_\mathcal{A} = k]. \tag{4}$$

We use the stars and bars [48] problem in combinatorics to calculate $\Pr[d_\mathcal{A} = k] = \alpha_\mathcal{A}^k \cdot \alpha_H^m \binom{k+m-1}{m-1}$ and gambler's ruin [49] for $P_w(k) = (\frac{\alpha_\mathcal{A}}{\alpha_H})^{m-k}$.

Plugging into Equation (4) we get:

$$\chi(A,m) \leq \alpha_{\mathcal{A}}^m \cdot \sum_{k=0}^{m-1} \alpha_H^k \cdot \binom{k+m-1}{m-1} + \alpha_H^m \cdot \underbrace{\sum_{k=m}^{\infty} \alpha_{\mathcal{A}}^k \cdot \binom{k+m-1}{m-1}}_{a_k} \leq$$

$$\alpha_{\mathcal{A}}^m \cdot \alpha_H^{m-1} \cdot m \cdot \binom{2m-2}{m-1} + \alpha_{\mathcal{A}}^m \cdot \alpha_H^m \cdot \binom{2m-1}{m} \cdot C \leq$$

$$\frac{\alpha_{\mathcal{A}} \cdot m}{\sqrt{\pi(m-1)}} \cdot (4\alpha_{\mathcal{A}}\alpha_H)^{m-1} + \frac{2 \cdot C}{\sqrt{\pi m}} \cdot (4\alpha_{\mathcal{A}}\alpha_H)^m = 2^{-\Omega(m)}, \quad (5)$$

where C is a constant that does not depend on n. We used the fact that $4\alpha_{\mathcal{A}}\alpha_H \leq 1$, the known inequality $\binom{2r}{r} \leq \frac{4^r}{\sqrt{\pi r}}$, the fact that a_H is monotonic for $k < r$ and that $\frac{b_{k+1}}{a_k} \leq 2\alpha_{\mathcal{A}}$ for $k \geq r$.

As the tail of a geometric sum decreases exponentially, we conclude that $\sum_{k=r}^{\infty} \chi(A,k) = 2^{-\Omega(r)}$, thus due to Equation (3) and Equation (5) we conclude that $S(r) \leq \sum_{i=0}^{\infty} \max_{A_i} \chi(A_i, r+i) = 2^{-\Omega(r)}$. □

5.5 Persistence and Progress

We are now ready to prove our main results. We first prove that persistence holds.

Lemma 7. *For $\Delta = 0$, and a minority attacker, persistence holds.*

Proof. Given $\sigma \in \Sigma_A$, step t_f and $r > 0$, denote by $\neg Pers(\sigma, t_0, r)$ the event that $r-$persistence is violated for some $t < t_f$ in σ. We say that a block violates $r-$persistence if it holds for this block at some step $t \leq t_f$ that the chain that includes the block is longer by at least r blocks than any chain that does not contain the block, but for some $t' > t$ the block is not in the main chain. We observe that $r-$persistence does not hold if for at least one block persistence is violated. Next, we consider a scenario where the attacker tries to violate persistence for any block at a specific depth i. Denote by $\neg Pers_i(\sigma, r)$ the event where persistence was violated for a block at depth i.

Finally, we break the race into a collection of sub-races where the adversary tries to violate persistence for a specific depth i by mining only on a specific private tree that starts at a specific honest block at depth $j < i$, denoted by $\mathcal{T}_{\neg j}^{\sigma}(t', i, r)$, we denote the event where the attacker was able to do so by $\neg Pers_i^j(\sigma, r)$. As before we denote by $\mathcal{T}_j^{\sigma}(t', i, r)$ the tree that starts at depth j and includes all blocks that are not in the adversary's private tree. Observe that persistence is violated if two conditions hold: (1) at some step t the chain that includes b at depth i in $\mathcal{T}_j^{\sigma}(t', i, r)$ is deeper by r than $\mathcal{T}_{\neg j}^{\sigma}$, and (2) at some step $t' > t$, $\mathcal{T}_{\neg j}^{\sigma}(t', i, r)$ is deeper than $\mathcal{T}_j^{\sigma}(t', i, r)$. The adversary can maximize the probability of the first condition to be 1, if she does not publish her blocks and keeps her chain private. Note to maximize the probability of the second condition the attacker should choose a strategy that maximizes $\mathcal{T}_{\neg j}^{\sigma}(t', i, r)$ and minimizes $\mathcal{T}_j^{\sigma}(t', i, r)$ for all t', as we saw in Corollary 1 and Lemma 5 LCM mining with interruptions on $\mathcal{T}_{\neg j}^{\sigma}(t', i, r)$ and MDNM mining on $\mathcal{T}_j^{\sigma}(t', i, r)$ achieve these goals respectively. Moreover, these two strategies can be used at the same time and therefore an optimal strategy to maximize the second condition is their combination. Therefore, we can think of the game where the attacker tries to maximize $\Pr[\neg Pers_i^j(\sigma, r) | \sigma \in \Sigma_A]$ as a race described in §5.4. Thus, it holds $\chi(A, r+i-j) = \Pr[\neg Pers_i^j(\sigma, r) | \sigma \in \Sigma_A]$. There are at most i possible honest blocks on the main chain before the i-th block, thus,

$$\Pr[\neg Pers_i(\sigma, r) | \sigma \in \Sigma_{A_i}] \leq \Pr[\bigcup_{j=0}^{i} \neg Pers_i^j(\sigma, r) | \sigma \in \Sigma_{A_i}]$$

Denote by t_i^{σ} the time when the first block at depth i was mined. We bound the probability that persistence does not hold for all A', q and r:

$$\Pr[\neg Pers(\sigma, t_0, r) | \sigma \in \Sigma_{A'}] \leq \sum_{i=1}^{t_f} S(r) = t_f \cdot S(r) = 2^{-\Omega(r)} \quad (6)$$

The full details of Equation (6) are in the full version of this paper [47]. We used union bound and Lemma 6.

We choose r such that: $\Pr[\neg Pers(A', t_f, r)] \leq \varepsilon$ for all A' and thus we conclude that for every ε, there exists r such that persistence holds with a probability at least $1-\varepsilon$.

Note that because the connection between r and t_f is polynomial, as they are both polynomial in a security parameter [30], for every ε there exists large enough t_f so there is r that is significantly smaller than t_f so that the probability of persistence is at least $1-\varepsilon$. Thus, persistence holds non-vacuously. □

Next, we prove that progress holds.

Lemma 8. *For $\Delta = 0$, and a minority attacker, progress holds.*

Proof. Given some $\varepsilon > 0$, we show that there exists δ so that progress holds with a probability larger than $1 - \varepsilon$ for all steps $t_0 \leq t_f$. To find such δ, we first denote by r a parameter, such that δ is a function of r and ε. To bound the probability that progress does not hold, we look at the first r honest blocks generated after step t_0; denote this set of blocks by $B^{\sigma}(t_0, r)$. Our goal is to find a δ such that all the blocks in $B^{\sigma}(t_0, r)$ were mined in the period $[t_0, t_0 + \delta]$ with high probability. For the adversary to exclude the blocks from $B^{\sigma}(t_0, r)$ from the main chain she has to build a chain that does not include any of them, i.e, this chain has to win the race against the tree that includes blocks from $B^{\sigma}(t_0, r)$. We look at the chain of all the ancestors of blocks in $B^{\sigma}(t_0, r)$ without the blocks themselves. Given this chain, we look at the subtrees that start at honest blocks and include only adversarial blocks. Similarly to what we did

with persistence, we separate into sub-races where every race is between an adversarial subtree and the honest chain.

Given an adversarial strategy A and $\sigma \in \Sigma_A$ we denote by $\Pr[\neg Prog_q^j(\sigma,t_0,r)|\sigma \in \Sigma_A]$, the probability that the attacker was able to exclude all the first r honest blocks after the first block of depth q, denote by b_q, by building a chain that has a common honest ancestor with $B^\sigma(t_0,r)$ at depth j. We denote this common ancestor by b_j and the step when it was mined by t_j.

We denote by $\mathcal{T}_H^\sigma(t,t_0,r)$ the tree that includes all blocks from $B^\sigma(t_0,r)$, their ancestors, and their descendants. We denote by $\mathcal{T}_\mathcal{A}^\sigma(t,t_0,r)$ the trees that includes all the ancestors of honest block b_j and all the descendants of b_j that are not in $B^\sigma(t_0,r)$ and are not decedents of blocks in $B^\sigma(t_0,r)$.

From Corollary 1 intermittent LCM is an optimal strategy on $\mathcal{T}_\mathcal{A}^\sigma(t,t_0,r)$. From Lemma 5, MDNM is a maliciously optimal strategy on $\mathcal{T}_H^\sigma(t,t_0,r)$. As intermittent LCM and MDNM can be executed in parallel, and as they are both optimal and maliciously optimal respectively on their respective trees, it is guaranteed that if the adversary uses both of them on $\mathcal{T}_\mathcal{A}^\sigma(t,t_0,r)$ and $\mathcal{T}_H^\sigma(t,t_0,r)$, she will maximize the probability that none of the blocks in $B^\sigma(t_0,r)$ will be in the main chain forever.

Given an adversarial strategy A, denote the probability that non of the first r honest blocks after step t_0 are in the main chain forever, by $P_1(A,t_0,r)$ and the corresponding event by $e_1(\sigma,t_0,r)$. Denote by $\neg Prog_q(\sigma,t_0,r)$ the event that the first r honest blocks that were mined after b_q was published do not stay in the main chain forever. As we showed, $\Pr[\neg Prog_q^j(\sigma,r)|\sigma \in \Sigma_A]$ is maximal when the adversary's strategy A is to mine using intermittent LCM on the adversarial chain and MDNM on the honest miners' chain. There are at most q honest blocks that are ancestors of the block from $B^\sigma(t_0,r)$. Thus,

$$\Pr[\neg Prog_q(\sigma,t_0,r)|\sigma \in \Sigma_A] \leq \Pr[\bigcup_{j=0}^{q} \neg Prog_q^j(\sigma,t_0,r)|\sigma \in \Sigma_A] \leq \max_{A'} \Pr[\bigcup_{j=0}^{q} e_\chi(\sigma,r+j)|\sigma \in \Sigma_{A'}] \leq S(r).$$

Denote by $e_{\mathsf{d}}(\sigma,t_0,q)$ the event where the deepest public block before step t_0 is of depth q.

Due to complete probability and the Poisson tail bounds [50], it holds that:

$$P_1(A',t_0,r) = \sum_{q=0}^{\infty} \Pr[\neg Prog_q(\sigma,t_0,r) \wedge e_{\mathsf{d}}(\sigma,t_0,q)|\sigma \in \Sigma_{A'}] \leq \max_A \sum_{q=0}^{n-1} \Pr[\neg Prog_q(\sigma,t_0,r)|\sigma \in \Sigma_A] + 2^{-\Omega(n-\lambda_T t)} \leq \sum_{q=0}^{n-1} S(r) + 2^{-\Omega(n-\lambda_T t)}.$$

Therefore, we can choose n and r_1 such that for $\frac{\varepsilon}{2}$ the probability $P_1(A,t,r_1)$ that one of the next r_1 blocks will not stay in the main chain forever is smaller than $\frac{\varepsilon}{2}$.

Next, for all r, we define $\delta(r) \triangleq r^2 + r \cdot \Delta_{PoD}$, where we add Δ_{PoD} so that the period is long enough to account for the times of proof of delays puzzles. We calculate the probability $P_2(A,\delta,r)$ (with the corresponding event $e_2(A,\delta,r)$) that there are fewer than r honest blocks within a period δ using Erlang distribution. For simplicity we look at $\Delta_{PoD} = 0$, as for $\Delta_{PoD} > 0$ we can increase the number of steps by $r \cdot \Delta_{PoD}$ to account for the times of proof of delay:

$$P_2(A,\delta,r) = 1 - \text{Erlang}(r^2;r,\lambda_H) = \sum_{n=0}^{r-1} \underbrace{\frac{1}{n!} e^{-\lambda_H r^2} (\lambda_H r^2)^n}_{a_n} \overset{(1)}{\leq} e^{-\lambda_H r^2} \cdot \lambda_H{}^r \cdot e^{2r\log r} = 2^{-\Omega(r)}.$$

For (1) we use the fact that $\frac{a_n}{a_{n-1}} \leq \lambda_H r^2$ and the formula for a sum of geometric series. Thus, there is r_2 such that the probability P_2 is smaller than $\frac{\varepsilon}{2}$. We choose $r_3 = \max(r_1,r_2)$. Using the union bound:

$$\Pr[e_1(A,t,r_3) \cup e_2(A,\delta,r_3)] \leq P_1(A,t,r_3) + P_2(A,\delta,r_3) \leq \frac{\varepsilon}{2} + \frac{\varepsilon}{2} = \varepsilon.$$

We conclude that the probability for a block in period $\delta(r_3)$ to stay in the main chain forever is at least $1 = 1-\varepsilon$. Therefore, at least one block that was mined in the period $[t,t+\delta(r_3)]$ will be included in the main chain forever with high probability and thus progress holds. □

We now combine both lemmas to prove our main theorem:

Theorem 1. Sprints *implements a ledger (Definition 1).*

Proof. Using Lemma 7 and Lemma 8 we can conclude that the *Sprints* fulfills the requirements in Definition 1. □

6 Implementation and Evaluation

We turn our attention to practical aspects of *Sprints*. Having addressed the scenario without network delay in our security proof in the previous section, we now investigate the scenario with network delay through experiments, aiming to assess the honest party's main chain extension rate with practical network latency.

We implement *Sprints* using Wesolowski VDF [22] for PoD. We apply optimization to reduce the network delay and dynamically adjust PoW and PoD difficulty (§6.1). Our attack threshold analysis (§6.2) and experiments (§6.3) with practical fork rates show that the security of our protocol is close (98%) to that of Bitcoin.

6.1 Implementation

We implemented a prototype of *Sprints* by modifying Bitcoin Core [51]. We made two major changes. First, we modified the data structure of block headers to include proofs of delay and adapted the mining process as well as the block validation process accordingly. Second, we modified the difficulty adjustment algorithm to adjust both the PoD and the PoW parameters.

To generate a block, a miner first calculates a VDF using the previous block hash as input. Then, the PoD is included in the block header and a standard proof of work with the new block header as input is calculated.

PoD implementation: In PoW systems, the mining algorithm is memoryless, permitting miners to dynamically alter the transactions within a block as they mine. Altering the block header, which constitutes the PoW puzzle, incurs no additional computational time, thus avoiding any notion of 'sunk cost.' In contrast, PoD is inherently not memoryless, which poses challenges for dynamic transaction inclusion. To mitigate this limitation in *Sprints*, the PoD algorithm has been designed to be independent of the block's content. Consequently, a miner needs to solve the PoD puzzle only once and can utilize that solution irrespective of subsequent modifications to the block.

We implement PoD as Wesolowski VDF [22], using the implementation provided by the POA Network [52]. To mitigate the risk of a single party gaining undue advantage through an algorithmic breakthrough in one specific VDF, a more robust implementation of PoD can require miners to solve multiple, distinct VDFs in parallel. Importantly, these VDFs would employ different, unrelated algorithms. A PoD would only be considered complete when all of these diverse VDFs have been successfully solved. This approach can reduces the likelihood that a single miner could dominate the process, as it would necessitate a breakthrough in multiple algorithms simultaneously. However, the introduction of parallel VDFs with varying algorithms presents new challenges, particularly that of difficulty adjustment. Addressing these challenges is beyond the scope of the current work and is deferred to future research.

Reducing propagation latency: In Bitcoin, blocks are verified before propagation to prevent spam. While PoW verification is quick, PoD verification is considerably slower. In our implementation, PoD verification typically takes 100ms to 500ms. Worse yet, since blocks are verified at every hop, repeated PoD verification can add significant propagation latency [53].

To address the problem, we postpone the VDF verification when propagating since PoW alone already creates a significant barrier for denial of service (rapid publication of invalid blocks). Specifically, each node that receives a block verifies the PoW, then concurrently broadcast the block and validates the PoD. A node processes a block only after the PoD puzzle was verified. Since both proofs are verified before a block is processed, this network-level optimization does not affect the logic of the consensus mechanism. Additionally, since PoW is verified before propagation, exploiting this optimization for a denial of service attack is costly and inefficient, as creating a block with valid PoW but invalid PoD is still computationally intensive.

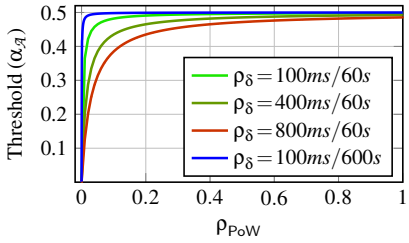

Figure 4: Attacker threshold against PoW time ratio ρ_{PoW} with different delay ratio ρ_δ.

Difficulty adjustment: We assume only principals with the fastest hardware for VDF computation participate in the protocol, but the best hardware is expected to get more efficient over time [54]. Meanwhile, the total hash power may fluctuate [55] due to hardware improvement or miners joining and leaving the system. Therefore, Sprints adjusts the difficulty parameters for PoD and PoW to keep both the block interval and the average PoW ratio, i.e., the portion of time spent on PoW, constant. It estimates PoD time and average PoW time based only on the total block generation times using the first and second moments. The details are in the full version of this paper [47].

6.2 Attacker threshold analysis

So far we analyzed *Sprints*' security without network delays, We now consider the effect of network delay on *Sprints* miners. The probability of forks is a function of the ratio between PoW time and PoD time. Intuitively, the less PoW time, the more likely for nodes to finish PoW around the same time which leads to forks.

Forked blocks are blocks not on the main chain. We refer to the ratio between forked blocks and all blocks as *fork rate*, denoted by ϕ. Conservatively assuming the adversary does not incur any forks (this means the adversary has strong control over the network which makes the result stronger), the honest mining power is reduced by $(1-\phi)$, thus the adversary threshold becomes $\alpha_{\mathcal{A}} < (1-\alpha_{\mathcal{A}})(1-\phi)$ [56], i.e., $\alpha_{\mathcal{A}} < \frac{1-\phi}{2-\phi}$.

To derive ϕ, we first calculate the probability that when a miner i mines a block at height h, another miner j also mines a block at height h before learning of i's block, creating a fork. Denote the propagation delay from miner i to miner j by T_{ij}. Let $\beta_j \in [0,1)$ denote node j's share of mining power. Assuming difficulty is well adjusted, miner j can mine a block in time Δ_{PoW} with probability β_j. Therefore, when $\Delta_{PoW} \neq 0$, node j can mine a block in time T_{ij} with probability $\frac{\beta_j T_{ij}}{\Delta_{PoW}}$. Once miner i generates a block, the mean number of forks generated by other miners is, therefore, $\sum_{j\neq i} \frac{\beta_j T_{ij}}{\Delta_{PoW}}$. Calculating the total probability over all

miners i, we obtain the average number of forks n_f as follows:

$$n_f = \sum_{i=1}^{N} \beta_i \left(\sum_{j=1, j\neq i}^{N} \frac{\beta_j T_{ij}}{\Delta_{PoW}} \right). \quad (7)$$

Data propagation in a decentralized blockchain system is performed with gossip over a p2p unstructured overlay network. The propagation delay is due to the transmission of blocks over multiple hops, and we express it based on the average one-hop delay between a pair of nodes, denoted δ. For each pair of miners denote by d_{ij} the number of hops between them, so the overall propagation delay is $T_{ij} = d_{ij} \times \delta$.

Assuming all nodes have same mining power, i.e. $\beta_i = \frac{1}{N}$ ($i = 1, 2, \cdots, N$), Equation (7) could be simplified as $n_f = \frac{N-1}{N} \cdot \frac{d_{avg}\delta}{\Delta_{PoW}}$ where d_{avg} is the average number of hops between any two nodes in the network. d_{avg} is determined by the network topology. Note that we have a coefficient $\frac{N-1}{N}$ because the average distance does not take the distance to the node itself into account. The fork rate is then

$$\phi = \frac{n_f}{1+n_f} = \frac{N-1}{N\frac{\Delta_{PoW}}{d_{avg}\delta} + (N-1)}. \quad (8)$$

According to the relationship between fork rate and attack threshold, the attack threshold is

$$\alpha_{\mathcal{A}} = \frac{1}{2 + \frac{N-1}{N} \cdot \frac{d_{avg}\delta}{\Delta_{PoW}}}.$$

The fork rate and attacker threshold are thus a function of the *delay ratio* between the one-hop propagation delay and the block interval, denoted $\rho_\delta = \frac{\delta}{\Delta_{block}}$ and the *PoW ratio* between PoW mean duration and the block interval, denoted as $\rho_{\mathsf{PoW}} = \frac{\Delta_{PoW}}{\Delta_{block}}$.

Figure 4 visualizes the attacker threshold for various ρ_δ and ρ_{PoW} values. With the increase of PoW ratio ρ_{PoW} and decrease of delay ratio ρ_δ, the attacker threshold increases and approaches 0.5. For example, suppose the one-hop network latency is 100ms (approximately the average latency in Bitcoin [33]) and the block interval is 600s (i.e., $\rho_\delta = \frac{100ms}{600s}$), even if *Sprints* performs PoW only for 5% of the time ($\rho_{\mathsf{PoW}} = 0.05$), the attacker threshold is still 49% (compared to 50% in Bitcoin.)

6.3 Evaluation

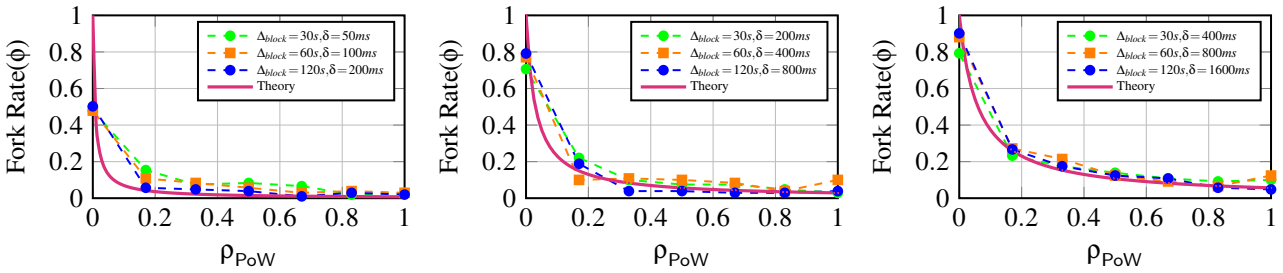
We have derived an analytical relationship between attacker threshold, fork rates, and network parameters. Now we empirically validate the analysis by running *Sprints* with real-world parameters. We describe our setup (6.3.1), validate our theoretical results (6.3.2), and evaluate *Sprints* under practical parameters (6.3.3).

6.3.1 Setup

We deploy a network of 100 nodes running *Sprints* on our testbed with two 64-core AMD processors (256 hardware threads in total). Each node is given two hardware threads, so they have roughly the same mining power. Like previous work [57], we create a random topology by connecting each node to four random neighbors and we fix the topology throughout the experiments. We added network latency to outbound traffic using the Linux `tc` tool. We did not explicitly limit the bandwidth since messages sent in our experiments are small; this is representative of the nominal block size in practice (e.g., Bitcoin's Compact Blocks [58] and Prism's Proposal blocks [57]).

From propagation traces, we identified that the average number of hops of block propagation in our network is $d_{avg} = 4.5$ (See our full report [47] for details).

6.3.2 Theory Validation



We now use our experimental setup to validate the analysis of §6.2. In all experiments, we run *Sprints* until 100 blocks are generated and calculate the fork rate from the log.

Parameter choice According to Equation (8), when N and d_{avg} are fixed, fork rates are determined by ρ_δ (network latency normalized by block interval) and ρ_{PoW} (PoW ratio). We choose $\rho_\delta \in \{\frac{100ms}{60s}, \frac{400ms}{60s}, \frac{800ms}{60s}\}$ to cover a wide range of latencies. For each ρ_δ, we run experiments with different block intervals $\Delta_{block} \in (30s, 60s, 120s)$ and thus different one-hop network latency $\delta = \rho_\delta \times \Delta_{block}$.

Results Figure 5 plots the results. The three subgraphs correspond to the values of ρ_δ. In all graphs, the y axis is the fork rate and the x-axis is the PoW ratio ρ_{PoW} ranging from zero to one. In each graph, there are four lines. The solid line shows fork rate by Equation (8). Markers, connected by dashed lines, show the experimental results for each block interval Δ_{block} (and thus network latency $\delta = \Delta_{block} \times \rho_\delta$). Each dot represents an experiment with 100 blocks.

We observe that the experimental results are closer to the theory with a larger one-hop delay δ. This is because the analysis only takes the network delay into account, while in reality there are other sources of delay, e.g., disk I/O, block validation, etc. These additional delays are more significant when δ is small. Nonetheless, the experimental results of each graph are close to each other, confirming that the fork rate is affected mostly by the ratio ρ_δ.

Finally, note that the measured fork rate without PoW is much smaller than the theory. From Equation (8), when taking $\Delta_{PoW} \to 0$, all the miners produce a block at about the same time. The fork rate is then $\phi = \frac{N-1}{N}$ (about one). However, in practice, variance in network delays and computation times

(a) $\rho_\delta = 100ms/60s$ (b) $\rho_\delta = 400ms/60s$ (c) $\rho_\delta = 800ms/60s$

Figure 5: Fork rate under different ρ_δ, ρ_{PoW} and Δ_{block}. Each graph corresponds to a different delay ratio ρ_δ. Solid lines plot the theoretical analysis in Equation (8). Dotted lines plot the experiment results under different Δ_{block}.

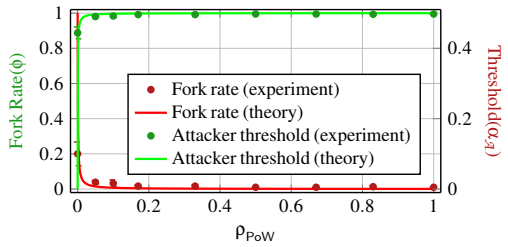


Figure 6: Fork rates and attack threshold under Bitcoin-like parameters (100ms network delay and 600s block interval.)

reduce the synchrony of block generation even with $\Delta_{PoW} = 0$, resulting in a smaller fork rate.

6.3.3 Real-world parameters

We conclude by studying *Sprints*'s behavior with practical, Bitcoin-like parameters: We measure the fork rate under $\Delta_{block} = 600s$ and the one-hop network delay $\delta = 100ms$ [33]. Figure 6 shows the results. The x axis is the ratio of PoW time ρ_{PoW}, while the left y axis shows the fork rate, and the right y axis shows the attacker threshold. The red line plots the fork rate in theory and the blue dots are the experiment results. Each dot represents 3 experiments, each with 100 blocks. The green line shows the attacker threshold derived from fork rates, and the orange dots represent the attacker threshold derived from experimental fork rates. According to Figure 6, *Sprints* achieves a good attacker threshold even with small ρ_{PoW}. For example, when $\rho_{\text{PoW}} = 0.05$, *Sprints* can withstand an attacker with $\alpha_{\mathcal{A}} =$ 49% mining power, close to the ideal attacker threshold 50%.

6.4 Non-Negligible Propagation Delay

The measurements (§6.2) demonstrate the practicality of *Sprints* when propagation delay is negligible compared to the block interval. Future work might consider a shorter block interval, in the order of Δ, to allow for better performance [57, 59]. However, this would call for a different security analysis; our approach (§5), which reduces *Sprints* to standard PoW, becomes inapplicable in the presence of staggered PoD within each branch—specifically, when honest blocks are subjected to PoD and propagation delays. Recall that the approach presented in previous work [10, 30, 31] does not apply to *Sprints* due to its inherently non-Markovian nature.

6.5 Imperfect PoD

So far we have assumed that the adversary cannot solve the PoD faster than the honest miners. This is the main difference between the PoD and VDF primitives. Let us briefly consider a weaker model where the adversary has an *advantage* A_{adv} in solving the PoD, i.e., the adversary can solve the PoD in $A_{adv}^{-1} \cdot \Delta_{PoD}$. In practice, a perfect PoD construction does not exist, although near-perfect PoD ($A_{adv} < 1.05$) may be feasible with trusted setup and hardware [25, 26].

To estimate the impact of the advantage on the adversary's probability, we derive the adversary's probability of finding a block, i.e., the portion of blocks she mines from the total block number, denoted by P^{blk}. Denote by P^H the probability that the attacker finds a block during her head-start while other miners still calculate the PoD. From complete probability, it holds that $P^{blk} = P^H + \alpha_{\mathcal{A}} \cdot (1 - P^H)$. Using the CDF of exponential distribution, $P^H = 1 - \exp(-\frac{\alpha_{\mathcal{A}}}{\rho_{\text{PoW}}}(1 - A_{adv}^{-1}))$. Combining the two equations, we get $P^{blk} = 1 - (1 - \alpha_{\mathcal{A}}) \cdot \exp(-\frac{\alpha_{\mathcal{A}}}{\rho_{\text{PoW}}}(1 - A_{adv}^{-1}))$. This result is presented graphically in Figure 7 with $A_{adv} = 1.05$ [25] and $A_{adv} = 2$. We plot the success probability for different values of $\alpha_{\mathcal{A}}$. This result indicates that when the advantage is small it can affect the adversary's probability of success primarily when the ratio of PoW time to PoD time (ρ_{PoW}) is small and the adversary's hash rate is large. However, a large advantage of $A_{adv} = 2$ significantly increases the adversary's success probability. In this scenario, at large values of ρ_{PoW}, the attacker's advantage grows significantly, making Sprints less fair towards smaller miners. This observation underscores a practical constraint on the ρ_{PoW} parameter. System designers tradeoff minimizing carbon footprint and maintaining robust security considering different potential A_{adv} values.

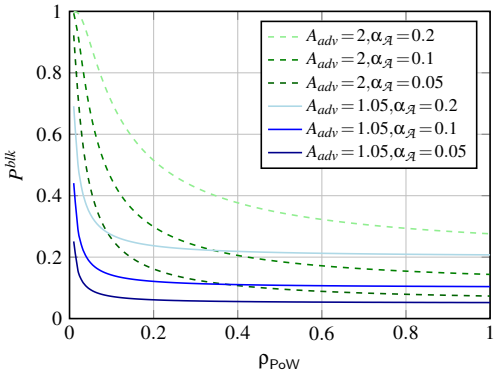

Figure 7: Attacker's block finding success probability P^{blk} against PoW time ratio ρ_{PoW} for various combinations of advantage ratios A_{adv}, attacker hash rates $\alpha_{\mathcal{A}}$.

7 Carbon Footprint Quantification

The primary objective of *Sprints* is to reduce carbon footprint while preserving the security standards that are characteristic of conventional pure Proof-of-Work (PoW) protocols. Our analysis uses conservative assumptions for a lower-bound estimate of carbon footprint reduction. To facilitate a fair comparison between *Sprints* and pure PoW, we compare them assuming the same revenue per second and profit margins for both systems and equal electricity costs so that the aggregate expenses, encompassing hardware acquisition and electricity-related costs, are equivalent in both systems. We compare the carbon footprint of the electricity and hardware that is utilized in both systems using CO2e (Carbon dioxide equivalent [35]). CO2e is a measure expressing the total impact of greenhouse gas emissions including power, hardware manufacturing, transportation and disposal in terms of the amount of CO2e that would have the same carbon footprint.

Most previous studies have focused solely on the carbon emission associated with electricity consumption (e.g., [60–63]). Another study [64] considered the carbon footprint of hardware production and disposal in a similar way to our analysis.

Although *Sprints* reduces each mining rig's electricity consumption by limiting its activity to a ρ_{PoW} portion of the time, this does not lead to a proportional reduction in the overall electricity consumption. This occurs due to the variation in the number of mining rigs between the two systems, i.e., a portion of the expenses are reallocated from electricity consumption to hardware acquisition and miners in *Sprints* purchase more mining hardware. However, the added electricity consumption due to the increased number of rigs in the system is less significant than the reduction in consumption achieved by shortening each rig's active time. For instance, when $\rho_{PoW}=0.05$, the total electricity consumption in *Sprints* is 15.7 times lower than in pure PoW. We conservatively assume that the lifespan of mining hardware is the same in both *Sprints* and pure PoW, this is despite the thermal cycling effect that is expected to reduce the lifespan of mining hardware in *Sprints* [65, 66]. This potential reduction in hardware lifespan could further amplify *Sprints*'s carbon footprint reduction, as it would necessitate more frequent hardware replacements, thereby increasing the CAPEX costs.

While reducing electricity consumption is important, our primary objective is to decrease the overall carbon footprint. To assure this, we take into account the environmental consequences of hardware production and disposal, using data from previous studies [67–69]. Our results (Figure 2) show that despite an increase in total hardware in *Sprints*, the system's overall carbon emission decreases while taking into account the carbon footprint of hardware production and disposal. For example, when ρ_{PoW} is set to 5%, the total carbon footprint of *Sprints* is reduced by 90.8% compared to pure PoW while rare metal depletion increases by 27%. Our OPEX assumptions are conservative and don't account for peak demand-based charges, potentially underestimating *Sprints*'s efficiency [70].

In our analysis, we exclude the electricity consumption and carbon footprint of PoD computation. This is because PoD's non-parallelizable nature inherently limits its power consumption. Thus, a single PoD-optimized device per miner is expected to suffice. In fact, Ethereum Foundation's plans to develop energy-efficient, cost-effective ASICs for similar computations, such as VDFs, in the form of low-power USB sticks [71].

The full details of our analysis are presented in the full version of this paper [47].

8 Conclusion

We present *Sprints*, a hybrid PoD-PoW protocol that shifts costs from OPEX to CAPEX, decreasing the carbon footprint with almost the same security threshold as pure PoW. Moreover, we show that even when keeping the same block interval as Bitcoin and reducing the PoW portion to 5%, the security threshold is only reduced from 50% to 49%, achieving a reduction of 10.9x in resource expenditure with an increase of 1.27x in rare metal depletion.

The *Sprints* design of a hybrid PoW-PoD system can pave the way to an eco-friendly decentralized PoW blockchain protocol.

Abstract

Trajectory prediction forecasts nearby agents' moves based on their historical trajectories. Accurate trajectory prediction (or prediction in short) is crucial for autonomous vehicles (AVs). Existing attacks compromise the prediction model of a victim AV by *directly* manipulating the historical trajectory of an attacker AV, which has limited real-world applicability. This paper, for the first time, explores an *indirect* attack approach that induces prediction errors via attacks against the perception module of a victim AV. Although it has been shown that physically realizable attacks against LiDAR-based perception are possible by placing a few objects at strategic locations, it is still an open challenge to find an object location from the vast search space in order to launch effective attacks against prediction under varying victim AV velocities.

Through analysis, we observe that a prediction model is prone to an attack focusing on a single point in the scene. Consequently, we propose a novel two-stage attack framework to realize the single-point attack. The first stage of prediction-side attack efficiently identifies, guided by the distribution of detection results under object-based attacks against perception, the state perturbations for the prediction model that are effective and velocity-insensitive. In the second stage of location matching, we match the feasible object locations with the found state perturbations. Our evaluation using a public autonomous driving dataset shows that our attack causes a collision rate of up to 63% and various hazardous responses of the victim AV. The effectiveness of our attack is also demonstrated on a real testbed car [1]. To the best of our knowledge, this study is the first security analysis spanning from LiDAR-based perception to prediction in autonomous driving, leading to a realistic attack on prediction. To counteract the proposed attack, potential defenses are discussed.

1 Introduction

Autonomous vehicles (AVs) are transforming transportation systems worldwide. Autonomous driving (AD) systems, e.g., Autoware.AI [1], typically consist of perception, prediction, and planning modules. In this AD system pipeline, the perception module utilizes sensors, such as LiDAR, to detect and track on-road objects; the prediction module forecasts the future trajectories of nearby agents; the planning module determines the AV's future driving behavior. The predicted trajectories are particularly vital for the subsequent planning module as they significantly influence an AV's driving behavior. The existing studies [9, 47, 61] directly compromise the prediction module of a victim AV by manipulating the historical trajectory of an attacker agent nearby, which is usually a vehicle. In these attacks, the attacker's vehicle must drive according to a specific *adversarial driving trajectory* to mislead the victim AV's prediction module into generating wrong future trajectory prediction for the attacker's vehicle. However, it is hard to precisely drive the attacker's vehicle along a pre-computed trajectory due to kinematic constraints. Moreover, such adversarial trajectories are designed based on

(a) A scene with adversarial cardboards placed around a parked car. (b) Random object locations cause a prediction error posing no threat. (c) Brute-force search finds object locations threatening victim vehicle. (d) No longer threatening for victim vehicle approaching at higher speed.

Figure 1: A motivation experiment.

*Equal contribution

[1] A demo video of our attack on a real testbed car is available at https://1drv.ms/v/s!Aoc_mWfaEyaGbrdCPNS9oKMjm9Q?e=f1GA6u.

a restrictive assumption that the victim AV would drive at a certain velocity.

To address these limitations, in this paper, we explore the possibility of indirectly compromising the prediction module via perturbing the perception module of the victim AV such that the perception errors can induce the prediction module to predict a wrong trajectory of a nearby agent. The existing physically-realizable attacks against the LiDAR perception [10, 38, 44, 45] provide a basis for such indirect attack on the prediction module. Among them, object-based attacks, which use specific shapes or common objects to introduce additional adversarial LiDAR points captured by the victim AV, have lower logistics overhead in attack implementation. However, the impact of the perturbed bounding box attributes (including coordinates, dimensions, and heading) as a result of the object-based attack on the subsequent prediction in the AD pipeline has never been systematically studied.

To study the feasibility of compromising the prediction model indirectly via object-based attacks to induce dangerous driving decisions, we conduct a motivation experiment on our custom-built real testbed AV. We employ an object-based attack method from [66], due primarily to its practicality, to plan the locations for placing two *adversarial cardboards* around a car parked roadside, called *adversarial vehicle*, as shown in Fig. 1(a). Then, the victim AV running the LiDAR-based AD pipeline drives by. Fig. 1(b) shows that random object placement may result in a wrongly predicted trajectory of the adversarial vehicle, which stays stationary in reality. However, as the predicted trajectory points to the left, it imposes no threat on the victim AV. Then, we employ brute-force search to find the locations of the two adversarial cardboards that lead to a collision between the victim AV's original trajectory and the adversarial vehicle's trajectory predicted by the victim AV. The search is based on the victim AV's original trajectory. As shown in Fig. 1(c), the attack-induced illusive collision leads to a sudden brake decided by the victim AV's planning module. This result shows the existence of object-based attacks that generate threatening effects penetrating the AV pipeline. However, when the victim AV runs at a varied velocity causing a deviation from the spatio-temporal trajectory assumed by the attacker's brute-force search, the attack becomes no threatening as shown in Fig. 1(d). This paper aims to design an efficient attack approach to identify locations for placing adversarial objects that lead to hazardous responses of the victim AV regardless of its driving velocity.

Our vulnerability analysis via experiments shows that the AV's trajectory prediction is prone to substantial perception errors when the moving victim AV is at a point in the scene. Based on this observation, we choose to reduce the attack design space to focus on a fixed *attack point* and perturb the victim AV's perception to induce prediction errors, when it arrives at the attack point. This strategy greatly reduces the search space yet largely preserves the potential of the attack in leading to the victim AV's hazardous responses. However, as the historical LiDAR frames captured before the victim AV arrives at the attack point form a part of the prediction model's input, the victim AV's velocity still affects the effectiveness of the single-point attack. In addition, the exhaustive search for the locations of multiple adversarial objects in the 3D proximity space of the adversarial vehicle, while considering all possible victim AV's velocity values for robustness to velocity variations, still incur undesirable overhead.

To address the above two issues related to the single-point attack strategy, we design a novel two-stage attack framework. In the stage of *prediction-side attack*, we maximize attack effectiveness by searching for input state perturbations for the prediction model that maximize the interference between the predicted trajectory of the adversarial vehicle and the victim AV's planned trajectory. To maintain attack effectiveness across various velocity conditions, we employ the Expectation over Transformation (EoT) technique. Our experiment shows that, with object-based attacks, the perturbed detection results (i.e., bounding boxes) of the adversarial vehicle exhibit distributional patterns. Thus, we utilize the distribution to guide the optimization of the state perturbations for the prediction model, which improves the efficiency of attack design. We use the Projected Gradient Descent (PGD) method to iteratively search for the state perturbations and select the perturbations that lead to collisions. However, the optimized state perturbations may not translate to feasible perturbed detection results caused by the placement of adversarial objects. To achieve attack feasibility, in the stage of *location matching*, we employ the Hungarian algorithm to match the adversarial locations with the optimized state perturbations and further refine the candidate adversarial locations by probing in their close vicinity for reducing the matching cost.

We conduct experiments on both the nuScenes [6] autonomous driving dataset and our real testbed AV. In the dataset-based experiments, our attack achieves a collision rate of up to 63%, effectively inducing various hazardous responses of the victim, including sudden brakes, accelerations, and unexpected lane changes, in the presence of object displacement errors and object size variations. In the physical-world experiments with our custom-built testbed AV, our attack is effective in various velocity conditions and achieves the highest attack success rate compared with the random location and the brute-force sampling attacks. The experiments also show that our attack is robust against object displacement errors and variations in the victim AV's direction.

Our main contributions can be summarized as follows:

- We design and launch the first physical-world attack on the AD system's trajectory prediction by strategically placing objects to indirectly induce prediction errors, leading to hazardous responses of the victim AV.
- We find that the prediction model is susceptible to the single-point attack. Built upon this, we design a novel two-stage attack framework that efficiently identifies adversarial locations for object placement, leading to

effective, velocity-insensitive, and feasible attacks.
- Our attack is evaluated on both a public autonomous driving dataset and a custom-built real-world testbed AV, achieving consistently higher threats compared with the baselines and attack robustness. Additionally, we propose potential defenses to mitigate the threat.

2 Background and Related Work

2.1 Autonomous Driving System

A typical AD system consists of perception, trajectory prediction, and motion planning modules, as detailed below.

LiDAR-based Perception, known for its precision in acquiring environmental data, is widely adopted in the default pipeline of open-source AD systems [5] and in commercial solutions [50, 51]. This process starts with 3D object detection, which analyzes a LiDAR point cloud to identify objects around the ego vehicle. Modern AD perception utilizes deep learning models, denoted by $M_{det}(\cdot)$, to process LiDAR point cloud D and produce a set of 3D bounding boxes $\mathbf{B} = M_{det}(D)$. A bounding box $\mathbf{b} \in \mathbf{B}$, characterized by coordinates, dimensions, heading, and a confidence score, represents a detected object. Existing 3D object detection methods can be divided into Bird's Eye View (BEV)-based [56], voxel-based [55, 57], and point-based [43]. They respectively map point clouds into 2D representation, discretize 3D space into voxels, and operate on raw point cloud directly. Detected objects are tracked over time by an object tracking model M_{track}.

Trajectory Prediction forecasts the future trajectories of road agents (vehicles and pedestrians) based on their current and historical states perceived over H time steps denoted by $\mathbf{X} = (\mathbf{X}^{-H+1}, \ldots, \mathbf{X}^0)$, where $\mathbf{X}^t = (\mathbf{x}_1^t, \ldots, \mathbf{x}_{N_a}^t)$ represents the states of N_a agents at time step t and each $\mathbf{x}^t$ includes an agent's coordinates, velocity, acceleration, and heading. The trajectory prediction for a horizon of T time steps by a predictor $M_{pred}(\cdot)$ is $\mathbf{Y} = (\mathbf{Y}^1, \ldots, \mathbf{Y}^T) = M_{pred}(\mathbf{X})$, where $\mathbf{Y}^t = (\mathbf{y}_1^t, \ldots, \mathbf{y}_{N_a}^t)$ is the predicted coordinates of the N_a agents at time step t. Existing trajectory predictors employ recurrent neural networks [28, 31], graph neural networks [29, 59], and transformers [30, 63]. Recent generative predictors such as Trajectron++ [39] and AgentFormer [58], which perform conditional sampling and selection, have shown superior performance and are therefore employed in this work.

Motion Planning takes into account road agents' current states $\mathbf{X}^0$ and trajectory prediction results $\mathbf{Y}$ to plan a safe, efficient, and feasible future trajectory $\mathbf{P} = M_{plan}(\mathbf{X}^0, \mathbf{Y})$ for the ego vehicle. Existing solutions can be divided into sampling-based [26], control-based [15], graph search-based [17], and learning-based methods [41, 60].

2.2 Adversarial Attacks

Deep learning models are shown to be vulnerable to adversarial examples [12, 19, 27, 32, 37, 42, 46, 48, 53, 62], which are perturbed input samples that mislead the model to generate erroneous outputs. Specifically, given a model $M(\cdot)$, for a benign input x with ground truth label y, the attack searches for a minimal perturbation δ such that $M(x+\delta) \neq y$ (non-targeted attack) or $M(x+\delta) = y'$ (targeted attack), where y' is the target label. Adversarial examples may pose great threat on the safety-critical AD systems that employ deep learning models for perception and prediction. In what follows, we review the existing adversarial attacks on LiDAR-based perception, trajectory prediction, and motion planning, respectively.

The attacks on LiDAR-based perception are studied in both simulations [20, 21] and physical environments. Physical-space attacks fall into two groups: *laser-based* [7, 10, 25, 38, 40, 44, 45] and *object-based* [8, 49, 64, 66]. The former, also known as spoofing, injects fake points by intercepting LiDAR's emitted laser pulses using a receiver and then transmitting counterfeit pulses back to the LiDAR sensor with a manipulated delay. However, such attacks require precise timing and specialized equipment, making them costly and conspicuous. Object-based attacks use physical objects to mislead LiDAR detection models. For example, in [66], a vehicle can be hidden from LiDAR detection by placing common objects at computed adversarial locations near the vehicle. Both laser-based and object-based attacks usually hide or create objects by manipulating bounding box confidence scores. Yet, their effects on bounding box parameters (coordinates, dimensions, and heading) and the impact of induced errors in estimating these parameters on subsequent AD modules remain largely unexplored. This work considers object-based attacks that are more realistic for real-world deployments.

In the tracking module, tracker hijacking attacks [13, 22–24, 34, 54] perturb camera image inputs to manipulate bounding box parameters. A primary goal of these attacks is object move-in, which manipulates the tracker of a roadside object towards the road center, potentially inducing falsified trajectories similar to ours due to pipeline effects. However, these studies focus exclusively on the tracking module, while our attack optimizes such effects in the downstream trajectory prediction module. Unlike these studies that focus on camera-only systems, our attack applies to LiDAR-based perception, introducing unique challenges and attack vectors that necessitate new methodologies.

The attacks on trajectory prediction perturb the input states of the adversarial vehicle and mislead the victim AV's prediction model. However, existing methods either neglect the kinematic laws governing the adversarial vehicle [47, 61] or disregard the driving uncertainties of the victim AV, including speed variations [9, 11], which could alter the adversarial vehicle's input states during the attack. Differently, this paper plans the object-based attacks that generate pipeline effect on LiDAR-based perception and then trajectory prediction.

There are a few studies focusing on physical attacks against motion planning. The work [52] uses common road objects to trigger a Semantic Denial-of-Service in the motion planning

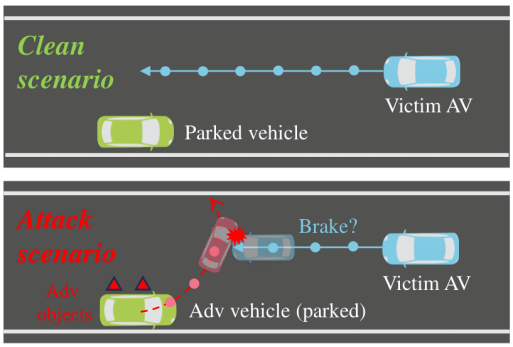

Figure 2: Our attack scenario. Solid blue arrows are victim AV's planned trajectories; dash red arrow is adversarial vehicle's future trajectory predicted by the victim AV.

module, causing emergency stops or critical driving decision failures. In comparison, this paper targets the trajectory prediction module in AD systems. Regarding methods, the work in [52] exploits flaws in programming code logic, while our attack focuses on vulnerabilities in learning-based perception and prediction models, highlighting a distinct approach in exploiting AD systems' weaknesses.

3 Threat Model

Attack Goal. We consider an attack scenario depicted in Fig. 2, where a static adversarial vehicle is parked on the roadside, while a victim AV is driving and approaching it on the adjacent lane. Such a scenario is common in urban driving environments, such as street parking, industrial areas, and parking lots. We assume that the victim AV runs the AD pipeline of LiDAR-based perception, trajectory prediction, and motion planning. The attack goal is to manipulate the victim AV's perception, such that the prediction forecasts an erroneous moving trajectory for the static adversarial vehicle and causes the victim AV's motion planning to decide a hazardous driving strategy. This can be motivated by intentional harm towards an individual, unhealthy competition among solution vendors aiming to undermine the safety reputation of rivals' self-driving products, or the intent to disrupt traffic mobility by causing traffic jams [36]. The manipulation of the victim AV's perception is achieved by placing some adversarial common objects, e.g., cardboards, around the adversarial vehicle. The key for the perception manipulation is to identify the *adversarial locations* for placing the adversarial objects, such that the victim AV's LiDAR-based perception generates inaccurate bounding boxes over time for the adversarial vehicle. The attack aims at misleading the victim AV to produce a falsified trajectory of the adversarial vehicle that intersects the victim AV's planned trajectory. As a result, the victim AV re-plans the motion to avoid the illusive collision with safety-undermining driving decisions, including emergent braking, sudden acceleration and/or lane change.

Attacker Capabilities. We assume that the attacker is capable of placing objects around an adversarial vehicle, which can be the attacker's own car or a random car parked on the roadside. We consider a realistic but challenging setting in which the attacker has no access to the real-time data (e.g., LiDAR point cloud) collected by the victim AV. We consider the white-box attacker that has comprehensive knowledge of the victim AV's AD pipeline. This enables the attacker to query and analyze $M_{det}(\cdot)$, M_{track}, and $M_{pred}(\cdot)$ for crafting attacks. To obtain these three models, the attacker can use social engineering on the system designers of the car manufacturers or reverse-engineer a vehicle identical to the victim AV. For the vehicles employing open-source AD systems [1, 2], the overhead of obtaining the three models $M_{det}(\cdot)$, M_{track}, and $M_{pred}(\cdot)$ can be lower. Before launching the attack, the attacker gathers data by driving a LiDAR-equipped vehicle to mimic the victim AV's behavior. The attacker uses the data to determine the locations for placing the objects.

4 Challenges and Problem Definition

4.1 Attack Challenges

Challenges to identify effective adversarial locations include:

Challenge C1: Maximizing Attack Effectiveness. Inducing errors in predicting the adversarial vehicle's trajectory, quantified by metrics such as average displacement error (ADE) and final displacement error (FDE), as in the literature, does not necessarily imply a threat to the victim AV. An erroneously predicted moving trajectory for an adversarial vehicle that is stationary in reality, if not intersecting the victim's planned trajectory, poses no actual danger. To maximize attack effectiveness, a meaningful objective is to minimize the distance between the adversarial vehicle's predicted trajectory and the victim AV's planned trajectory.

Challenge C2: Velocity-Induced Uncertainty in Attack Effectiveness. The victim AV may drive by the adversarial vehicle at varying velocities. When the victim AV's velocity is different from that used for attack construction, the victim AV's perception results and the consequent predicted trajectory of the adversarial vehicle may differ from those expected by the attacker. Thus, should the victim AV deviate from its expected trajectory, the effectiveness of the pre-determined adversarial locations may be reduced.

Challenge C3: Vast Search Space for Adversarial Locations. Given the non-differentiable processes within the AD system's independent modules, employing gradient-based optimization to achieve the attack goal presents significant difficulties. A straightforward approach would be exhaustively sampling a multitude of locations in the vicinity of the adversarial vehicle in order to identify the most effective set of adversarial locations. However, such a brute-force sampling approach faces efficiency challenges, particularly in time-sensitive scenarios. For instance, if an attacker can only

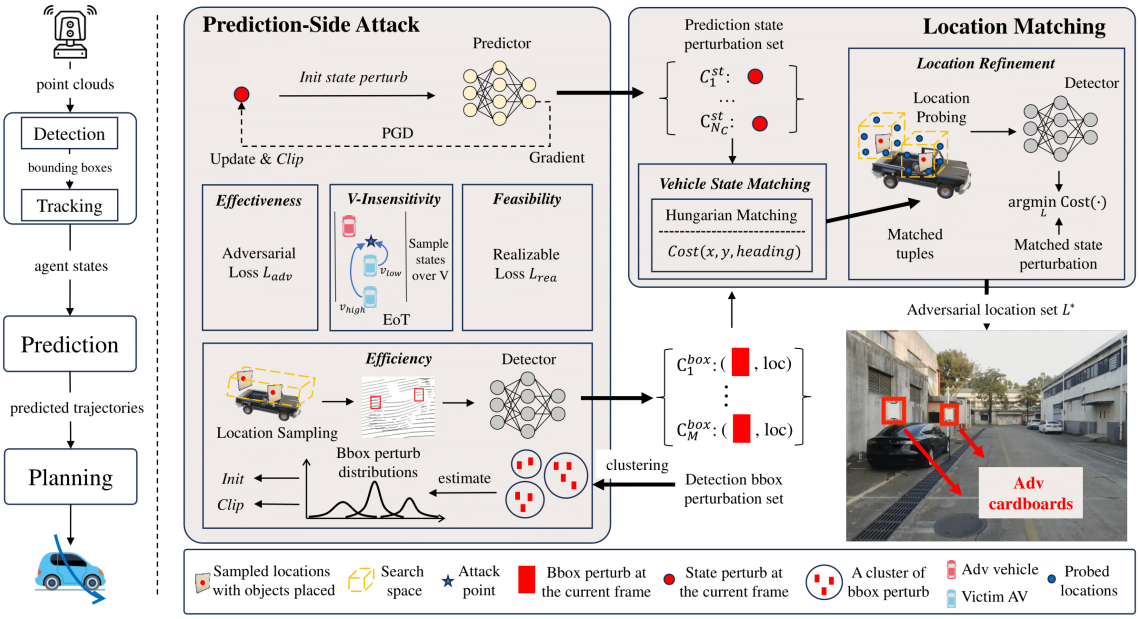

Figure 3: Our proposed inverse attack framework for identifying the adversarial locations to place objects (cardboards in red boxes). The framework operates within the AD system pipeline, which is outlined on the left for reference.

determine the victim AV's route after it departs, it has limited time to plan and deploy the attack. First, even if we restrict the search area to only the top of the adversarial vehicle and its immediate surroundings, the search space is still extensive and grows exponentially with the number of adversarial objects. Second, if the search further accounts for the victim AV's velocity as an additional dimension to address **C2**, the search space is even larger.

4.2 Problem Definition

We aim to identify a set of adversarial locations $L = \{l_n | n = 1, ..., N_L\}$, where $l_n \in \mathbb{R}^3$ is the 3D coordinates of the n-th adversarial location and N_L is the number of locations we consider, to achieve the attack goal. Inspired by the finding **F1** in Section 5.2, we propose to establish a fixed *attack point* and manipulate the prediction of the adversarial vehicle when the victim AV reaches this point. In this way, the perception of the adversarial vehicle at the attack point is independent of the victim AV's velocity. We let $t = 0$ denote the time step when the victim AV arrives at the attack point. The point cloud frame captured by the victim AV's LiDAR at $t = 0$ is referred to as the *current frame*. We formulate the problem of identifying L as:

$$\begin{aligned} \arg\max_{L} \quad & \mathbb{E}_{v \in V}[\text{Interference}(\tilde{\mathbf{Y}}^v, \mathbf{P}^v)], \\ \text{s.t.} \quad & \tilde{\mathbf{Y}}^v = M_{pred}(\tilde{\mathbf{X}}^v), \\ & \tilde{\mathbf{X}}^v = M_{track}(\{M_{det}(D_t^v(L)) | t = -H+1, \ldots, 0\}), \end{aligned} \tag{1}$$

where v is the victim AV's velocity sampled from a range V; $D_t^v(L)$ is the LiDAR point cloud captured by the victim AV with velocity v at time step t when the adversarial objects are placed at L; the $\{M_{det}(D_t^v(L)) | t = -H+1, ..., 0\}$ is the sequence of the victim AV's detection results regarding the adversarial vehicle over H time steps; $\tilde{\mathbf{X}}^v$ represents the adversarial vehicle's states observed by the victim AV, determined by the tracking model $M_{track}(\cdot)$ based on the detection results; $\tilde{\mathbf{Y}}^v$ is the trajectory of the adversarial vehicle predicted by the victim AV; $\mathbf{P}^v$ is the original planned trajectory of the victim AV; Interference$(\tilde{\mathbf{Y}}^v, \mathbf{P}^v)$ represents the interference between the trajectories $\tilde{\mathbf{Y}}^v$ and $\mathbf{P}^v$. One meaningful definition of the interference is the reciprocal of the average distance between the adversarial vehicle moving on $\tilde{\mathbf{Y}}^v$ and the victim AV moving on $\mathbf{P}^v$. In the above formulation, the quantities with the superscript v are affected by the victim AV's velocity v.

5 Attack Design

To achieve the attack goal defined in Eq. 1 while addressing the attack challenges summarized in Section 4.1, we design a novel two-stage attack framework as shown in Fig. 3. This framework aims to identify adversarial locations for placing objects that mislead the victim AV into forecasting a falsified future trajectory of the adversarial vehicle, inducing dangerous driving behaviors conducted by the victim AV.

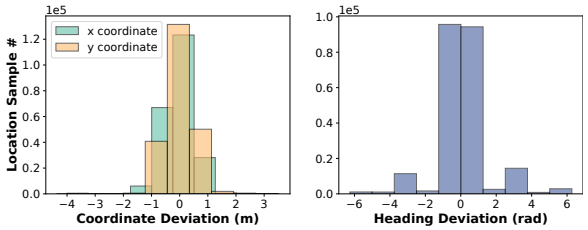
5.1 Approach Overview

Our attack framework is built upon two key insights. First, the widespread use of learning-based models in AD systems, which are vulnerable to adversarial inputs, presents a potential attack surface to impact downstream modules such as trajectory prediction through pipeline effects. Second, in contrast to

Table 1: Average distance between predicted trajectory of adversarial vehicle and victim AV's planned trajectory. A smaller distance indicates a higher collision risk.

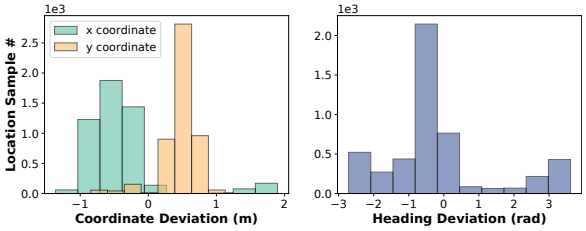
Model	Average Distance (m)					
	Clean	Attacked Frame Index				
		-4	-3	-2	-1	0
Trajectron++	6.3	6.1	6.1	5.9	3.0	2.7
AgentFormer	6.3	5.9	5.8	5.8	5.0	3.9

the brute-force forward sampling attack that is inefficient and often gets stuck in local optima, our inverse attack strategy effectively exploits vulnerabilities in the prediction module for enhanced effectiveness and efficiency.



At a high level, our framework compromises modules from prediction to perception. It initiates by conducting adversarial attacks on the prediction module to generate adversarial states, i.e., the adversarial inputs of the trajectory prediction module that can mislead the module into forecasting a falsified future trajectory of the adversarial vehicle. Then, we conduct object-based attacks on the perception module, which generates adversarial locations. Placing objects at these locations can mislead the perception module to generate the adversarial bounding box perturbations, resulting in the desired adversarial states in the previous step.

The first stage, called *prediction-side attack* as detailed in Section 5.3, is designed to find state perturbations that mislead the victim AV's prediction model. Firstly, we address the attack effectiveness challenge **C1** by minimizing the distance between the predicted trajectory of the adversarial vehicle and the planned trajectory of the victim AV. Secondly, we propose a fix-point attack based on a key finding **F1** presented in Section 5.2 that the trajectory prediction models are especially susceptible to the adversarial attack at the current frame. Together with the Expectation over Transformation (EoT) technique applied to various velocities of the victim AV, we address the velocity-insensitivity challenge **C2**. Thirdly, we address the vast search space challenge **C3** by utilizing a feasible set of detection results to guide the searching for effective state perturbations against the prediction model, which is based on a key finding **F2** presented in Section 5.2, i.e., the detection results under object-based attacks are limited and exhibit distributional patterns. Lastly, we employ the Projected Gradient Descent (PGD) method to iteratively update the state perturbations and select the perturbations that lead to collisions.



The second stage, called *location matching* as detailed in Section 5.4, finds the adversarial locations for placing common objects that can implement the state perturbations found by the prediction-side attack.

5.2 Findings

We conduct experiments to gain key insights for the design of our attack, as detailed below.

(a) nuScenes Dataset.

(b) Self-Collected Scene.

Figure 4: Histogram of coordinates and heading perturbations in nuScenes dataset scenes and a self-collected real-world scene under object-based attacks.

Finding F1: Trajectory prediction models are vulnerable to single-point attack at the current frame. To address challenge **C2**, we conduct a vulnerability analysis of two representative trajectory prediction models: Trajectron++ [39] and AgentFormer [58]. Both models take five historical states as input to predict the future trajectory. We apply the PGD method to perturb each of the five historical states. We add random noises to the remaining states to simulate noisy conditions in practice. The PGD attack minimizes the average distance between the predicted trajectory of the adversarial vehicle and the victim AV's planned trajectory. Then, we measure this average distance under both clean and single-point attack scenarios. The results presented in Table 1 show that perturbing the current state (i.e., $t = 0$) achieves the smallest average distance, indicating the highest threat for collision. The reasons are two-fold. First, models such as Trajectron++ sequentially process input states using LSTM, which relies heavily on the most recent input state. Second, models including AgentFormer transform input states into a local coordinate system centered on the current frame. Thus, a small perturbation on the current state has the largest impact on the prediction result. The finding reveals that for a trajectory prediction model $M_{pred}(\cdot)$ and a sequence of H input states $\mathbf{X} = (\mathbf{X}^{-H+1}, \cdots, \mathbf{X}^{0})$, the model is particularly susceptible to adversarial attacks targeting the current state $\mathbf{X}^{0}$, despite variations in historical states due to say different velocities. Therefore, by focusing the design of the attack on a fixed *attack point* that the victim AV arrives at, we can simplify the problem and preserve the potential of the attack in inducing victim AV's hazardous responses.

Finding F2: 3D object detection results under attack exhibit distributional patterns that help improve attack efficiency. We follow the approach in [66] to compromise

LiDAR-based 3D object detection systems. The principle behind this attack is that strategic placement of adversarial objects distorts the vehicle's perceived shape, perturbing the object detector's geometric feature recognition. To analyze the resulting bounding box perturbations, we conduct experiments to launch attacks on 100 driving scenes from the nuScenes dataset [6] and a self-collected real-world driving scene. For each driving scene, we uniformly sample 500 candidate locations around the adversarial vehicle to place objects and record the resulted *bounding box perturbation* in five consecutive frames, which is defined as the deviation of the bounding box for the adversarial vehicle with and without attack. To be more specific, we measure the deviations of the x and y coordinates and the heading h of the bounding box, which serve as the inputs to the downstream trajectory prediction. Based on the experiment results in Fig. 4, we can observe that the bounding box perturbations caused by placing adversarial objects exhibit distributional patterns. The deviations of x and y coordinates are primarily distributed within the interval [-1, 1]. The distribution of heading deviations exhibits distinct clusters. Note that heading deviations of around $\pm$1rad mean that the adversarial vehicle is perceived to have a heading close to its actual heading, while deviations of $\pm$3rad indicate a heading in the opposite direction. This finding is key to address the vast search space challenge **C3**. This is because, instead of exhaustive location sampling, we only need a limited number of location probes to recognize the bounding box perturbation distribution, thus improving efficiency in finding adversarial locations.

5.3 Prediction-Side Attack

To mislead victim AV's trajectory prediction model, we need to identify the *state perturbation* at the current time step, which is added to the input states of the prediction model. It is denoted by $\delta^{\text{st}} = \{\delta_x^{\text{st}}, \delta_y^{\text{st}}, \delta_h^{\text{st}}\}$, where x, y, and h indicate x coordinate, y coordinate, and heading, respectively. Now, we discuss the considerations when designing δ^{st} to address the three challenges presented in Section 4.1.

Attack Effectiveness. To find the state perturbation at the current time step that can address challenge **C1** and achieve the attack goal defined in Eq. 1, we propose *Adversarial Loss* $\mathcal{L}_{adv} = \|\tilde{Y}^v - P^v\|_2$, which maximizes attack effectiveness by minimizing the ℓ_2 distance between the predicted trajectory of the adversarial vehicle $\tilde{Y}^v$ and the original planned trajectory P^v of the victim AV.

Attack Efficiency. Given the vast search space as mentioned in challenge **C3** in Section 4.1, finding a physically feasible state perturbation achieved by placing objects around the adversarial vehicle is costly. To address this, we rely on the finding **F2** and leverage a set of physically feasible detection results under object-based attack to efficiently guide the searching for the effective state perturbation. Specifically, we evenly sample a small number of locations around the adversarial vehicle to derive a *bounding box perturbation* set

C^{box}. Each element in this set consists of a bounding box perturbation $\delta^{\text{box},m} = \{\delta_x^{\text{box}}, \delta_y^{\text{box}}, \delta_h^{\text{box}}\}$ and its corresponding location set L_m. Based on the distribution of the bounding box heading perturbation, we divide C^{box} into a set of clusters R. For each cluster r in R, the bounding box perturbation δ_i^{box} follows the distribution $\mathcal{N}(\mu_i^r, \sigma_i^r)$, where $i \in \{x, y, h\}$. Then, for each r in R, we leverage the estimated bounding box perturbation distribution to constrain the searching for the state perturbation by the following two steps. (1) At the start of each attack epoch, we initialize the state perturbation δ_i^{st} from the estimated distribution $\mathcal{N}(\mu_i^r, \sigma_i^r)$, $i \in \{x, y, h\}$, and then conduct iterative updates for attack optimization. At the end of each update, we clip δ_i^{st} within the range $[\mu_i^r - 2\sigma_i^r, \mu_i^r + 2\sigma_i^r]$ for $i \in \{x, y, h\}$. (2) We define a *Realizable Loss* as $\mathcal{L}_{rea} = \|\delta^{\text{st}} - \underset{\delta^{\text{box}} \in C^{\text{box}}}{\text{argmin}} \|\delta^{\text{st}} - \delta^{\text{box}}\|_1\|_1$, aiming to minimizes the ℓ_1 distance between δ^{st} and its closest δ^{box} in C^{box}. An advantage of constraining the state perturbation within multiple clusters is that the generated perturbations are diversified, which enhances the probability of finding adversarial locations capable of achieving the desired perturbation.

Velocity-Insensitivity. To address challenge **C2**, we rely on the finding **F1** and aim to identify a state perturbation δ^{st} effective for the victim AV passing the attack point at various velocities. To achieve this, we employ the Expectation over Transformation (EoT) technique [4]. Specifically, we compute the expected sum of adversarial and realizable losses over a range of possible adversarial and victim AV input states associated with various velocities. To simulate the historical

states of the victim AV, we fix the current frame at the attack point and backtrack the vehicle's motion using a kinematic model to obtain historical frames, ensuring compliance with vehicle dynamics. For the adversarial vehicle, we randomly sample states from the bounding box perturbation distribution. In each iteration, we update the state perturbation using the average losses across sampled velocities.

Optimization Procedure. To summarize, we propose the optimization problem in Eq. 2.

$$\begin{aligned} \arg\min_{\delta^{\text{st}}} \quad & \mathbb{E}_{v\in V}[\mathcal{L}_{adv}(\tilde{Y}^v, P^v) + \mathcal{L}_{rea}(\tilde{X}^v, C^{\text{box}})], \\ \text{s.t.} \quad & \tilde{Y}^v = M_{pred}(\tilde{X}^v), \quad \tilde{X}^v = X^v + \delta^{\text{st}}, \\ & \delta_i^{\text{st}} \in [\mu_r^i - 2\sigma_r^i, \mu_r^i + 2\sigma_r^i], \forall i \in \{x,y,h\}. \end{aligned} \tag{2}$$

The attack procedure is summarized in Alg. 1. The goal is to identify a set of candidate state perturbations, denoted as $C^{\text{st}} = \{\delta^{\text{st},n}\}_{n=1}^{N_C}$, that are effective and velocity-insensitive. Given the bounding box perturbation set C^{box} and corresponding distribution clusters R, for each cluster r in R, we conduct multiple attack epochs starting from initializing δ^{st} within its respective distribution (line 3). We compute the average loss on different victim AV's velocities and use it to iteratively update δ^{st} with the PGD method (lines 5-10). At the end of each iteration, we clip δ^{st} to its distribution range (line 11). Due to the randomness in initialization and optimization, the candidate δ^{st} may not lead to a successful attack. To select effective state perturbations for forming the set C^{st}, we utilize the criteria in [14] to evaluate collision likelihood between the adversarial vehicle's predicted trajectory $\tilde{Y}$ and the victim AV's planned trajectory P. In particular, a collision is defined when the outer circumferences of both vehicles intersect. We choose only perturbations that cause collisions to form the final set C^{st} (lines 13-15).

5.4 Location Matching

In prediction-side attack, we efficiently identify a set of state perturbations of the adversarial vehicle that are effective and velocity-insensitive. To launch a successful attack in the real world, we must also identify an adversarial location set L^* that can achieve the desired state perturbations. To achieve this feasibility, we adopt a two-step solution, including the *Vehicle State Matching* and *Location Refinement*. The procedure is illustrated in Alg. 2.

Vehicle State Matching. In this step, we utilize the sampled bounding box perturbation set C^{box} in Section 5.3 to estimate the object locations that can achieve the desired state perturbations. Specifically, we employ the Hungarian algorithm to find the matched bounding box perturbation $\hat{\delta}^{\text{box},m}$ and its corresponding adversarial location set $\hat{L}_m$ in C^{box} with each desired state perturbation $\delta^{\text{st},n}$ in C^{st}. The cost matrix for the Hungarian algorithm is defined as:

$$\text{cost}(m,n) = \sum_{i\in\{x,y,h\}} w_i \cdot |\delta_i^{\text{box},m} - \delta_i^{\text{st},n}|. \tag{3}$$

Algorithm 2 Location Matching

Require: State perturb set C^{st}, bbox perturb set C^{box}

1: *// Vehicle State Matching*
2: $N_C \leftarrow$ size of C^{st}, $M \leftarrow$ size of C^{box};
3: Init. cost matrix of size $N_C \times M$;
4: **for** $n \leftarrow 1$ to N_C **do**
5: **for** $m \leftarrow 1$ to M **do**
6: Calculate $cost(m,n) \leftarrow \sum_{i\in\{x,y,h\}} w_i \cdot |\delta_i^{\text{box},m} - \delta_i^{\text{st},n}|$;
7: **end for**
8: **end for**
9: Apply Hungarian Algorithm to *cost*;
10: Generate matched tuples $(\hat{\delta}^{\text{box},n}, \hat{L}_n, \delta^{\text{st},n})_{n=1}^{N_C}$;
11:
12: *// Location Refinement*
13: $L^* \leftarrow$ null;
14: **for** each tuple $(\hat{\delta}^{\text{box},n}, \hat{L}_n, \delta^{\text{st},n})$ **do**
15: Init. $f_{\min} \leftarrow$ current cost, $L_{\min} \leftarrow \hat{L}_n$;
16: **for** each location set L near $\hat{L}_n$ **do**
17: Calculate cost $f = \sum_{i\in\{x,y,h\}} w_i \cdot |\delta_i^{\text{box},L} - \delta_i^{\text{st},n}|$;
18: **if** $f < f_{\min}$ **then**
19: $f_{\min} \leftarrow f$, $L_{\min} \leftarrow L$;
20: **end if**
21: **end for**
22: $L^* \leftarrow L^* \cup \{L_{\min}\}$;
23: **end for**
24: **return** Adversarial location set L^*

Here, $\text{cost}(m,n)$ is the matching cost between the m-th bounding box perturbation $\delta_i^{\text{box},m}$ and the n-th state perturbation $\delta_i^{\text{st},n}$, for $i \in \{x,y,h\}$. The w_i represents the pre-set weights corresponding to $\{x,y,h\}$, where elements with larger normalized perturbation in δ^{st} are assigned greater weights. For instance, if a desired state perturbation has a larger normalized δ_x^{st} value compared with the normalized δ_y^{st} and δ_h^{st}, we will assign a larger weight to x. This is inspired by our empirical observation that a larger perturbation is more related to the change of a prediction result. For each desired state perturbation, this step finds all the matched bounding box perturbation and its corresponding location set, generating matched tuples $(\hat{\delta}^{\text{box},n}, \hat{L}_n, \delta^{\text{st},n})$, for $n = 1, \ldots, N_c$.

Location Refinement. Due to the limited samples in C^{box}, the bounding box perturbation $\hat{\delta}^{\text{box},n}$ matched in the above Vehicle State Matching step might not precisely align with the desired state perturbations $\delta^{\text{st},n}$. This step aims to refine candidate adversarial locations, thereby further aligning the corresponding bounding boxes towards the desired state perturbations. Specifically, we search for refined adversarial location set in close proximity to $\hat{L}_n$, aiming to reduce the cost $f = \sum_{i\in\{x,y,h\}} w_i \cdot |\delta_i^{\text{box},L} - \delta_i^{\text{st},n}|$, where $\delta_i^{\text{box},L}$ is a bounding box perturbation after placing objects at L near $\hat{L}_n$. We ran-

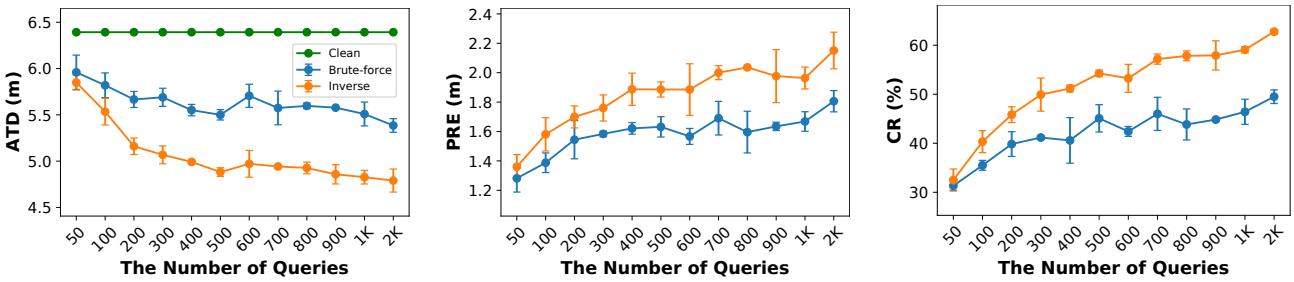

Figure 5: Average Trajectory Distance (ATD), Planning-Response Error (PRE), and Collision Rate (CR) under clean, brute-force sampling attack, and our inverse attack scenarios.

domly probe multiple locations in the vicinity of $\hat{L}_n$. The probing space is defined as small cubes centered around each $\hat{l}_n$ in $\hat{L}_n$, as shown in Fig. 3. We set the cube size to be nearly equal to the voxel size of the LiDAR detector, allowing for moderate detection shifts. Finally, the refined location set leading to the smallest cost value is selected to form the final adversarial location set L^*.

6 Experiments on Dataset

In this section, we evaluate our attack using a public real-world autonomous driving dataset. This data-driven evaluation quantifies the effectiveness and robustness of our attack.

6.1 Experiment Setting

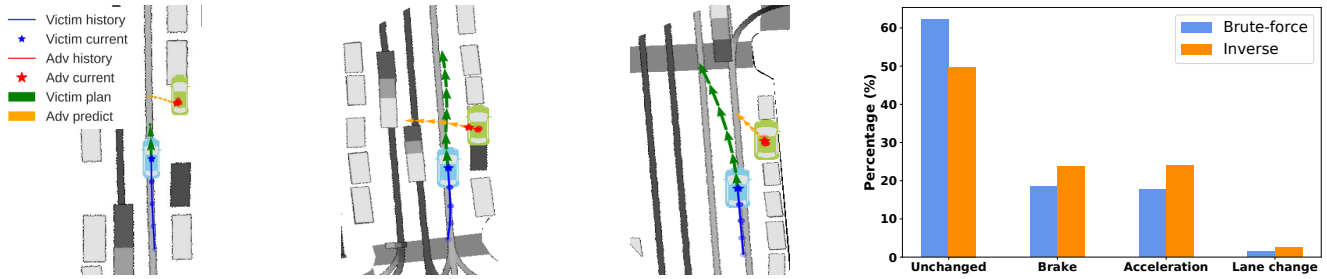
Dataset. We select 100 driving scenes from the nuScenes dataset [6], a large-scale autonomous driving dataset consisting of extensive data and labels covering both perception and prediction. The scene selection criteria are as follows. We select driving scenes aligned with our specified attack scenario, in which the ego vehicle approaches a static vehicle parked on the roadside. The parked vehicle is viewed as the adversarial vehicle; the ego vehicle serves as the victim AV. In each scene, we ensure that the victim AV starts with a minimum separation of 20 meters from the adversarial vehicle and reaches an attack point at a distance of less than 10 meters. During the attack planning, we leverage the annotated key frames captured at 2 Hz in the nuScenes dataset to identify the adversarial location set. We then evaluate these locations on frames that simulate various velocities of the victim AV, selected via a kinematic model from the unannotated nuScenes dataset sampled at 20 Hz. We simulate variations in the victim AV's velocities at 1.5x, 1.25x, 0.75x, and 0.5x of the original recorded speed.

AD Models. We employ representative models for the victim AV's AD system. We use PIXOR [56] for LiDAR-based detection, CenterPoint Tracker [57] for tracking, Trajectron++ [39] for trajectory prediction, and a Model Predictive Control (MPC)-based planner [15] for motion planning. Note that Trajectron++ is a widely used and open-source prediction model on the nuScenes dataset. We train both PIXOR and Trajectron++ using their default configurations.

Adversarial Object. Following [66], we simulate adversarial objects at three adversarial locations. Each object is represented by a random point cluster with a radius of 0.2 m. The number of points in each cluster is set to 4. During the location sampling step to derive C^{box}, the search space is a $4 \times 4 \times 1\,\text{m}^3$ cube above the adversarial vehicle. In the location refinement, we reduce the search space to a sphere with a radius of 0.1 m, allowing for more precise adjustments.

Evaluation Metrics. We employ the following three metrics to measure the attack performance:

Average Trajectory Distance (ATD): This is the average distance between the predicted trajectory of the adversarial vehicle and the victim AV's original planned trajectory. It inversely quantifies the efficacy for the interference of the adversarial vehicle's trajectory to the victim AV. A smaller ATD suggests a larger interference.



Planning-Response Error (PRE): The average displacement error between the victim AV's planned trajectories in the presence and absence of attack, respectively. A greater PRE signifies an increased tendency for the victim AV to deviate from its original action.

Collision Rate (CR): The proportion of the adversarial vehicle's predicted trajectories that intersect with the victim AV's planned trajectories in any future frame. Such intersections imply hazardous driving actions by the victim AV.

Baseline: Brute-Force Sampling. This straightforward baseline samples numerous locations around the adversarial vehicle and identifies the location set that results in the smallest ATD as the adversarial location set. We employ this customized baseline because there is no existing attack that can achieve the goal of this work.

6.2 Attack Effectiveness

Fig. 5 shows the error bars representing the mean and standard deviation of ATD, PRE, and CR values achieved by three repeated experiments. "The number of queries" refers to the maximum number of queries the attacker can make to the victim's AD system. For instance, if the number of queries is set to 100, the attacker is limited to sample at most 100 locations around the adversarial vehicle and restricted to a total of 100 queries across all interactions with the victim AV's detection, tracking, prediction, and planning models. From

(a) Sudden brake scene. (b) Sudden acceleration scene. (c) Lane change scene. (d) Attack impacts categorization.

Figure 6: The attack impacts are categorized into *unchange*, *sudden brake*, *acceleration*, and *lane change*, with the latter three indicate hazardous driving behaviors.

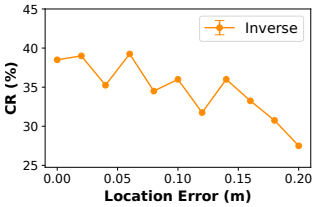


Figure 7: Attack robustness against object displacement.

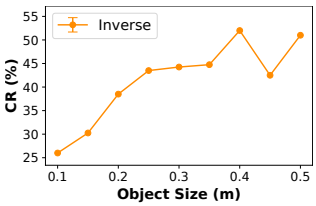

Figure 8: Attack robustness against object size.

the results, we can see that our method with 2,000 queries achieves the best attack performance, with the lowest ATD (4.7 m), the highest PRE (2.2 m), and the highest CR (63%). We can also observe that the attack performance is better for both brute-force sampling and our inverse attacks when the number of queries is larger. Notably, under the same number of queries, our method consistently outperforms the brute-force sampling. In particular, our method with 400 queries results in a higher CR than the brute-force sampling with 2,000 queries, indicating a reduction of the attack overhead by a factor of five.

To illustrate the attack impact, we categorize the victim AV's driving behaviors under attacks into four categories, i.e., *unchanged*, *sudden brake*, *sudden acceleration*, and *lane change*. Note that the victim AV's original driving behavior is moving forward within its current lane. Thus, the latter three behaviors are considered hazardous because they deviate from the victim AV's original driving intent. The categorization is based on the metrics of Maximum Lateral Deviation (MLaD) and Longitudinal Deviation (MLoD). MLaD measures the lateral deviation between the victim AV's planned trajectories in the presence and absence of attack, while MLoD measures the longitudinal deviation. A trajectory with an MLoD greater or smaller than ± 2 m is categorized as a sudden acceleration or brake. An MLaD greater or smaller than ± 1 m indicates a left or right lane change. Figs. 6(a), 6(b), and 6(c) visualize three representative scenes of sudden brake, sudden acceleration, and lane change, respectively. Fig. 6(d) displays the categorization results for 400 victim AV's planned trajectories under attacks. These trajectories are generated on 100 driving scenes at four different velocities. The number of queries is set to 100. The results show that our method induces hazardous driving behaviors of the victim AV for more than 50% of the trajectories, while the brute-force method results in 12% fewer hazardous trajectories. This suggests that our attack not only induces errors in trajectory prediction but also forces the victim AV's planning module to adopt unsafe maneuvers as corrective measures to avert potential collisions with the adversarial vehicle's incorrectly predicted future trajectory.

6.3 Attack Robustness

Robustness against Object Displacement. In real-world deployment, precisely placing objects at pre-computed locations may be challenging. To evaluate the robustness of our attack against object displacement errors, we randomly shift the identified adversarial locations and evaluate our attack's effectiveness. In this experiment, we use the adversarial location set generated by our attack method with a limit of 100 queries. Fig. 7 illustrates CR as the location shift changes from 0 to 0.2 m in intervals of 0.02 m. The corresponding ATD and PRE results are presented in Appendix B.1. The results show that ATD gradually increases, while PRE and CR decrease, as the location shift increases. This is because when the shift exceeds the grid cell/voxel size of the object detector, the additional point clusters caused by the objects might be assigned to a different grid cell/voxel than the originally intended one, leading to a detection bounding box that deviates from the desired state perturbation. However, within the grid cell/voxel size limit of 0.1 m, the location sets generated by our attack demonstrate relative robustness, making them deployable in real-world scenarios.

Robustness against Object Size. In this work, the attacker launches the attack by placing objects, such as cardboards or boxes, at designated locations. These objects vary in size and shape. To evaluate robustness of our attack against object size variations, we generate random point clusters with varying radius, ranging from 0.1 m to 0.5 m, and position them at same adversarial locations. Following the setting in [66], we set the number of points in each cluster proportional to the square of the object size. Fig. 8 illustrates the CR under different

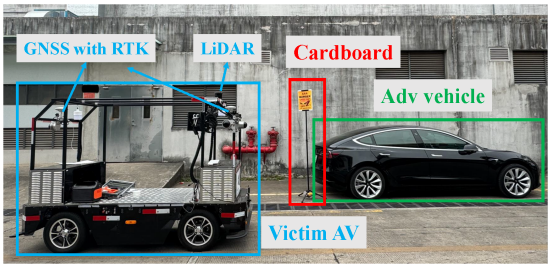

Figure 9: Experimental setup for physical world attack.

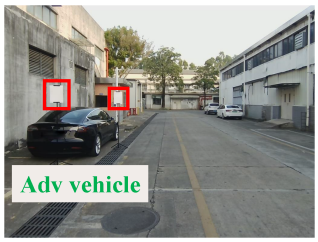
object sizes. The corresponding ATD and PRE results are presented in Appendix B.1. We can observe that a smaller object size results in weaker attack performance, indicated by a higher ATD and lower PRE and CR. This is because smaller objects induce fewer points, leading to limited perturbing effect in detection results. Object sizes in the range of 0.2 m to 0.4 m demonstrate stable, optimal performance across all metrics. However, the performance declines and becomes much more random beyond this range. This is likely due to larger objects occupying numerous grid cells/voxels, resulting in a significant deviation from the original detection results.

6.4 Attack Transferability

We also evaluate the transferability of our attack under the black-box scenario. In this experiment, we assume the victim AV uses AgentFormer as its trajectory prediction model. We assume a black-box condition where the attacker generates locations of adversarial objects based on Trajectron++ and uses these locations to compromise the target model, i.e., AgentFormer. The results (see Appendix B.1) indicate that our attack effectively compromises a different predictor, achieving a maximum CR of 31% with 500 queries. Similar to the white-box results, our attack consistently outperforms the brute-force approach across different numbers of queries, demonstrating its superior transferability and efficiency.

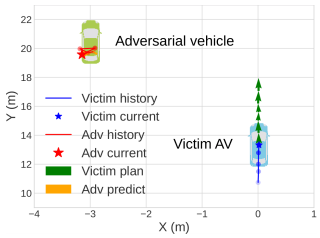
7 Experiments in Physical World

7.1 Experimental Settings



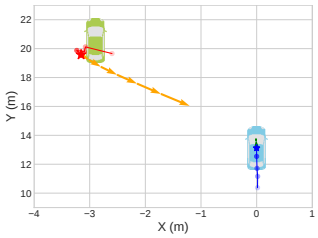
Testbed Car. As illustrated in Fig. 9, our testbed car includes a LiDAR and a Global Navigation Satellite System receiver (GNSS) with Real-Time Kinematic (RTK). The testbed car serves as both the attacker's data collection car during the attack planning stage and the victim AV during the evaluation. We integrate the commonly used Robosense Helios-32 LiDAR for perception, featuring 32 lines and a 10 Hz frame rate. The LiDAR is mounted on the top front center of the testbed car at the height of 1.6 m from the ground. We use the BYNAV X1 high Precision GNSS/INS Receiver with RTK to construct accurate coordinates for prediction and planning, achieving centimeter-level precision in vehicle localization by correcting GPS errors with differential signals. Our testbed car uses the same models as in the dataset-based experiments for perception, prediction, and planning.

Adversarial Vehicle and Objects. Our proposed attack does not have any requirements on the size or color of the adversarial vehicle, which can be any car parked on the roadside. In our experiments, we use a black Tesla Model 3 as the adversarial vehicle. For the adversarial objects, we utilize two cardboards measuring 0.3 m in width and 0.42 m in height, equivalent to the standard A3 paper size. During the attack planning phase, to simulate realistic point clusters of cardboards akin to those captured in the real world, we use the ray-casting method [3] to sample points. In the attack deployment phase, each cardboard is mounted on a tripod for flexible placement at various locations around the adversarial vehicle. The cardboards are tilted at a 45° angle to face the side of the victim AV. While our experiments use white cardboards for better visibility, they can be substituted with ubiquitous roadside objects, such as billboards, for stealthiness.

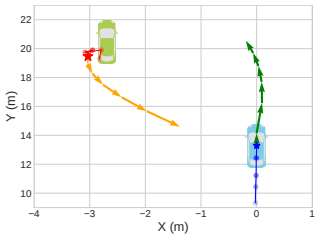


Attack Planning and Deployment. During the attack planning phase, we establish a start point as the origin of the global coordinate system. The testbed car, acting as the attacker's data collection car, drives from the start point and passes by the attack point at a velocity of 5 km/h, simultaneously collecting the LiDAR point cloud and the corresponding GNSS data. The input states to the prediction model are computed in this global coordinate system, originating at the start point. Specifically, we transform the GNSS data in geodetic coordinates (latitude, longitude, altitude) into ENU (East, North, Up) coordinates based on this origin. This conversion enables us to obtain the states of victim AV and combine these coordinates with detection results to obtain the adversarial vehicle's states. Based on the collected data in the absence of attack, we derive two adversarial locations aiming to mislead the victim AV's trajectory prediction. Considering the practicality of placing the cardboards, we limit the location search space to the vicinity of the adversarial vehicle. Specifically, we define the side search region to be $5.2 \times 0.4 \times 0.8\,\mathrm{m}^3$, matching the length of the adversarial vehicle, and the rear/front search regions to be $0.4 \times 2.2 \times 0.8\,\mathrm{m}^3$, aligning with the vehicle's width. During the attack deployment, the cardboards are positioned at the decided adversarial locations. The testbed car, now acting as the victim AV, drives from the start point established during the attack planning phase towards the attack point at various velocities to collect LiDAR point cloud and GNSS data. The collected data under attack are then fed into the victim AV's AD system for evaluation.

7.2 Attack Effectiveness

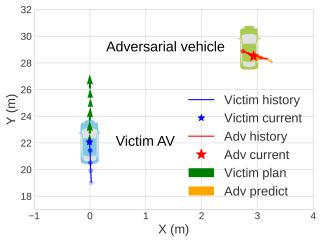


In this section, we evaluate our attack's effectiveness in two real-world scenarios, where the victim AV drives on the road with an adversarial vehicle parked either on its left or right side, referred to as the "left-side scenario" and the "right-side scenario", respectively. We compare our attack with the random location attack and the brute-force sampling attack. An

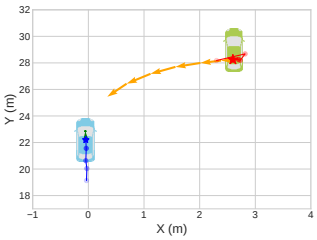


(a) Left-side scenario with adversarial objects deployed (victim AV's view).

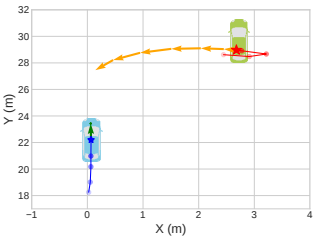
(b) Result of left-side scenario when no adversarial objects are deployed.



(c) Result of left-side attack(ours) at a velocity of 5 km/h. Success ratio: 5/5.



(d) Result of left-side attack(ours) at a velocity of 10 km/h. Success ratio: 4/5.



(e) Right-side scenario with adv objects deployed (victim AV's view).

(f) Result of right-side scenario when no adversarial objects are deployed.

(g) Result of right-side attack(ours) at a velocity of 5 km/h. Success ratio: 4/5.

(h) Result of right-side attack(ours) at a velocity of 10km/h.Success ratio:5/5.

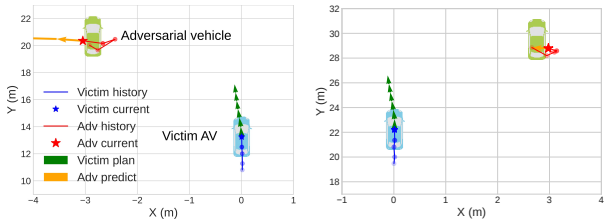


Figure 10: Two real-world scenarios with a parked black Tesla car as the adversarial vehicle. The adversarial objects (cardboards) placed at the locations computed by our inverse attack are highlighted with red boxes. The attack results are illustrated in grid maps, where the blue car represents the victim AV and the green car represents the adversarial vehicle.

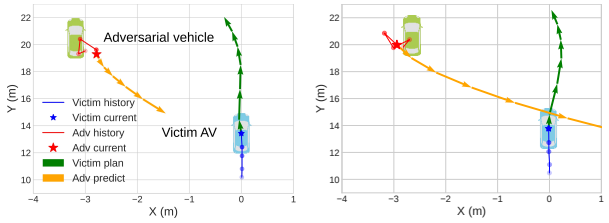
attack is viewed as successful when the PRE exceeds a threshold of 1 m, which is a significant change in the victim AV's planning decision due to the erroneously predicted trajectory.

Inverse Attack (Ours). In these experiments, we place objects at the adversarial locations identified by our attack during the attack planning phase, using data collected at a velocity of 5 km/h. We then evaluate the effectiveness of these locations when the victim AV drives at velocities of 5 km/h or 10 km/h, with slight variations for each trial, capturing the uncertainties encountered in real driving environments. Figs. 10(a) and 10(e) present the scenarios when our attack is deployed. Corresponding LiDAR point clouds perceived by the victim AV under attack can be found in Appendix B.2. In non-attack scenarios, the adversarial vehicle is predicted static and thus poses no threat to the victim AV's trajectory planning, as depicted in Figs. 10(b) and 10(f). In the left-side scenario, our attack succeeds in five out of five trials at an evaluation velocity of 5 km/h. Fig. 10(c) shows a successful attack where our attack misleads the victim AV at a velocity of 5 km/h to predict a future trajectory heading towards itself, forcing the victim AV to an emergency brake. Our attack, utilizing adversarial locations planned using data at a velocity of 5 km/h, succeeds in four out of five trials at an evaluation velocity of 10 km/h. Fig. 10(d) presents a successful example, where our attack induces a similar prediction error as in the scene at a velocity of 5 km/h in Fig. 10(c), demonstrating our attack's velocity insensitivity. In the right-side scenario, the planned adversarial locations achieve four successes out of five trials at an evaluation velocity of 5 km/h and five out of five at 10 km/h. Example successful attack scenes at velocities of 5 km/h and 10 km/h are shown in Figs. 10(g) and 10(h), with similar trajectory prediction errors and the same sudden brake decision taken by the victim AV in both scenes. In both left- and right-side scenarios, successful attack examples at different evaluation velocities demonstrate similar perception errors at the current time step, as marked by red stars in Fig. 10. This indicates the effectiveness of single-point attack in inducing prediction error at the current frame. Detailed quantitative results, including comparisons of ATD and PRE, are presented in Appendix B.2.

Baseline 1: Random Location Attack. In this set of experiments, adversarial cardboards are randomly placed around the adversarial vehicle. Some example scenes are shown in Appendix B.2. In both left-side and right-side random location attack scenarios, our evaluation yields no successful attacks out of five trials. Fig. 11(a) illustrates a left-side attack example where cardboards, randomly placed on the right side of the adversarial vehicle, cause a predicted trajectory of the adversarial vehicle moving to the left of the victim AV, posing a limited threat. Fig. 11(b) shows a right-side attack example with cardboards randomly placed at the rear, leading to a static predicted trajectory of the adversarial vehicle with no threat to the victim AV. The results demonstrate that, objects placed at random locations may affect the predicted trajectories of the adversarial vehicle, while failing to achieve the attack goal defined in Eq. 1. This underscores the importance of strategic object placement at adversarial locations, which is facilitated by our inverse attack.



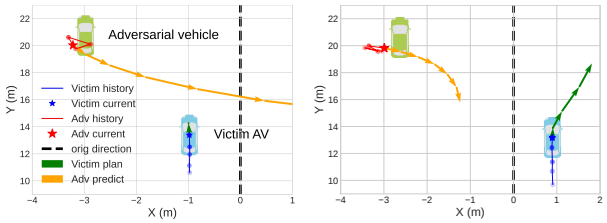
Baseline 2: Brute-force Sampling Attack. We evaluate the attack effectiveness of the brute-force sampling method

(a) Result of left-side random location attack. Success ratio: 0/5.

(b) Result of right-side random location attack. Success ratio: 0/5.

Figure 11: Random location attack results.

(a) Result of coordinate shift (0.1m). Success ratio: 3/5.



(b) Result of orientation shift. Success ratio: 5/5.

Figure 12: Robustness against object displacement errors induced by shifts in object coordinates or orientations.

using locations derived from data at a velocity of 5 km/h in the planning phase. The evaluation is conducted in the left-side scenario at velocities of 5 km/h and 10 km/h. This method achieves a success ratio of three out of five trials at both velocities. The reason for the reduced attack success ratio compared with our inverse attack, even under the less challenging condition at a velocity of 5 km/h, is likely due to small fluctuations in the victim AV's velocity between trials. These variations can render velocity-sensitive adversarial locations ineffective, leading to attack failures due to minor discrepancies from the original scene in the attack planning phase.

7.3 Attack Robustness

Robustness against Object Displacement. When deploying cardboards at the adversarial locations, there may be deviations in their 3D coordinates and orientations. To evaluate our attack's robustness against these deviations, we conduct experiments to randomly shift each cardboard's 3D coordinates and orientation, respectively. The experiments are performed in the left-side attack scenario, with the victim AV driving at a velocity of 5 km/h. Some example scenes are illustrated in Appendix B.2. To simulate the shifts, we move each cardboard 0.1 m from its planned location in random directions. Results show that shifting cardboards' coordinates by 0.1 m leads to three successful attacks out of five trials. Fig. 12(a) illustrates an example successful attack, achieving a similar attack result as in the original attack scene in Fig. 10(d). This robustness is due to the majority of points, even after shifting, still falling within the same grid cell or voxel after LiDAR detection processing. However, when the shift increases to 0.3 m, which exceeds the grid cell/voxel size, the attack success ratio drops

(a) Result of victim AV in left driving direction. Success ratio: 2/5.

(b) Result of victim AV in right driving direction. Success ratio: 3/5.

Figure 13: Robustness against various driving directions of the victim AV.

to one out of five trials. To simulate orientation shifts, the cardboards are rotated randomly within $[-30°, 30°]$. In all five trials, our attack is successful. Fig. 12(b) shows a successful attack. This robustness may stem from the observation that, despite substantial orientation shifts, the points on a cardboard mostly remain within the original grid or shift to an adjacent grid, resulting in similar perception and prediction outcomes. To summarize, the adversarial locations identified by our inverse attack remain effective within a reasonable range of object displacement errors induced by coordinate and orientation shifts.

Robustness against Varied Driving Direction. During the evaluation , the victim AV remains in the same lane as in the planning phase. However, it may not maintain a perfectly straight path and occasionally steer slightly to the left or right. To evaluate the robustness of our inverse attack against the variations in victim AV's driving direction, we conduct an experiment in the left-side scenario at a velocity of 5 km/h, with example scenes shown in Appendix B.2. With the planned adversarial locations unchanged, we shift the victim AV's starting and attack point by 1 m to the left or right of their original positions, simulating the victim AV going slightly rightward or leftward. When shifting the victim AV's driving direction to the left, two out of five attack trials are successful. When shifting to the right, the attack success ratio is three out of five. Figs. 13(a) and 13(b) show example successful attack results. When shifting to the left direction, the victim AV is forced to brake urgently due to the reduced distance from the predicted trajectory of the adversarial vehicle, while shifting to the right direction leads to a lane change to avoid intersection with the adversarial vehicle's predicted trajectory.

8 Discussions

8.1 A Potential Defense

This work shows that a lack of awareness for adversarial vehicle states can lead to hazardous results, which our proposed attack exploits. As depicted in Fig. 4, in a sequence of adversarial states under attack, the coordinates are typically perturbed within a reasonable range ($\pm$1m), but the heading shows significant volatility. For instance, an adversar-

ial vehicle's heading might abruptly reverse from one frame to the next, which violates the vehicle physical dynamics. Inspired by this, we propose a *heading-centric adversarial state detector* based on the kinematic bicycle model as the defense for our proposed attack. It scrutinizes the discrepancy between observed and physically plausible heading changes across consecutive frames. Given a wheelbase L_w and a maximum steering angle $\theta_{\max}$, following the kinematic bicycle model, the expected maximum heading change is denoted as $\Delta h_{\max} = \frac{v\Delta t \tan(\theta_{\max})}{L_w}$, where v represents the vehicle's velocity and Δt is the time interval between two consecutive frames. A scene is labeled adversarial if the observed heading changes in at least two frames exceed the calculated $\Delta h_{\max}$. This serves as a criterion for detecting abnormal behaviors, such as those of a vehicle under object-based attacks. As the defense, the detected adversarial states are replaced with the states predicted by the kinematic bicycle model using preceding states. We evaluate the detector on 400 attack scenes under the same experiment setting as in Section 6. We set L_w at 2.5 m and $\theta_{\max}$ at 1 rad, following standard vehicle configurations. The results show that, 44.5% (178/400) attacked scenes are detected. With defense, the ATD changes from 5.45 m to 6.03 m, PRE from 1.51 m to 1.15 m, and CR from 40% to 25%.

8.2 Other Possible Defenses

Based on the nature of our attack mechanisms, three types of existing general defense approaches might be applied. We discuss and evaluate the effectiveness of such defenses against our attack strategy.

Spatial-temporal consistency checks: Recent studies [16, 33, 35] have explored spatial-temporal consistency checks to detect perception attacks. PercepGuard [33] is a representative method that leverages the spatial-temporal properties of bounding boxes across different classes to detect anomalies. In our experiments, PercepGuard detects anomalies in 4 out of 400 attack scenes, with a limit of 100 queries, under the same settings as in the dataset-based experiments. Unlike typical attacks that aim to induce object disappearance, creation, or misclassification, our attack subtly perturbs bounding boxes, presenting a challenge for spatial-temporal checks.

Adversarial training: Following adversarial training [19], we fine-tune the Trajectron++ predictor with adversarial states generated by our attacks for an additional 10 epochs. After training, the CR decreases from 40% to 35%, while the mean Final Displacement Error increases from 2.18m to 2.22m in clean scenes. This illustrates a trade-off between robustness and accuracy in the trajectory prediction model. Moreover, effective adversarial training requires the defender to know the attack methods, which is not always possible.

MC-dropout: We also explore MC-dropout [18], a technique that introduces randomness into the perception model during inference, thus disrupting the matching between bounding box perturbations and adversarial states. Implementing MC-dropout with 5 runs led to a reduction in the collision rate from 40% to 18%. However, this defense significantly increases the computational overhead during inference, impacting the real-time performance capabilities of AD systems.

In conclusion, existing methods can partially defend against our attack but also introduce some additional overhead. Our proposed lightweight defense method checks key adversarial states against vehicle dynamics, achieving a good balance of efficacy and cost.

8.3 Limitations and Future Work

Single-Point Attack Impact. A limitation of our attack is its diminishing impact once the victim AV passes the attack point. For example, a victim AV brakes suddenly at the attack point may resume normal behavior in subsequent frames. This occurs because the current frame at the attack point becomes one of the historical frames as the victim moves, being less effective as shown in finding **F1** in Section 5.2. To address this limitation, developing a temporally effective attack to maintain consistent impact over time is interesting.

Different Attack Scenarios. Another limitation is that our attack focuses on the driving scenario where a victim AV passes a roadside-parked adversarial vehicle. Future work can explore other common scenarios, such as an adversarial vehicle stopped at an intersection, potentially impacting more vehicles in dense traffic scenarios. Moreover, it is interesting to extend our attack to scenarios where both the adversarial vehicle and the victim AV are moving. In these cases, drones can act as movable adversarial objects, utilizing advanced drone localization and tracking technologies. This approach opens up an opportunity for a continuous and dynamic attack, adapting to the changing positions of the adversarial vehicle.

Attack Multi-sensor Fusion. Our attack can be extended to multi-sensor fusion systems by optimizing existing perception attacks for different sensing modalities. For example, we can use adversarial objects with specific shapes and textures to compromise both LiDAR and camera perceptions, akin to techniques discussed in [8, 65]. Specifically, the shape and texture attributes of the adversarial objects can be randomly sampled to create the bounding box perturbation set. Then, our prediction-side attack methodology can be applied to generate a set of adversarial states. Lastly, a matching and refining phase is applied, where the shape and texture parameters are adjusted to optimize the attack's effectiveness across sensors.

9 Conclusion

In this paper, we investigate the possibility of compromising trajectory prediction in autonomous driving systems via physically realizable object-based LiDAR attacks on perception modules. We find that prediction models are vulnerable to single-point attacks. Building on this insight, we introduce a novel two-stage attack framework that efficiently identifies an effective, velocity-insensitive, and feasible adversarial location set. By strategically placing objects at these locations,

the attacker can manipulate the victim vehicle to predict a wrong trajectory of a nearby agent, potentially inducing hazardous victim AV responses. We evaluate the proposed attack framework on both a public autonomous driving dataset and a custom-built real testbed car. The results demonstrate that our proposed attack consistently achieves the highest threat across various driving conditions and shows robustness against different types of noise.

Appendix

A Generalizability Across Models

To extend our analysis beyond Trajectron++, the primary trajectory prediction model utilized in this study, we apply our attack to AgentFormer [58], another advanced trajectory predictor, to assess its generalizability. We follow the same experimental settings as those used in the dataset-based experiments, and the AgentFormer model is also trained on the nuScenes dataset using its default configuration. Fig. 14 compares the Average Trajectory Distance (ATD), Planning-Response Error (PRE), and Collision Rate (CR) metrics between our inverse attack method and the brute-force sampling method when applied to the victim AV system utilizing AgentFormer. The number of queries ranges from 100 to 500. The results show that our inverse attack consistently outperforms the brute-force sampling method on three metrics across all query limitations. These outcomes, similar to those presented in Fig. 5, further demonstrating the generalizability of our attack.

B Supplementary Experiments

B.1 Experiments on Dataset

Fig. 15 shows the Average Trajectory Distance (ATD) and Planning-Response Error (PRE) of our inverse attack method under varied object displacements. Fig. 16 demonstrates how different object sizes affect the ATD and PRE metrics of our inverse attack method. Fig. 17 illustrates the ATD, PRE, and CR metrics in the attack transferability experiments, where

Table 2: ATD and PRE under clean scenario and our inverse attack at velocities of 5 km/h and 10 km/h.

Scenario	Left			Right		
	Clean	5 km/h	10 km/h	Clean	5 km/h	10 km/h
ATD	4.78	3.50	4.12	4.71	3.14	3.62
PRE	0.00	1.36	2.01	0.00	1.17	1.83

B.2 Experiments in Physical World

Experimental Settings Fig. 18 provides a detailed view of the testbed car and cardboards used in the physical-world experiment. The top LiDAR, marked in the green box, is responsible for collecting point cloud data. The GNSS Receiver with RTK, highlighted in blue, enables precise localization of the testbed car, facilitating the construction of an accurate coordinate system essential for prediction and planning. Regarding the cardboards, we design them to mimic traffic signs and billboards, which are common in driving scenarios, thereby enhancing the stealthiness of our attack.

Attack Effectiveness Figs. 19(a) and 19(b) depict the LiDAR point cloud views captured by the victim AV (our testbed car) in the left- and right-side attack scenarios, respectively. Notably, cardboards, outlined in red boxes, contribute additional point clusters to the collected LiDAR point cloud data. These point clusters serve as the basis of our attack, inducing perception and prediction errors. Table 2 presents the ATD and PRE metrics in the absence and presence of our inverse attack, across evaluation velocities of 5 km/h and 10 km/h, within both the left- and right-side scenarios. The results indicate that, compared to the clean scenario (without attack), our inverse attack significantly reduces ATD and increases PRE, quantitatively demonstrating its effectiveness.

(b) Driving direction to right.

Figure 22: Scenes under various driving directions of the victim AV.

Attack Robustness Fig. 20 shows example scenes of the random location attack, with their corresponding results presented in Fig. 11. In each trial, we sample a varied set of adversarial locations beyond those depicted, including positions beside and behind the adversarial vehicle.

Fig. 21 illustrates example scenes with object displacements. Specifically, in Fig. 21(a), the cardboards are adjusted to face forward, deviating from their initial orientations toward the victim vehicle. In Fig. 21(b), the coordinates of cardboards are shifted by 0.3 m from the predetermined adversarial locations, notably moving them toward the road. In real-world deployment, attackers equipped with distance-measuring devices, such as a tape measure, can precisely place objects at specific adversarial locations.

The example scenes depicting various driving directions of the victim AV are presented in Fig. 22, with the associated attack results shown in Fig. 13.

On Data Fabrication in Collaborative Vehicular Perception: Attacks and Countermeasures

Abstract

Collaborative perception, which greatly enhances the sensing capability of connected and autonomous vehicles (CAVs) by incorporating data from external resources, also brings forth potential security risks. CAVs' driving decisions rely on remote untrusted data, making them susceptible to attacks carried out by malicious participants in the collaborative perception system. However, security analysis and countermeasures for such threats are absent. To understand the impact of the vulnerability, we break the ground by proposing various real-time data fabrication attacks in which the attacker delivers crafted malicious data to victims in order to perturb their perception results, leading to hard brakes or increased collision risks. Our attacks demonstrate a high success rate of over 86% on high-fidelity simulated scenarios and are realizable in real-world experiments. To mitigate the vulnerability, we present a systematic anomaly detection approach that enables benign vehicles to jointly reveal malicious fabrication. It detects 91.5% of attacks with a false positive rate of 3% in simulated scenarios and significantly mitigates attack impacts in real-world scenarios.

1 Introduction

The perception system of connected and autonomous vehicles (CAVs) is safety-critical as its performance directly affects driving decisions [7, 8]. However, CAV's perception is confronted with the basic limitation that onboard sensors have limited sensing capabilities. For instance, LiDAR, the commonly adopted 3D sensor, cannot see through occlusions and may render low resolutions for far-away objects, leading to imperfect detection performance. Many recent efforts have proposed LiDAR-based collaborative perception algorithms [32, 73, 79, 87], where different nearby vehicles exchange perception information (e.g., raw sensor data or feature maps processed by neural networks) and perform object detection algorithms on the fused data. In terms of the accuracy of object detection, the approach significantly outperforms the traditional CAV collaboration [37, 38, 64] sharing simple GPS messages or object locations, as illustrated in related studies [73, 79]. CAV industry [2–4, 9, 14, 16, 81] also proposes solutions of collaborative perception and launch road testing across the globe.

Although collaborative perception is evolving quickly towards maturity, it introduces a severe vulnerability to vehicle safety because the safety-critical perception algorithms now rely on sensor data or feature maps from remote untrusted vehicles. With the control of a remote vehicle via physical access to either software or hardware, an attacker can fabricate the data to share, aiming to inject fake object detection results into the view of victim vehicles and even mislead them to trigger accidents. However, the impact of such a severe data integrity threat has not been comprehensively evaluated. Existing studies of CAV security [61, 86] either focus on other scopes (*e.g.,* physical sensor security [30, 69], network protocols [25, 80]) or assume a different threat model (*e.g.,* single-vehicle perception [55, 69], object-sharing collaboration [23, 88]), thus existing mitigation methods are not effectively designed for the new threat.

To bridge the gap, we propose a series of stealthy, targeted, and realistic attacks exploiting LiDAR-based collaborative perception in this study. Our proposed attacks can spoof or remove objects at specified locations in the victim's perception results, making all mainstream types of collaborative perception schemes vulnerable. For early-fusion systems which directly merge LiDAR point clouds, we propose black-box ray casting to reconstruct malicious but natural raw point clouds. We design offline adversarial object generation and run-time occlusion-aware point sampling to further optimize the distribution of modified points. For intermediate-fusion systems which merge feature maps as intermediate results of object detection models, we design a white-box adversarial attack to perturb the feature maps. For optimal efficiency, the adversarial attack initializes the perturbation vector via a black-box method and runs one-step backward propagation in each LiDAR cycle (*e.g.,* 100 ms). More importantly, we propose zero-delay attack scheduling to make attacks realizable in the real world. To be specific, in order to attack the perception of frame i, attackers prepare a fabrication plan

based on the knowledge of frame $i-1$ before the next frame comes. In this way, attackers earn one LiDAR cycle time to complete attack generation without introducing a noticeable delay in the fabricated data.

We evaluate the attack effectiveness on 211 traffic scenarios in a simulated dataset Adv-OPV2V and a real-world dataset Adv-MCity (including 8 scenarios collected from a real-vehicle testbed MCity [19]). On the simulated dataset, all attacks have a success rate of more than 86% regardless of fusion methods and model configurations. In our real-world experiments, we deploy three vehicles equipped with LiDAR/GPS sensors and the latest Baidu Apollo autonomous driving software [8]. Our attacks can be launched in real-time and trigger safety hazards such as collisions and emergent hard brakes. We also provide a comprehensive analysis of how the attack effectiveness is affected by various factors including attack methods, fusion schemes, and scenarios. Our findings will guide system designers to build robust collaborative perception schemes.

To mitigate the demonstrated attacks, we propose Collaborative Anomaly Detection (CAD), a system that detects data fabrication attacks by revealing geometry inconsistencies of the shared data from different vehicles. To achieve this, CAD requires each vehicle to generate and share an occupancy map, which is a 2D map labeling the 2D space into three classes, free, occupied, and unknown. On receiving occupancy maps from others, the vehicle validates the consistency of the maps, *i.e.,* there is no region classified as occupied and free at the same time. Then the vehicle carries out the second check by merging the occupancy maps into one and checking perception results against it. For instance, free regions should not overlap with detected bounding boxes; each on-road moving occupied region should have one bounding box overlap with it. In this way, abnormal detection results caused by either fabricated data or perception faults are revealed if the attacked region is observed by at least one benign CAV. CAD detects 91.5% attacks with a false positive rate <3% on datasets Adv-OPV2V and Adv-MCity.

As the first comprehensive security analysis of collaborative perception, we will open-source all the above attack-/defense practices as a benchmark tool to facilitate future research. Our contributions can be summarized as three-fold:

- We compile the benchmark datasets Adv-OPV2V and Adv-MCity for evaluating the security of collaborative perception. Especially, Adv-MCity is the *first* multi-vehicle collaboration dataset collected on real vehicles and real roads.
- We propose multiple data fabrication attacks, where one attacker, as a collaborative perception participant, can successfully spoof or remove objects at specified locations. We conduct an extensive study on the impact of such attacks.
- We develop CAD, a defense system of collaborative perception for detecting our proposed data fabrication attacks. CAD reveals abnormal perception results through the sharing of fine-grained occupancy maps.

2 Background and Related Work

Connected and autonomous vehicles (CAVs) are transforming the transportation systems by enabling automatic and intelligent vehicle driving control. CAVs are complicated cyber-physical systems equipped with sensors such as LiDAR, camera, and radar to perceive the surroundings, and software to make appropriate driving decisions. By the end of 2022, numerous companies including Waymo, Honda, Baidu, and Tesla [6, 8, 10, 13] have developed models of CAVs.

Collaborative perception has been proposed to enhance CAV perception [21, 47, 49, 52, 66] by sharing raw or processed sensor data among infrastructure or vehicles. Mainstream solutions focus on LiDAR sensors because of the rich 3D geometry features brought by LiDAR images. Collaborative perception has three major types according to the sharing data, as shown in Figure 1. CAVs in early-fusion sharing schemes [31, 33, 48, 62, 85, 87] directly exchange raw sensor data, whose format is usually universal and can be naively concatenated, at a cost of data transmission bandwidth; intermediate-fusion schemes [32, 34, 73, 78, 82] ask CAVs to transmit feature maps, the intermediate product of perception algorithms, offering a good tradeoff between network efficiency and perception accuracy; in late-fusion schemes [54, 67, 68] lightweight perception results such as object bounding boxes are shared.

Collaborative perception is advancing quickly towards real-world deployment. 3GPP standardized for Cellular Vehicle-to-Everything (C-V2X) techniques in 2017 [1], indicating the maturity of roadside communication. Since then, major technology companies such as Huawei, Intel, Bosch, Infineon, and Qualcomm [2–4, 9, 14] have strived to build various C-V2X solutions. Road trials have been launched across the globe in countries like Germany, France, the United States, and Japan. Ford [16] and Baidu Apollo [81] built real-world collaborative perception datasets.

Attacks on CAV perception. Several attacks can harm LiDAR perception systems as listed in Table 1. First, LiDARs on CAVs are vulnerable to physical attacks, such as GPS spoofing [51, 65], LiDAR spoofing [29, 40, 44, 51], and physical realizable adversarial objects [71, 84, 91]. These attacks are against one single autonomous vehicle. Late-fusion collaborative perception shares object locations [37–39, 64] thus

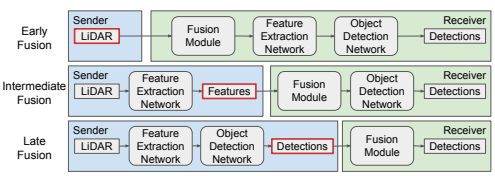

Figure 1: Taxonomy of cooperative perception systems.

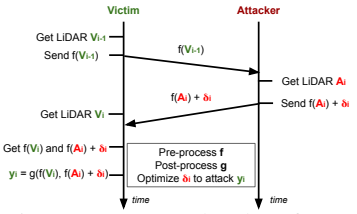

Figure 2: Temporal order of message exchanges.

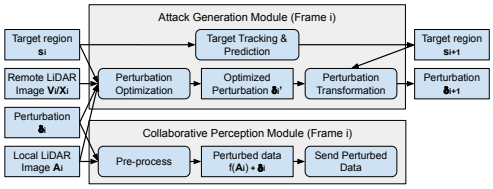

Figure 3: Framework of real-time targeted attacks on collaborative perception.

the attacker can trivially modify these locations, which is the threat model of many existing studies [26, 27, 46, 57]. Tu *et al.* [72] is the first attack specific to intermediate-fusion collaborative perception, which is an untargeted adversarial attack creating inaccurate detection bounding boxes as many as possible by perturbing feature maps in intermediate-fusion systems. However, the attack is not realistic considering the constraints of real systems, as discussed in §3.3. We propose real-world realizable attacks that challenge both early-fusion and intermediate-fusion systems.

Defenses on CAV perception. As shown in Table 2, existing defense mechanisms are not designed for our proposed attacks thus cannot resolve them effectively. Several Vehicle-to-Everything (V2X) communication standards [15, 17, 18, 20, 43] define security practices of network protocols (*e.g.,* access control, message integrity). They cannot block the data fabrication attacks because the attackers can modify data before wrapping it into protocol messages where the protection is enforced. Trusted Execution Environments (TEEs) [42] can potentially safeguard perception algorithms via secure hardware, but its deployment is difficult and vulnerable to side-channel attacks. Against physical sensor attacks, various anomaly detection methods are proposed [22, 41, 55, 56, 63, 69]. For LiDAR systems especially, CARLO [69] detects abnormal point clouds that violate occlusion features and LIFE [55] detects temporal and sensor-fusion inconsistencies. Above defenses rely on physical rules but attackers in collaborative perception can simulate the physics to craft realistic but malicious data, as discussed in §5.1. For connected vehicle applications, many efforts model the benign behaviors of ego/remote vehicles and detect model outliers as anomalies [26, 27, 46, 57]. The models may involve various aspects including temporal consistency [27], physical constraints on message delivery or vehicle control [26, 46], cross-validation with local sensor [57], etc. However, existing works assume the systems to share simple GPS/OBU data, making it challenging to adapt them effectively for addressing anomalies in complicated LiDAR images or feature maps. We propose joint anomaly detection leveraging the sensing of spatial space from all connected vehicles, which enhances the spatial coverage of effective anomaly detection compared with the previous approaches.

3 Problem Definition

We define the data fabrication problem in §3.1 and the threat model in §3.2. We emphasize the technical challenges for such new attacks compared with existing attacks in §3.3.

3.1 Formulation

In a scenario where multiple vehicles jointly execute collaborative perception, the attacker aims to spoof or remove road objects (*e.g.,* vehicles, pedestrians) from designated locations in the victim's perception results.

We formulate the problem of data fabrication as an optimization problem. We denote LiDAR data at frame $i \in \mathbb{N}$ from the attacker, the victim, and other benign vehicles by A_i, V_i, and $X_i^{(j)}$, $j \in \{0, 1, \ldots N\}$, respectively. LiDAR data with the same frame index will be merged on the victim side to generate perception results. From Figure 1, we denote preprocess before data sharing as f and post-process after data sharing as g. A normal collaborative perception for the victim on frame i can be described as:

$$y_i = g(f(V_i), f(A_i), f(X_i^0), f(X_i^1), ..., f(X_i^N)). \quad (1)$$

As the attacker can replace $f(A_i)$ by malicious data. For instance, the attacker can append a minor perturbation δ_i to craft malicious data as $f(A_i) + \delta_i$, which will change the original perception result from y_i to y_i':

$$y_i' = g(f(V_i), f(A_i) + \delta_i, f(X_i^0), f(X_i^1), ..., f(X_i^N)). \quad (2)$$

Given a fitness function I evaluating attack success and attack constraints C restricting the perturbation, the attacker solves:

$$\max_{\delta_i} I(y_i') \quad \text{s.t. } C(\delta_i). \quad (3)$$

3.2 Threat Model

We assume that CAVs execute collaborative perception in a Vehicle-to-Vehicle (V2V) scenario. Our results can be easily generalized to vehicle-to-infrastructure (V2I) settings by replacing one or more vehicles with edge computing devices.

We assume the attacker can physically control at least one vehicle participating in collaborative perception. This allows the attacker to gain privileges on the vehicle's software and hardware, enabling them to manipulate the sensors, tamper with the local execution of algorithms, and send arbitrary data through the network. In other words, attackers can directly alter the data to share, *i.e.,*, LiDAR point clouds, feature maps, and bounding boxes in early-fusion, intermediate-fusion, and late-fusion perception schemes, respectively.

We focus on early-fusion and intermediate-fusion collaboration schemes where attackers need to subtly craft complicated structured data. In terms of perception models, as the attackers locally install the perception model for joining

the collaborative perception, we assume they have white-box access (i.e., model parameters). Some of our proposed attacks require no model access or only inference API.

Meanwhile, we assume the presence of benign vehicles which the attacker cannot invade. The assumption that the attacker would control all vehicles surrounding a victim vehicle on a busy road is deemed too impractical and financially prohibitive. We do not consider physical sensor attacks such as LiDAR spoofing [44] and GPS spoofing [74]. They are general threats to CAVs while we focus on new vulnerabilities brought by collaborative perception. Besides, the attacker cannot break the cryptographic protection thus cannot compromise the secure communication channels among vehicles.

3.3 Attack Constraints

In addition, the attacks must be realizable on real collaborative perception systems. Though Tu *et al.* [72] proposed a feature-perturbing attack against intermediate-fusion systems, it violates attack constraints as follows.

Sensor physics and definition ranges. We require the attacker to obey basic rules in terms of the data format, otherwise it is trivial to detect the anomalies. The attackers' LiDAR point clouds should have a reasonable distribution of point density and the angle of the lasers should comply with the LiDAR configuration. In addition, the point clouds must present reasonable occlusion effects, in order to bypass anomaly detection methods based on the occlusion features [69]. The attackers' shared intermediate features should be within the definition ranges, avoiding absurd values.

Targeted attacks. The attacker should be able to designate a target region for either spoofing or removal attacks, in order to support delicate creation of hazardous scenarios. Otherwise, the untargeted and uncontrollable attack impact as presented in Tu *et al.* [72] damages attack effectiveness and stealth.

Real-time temporal constraints. Collaborative perception is an asynchronous multi-agent system where each vehicle produces LiDAR images in cycles but is not synchronized in time. Figure 2 illustrates a typical order of events in collaboration perception. To attack the victim's perception at frame i (y_i), the optimization of δ_i has the following constraints:

• *Limited knowledge*. Optimization of δ_i must be finished before the victim's processed LiDAR data V_i is generated. Therefore, attack generation cannot leverage the victim's data on the same frame. Similarly, data from other benign vehicles at frame i may not be available either. The attacker can for sure rely on the shared data in previous frames from all vehicles, provided that the data transmission delay is much smaller than the LiDAR cycle. Tu *et al.* [72] assumes the availability of all data in the frame to attack thus it is impractical.

• *Real-time attack without observable delay*. The optimization of δ_i takes time, especially when the attack involves online adversarial machine learning. To make sure δ_i is produced and transmitted before the fusion stage of the victim, the attacker can either design fast real-time attacks or optimize the perturbation before frame i arrives.

4 Attack Methodology

We present realistic data fabrication attacks against various types of collaborative perception. We first introduce a general framework for real-time targeted attacks in §4.1 and elaborate on the details of ray casting attacks against early-fusion systems (§4.2) and adversarial attacks against intermediate-fusion systems (§4.3). Attackers can trivially send fake bounding boxes in late-fusion systems so we omit the discussion.

4.1 Zero-delay Attack Scheduling

As analyzed in §3, the attacks must be effective to trigger safety hazards while fast enough to satisfy real-time constraints. To satisfy both requirements, we propose an attack framework as shown in Figure 3, whose key idea is to parallelize attack generation and perception processes.

First of all, the attacker can identify the set of vehicles collaborated with the victim vehicle and align frame indices of their shared sensor data based on timestamps. The attack generation module is triggered on each LiDAR cycle. It first tracks the target region: (1) for object spoofing, the trajectory of the object to spoof is predefined; (2) for object removal, the attacker needs a simple object detection algorithm to localize the target object to remove. Then it optimizes the malicious perturbation that can be used to attack the victim's perception at the current frame. Note that the optimized perturbation is generated overtime and cannot be used to attack due to the real-time constraints (§3.3). We need to transform the perturbation into one that has a similar attack impact on the next frame. In this way, the perturbation is ready to apply when the next frame arrives, introducing no additional delay to the original collaborative perception pipeline. As the attack generation occurs one frame in advance, it affords the attacker up to one LiDAR cycle time to complete the optimization.

The optimization and transformation of the perturbation highly depend on the configuration of the collaborative system and will be discussed in later sections.

4.2 Black-box Ray Casting Attack

In early-fusion collaborative systems, CAVs share LiDAR point clouds. Thus, the attacker will perturb the location of LiDAR points directly but must obey the physical rules of LiDAR sensors as mentioned in §3.3. Note that a white-box adversarial attack [30] is not applicable because (1) most perception models involve non-differential pre-processing and (2) even if the gradient can be approximated, the heavy computation can hardly achieve real-time attacks.

Insights. First, we find that a higher point density on the object surface leads to more successful detection. Mainstream 3D object detection models learn spatial features from voxelized point groups (§2). It is therefore natural that a higher point density strengthens the learned feature toward object classes. Second, a higher coverage on object surfaces also contributes to better detection, as the shape features of objects

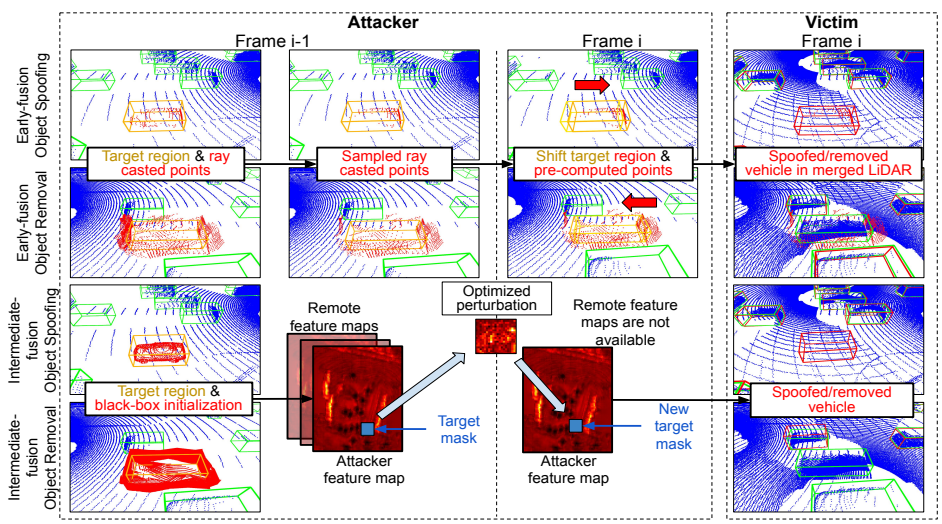

Figure 4: Demonstration of collaborative perception attacks. The orange box is the target region, the green boxes are ground-truth labels, and the red boxes are predicted objects.

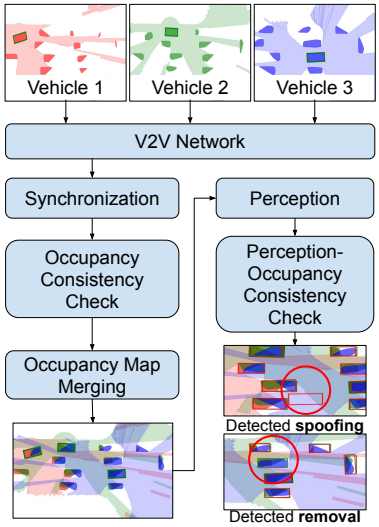

Figure 5: Workflow of CAD's anomaly detection.

Algorithm 1: Black-box ray-casting attacks.

Input: A target region y_t, LiDAR image X, an 3D object model S (generated offline using an initial model S_0 and an attack dataset D).
Output: Fake LiDAR image X_a.

Function `BlackboxAttack`(X, y_t, S)**:**
  $S_t \leftarrow$ `Transform`(S, y_t);
  $X_r \leftarrow$ `NonOcclusionRayCasting`(X, S_t);
  $X_a \leftarrow$ `PointSampling`(X_r, S_t);
Function `AdversarialShape`(S_0, D)**:**
  $S \leftarrow S_0$; ▷ Only for object removal.
  for *Iteration* $1 \ldots K$ **do**
    for $X^{(i)}, y_t^{(i)} \in D$ **do**
      $X_a^{(i)} \leftarrow$ `BlackboxAttack`$(X^{(i)}, y_t^{(i)}, S)$;
      $Y^{(i)} \leftarrow$ `Perception`$(X_a^{(i)})$;
      Optimize S by maximizing $\sum_{y \in Y^{(i)}}$ `IoU`$(y, y_t^{(i)}) \cdot log(y_\sigma)$;
      ▷ y_σ is the confidence score.
    end
  end

become more explicit. This is also one of the key benefits of collaborative perception, as multi-view LiDAR data allows for a more comprehensive perception of objects. Given the two insights, the object spoofing attack aims to spoof denser LiDAR points of objects and cover a larger surface area of the object. The goal of the object removal attack is to obscure the surface of the original object as thoroughly as possible. We confirm the insights in our ablation study (§6.3.3).

Attack methods The attacker pretends that an object is spoofed or removed and reconstructs the LiDAR point cloud via ray casting techniques. The traced rays follow the physical laws of the original lasers so the reconstructed point cloud is realistic. The spoofing attack requires no model access while the removal attack requires the model's inference API. The attack is demonstrated in Figure 4 and Algorithm 1.

Preparation of 3D object model. The attacker first constructs a 3D model (*e.g.,* a triangle mesh) of the object they wish to fabricate. In later attack steps, we will place the 3D model in the target region and cast malicious points on its surfaces. For object spoofing, the model can represent a real object such as a car. For object removal, we optimize a universal adversarial shape offline as the model. We initialize a cuboid triangle mesh and use a black-box genetic algorithm to optimize the perturbation on mesh vertices. As shown in Algorithm 1 (`AdversarialShape`), in each iteration, we launch the object removal attack on a dataset of attack cases and optimize the object model to maximize a fitness score representing the success of attacks (i.e., minimizing the confidence of detection proposals in the target region). A detailed explanation is in Appendix A.1.

Non-occlusion ray casting. We set up a ray casting scenario where the 3D model is placed at the designated location and the rays are lasers in the attacker's LiDAR image. Though the predefined object models have fixed sizes, we will dynamically adjust size, location, and orientation of them to fit the target region during the scenario creation (`Transform` in Algorithm 1), making the object models universal for various attack situations. The ray casting algorithm calculates the points of intersection between the rays and the 3D model. To maximize point density on the target object, the ray casting is customized to ignore occlusion effects, ensuring that each ray is not blocked and goes through model surfaces to leave multiple intersection points.

Point sampling. We resolve the occlusion violations by sampling one intersection point per ray. Specifically, for each ray with one or more intersection points with the 3D model, its original LiDAR point is replaced by one of the intersection points. The selection of intersection points is through customizable weighted random sampling. In our implementation, intersection points closer to benign vehicles have a higher probability of being selected. In this way, spoofed fake points tend to have a higher density close to benign points, increasing the chance of obscuring the original point distribution. Also, the randomness ensures high coverage on object

surfaces. More details are presented in Appendix A.2.

Attack transformation. To transform the attack into a future frame, we need to record the modified LiDAR points and corresponding ray angles. When the next frame is produced, the attacker removes points with the same ray angles, transforms recorded points to the new target region, and appends the transformed points. Since two frames have a minor time interval (100 ms), the transformation preserves physical laws.

Time constraint. The attack generation can start when the attacker's LiDAR image is produced. Though *point sampling* requires the locations of remote LiDARs, they can be predicted using simple linear velocity estimation. The ray casting should be done within one LiDAR cycle.

4.3 White-box Online Adversarial Attack

Intermediate-fusion systems require CAVs to exchange feature maps, the intermediate result of neural network processing. Such systems are immune to the black-box ray casting attacks (§4.2) because the presence of benign feature maps will drop the attack success rate significantly, as demonstrated later in our experiments (§6.3.3). Adversarial machine learning, on the other hand, is able to generate adversarial feature maps. The attack assumes that the attacker has white-box knowledge of perception models.

Insights. We optimize a perturbation on the attacker's feature map by performing a backward pass in each LiDAR cycle and reusing the perturbation over frames as an online attack, similar to Tu et. al. [71]. We introduce two new ideas to achieve realistic real-time targeted attacks.

First, we initialize the perturbation using results from black-box ray casting attacks, making the initial perturbation vector closer to the optimal choice. This step is crucial for achieving real-time attacks as it significantly reduces the number of optimization iterations required.

Second, to restrict attack impact to a specific region, we mask the feature map. This is based on the fact that convolution networks preserve the relationship between feature map indices and real-world locations [49]. Another conventional approach to enforce spatial constraints is to add a regularization term to the loss function (*e.g.,* penalize detection errors in non-attack regions). However, this requires multiple iterations to converge, making it unsuitable for real-time attacks.

Attack methods. The attacker optimizes a perturbation on their feature map over continuous frames. For each frame, the attacker spoof/remove objects in the point cloud first as initialization, then updates the latest perturbation map through an iteration of projected gradient descent (PGD). As the target region moves, the perturbation is re-indexed accordingly in each cycle. The key steps are demonstrated in Figure 4.

Black-box initialization. The attacker starts by modifying the raw point cloud. Unlike the ray casting attack in §4.2, there is no restriction on this modification in terms of the physical laws. Therefore, the attacker tends to inject high-density high-coverage LiDAR points representing the 3D models mentioned in §4.2, which can be prepared offline.

Feature map masking. We make the assumption that each feature map index is associated with a voxel/pillar in the 3D real-world coordinate system. Given the target region, we extend the region by a fine-tuned parameter and extract corresponding feature indices. The masking operation ensures that only features with the selected indices are perturbed. If the index mapping is not explicit, it can be approximated by comparing the feature map before and after the black-box initialization and identifying the indices where the feature values have been altered.

Loss objective. The optimization objective is to increase/decrease the score of the bounding box proposal on the labeled attack region, for spoofing/removing objects. We define the objective function as Equation 4, where Z' denotes the set of bounding box proposals after the perturbation, z'_σ is the score associated with the proposal z', and z_t represents the target region to attack. The objective function maximizes/minimizes the confidence score of proposals overlapping with the target.

$$\begin{aligned} l_{spoof}(Z') &= \sum_{z' \in Z'} \text{IoU}(z', z_t) \cdot \log(1 - z'_\sigma) \\ l_{remove}(Z') &= -\sum_{z' \in Z'} \text{IoU}(z', z_t) \cdot \log(1 - z'_\sigma) \end{aligned} \tag{4}$$

Constraints on perturbation. We clip the perturbation by restricting feature values to their normal range, which is measured on a set of non-attack test cases. As feature values do not explicitly deliver spatial semantics that can be used for anomaly detection, there is no need to restrict feature perturbation to minor thresholds.

Attack transformation. Given the centers of target regions between two consecutive frames, one can get corresponding feature map indices (x_0, y_0) and (x_1, y_1) respectively. Then each index (i, j) in the feature map is mapped to $(i - x_0 + x_1, j - y_0 + y_1)$.

Time constraint. The PGD optimization needs feature maps shared from as many vehicles that cooperate with the victim. Assuming all benign vehicles continuously broadcast and process feature maps at a frequency equal to the LiDAR cycle (T) and the transmission delay is below a threshold t_T, the optimization must be done within $T - 2t_T$.

5 Anomaly Detection

We propose CAD, a Collaborative Anomaly Detection system to mitigate the security threats presented in §4. We enumerate the design challenges in §5.1. In §5.2, we outline our system, followed by the details of key components in §5.3 and §5.4.

5.1 Challenges

As discussed in §2, existing defense mechanisms [23, 55, 69] mainly focus on finding temporal or spatial inconsistencies but they cannot handle attackers who can generating fake data that conform with physics laws. We propose a cross-agent consistency check where all benign vehicles exchange evidence of anomalies to reveal adversarial behaviors jointly. To ensure

the effectiveness, robustness, and generality of the proposed method, we have to overcome the following challenges.

Affordable bandwidth and computation cost. Collaborative perception systems must finish a perception cycle within a hard deadline (*e.g.,* 100 ms [53]). Therefore, CAD should only share minimal, essential data to save bandwidth and distribute data processing on different vehicles to minimize latency. Our method only shares small-sized metadata.

Detection of stealthy attacks. As the attacks may inject malicious data into a specific small region in 3D space, fine-grained anomaly detection is required. For instance, spoofing a ghost vehicle affects a region of approximately 10 m^2 while the perception range is over 4,000 m^2. CAD uses fine-grained occupancy maps to precisely reveal abnormal regions.

Robustness to benign errors. LiDAR data captured by different vehicles have slight differences in timestamps [67, 73]. CAD leverages motion estimation and prediction to synchronize occupancy maps. Localization error is another potential source of faults. As nowadays vehicle localization achieves an accuracy of less than 0.1 m [11], CAD can tolerate minor errors with proper threshold parameters.

5.2 System Overview

CAD is a system deployed on CAVs against data fabrication during collaborative perception. As shown in Figure 5, besides the original perception pipeline, CAVs are required to perform anomaly detection tasks in parallel.

When a local LiDAR image is produced, each vehicle generates an occupancy map that labels on-road objects, free-to-drive regions, and invisible regions in the 2D space. Then the occupancy map is broadcast via a V2V wireless network. The occupancy map is represented in fine-grained polygons, balancing precision and transmission overhead. In addition, motion information of on-road objects is attached for synchronizing occupancy maps from different vehicles.

After collecting occupancy maps from other vehicles, each vehicle launches two consistency checks. *Occupancy consistency check* reveals inconsistencies of occupancy maps, *e.g.,* one region identified as free and occupied by two different vehicles indicates that one of the participants is faulty or malicious. Occupancy maps are then merged into one, with inconsistent regions marked as unknown. *Perception-occupancy consistency check* then ensures the results of collaborative perception are consistent with the merged occupancy map - bounding boxes should overlap with occupied regions instead of free regions; on-road occupied regions should be detected in at least one bounding box. Even though attackers can launch strong stealthy attacks and fake occupancy maps, the attack impact is always reflected by perception results and can be revealed as malicious by benign occupancy maps.

5.3 Occupancy Map

The occupancy map generation involves three steps: point segmentation, space segmentation, and motion estimation.

Point segmentation. First, we eliminate less useful background points that are not on the road using HD maps provided by autonomous driving systems [7, 8]. Then, we apply ground fitting algorithms (*e.g.,* RANSAC [36] to detect the ground plane and remove LiDAR points on it. By clustering the remaining points based on point density, we can identify all non-ground objects on the road, with each cluster representing a unique on-road object. The method has been proven to be effective in prior research [35, 76, 83].

Space segmentation. After identifying on-road objects, we generate a fine-grained representation of 2D space occupancy, which classifies the 2D space into three categories: *free*, *occupied*, and *unknown*. (1) Occupied regions are the convex hulls [24] of the object clusters. (2) Free regions represent the region surrounded by only ground points. We evenly divide the 2D space into equal sectors whose vertex is the LiDAR sensor location. The number of sectors can be adjusted for different levels of granularity. In each sector, we measure the distance from the LiDAR to the closest non-ground point and label the region within the distance as a free region. A basic implementation of free regions is described above, while we introduce an optimized implementation in Appendix A.3. (3) The remaining region is classified as unknown due to occlusion or the limited range of LiDAR sensors. Since the accuracy of segmentation and clustering drops as LiDAR points get sparser, in the implementation, we define a 2D space as unknown if its distance to the LiDAR sensor exceeds a threshold (*e.g.,* 50 m). Unlike conventional grid-based occupancy maps [45, 50, 62], our occupancy map divides regions using polygon representation. Our approach offers two advantages over grid representation: (1) polygons can more precisely depict arbitrary shapes; (2) by adjusting the outline smoothing factor, polygon representation provides greater flexibility to strike an optimal balance between precision and size.

Motion estimation. First, each CAV executes a multi-object tracking (MOT) process on object point clusters. Inspired by AB3DMOT [75], a baseline solution of MOT, we assign an affinity score to each object pair between two consecutive frames. This affinity score indicates the level of similarity considering factors such as distance and point density. Using the scores, MOT algorithms can match the same object across frames. Second, given two point clusters that refer to the same object but on two consecutive frames, we use point cloud registration to derive a transformation matrix between them. Formally, if two object clusters with timestamp t' and t ($t - t' \approx T$ where T is LiDAR cycle time) are denoted as $X_{t'}$ and X_t respectively, the transformation matrix T_t satisfies $X_t = T_t \cdot X_{t'}$. We then standardize the matrix to *motion per time unit* - divide translation and rotation extracted from T_t by the time gap $t - t'$ and reconstruct the matrix as T_e. We define this operation as SCALE: $T_e = \text{SCALE}(T_t, \frac{1}{t-t'})$. T_e represents the latest motion of the specific object and is attached to the corresponding occupied region in the occupancy map. Also, the maps should be transformed into a global coordination

system as a consensus of all CAVs.

5.4 Consistency Checks

The processes of consistency checks are triggered simultaneously with the data fusion, involving occupancy map synchronization, occupancy consistency checks, and perception-occupancy consistency checks.

Occupancy map synchronization. After receiving a set of occupancy maps with slightly different timestamps, each vehicle aims to synchronize all maps to the timestamp of the latest local LiDAR image. For each on-road occupied region in each occupancy map (except the local map), we first calculate its time gap to the target timestamp, denoted by Δ_t. We then transform the occupied region by applying the transformation $\textsc{Scale}(T_e, \Delta_t)$, where T_e is the corresponding motion per time unit. After moving all occupied regions, we post-process the occupancy map by excluding new occupied regions from the original free regions to resolve conflicts. In this way, all occupancy maps can be directly merged as they have been synchronized spatially and temporally. Formally, we denote synchronized occupancy maps by $M^{(i)} = (S_O^{(i)}, S_F^{(i)})$ where $i \in \{0, 1, \ldots, N\}$ denotes vehicle IDs ($t = 0$ denotes the ego vehicle) and S_O/S_F denotes occupied/free regions.

Occupancy consistency check reveals inconsistencies among synchronized occupancy maps. A region is considered conflicted if it is identified as occupied by one vehicle and free by another. We can define conflicted regions as

$$\varepsilon_{occ} = \bigcup_{i,j \in 0 \ldots N} S_O^{(i)} \cap S_F^{(j)}. \tag{5}$$

Considering the inevitable imperfection of synchronization, in the implementation, CAD will ignore conflict regions whose area is below a threshold (*i.e.,* σ_{occ}). Alerts are raised indicating the uncertain risks on conflicted regions.

Next, each vehicle generates one consistent occupancy map by merging available occupancy maps and dropping conflicted regions. Particularly, the occupancy map produced by the ego vehicle is trusted and retained in the merged map, unless sensors of the ego vehicle is detected as compromised by existing detection of LiDAR spoofing [55, 69]. The new occupancy map $M' = (S'_O, S'_F)$ is generated as:

$$\begin{aligned} S'_O &= S_O^{(0)} \cup \Big(\bigcup_{i=1 \ldots N} S_O^{(i)} - \varepsilon_{occ} - S_F^{(0)} \Big) \\ S'_F &= S_F^{(0)} \cup \Big(\bigcup_{i=1 \ldots N} S_F^{(i)} - \varepsilon_{occ} - S_O^{(0)} \Big) \end{aligned} \tag{6}$$

Perception-occupancy consistency check aims to reveal inconsistencies between the perception results and the merged occupancy map based on two rules. First, free regions should have overlap with predicted object bounding boxes. According to LiDAR sensor physics, objects on the road, if observable, always leave LiDAR points above the ground and should be clustered as occupied regions. This rule can counter object spoofing attacks, as attackers may spoof fake objects in free regions perceived by benign vehicles. Second, occupied regions should be within predicted bounding boxes. Similarly, point clusters on roads are potential obstacles and should be detected to avoid a collision. It serves as a countermeasure against object removal attacks where attackers make real objects undetectable. By checking the two rules, alerts are raised on conflicted regions, similarly filtered by a threshold of area (*i.e.,* σ_{spoof} and σ_{remove}). Formally, if we denote predicted bounding boxes as Y, alerted regions include:

$$\varepsilon_{spoof} = \bigcup_{y \in Y} y \cap S'_F \quad \varepsilon_{remove} = \bigcup_{s'_O \in S'_O} s'_O - Y \tag{7}$$

5.5 Limitations

CAD is a mitigation other than elimination of our proposed attacks. First, CAD cannot work in certain extreme scenarios. The detection could be successful only when at least a benign CAV observes the attacked region. Otherwise, the attacked region is an occluded region for all benign CAVs thus no conflict will appear in Equation 7. Second, CAD detects but may not resolve the anomalies. Though the system may identify the possible attackers via majority voting, it is limited in effectiveness if benign CAVs do not dominate the road.

6 Evaluation

We introduce our dataset creation in §6.1 and the implementation details in §6.2. Then, we present a comprehensive evaluation of the proposed attacks and defenses in §6.3 and §6.4.

6.1 Data Collection

Adv-OPV2V. OPV2V [79] is a benchmark dataset for collaborative perception algorithms, with data collected from a combination of simulators, CARLA [5] and SUMO [12]. We generate Adv-OPV2V from OPV2V, as a benchmark for testing collaborative perception attacks and defenses. We select 300 scenarios for object spoofing and removal attacks respectively. Each scenario features 10 consecutive frames and 3 to 5 CAVs among which one attacker and one victim are designated. Each scenario also has predefined attack targets, such as a trajectory of a ghost vehicle for object spoofing or a trajectory of an existing vehicle for object removal. To ensure the real-world impact of the attacks, we limit the distance between the victim and the target to less than 30 m.

Adv-MCity. We create a real-world multi-vehicle collaborative perception dataset using testbed MCity [19], which is a real-world mock city for testing CAV applications. On real roads, we deploy 3 Lincoln MKZ vehicles as CAVs, which are equipped with OxTS RT3000v3 GPS, Velodyne VLP-32C LiDAR, and Cohda MK6C OBU as a C-V2X receiver. We also deploy several other vehicles as perception targets. We create 8 attack scenarios that contain potential safety hazards, with 4 for object spoofing and 4 for object removal. We collect LiDAR, GPS, and C-V2X network traces from all CAVs to allow for emulation of collaborative perception.

6.2 Implementation

Collaborative perception models. For Adv-OPV2V, we utilize pre-trained models provided by OPV2V, which employ

Table 3: Performance of attacks and defenses on Adv-OPV2V.

Attack setting: Method-Fusion-Goal	Attack results				Defense results		
	Succ.	IoU	Score	ΔAP	Succ.	TPR	FPR
[72]-Int.-Spoof	21.7%	0.01	0.06	-62.8%	100%	34.0%	10.3%

Notes: *Int.* - intermediate-fusion. *RC* - ray casting. *Adv.* - adversarial attack. *Succ.* - success rate.

naive point cloud merging in early-fusion and attentive learning in intermediate-fusion. In early-fusion methods, the point clouds are naively concatenated together. In intermediate-fusion methods, the fusion is defined by the models. For Adv-MCity, we augment the OPV2V training data to approximate the LiDAR images collected in the testbed MCity and fine-tune the pre-trained models. During the training of models, an uniform noise of at most 0.2 m or 0.2° is injected to vehicle locations or rotations respectively, in order to better tolerate localization/synchronization errors in real scenarios, following the previous work [58, 73, 78].

Attacks are implemented in 4,874 lines of code (LOC) in Python. The adversarial shape generation is based on a classic genetic algorithm with a population size of 10 and for 5 generations. Adversarial attacks are based on Torch. We fine-tune the learning rate to 1 and optimize for a maximum of 25 iterations. The perturbation of feature maps is restricted in a 5 m×5 m square centered by the target location.

Anomaly detection is implemented in 1,629 LOC in Python, which uses polygon operations in shapely and implementation of RANSAC and DBSCAN from Open3D. The system parameters (*i.e.*, $\sigma_{occ}, \sigma_{spoof}, \sigma_{remove}$) are not fixed but evaluated through the receiver operating characteristic (ROC) curve.

In-vehicle execution environment. To demonstrate system deployment on real vehicles, we implement a collaborative perception framework based on Robot Operating System (ROS), consisting of 3,154 LOC in C++ responsible for V2V communication and basic sensor data processing. Our implementation of attacks and anomaly detection can be plugged into the framework as ROS nodes. For performance measurement, we use an in-vehicle machine with an Intel Xeon Silver 4110 CPU and an Nvidia RTX 2080 Ti GPU.

Our implementation is open source at https://github.com/zqzqz/AdvCollaborativePerception.

6.3 Evaluation of Attacks

We present our attack results in §6.3.1. We further analyze the impacting factors in attacks (§6.3.2) and present an ablation study (§6.3.3). We realize attacks in the testbed MCity, evaluate the overhead (§6.3.4) and conduct case studies (§6.3.5).

6.3.1 Attack Results

To evaluate attack effectiveness, we launch each proposed attack on 300 attack scenarios in Adv-OPV2V against baseline perception models using PointPillars [49] as the backbone. Attack results are listed in Table 3. In each attack scenario, we identify the best predicted bounding box having the largest Intersection over Union (IoU) with the target region. A spoofing attack is considered successful if the IoU is greater than zero while a removal attack is considered successful if the IoU is zero. For late-fusion systems, object spoofing is trivial to reach almost 100% success rate while object removal is hard as long as one benign vehicle observes the object. Our proposed attacks against early/intermediate-fusion are generally successful with a success rate above 86%.

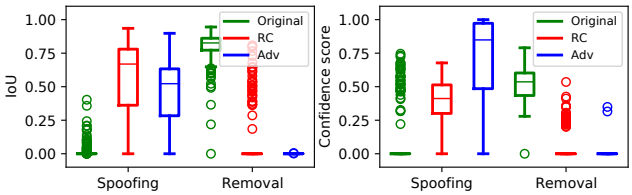

Figure 6: IoU/confidence on target region under the prior attack, our ray casting (RC) and adversarial (Adv) attacks.

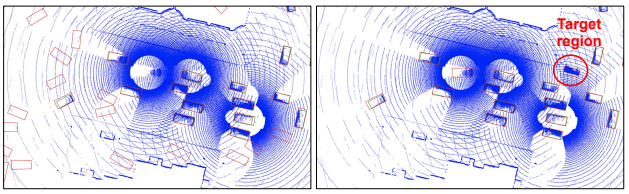

Figure 7: Different stealth of untargeted/targeted attacks.

In addition, we illustrate the change of IoU and confidence score on target regions in Figure 6. We observe that attacks make a significant change in the two metrics. For spoofing attacks, the early-fusion ray casting attack achieves a larger IoU meaning more accurate spoofed bounding boxes while the intermediate-fusion adversarial attack pushes the confidence score to extremely high (> 0.8). The result indicates that attacker is easier to launch sophisticated attacks against early-fusion systems since attackers can directly manipulate the subtle spatial features - LiDAR points. The intermediate-fusion system enforces fewer constraints on malicious perturbation thus the upper bound of the attack impact is higher. The change of Average Precision (ΔAP) on non-attack regions is minor, which means all attacks focus on perturbing the target region. However, ΔAP of intermediate-fusion attacks is higher because the perturbation on feature maps inevitably propagates to a larger region through convolution layers.

We also reproduced the prior attack proposed by Tu *et al.* [72] We use the loss function and attack parameters from the paper and the constraint of perturbation the same as our adversarial attack. We also allow the unrealistic attack constraints as discussed in §3.2. Attack results on Adv-OPV2V are shown in Table 3 and Figure 6. The prior attack is successful in its attack goal to inject as many false perception bounding boxes as possible, by injecting on average 56.2 FPs and 3.6 FNs in each LiDAR frame. The overwhelming FPs drop *AP* to nearly 1%. However, when attacking a certain region, it only yields 14%-22% success rate because the attack is untargeted fundamentally. The major problem of the

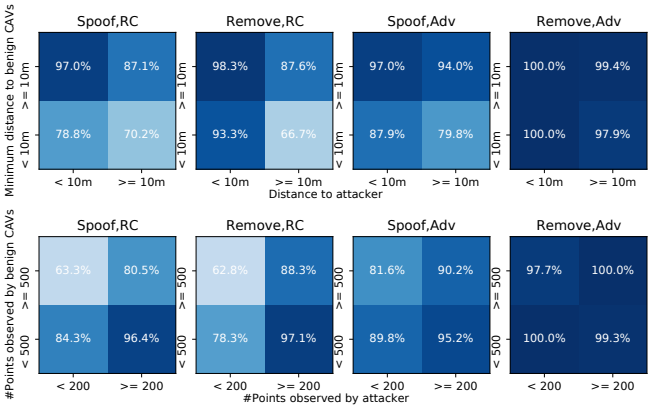

Figure 8: Attack success rate w.r.t. target visibility.

untargeted approach is stealth of attacks. The untargeted attack generates a significant number of abnormal bounding boxes that are out of the road or heading away from the lane direction, as shown in Figure 7. The uncontrollable attack impact can be easily recognized by either humans or automatic anomaly detection.

6.3.2 Impacting Factors

Visibility of the target region. We hypothesize that the attack is more successful when the target region is clearly visible to the target but not benign CAVs. Intuitively, the target is more visible if it is closer to the LiDAR or there are more LiDAR points on it. To validate the hypothesis, we draw relationship between attack success rate and the two metrics in Figure 8. The result shows that the attack is more successful when the attacker is closer to the target while benign CAVs are further away, or the attacker has more LiDAR points in the target region while benign vehicles have fewer. The impact of the visibility is obvious in early-fusion systems but not intermediate-fusion systems. The difference is reasonable because for early-fusion schemes, more LiDAR rays interact with closer targets thus attackers can manipulate more LiDAR points without violating LiDAR sensor physics.

Benign errors. It is worth nothing that attacks should tolerate errors in real systems. To simulate the worst-case synchronization errors, we delay any LiDAR frame by 100ms at a probability of 0.5. To simulate localization errors, we incorporate uniform noise into vehicle locations (0 – 0.2 m) and orientations (0 – 0.2°), following existing works [11, 78]. Network errors can manifest as delays, corruptions, or dropped messages, all of which hinder the proper sharing of data. If the attacker's malicious data fails to reach the victim, the attack on that frame will certainly fail. Conversely, if benign vehicles' data cannot reach the attacker, less data is used for attack optimization, potentially leading to less successful attacks. To simulate such scenarios, we randomly drop 10% of data sharing during the attacks. The 10% error rate is regarded as the highest threshold of acceptable network connection by previous studies [70, 89].

From the results in Figure 9, synchronization and localization errors have very minor impact on the attacks. Network errors decrease the success rate by 10-20%, with a 10% reduction attributable to the fact that 10% of the attacker's messages fail to reach the victim. Even with the barely acceptable network connection, our attacks can achieve at least 60% success rate, showing the robustness against benign errors.

Model configuration. Our attacks are general for various collaborative perception models. In Figure 10, the attack success rate is stable if (1) replacing the backbone model by VoxelNet [90] in either early-fusion or intermediate-fusion methods; (2) changing the fusion network of intermediate-fusion system to V2VNet [73] or CoBEVT [77]. However, FPV-RCNN [82] involves a second-stage non-differential fusion on bounding box proposals (similar to late-fusion), making object removal hard.

Object types. We generalize our attacks from vehicle targets to pedestrians and cyclists. As OPV2V [79] only has vehicles originally, we augment OPV2V to include pedestrians and cyclists by modifying the simulation settings and re-training the models. As shown in Figure 11, the attacks are generally effective for different object types. Especially, removing pedestrians is easier than removing other object types because they usually comprise a small number of LiDAR points and have a low detection confidence.

Number of attackers. One attacker is strong enough to break collaborative perception. Adding another attacker can further increase the success rate of ray casting attacks and adversarial attacks by around 5% and 2%, respectively.

6.3.3 Ablation Study

For each attack we propose, we provide a set of variants by removing one or more components from the original design. Attack results are summarized in Figure 12 and the complete quantitative results are in Appendix C.

For ray casting attacks against early-fusion systems, we design the following variants. (1) *RC*. Baseline ray casting pretending the object to spoof/remove emerged/disappeared. Especially for object removal, *RC* uses the adversarial shape while *NoAS-RC* does not. (2) *Dense-A-RC*. Based on *Naive-RC*, make the spoofed points denser by placing the origin of rays only 5-meter away from the target during ray casting. (3) *Dense-All-RC*. More than *Dense-A-RC*, add multiple virtual LiDARs around the target to further increase point coverage. (4) *Sampled-RC*. Based on *RC*, do non-occlusion ray casting and point sampling as mentioned in §4.2. (5) *Async-Sampled-RC*. The proposed attack. Based on *Sampled-RC*, optimization is done one frame before the attack happens.

The attack results validate our assumptions and prove our design components are useful. *Point density* and *Point coverage* lead to stronger attacks. *Dense-A-RC*'s success rate is 12%/15% higher than *RC* for spoofing/removal. *Dense-All-RC*'s success rate is 6%/31% higher than *Dense-A-RC* for spoofing/removal. However, *Dense-A-RC* and *Dense-All-RC* are not stealthy attacks as spoofed points have abnormal den-

Figure 9: Attack success w/ and w/o benign errors.

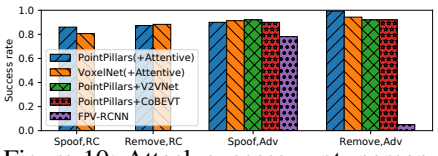

Figure 10: Attack success w.r.t. perception model configurations.

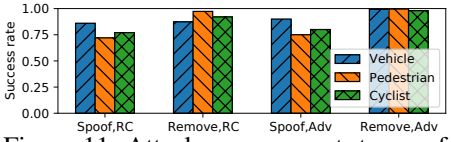

Figure 11: Attack success w.r.t. types of target objects.

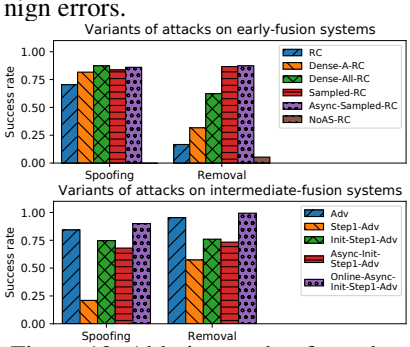

Figure 12: Ablation study of attacks.

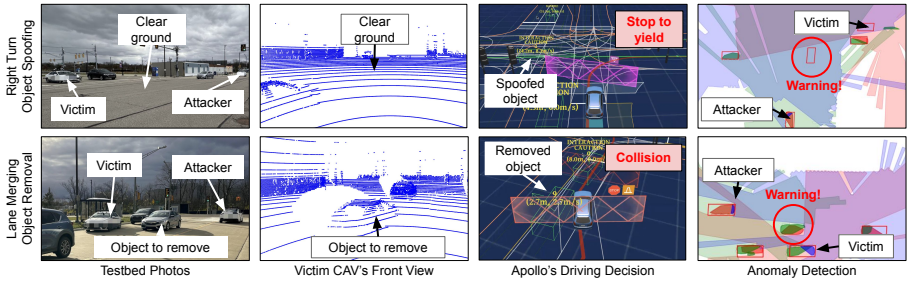

Figure 13: Real-world experiments of attacks and anomaly detection, involving early/intermediate-fusion attacks on two scenarios.

sity. Therefore, we propose *Sampled-RC*, whose success rate is 14%/50% higher than the naive ray casting while preserving LiDAR's physical laws. Finally, our asynchronous attack scheduling makes *Async-Sampled-RC* deployable in real-time systems, without a significant drop in success rate. In addition, the universal adversarial shape is crucial for object removal. Naively replacing object points with ground points only achieves a 5% success rate and the usage of adversarial shapes raises the number to 17%.

For adversarial attacks against intermediate-fusion systems, we design the following variants. (1) *Adv*. Basic implementation of PGD. It does not constrain the attacker's knowledge or number of optimization steps and disables black-box initialization. Instead of using perturbation masking, we add a regularization term to achieve a targeted attack. (2) *Step1-Adv*. Based on *Adv*, do optimization for only one iteration. Parameters are set the same as §6.2. (3) *Init-Step1-Adv*. Based on *Step1-Adv*, add black-box initialization. (4) *Async-Init-Step1-Adv*. Based on *Init-Step1-Adv*, optimization is done one frame before the attack happens. (5) *Online-Async-Init-Step1-Adv*. Our proposed attack (§4.3). Online attack optimizing one perturbation vector over consecutive frames.

We conclude the effectiveness of our key designs. *Adv* is a standard white-box adversarial attack with the minimum constraints and maximum resources, representing the empirical upper bound of attack impact. Limiting optimization iteration to only one per frame, though significantly lower computation cost, drops attack success rate by 63%/48% for spoofing/removal. To address the problem, we propose black-box initialization. The design is very useful, especially for object spoofing: *Init-Step1-Adv* achieves 53%/8% higher attack success rate than *Step1-Adv*. Finally, *Async-Init-Step1-Adv* integrates the zero-delay attack scheduling without dropping attack effectiveness and *Online-Async-Init-Step1-Adv* builds an online attack pipeline which further enhances the attacks.

6.3.4 Overhead

We measure the execution latency of our attack algorithms in the in-vehicle execution environment. For ray casting attacks, 3D object model preparation is done offline. The non-occlusion ray casting takes 54 ms on average. Our implementation of ray casting is CPU-only and can be further improved by hardware acceleration. The point sampling takes only <3 ms. Attack transformation introduces a negligible overhead of <1 ms. For adversarial attacks, the point cluster for black-box initialization is prepared offline thus the initialization simply appends pre-computed points to the LiDAR image, incurring a negligible overhead of <1 ms. The one-step PGD optimization is computationally intensive and requires GPU resources, taking 67 ms on average. The total attack generation is finished in 89 ms on average within one LiDAR cycle. The cost of attack transformation is negligiable.

6.3.5 Real-world Case Study

Attacks must be realizable. We test attack algorithms by emulating driving scenarios using dataset Adv-MCity. In this section, we focus on case studies on two scenarios, as shown in Figure 13. All scenarios are described in Appendix B.

Object spoofing during right turn. The victim CAV is turning right at green while the attacker CAV stops on another road. The attacker's goal is to spoof one fake vehicle to stop the victim, forming a denial-of-service (DoS). First, we launch ray casting attack assuming CAVs use early-fusion collaborative perception. Since the victim is far away from the attacker (>30 m), it is hard to directly spoof an object in front of the victim. However, the attacker can leverage the traffic rule implemented in CAVs by spoofing a moving vehicle whose trajectory blocks the victim's path. In 5 seconds, the attack succeeds to spoof the vehicle in 76% of frames. Baidu Apollo indeed stops the vehicle to yield the spoofed vehicle. Second, if CAVs use an intermediate-fusion system, the adversarial attack can achieve a stronger attack by spoofing an obstacle

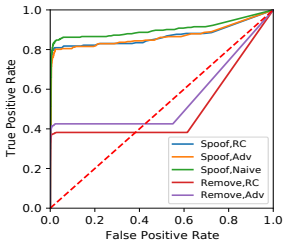

Figure 14: ROC curve of anomaly detection.

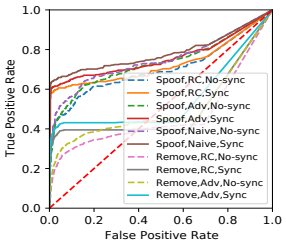

Figure 15: ROC curve w/ and w/o synchronization.

right in front of the victim in 92% of frames.

Object removal during lane merging. The victim CAV is starting from a parking place to merge into the main road while another vehicle is going through from behind. Normally, the victim should yield the right of way. The attacker sits on another lane, aiming to remove the moving vehicle from the view of the victim. The ray casting attack succeeds in removing the vehicle in the first 45 frames but fails in the last 5 frames because the target is further. Nevertheless, it is too late when the victim perceives the target and Baidu Apollo reports a collision. Also, using the white-box adversarial attack against intermediate-fusion perception has a similar attack impact, removing the vehicle in 96% of frames.

6.4 Evaluation of Anomaly Detection

We evaluate effectiveness and efficiency in §6.4.1 and §6.4.3. We then compare CAD with existing defenses in §6.4.4. We demonstrate the real-world deployment in §6.4.5.

6.4.1 Defense Results

We apply CAD on attacked frames in Adv-OPV2V. Note that CAD is supposed to detect both attacks and perception faults, as long as the predicted bounding box has no overlap with ground-truth or the ground-truth bounding box is not detected. We consider adaptive attacks, where the attacker fakes his/her occupancy map to avoid conflicts with other occupancy maps or detected bounding boxes. Therefore, *occupancy consistency check* in §5 cannot defend adaptive attacks but serves as input validation before merging occupancy maps.

In Table 3, true positive rate (TPR) and false positive rate (FPR) are calculated on the whole LiDAR images, including the detection of both malicious attacks and benign perception faults. On the other hand, success rate measures the detection of only malicious attacks, which is the ratio of positive detection on the target region and the total number of attack scenarios. We also show the ROC curves in Figure 14. CAD is generally effective against various attack methods. If selecting thresholds σ_{spoof} and σ_{remove} to maximize AUC score, CAD achieves FPR <3% and TPR >80%/38% against spoofing/removal while detecting around 90% of anomalies caused by our attacks. From the split-down of alarms in Figure 16, low TPR against removal threats is mainly caused by undetected benign perception faults which are out of the range of occupancy maps. The "false alarms" are mostly the cases where predicted bounding boxes is not accurate (IoU < 0.5). Though considered as normal cases by our criteria, they have significant differences with accurate object detection.

We also apply CAD on the prior attack [72]. As the prior attack is untargeted and injects a few dozens of fake detection results in each LiDAR image, it is easy for CAD to reveal 100% of the attacked frames, as shown in Table 3. The low TPR (around 30%) is because the occupancy maps cannot cover lots of the far-away fake detection results.

Other adaptive attacks. The attacker may exploit *occupancy consistency check* to create as many conflicts as possible to minimize the coverage of the merged occupancy map and decrease TPR. However, if the occupancy conflict is with the victim's local map, the attacker is directly identified because the local data is trusted. This ensures a lower bound of TPR by using only local occupancy maps (71.7%/24.0%/70.4%/28.7%/78.1% against the attacks in Table 3). Also, occupancy conflicts obviously indicate the existence of attackers and are useful messages for other defense mechanisms such as reputation systems.

The attacker may also choose to launch attacks at locations out of the coverage of occupancy maps. However, our experiments on Adv-OPV2V show that benign occupancy maps cover 95.6% in 30 meters and 99.9% in 10 meters around the victim. It is very little chance for the attacker to spoof/remove objects stealthily at a safety-critical distance.

6.4.2 Impacting Factors

Distance to LiDAR sensors. As shown in Figure 17, over 80% false alarms are 60 meters away from any benign vehicles. Within the range of occupancy maps (50 meters in our configuration), CAD can stably make true detection.

Synchronization. With injected synchronization errors as introduced in §6.3.2, CAD's synchronization provides significant robustness. As shown in Figure 15, CAD is not effective without synchronization, having TPR 35%/15% against spoofing/removal when FPR is low (<5%). With synchronization, CAD achieves TPR 60%/40% against spoofing/removal, close to the detection rate on ideal synchronized data.

Localization errors. With the injected localization errors as stated in §6.3.2, we observe a minor decrease of accuracy (TPR -3.1%, FPR +0.2%), showing CAD's robustness.

Object types. As CAD uses the area of conflicted regions as the key metric, smaller object sizes result in higher FPR, e.g., minor conflicts caused by errors of occupancy maps may be falsely considered as anomalies. By choosing the best AUC score of the ROC curve, CAD detects pedestrian spoofing, pedestrian removal, cyclist spoofing, and cyclist removal in FPR/TPR of 78.4%/14.5%, 38.2%/13.9%, 81.7%/6.5%, and 29.4%/6.2%, respectively. When compared with the detection of fake vehicles, CAD yields around 12%/4% higher FPR on pedestrians/cyclists while maintains TPR stable.

Number of attackers. More attackers decrease the coverage of benign occupancy maps and cause more false negatives.

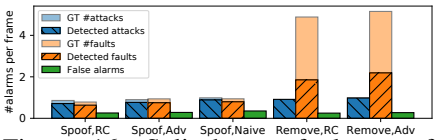

Figure 16: Split-down of alarms of anomaly detection.

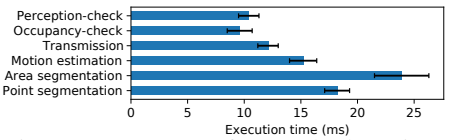

Figure 18: Latency of anomaly detection.

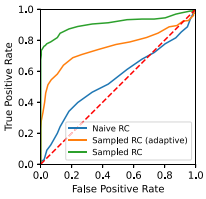

Figure 19: ROC curve of CARLO.

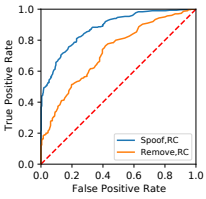

Figure 20: ROC curve of LIFE.

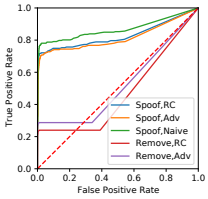

Figure 21: ROC curve of MDS.

Adding another attack decreases TPR by 5% on average.

6.4.3 Overhead

We measure the latency of the anomaly detection using the in-vehicle execution environment and recorded network traces [60]. Segmentation/clustering algorithms are relatively expensive but they can be further boosted using hardware acceleration [28]. Occupancy map transmission is as fast as 10ms. Each map contains around 300-1000 polygon vertices and lightweight metadata of object motion, in a small size of around 10 KB. Consistency checks are simple polygon operations that can be finished in 15ms. The end-to-end anomaly detection takes 92ms, which means the CAV can be aware of abnormal bounding boxes before the LiDAR cycle ends.

6.4.4 Comparison with Other Defense Approaches

CARLO [69] is an anomaly detection algorithm detecting LiDAR spoofing attacks. Given the fact that detected bounding boxes should host solid objects, CARLO validates that the volume of "free space" (conical spaces between the LiDAR sensor and rendered points) in bounding boxes is under a threshold. In collaborative perception, we assume the victim CAV applies CARLO on each received LiDAR point cloud.

Results are shown in Figure 19, which detects our proposed ray casting attack (Sampled RC) with TPR 77.7% and FPR 3.9%. However, attackers can adjust the rule of point sampling in §4.2 to launch adaptive attacks. For instance, the attacker can restrict the number of points that can penetrate object surfaces to be <30% (Sampled RC adaptive). As a result, TPR decreases to 63.8% and FPR increases to 14.7% while the success rate only drops by 5.6%. If forbid ray penetration completely (Naive RC), CARLO is close to random guessing while the success rate of our attack is still above 70%. In contrast, CAD achieves higher TPR and, more importantly, is independent of attack methods.

LIFE [55] is a hybrid anomaly detection system against sensor attacks. First, it checks the temporal consistency of depth camera images based on machine learning methods. As discussed in §5.1, attackers have the capability to continuously launch attacks thus the check is fundamentally not useful. Besides, an object matching algorithm checks the consistency between objects detected in the camera and the LiDAR. In early-fusion systems, CAVs can launch object matching on remote LiDAR and local camera images. To reproduce LIFE, we use the same LiDAR segmentation as CAD and train a EfficientPS [59] model for camera image segmentation.

We draw the ROC curve of object matching in Figure 20. LIFE's object matching achieves around 80% TPR and 26% FPR against early-fusion ray casting attacks. LIFE suffers from a higher FPR because multiple machine learning processes introduce more errors - inaccurate detection from either camera or LiDAR, which is usual on far-away objects, may trigger a false alarm. Compared with LIFE, CAD has a higher detection rate with much lower computation/bandwidth consumption, thanks to the collaboration among CAVs.

MDS [23] is an anomaly detection framework assuming CAVs to share bounding boxes. Besides checks on message format and temporal consistency which are not relevant to our attacks, each CAV evaluates the consistency between the local occupancy map and final perception results, and also merges anomaly detection results from multiple CAVs by majority voting. However, the attackers can launch adaptive attacks to only send falsified data to the specific victim instead of all other CAVs, thus the majority voting is actually not helpful. Compared with CAD, the spatial check is restricted on the local occupancy map (without the sharing of occupancy maps) thus TPR is lower by 9-15%, as shown in Figure 21.

CAD has no conflicts with the above defenses. Users can deploy multiple defenses to strengthen sensor data integrity.

6.4.5 Real-world Case Study

We demonstrate CAD on the same attack scenarios discussed in §6.3.5, shown in Figure 13. In the scenario of the right turn, though the spoofed object is in the blind spot of the victim (red), another benign vehicle (blue) observes that region and identifies the anomaly when it is 15 meters away from the victim. In the scenario of lane merging, the victim vehicle recognizes an object point cluster on the left but is not detected by the perception system, triggering a warning of object removal 2.1 seconds before a potential collision. In other scenarios in Appendix B, our anomaly detection can detect attacks at least 1.5 seconds before a collision or hard brake happens. The anomaly detection can be more robust when there are more benign vehicles on busy roads.

7 Conclusion

In this work, we pioneer to examine the threats posed by data fabrication on collaborative perception systems. We unleash novel attacks that successfully spoof or remove on-road objects in various types of collaborative perception schemes and demonstrate the attack impact on real traffic scenarios. To mitigate the threats, we introduce a cross-vehicle validation solution powered by fine-grained occupancy maps, which detects anomalies seconds before potential road hazards occur. Our attempts of both attacks and defenses serve as a benchmark to spur future research on collaborative perception security.

A Algorithm Details

We introduce more implementation details of attack and defense algorithms proposed in §4 and §5.

A.1 Universal Adversarial Shape

As mentioned in §4.2, the universal adversarial shape is for early-fusion object removal attacks. We find that spoofing an adversarial shape covering the original object to remove is

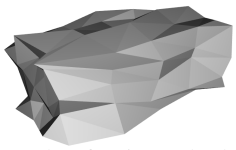

Figure 22: Example of universal adversarial shape.

Algorithm 2: Universal adversarial shape generation.

Input: An initial 3D shape S_0, a set of attack cases X.
Output: A universal adversarial shape S_{adv}.
Initialize a set of perturbation on vertices of S_{in}: P;
Initialize genetic algorithm instance: GENETIC(P);
for *Iteration* $1 \ldots K$ **do**
  for $p_i \in P$ **do**
    for $x_j \in X$ **do**
      $x'_j \leftarrow \text{REMOVALATTACK}(x_j, S_0 + p_i)$;
      $y'_i \leftarrow \text{PERCEPTION}(x'_j)$;
      $I_i \leftarrow I_i - \sum_{y \in Y'_i} \text{IoU}(y, y_t^{(j)}) \cdot log(y_\sigma)$;
    end
  end
  $S_{adv} \leftarrow S_0 + \text{BESTSOLUTION}(P,I)$ $P \leftarrow \text{GENETICUPDATE}(P,I)$;
end

surprisingly useful. As the generation of adversarial shapes involves time-consuming optimization, we aim to generate a universal shape that can be pre-computed offline and is general for different scenarios.

As shown in Algorithm 2, the generation algorithm is based on black-box genetic optimization. In our implementation, we create the initial shape as a cuboid and randomly select 50 diverse object removal attack scenarios as X. For the genetic algorithm, the initial population is a set of random perturbations on the initial shape and other parameters are set as mentioned in §6.2. For each perturbed shape, we launch the attack defined in §4.2 on each attack case and calculate an average fitness score as Equation 8:

$$F(y) = \sum_{y \in Y} \text{IoU}(y, y_t) \cdot log(1 - y_\sigma), \tag{8}$$

where $y \in Y$ denotes predicted bounding boxes, y_σ denotes confidence scores, and y_t denotes the target region. The black-box optimization minimizes Intersection over Union (IoU) on the target region and confidence score simultaneously. Note that we will scale and transform the shape to a bounding box that has the same center as the target region but is 0.6 m (fine-tuned by experiments) larger on all dimensions, making sure the adversarial shape covers the original object edges. The remaining optimization steps are handled by the genetic algorithm itself. Figure 22 shows the universal adversarial shape we used for attacking Adv-OPV2V.

A.2 Point Sampling

The point sampling resolves occlusion conflicts after ray casting and meanwhile maximizes attack effectiveness, as shown in Algorithm 3. Each ray after non-occlusion ray casting has a set of intersection points with the target 3D model and the point sampling algorithm assigns each intersection point with a probability, which is larger when the points are closer to benign LiDARs, as mentioned in §4.2. The location of LiDARs is broadcast in collaborative perception, which is necessary to merge multi-source LiDAR images. Also, there is a parameter tuning how much rays can penetrate object surfaces. The fewer rays that can penetrate surfaces, the more natural the spoofed point clouds are, as discussed in §6.4.4.

Algorithm 3: Point Sampling.

Input: A mapping from one ray to a set of points intersected with 3D model M, LiDAR poses of benign vehicles L, a parameter of the probability of penetration $0 \leq \sigma_p \leq 1$.
Output: A mapping from one ray to one intersection point M'.
for $r, X \in M$ **do**
  if $\text{RANDOM}() < \sigma_p$ **then**
    $D \leftarrow \text{COMPUTEDISTANCE}(X, L)$;
    $P \leftarrow \text{PROBABILITY}(D)$;
    $M'(r) \leftarrow \text{RANDOMCHOICE}(X, P)$;
  else
    $M'(r) \leftarrow \text{CLOSEST}(X)$;
  end
end

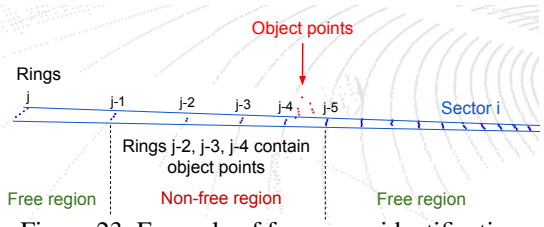

Figure 23: Example of free space identification.

A.3 Space Segmentation

We provide implementation details for identifying free regions to the best precision.

LiDAR sensors equip vertically placed laser transmitters. In each LiDAR cycle, the LiDAR sensor rotates itself thus the lasers scan the object surfaces. Therefore, points in the LiDAR image can be grouped according to which laser they belong to, called "rings". Inner rings are closer to the LiDAR sensor, and vice versa. Also, we can group LiDAR points by splitting the bird-eye view 2D space into sectors whose vertex is the location of the LiDAR sensor. In this way, each LiDAR point has a ring ID and a sector ID, as shown in Figure 23. After grouping LiDAR points into rings and sectors, we execute Algorithm 4 to label free regions. First of all, we identify point groups that entirely consist of ground points. Then, we search in each sector i for consecutive rings from j to $j+k$ which are all ground point groups and generate a polygon covering a segment of sector j between the furthest point of ring i and the closest point of ring $j+k$. For now, we ensure that this region is not occluded by other objects, otherwise at least one point in these rings is an object point. Next, we double check no object point falls in the polygon, in case there are objects above the ground. If no object points are found, we can finally label the polygon as a free region.

Our free space segmentation is precise in two folds. (1) The grouping of LiDAR points follows the physical laws of LiDAR sensors thus each group has a similar number of points, making the segmentation stable even in far-away regions. (2) The identification of free regions is conservative by taking occlusion and floating objects into account.

Note that the size of sectors and rings is configurable for a good trade-off between precision and data size. In our implementation, we split the 2D space into 360 sectors, each for 1°. The number of rings depends on the number of lasers

Algorithm 4: Segmentation of free regions.

Input: Point cloud X, rings R, sectors E, object points $X_{obj} \subseteq X$, ground points $X_{grd} \subseteq X$.
Output: Polygons S_F as 2D free regions.

$S_F \leftarrow \emptyset$;
$F \leftarrow \emptyset$ as the set of ground point groups;
for $e_i \in E$ **do**
  for $r_j \in R$ **do**
    $X_{i,j} \leftarrow \text{GetPoints}(e_i, r_j)$;
    if $X_{i,j} \cap X_{obj} = \emptyset$ *and* $X_{i,j} \subseteq X_{grd}$ **then**
      Push $X_{i,j}$ to F;
    end
  end
  while *Find* $r_j, r_{j+1}, \ldots, r_{j+k} \in F$ **do**
    Get P as a polygon in sector e_i and rings r_j, r_{j+k};
    if *Cannot find* $x \in X_{obj}$ *in* P **then**
      Push P to S_F;
    end
  end
end

the LiDAR sensor has, for instance, LiDARs in Adv-OPV2V have 64 lasers while LiDARs in Adv-MCity have 32 lasers.

B Testbed MCity

Figure 24 depicts the 8 attack scenarios we created in Testbed MCity. We show the topology of on-road vehicles as well as expected attack impacts. We create 4 traffic scenes: (1) a right turn on green in an intersection, (2) an unprotected left turn in an intersection, (3) an unprotected right turn in a T intersection, and (4) a lane merging from a parking place. Each scene contains one attacker CAV, one victim CAV, one benign CAV, and 1-2 regular vehicles. In each traffic scene, we craft one object spoofing attack case and one object removal attack case. Object spoofing intends to spoof a vehicle to the view of the victim. It aims to stop the victim from moving for as long time as possible, forming a denial of service. Object removal aims to remove an on-road vehicle, which is important for driving safety, from the victim's perception results. Therefore, object removal tends to trigger severe safety hazards such as collisions. We recorded 5-second LiDAR/GPS packets and network traces for each scenario to emulate attacks.

In experiments, we launch both black-box ray casting attacks (§4.2) and white-box adversarial attacks (§4.3) on 8 scenarios, assuming the CAVs may host either early-fusion or intermediate-fusion collaborative perception. All attacks impact (e.g., stop or collision) are successfully produced. Among the 400 frames of perception (5 seconds of 10 Hz LiDAR images for 8 scenarios), the ray casting attacks succeed in object spoofing/removal in 87%/79% of frames while the adversarial attacks succeed in object spoofing/removal in 92%/95% of frames. Adversarial attacks in general have stronger attack effects as their success rate is not restricted by the distance between targets and the attacker.

We also launch an anomaly detection CAD on attacked data, achieving 85.3% TPR and 2.6% FPR on average. The alarms are useful to avoid safety hazards as they are delivered 1.5 seconds on average before collisions or brakes happen.

C Results of Attack Variants

In Table 4, We list the quantified attack impact of all attack variants mentioned in our ablation study 6.3.3, including evaluation metrics in §6.3.1: success rate, IoU, confidence score, and ΔAP. All results in Table 4 are run on OPV2V's pre-trained models, using PointPillars as the backbone. Similar to §6.3.3, the following abbreviation words stand for various design choices:

- *RC*. Ray casting algorithm to reconstruct point clouds.
- *Adv*. Adversarial machine learning to optimize attacks.
- *Async*. Use the data in frame $i-1$ to attack frame i.
- *AS*. Universal adversarial shape generated offline, used in ray casting.
- *Dense-A*. During ray casting, increase the point density of the point cloud in the target region, by moving the origin of LiDAR rays closer to the target.
- *Dense-All*. During ray casting, increase the point density of the point cloud by pretending to have multiple LiDARs from different angles.
- *Sampled*. First perform non-occlusion ray casting and then sample points to resolve occlusion conflicts.
- *Step1*. During adversarial attacks, do one-step PGD instead of unlimited iterations in each LiDAR cycle.
- *Init*. During adversarial attacks, initialize the point cloud using a dense point cluster generated offline.

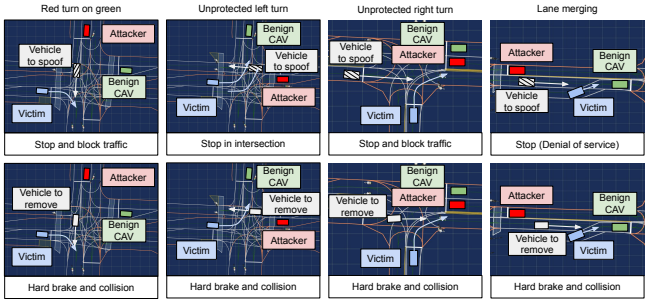

Figure 24: 8 attack scenarios in Adv-MCity.

Abstract

Object Detection (OD) and Object Tracking (OT) are an important part of autonomous systems (AS), enabling them to perceive and reason about their surroundings. While both OD and OT have been successfully attacked, defenses only exist for OD. In this paper, we introduce VOGUES, which combines perception algorithms in AS with logical reasoning about object components to model human perception. VOGUES leverages pose estimation algorithms to reconstruct the constituent components of objects within a scene, which are then mapped via bipartite matching against OD/OT predictions to detect OT attacks. VOGUES's component reconstruction process is designed such that attacks against OD/OT will not implicitly affect its performance. To prevent adaptive attackers from simultaneously evading OD/OT and component reconstruction, VOGUES integrates an LSTM validator to ensure that the component behavior of objects remains consistent over time. Evaluations in both the physical domain and digital domain yield an average attack detection rate of 96.78% and an FPR of 3.29%. Meanwhile, adaptive attacks against VOGUES require perturbations 30× stronger than previously established in OT attack works, significantly increasing the attack difficulty and reducing their practicality.

1 Introduction

Autonomous systems (AS) with camera-focused perception pipelines are employed in various domains, including autonomous vehicles [15, 31], automated surveillance [34], and drones [40]. Central to these pipelines is object detection (OD), which identifies the class and size of surrounding objects to give the system an understanding of the environment. The importance of OD has made it a target of various attacks, including object deletion [22], which can hide safety-critical objects from a system; object misclassification [10], which mislabels certain objects in order to influence autonomous planning; and object creation [37], which causes the target system to hallucinate objects that do not exist. To combat these attacks, OD defenses have leveraged methods such as feature processing [56], which reduces the available search space needed to conduct an attack, certified robustness [53], which aims to formally guarantee a certain degree of resistance against adversaries, and contextual consistency [16], which leverages context information such as the movement and position of objects to detect attacks.

Despite their efficacy, these defenses have limitations. Spatial smoothing can be circumvented by attackers aware of its usage [5], certified robustness faces scalability challenges due to complex mathematical processes, and contextual consistency suffers in environments lacking contextual cues (e.g., for or darkness). To increase the robustness of perception, object tracking (OT) has been added to modern AS perception pipelines, working on top of OD to associate the same objects over time across multiple video frames. OT enforces *spatiotemporal consistency* onto the OD results, ensuring that there are no impossible changes in the velocity or trajectories of tracked objects. This boosts tracking accuracy and resilience against OD attacks [24].

Recent work has shown that OT is vulnerable to a variety of attacks, once again putting the perception pipeline at risk. The attacks include *tracker-hijacking* [24, 36], where an attacker moves the predicted bounding box of a tracked object to cause physical consequences such as vehicle collisions, and *cooling-shrinking* [57], where an attacker disables OT entirely to hide safety-critical objects.

Because OD and OT have different objectives, OD defenses do not work against OT attacks. For example, a recent work that leverages contextual consistency against object misclassification [33] examines object movements in OD to verify the correctness of perception results. Yet, it does not consider whether the movement itself is modified by an attacker to behave in a consistent manner, e.g., via tracker hijacking. Such an attack would be outside the scope of OD and its attacks. Although a single defense against OT attacks has been proposed [23], it is not practical for real-world use. The defense creates perturbation-canceling noise to counter the effects of tracker hijacking. Yet, when no attack is conducted, this noise

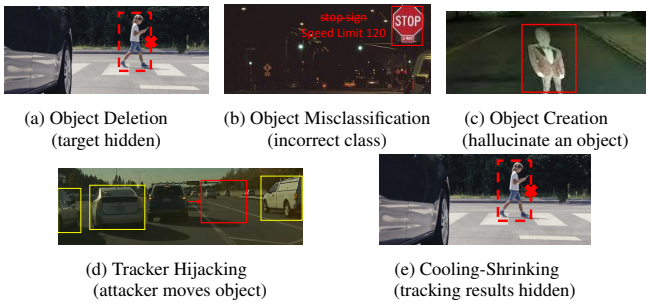
can unintentionally hijack its own tracking results [36].

In this paper, we introduce VOGUES, the first work to detect tracker hijacking and cooling-shrinking attacks against OT. Inspired by neuro-symbolic AI [47] and sensing-reasoning [58], we combine distinct neural networks to model human visual reasoning, which verifies that the constituent components (e.g., the bumpers/roof/wheels of vehicles, the head/limbs/torso for pedestrians) of a seen object are detectable alongside the object itself. We first use a Spatial Transform Network (STN) and Region Proposal Networks (RPN) to isolate objects within an image frame into tightly cropped instances. Next, we extend *pose estimation* models, used by modern AS such as Waymo [50], to extract *key points* we define as important components for objects of a specified class. Lastly, we process the key points into *component sets*, one per object in the image frame, and leverage bipartite matching to check that these component sets are consistent with our OD and OT results. If an object's component set is separated from its tracker, this indicates an attack.

When extracting component sets, we select algorithms with significantly different weaknesses than OD and OT algorithms. This minimizes the likelihood of OD/OT attacks from implicitly affecting our defense. To further guard against attacks simultaneously targeting both our component extraction algorithms and OD/OT pipeline, we train an LSTM verifier. The verifier fuses class-based spatiotemporal consistency checking with our component extraction algorithms to detect tampering in component extraction.

We evaluate the efficacy of VOGUES for both physical and digital-domain attacks against object tracking and detection. We consider non-adaptive attackers, who use the same threat model as previous work and are unaware of VOGUES, and adaptive attackers, who are aware of VOGUES and actively alter their attacks to evade it. For instance, to conduct a successful tracker hijacking attack, an attacker would need to simultaneously hijack the object tracker and spoof the object's component reconstruction results to be spatiotemporally consistent over time with respect to its class.

VOGUES achieves a detection rate of 99.49% for non-adaptive attacks in the digital domain and 93.88% for non-adaptive attacks in the physical domain. In benign settings, VOGUES has a false positive rate of 1.78% in the AV and 2.98% in the autonomous surveillance domains. Additionally, for an adaptive attack to simultaneously compromise perception and evade VOGUES, the perturbations must be 49.9% stronger than a non-adaptive attack. Thus, adaptive attacks launched in the digital domain are unsuccessful against VOGUES when launched in the physical domain, requiring a more powerful perturbation method than proposed in prior work [21, 36].



In this paper, we make the following contributions:

- We introduce VOGUES[1], the first practical detection framework for tracker hijacking and cooling-shrinking attacks against object tracking. VOGUES includes systematic approaches to isolate and extract object components via a neural network pipeline and check them against OD/OT results through bipartite matching.

- To improve robustness and increase the difficulty of adaptive attacks, we propose a special LSTM verifier to detect invalid sequences of extracted components over time.

- VOGUES achieves an average detection rate of 99.49% against attacks in the digital domain and 94.06% against real-world attacks, with an overall false positive rate of 3.29%. We also demonstrate the difficulty of employing adaptive attacks against VOGUES in the real world.

2 Background and Related Work

2.1 Object Detection and Tracking

Autonomous systems (AS) used in different domains have similar perception pipelines. The first component of their perception pipelines is classifying the surrounding objects and determining their sizes. This is the task of object detection (OD). Object detectors in AS are typically built on Convolutional Neural Networks (CNNs) designed to yield results in real time. YOLO [44] is a popular architecture used in many domains, including AS. It has high speed and maintains competitive performance compared to other popular architectures such as Faster R-CNN [45].

The next stage in the perception pipeline is object tracking (OT), which aims to associate the same objects over time across frames. There are two main methods. First, tracking-by-detection (e.g., SORT [4]), predicts bounding boxes using a Kalman Filter and associates objects based on similarity metrics (e.g., Intersection over Union). Second, the more recent Siamese trackers [41] employ Siamese Region Proposal Networks (RPNs) within a Joint Detection-Association paradigm. Siamese trackers classify pixels as "target" or "background" before locating objects to track via CNN, reducing search space for high accuracy and real-time performance [61].

2.2 Perception Attacks

Perception Attacks against Object Detection. Figure 1 illustrates the attacks against OD and OT. There are three primary attacks against OD. Object deletion [60] (Figure 1-a) seeks to suppress one or more object detection results, causing the target to disappear. In this case, this could cause a vehicle collision with a pedestrian. Object misclassification (Figure 1-b) changes the class of one object to another object, such as a stop sign to a speed limit sign [10]. In this example, the autonomous vehicle may illegally speed up instead of coming to a stop, placing itself and others in danger. Lastly, object creation [37] (Figure 1-c) creates fake objects in the scene that OD sees as valid. This specific instance may cause an autonomous vehicle to halt unnecessarily.

Perception Attacks against Object Tracking. In addition to bringing greater accuracy, OT brings robustness against OD attacks. Thus, two major attacks have recently been put forward against OT itself. First, tracker hijacking attacks [24, 36] (Figure 1-d) move the bounding box of an object in a controlled direction. For example, against autonomous vehicles, an attacker can move the bounding box of an object in a victim vehicle's path to the side of the road. Thinking that the path is clear, the victim may continue its course and collide with the hijacked object. Second, cooling-shrinking [57] (Figure 1-e) targets OT to completely suppress all tracking results. For example, an attacker seeking unauthorized entry into a building with autonomous surveillance may leverage cooling-shrinking to remove their tracker and enter a restricted area undetected. Both attacks can be performed by using perturbations to shift the *attention* of OT, which causes it to search for objects in a different area. For tracker hijacking, the attention is moved to where the attacker desires the tracker to move [36], while for cooling-shrinking, the attention is set to *no* area, causing OT to abort searches for tracked objects [57].

2.3 Existing Countermeasures

2.3.1 OD Defenses

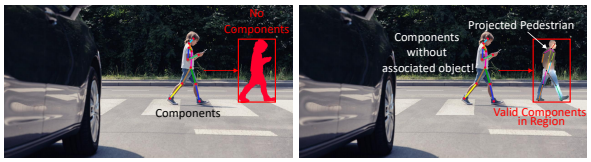
We describe three broad categories of OD defenses, focusing on why they fail for OT attacks.

Information Reinterpretation. These defenses alter the input data or model to provide additional context that can be leveraged to diminish the effect of adversarial perturbations. For example, defensive distillation [43] reconfigures the last layer of a deep neural network with a transformation computing the probability of a sample being a member of a given class, which provides additional robustness against misclassification attacks against OD. Meanwhile, feature squeezing [56] condenses samples with many different features into a single sample that is more robust to adversarial perturbations. However, both can be evaded by an adaptive attacker, e.g., by leveraging a CW attack [5].

Adversarial Input Detection. Another line of work detects and counters patch-based perturbations against classification-based convolutional neural networks (CNNs) [54]. These defenses also offer mathematical proofs that can guarantee a discrete level of performance against a given set of attacks. While effective for that domain, they are limited in scope to patch attacks and have only been demonstrated in the digital domain, whereas both OD and OT attacks have been affected by a wide variety of methods, digitally and in the real world.

Spatiotemporal and Contextual Consistency. Spatiotemporal and contextual consistency countermeasures are recent state-of-the-art OD defenses. Previous approaches leveraged clues about inter-object relationships [29], learned information about the environment [33], and/or extracted additional contextual information from the environment [16]. They ensure that the contextual information of the scene matches prior knowledge about object behavior (e.g., cars should not fly).

Current defenses, however, have only demonstrated efficacy against specific OD attack types: object misclassification [33] and object creation [37]. Because these works focus on attacks against OD, they do not consider attacks against OT that may not affect consistency. For example, a tracker hijacking attack can create an illusory lane-change movement on a vehicle driving forward. This motion is contextually consistent, but can cause a trailing autonomous vehicle to accelerate and hit the affected object [24, 36]. Additionally, these defenses suffer in situations where there is a lack of context to use for reasoning, e.g., in rural or low-light areas with very few objects. OT attacks such as cooling-shrinking [57] can take advantage of this by suppressing object tracking results and preventing them from being used in contextual reasoning.



2.3.2 OT Defenses

Unlike OD attacks, OT attacks have different objectives than what is accounted for by current OD defenses. Current OT attacks alter the trajectory [24, 36] or suppress the tracking of objects [57] as opposed to changing an object's class or creating a new object. These attacks did not exist before the introduction of OT, and are understudied.

To our best knowledge, only one defense has been proposed against these attacks, utilizing noise cancellation to enhance tracking robustness [23]. However, while effective theoretically, this defense falls short in practice. Firstly, it relies on perfect projection of adversarial perturbations onto each frame, ignoring imperfections in the physical domain due to environmental conditions. Secondly, it assumes a constant attack presence, risking unintentional tracker hijacking when attacks are absent [36].

3 Threat Model

VOGUES is mainly designed to detect both tracker hijacking and cooling-shrinking attacks. Following the threat model

(a) (b)

Figure 2: (a) Component consistency under tracker hijacking. (b) A naive attempt to evade component consistency by projecting a fake pedestrian into the hijacked tracker's position.

common to these attacks, we assume *physical domain* attacks, where the attacker physically modifies the environment (via a projector [36]) or objects (via patches [33]) with adversarial noise. The attacker does not apply a norm-bound to the noise magnitude; instead, the strength of the perturbations is minimized to reduce the *attack cost*, which encapsulates three factors: stealthiness, required luminance to compete with other light sources, and the financial cost to the attacker (Section 7.4). Although we assume physical domain attacks, we also evaluate VOGUES against even more powerful attackers with *digital domain attacks* that remove real-world constraints (e.g., perturbations can be infinite). This puts a lower bound on the performance of VOGUES. However, we assume that the attacker is only able to manipulate input to the victim's sensors, and does not have access to the victim system's hardware.

We assess VOGUES against non-adaptive attackers not aware of VOGUES, and adaptive attackers aware of VOGUES and attempting to evade it while accomplishing attack goals. While VOGUES implicitly detects misclassification and deletion attacks (see Section 4), it cannot detect object creation attacks. This is because VOGUES is built to model human perception, and previous work has shown that creation attacks can look realistic to the human eye [37].

4 Motivation and Challenges

4.1 Rationale

VOGUES detects tracker attacks by enforcing the principle that every detected/tracked object must have corresponding components, obtained via the pose and orientation of the object, and vice versa. This follows from the principle that objects of interest generally consist of observable components that are arranged and move in expected ways. We add a further constraint that components must act consistently relative to each other and the object as a whole over *multiple frames.* This adds a layer of difficulty to adaptive attacks, as an attacker must simultaneously accomplish their original attack goal while altering the original object's components to maintain consistency.

Figure 2-a illustrates how VOGUES works against a tracker hijacking attack, which can lead to a failure to brake and a possible collision. Normally, an object's tracker and its components correlate with each other, being of similar size and in similar positions. However, the attack moves the tracker to a different location. To detect attacks, VOGUES compares extracted components with OT results to find *inconsistencies*. In this example, OT identifies the pedestrian in the attacker-specified location, but the pedestrian has no associated components, which is the first inconsistency. Meanwhile, VOGUES extracts components via pose estimation at the object's original location, but there is no tracker there, which is the second inconsistency. VOGUES can leverage the inconsistencies inherent in tracker hijacking, cooling-shrinking, and misclassification/deletion to offer a broad defense.

For this example, an attacker might take a naive adaptive approach and project a realistic-looking pedestrian into the hijacked tracker's position, as shown in Figure 2-b. In this case, the OT result has a component set, derived from the projected pedestrian, that it can be matched to. Yet, the hijacked pedestrian's original components still exist, and have no associated OT results. Thus, an inconsistency can still be found, and an alert can be raised. Adaptive attackers must suppress or change the original component results (e.g., via adversarial perturbations) to bypass VOGUES (See Section 7.4).

Inconsistency between objects and components manifests differently depending on the attack. For *tracker hijacking* attacks, the OT result and the original components remain unmatched, as they are forcefully separated from each other. For *cooling-shrinking* and *object deletion* attacks, stranded component sets without a parent object are the result, as the components remain when the objects are deleted. For *misclassification attacks*, though the component set and bounding box may occupy the same space, their *class* will be different, e.g., a car's components are seen for an object classified as a person.

4.2 Design Challenges

VOGUES models human perception by combining distinct neural networks based on human reasoning, which poses several challenges. These challenges stem from the interactions between the algorithms used, the difficulty in bridging their gaps with reasoning, and the ability of an adversary to adapt to detection methods they know are employed.

(C_1) Component Reconstruction Algorithm Selection. VOGUES is modeled after human perception, where an object's constituent components (e.g., the head, torso, and limbs of a pedestrian) should always be apparent. Additionally, components should behave consistently relative to each other and their parent object over a continuous timeframe However, the selection of the correct algorithms for this is nontrivial.

First, each component reconstruction algorithm should have orthogonal vulnerabilities compared to the OD/OT pipeline. Previous work demonstrated that models with different architectures, but similar vulnerabilities, can be exploited by transferring perturbations computed on one model to another [51]. Intuitively, using models based on

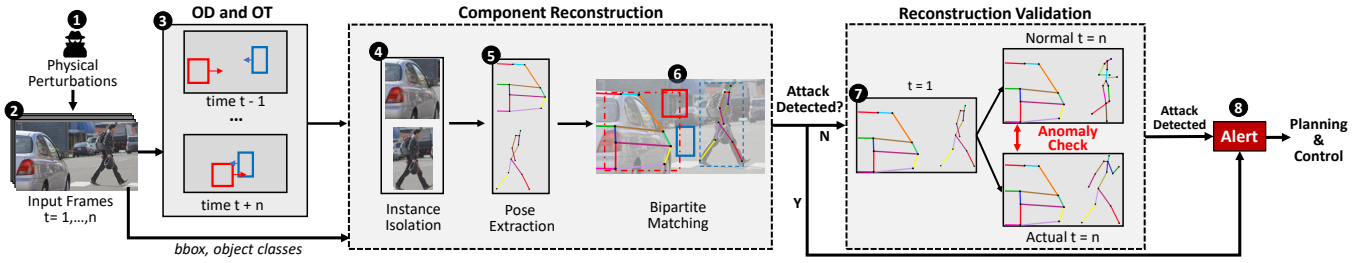


Figure 3: Illustration of VOGUES's stages.

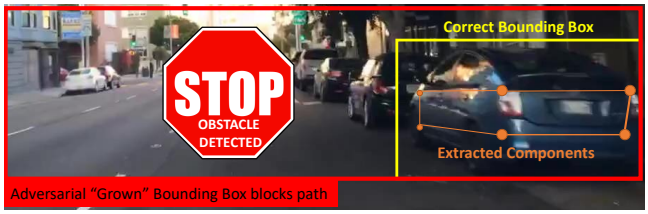

Figure 4: A tracker hijacking attack grows an object into a victim's path, evading an intersection-based consistency check.

different architectures and with different parameters makes it harder to create transferable/universal perturbations. We outline in Section 6.3 how using additional models that extract different features increases robustness, and we evaluate in Section 7.4.1 that forcing an attacker to exploit independent vulnerabilities greatly increases the amount of perturbations compared to dependent vulnerabilities.

Second, the algorithms must work in real-time. Domains such as AVs and video surveillance are time sensitive, with heavy consequences for delayed results, including collisions [36]. Therefore, while algorithms like Mask-RCNN [17] can classify objects at a pixel level in arbitrary detail, they are usually large networks that are difficult to scale. The typical running speed of < 10 fps achieved by most image segmentation algorithms [6, 17] will significantly delay results compared to the 10-30 fps accepted baseline [2].

(C_2) Consistency between Reconstruction and Perception. "Consistency" must be carefully defined to account for inherent error in ML predictions. For example, a naive approach demanding that the reconstructed details perfectly match the perception output 100% of the time would generate many false positives. Meanwhile, an overly flexible definition of consistency impairs the approach to detecting certain attacks.

As a metric, component consistency bridges the gap between ML algorithms in OD/OT and our component extraction algorithms. If consistency is defined in a way that does not reflect equivalent concepts in both perception and reconstruction, it can be evaded. For example, a naive reconstruction approach may use a simple intersection check to ensure the components of an object are within an object's bounding box. As illustrated in Figure 4, tracker hijacking could result in a bounding box on the side of the road to expand into a victim vehicle's path. As all the components of the vehicle on the side of the road are within the adversarial bounding box, a targeted vehicle may stop unnecessarily to avoid the incorrectly large adversarial object.

(C_3) Accounting for Adaptive Attacks. Given no restrictions on time, computational power, and perturbations, an adaptive attacker may succeed in achieving their goal. A trivial example is an attacker who causes an input video to darken in order to obscure all tracks. We note that with realistic constraints on the resources given above, such an attack is difficult.

Previous work has sought to address adaptive attackers by making it difficult to achieve the attack goal without a large number of perturbations [33]. This makes adaptive attacks highly visible and expensive to deploy using projector-based attacks (Section 7). However, recent advances in optimizing adversarial perturbation generation [5] have made effective countermeasures much more difficult to design.

5 VOGUES

In this section, we introduce how VOGUES defends against tracker hijacking, cooling-shrinking, object misclassification, and object deletion. Figure 3 presents the stages of VOGUES, which works as an addition to the perception pipeline of an AS. An attacker perturbs the environment, which is then picked up by the victim's video feed, to launch the attack against OT. The video feed is processed by the AS's perception pipeline, which outputs the bounding boxes and classes of every relevant object in the scene (❶-❸).

From here, VOGUES checks for *component consistency*, where the components, i.e., the key points forming an object, are checked for congruity with their parent object. The extraction of these components is split into three distinct steps to reduce mutual vulnerabilities with OD/OT attacks, addressing challenge C_1. In the first step, we perform *instance isolation*, performing a spatial transformation on the original input frames to enhance the accuracy of subsequent steps (❹). We next leverage the *pose estimation* algorithms to extract key points that form the "components" of each isolated object instance (❺). These components are then passed into *post-processing*, which uses non-max suppression

and pose-flow tracking to improve the component extraction results, before mapping them into *component sets*, each representing the components of one whole object, to be verified by *bipartite matching* against the supplied OD/OT results to ensure a 1-1 correspondence (❻).

We calculate the matching based on an Intersection over Union (IoU) metric, ensuring similar dimensions between components and their objects. More specifically, we define a bounding box for each component that covers their maximal bounds on the x-axis and y-axis, and compute their IoU with every other tracked object in the scene. Based on an application-specific IoU threshold, above which there is a significant similarity between an object and a component set, we first create a graph encoding potential associations between the object/set. We then conduct maximum bipartite matching on this graph to find if every object can be associated with exactly one component set and vice versa. This tunable spatial similarity metric for consistency addresses challenge $\mathtt{C}_2$.

If no bipartite matching solution is found, we alert the user and pass it to the AS's planning and control modules (❽). Yet, if a bipartite matching solution is found, and thus no attack is detected, we perform a final *reconstruction validation* check via a one-class LSTM anomaly detector trained to predict how the component sets should change over time (❼). The LSTM prediction, which takes the component sets of previous frames into account, is compared against the component data received via component reconstruction. If the reconstructed component data is substantially different from what the LSTM predicts, VOGUES raises an alert. Thus, an adaptive attacker must simultaneously complete their attack goal and hijack the components to realistically match that goal, addressing challenge $\mathtt{C}_3$.

5.1 Isolating Object Instances

To reduce interference from outside sources (e.g., other nearby objects of the same class), we first separate individual instances of the desired object class into tightly cropped samples. There exist a variety of computer vision techniques that can be used to accomplish this goal. For general object classes, we extend fully convolutional Region Proposal Networks (RPN) [28]. This is because RPNs learn transformations to apply to input video frames in order to isolate and crop specific object instances. The transformation-based process makes them suitable for applications where the target object may appear in a variety of configurations, positions, or rotations [25].

Given an input image, an RPN first uses feature mapping to generate a *heatmap* encoding of pixels likely to contain target object(s). We use this information for *region proposal*, which searches regions likely to contain targets in order to define bounding boxes per object. Lastly, both the heatmap and the region proposal results are merged via Region-of-Interest pooling by the RPN classifier, which returns the final instances of tightly-cropped isolated objects. This process is fully illustrated in Figure 12a in Appendix A.

On the other hand, for objects typically dispersed among crowds or at long distances, such as pedestrians, we leverage Spatial Transformer Networks (STNs), which perform better than RPNs under crowded/distant conditions [20]. A localization network first takes the input image and finds a set of affine transformation parameters (θ) to isolate the object instances. These parameters determine how the image should be altered in order to extract an individual object, e.g., how much scaling or rotation should be applied. Using θ, the original coordinate space G is converted into a sampling coordinate space T_θ, encoding the locations of the transformed image from which objects can be extracted via the 2D affine transformation:

$$T_\theta(G) = \begin{pmatrix} x_i^b \\ y_i^b \end{pmatrix} = [\theta_1\ \theta_2\ \theta_3] \begin{pmatrix} x_i^a \\ y_i^a \\ 1 \end{pmatrix}$$

where $\theta_1, \theta_2, \theta_3$ are vectors in $\mathbb{R}^2$, $\{x_i^b, y_i^b\}$ are the coordinates prior to the transformation, and $\{x_i^a, y_i^a\}$ are the coordinates after the transformation.

Lastly, to extract the cropped instances from the transformed coordinate space, a *sampler* converts grid segments within the image and transforms them into usable, tightly cropped instances. Figure 12b in Appendix A fully illustrates how we leverage the STNs for object isolation.

5.2 Pose Extraction

Once object instances are isolated, we extract the pose from the instances to use as components. The pose of objects is represented in the form of a graph, with nodes encoding the position and object class of user-defined key points within the object (e.g., joints for humans and bumpers for vehicles), and edges encoding the relationships between points (e.g., heads should be connected to necks).

To extract object poses, object instances are fed into a fully convolutional network (FCN) to yield a set of 2D *key points* describing visible details. For example, a vehicle's key points may consist of the left front wheel, the right side of the bumper, top, and bottom of the license plate, whereas a pedestrian's key points may consist of their arms, legs, spine, and head. Edges are then extrapolated based on class-based rules; for example, license plates should be connected to bumpers.

Given an image, the network minimizes the loss function:

$$L = \frac{1}{N}\sum_i (p_i - g_i)^2 + \log\left(\frac{e^{y_i}}{\sum_i e^{y_i}}\right)$$

where p_i is the predicted location of key point i, g_i is the keypoint's ground-truth location, and y_i is the ith position of the output layer. The pose extractor iteratively reduces the error in prediction p_i over a set number of attempts N.

At runtime, the pose extractor distills the image into feature sets, which are compared to the features of known, previously learned key points (e.g., the arm of a human or the license

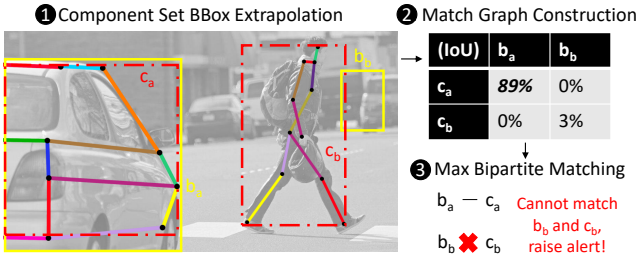

Figure 5: Our approach for component consistency checking.

plate of a car). The pose extractor produces a set of most likely predictions (each containing the proposed pose information of the object), along with a confidence score for each prediction, and returns the highest-scoring prediction as the final pose. This encodes all *visible* key points for an object, but not necessarily all the points: points that are occluded or otherwise obscured in a way that an object detector cannot cover (e.g., by deep shadow) are not returned.

5.3 Post-processing

Once poses for objects are extracted, we process the results to enhance the extraction accuracy and turn the pose information into usable component sets. For each object, we run non-maximum suppression [38] on all of the returned component sets. Specifically, we order component sets by their confidence scores, then eliminate any component sets that are within a class-specific *pose similarity distance* [11] to a higher-confidence set. This ensures that closely clustered, similar-looking component sets will be reduced to the single most confident set, which helps eliminate any duplicate component information (e.g., two sets returned for one pedestrian).

For objects extracted via STN, we map the pose information of each object back to the original coordinate space via a spatial de-transformer network (SDTN). The SDTN takes transformation vectors (θ_1, θ_2) and computes de-transformation vectors $(\gamma_1, \gamma_2, \gamma_3)$:

$$[\gamma_1\ \gamma_2] = [\theta_1\ \theta_2]^{-1}$$

$$\gamma_3 = -1 * [\gamma_1\ \gamma_2]\theta_3$$

These are used to invert the original transformation:

$$\begin{pmatrix} x_i^a \\ y_i^a \end{pmatrix} = [\gamma_1\ \gamma_2\ \gamma_3] \begin{pmatrix} x_i^b \\ y_i^b \\ 1 \end{pmatrix}$$

where (x_i^a, y_i^a) are the coordinates post-transformation and (x_i^b, y_i^b) are the coordinates pre-transformation.

To improve the accuracy of pose-extraction results, once the estimated poses are mapped back into the original coordinate space, we run pose-flow tracking [55]. Pose-flow tracking enforces spatio-temporal consistency in pose estimation between consecutive video frames, improving accuracy with minimal overhead to the component reconstruction process.

Once post-processing is complete, we aggregate the pose information of extracted classes and turn them into *component sets* to be used for consistency checking. Each component set represents a single object, and encodes the object's class, the image frame number, the absolute coordinates of each key point extracted by pose estimation, the class of each key point (e.g., hand, bumper), and their *relationships* to each other. The relationships between key points are created through class-based rules (e.g., hips should be connected to legs), and work for both complete key point sets and partially occluded ones. All final component sets found within a video frame are passed into the consistency-checking module to detect tracker hijacking and cooling-shrinking attacks.

5.4 Consistency Checking

We judge component consistency based on the similarity of dimensions between each component set and their corresponding tracking result. Figure 5 illustrates how our component consistency checking operates. For comparison against the original tracker bounding boxes (❶ in yellow, solid lines), we first extrapolate a bounding box from each component set by computing the maximum extent of the overall component set on the x- and y-axis (in red dashed lines).

We next create a *match graph* by examining the IoU between each tracker bounding box and each component set (❷). This forms the mathematical basis of our component consistency metric. The IoU computes the dimensional similarity between two bounding boxes, encoding the percentage that two bounding boxes overlap over their combined area. The less they differ in location, size, and shape, the higher the IoU. An IoU of 1 indicates that the two bounding boxes are identical. If the IoU is above a similarity threshold v, we construct an edge in the match graph (represented by bold text) between the relevant component set and the tracker bounding box, to represent potential 1-1 correspondence between them.

Lastly, we run maximum bipartite matching on the match graph to map every tracker bounding box to exactly one component set (❸). If a matching cannot be found, an inconsistency exists. In Figure 5, the bounding box b_b has been hijacked away from its component set c_b.

We formalize our consistency checking approach in Algorithm 1. We take, as inputs, the object bounding box sets b from the OD/OT pipeline, the component sets k from our reconstruction pipeline, and the acceptable similarity threshold $v \in [0, 1]$. The threshold v can be adjusted based on the inherent error in the constituent algorithms and depending on the domain (see Section 7.1). For example, if a security camera guards a large open area leading to a restricted space, a smaller, less strict v can be used, whereas autonomous vehicles can set v to ≥ 0.5 to accommodate the more time-sensitive nature of the application.

Algorithm 1 Component-Object Consistency Checker

Input: List of bounding boxes and corresponding classes $\texttt{b} = (\texttt{class} : \texttt{box})$, List of component sets and corresponding classes $\texttt{k} = (\texttt{class} : \texttt{components})$, acceptable similarity threshold $\texttt{v}$.
Output: Inconsistency indicator bit (`alert`).

```
1: function CHECK_CONSISTENCY(b, k, v)
2:     for class c ∈ b do
3:         if LENGTH(b[c]) ≠ LENGTH(k[c]) then
4:             return alert = 1                ▷ Unmatched components exist
5:         end if
6:         match_graph = {V = [b[c] ∪ k[c]], E = []}
7:         for box ∈ b[c] do
8:             for cmpnt ∈ k[c] do
9:                 cpt_box = MAX_EXTENTS(cmpnt)
10:                if box ∩ cpt_box/(box ∪ cpt_box) ≥ v then
11:                    match_graph[E].append(box ↔ cmpnt)
12:                end if
13:            end for
14:        end for
15:        bp_match_graph = ADD_SRC_SINK(match_graph)
16:        if FORD_FULKERSON(bp_match_graph) ≠ |k| then
17:            return alert = 1                ▷ Unmatched components exist
18:        end if
19:    end for
20: end function
```

Our consistency checking algorithm verifies each class separately in turn (Line 2), preventing objects and component sets from different classes from being matched together. Next, it ensures that the number of object bounding boxes and the number of component sets for a given class are equal (Lines 3-5). Here, inequality means that either one or more object bounding boxes have no components (indicative hijacking or misclassification), or one or more components have no parent object (indicative of cooling-shrinking or object deletion).

Assuming that there are an equal number of object bounding boxes and component sets, we initialize the match graph (Line 6) encoding which object may belong to which component set. We extrapolate each component set's 2-dimensional bounds (Line 9) to compare its location and size to OD/OT results. We draw an edge between an object and a component set if their IoU is greater than or equal to the acceptable similarity threshold v (Lines 10-12).

After the construction of the match graph, we run maximum bipartite matching between the components and the object bounding boxes to ensure that there is a one-to-one mapping. Specifically, we add a source node to all object bounding boxes in the match graph and a sink node to all component sets (Line 15). We then run the Ford-Fulkerson algorithm [12] to obtain the *maximum flow* of the match graph (Line 16). A maximum flow equal to the number of component sets/objects indicates that a one-to-one mapping exists. If such a mapping cannot be achieved, it means that at least one bounding box does not have a corresponding component, and vice-versa; therefore, we trigger an alert (Line 17).

6 Adaptive Attacks

Our component reconstruction pipeline is built to address previous OD and OT attacks. However, if an attacker is aware of VOGUES, they may attempt to adapt their attack to alter both the perception pipeline and VOGUES's consistency checking at the same time, disguising their attack. We detail our formulation on how such an adaptive attack might be launched, and introduce *reconstruction validation* to counter adaptive attacks.

6.1 Formulation

We create a new adaptive attack that aims to evade VOGUES while accomplishing the original attack goal. Although certain naive attacks can also be considered adaptive, e.g., wearing a camouflaged ghillie suit to hide a pedestrian, these methods are both conspicuous and capable of fooling human perception, which we consider outside of our threat model (Section 3). Thus, we extend the CW attack [5] to find the optimal minimized perturbations that avoid VOGUES's component reconstruction algorithms while still achieving the attack goal.

We minimize the perturbation amount with respect to the ℓ_2 *distance*, which takes the root-mean-square of the amount of perturbations applied to the image. We choose the ℓ_2 norm over ℓ_∞ because numerous small modifications to the image will generally lead to a smaller *maximum perturbation*, as opposed to a small number of large changes. A higher maximum perturbation increases the attack's visibility, required luminance, and cost to project (Section 7.4), thus previous work considers ℓ_2 the strongest metric to minimize adaptive attack perturbations [5,49]. Formally, we minimize the ℓ_2 norm $\|\delta\|_2$ for an image x to generate perturbation δ as follows:

$$\begin{aligned} &\text{minimize} \;\; \|\delta\|_2 + c \cdot f(x+\delta) \\ &\text{subject to} \;\; x+\delta \in [0,1]^n, \end{aligned}$$

where c is a tunable scaling constant that balances the importance between the two objectives [5], and $f(x+\delta)$ represents the attack success loss. Specifically,

$$f(x) = g(x) + \sum_i \left| p'_i(x) - p_i(x) \right|, \tag{1}$$

where $p(x)$ is the matrix of the predicted pose for x, and $p'(x)$ is a *target pose* for an object, which defines the targeted absolute coordinates that the targeted object's pose should be mapped. $p'(x)$ can be manually specified (e.g., an empty set meaning no pose for cooling-shrinking), or be derived from the original pose information (e.g., the same pose shifted 200 pixels left for tracker-hijacking), depending on the attack goal.

We use derived target poses for adaptive tracker hijacking, whereas we manually specify target poses based on the empty set for tracker deletion and cooling shrinking. We manually specify target poses for object misclassification attacks based on sample poses extracted from benign footage. Further, in

Figure 6: An adaptive attack hijacking the pedestrian's pose and the tracker. The component set dimensions (yellow, dotted line) are consistent with the hijacked tracker, but the pose is in an invalid shape and detected by reconstruction validation.

Equation 1, $g(x)$ represents the original objective function of the non-adaptive attack with constraints. For example, for tracker hijacking [36], $g(x)$ is given as:

$$\sum_{n=1}^{N} (L_c(I_n, p_c, \theta) - L_c(I_n, p_c^*, \theta)) + \lambda(L_r(I_n, p_r, \theta) - L_r(I_n, p_r^*, \theta))$$

where I_n is the proposal for input frame I at proposal n, λ is a fixed weight used to smooth ℓ_1 loss for regression, θ is the region proposal network's parameters, and N is the number of frames. Additionally, L_c and L_r are the OT classification and regression loss functions, and p_c/p_c^* and p_r/p_r^* encode the labels/pseudolabels for OT classification and regression.

We ensure with Equation 1 that both the original objective function $g(x)$ is achieved and that the achieved pose is as similar to the target pose as possible (and thus the difference between the two is 0). Using the CW objective function with the ℓ_2 optimization, the attacker finds the minimally visible amount of perturbations to accomplish the attack goal and evade VOGUES's detection. An adaptive attacker will continue to optimize their perturbations until a working solution is found. A solution is always possible given an infinite perturbation budget. However, finding the solution is not trivial, as the attack must simultaneously minimize Equation 1 and achieve the target pose. We quantify the difficulty of doing so theoretically in Section 6.3, and experimentally in Section 7.4.

6.2 Reconstruction Validation

Pose Hijacking. Previous work studied *pose hijacking*, which use adversarial perturbations to transform the correct pose into a target-specified pose anywhere in the image [21]. Our adaptive attack conducts pose hijacking to alter the victim's pose to match the attacked OD/OT data. Yet, it is difficult to hijack the entire pose of an object, as certain key points (e.g., the head and neck in humans) are more robust against attack than others [21]. Thus, hijacked poses tend to be unnatural and unrealistic, requiring extra perturbations to correct. We discuss the the behavior of poses under hijacking further in Appendix B.

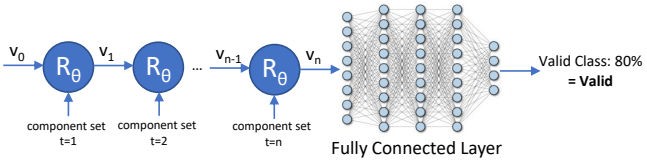

Figure 7: VOGUES's reconstruction validation remembers features (v) between frames, which are continually updated by the current component set via recurrent feedback loop (R_θ).

Validating Components. Leveraging the unusual appearance of hijacked poses, we develop a *reconstruction validation* pipeline against adaptive attacks. While an adaptive attacker may evade consistency checking, extracted components will likely have an unusual shape unless the attacker uses a much larger amount of noise (see Section 7.4.1), as illustrated in Figure 6. The hijacked pose (bounded by yellow, dotted lines) is consistent with the hijacked tracker bounding box. Thus, component reconstruction will not detect an attack. Yet, the pose indicates a flailing posture that should be impossible from a running start. We thus perform validation through anomaly detection against our component sets to detect adaptive attacks. With validation in place, an adaptive attacker's goal requires even less difference between the target and predicted poses; greater deviations can be picked up as invalid. We quantify how difficult this stricter goal is to achieve in the real world in Section 7.4.

We conduct reconstruction validation via a one-class LSTM network, similar to those used in anomalous network traffic detection [30]. The LSTM architecture is selected to learn order dependence in predicting the sequence of components [14]. For our system, we pass in a sequence of components across object classes, collected over the course of several video frames to allow for a complete analysis of the poses over time. Figure 7 illustrates the pipeline for reconstruction validation. Intuitively, the LSTM works by "remembering" the sequence of component sets of previous frames as it updates with the information from the current frame. Formally, it takes a sequence of features v for each frame over time, updating with current information via recurrent feedback loop:

$$v_i = R_\theta(f_i, v_{i-1}),$$

where v_i is the hidden feature vector calculated from previous feature vectors v_{i-1}, f_i is the raw feature vector at time i, and θ is a learned parameter identical for all recurrent operations.

Once all features are extracted at time n-1, the LSTM outputs the prediction of what the next component set should look like, taking into account the history of previous component sets. For example, if a pedestrian has been running beside an oncoming vehicle, the pedestrian will likely continue running in the next frame and not be suddenly at rest on the other side of the image.

This prediction is compared to the actual component information at time n, and passed into a fully connected

layer to return a validity score $\in [0,1]$, which encodes the likelihood that the component set at time n is compatible with the predictions of previous frames. This score is checked against a tuned hyperparameter threshold d, which is set based on our experiments (see Section 7.1). If a validity score of less than d is returned, the autonomous system is alerted to potential tampering with the component reconstruction pipeline. However, declaring components as valid does not preclude an alert from being thrown: the alert generated by consistency checking (Section 5.4) always takes precedence over the validation results.

6.3 Adaptive Attack Analysis

We provide a theoretical justification of the higher robustness of VOGUES against adaptive attacks due to the combination of multiple diverse models (ODT, pose estimation, and reconstruction validation). Previous work has shown that pose estimation models extract different, more detailed features from objects than ODT models [8]. With different extracted features, different errors occur when ODT models and pose estimation models are attacked (Section 7.3). The defensive value of utilizing additional models that have different errors has been examined by KEMLP [16], which utilizes additional task-specific models to integrate domain knowledge into OD to make it more robust. Although VOGUES works differently to KEMLP, providing independent results to be checked against ODT instead of feeding domain knowledge results directly into OD, our pose extraction system is a *permissive* type model [16] (i.e., if a pose is extracted for an object, a bounding box should be extracted as well), and our component consistency LSTM is a *preventative* type model [16] (i.e., given a set of poses relating to an object over time, these poses *must* move in a consistent manner). Thus, we can use KEMLP's Theorem 2 to describe the conditions where VOGUES will be more robust than ODT alone. We leverage the definition of a *truth rate* [16], which defines the rate at which a model gives results that are consistent with ground truth. Specifically, given an input distribution D containing both benign samples D_b and attacked samples D_a, the weighted accuracy of ODT can be described as a truth rate:

$$\alpha_* := \sum_{D \in \{D_b, D_a\}} \pi_D \alpha_{*,D}$$

where π_D is the probability distribution function for if a sample is in D_b or D_a, $\alpha_{m,I}$ is the truth rate at which a model m gives results that match ground truth for input samples I, and $*$ represents the ODT models.

Given this, the *combined* truth rate of the component reconstruction models $\mathcal{K}$ and the ODT models can be described. Let $\mathcal{K}, \mathcal{K}' \in \{I, J\}$, where I is the set of permissive models and J is the set of preventative models, and $\mathcal{K} \neq \mathcal{K}'$. Then:

$$\gamma_D := \frac{1}{n+1} \min_{\mathcal{K}} \left\{ \alpha_{*,D} - \frac{1}{2} + \sum_{k \in \mathcal{K}} \alpha_{k,D} - \sum_{k' \in \mathcal{K}'} \varepsilon_{k',D} \right\} \quad (2)$$

where n is the number of models represented by $\mathcal{K}$ and $\varepsilon_{m,D}$ is the *false rate* at which a model m gives results that do not match the ground truth. Intuitively, Equation 2 explains the accuracy of VOGUES, based on both ODT's accuracy and the accuracy/error rate of VOGUES.

According to Theorem 2 of KEMLP, by Chernoff bound on the true and false rates, as long as $\gamma_D > \sqrt{\frac{4}{n+1} \log \frac{1}{1-\alpha_*}} \quad \forall D \in \{D_b, D_a\}$, our defense can detect attacks against ODT. As a corollary, an adaptive attacker must increase their perturbations in order to lower γ_d to evade VOGUES and ODT. VOGUES achieves sufficient γ_D to detect attacks (Section 7.3), and we further support the theorem in Sections 7.4.1 to 7.4.3 with empirical data illustrating how real-world constraints significantly reduce an attacker's ability to find a solution that evades VOGUES.

7 Evaluation

Using both digital and real-world attacks, we evaluate VOGUES against non-adaptive attackers (Section 7.3) and adaptive attackers (Section 7.4) for autonomous driving and video surveillance applications. To evaluate successful detections by VOGUES, we consider only the scenarios where the given attack is already successful. Therefore, a "successful detection" is determined by whether VOGUES generates an alert for the successful attack. We also evaluate the false positive rate of VOGUES by measuring the number of alerts in benign scenarios, where no attacks are conducted (Section 7.5).

We evaluated our system on a laptop with a 9th Generation Intel i5-9300H processor, an NVIDIA GTX 1650 GPU, and 8 GB RAM running Python 3.8.10. With this setup, we achieved an average of 23 fps runtime, with 0.03s for instance isolation, 0.04s for component extraction, 0.0005s for matching, and 0.0007s for reconstruction validation.

VOGUES is able to detect 99.49% of digital attacks and 94.06% of physical attacks, with false positive rates of 1.78% in autonomous driving and 2.98% in video surveillance. Adaptive attacks require 49.9% stronger perturbations than non-adaptive attacks, significantly increasing the attack difficulty and making them impractical in the real world.

7.1 Implementation

We employ YOLOv3 [44] as our object detection platform and DaSiamRPN [61] as our object tracking platform, both of which have been used in recent previous work in object detection and tracking attacks [33, 36].

Component Reconstruction. We implemented all ML models in PyTorch 1.9.0cu102. For pedestrian component

reconstruction, we run a stacked hourglass network [11, 39] based on single-person pose estimation that extracts the pose information of each individual separately. For vehicle component reconstruction, we implement a real-time keypoint extraction model for vehicles, similar to approaches used for vehicle pose estimation and six-degrees-of-freedom 3D reconstruction of tracked objects [25, 26, 32, 46]. It is trained on the KITTI dataset [13] to extract up to 20 2D vehicle key points as pose information. We set our acceptable similarity threshold (v) to 0.5 for consistency checking.

Reconstruction Validation. To train the reconstruction validation LSTM model, we collected the output of our component reconstruction pipeline across 13000 videos in the UFC101 dataset [48] and 606 videos in the BDD100K dataset [59]. For each video, a sequence of components in each frame was encoded. We then trained the LSTM network to classify these sequences as valid component sequences. A randomly chosen 80% of the original data was used to train the LSTM, while the other 20% was used to validate the LSTM at each performance step. We set our hyperparameter validity score threshold (d) to 0.5, based on tuning via grid search in initial experiments.

Adaptive Attacks. For maximum compatibility with our existing model implementations, we adapted a PyTorch version of the original Carlini-Wagner attack [27] for adaptive experiments. Our modified version accepts target poses as inputs as opposed to classes and modified the constraints to account for both the original attack goal and evading VOGUES.

7.2 Evaluation Setup

7.2.1 Attacks

We evaluate VOGUES against previous attacks on the OD/OT pipeline. For digital attacks, we evaluate it against (a) tracker hijacking [36], (b) cooling-shrinking [57], (c) object misclassification [7], and (d) object deletion [19]. For physical attacks, we evaluate it against (a) tracker hijacking [36] and (b) object misclassification [7]. This is because, to our knowledge, they are the only two attacks against camera-based systems reliably demonstrated in the physical domain. We also modify these attacks with the formulation in Section 6.1 for adaptive attacks.

In these attacks, we focus on vehicle and pedestrian classes as they are the most safety-critical, causing physical injury and masked entry into restricted areas. Extending VOGUES for new object classes is straightforward, as discussed in Section 8.

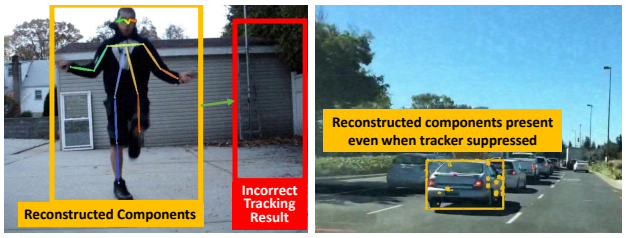
7.2.2 Digital Datasets

We use two datasets to simulate physical attacks against our system in the digital domain: 197 videos from BDD100K [59] for autonomous vehicles and a curated subset of 19,562 images from MPII [1] for pedestrian video surveillance. We selected videos and images based on compatibility with the attacks evaluated, removing those with strong noise that prevents OD/OT from working. Together, these datasets cover a rich diversity in lighting conditions, driving environments, and human behaviors encountered in the real world. We conducted all four attacks, and their adaptive versions, against each video/image for a total of 19,759 samples per attack.

We implemented tracker hijacking attacks by moving trackers 200 pixels in the opposite direction of the victim object, e.g., moving the tracker of a left-of-center object to the right. For cooling-shrinking attacks, we removed all trackers from the image or video sample. For object misclassification attacks, we changed pedestrians to vehicles and vice versa. For object deletion attacks, we deleted the pedestrian or vehicle with the highest confidence from the OD output.

Table 1: VOGUES detection rate against non-adaptive attacks.

Attack Goal	Digital Attacks Pedestrian‡	Digital Attacks Vehicle‡	Real-world Attacks Pedestrian	Real-world Attacks Vehicle
Tracker Hijacking	99.49%	100%	100%	90.9%
Cooling-Shrinking	99.49%	100%	N/A†	N/A†
Misclassification	99.49%	100%	100%	91.67%
Object Deletion	99.49%	100%	N/A†	N/A†



† Tracker-hijacking and misclassification attacks are conducted for real-world experiments as cooling-shrinking and object deletion have not been reliably demonstrated in the physical domain.
‡ Non-adaptive attacks do not affect component reconstruction, leading to identical detection performance regardless of digital attack method.

7.2.3 Real-world Physical Experiments

We conducted physical domain non-adaptive and adaptive attacks against moving vehicles and pedestrians using the same methods as previous work [18, 36]. For non-adaptive attacks, we collected 49 videos for successful tracker hijacking (33 for AVs and 16 for pedestrians) and 52 videos for successful misclassification attacks (36 for AVs and 16 for pedestrians). For adaptive attacks, we collected 43 videos each for tracker hijacking and object misclassification (33 for AVs and 10 for pedestrians). In these attacks, we chose videos in different locations and lighting conditions to represent as diverse an amount of variables and conditions as possible. We detail our attack setup and data in Appendix C.

In real-world tracker hijacking attacks, we aim to cause vehicle collisions or stoppages in AVs via tracker hijacking, or disguise entry into unauthorized areas in video surveillance. In misclassification attacks, we altered vehicles into pedestrians to cause incorrect AV planning & control decisions. To fool video surveillance, we misclassified pedestrians as other appropriate classes to ignore unauthorized entry.

We prioritized safety in real-world experiments by choosing low-traffic locations and times, engaging a third-party spotter, and obtaining permission from local police. We discuss our safety measures further in Appendix C.3.

(a) Tracker Hijacking (b) Cooling-shrinking

Figure 8: Detection against non-adaptive (a) tracker hijacking and (b) cooling-shrinking attacks in the digital domain.

7.3 Non-adaptive Attacks

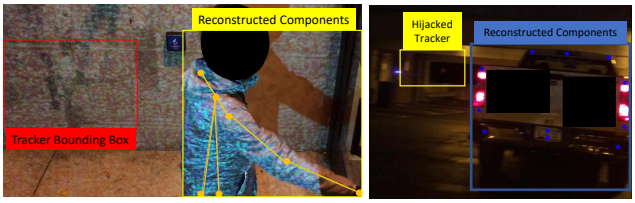
Table 1 shows the detection success rate of VOGUES against non-adaptive attacks across digital and real-world domains. For digital attacks, we observed the same success rate regardless of attack type: 99.49% for pedestrians and 100% for vehicles. If an attack was detected in an image or video sample, VOGUES detected all attacks against that sample. Similarly, if an attack was not detected for a sample, VOGUES would always fail to detect the attacks against it. This indicates that the perturbations of non-adaptive attacks do not affect pose extraction performance.

In Figure 8, we illustrate two successful detections against OT attacks in the digital domain. In Figure 8-a, the pedestrian's components remain in their original place despite the tracker being hijacked to the right, raising an alert via consistency checking. In Figure 8-b, all tracking results are suppressed, but the components of a targeted vehicle are still present, again raising an alert via consistency checking.

In our real-world experiments, VOGUES detected 100% of tracker hijacking and misclassification attacks against pedestrians, and 90.9% / 91.67% of tracker hijacking / misclassification attacks against vehicles. Real-world attacks against pedestrians in restricted areas focus on attackers disguising their entry. Unlike digital domain attacks, these areas are typically well-lit and freer of crowds and occlusions, which enables VOGUES to extract components more precisely, improving the success rate.

However, overall we observe that VOGUES is slightly more successful in the digital domain than in the physical domain, with an average success rate of 99.49% vs. 94.06% in the real world. We attribute this to the larger sample size of digital attacks compared to physical attacks. In the real world, the detection failures were for very similar cases, such as misclassified vehicles that were distant and shrouded in darkness.

Figure 9 shows how VOGUES successfully detects physical-domain tracker hijacking attacks. On the left, the attacker hijacks the pedestrian's tracker to the left of the image to disguise their entry into an unauthorized area to the right. However, the pedestrian's components remain perceivable as they enter the restricted area. As they appear in distinct



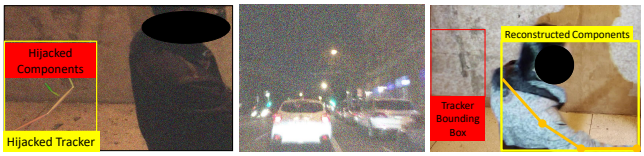


Figure 9: Two successful detections against non-adaptive tracker hijacking for physical domain video surveillance and autonomous driving.

(a) Without Validation (b) With Validation (c) Real World

Figure 10: Adaptive attacks (a) digitally applied against a real-world video, **without** reconstruction validation, causing an unnatural component reconstruction, (b) against a digital dataset **with** reconstruction validation, removing component reconstruction results entirely to conduct cooling-shrinking, and (c) in the real world, where adaptive attacks failed to fully suppress component reconstruction.

locations, this raises a component consistency alert. On the right, a tracker hijacking attack moves the truck's bounding box outside the path of the AV, attempting to induce a collision. However, the vehicle's reconstructed components remain in their original position, and an alert is raised.

7.4 Adaptive Attacks

We assess VOGUES against adaptive attackers (formulated in Section 6.1), which aims to simultaneously evade its component reconstruction and accomplish the attack goal.

7.4.1 Digital Attacks

In this set of experiments, we do not place any physical constraints on digital attacks, i.e., realistic perturbation regions. We compute the average per-pixel perturbation required to evade VOGUES successfully, quantifying the physical realizability of the attacks, rather than examining the attack success rate (which would be 100%). Below, we empirically demonstrate that increasing required perturbations also increases adaptive attack difficulty against VOGUES.

Without Reconstruction Validation. We measure the utility of reconstruction validation by comparing adaptive attack requirements with and without validation deployed. That is, without validation, the attacker simply specifies a *target zone* for the pose information (given as a bounding box) rather than a target pose. This method has looser success requirements,

as the attacker simply has to hijack the pose into the correct region without worrying about a valid shape over time. In this case, any choice of target pose successfully evades VOGUES.

We find that, across all attacks, the average change in perturbation amount between non-adaptive and adaptive attacks *without* reconstruction validation is $21.91\% \pm 4.92\%$. Figure 10-a illustrates the visual impact of such an attack. Both the tracker and the pedestrian's components have been hijacked to the left of the image, away from the restricted area. Although the pose is consistent, it is in an unnatural shape, with several joints missing and the remaining limbs unnaturally stretched. The looser success requirements lead to fewer required perturbations, which are certainly more visible than the almost imperceptible noise in Figures 8 and 9. However, employing validation makes the required perturbations even stronger.

With Reconstruction Validation. With reconstruction validation, the attacker must now achieve a target pose that evades our one-class LSTM network. Although one or more solutions always exist, and our adaptive attack will choose the target pose that has the least required perturbations to achieve, reconstruction validation ensures that a large perturbation amount is required to evade detection, which is conspicuous and difficult to achieve in real-world settings (Section 7.4.3).

Specifically, the average change in perturbation between non-adaptive and adaptive attacks *with validation* is $49.9\% \pm 3.3\%$ across all attacks, approximately doubling the without-validation amount. This comes with only a 0.05 fps increase in running time, making it feasible to employ. The average per-pixel difference ($|I - I_p|$) between the perturbed image and the original image amount is 127.27 ± 8.43, with a max difference of 255 (black areas of the image become white). Overall, the required perturbation for each sample depends on the brightness of the environment, with the least bright sample (averaged over all pixels) having the lowest change in perturbation of 33.14% between non-adaptive and adaptive attacks, and successively brighter samples requiring further perturbations to prevent being washed out.

Figure 10-b shows the visual impact of adaptive attacks under reconstruction validation, where an adaptive cooling-shrinking attack removes all trackers and component sets. Although both object detection and pose extraction have had their results completely suppressed, the required perturbations are visually striking.

Previous user studies [21] for visibility of similar pose-hijacking adversarial perturbations showed that, above a maximum $||I - I_p||_\infty$ value of 32, over 97.84% of participants are able to clearly see the perturbations. This increases the chance of an AV operator taking manual control over their vehicle, or a pedestrian notifying authorities and interrupting the attack.

7.4.2 Constrained Digital Attacks

To quantify the effect of the surrounding layout on the success of adaptive attacks, we constrain the perturbations through LiDAR-based attack zone generation [36]. Applying this approach to DriveTruth [35], an autonomous driving data generator built on the CARLA simulator, we create a dataset with identified physically perturbable regions. This allows us to generate attacks that perturb invalid areas, e.g., the sky and bright lights in an environment. Our final dataset contains 40 videos with randomized environmental factors, including road traffic, victim speed, and traffic light timing.

Under constraints enforced on the perturbable regions, the adaptive attack success rate drops by 15%. 10% of attacks are detected and 5% of attacks fail to achieve their goals. The failure cases are due to the limited perturbable regions in a sample, which are smaller than the successful cases.

These results show that the layout of the environment influences whether or not an adaptive attack can work in the physical world, even when we assume the projector's strength is infinite and unaffected by any light source.

7.4.3 Real-world Attacks

In this set of experiments, we constrain noise generation to physically perturbable regions for physical domain adaptive attacks; however, unlike digital attacks, the projector no longer has infinite perturbation strength. This makes the projected perturbations more susceptible to environmental lighting conditions, overpowering and washing out the adversarial noise [35]. As a result, VOGUES detects 100% of the successful physically launched adaptive attacks.

Figure 10-c shows an example of a physically launched tracker-hijacking attack. The adaptive noise suppresses the component reconstruction elements, such as the neck and much of the torso. However, the effect is incomplete, and the remaining unaffected reconstructed components are enough for VOGUES to detect the inconsistency and generate an alert.

Projectors with higher power can generate the required adaptive perturbations in the physical domain, but they are also more expensive. To estimate the projector perturbation cost [33], we calculate the luminance required for projected noise with ℓ_∞, ambient luminance, and distance square, i.e., $\text{Lumen} \propto \ell_\infty(\Delta) \cdot \text{Illum} \cdot d^2$.

We observed an ambient luminance of 301x, and our $\sim$200 projector was able to effect perturbations at $\ell_\infty = 0.1$ at a distance of two meters. Scaling to the required ℓ_∞ of 1 for adaptive attacks, an attacker would need a 9K-lumen projector, typically priced at \$13K [9], and in daytime lighting conditions, where ambient illuminance is 40 klx, a 75K-lumen projector would be required, which is priced around \$375K [3].

Table 2: Comparison of VOGUES's performance with other OD defenses at detecting **object misclassification**, changing stop signs into pedestrians in the BDD100K dataset. We note that none of the other systems are able to detect tracker hijacking and cooling-shrinking attacks on OT.

Method	Detection Rate	FPR
VOGUES	98.48%	1.78%
PercepGuard [33]	99%	5%
SCEME [29]	81.67%	8.33%
KEMLP [16]	93.75%	0%

7.5 False Positive Rate Analysis

We evaluated VOGUES on 1,600 benign samples from the BDD100K dataset and 1,442 samples from the MPII dataset, for a total of 3,042 samples. Because no attacks were conducted for this set of experiments, we counted a false positive for every sample that VOGUES generated an alert.

Across all samples, VOGUES has a total false positive rate of 3.29%, 2.98% for video surveillance, and 1.78% for autonomous driving. 8% of FPs were caused by errors in the victim's object detection and tracking pipeline rather than errors in VOGUES. For example, in cases where an object is obscured by motion blur, the object detection and tracking pipeline fails to lock onto the object while the reconstruction pipeline perceives it, creating an inconsistency between components.

All other FPs were due to component reconstruction errors, such as extracting two or more component sets for one object. This can occur in uneven lighting conditions or when the object is obscured by the environment. As computer vision advances and pose estimation models improve, component reconstruction will be able to better handle these edge cases.

8 Discussion and Limitations

Comparison of VOGUES with Existing Countermeasures. To our knowledge, there are currently no practical defense or detection approaches against OT attacks. However, several state-of-the-art defenses for OD exist, which aim to mitigate misclassification attacks in the AD domain. These defenses do not work against tracker hijacking and cooling-shrinking attacks. Specifically, using the BDD100K dataset [59], we evaluated PercepGuard [33], SCEME [29], and KEMLP [16] against both attacks, and all three defenses had a 0% detection rate. Our tracker hijacking attacks, moving a vehicle 200 pixels to the left or right, emulated real-world lane changes, while our cooling-shrinking attacks, removing suppressing all OD/OT results from the start of the attack, emulated empty environments without objects. Both scenarios are contextually consistent under previous OD defenses.

However, previous defenses were built for the *OD* domain, whose attacks have different characteristics. In Table 2, we compare these defenses with VOGUES against *misclassification* attacks on OD, changing the stop sign class into the pedestrian class. We note that VOGUES is not mutually exclusive with any of these defenses, and we encourage using OD-specific defenses alongside VOGUES for the best coverage against different attacks.

We found that KEMLP [16] yields a 0% FPR, with its first-order logic approach less susceptible to FPs compared to approaches relying on neural networks, including VOGUES. However, KEMLP's detection rate is 4.73% lower than VOGUES's, requiring more precise application-specific knowledge rules to detect attacks. In contrast, VOGUES does not need application-specific knowledge since component consistency principles apply to all objects with extractable components. PercepGuard [33], similarly, yields a 0.52% higher detection rate than VOGUES, but its FPR is 3.22% higher because it can detect certain benign movement behaviors (e.g., aborting a lane change by swerving back into the original lane) as attacks. Unlike PercepGuard, VOGUES relies less on temporal features, such as movement, to detect attacks and more on the appearance of objects. Lastly, SCEME yields a 16.81% lower detection rate and 6.55% higher FPR than VOGUES. Unlike VOGUES, SCEME is heavily affected by the richness of object context and performs poorly when there are fewer objects in a scene (e.g., in foggy or dark driving conditions).

Extending Object Classes. We demonstrated the effectiveness of VOGUES on the pedestrian and vehicle classes as they are the most critical object classes in safety-critical autonomous driving and video surveillance. Here, we study how VOGUES can extend to other classes and domains.

To make VOGUES work for arbitrary classes, users first need to create appropriate component definitions for each new object class. Once components are defined, the other algorithms of VOGUES work without any additional implementation. For example, Figure 11 shows how a DriveTruth [35] dataset is used to define components for a traffic sign or traffic light. We use the semantic LiDAR data to define a traffic sign's components as a hexagon encompassing the sign's corners, or a traffic light's components as its four corners and active light. Once the class's general shape is defined, it can be automatically fitted to semantically segmented data to train a neural network model for extracting components, as we described in Section 5.2.

However, we note that it is more challenging to define components for certain classes of objects with irregular, unique patterns, such as trees. Evaluations on a generalized VOGUES without class-specific post-processing shows that it has 0.99% higher attack detection rates in the real world, albeit with a 0.81% higher FPR (Appendix D). Future work can extend experiments to assess VOGUES in rare scenarios, such as extreme weather conditions.

VOGUES as a Full Defense. VOGUES alerts the system when an attack is detected, but does not take any automated recovery actions, such as issuing commands to an AV to mitigate or prevent the attack. It is challenging to anticipate all the

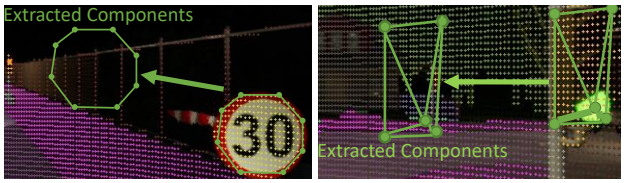

Figure 11: Example of how VOGUES generalizes to other object classes: Components extracted from a traffic sign (left) and a traffic light (right).

consequences of attacks in different application domains. By outputting alerts, VOGUES gives the user or system the flexibility to decide how to respond optimally to an attack.

We plan to extend VOGUES into a complete defense by implementing a continuous scoring system, e.g., using the IoU between objects and their components, to allow ASs to make robust decisions. To prevent false positives from impeding the operation of an AS, alerts from VOGUES can be used as an indicator or confidence value to be used by a higher-level, decision-making security system. For example, in the AV domain, the victim system can adopt more cautious driving behavior in response to a single isolated alert. For consecutive alerts, the victim vehicle might yield control to a human driver. Similarly, in video surveillance, a single alert might notify a human security guard, while consecutive alerts should directly sound the alarm for unauthorized entry. As the accuracy of the perception and component reconstruction algorithms improve, VOGUES can be updated to have a lower FPR.

9 Conclusions

We introduce VOGUES, the first practical countermeasure against tracker hijacking and cooling-shrinking attacks. VOGUES models the human principle that any visible object must also have tangible constituent components. VOGUES is also effective against OD attacks, including misclassification and object deletion. VOGUES leverages pose estimation to reconstruct the key components of objects in a video frame. To enhance robustness against adaptive adversaries, we propose an LSTM validator to detect adaptive attacks against the reconstruction framework. We evaluated VOGUES against adaptive and non-adaptive attackers, using digital datasets alongside data collected in the real world. VOGUES successfully detects 99.49% of attacks in the digital domain and an average of 93.81% in the physical domain.

Appendix

A RPN and STN Isolation

VOGUES uses two methods to isolate object instances, which are selected to account for different conditions the objects may appear in. RPNs (Figure 12a) learn how to generate feature maps based on an input image. The maps can be used to regress the tightly cropped object instance. This is ideal for targets that can appear from many different angles and positions, such as vehicles. Meanwhile, Spatial Transformer Networks (Figure 12b) regress scaling and plane rotation parameters (θ) to better isolate objects that are among crowds or at long distances, such as pedestrians.

B Pose Hijacking

Our adaptive attack seeks to "hijack" the pose estimation results of component reconstruction to match VOGUES's results with the adversarial attack goal. However, attacks against pose estimation often result in unnatural poses, with limbs or the spine bent at odd angles. Figure 13 demonstrates pose hijacking attempts against two common HPE models, attention [8] (Figure 13-a) and 8-stacked [39] (Figure 13-b).

In these attacks, the attacker aims to hijack the original pose (in orange) into the pose of a man sitting (in red, on top of the original pose). Different model architectures result in slightly different behavior: for example, attention HPEs may experience less displacement in the overall pose, but they may fail to detect certain limbs. Meanwhile, stacked HPEs may have a greater pose displacement, creating a warped shape as individual key points within the pose are shifted independently. No matter the architecture, the difference in resistance to perturbation between key points means that exponentially stronger perturbations are required for a full pose hijacking. According to user studies, the required perturbations can be detected 97.84% of users [21].

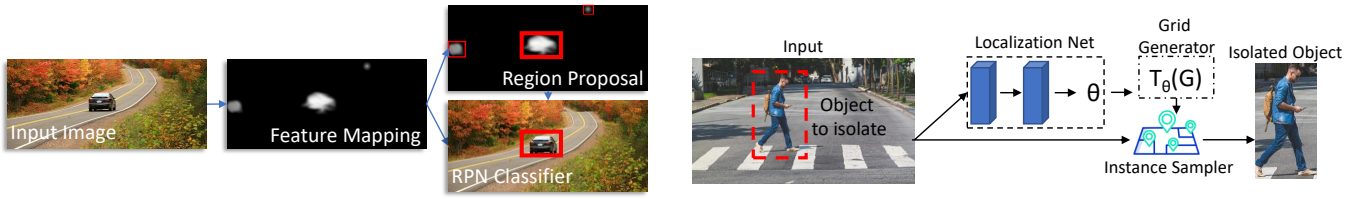
C Real-World Attack Details

C.1 Attack Setup

For tracker hijacking attacks, we used an Optoma LV130 mini projector [42] to project adversarial perturbations onto the environment. Against AVs, we place the projector on the dashboard of the victim vehicle, while against surveillance, we place the projector directly behind our security camera to effect perturbations within its field of view.

For misclassification attacks against AVs, we mounted a 40-inch LCD monitor to the back of a vehicle via a tailgate hitch mount and used the monitor as a dynamic adversarial patch. The vehicle was driven normally, but extra caution was taken when making sharp turns to prevent the mount from swinging.

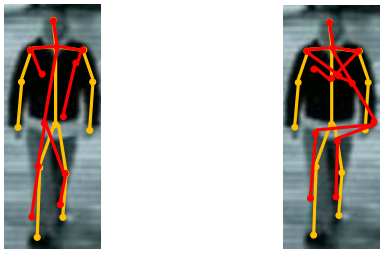
In our real-world experiments, we used an HD camera to record footage in 1920x1080 resolution. For vehicle-based experiments, the camera was mounted directly above the dashboard to simulate the camera of an autonomous vehicle. For surveillance experiments, the camera was placed high on a wall looking downward at a building entrance to simulate a security camera watching a restricted area.



C.2 Video Selection

In our evaluation of real-world non-adaptive attacks against AVs, we have three extra videos for misclassification attacks compared to tracker hijacking attacks. This is due to three more classification attacks against AVs succeeding than tracker hijacking. For both adaptive and non-adaptive attacks, we removed videos that were too similar to other samples. This was done to reduce repetitive videos that may artificially boost detection rates by having the exact same structure. No removal was necessary for the AV domain, as variations in traffic, pedestrians crossing roads, and other environmental factors created a large variety in collected videos. Yet, in the surveillance domain, with a static camera observing the same position, more similarity between videos was encountered, resulting in fewer pedestrian examples than AV examples.

C.3 Safety in Real-World Experiments



We made safety our highest priority during real-world experiments. We obtained permission to conduct our experiments from the Special Services Division of the local police department, and patrol officers were notified before the experiments. We carefully selected empty locations with sufficiently little traffic, as determined by a third-party spotter who continually supervised conditions to ensure safety. For monitor experiments, we secured the LCD monitor via bungee cord to absorb shock from sharp movements and prevent it from swinging around the environment.

During all vehicle experiments, we drove on roads where the speed limit was 25 MPH, and we did not exceed 20

Table 3: VOGUES's attack detection performance with/without class-specific post-processing.

Mode	Digital Attacks	Real-World Attacks	FPR
Class-specific	99.49%	94.06%	3.29%
Generalized	99.49%	95.05%	4.1%

MPH when driving. We avoided aggressive acceleration and braking and obeyed traffic rules. Experiments were paused every 5 minutes in order to check the equipment and ensure it had not come loose or unstable.

All experiments were conducted with three experienced personnel at a time: an attack equipment operator, a victim equipment operator, and a third-party spotter to supervise the experimental conditions. All 3 maintained constant communication via phone during the experiments. The experiments were supervised and approved by professors experienced in autonomous vehicle research and experiments. In line with standards set by previous works [33, 36, 37], we conducted experiments without direct exposure to sunlight to reduce the effects of ambient lighting conditions on the effectiveness of the tested attacks.

D Extension to Other Classes and Domains

D.1 Ablation Study on General Pipeline

To comprehensively evaluate the effectiveness of VOGUES on general classes, we evaluate VOGUES with both class-specific post-processing, such as pose-flow tracking for pedestrians, and with a general pipeline where all classes conform to the minimum specifications outlined in Sections 5.1 to 5.3. The results are described in Table 3. Overall, we observe identical performance in digital attacks and a 0.99% greater attack detection rate for the generalized system than the class-specific system. However, this comes at a 0.8% higher false positive rate for the general system. The general system is more aggressive in outputting detection alerts because the pose results are no longer corrected through tracking. The lack of correction generates incorrect component reconstructions more often, whether or not an actual attack is performed. These results suggest that although the general specifications for all classes can achieve promising performance, victims may choose to enhance the pipeline with class-specific post-processing for more accurate results, depending on their requirements.

Figure 14: A common false positive case in sports tracking, where a crowd of people not in camera focus will be extracted as one bounding box by OD but have multiple components extracted. These cases are uncommon in the safety-critical domains of autonomous driving and surveillance due to the use of focus-free cameras.

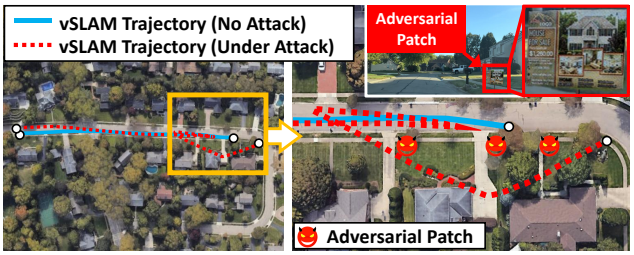
D.2 Non-Safety Critical Domains

We evaluated VOGUES's performance in the sports tracking domain, where a camera automatically tracks the movements of athletes to keep them in focus. Sports tracking is less safety-critical compared to autonomous driving and surveillance but contains very different behaviors. Across 782 sports tracking examples from the MPII dataset, VOGUES obtains a 100% attack detection rate, but also a 20.2% false positive rate.

Figure 14 illustrates such an example of a common sports tracking-related false positive. An out-of-focus crowd is extracted as a single object by object detection, but multiple objects are seen by component extraction. Autonomous vehicle and surveillance applications typically use focus-free cameras [52], and do not suffer from focus-related blurring issues. Sports tracking can also contain more contorted poses that are more difficult to extract than poses from other applications. As pose estimation models are improved, component reconstruction may better handle more difficult domains.

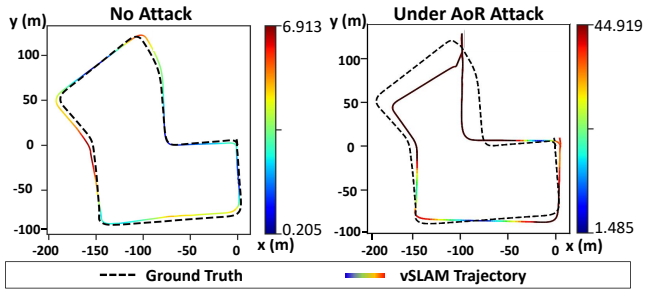
Adversary is on the Road: Attacks on Visual SLAM using Unnoticeable Adversarial Patch

Baodong Chen[1,*], Wei Wang[2,*], Pascal Sikorski[2], Ting Zhu[1,†]
[1]*The Ohio State University,* [2]*Saint Louis University*



Abstract

Visual Simultaneous Localization and Mapping (vSLAM) plays a pivotal role in numerous emerging applications, including autonomous driving and robotic navigation. It mainly utilizes consecutive frames captured by image sensors to conduct localization and build high-definition maps. However, existing approaches mainly focus on building reliable and accurate vSLAM systems, while little work has been done to investigate the vulnerability of existing vSLAM systems.



To fill the gap, we introduce an **AoR** (**A**dversary is **o**n the **R**oad) attack, which can effectively alter localization and mapping results of widely used vSLAM systems without being detected by the legitimate user. To do this, we conducted in-depth investigations on existing vSLAM systems and found that these systems are very sensitive to environmental texture changes. Building upon this insight, we design a novel adversarial patch generation mechanism that can generate unnoticeable adversarial patches to attack existing vSLAM systems. We extensively evaluate the effectiveness of the AoR attack on industry-level vehicles, robotic platforms, and four well-known open-source datasets. The evaluation results show that the AoR attack can effectively attack existing vSLAM systems and introduce extremely high localization errors (up to **713%**). To mitigate this attack, we also designed an innovative defense module to simultaneously detect abnormal environmental texture distributions and support reliable vSLAM. Our defense module is lightweight and has the potential to be applied to existing vSLAM systems.

1 Introduction

Simultaneous Localization and Mapping (SLAM) has emerged as one of the most important technologies to support real-time localization for various robotic applications, including autonomous driving [1–3], robotic navigation [4–6], and robot delivery [7–9]. To conduct SLAM, a variety of sensors, such as cameras [10, 11], LiDAR [12, 13], and radar [14, 15], are employed to sense and interpret the surroundings of the robot. Among these sensors, camera-based solutions (Visual SLAM) have distinct advantages, including low cost, high accuracy, and low system complexity. As a result, Visual SLAM (vSLAM) has been considered a practical solution and widely applied to many real-world applications [16–21].

(a) AoR Attack on a Real Vehicle in the Residential Area.

(b) Comparison of vSLAM Results on the KITTI Dataset.

Figure 1: Examples of the AoR attack on a real vehicle and KITTI Dataset: AOR attack can introduce huge errors to existing SLAM systems.

To build a vSLAM system, the key idea is to leverage the consecutively captured frames to estimate the motion and location of the camera. Then, according to the localization result, we can simultaneously construct the map using the captured camera frames. To improve the robustness and accuracy of vSLAM systems, researchers have introduced numerous novel techniques. Specifically, to design a holistic vSLAM system, one of the most well-known vSLAM algorithms, ORB-SLAM2 [22], introduced the first open-source vSLAM system for real-time and accurate localization and

*These authors contributed equally to this work.
†Corresponding author: Prof. Ting Zhu (zhu.3445@osu.edu)

mapping. Built on top of ORB-SLAM2, researchers have also introduced several novel vSLAM algorithms to improve the robustness of the vSLAM systems in different scenarios [23–26]. For example, DynaSLAM [26] can detect and filter out the moving objects in each frame to reduce the motion estimation error and improve localization accuracy in dynamic scenarios. Recently, ORB-SLAM3 [27] introduced a multi-map data association technique to further improve the accuracy and robustness of vSLAM systems.

However, existing techniques mainly focus on improving the performance of vSLAM systems, while little work has been done to study the vulnerability of these systems. Also, existing studies have only targeted specific components of vSLAM [28, 29] and often require customized hardware, performing attacks in limited scenarios [30]. Furthermore, they have not systematically analyzed the security issues in vSLAM, resulting in a significant gap in understanding potential threats and mitigation strategies.

In this work, for the first time, we comprehensively analyze the unique vulnerabilities within vSLAM and strategically exploit these weaknesses to do targeted end-to-end attacks. We discovered that the performance of the vSLAM system is intrinsically sensitive to various visual environmental factors, including texture distribution, lighting conditions, and the shapes and colors of objects. Changes in these factors can easily affect the localization and mapping accuracy. Furthermore, most of the current vSLAM systems treat all the features (e.g., key pixel points, key objects, etc.) in a frame equally without analyzing the current environment. Questions such as "Which feature is more reliable?" or "Is this feature real?" often remain unaddressed. For example, features susceptible to changing light conditions should be assigned lower importance since they may introduce high noise to vSLAM systems. However, in practice, to improve the reliability of vSLAM systems in low-texture environments, every feature in a frame is utilized for localization and mapping, which introduces inevitable errors to vSLAM systems.

Based on the above insight and analysis, we propose to attack the vSLAM systems by introducing adversarial features to existing vSLAM systems. We also aim to provide a defense strategy to mitigate this attack. To achieve this goal, we need to overcome three main challenges. **First**, existing vSLAM systems leverage various optimization techniques (e.g., Least-Square algorithm [31], RANSAC [32], etc.) to reduce errors introduced by the features in a frame. As a result, simply introducing random adversarial features may not attack vSLAM systems effectively. Therefore, we need to find the optimal adversarial features to effectively attack the vSLAM system. **Second**, most vSLAM systems are designed for autonomous vehicles and robots which operate in dynamic environments. Therefore, instead of attacking vSLAM in ***static*** scenarios, the proposed attack approach should stealthily attack existing vSLAM systems under ***dynamic*** environments. **Third**, we need to find a solution to identify the stealthy attack and mitigate its impact effectively.

To overcome the above challenges, we introduce the **AoR** (**A**dversary is **o**n the **R**oad) attack, which can effectively attack existing vSLAM systems without alerting legitimate users. The key idea of our attack is to inject unnoticeable adversarial patches into objects in the dynamic environment. These patches will introduce huge errors to vSLAM systems and can be seamlessly incorporated into common objects (i.e., advertising stickers in public spaces) without being detected by the naked eye. To generate these patches, we design a novel adversarial patch generation network to generate patches containing optimal and unnoticeable adversarial vSLAM features. Moreover, we also introduce a dynamic adjustment model to make the AoR attack robust under dynamic scenarios. Figure 1 shows examples of AoR attacks on a real vehicle platform and one of the most well-known autonomous driving datasets - KITTI [33]. As we can see from Figures 1 (a) and (b), the AoR attack introduces huge errors to the vSLAM system in both the real-world scenario and open-source dataset. In this case, robots or autonomous vehicles will get the wrong localization results and create a distorted map. Consequently, users relying on these inaccurate maps for navigation can be misled, leading to significant security risks.

To defend against the AoR attack, we propose an innovative and lightweight defense module that can identify abnormal patterns in each frame. To do this, we first convert each frame into the texture space to analyze potential adversarial patches. We then employ a variational auto-encoder model to recognize abnormal texture distributions. At last, we introduce a cross-frame optimization technique to dynamically select features in each frame for reliable localization and mapping.

Overall, our key contributions are summarized as follows:

- To the best of our knowledge, this is the ***first work*** that in-depth investigates the vulnerability of vSLAM systems. Specifically, we introduce an AoR attack, which injects unnoticeable adversarial patches into common objects. The proposed attack can effectively attack widely used vSLAM systems, introducing significant localization and mapping errors in dynamic settings without detection by legitimate users.
- We conduct extensive real-world experiments using industry-level vehicles and robot platforms under various scenarios and settings. The experiment results prove that our attack approach can attack widely used vSLAM systems and introduce harmful impacts.
- To defend against the AoR Attack, we also design a novel lightweight defense module that can detect the AoR attack and improve the reliability of vSLAM systems simultaneously. The experiment results show the effectiveness of our defense approach.

2 Vulnerability of vSLAM Systems

In this section, we first introduce and analyze the background and vulnerability of vSLAM systems. Then, we present real-world experiments to validate our findings.

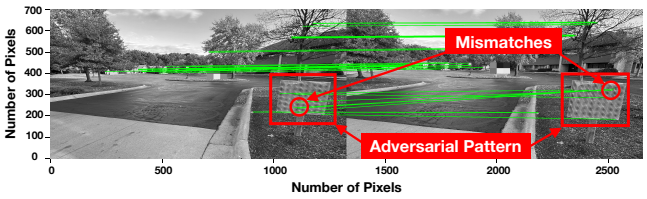


Figure 2: An example of mismatched features introduced by adversarial patterns.

2.1 Vulnerability Analysis of vSLAM Systems

The modern vSLAM system mainly consists of four core modules: (i) visual odometry (VO), (ii) backend optimization, (iii) loop closing, and (iv) map construction. The goal of VO is to estimate the motion and location of the camera between consecutive frames. The goal of backend optimization and loop closing is to reduce the noise and error introduced during the VO process. Based on the localization results, the map is then concurrently constructed using the frames captured by the camera in the map construction module.

In this paper, we found that ***the absence of a verification process during the VO process will introduce huge errors to vSLAM systems.*** Furthermore, we believe that a potential attacker may take advantage of this vulnerability to attack the vSLAM systems. Specifically, in the VO process, the first step is to extract distinctive visual features from the input images or video frames captured by the camera. These features may include corners, edges, or other salient points that can be reliably detected and tracked. Then, by mapping the same features across consecutive frames, we can find the position changes of these features and calculate the location and moving trajectory for autonomous vehicles or robots.

However, the ***first*** vulnerability issue arises as the VO process in vSLAM systems tends to select features solely based on their qualities without considering reliability, especially in environments with sparse textures. Moreover, there is no verification mechanism to validate the authenticity of these features. As a result, unreliable and untrustworthy features may be selected for localization and tracking, which introduces localization and mapping errors to vSLAM systems. The ***second*** vulnerability issue is that vSLAM systems are prone to mismatch features when pixels in a frame show similar intensity distributions. In some extreme cases, multiple selected features in one frame may be matched to a single feature in another frame. Then, during the backend optimization process, these mismatches will lead the vSLAM system in the wrong optimization direction, which introduces significant errors to vSLAM systems.

Based on the above analysis of these inherent vulnerability issues in vSLAM systems, a malicious attacker can easily attack vSLAM systems by injecting carefully designed adversarial patterns into each frame.

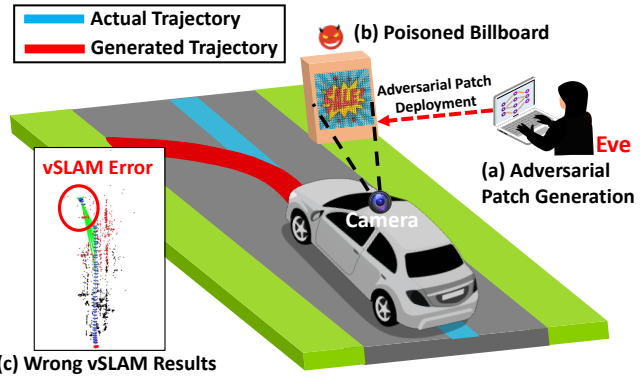

Figure 3: The Threat Model: (a) a malicious attacker (Eve) generates the unnoticeable adversarial patch and (b) deploys the patch on the billboard. In (c), the vSLAM system detects the key features in adversarial patches and outputs wrong localization and mapping results.

2.2 Preliminary Results of vSLAM Systems

To validate our analysis, we conduct a preliminary experiment in a real-world scenario in Figure 2. In this experiment, we generated an adversarial pattern containing numerous repetitive pixels. The grayscale values of these pixels are the same as each other but significantly different from the background pixels. We positioned this adversarial pattern at the roadside and utilized the implemented vSLAM system (ORB-SLAM2) [22] on our vehicle platform introduced in Section 5.1.1 for localization and mapping. During the experiment, we leveraged the widely-used ORB features [34] to extract key pixels from each frame, while leveraging the RANSAC algorithm [35] to filter out anomalies. As shown in this figure, key pixels outside the adversarial pattern are all correctly matched. However, since the features within the adversarial pattern are indistinguishable from one another, the VO process fails to accurately match these features between consecutive frames. This experiment not only proves the vulnerability of vSLAM systems but also points out a high-level strategy to attack the vSLAM system: ***the attacker can generate adversarial patterns that contain similar features to introduce errors to vSLAM systems.***

3 Models and Assumptions

In this section, we first describe the system model. Then, we introduce our threat model.

3.1 System Model

In this work, we mainly focus on investigating the vulnerability of commonly used vision-based SLAM (vSLAM) systems for autonomous vehicles and robotic applications. These vSLAM systems mainly utilize frames captured by cameras for real-time localization and mapping in both indoor and outdoor scenarios. Specifically, a vSLAM system will first select multiple key pixels in each frame as the key features during

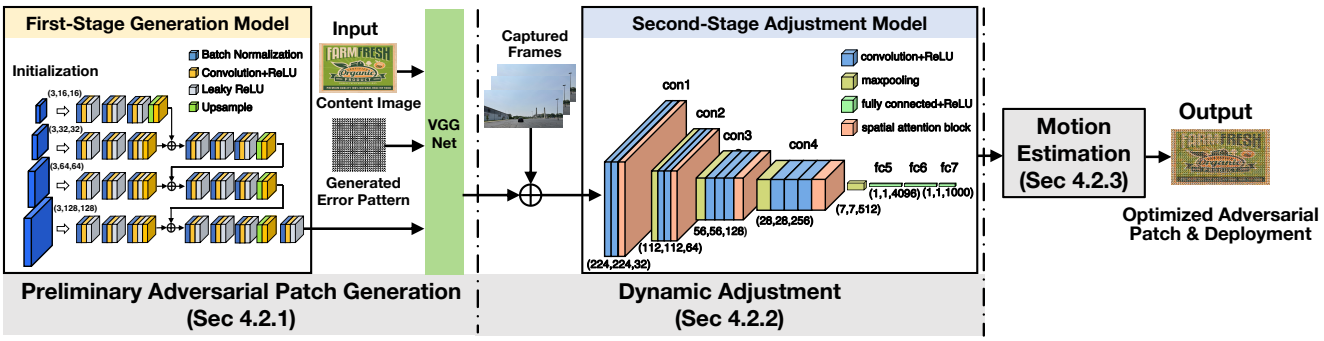

Figure 4: An overview of the AoR attack.

the visual odometry (VO) process. These selected features are then mapped and tracked across consecutive frames. Finally, based on the movement of these key features, the vSLAM system can conduct localization and mapping accurately.

3.2 Threat Model

Attack Goal. The goal of the AoR attack is to alter the localization and mapping results of vSLAM systems in autonomous vehicles or robots without being detected by the legitimate user. By doing this, a malicious attacker can potentially cause car accidents involving autonomous vehicles or divert the robots to fallacious destinations.

Assumptions. To orchestrate such an attack, we assume the attacker (Eve) can rent or buy the same hardware as the victims to know the potential attack environment and the victim's hardware platform (e.g., autonomous vehicle, robot, etc.). The attacker cannot access the victim's camera frames but can use the same hardware to collect the frames of the attack environment before launching the attack. We also assume the attacker has basic knowledge of machine learning techniques to generate optimal adversarial patches using the collected frames, but no additional computer science expertise is required to execute the attack. Then as long as the victim uses commonly-used vSLAM systems [22, 24–27], the AoR attack can effectively alter the localization and mapping results without detection by the legitimate user. The AoR attack is under a **grey-box** access assumption, where the attacker knows that the victim employs the target vSLAM system but does not have any internal technical details of the victim's system. We consider this assumption reasonable because the attacker can infer such information through preliminary experiments (Figure 2) to see if high-texture patches can affect the system's performance.

To attack the vSLAM systems in real-world scenarios, an attacker can implement unnoticeable adversarial patches on common real-world objects (e.g., billboards). While these patches appear harmless to humans, they deceive vSLAM systems used for localization in autonomous vehicles or robots. As a result, the AoR attack can stealthily introduce high localization and mapping errors to vSLAM systems. For example, as shown in Figure 3, the attacker generates and deploys adversarial patches on roadside billboards. Then, the poisoned billboard containing unnoticeable features can be easily detected by vSLAM systems in autonomous vehicles or robots and introduce errors to vSLAM results.When the victim system relies on such inaccurate vSLAM maps for decision-making, it may result in collisions with nearby objects.

4 Design of the AoR Attack

In this section, we first introduce the design overview of the AoR attack. Then, we describe the design in detail.

4.1 Design Overview

The AoR attack design, shown in Figure 4, comprises three modules: **Preliminary Adversarial Patch Generation**, **Dynamic Adjustment**, and **Motion Estimation**.

The objective of preliminary adversarial patch generation is to produce adversarial patches that contain unnoticeable adversarial features. To achieve this goal, we first select images suitable for roadside deployment as the base content image. Then we embed an ideal error pattern image that can introduce mismatches to vSLAM systems into the content image. The error pattern is designed based on the feature extraction mechanism in the VO process of vSLAM systems. To do the embedding, we design a first-stage generation model to merge the content image and the error pattern.

In the second-stage adjustment model, dynamic adjustment is designed to optimize the adversarial pattern using environmental information and maximize the attack's effectiveness. Specifically, we found that the effectiveness of the adversarial patch may vary according to different attack scenarios. Therefore, the attacker should conduct optimization based on the potential attack scenarios before attacking the target autonomous vehicle or robot. To do this, the attacker can use the same hardware to collect frame sequences of the target attack scenario. Then, the dynamic adjustment module will optimize the adversarial patterns from the preliminary adversarial patch generation module based on the captured frames. It will optimize the inner texture to make the adversarial patch targeted to the designated attack scenario while remaining benign in other situations.

We also design a motion estimation module to roughly estimate the potential movement of the target autonomous

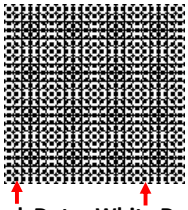

Figure 5: The ideal error pattern contains repetitive black and white dots.

vehicle or robot. Using these processes, we can find the best locations to deploy multiple adversarial patches in the target attack scenarios.

4.2 Detailed Design

In this section, we first introduce the preliminary adversarial patch generation module. Then, we show the detailed design of the dynamic adjustment module. At last, we introduce the motion estimation technique.

4.2.1 Preliminary Adversarial Patch Generation

The goal of preliminary adversarial patch generation is to create adversarial patches that can introduce vSLAM errors without being detected by legitimate users. To achieve this goal, as shown in Figure 4, we design a first-stage generation model to efficiently introduce adversarial features into the content image.

Error Pattern Design. To produce an effective error pattern, the features of the pattern must be both detectable by vSLAM systems and capable of causing mismatches over successive frames. Specifically, we generate the error pattern based on the principle of the FAST (Features from Accelerated Segment Test) [36] key feature selection algorithm which is commonly used in industry. The algorithm identifies key features by analyzing brightness differences around specific pixels, marking a pixel as a corner point if its surrounding pixels are significantly brighter or darker. As depicted in Figures 2 and 5, we created an error pattern of alternating black and white dots, distinct from the background. Because these dots are so different, the vSLAM system is likely to recognize them as key features. Moreover, due to the similarity of these dots, vSLAM systems struggle to accurately match the selected key features across consecutive frames, which introduces high errors to vSLAM systems.

Content Preservation. To attack the vSLAM system stealthily, the final adversarial patch should also look benign to legitimate users. To achieve this goal, we embed the ideal error pattern on commonly seen objects (e.g., advertisements on billboards) to hide the error pattern. Specifically, we first select multiple advertisement posters as foundational content images that are contextually suitable for roadside use. We then employ a multi-scale feed-forward neural network as the first-stage generation model to embed the ideal error pattern into the advertisement posters seamlessly. We also use a pre-trained VGG-16 model [37] as our fixed backbone to facilitate the training phase.

To preserve the high-level information (e.g., shape, spatial relationships, etc.) of the content image in the first-stage generation model, we introduce a content loss function L_c that calculates the similarity between the final generated adversarial patch x' and the original content image x_0:

$$L_c(x', x_0) = \sum_{i=1}^{N} [F_i^l(x') - F_i^l(x_0)]^2 \quad (1)$$

In the above equation, $F_i^l(x)$ represents the $i-th$ feature map computed by the backbone network applied to image x at the $l-th$ convolutional layer and N is the number of feature maps in layer l. In practice, it has been proven that the higher layers of the network correspond to high-level information about the image, while the lower layers affect pixel-level details [38]. In this step, since our goal is to preserve the ***high-level*** information of the content image so that the final generated adversarial patch looks benign to the naked eye, we utilize the inner product of ReLU activations from the fourth layer ($l = 4$) of the VGG-16 backbone network to calculate the loss function L_c.

Adversarial Features Integration. To ensure the features in the final adversarial patch effectively introduce vSLAM errors, we introduce a feature loss function L_f to optimize the discrepancy between the generated patch and the ideal error pattern in the feature space. Here, the feature loss function L_f uses lower layers ($l = 1, 2$) of the VGG-16 model and focuses on capturing ***pixel-level*** information, such as grayscale distribution and fine textures. Specifically, the feature loss function L_f can be calculated as:

$$L_f(x', x_f) = \omega_l \sum_{l \in L_F} \sum_{i,j} \left[G_{ij}^l(x') - G_{ij}^l(x_f) \right]^2 \quad (2)$$

Here, x_f is the ideal error pattern. L_F denotes the selected layers in the backbone network, and the weight assigned to each layer is ω_l. The Gram matrix, $G_{ij}^l(x)$, calculated by multiplying the feature maps i and j in layer l, models the correlation between different feature maps in the network. Finally, we generate the optimal adversarial patches by using the high-level loss function L_c and the pixel-level loss function L_f.

4.2.2 Dynamic Adjustment

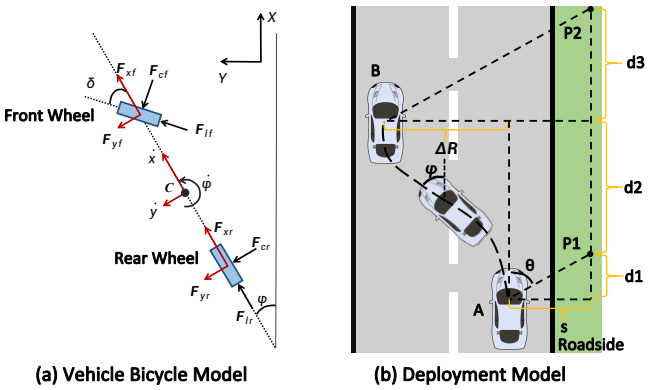
The preliminary adversarial patch generation module produces optimal adversarial patches that can work effectively in ideal attack scenarios. However, in real-world scenarios, environmental factors (e.g., the texture and color of surrounding objects, the density of objects on the road, etc.) may also affect the attack results. For example, if the texture distribution of the target environment deviates too far from the normal distribution, then the effectiveness of the adversarial patch may be diminished. To address this challenge, we introduce a dynamic adjustment module that guides the generation network in finding the optimal adversarial patch according to real-world environmental factors. The high-level idea of the dynamic adjustment module is to dynamically adapt the internal feature distribution of the generated patch in response to environmental factors.

Adjustment with Environment Loss. As depicted in Figure 4, our second-stage adjustment model employs a convolutional neural network (CNN) with attention modules. During the dynamic adjustment, this model integrates the optimal adversarial patch with frames reflecting environmental factors to create a sequence of poisoned frames. Then, the poisoned and original frame sequences are fed into the adjustment model. This adjustment model aims to maximize the difference between the poisoned and the original frames in the feature space according to the attack scenario. To achieve this, we design an environment loss function L_e that **(i)** measures the difference between the poisoned and the original frames, and **(ii)** measures the feature difference between adjacent poisoned frames simultaneously. Formally, the environment loss function L_e can be formulated as:

$$L_e = -\omega_e \sum_{e \in L_E} ([M^e(F(y)) - M^e(F(x'+y))]^2 - [F^e(x'+y) - F^e(x'+y_p)]^2) \quad (3)$$

where x' is the optimal adversarial patch, y is the captured camera frame and y_p is the previous frame of y. It's important to highlight that y and y_p are frames captured by the attacker's camera, not the victim's. They are collected before the attack to find the most effective adversarial patch for the target scenario. The combination $x'+y$ represents the poisoned frame. $F(x'+y)$ is the output from each layer in the adjustment model, while $M(F(x'+y))$ is the attention map. The set of the selected layers in the backbone network is represented by L_E, while the weight of each layer is denoted by ω_e. By using the loss function L_e, the adjustment model effectively identifies regions that have dense feature points in a frame.

Enhance Robustness. To enhance the attack's robustness to various environmental conditions in a genuine driving environment, we collect frames of the attack environment at different times under diverse weather and lighting conditions. Additionally, to address the differences in trajectory between the victim and the attacker as they navigate through the attack scenario, we employ perspective warping to adjust the perspective of the collected frames for further training.



At last, a total loss function L_{total} combines the content loss, feature loss, and environment loss with weighted parameters, which can be expressed as:

$$L_{total}(x_0, x_f, x') = \alpha L_c + \beta L_f + \gamma L_e \quad (4)$$

We optimize our model using the Adam optimizer, setting an initial learning rate of 0.001 and beta coefficients at 0.9 and 0.999. To combat overfitting, we apply dropout with a rate of 0.5 and L2 regularization at a lambda value of 0.01. The training is conducted over 50 epochs with a batch size of 64, utilizing NVIDIA RTX 3080 Ti GPUs.

4.2.3 Motion Estimation

To deploy the adversarial patch and improve the effectiveness of the AoR attack in real-world scenarios, it is also important to ensure the victim's camera can see the adversarial patch.

(a) Vehicle Bicycle Model (b) Deployment Model

Figure 6: The bicycle and deployment models used for adversarial patch deployments.

We use the well-known bicycle model [39] to estimate the potential motion of the target vehicle or robot. This model, illustrated in Figure 6, defines key parameters: δ for the steering angle, C for the center of mass with front and rear distances l_f and l_r, and φ for the angle between the vehicle's longitudinal axis and the X-axis. It also includes forces such as lateral tire forces F_{cf} and F_{cr}, air drag F_a, and rolling resistance F_r. Additionally, it considers the vehicle's mass m and inertia I. The detailed bicycle model can be represented as:

$$\begin{cases} \dot{X} = v_x\cos(\varphi) - v_y\sin(\varphi) \\ \dot{Y} = v_x\sin(\varphi) + v_y\cos(\varphi) \\ \dot{\varphi} = \dfrac{v_x}{l_f + l_r}\tan(\delta) \\ m\dot{v}_x = F_x + mv_y\dot{\varphi} - 2F_{cf}\sin(\delta) - F_a - F_r \\ m\dot{v}_y = -mv_x\dot{\varphi} + 2\left(F_{cf}\cos(\delta) + F_{cr}\right) \\ I\ddot{\varphi} = 2\left(l_f F_{cf}\cos(\delta) - l_r F_{cr}\right) \end{cases} \quad (5)$$

Typically, the maximum steering angle of a vehicle is less than 40° [40]. An attacker can acquire additional vehicle or robot parameters by renting or purchasing a model identical to the target. According to this bicycle model, we can estimate the motion of the target vehicle or robot and find the optimal location to deploy the adversarial patches. As illustrated in Figure 6 (b), the vehicle transitions from $P1$ to $P2$, altering lanes from A to B. The distances involved are $d1$ (from A to $P1$), $d2$ (from $P1$ to B), and $d3$ (from B to $P2$). Analyzing these distances using the camera's angle of view, set around 62.5° [41], allows for calculating the maximum transverse (ΔR) and longitudinal (ΔR_x) displacements of the vehicle during the time window T:

$$\Delta R = \int_0^T (v_x\sin\varphi + v_y\cos\varphi)\,dt \quad (6)$$

Similarly, maximum movement ΔR_x of the victim in X direction can be estimated as:

$$\Delta R_x = d_2 + \frac{s}{\tan\theta} = \int_0^T (v_x\cos\varphi - v_y\sin\varphi)\,dt \quad (7)$$

(a) Experimental Setup (b) Campus (c) Rural Area (d) Warehouse (e) City Center (f) Parking Garage

Figure 7: The implementation of AoR attack and attack scenarios.

Based on the above equations, the distance between the adversarial patch and the victim should be larger than ΔR_x to ensure that every patch appears on the victim's camera.

5 Evaluation

To evaluate the effectiveness of the AoR attack, in this section, we conduct extensive experiments in real-world scenarios using a vehicle and a robotic platform. Then, we also study the effectiveness of the AoR attack using multiple well-known open-source datasets.

5.1 AoR Attack on the Vehicle Platform

In this subsection, we first introduce the experiment setup. Then, we show the AoR attack results on the vehicle platform.

5.1.1 Experiment Setup

vSLAM Platform. We built a standard autonomous vehicle testing platform based on a BMW X3, which is shown in Figure 7 (a). Specifically, we deployed an industry-level Orbbec Astra Pro camera [42] and implemented the target vSLAM algorithms on this platform to conduct localization and mapping. We also adapted vSLAM algorithms using BMW's parameters to handle real-world challenges, including vibration, slip, and chassis dynamics.

vSLAM Selection. We selected five popular vSLAM algorithms that are widely used in autonomous driving [16–19]. These algorithms include ORB-SLAM2 [22], ORB-SLAM3 [27], DynaSLAM [26], pl-SVO [24], and SVO Pro [25]. These algorithms deliver excellent performance with high accuracy and modest hardware resource requirements [43, 44].

Attack Execution. Under the grey-box assumption, the attacker first used the same vehicle platform as the victim to capture frames in the attack environment. These frames were then used to generate the optimal adversarial patch with our generation framework. The attacker placed the generated patches on self-made billboards and determined the optimal locations for deploying these billboards by the roadside using our proposed motion estimation approach. Once the patch was deployed at the roadside, victims using the same platform passed through the attack environment to assess the effectiveness of our attack. We conducted experiments in various real-world scenarios, including a campus, rural area, warehouse, city center, and parking garage, as depicted in Figure 7 to fully assess the AoR attack. Each scenario varied from $20m$ to $80m$. We also explored the impact of the patch configuration and various environmental conditions, with the results presented in Section 5.2. To accurately evaluate the performance of the AoR attack, we used a Real-Time Kinematics positioning device [45] to provide ground truth data and calculated the average Root Mean Square Error (RMSE) [46] within each scenario to assess the vSLAM errors.

5.1.2 The AoR Attack Results

Since the evaluation results show similar trends, we mainly show the attack results on ORB-SLAM3. The full results are presented in Appendix A.2. Figure 8 shows the vSLAM errors introduced by the AoR attack in each scenario. The AoR attack significantly impacts the accuracy of vSLAM systems, as illustrated in the figures. Under normal conditions, the ORB-SLAM3 system can conduct relatively accurate localization and mapping and achieves a maximum localization error of 13.92m in rural areas. However, when the ORB-SLAM3 system is under attack, the vSLAM errors increase to $25.40m$ in rural areas, which is around **two times** as high as that of the no-attack scenario. Moreover, the increase in vSLAM errors is particularly noticeable in the warehouse scenario, where the RMSE escalates by 75%. This significant rise is attributed to the sparse textures and limited distinct features in both rural and warehouse environments. The camera has to rely more on features from the adversarial patches, thereby magnifying the vSLAM errors. It should be noted that the RMSE exceeds 13 meters across all scenarios. Given that road widths are typically less than 12 feet (3.7m) in real driving environments, such substantial errors can lead to severe outcomes, such as causing the vehicle to collide with others or veer off the road when navigating based on a distorted vSLAM map. These inaccuracies highlight the potential risks of car accidents in practical applications. **In summary,** the AoR attack can introduce high errors to vSLAM systems in various scenarios and introduce serious security risks to legitimate users.

5.2 Insight and Impact Analysis

To study the insight and impact of the AoR attack, we conduct experiments by changing different influencing factors, including the dynamic adjustment module, the number, size, orientation, and height of adversarial patches, along with different environmental conditions.

5.2.1 Effectiveness of the Dynamic Adjustment Module

To study the impact of our dynamic adjustment module, we implement a baseline attack method (named w/o DA). This method only uses the preliminary adversarial patch module

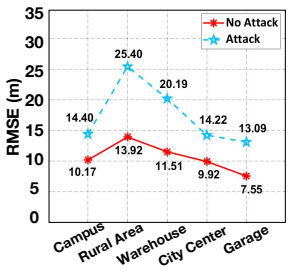


Figure 8: vSLAM errors of the AoR attack in different scenarios.

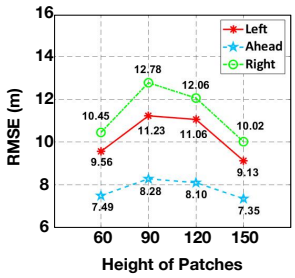

Figure 11: Impact of height and direction of patches.

Table 1: The vSLAM errors introduced by the AoR attack with various environmental conditions.

	Lighting condition			Weather			Moving objects		
	low	moderate	bright	sunny	light rain	heavy rain	< 5	5 - 10	> 10
ORB-SLAM2	9.25 / 14.31	3.22 / X	3.06 / 12.20	**2.59 / 10.27**	**14.10 / 19.82**	X / X	5.70 / 17.36	9.24 / 16.33	10.74 / 12.05
DynaSLAM	**8.16 / 15.33**	4.48 / 16.30	4.50 / 15.59	3.63 / 11.50	14.11 / X	X / X	3.14 / 15.20	**6.29 / 13.85**	**7.28 / 10.00**
ORB-SLAM3	9.34 / 15.66	**3.92 / 14.40**	**3.45 / 14.75**	2.59 / 9.40	10.82 / 14.20	9.10 / X	**3.26 / 16.06**	10.04 / 14.22	13.20 / 14.05
pl-SVO	10.63 / 15.80	13.92 / 20.10	15.49 / X	9.32 / 16.28	14.01 / X	X / X	12.84 / 19.66	12.65 / 18.53	20.16 / 23.99
SVO Pro	18.89 / 21.51	10.55 / 20.23	10.23 / 20.56	14.20 / 19.57	20.90 / 27.35	22.19 / X	8.22 / 15.29	9.10 / 13.96	18.73 / X

* For each A/B, A is the vSLAM error without the attack and B with the attack. Bold values highlight the largest change (B/A) per column.
* X means the track is lost.

to produce the adversarial patches without considering the real-world attack scenarios. We show the attack results in the rural area, warehouse, and parking garage in Figure 9.

As we can observe from the figure, the baseline attack method can only slightly affect the vSLAM results. This is because environmental factors will affect the VO process in vSLAM systems. As a result, the camera may not select the features on the adversarial pattern. On the other hand, after applying the dynamic adjustment (DA), the performance of the baseline method improved on average by 60%. This improvement is because the DA module adjusts adversarial patches dynamically based on environmental conditions. **In summary,** the dynamic adjustment module can significantly improve the effectiveness of the AoR attack.

5.2.2 Impact of the Patch Numbers and Sizes

In our experiments, we also explore the effects of varying the number and size of adversarial patches. Patch sizes are defined as Small (20×20 inches), Medium (30×30 inches), and Large (40×40 inches). We varied the number of patches placed by the roadside from 1 to 4, positioning all patches on the same side of the road.

In Figure 10, we show the vSLAM errors of ORB-SLAM3 under each setting. Notably, medium and large patches yield high errors, while the errors are significantly lower with small patches. This is because the smaller patches occupy a smaller area in the victim's camera and limited pixels in the camera can be used to render the adversarial patches. As a result, fewer features are selected from the patches, reducing the attack's effectiveness. Therefore, attackers should ensure that patch sizes are large enough for real-world effectiveness. We believe that this is a reasonable requirement since a standard advertising billboard is much larger than 20×20 inches [47]. We also notice that the vSLAM errors increase rapidly as the number of adversarial patches increases in most cases. This is because more patches will introduce severe mismatches across consecutive frames. In this case, the vehicle keeps capturing the poisoned frames, which increases the vSLAM errors. Interestingly, even if small patches collectively cover the same area as medium patches, their impact is less significant. This reduced effectiveness arises because features on a larger patch are more likely to be selected and mismatched when they are concentrated together.

5.2.3 Impact of the Patch Directions and Heights

In Figure 11, we study the effectiveness of both the patch direction and height. Throughout our experiments, adversarial patches of varying heights were positioned in distinct directions relative to the target vehicle: on its left, on its right, and directly in front of it. As shown in this figure, we can observe that the optimal heights of the adversarial patch are from 90*cm* to 150*cm*. When the height is reduced to 60*cm* or increased to 150*cm*, the camera cannot fully capture the adversarial patch. As a result, the vSLAM errors introduced by the AoR are reduced. Counterintuitively, we also notice that the AoR attack introduces higher vSLAM errors when the adversarial patches are not deployed in front of the target vehicle. This is because the features along the roadside change faster than the features in the camera's center of view as the vehicle moves on the road. This finding demonstrates

(a) Corridor (b) Office (c) Library (d) Classroom (e) Shopping Mall

Figure 12: AoR attack on the robotic platform in indoor scenarios.

the effectiveness of the AoR attack. **In summary**, the attacker can easily achieve high AoR attack effectiveness by simply deploying the adversarial patches by the roadside.

5.2.4 Robustness to Environmental Conditions

To evaluate the practicality of the AoR attack, we conduct experiments under various environmental conditions, including different lighting and weather conditions, as well as the presence of moving objects. To assess the impact under various lighting conditions, we performed the attack in low (<1000 lux), moderate (1000 to 10,000 lux), and bright light (>10,000 lux) environments. Regarding weather conditions, we evaluated the effects during sunny, light rain, and heavy rain scenarios. Additionally, we examined the influence of moving objects on the AoR attack by considering three different levels of moving object density: fewer than 5, between 5 and 10, and more than 10. In Table 1 of the evaluation results, we observe that extreme conditions such as heavy rain and a large number of moving objects may degrade the performance of the attack due to reduced visibility of the patch. However, vSLAM errors still increase significantly compared to scenarios with no attack, demonstrating the AoR attack's robustness across various environmental conditions.

5.3 AoR Attack on the Robotic Platform

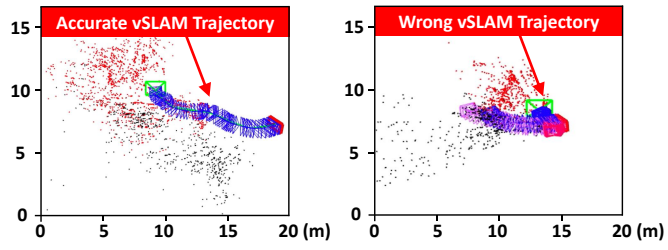
To extensively study the effectiveness of the AoR attack, we also evaluate a robotic platform in indoor scenarios.

5.3.1 Experiment Setup

vSLAM Platform and vSLAM Selection. To evaluate the effectiveness of the AoR Attack on a robotic platform, we built a robotic navigation platform based on the ROSMASTER R2 [48] for indoor scenarios. We implemented vSLAM algorithms including ORB-SLAM2 [22], ORB-SLAM3 [27], DynaSLAM [26], pl-SVO [24], and SVO Pro [25] on the platform for evaluation since they are widely used in robot navigation [20, 21].

Attack Execution. To perform the AoR attack on the robotic platform, the attacker first used the same type of robotic platform as the victim to collect frames within the attack scenario under the grey-box assumption. Following this, the attacker created adversarial patches and deployed them in the environment. The victim robot then navigated through this setup to assess the effectiveness of the attack. We conducted experiments in various real-world scenarios, including a corridor, office, warehouse, library, classroom, and shopping mall, as depicted in Figure 12 to fully assess the AoR attack. Each scenario varies from $5m$ to $20m$. To quantitatively assess the attack, we utilized an Ultra-Wideband (UWB) module to provide accurate indoor positioning as ground truth to measure the Root Mean Square Error (RMSE).

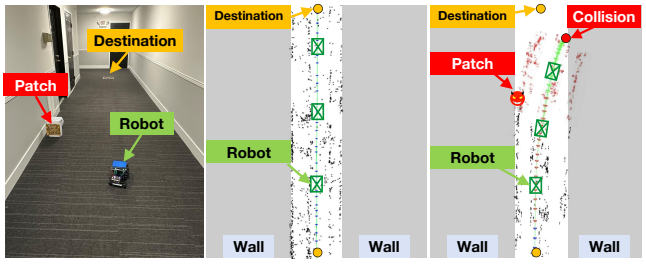
Table 2: The vSLAM errors when the robotic platform is under the AoR attack in indoor scenarios.



Scenarios	Corridor	Office	Library	Classroom	Mall
ORB-SLAM2	2.15 / X	**1.42 / 3.78**	2.93 / 7.20	1.90 / 4.33	2.79 / 5.20
DynaSLAM	1.98 / 5.77	1.60 / 4.08	**2.34 / 6.27**	1.87 / X	**2.53 / 5.59**
ORB-SLAM3	**1.52 / 7.02**	1.37 / 3.26	2.59 / 5.81	**1.46 / 5.96**	2.19 / 4.77
pl-SVO	5.50 / X	5.31 / 9.88	7.29 / 11.30	4.84 / 7.50	6.92 / 12.18
SVO Pro	5.39 / 9.16	4.07 / 7.59	7. 58 / 10.05	4.29 / 6. 55	7.03 / 14.11

* For each A/B, A is the vSLAM error without the attack and B with the attack. Bold values highlight the largest change (B/A) per column.
* X means the track is lost under the AoR attack.

Safety-Critical Scenario. For safety reasons, we demonstrate the specific safety-critical consequences of the AoR attack using a robotic platform in a $2m$ wide corridor, as depicted in Figure 14. Specifically, the attacker placed a 12×12 inch adversarial patch on a trash bin to attack the robot. We set a destination for the robotic platform $8.5m$ away from the starting location. The victim utilized the ORB-SLAM3 algorithm for indoor localization and mapping and navigated based on the vSLAM results to see the impact of the attack. To establish a baseline for the robot's performance without attack, we also use the robotic platform for navigation in the same environment without attack.



5.3.2 The AoR Attack Results

Table 2 shows the significant increase in vSLAM errors when the robotic platform is under the AoR attack in indoor scenarios. This is because the adversarial patch can continuously introduce mismatches and errors to the vSLAM systems. For example, in the corridor scenario, the RMSE of ORB-SLAM3 reaches 7.02 under the AoR attack, which is more than **4.62 times** higher than that of the no-attack scenario (1.52). Figure 13 illustrates the corresponding localization and mapping results in this scenario. As we can see from this figure, the vSLAM system accurately locates and maps the environment without attack. When the vSLAM system is under attack, it suffers from high localization errors. As a result, the vSLAM system believes that it is at the same location in the corridor due to the mismatches introduced by the adversarial patches.

(a) vSLAM results without attack. (b) vSLAM results under attack.

Figure 13: The AoR attack on the robotic platform in the corridor scenario. The green box is the current frame, and the blue boxes are past frames. Other colored boxes indicate frames relocalized after losing track.

(a) Attack scenario (b) Trajectory (no attack) (c) Trajectory (attack)

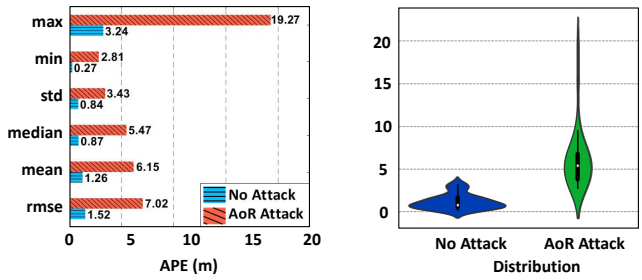


Figure 14: The safety-critical scenario experiments.

Figure 15 shows the corresponding translation errors when ORB-SLAM3 is under the AoR attack. This error defines the distances between the generated vSLAM trajectory and the ground truth driving trajectory. As seen in Figure 15 (a), the maximum translation error is as high as 19.27m. Given that the width of the corridor is less than 3m, the vSLAM system believes that the robot is actually outside the building. Figure 15 (b) illustrates the variation in translation errors, showing that while the Absolute Pose Error (APE) normally stays below 5m without an attack, it can exceed 20m in severe cases under attack.

Figure 14 illustrates the severe safety consequences of an AoR attack on a victim robot. In Figure 14 (b), the robot navigates safely to its destination in a straight line. However, as shown in Figure 14 (c), the robot believes the corridor ahead is curved after it encounters the adversarial patch on its road to the destination. Consequently, it started to turn to the wall according to this altered vSLAM map instead of moving straight. The vSLAM trajectory (green line) intersects with the corridor wall (grey), indicating a collision. In real-world applications, a delivery robot relying on such a distorted vSLAM map could be diverted to incorrect destinations and become trapped. **In summary,** the AoR attack can effectively attack vSLAM systems on robotic platforms in various indoor scenarios and introduce serious security risks.

5.4 AoR Attack on Public Datasets

In this section, we conduct experiments to study the performance of the AoR attack using well-known public datasets,

(a) Translation errors. (b) Distribution of translation errors.

Figure 15: Translation errors introduced by AoR attack in the corridor scenario.

including KITTI [33], RobotCar [49], 4Seasons [50], and Complex Urban [51].

5.4.1 Experiment Setup

The target public datasets, collected in real-world scenarios, feature diverse environmental conditions including lighting, weather, and moving objects, which reflect the complexity and reality of actual driving environments. The attacker carefully selected frames containing the target scenario to generate optimal adversarial patches. These patches were then embedded into the original benign frames at suitable locations, such as the roadside, to evaluate the effectiveness of the real-world attack. Specifically, we also performed an affine transformation on the patches during embedding to ensure the results accurately reflect genuine driving environments. The output size of each patch is set to 80×80 pixels. The average length of the selected frames ranges from 20 to 40, depending on the attack scenarios.

5.4.2 The AoR Attack Results

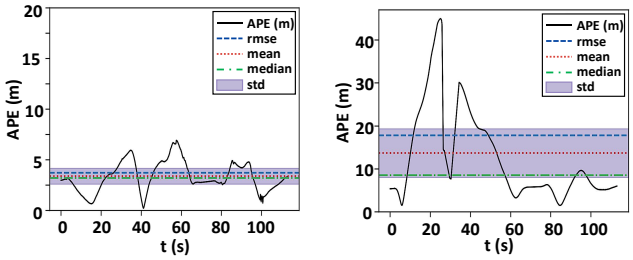

Table 3 shows the vSLAM errors introduced by the AoR Attack in city, rural areas, and parking garage scenarios. As we can see, the errors of all five vSLAM systems become much larger under the AoR attack. Moreover, all these vSLAM systems suffer track loss during the experiments, which means the autonomous vehicle or the robot cannot conduct localization and mapping at all in these scenarios. Figure 16 shows that the absolute pose error (APE) for DynaSLAM on the KITTI dataset Seq 07 is nearly **10 times** higher than that of the no-attack scenario. This experiment result demonstrates the effectiveness of the AoR attack in city scenarios.

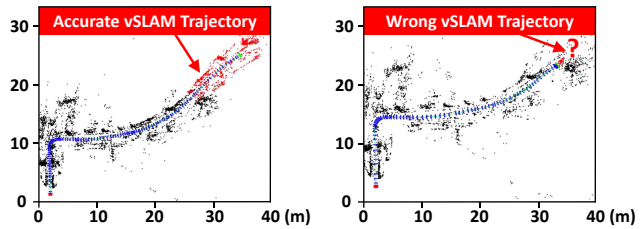
We also notice the surprisingly high vSLAM errors in rural areas and parking garages. For example, the vSLAM error for ORB-SLAM2 is 26.03m (4Seasons-Countryside), which is around **5 times** higher than that of the no-attack scenario. Figure 17 shows the corresponding calculated vSLAM trajectory. As we can see from Figure 17 (b), the vSLAM system believes that the vehicle stops at a distance of 35m. This is because the rural area has sparse textures and fewer good features. Therefore, the vSLAM system has to select the features from the adversarial patch, which introduces significant

Table 3: The vSLAM errors introduced by the AoR attack on public datasets.

Scenarios	City		Rural Area		Parking Garage
Datasets	**KITTI**	**RobotCar**	**4Seasons**	**Complex Urban**	**4Seasons**
Sequences	Seq 07	2014-05-19	Countryside	Urban28	parking_garage_1_train
ORB-SLAM2	3.31 / 20.39	12.77 / X	**5.27 / 26.03**	10.73 / 34.94	3.78 / X
DynaSLAM	**3.25 / 23.20**	**9.04 / 19.73**	5.63 / 17.29	9.28 / 28.35	**1.58 / 9.20**
ORB-SLAM3	3.37 / 14.50	8.11 / 15.24	3.22 / 11.59	**9.30 / 31.05**	1.60 / 8.37
pl-SVO	17.62 / 23.21	15.60 / 22.29	10.17 / X	16.47 / 29.30	14.75 / X
SVO Pro	14.77 / 21.82	18.73 / X	12.49 / X	15.90 / 25.15	10.03 / X



* For each A/B, A is the vSLAM error without the attack and B with the attack. Bold values highlight the largest change (B/A) per column.
* X means the track is lost under the AoR attack.

SLAM errors. **In summary,** the AoR attack can effectively attack the vSLAM systems in various complex scenarios.

6 Defending Against the AoR Attack

Due to the severe security issues introduced by the AoR attack, we introduce a novel defense module to secure the vSLAM systems. This section first discusses the potential challenges in designing the defense module. Then, we introduce the detailed design.

6.1 Challenges in Defense

Since the vSLAM systems operate in dynamic scenarios, traditional defense strategies that are designed for static situations, such as model and input analysis approaches [52, 53], cannot work effectively to secure the vSLAM systems. Moreover, since the AoR attack uses commonly seen objects to attack the vSLAM systems, it is very difficult for common anomaly detection [54, 55] or contextual analysis [56] approaches to detect adversarial patches. In addition, although recent advances in deep learning have shown inspiring results in most vision-based tasks, the substantial computational resources and extensive training time required make them impractical for vSLAM systems. Furthermore, since the backend optimization methods in vSLAM systems barely consider the reliability of the features extracted during the VO process, the optimization direction can be easily misled by the AoR attack. Therefore, a suitable defense module should satisfy the following requirements: **(i)** high attack detection effectiveness, **(ii)** low computational overhead, and **(iii)** improving the robustness of the backend in vSLAM systems.

6.2 Design of the Defense Module

As shown in Figure 18, to defend against the AoR attack, we introduce a lightweight defense module that can effectively detect the adversarial features and improve the robustness of the vSLAM systems. This module mainly consists of three key components: **Texture Extraction**, **Anomaly Detection**, and **Cross-Frame Optimization**.

The texture extraction aims to extract the texture of captured frames using the Weber Local Descriptor (WLD) [57]. By doing this, we can make the texture of the adversarial patch noticeable in the whole frame. Then, to detect abnormal textures, the anomaly detection component uses a variational auto-encoder to identify the position of the abnormal texture in a frame sequence. To enhance the robustness of vSLAM systems against potential attacks, we've developed a cross-frame optimization component that utilizes the reliability factors of features across multiple frames. Finally, if the AoR attack is detected, the defense module will send alerts to legitimate users. In the following sections, we will introduce the details of each component in our defense module.

6.2.1 Texture Extraction

Since the adversarial patches generated by the AoR attack are natural and unnoticeable in real-world scenarios, it is hard to detect such patches directly from the captured frame sequence using traditional vision-based detection approaches. To address this challenge, the **key insight** we found is that although adversarial patches on common objects (e.g., billboards and walls) are hard to detect, they show notably denser internal

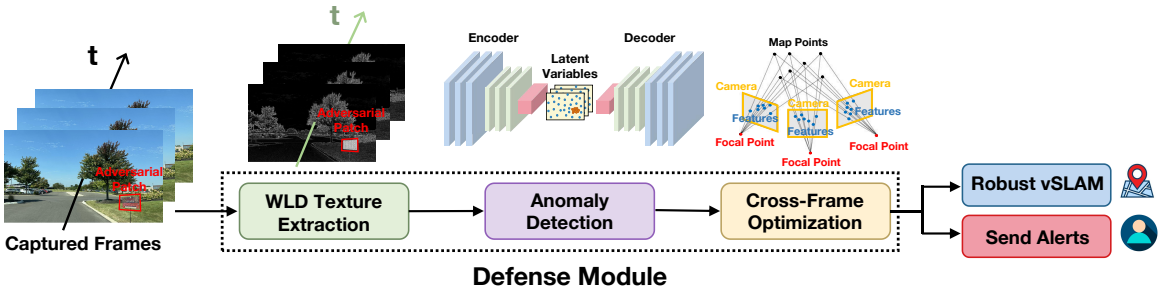

Figure 18: The overall architecture of our defense module.

textures than their surrounding common objects. To exploit this characteristic, we use Weber's Local Descriptor (WLD), which is designed to enhance texture analysis. WLD works by transforming the captured frames into a texture space, highlighting the denser textures of adversarial patches. This transformation is achieved by calculating the relative intensity difference between a pixel and its neighbors in horizontal and vertical directions, which helps to emphasize textural features. The texture distribution can be formulated as:

$$\xi(x_c) = \arctan\left(\sum_{i=0}^{P-1} \frac{x_i - x_c}{x_c}\right) \tag{8}$$

$$\Phi(x_c) = \arctan\left(\frac{D_V}{D_H}\right) \tag{9}$$

Here, x_c represents the intensity of the central pixel, while x_i refers to the intensity of a neighboring pixel, with P indicating the total number of neighbors. The variables D_V and D_H are defined as the vertical and horizontal intensity differences between the central pixel and its neighbors, respectively. To enhance efficiency and reduce complexity, the intensity difference is calculated using a sliding window with adaptive step sizes, focusing on probable regions like roadsides and buildings. This selective approach streamlines the texture extraction process, making it more manageable and effective.

6.2.2 Anomaly Detection

Since the adversarial patch becomes noticeable in texture space compared to its neighboring regions, the question now is: how can the abnormal region in the texture space be detected? To answer this question, we utilize a lightweight variational auto-encoder (VAE) [58] model to identify anomalies. The goal is to enable the model to find the abnormal regions that significantly deviate from the normal distribution. During detection, the VAE encoder first transforms the input texture images into latent variables. Then, based on the differences between the input and the output, the model can predict whether the current scenario contains the adversarial patch. Specifically, the loss function L_{oss} of the VAE model consists of the reconstruction error and a regularization parameter:

$$L_{oss} = \frac{\alpha}{m}\sum_{i=1}^{m} \|x - \hat{x}\|^2 + \frac{\beta}{2} \cdot Reg(\sigma, \mu) \tag{10}$$

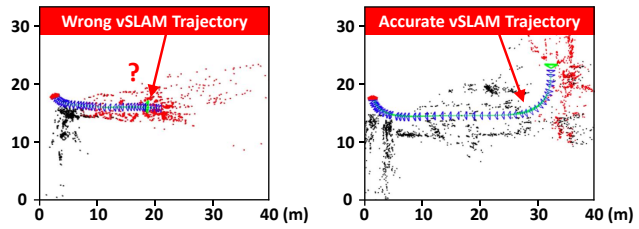
In this equation, x and $\hat{x}$ are the ground truth and the prediction value, respectively. m is the number of frames. The first term is the reconstruction error, while the second term, Reg, is the regularization parameter. α and β are the weight factors for each term. Formally, Reg can be calculated as:

$$Reg(\sigma, \mu) = -\sum_{i=1}^{n} \left(1 + \log\left(\sigma_i^2\right) - \mu_i^2 - \sigma_i^2\right) \tag{11}$$

Here μ_i is the mean of the reconstructed output for feature i, and σ_i is the standard deviation of the reconstructed output.

6.2.3 Robust Optimization

An important reason why vSLAM systems do not work under the AoR attack is that adversarial features introduce huge errors during the pose optimization in the backend. Specifically, the features in the adversarial patches are carefully designed to follow the feature extraction algorithms in the VO process of vSLAM systems. As the camera captures frames when the vehicle or robot moves on the road, the adversarial features are likely to be selected as key points for pose optimization. To improve the robustness of the vSLAM system, we introduce a robust cross-frame error function E' to reduce the effects of adversarial features during optimization in the backend. Formally, we define a reliability factor r_j to measure the reliability of the feature points in each frame and its value is positively correlated with the density of surrounding features. Then, the cross-frame error function E' can be formulated as:



$$E' = \min_{R_i, t_i, X_j} \sum_{i=1}^{N}\sum_{j=1}^{M} \left(\frac{r_j}{\mu}\right)^2 \log\left(1 + \left(\frac{\mu}{r_j}\right)^2 E(x, p)\right) \tag{12}$$

Here μ is the weighted coefficient determined by the defender. N is the set of captured frames and M is the set of map points. $E(x, p)$ is the re-projection error that can be calculated as:

$$E(x, p) = \| x_{ji} - p(X_j, R_i, t_i, K_i)\|^2 \tag{13}$$

Here X_j denotes the jth map point, and x_{ji} represents its position in camera coordinates on the ith frame. The function p projects the map point from world coordinates to camera coordinates. The rotation matrix R and translation vector t define the pose for each frame, while K is the camera's intrinsic matrix, typically available from the manufacturer's website.

In our approach, the weight of feature points with low reliability is reduced during optimization, enhancing the influence of feature points from sparser regions (clean features). This adjustment makes the vSLAM system depend more on clean features, increasing its robustness against the AoR attack.

(a) vSLAM results under the AoR attack. (b) vSLAM results using our defense module.

Figure 19: An example of the effectiveness of our defense module on autonomous vehicle testing platform in the city center scenario.

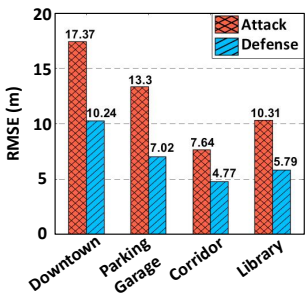


Figure 20: vSLAM errors in real-world scenarios.

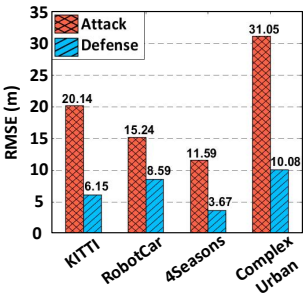

Figure 21: vSLAM errors on public datasets.

6.3 Experiment Setup

To extensively evaluate the effectiveness of our defense module, we conduct experiments in the same real-world scenarios depicted in Figure 7 and on famous public datasets including KITTI [33], RobotCar [49], 4Seasons [50], and Complex Urban [51]. During the experiments, we integrated our defense module into five commonly used vSLAM systems: ORB-SLAM2 [22], ORB-SLAM3 [27], DynaSLAM [26], pl-SVO [24], and SVO Pro [25]. In addition, we also assessed its performance in benign cases to ensure that the module does not degrade system performance. Specifically, we evaluated the precision of attack detection across 100 scenarios, comprising 38 with attacks and 62 without attacks. These scenarios are all real-world driving environments containing various environmental conditions, legitimate billboards, and moving pedestrians. Tables 4 and 5 summarize the defense results in real-world scenarios. The results on public datasets are presented in Appendix A.3.

6.4 Experiment Results

Figure 19 demonstrates the performance of our defense module in a city center scenario. In Figure 19 (a), when the autonomous vehicle makes a left turn, the vSLAM trajectory is missing due to the AoR attack. After applying our defense module, as shown in Figure 19 (b), the vSLAM system accurately conducts localization and mapping.

Figures 20 and 21 show the effectiveness of the defense module by comparing the RMSE on ORB-SLAM3. We can see that our defense module significantly reduces the vSLAM errors when vSLAM systems are under attack. For example, as shown in Figure 21, when we apply our defense module to the Complex Urban dataset, the vSLAM errors are reduced by more than **three times** compared to the attack scenario.

Table 4 demonstrates that our defense module significantly reduces vSLAM errors in real-world scenarios. More importantly, by using our defense module, the vSLAM systems never face the problem of lost tracking, demonstrating our defense module's effectiveness. Table 5 shows the detection results of our defense module in real-world scenarios. Our system correctly raises alarms for all 36 potential threats, resulting in no false alarms. This indicates that our defense module does not impact vSLAM performance when there is no attack, as it only switches to the robust mode when attacks are detected. **In summary**, our defense module can **(i)** effectively detect the AoR attack and reduce the vSLAM errors, **(ii)** enhance the security of the vSLAM system, and **(iii)** enable reliable localization and mapping under the AoR attack.

Table 4: The effectiveness of the defense module in real-world scenarios.

Scenarios	City Center	Parking Garage	Corridor	Library
ORB-SLAM2	X / 5.21	7.23 / 4.24	X / 3.10	5.26 / 3.52
DynaSLAM	**10.95 / 5.31**	7.45 / 4.21	5.77 / 3.95	**6.27 / 2.59**
ORB-SLAM3	17.37 / 10.24	13.30 / 7.02	7.64 / 4.77	10.31 / 5.79
pl-SVO	8.22 / 5.20	4.09 / 3.13	**7.02 / 4.18**	5.81 / 2.56
SVO Pro	X / 12.14	**19.70 / 10.58**	9.16 / 8.60	10.05 / 9.32

* For each C/D, C is the vSLAM error under attack, and D is with our defense module. Bold values highlight the largest change (C/D) per column.
* X means the track is lost under the AoR attack.

Table 5: Robustness of the defense strategy.

	Detection Results	
	Alarm	**No Alarm**
Attack	TP = 36	FN = 2
No Attack	FP = 0	TN = 62

7 Discussion

7.1 Ethics and Safety Considerations

Our research does not target specific commercial products; the BMW X3 is used solely as an example within our vehicle-based vSLAM system testing setup. Furthermore, all safety-critical experiments are conducted in controlled environments, enabling human operators to intervene at any time to prevent harm to users or public systems. For instance, a human driver can immediately take over the vehicle, and we can remotely take control of the wheeled robot, equipped with a remote controller, to mitigate potential risks. We found that the AoR attack could introduce significant errors into vSLAM systems, misleading those who rely on vSLAM maps for navigation. Given the crucial role of vSLAM algorithms in autonomous driving [16–19] and robot navigation [20, 21], their vulnerabilities pose significant threats. We hope our findings will highlight these security issues and enhance the robustness of

vSLAM systems.

7.2 Limitations and Future Work

One limitation of our attack is that position changes caused by the attack may diminish its effectiveness. During the attack, its position changes as the vehicle or robot navigates using the distorted vSLAM map. These changes make the attack-influenced frames somewhat different from those used for patch generation, potentially reducing the attack's effectiveness. However, our design ensures that the adversarial patch remains effective as long as it is visible to the camera, even if the patch's position in the frames shifts slightly. When the position changes are significant, the victim has likely already been diverted from the driving area, indicating a successful attack. In future work, we will explore the impact of such position changes during the attack more deeply and try to incorporate them during patch generation to realize more accurate attacks.

Additionally, our defense strategy could potentially be bypassed by attackers. Attackers might develop new adversarial patches specifically designed to evade the detection techniques currently used by our defense module. For instance, they could use machine learning models to generate patches that more closely mimic legitimate environmental textures. However, our defense strategy can also continually learn from new types of attacks and automatically adjust the defense mechanisms. This adaptive security approach is essential for recognizing and addressing changing threats over time.

8 Related Work

Simultaneous Localization and Mapping (SLAM) plays a pivotal role in enabling robots and autonomous vehicles to understand their current locations and make navigation decisions. Among existing solutions [10–15, 59–62], camera-based solutions (Visual SLAM) have been adopted for many real-world applications [16–21] due to their lightweight nature, cost-effectiveness, and ability to provide richer environmental representations [60].

One of the most widely recognized Visual SLAM(vSLAM) systems is ORB-SLAM2 [22], which provides a robust and efficient method with various camera setups. To enhance the ability to handle dynamic elements, DynaSLAM [26] effectively detects moving objects and filters them out to build a reliable map. Building upon its predecessors, the ORB-SLAM3 [27] system utilizes a multi-map data association technique to achieve highly accurate and robust real-time localization and mapping. To integrate the benefits of feature-based and direct method-based vSLAM systems, SVO [23] introduced a novel VO method enhancing vSLAM performance. Building on this, pl-SVO [24] utilizes point and line features for a more robust vSLAM system. SVO Pro [25] upgrades SVO by incorporating a sliding window backend and loop closure technique, further enhancing mapping accuracy.

However, existing works mainly focus on improving the performance of the vSLAM system, while little work has focused on the vulnerability of the vSLAM systems. Several studies [28, 29] attack certain components of the vSLAM system using highly noticeable images for human eyes. In addition, the ICSL attack [30] introduces an IR light-based attack approach to attack the SLAM system. However, their work requires customized hardware and can only attack ORB-SLAM2 in an indoor parking lot at night. Importantly, these studies often do not investigate the underlying reasons and conditions for their success, leading to uncertainty about the effectiveness of these attacks. Different from their works, in this paper, we are the first to conduct an in-depth analysis of the unique vulnerabilities within vSLAM systems and to strategically exploit these vulnerabilities to implement targeted end-to-end attacks. Specifically, we propose an AoR attack, which can effectively attack multiple commonly used vSLAM systems in various real-world scenarios. Furthermore, we also designed a defense module to protect vSLAM systems from the harmful impact of the AoR attack.

Attacks on Image Recognition Systems. There are extensive works that explored the security issues of camera-based systems on autonomous vehicles [63–67]. Using adversarial patches can harm the image recognition system [68–70] on various tasks. For example, GhostImage [68] exploits lens flare effects and auto-exposure control to project adversarial patterns into camera-based image classification systems and causes misclassification. TPatch [69] introduces a physical adversarial patch that uses specific signals to execute hiding, creating, and altering attacks on the vision-based perception module of a targeted autonomous vehicle. In contrast to previous work, our goal is to disrupt the crucial processes of real-time localization and mapping in vSLAM rather than simply causing image misclassification. Additionally, our attack is effective across sequential frames within dynamic environments and leads to serious safety issues. Thus, these previous works are not applicable to attack vSLAM.

9 Conclusion

In this paper, we propose the first work that in-depth investigates security issues in vSLAM systems. Specifically, we introduce the AoR attack, which can effectively attack commonly used vSLAM systems in autonomous vehicles and robots. Our attack has the following advantages: **(i)** it can easily be implemented in various real-world scenarios; **(ii)** no need for expensive hardware, and **(iii)** it can introduce significant errors to vSLAM systems without being detected by legitimate users. Moreover, given the severe harmful impacts of the attack, we also present a lightweight defense module to counter the AoR attack. We believe that the attack method and defense strategy outlined in this paper will contribute to the development of more secure vSLAM systems.

A Appendix

A.1 Effect of Random Adversarial Features

Since existing vSLAM systems leverage various optimization techniques (e.g., Least-Square algorithm [31], RANSAC [32], etc.) to reduce potential errors introduced by the features in a frame, simply adding random features in the environment won't effectively affect the performance of the system. To show the impact of random features, we tested ORB-SLAM2

(a) Extracted features

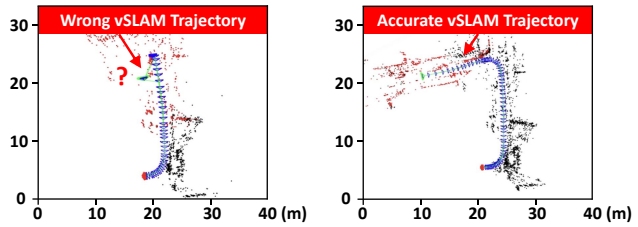
(b) Feature matching results

Figure 22: The effect of random adversarial features.

Table 6: The vSLAM errors when the vehicle platform is under the AoR attack.

Scenarios	Campus	Rural Area	Warehouse	City Center	Garage
ORB-SLAM2	13.54 / 18.04	12.14 / 20.30	14.95 / X	8.69 / 18.93	**7.20 / 16.15**
DynaSLAM	**11.85 / 20.36**	13.03 / X	14.35 / 20.05	**8.34 / 20.17**	8.10 / 16.33
ORB-SLAM3	10.17 / 14.40	13.92 / 25.40	11.51 / 20.19	9.92 / 14.22	7.55 / 13.09
pl-SVO	16.39 / 22.25	15.36 / 22.92	**12.96 / 23.37**	15.39 / X	13.32 / 21.51
SVO Pro	15.28 / 20.30	**12.03 / 25.64**	16.84 / 27.97	15.60 / 22.18	10.33 / 19.70

* For each A/B, A is the vSLAM error without the attack and B with the attack. Bold values highlight the largest change (B/A) per column.
* X means the track is lost under the AoR attack.



in real-world driving environments by altering grayscale values of randomly selected pixels in consecutive frames. However, as shown in Figure 22 (a), these injected features were rarely chosen as key features, and mapping results remained unaffected (Figure 22 (b)).

A.2 AoR Attack Results on Vehicle Platform

Table 6 shows the impact of the AoR attack on vSLAM systems in various environments. The RMSE (Root Mean Square Error) consistently increases under attack. For example, in the city center, DynaSLAM's RMSE rises from 8.34m to 20.17m, indicating significant navigational disruptions due to the AoR attack. The provided data in Table 6 not only quantifies the severity of AoR attacks across different scenarios but can also serve as a benchmark for evaluating the robustness of various vSLAM systems under adversarial conditions.

A.3 Defense Effectiveness on Public Datasets

Table 7 shows that our defense module significantly reduces vSLAM errors across all four datasets. Figure 23 shows an example of using our defense module on 4Seasons dataset. During an AoR attack, as the victim vehicle makes a left turn (Figure 23 (a)), the vSLAM map inaccurately shows it still facing forward with a slight position change, potentially leading to accidents. After implementing our defense, the vSLAM map is corrected and reliably accurate for navigation, which confirms the effectiveness of our defense module.

(a) vSLAM results under the AoR attack.

(b) vSLAM results using our defense module.

Kenneth G. Paterson
ETH Zurich

Abstract

We analyse the cryptographic protocols underlying Delta Chat, a decentralised messaging application which uses e-mail infrastructure for message delivery. It provides end-to-end encryption by implementing the Autocrypt standard and the SecureJoin protocols, both making use of the OpenPGP standard. Delta Chat's adoption by categories of high-risk users such as journalists and activists, but also more generally users in regions affected by Internet censorship, makes it a target for powerful adversaries. Yet, the security of its protocols has not been studied to date. We describe five new attacks on Delta Chat in its own threat model, exploiting cross-protocol interactions between its implementation of SecureJoin and Autocrypt, as well as bugs in rPGP, its OpenPGP library. The findings have been disclosed to the Delta Chat team, who implemented fixes.

1 Introduction

Delta Chat[1] is an open-source decentralised messaging application based on e-mail infrastructure. It can be seen as a custom-built e-mail client: users log into Delta Chat with their existing e-mail accounts, and messages in Delta Chat are specially formatted e-mails. It does not have a central server, since users can choose different e-mail providers or even host their own e-mail servers. It provides end-to-end encryption by implementing the Autocrypt standard [53] and the SecureJoin protocols [23], both based on a subset of the OpenPGP standard [34]. It functions in two modes, with different security: *verified chats* guarantee end-to-end encryption, while *unverified chats* are not intended to be secure against active network attackers, i.e. they are vulnerable to machine-in-the-middle (MITM) attacks, and may not even be encrypted.

While Delta Chat does not explicitly advertise itself as suitable for high-risk users, these users likely make up a noticeable part of Delta Chat's user base. For example, Delta Chat's website lists feedback from people in regions with strict Internet governance [22]. Delta Chat works with activist groupings and researchers to improve the usability and security of the application for high-risk users, and has produced several need-finding reports by engaging with journalists and activists in Ukraine [32, 33] and elsewhere [31].

Delta Chat has been supported or recommended by several organisations in the human rights context. Among other funding sources, Delta Chat has received support from the U.S. Bureau of Democracy, Human Rights and Labor to make Delta Chat "more resilient and secure in places often affected by internet censorship and shutdowns" [20]. Front Line Defenders, a human rights organisation, recommended Delta Chat for secure communication during COVID-19 [27]; eQualitie, a digital security organisation, recommends Delta Chat to Ukrainian users in the ongoing Russia-Ukraine war [49].

Despite being perceived as secure and engaging with high-risk users, the security of Delta Chat is still largely unclear, especially for its cryptographic components and protocol implementations. Further, while its position as both an instant messenger and an e-mail client ensures easier adoption, it also brings more complexity to its protocols, thereby enlarging its attack surface. The Autocrypt and SecureJoin protocols have received considerable input from academia [45], but have never been formally analysed. This is especially concerning since these protocols use OpenPGP in non-standard ways, and the Delta Chat team has made substantial changes to the SecureJoin protocols. Further, the OpenPGP library used by Delta Chat, rPGP, has received relatively little attention compared to other OpenPGP libraries.

Recent works have uncovered serious security flaws in several messaging applications deploying custom cryptographic protocols such as Bridgefy [3, 6], Matrix [4] and Threema [47]. In the last two, flaws were found after the application in question was "vetted" via security audits, showing that audits alone cannot establish a protocol as secure and trustworthy. Indeed, Delta Chat too has undergone two audits that covered its use of cryptography [51, 52]; as we will see, this was not sufficient to prevent attacks.

[1] https://delta.chat/

1.1 Contributions

We have analysed the core cryptographic protocols used by Delta Chat, discovering five new attacks:

1. **Gossip key injection.** An attacker can send an e-mail to the target such that the target will replace the public key of a given contact of the target with an attacker-controlled key and mark it as verified.

2. **Group member removal.** An attacker can remove arbitrary members from a verified group as if they were removed by other members by adding a carefully constructed plaintext e-mail header to a normal group message.

3. **Synchronisation forgery.** An attacker capable of spoofing self-addressed e-mails for the target can trivially forge synchronisation messages. This allows the attacker to verify themselves to the target or change chat statuses.

4. **InsecureJoin observer.** An attacker can exploit the fact that clients observe self-sent SecureJoin protocol messages from other devices to trick the target into marking an attacker-controlled key as verified.

5. **Autocrypt Setup forgery.** An attacker can forge an Autocrypt Setup Message, which is used to transfer a user's secret key between different e-mail clients. This enables the attacker to make the target use a key known by the attacker.

Overall, our analysis demonstrates that Delta Chat users were vulnerable to: a MITM attacker reading and modifying their messages even in verified chats, being impersonated to other Delta Chat users (or vice versa), their chat statuses and setup being modified, being deceived to use an attacker-controlled OpenPGP key and consequently losing most security guarantees, and denial-of-service attacks.

1.2 Related Work

No prior works to date provide an in-depth security analysis of Delta Chat or its specialised protocols. ClaimChain [41], a part of the CounterMITM [46] specification which served as the basis for SecureJoin, is a solution for privacy-preserving key distribution for Autocrypt, but it was never implemented in Delta Chat. A recent work [28] proposed to extend the OpenPGP library used by Delta Chat with post-quantum primitives, but did not include a security analysis.

OpenPGP itself has a long history in the literature as evidenced by EFAIL [48], attacks on signatures [44] and ElGamal implementations [26], format oracle attacks [39] and key overwriting attacks [17]. It has also been criticised for its lack of usability [50, 56] and wider standardisation and deployment issues [35]. Yet, efforts are underway for updating the cryptographic building blocks of OpenPGP [57].

Delta Chat has undergone four independent security audits [20], and is planning a fifth audit in 2024 [37]. Two of the audits covered the cryptographic components of Delta Chat, including one in 2019 on its OpenPGP and RSA libraries [51], and another in 2020 on its core Rust libraries [52], both conducted by Include Security.

Our work fits within the larger area of cryptographic study of secure messaging protocols. A number of works show attacks on messaging apps [3, 4, 6, 7, 47], while other works provide security proofs, largely focusing on Signal-based protocols [9, 15, 24], though attacks may still be possible [25]. From a wider perspective, analysis of TLS 1.2 has provided both security proofs [40, 43] and practical attacks [1, 8, 13].

In Signal, verification of user keys is more invisible than in Delta Chat, relegated to an optional feature of verifying "safety numbers". Recent works have focused on both its usability aspects [54] and enhancing its security guarantees [29, 30]. For group communication, Messaging Layer Security (MLS) [14] could provide an alternative, provably secure design [10, 11, 18]; however, implementing it in a decentralised fashion remains an open problem [12].

Notably, Delta Chat's need-finding reports [31–33] uncovered many of the information security practices of higher-risk users that were later replicated in a different context [2].

1.3 Methodology

We conducted a security analysis on the cryptography used in Delta Chat, covering Delta Chat's cryptographic components as well as Delta Chat's implementation of the Autocrypt and SecureJoin protocols. We manually analysed Delta Chat's core Rust implementation[2] as well as the relevant parts of rPGP,[3] Delta Chat's OpenPGP library: we analysed version 1.132.0 of the Delta Chat core library,[4] released on 6 December 2023, and version 0.10.2 of the rPGP library,[5] released on 24 July 2023. We studied the specifications of OpenPGP [34], Autocrypt [53], and SecureJoin [23] and compared them with their implementations in Delta Chat and rPGP.

We implemented our attacks using the Python bindings for the Delta Chat core library.[6] We instantiated eavesdroppers and network attackers as malicious SMTP proxies, and we used a local testing e-mail server for attack simulation. We verified our proof-of-concept attacks on Delta Chat core versions 1.132.0 and 1.133.2[7] and Delta Chat Desktop 1.42.2.

Since Delta Chat and its dependencies are open-source, we did not perform any reverse engineering for our analysis. Our analysis and tests did not involve any real Delta Chat users or target the Delta Chat infrastructure.

1.4 Responsible Disclosure

We disclosed our findings to the Delta Chat development team on 2 February 2024, suggesting a 90-day disclosure period. They acknowledged receipt and agreed to a coordinated disclosure on 7 February 2024. The team implemented fixes for all of the main attacks as well as for a number of additional issues identified during our analysis. Some of the fixes were implemented in rPGP. The fixes were released to end users as part of Delta Chat application versions 1.44 on 12-16 March 2024, with a public disclosure describing the issues on 25 March 2024 in order to allow time for users to update [21].

1.5 Overview of the Paper

We describe Delta Chat's threat model in Section 2 and its architecture in Section 3. We describe our attacks in Section 4 and discuss the implications of our findings in Section 5. For extended background and other details we may refer the reader to the full version of the paper.[8]

2 Threat Model

Delta Chat provides different levels of security for different types of chats. *Verified chats* provide guaranteed end-to-end encryption with the SecureJoin protocols, protecting against network attackers that can actively modify messages, such as malicious e-mail servers. *Unverified chats* are opportunistically end-to-end encrypted via Autocrypt, protected only against passive eavesdropping attackers. Hence, for unverified chats, MITM attacks are outside of the threat model [37]; it is also possible to use them to send unencrypted messages.

Delta Chat does not offer advanced properties such as forward secrecy and post-compromise security, and verified chats do not aim to protect against insider attacks. Our threat model follows Delta Chat's security claims and assumptions, thus only capturing a subset of the attackers typically considered for other end-to-end encrypted messaging applications.

Capabilities. We consider attackers with one or more of the following capabilities, ordered roughly by their strength. Note that different capabilities may overlap with each other.

Sending e-mails. The attacker knows the target's e-mail address and is able to send e-mails to the target without being flagged by the spam detector or blocked by the target. In Delta Chat, it is possible to receive e-mails from non-contacts, in which case the e-mails appear as "message requests" [20].

Knowledge of public keys. The attacker knows the target's public key. This capability is trivial for eavesdropping attackers since they can observe the Autocrypt headers attached to all of the target's outgoing e-mails. The attacker may also learn the target's public key by tricking the target into sending an e-mail to an attacker-controlled e-mail address, or through the Autocrypt key gossip mechanism (Section 3.1.3).

Eavesdropping. The attacker is able to observe messages on the network, including the target's incoming and outgoing e-mails; this is assumed in the Autocrypt standard [53].

E-mail spoofing. The attacker is able to create and send e-mails to the target with the `From` header arbitrarily chosen by the attacker, e.g. through an insecure SMTP server [42]. A special case is spoofing an e-mail as if it were sent from the target to themselves, where both the `From` and `To` headers represent the target's e-mail address.

Control of network messages. The attacker can read, create, modify, and delete messages. The SecureJoin protocols [23, Section 1.1] as well as Delta Chat [20] consider such a network attacker in their threat model.

Limiting assumptions. Attackers targeting unverified chats are assumed to not spoof e-mails or modify network messages.

We assume that users can share their QR invite codes via a secure out-of-band channel that cannot be observed or modified by the attacker [23, Section 1.1].

All verified contacts of the target are honest, and no infiltrators colluding with the attacker are present in the verified groups where the target is a member [23, Section 2.2.3]. This assumption does not exclude the attacker from communicating with the target through unverified chats, or establishing themselves as by exploiting vulnerabilities in Delta Chat.

Goals. The Autocrypt standard does not specify the attacker's goals, but it can be inferred that Autocrypt intends to protect the content of encrypted messages. The SecureJoin protocols specify the attacker's goals as "i) read the content of messages, and to ii) impersonate peer devices" [23, Section 1.1]. Finally, Delta Chat states that messages in verified chats "can not be read or altered by compromised e-mail servers or Internet providers" [20]. Thus, the attacker's goal is to break the confidentiality or integrity of encrypted messages, break authenticity by forging messages in verified chats, and break verification guarantees in Delta Chat. The latter includes the attacker getting themselves or some honest peer to be verified by the target under a key controlled by the attacker, and changing the setup of verified chats.[9]

We do not consider removing, duplicating, or reordering messages as among the goals of the attacker, even though they are trivial for network attackers and can become real threats.

3 Delta Chat

In this section, we introduce Autocrypt (Section 3.1) as well as the SecureJoin protocols (Section 3.2), which together form

[8] Available at https://eprint.iacr.org/2024/918.

[9] Having the target verify a key controlled by the attacker allows the attacker to perform a "Bob in the middle" attack [23, Section 2.2.3] to the target as a malicious insider and break all previous security properties. Changing the verified chat setup qualifies as breaking integrity or authenticity.

the cryptographic core of Delta Chat. Delta Chat relies on a subset of the OpenPGP standard for end-to-end encryption that Delta Chat claims to be secure [20], implemented in the rPGP library. We summarise the relevant parts of OpenPGP in Appendix A of the full version of the paper.

User's perspective. Upon installation, Delta Chat prompts the user to log into their e-mail account or import an existing Delta Chat account from another device. The user can add a contact by scanning a QR code of another user, inputting an e-mail address or being part of the same group chat. When the user sends an encrypted message, it is shown with a small padlock. If the encryption material for a contact is considered *verified*, chats with that contact are shown with a green checkmark. Verification needs little effort from the user: a contact is verified when added using their invite code or from a verified chat, and a chat is verified if all members are verified.

Public keys. Delta Chat associates each contact or *peer* with several OpenPGP keys. In the context of Autocrypt, these will be referred to as the peer's *Autocrypt (public) key* and the peer's *gossip key*. In the context of SecureJoin, we will also define *verified keys*. The functions of these keys will be explained in later subsections.

AEAP. Automatic E-mail Address Porting (AEAP) [36] allows a user to switch to a new e-mail in Delta Chat and optionally set up forwarding from their old e-mail. When the user sends a message to an existing verified contact from the new address, the contact automatically changes the address for the user with minimal interruption to their chats.

3.1 Autocrypt

Autocrypt [53] is a set of guidelines for e-mail clients to provide low-effort end-to-end e-mail encryption to users by automating key management. The current version, Autocrypt Level 1 (release 1.1.0), provides opportunistic encryption with OpenPGP. It is based on the trust on first use (TOFU) principle and does not support key verification, only aiming to defend against passive data collection attacks. In Autocrypt, an "encrypted" e-mail is always signed and encrypted.

Autocrypt e-mail clients attach their public keys in the `Autocrypt` e-mail header. They may also include `Autocrypt-Gossip` MIME headers in e-mail messages to distribute the public keys of their peers. Autocrypt e-mail clients maintain states for communication peers in a table based on the Autocrypt-related headers in incoming e-mails, and use this to check whether encryption is possible or recommended for a particular e-mail message.

Delta Chat implements all functionalities in the Autocrypt standard. Other e-mail clients have, if any, only limited support for `Autocrypt` headers. Where relevant, we describe Delta Chat's additions to the standard Autocrypt features.

3.1.1 OpenPGP Keys

We cover a subset of OpenPGP keys that have the same structure as the OpenPGP transferable public key in the Autocrypt standard, which we call Autocrypt-compliant. An Autocrypt-compliant OpenPGP key consists of five parts: (i) a primary key for signing, (ii) a User ID, (iii) a self-signature that certifies the User ID and the primary key, (iv) an encryption subkey, and (v) a signature that binds the subkey using the primary key [53, Section 3.1.1]. While Delta Chat only generates Autocrypt-compliant OpenPGP keys, it actually supports the usage of most valid OpenPGP keys.

The OpenPGP key fingerprint is a 20-byte SHA-1 digest derived from the the public part of the primary key. Other parts of the OpenPGP key do not contribute to the fingerprint.

3.1.2 Autocrypt Header

The `Autocrypt` header is an e-mail header that contains the sender's address `addr` and public key data `keydata`, as well as an optional `prefer-encrypt` attribute that indicates the agreement to perform encryption with peers having the same preference. Autocrypt e-mail clients should include these headers in every message for peers that also use Autocrypt. For this reason, Autocrypt traffic is easily recognisable.

The `keydata` attribute represents an OpenPGP transferable public key (Section 3.1.1). The default signing and public-key encryption algorithms in Autocrypt are Ed25519 and ECDH over Curve25519 respectively, and RSA PKCS#1 v1.5 should also be supported. Delta Chat additionally supports NIST P-256 and P-384 curves. See [53, Section 7.2] for an example e-mail with an `Autocrypt` header.

In Autocrypt, the party receiving a message with an Autocrypt header should check whether the `addr` attribute matches the `From` header in the e-mail, rejecting the header but keeping the message if not. Then, it should place the peer's public key in the peer state table (Section 3.1.4) unless there is already an entry for the peer's Autocrypt public key, and the *effective date* (sending time of the message, capped to now) of the message is less recent than that of the existing entry.

3.1.3 Autocrypt Key Gossip

Autocrypt specifies the key gossip mechanism to allow users to send encrypted replies to a group of recipients without having to communicate with each of them in advance. Autocrypt e-mail clients may include `Autocrypt-gossip` headers in the outbound message, one for each of the intended recipients (excluding Bcc). They must be placed in the root MIME part of the encrypted message payload. Each `Autocrypt-gossip` header contains the address and the public key of a recipient. The public key is taken from the peer state table (Section 3.1.4), and for this purpose, Autocrypt prefers the peer's public key (updated with the `Autocrypt` header) over the gossip key in the peer state table. In Delta

Chat, the `Autocrypt-gossip` header has the same format as the `Autocrypt` header.

Gossip keys in the peer state table are updated in a similar way to Autocrypt keys. Namely, the receiver checks if the address in an `Autocrypt-gossip` header matches some address in the e-mail's `To`, `Cc`, or `Reply-To` header, ignoring the header if not, and updates the peer's gossip key in the peer state table accordingly unless the peer's current gossip key in the table has a more recent *effective date*.

3.1.4 Peer State Table

Autocrypt e-mail clients maintain a state for each peer in a *peer state table*. A peer state records the encryption information of the peer, such as keys and the encryption preference, as well as metadata that can be used by the client to decide on whether to update the state. The client updates the peer states automatically based on the incoming e-mails, relieving the user from OpenPGP key management. When sending a message, the e-mail client uses the peer state table to check whether encryption is possible or preferred, and the client automatically selects the appropriate keys for encryption based on the recipients' states in the peer state table.

Figure 1: Simplified overview of a peer state in Delta Chat.

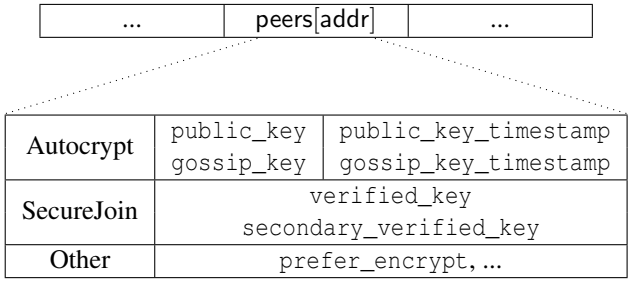

Figure 1 gives an overview of a peer state in Delta Chat, which is augmented with fields for verified keys for the SecureJoin protocols (Section 3.2). Unlike Autocrypt keys, a network attacker should not be able to change verified keys in the peer state table to attacker-controlled keys by modifying network messages. Verified chats in Delta Chat, implemented as verified groups (Section 3.2.3), use exclusively verified keys for chat messages.

Delta Chat also adds a secondary verified key column to the peer state table. This seems to be in place to enable a faster recovery from key changes.[10] When marking a gossip key as verified, if there is already a verified key for the peer and the gossip key is different from the verified key, then Delta Chat sets the peer's secondary verified key to be the gossip key. When receiving an encrypted message from the peer signed with the verified key, Delta Chat removes the secondary verified key for the peer; otherwise, if the message is signed with the secondary verified key, Delta Chat replaces the verified key with the secondary verified key. That is, depending on which key part is actually used by the peer, the two verified keys in the peer state table "resolve" into one.

3.1.5 Autocrypt Setup Message

The Autocrypt specification defines a mechanism to transfer a user's secret key between different Autocrypt e-mail clients via the Autocrypt Setup Message.

The Autocrypt Setup Message is a self-addressed e-mail that contains the user's OpenPGP transferable secret key, ASCII-armored and encrypted with a machine-generated random passphrase called the Setup Code. The user first generates the Autocrypt Setup Message on the old Autocrypt-enabled e-mail client and writes down the Setup Code displayed on screen. Then, the user logs into the new e-mail client with the same e-mail address. The new client finds the Autocrypt Setup Message in the inbox and checks it is well-formed. Then, the new client should ask the user for their approval of the import.[11] If the user agrees, the new client prompts the user to enter the Setup Code for decryption. The new client tries to decrypt the message with the entered Setup Code, and if successful it imports the decrypted secret key.

The Autocrypt Setup Message contains an `Autocrypt-Setup-Message: v1` header but not an `Autocrypt` header. The e-mail body contains instructions in plaintext, and an HTML attachment that contains the user's ASCII-armored and symmetrically-encrypted secret key. Decryption with the correct Setup Code yields the user's ASCII-armored OpenPGP transferable secret key. The Setup Code is used to both decrypt and authenticate the Autocrypt Setup Message. It contains 36 random digits, separated by dashes into blocks of four digits.

3.2 SecureJoin

The SecureJoin protocols [23], namely the Setup Contact protocol and the Verified Group protocol, protect Autocrypt from active network attackers through key verification. They were originally developed as part of the CounterMITM protocols [46], but Delta Chat's implementation has diverged from the original specification in non-trivial ways.[12]

3.2.1 Verification in Delta Chat

A chat being verified indicates that it is a verified group (Section 3.2.3), while a contact being verified indicates that the one-on-one chat with the contact is verified, and the user can

[10] https://github.com/deltachat/deltachat-core-rust/issues/4541

[11] In Delta Chat, users are not alerted directly but must click on the displayed Setup Message.

[12] Note that at the time of writing, the new specification for SecureJoin [23] was not complete with respect to the implementation in Delta Chat.

add the contact to verified groups. In Delta Chat, key verification is invisible to the user, but it is an important building block for both chat and contact verification.

A contact can become verified by performing the Setup Contact protocol (Section 3.2.2) with the user, or being introduced to a verified group in which the user is a member. Delta Chat marks a contact as verified if (i) it obtains a verified key of the contact, and (ii) it is convinced that the contact is currently using the verified key. For the latter, the contact's verified key should have the same fingerprint as the contact's Autocrypt key in the peer state table, or the gossip key if the Autocrypt key is unavailable. A chat is marked verified upon creation if all chat members are verified. Note that from version 1.133.0, Delta Chat separates contact verification into forward and backward verification (see Appendix B of the full version of the paper).

3.2.2 Setup Contact Protocol

The Setup Contact protocol allows two peers to exchange e-mail addresses and public keys in a verified manner.

A peer (Alice) first shows her invite code to the other peer (Bob) through a second, out-of-band channel. In Delta Chat, the invite code is usually a QR code, but it can also be a string that the QR code represents. Alice's invite code contains her fingerprint, address, nickname, and two random tokens, INVITE and AUTH, taken from her token database. These tokens do not expire unless Alice manually revokes the corresponding QR code.

After scanning Alice's QR code, Bob's device displays the name and address contained in the QR code, and asks Bob to manually accept the new contact. The rest of the protocol does not require further user interaction, and messages are automatically exchanged using Autocrypt through the channel potentially controlled by the attacker. At the end of the protocol, both participants will have learned and validated the contact information and the public key of their peer. Delta Chat will mark the peer as verified.

A detailed overview of the protocol flow can be found in Fig. 4 in Appendix A, however it is not necessary for the understanding of our attacks.

The SecureJoin document gives an informal argument why the Setup Contact protocol is resistant to impersonation from active attackers that can modify, create and delete messages [23, Section 2.1.2]. However, it acknowledges that an attacker could replay Bob's messages in the protocol to Alice, which could potentially be used to make Alice switch to a compromised key of Bob [23, Section 2.1.3].

3.2.3 Verified Group Protocol

The verified group in Delta Chat is a type of group chat that is secure against network attacks. Members in a verified group are verified to each other, and all messages in a verified group are signed and encrypted using verified keys.

Initialisation. The SecureJoin document does not specify how to create a verified group. In Delta Chat, a user first creates the group locally with a random group identifier. If all members are verified to the creator, the group is automatically marked as verified. The group is invisible to other members until the creator sends the first message in the group. When a group member receives this message, Delta Chat creates the group locally for that member.

Preparing for joining a verified group. Suppose Alice is a member in some verified group, while Bob is not. For Alice to add Bob to the verified group, Alice should have verified Bob's key, e.g. by performing the Setup Contact protocol with Bob, or by being in another verified group with Bob. If this is not the case, Alice can perform a process very similar to the Setup Contact protocol to prepare for adding Bob to the group, which we summarise below.

First, Alice shares the QR code of the verified group with Bob. The QR code contains Alice's fingerprint and address, the group name and identifier, and two random tokens associated with the group, INVITE_g and AUTH_g, taken from Alice's token database. Tokens are associated with their groups, so different groups use separate tokens.

Bob scans the QR code shared by Alice and manually confirms joining the verified group specified in the QR code. No further user interaction is required for the rest of the process. After that, the peers' clients perform a variant of the Setup Contact protocol. After verifying Bob's key, Alice's client adds Bob to the verified group similar to the process we describe below.

Joining a verified group. Suppose Alice and Bob are verified to each other. For Alice to add Bob to a verified group, Alice's client first adds Bob to the group locally, and then sends a `Chat-Group-Member-Added` message to all members, including Bob. The message contains the verified keys of all members except Alice herself as `Autocrypt-Gossip` headers in the signed and encrypted payload.

On receiving the message, Bob's client creates the group locally and marks peers as verified using the gossip keys. Other group members' clients check that Alice and they are both members of the group (while Bob may or may not be in the group in their views), mark the gossip keys as verified, and add Bob as a group member.

4 Attacks

In this section, we describe our attacks within the Delta Chat threat model outlined in Section 2. Further attacks outside of their threat model can be found in Appendix B.

4.1 Gossip Key Injection

Delta Chat's implementation of the Verified Group protocol allows an attacker to trick the target into marking an attacker-controlled gossip key as verified. This attack does not require a network attacker: the attacker only needs to know the target's public key and send a future-dated e-mail to the target.

Vulnerability. In a verified group, some messages contain one or more `Autocrypt-Gossip` headers in the protected payload. When adding a member to the group, the introducer sends a `Chat-Group-Member-Added` group message that contains the verified keys of all members, including the new member. In addition, Delta Chat periodically attaches the gossips of other members' verified keys to verified group messages, to allow for a faster recovery from key changes. The recipient's client marks the gossiped keys as verified in the peer state table as described in Section 3.2.3.

Since `Autocrypt-Gossip` headers should only be present in the signed and encrypted payload, the attacker cannot add or modify `Autocrypt-Gossip` headers in verified group messages. However, it is possible for the attacker to trick the target's client into marking a different gossip key than that in the message as verified.

When marking a gossip key as verified, Delta Chat iterates over the intersection of addresses in the gossip headers and addresses in the `To` header.[13] For each address, Delta Chat sets its verified key to be the gossip key in the peer state table, or sets a secondary verified key to be the gossip key if a different verified key is already present in the table. The problem is that there is no guarantee that the peer's gossip key in the peer state table actually corresponds to the gossip key in the message, and it is possible that the peer's gossip key does not get updated by the message.

Delta Chat only updates the peer's gossip key in the table if the gossip key in the message is more recent.[14] When comparing the two timestamps, Delta Chat does not cap the send time of the e-mail as required by the Autocrypt standard [53, Section 3.3, 3.6]. Therefore, if the gossip key for some contact in the peer state table has a more recent timestamp than the verified group message with a gossip for the contact, then Delta Chat marks the gossip key in the table as verified. This is potentially different from the contact's real key.

Attack. Suppose Alice is a member of a verified group, while Bob is either a member in the verified group or is about to be added to the verified group by another member Carol with a `Chat-Group-Member-Added` message. Alice and Bob have not communicated in Delta Chat before. Mallory is an attacker outside the group that can send messages to Alice and knows Alice's public key. Mallory does not need to be able to eavesdrop on, spoof or modify network messages, but these capabilities would be helpful in making use of the attack. Figure 2 illustrates the following attack.

First, Mallory sends an e-mail message to Alice, with Bob also in the `To` header of the e-mail. The message includes a malicious gossip key for Bob in its protected payload. The e-mail is dated from the future, which is not expected behaviour but often occurs in practice since client time misconfiguration issues are common. Alice's client parses the message and updates Bob's gossip key in the peer state table accordingly. The malicious gossip key remains in Alice's peer state table, even if Alice deletes the message or blocks Mallory afterwards.

After a short while, suppose Alice receives a message in the verified group with a gossip key for Bob. Because the malicious gossip key for Bob has a more recent timestamp, the verified group message does not update Bob's gossip key in Alice's peer state table. Alice's client then tries to mark the gossip key for Bob as verified, which has the effect of marking the malicious gossip key as verified instead.

If Bob is a new member to be added to the group, then Mallory already controls Bob's verified key in Alice's view. Otherwise, Mallory controls a secondary verified key for Bob, and in order to promote the malicious key to a verified key, Mallory would need to spoof a message from Bob to Alice that is signed with the malicious gossip key.

Mallory as a network attacker could also perform the attack without sending a future-dated e-mail to Alice. Mallory could intercept a verified group message to Alice that contains gossips, which is easily recognisable from the payload size or from new recipients in the `To` header, and, after sending an e-mail with the malicious gossip key, modify the `Date` header to an earlier time before forwarding the message to Alice.

For Alice to mark Bob as verified, Alice's client also needs to be convinced that Bob is actually using the verified key. If Alice already had Bob's real public key in her peer state table, then Alice's client would not mark Bob as verified, since Bob is potentially using a different key. In that case, to complete the attack, Mallory just needs to also spoof a message from Bob to Alice with the malicious key in the Autocrypt header.

Consequences. By tricking Alice's client to verify a malicious key for Bob, Mallory can eavesdrop on messages from Alice to Bob or in any verified group where Bob is a member. Mallory can also perform a machine-in-the-middle attack between Alice and Bob, despite Alice believing that her communications with Bob are protected with guaranteed end-to-end encryption. Furthermore, Mallory can cause Alice to mark any contact or key as verified by spoofing a message from Bob to Alice which adds Alice to a non-existent verified group with malicious gossips in the message.

Using Delta Chat's AEAP feature (Section 3), Mallory

[13] https://github.com/deltachat/deltachat-core-rust/blob/1edd7045bec1f8fa0761e26a975cb9f07596feb8/src/receive_imf.rs#L2479

[14] https://github.com/deltachat/deltachat-core-rust/blob/1edd7045bec1f8fa0761e26a975cb9f07596feb8/src/peerstate.rs#L332

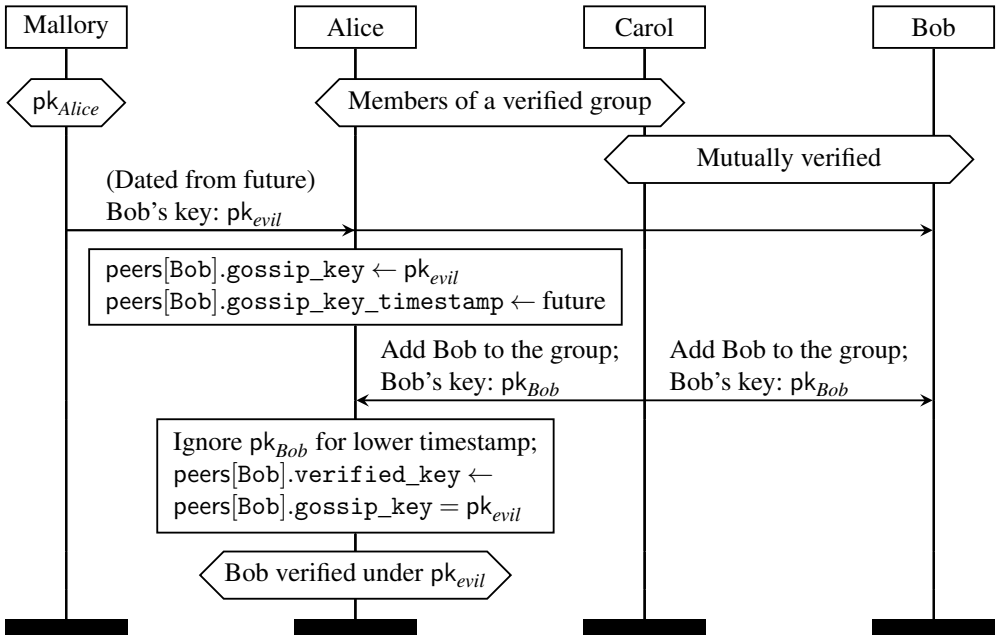

Figure 2: The message sequence for the example gossip key injection attack. Note that the initial message from Mallory to Alice may or may not be actually sent to Bob.

could change Bob's address in Alice's view by sending an e-mail to Alice from the new address. Indeed, Mallory could also use AEAP to make herself verified to Alice, avoiding the need for spoofing e-mails from Bob. However, AEAP would leave a visible user notification to Alice, which could alert her about the attack.

Finally, Alice could unknowingly disseminate the malicious key further in verified groups where Alice is a member, causing more users to verify the malicious key for Bob.

Mitigation. When marking gossiped keys as verified, Delta Chat should not rely on the untrusted gossip key entry in the peer state table. Instead, Delta Chat should directly mark the gossip keys contained in the protected e-mail payload as verified. Further, Delta Chat should use the effective date defined in the Autocrypt standard and cap the message date before updating the peer state table.

4.2 Group Member Removal

By manipulating message headers, it is possible for a network attacker to change a normal group message into the special message for group member removal. As a result, the attacker can remove arbitrary members from a verified group, as if they were removed by some other member in the group.

Vulnerability. Despite the signing and encryption of messages, message headers are surprisingly malleable. By adding or modifying unprotected e-mail headers of an encrypted message, the attacker can drastically change the meaning and effect of that message. Table 1 lists the manipulatable headers relevant to our attacks. A header in Delta Chat may appear as an IMF header in the unprotected part of the e-mail, or as a MIME header in the possibly signed and encrypted payload. Delta Chat internally categorises headers into four types.

Unprotected: these headers must appear as IMF headers, e.g. `Date` and `Chat-Version`. *Hidden*: these headers can be large and therefore must not appear as IMF headers, e.g. `Chat-User-Avatar`. *Protected*: these headers are encrypted whenever the message is encrypted, e.g. `Chat-Group-Name`. *Secured*: these headers should only be present in the signed and encrypted payload. The `Chat-Verified` and `Secure-Join-Fingerprint` headers are explicitly marked as secured. In addition, Delta Chat treats the `Autocrypt-Gossip` header as secured.

The e-mail parser removes or ignores secured headers that appear in the unencrypted part. However, perhaps counterintuitively, a protected header can appear as an unencrypted IMF header even if the e-mail is signed and encrypted. This design choice is necessary for headers like `Subject` and `From`, which are generally required for well-formed e-mails, but is incorrect for other protected headers, such as `Chat-Group-Member-Removed`, which should only appear in the possibly encrypted e-mail body.

The situation is more complicated when the same protected header appears in both encrypted and unencrypted

Table 1: The types and susceptibility to overwriting of the manipulatable headers in Delta Chat that are relevant to our attacks.

Header	Type	Overwriting	Reference
`Chat-Group-Avatar`	hidden	no	Section 4.2
`Chat-Group-Member-Removed`	protected	no	Section 4.2
`From`	protected	yes	Appendix B
`Message-ID`	protected	yes	Section 4.2
`Secure-Join`	protected	yes	Section 4.4
`Secure-Join-Auth`	protected	yes	full version of the paper (App. E)

parts. Delta Chat parses the unencrypted headers before the encrypted headers, preferring a new header over an already parsed one if the header is considered as "known" or starts with `Chat-`. Therefore, the encrypted header generally takes precedence over the unencrypted header. For example, the encrypted `Subject` header is preferred over its unencrypted counterpart, which reflects a common practice in OpenPGP e-mail clients to hide e-mail subjects.

However, because of several oversights in Delta Chat's e-mail parser implementation, there are cases where the unencrypted header could overwrite the encrypted header, including `Secure-Join`, `Secure-Join-Auth` and `Secure-Join-Group`, which are not included in the list of known headers. Moreover, `Secure-Join-Auth` should have been treated as secured instead of protected, as it never appears unencrypted in honest executions.

In addition, the `Message-ID` header and the `From` header are in effect susceptible to overwriting. The `Message-ID` header, while not susceptible to overwriting per se, can be overwritten by the unprotected `X-Microsoft-Original-Message-ID` header, which was used in older versions of Delta Chat and remains for compatibility. For the `From` header, Delta Chat decided not to reject an e-mail whose encrypted `From` header is different from its unencrypted `From` header; however, Delta Chat considers such an e-mail as having an unsigned `From`, meaning that it cannot be used to initiate the AEAP mechanism.

Attack. Suppose Alice and Bob are in the same verified group. If Alice wished to remove Bob from the group, Alice would send a message with a `Chat-Group-Member-Removed` header containing Bob's e-mail address to the members of the verified group. Upon seeing the message, all members' clients, including Bob's, would remove Bob from the verified group, and display a notification saying that Bob has been removed from the group by Alice.

Suppose Mallory is an eavesdropping attacker outside the group that is also capable of spoofing messages to Alice; Mallory can also be a network attacker. First, Mallory captures a non-administrative message that Alice has sent to the verified group at some point in the past. Mallory should be able to capture such a message with reasonable probability, and she can use some characteristics of the message, such as size and the `To` header, to help distinguish it from administrative messages. Mallory can easily distinguish messages in different groups, since the group ID is a part of the plaintext `Message-ID` header.

Then, Mallory modifies the captured message by adding a `Chat-Group-Member-Removed` header with Bob's address to the unprotected IMF header section of the message. Mallory also modifies the unprotected `Message-ID` header so that the message will not be treated as a duplicate by Alice. Newer versions of Delta Chat place a copy of the `Message-ID` header in the protected payload, but the attacker can instead set the unprotected `X-Microsoft-Original-Message-ID` header, which takes precedence over `Message-ID`. (If Mallory could intercept and modify a non-administrative message from Alice to the verified group before it is delivered to the group, she could instead directly add the `Chat-Group-Member-Removed` header with Bob's address to its IMF headers.)

After that, Mallory sends the modified message to all members of the verified group. The members' clients incorrectly interpret the modified message as a group member removal message initiated by Alice. Mallory may choose to send this message to Alice too; her client would also remove Bob upon receiving the message.

Consequences. While the attacker cannot read messages in the verified group, they are able to arbitrarily remove members of the group, which could create confusion about the group's membership state or dissolve the group.

There could be other potential attacks that leverage header manipulation. For example, it is possible to add or remove the avatar of a verified group by adding a `Chat-Group-Avatar` header to a normal group message. It is also possible to change the group name for two peers in a verified group by reusing another message from their one-on-one chat, where other members could not see the change.

Mitigation. An immediate fix to the attack would disallow headers starting with `Chat-` to appear in the unencrypted part

if the message is encrypted. However, it takes more careful checks to completely eliminate such attacks. In general, if a protected header appears in the plaintext part of an encrypted message, then Delta Chat should regard the message as invalid. There are a few exceptions for headers generally required for a well-formed e-mail message, such as `Subject` and `From`, in which case Delta Chat should prefer the encrypted header, and only reject the message if the encrypted header is meant to match the unencrypted header but does not.

4.3 Synchronisation Forgery

Delta Chat verifies self-addressed messages with the user's own Autocrypt public key in the peer state table. Consequently, an attacker capable of spoofing self-addressed e-mails could trivially forge self-addressed messages for the target, including synchronisation messages.

Vulnerability. Delta Chat synchronises certain changes in the account across devices. These include the addition or deletion of QR invite code tokens for the SecureJoin protocols, changes to chat statuses like blocking contacts or archiving chats, and changes to a limited set of account configurations like display names. Synchronisation is enabled by default, even if the user only uses Delta Chat on one device.

Delta Chat synchronises these changes by sending a synchronisation message, which is a self-addressed e-mail with a `multi-device-sync.json` file attached. The attachment contains the synchronisation items represented in JSON. Like other messages, the synchronisation message should be signed and encrypted. While Delta Chat encrypts the message correctly with the user's real public key, the verification of a self-addressed e-mail message uses the user's Autocrypt public key as it appears in the peer state table, similarly as for other opportunistically protected one-on-one chats. As with other contacts, Delta Chat updates the user's own Autocrypt key in the peer state table using the Autocrypt headers from the received self-addressed messages.

Attack. An attacker in the possession of the target's public key and capable of spoofing self-addressed e-mails for the target could make the target's client execute malicious synchronisation items crafted by the attacker.

To mount this attack, the attacker creates a message containing the malicious synchronisation items, signed with a key known by the attacker and encrypted with the target's public key. This message contains an Autocrypt header that corresponds to the public part of the signing key. The attacker then sends the message to the target, spoofed to appear as if it was sent by the target.

On receiving the message, the target's Delta Chat client first updates the target's own Autocrypt key entry in the peer state table to the public key in the Autocrypt header, then decrypts the message with the target's own private key, and finally verifies the message with the target's own Autocrypt key in the peer state table, which succeeds since the message is indeed signed with the private counterpart of the Autocrypt key; see Fig. 3. The target's client now processes the message as a valid synchronisation message and proceeds to execute the malicious synchronisation items in the message.

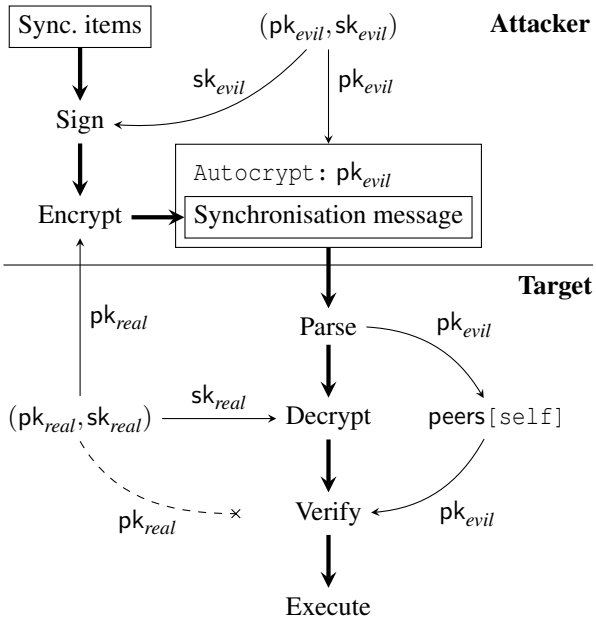

Figure 3: Keys involved in the synchronisation forgery attack, where $(\mathsf{pk}_{real}, \mathsf{sk}_{real})$ is the target's key pair, and $(\mathsf{pk}_{evil}, \mathsf{sk}_{evil})$ is a key pair known by the attacker. Ideally, Delta Chat should use pk_{real} to verify the synchronisation message (dashed line).

Consequences. By planting AUTH and INVITE tokens in the synchronisation items to the target, the attacker could verify themselves to the target, or impersonate other contacts to the target in the Setup Contact protocol or the Verified Group protocol. The recent Delta Chat updates on synchronisation[15] equip the attacker with more capabilities. The attacker could now change chat statuses on the target's device, such as blocking contacts or muting chats, and force the target to change several configurations, such as the display name. Note that in most cases, executing synchronisation items does not result in a notification to the user.

More generally, the attacker can forge self-addressed messages with similar techniques, which appear to be encrypted in the "Saved Messages" chat on the victim's client. While this chat does not bear a green checkmark, the target (e.g. a Delta Chat bot[16]) may still perceive it as verified and incorrectly regard the forged message as self-addressed.

[15] See e.g. https://github.com/deltachat/deltachat-core-rust/pull/4843 and https://github.com/deltachat/deltachat-core-rust/pull/5023.

[16] https://bots.delta.chat/

Mitigation. Delta Chat should handle self-addressed messages separately from other messages, and in particular only use the user's own key to verify self-addressed messages.

Device synchronisation could be made more secure by notifying the user about the changes that were executed, and using timestamps to prevent synchronisation replays.

4.4 InsecureJoin Observer

We describe another attack that leverages header manipulation (Section 4.2) to trick Delta Chat into marking an attacker-controlled key as verified. The attack relies on a mechanism in Delta Chat that observes the SecureJoin protocol instance on other devices.

Vulnerability. When Delta Chat sees a self-sent SecureJoin message not originating from the current device to a peer, it interprets it as the user establishing contact with the peer on another device. If the message is correctly signed and encrypted, then Delta Chat tries to use the SecureJoin message in order to achieve some form of synchronisation between devices. Further, if the message indicates the final stages of the protocol, i.e. it can be deduced that the other device has verified or will shortly be able to verify the peer, then Delta Chat also marks the gossip key for the peer as verified on this device.

Similar to the group member removal attack (Section 4.2), the vulnerability we exploit in this attack is the lack of protection for headers in Delta Chat, and more specifically, the flexibility of the `Secure-Join` header. Delta Chat uses the `Secure-Join` header to indicate a SecureJoin message and denote its type (e.g. `vc-request`). The `Secure-Join` header is treated as protected, meaning that it should be encrypted whenever the message is encrypted. However, this header is incorrectly allowed to appear unencrypted even when the message is encrypted. Moreover, an unencrypted `Secure-Join` header overwrites an encrypted `Secure-Join` header in the same message.

In addition to the attack we describe here, a variant of the gossip key injection attack (Section 4.1) still seems applicable in this context, because when marking a peer's gossip key as verified based on the observed SecureJoin message, Delta Chat would look for the gossip key in the peer state table rather than in the protected message payload. Our attack does not exploit this vulnerability. An attacker cannot use the technique in the synchronisation forgery attack (Section 4.3) to forge a self-sent SecureJoin message, because Delta Chat would check that the message is signed with the user's real key.

Attack. Suppose the attacker is able to spoof messages sent from the target. In addition, we assume the attacker is able to eavesdrop on the communications of the target; alternatively, we could instead assume that the target replies to messages sent from the attacker. To make the target verify an attacker-controlled key, the attacker crafts a message perceived by the target's Delta Chat client as a valid SecureJoin message from the target to the attacker or to an address of the attacker's choice, which actually contains an attacker-controlled key as a gossip header.

The general idea of crafting such a message is to first trick the target into signing a message that contains the attacker-controlled key as a gossip key, and then add a `Secure-Join` header indicating a SecureJoin message in a final protocol stage (e.g. `vc-contact-confirm`) to the unprotected IMF headers of the message.

There are several possible ways of making the target sign the attacker-controlled gossip key. For example, the attacker could send messages to the target in unverified one-on-one chats or groups, hoping the target would reply. The first reply would carry a gossip of the attacker's public key, and gossips would also occur in replies periodically. The attacker could also send a `vc-request` message to the target. The `vc-request` message is a cleartext message in the Setup Contact protocol that carries an INVITE token in the target's QR invite code; the attacker can eavesdrop on past Setup Contact protocol instances to learn a valid INVITE for the target. The target replies with a `vc-auth-required` message, which contains a gossip of the attacker's public key in the protected payload. Because the unprotected `Secure-Join` header takes precedence, adding an unprotected `Secure-Join` header to the target's reply can change the SecureJoin message to a desired type.

The attacker then sends the crafted message to the target via Bcc as if the target sent it from another device. The target's Delta Chat client would recognize the message as a valid SecureJoin message on another device that indicates final stages of the protocol, and mark the attacker's gossip key in the message as verified.

The changes to Delta Chat core that introduce forward and backward verification would only impact the attack slightly – the attacker would need to send one more message to the target (see Appendix B of the full version of the paper).

Consequences. The consequences for this attack largely overlap with the gossip key injection attack (Section 4.1). However, this attack is harder to mount, as it requires stronger capabilities for the attacker.

Mitigation. As this attack stems from header flexibility, fixing the header manipulation vulnerability, and in particular, disallowing the `Secure-Join` header to appear unencrypted whenever the message is encrypted, would prevent the attack.

4.5 Autocrypt Setup Forgery

The Autocrypt Setup Message transfers the user's encrypted secret key over an insecure channel, which could make it

vulnerable to key overwriting attacks [17]. However, the Autocrypt Setup Message includes the user's public key, which prevents classical attacks of this type. Despite this, because the rPGP library has a bug that allows decryption using the "plaintext" algorithm, it is easy to forge a valid Autocrypt Setup Message under an unknown Setup Code.

Vulnerability. The Setup Code plays an important role in guaranteeing the security of the Autocrypt Setup Message. To quote the Autocrypt specification: *"The Code serves both for decryption as well as authenticating the message. Extra care needs to be taken with some PGP implementations that the Setup Code is actually used for decryption. For example, this is difficult to do correctly with GnuPG."* [53, Section 5.4.4]

While RFC 4880 specifies "plaintext" as a symmetric-key algorithm with ID 0, the specification also stresses that the plaintext algorithm *"may only be used to denote secret keys that are stored in the clear"*, and that *"Implementations MUST NOT use plaintext in Symmetrically Encrypted Data packets"* [34, Section 13.4]. However, it is possible in rPGP to use the plaintext algorithm to "decrypt" session keys or data. In rPGP, the plaintext algorithm has a "key size" and a "block size" of 0. There are no checks on the key size for the plaintext algorithm. The algorithm simply strips the first two bytes of the data, which it perceives as the random block and "quick check" bytes, and returns the rest.

Attack. The attack idea is straightforward: a network attacker can substitute the encrypted data in the target's Autocrypt Setup Message with a secret key controlled by the attacker, encrypted under the plaintext algorithm. The malicious message "decrypts" correctly to the attacker-controlled key under the original Setup Code. This breaks the expectation of the Autocrypt standard which claims that Setup Codes always authenticate the message. In the end, the target's client imports and uses a key controlled by the attacker.

Alternatively, if the attacker was only able to spoof self-addressed messages for the target, the attacker could still send the malicious message along with the honest one, hoping the target would click on the malicious message. As a last resort, since Delta Chat allows Setup Messages that are not self-addressed, the attacker could simply send the malicious message to the target in an unverified chat, possibly changing the avatar and name to resemble the chat "Saved Messages" so as to confuse the target. Details of how to construct the OpenPGP packets required to exploit the plaintext algorithm can be found in Appendix D of the full version of the paper.

Consequences. The attacker can make the target accept a malicious Autocrypt Setup Message and start to use a key controlled by the attacker. The attacker is then able to read all of the target's future communications as well as impersonate the target to others after the target verifies the malicious key to them. However, since the malicious key does not contain the secret key materials of the real key, if the target did not stop using their old Autocrypt e-mail client or Delta Chat client, they would soon notice a discrepancy in the messages seen on different devices.

Mitigation. The rPGP library should disable the plaintext algorithm, and Delta Chat should update to the patched version of rPGP. In addition, Delta Chat should not allow Autocrypt Setup Messages that are not self-addressed, and should consider warning users about possible phishing attacks related to such messages.

A Delta Chat user could also manually export and import the secret key or the whole backup, both unencrypted, or use an experimental Delta Chat feature to transfer encrypted account data between two devices within the same network.

4.6 Compression Quine

We describe a known attack on OpenPGP libraries that we found applicable to rPGP. The rPGP library does not have a maximum recursion depth for OpenPGP messages, so it is possible to perform a denial-of-service attack on rPGP, and consequently Delta Chat.

Vulnerability. First publicly identified by Campbell [19], it is known that some OpenPGP implementations could be vulnerable to a denial-of-service attack that leverages an OpenPGP *compression quine*, which is an OpenPGP Compressed packet that decompresses to itself. Trying to decompress the compression quine may cause the program to exhaust memory and crash, and, in the worst case, dump secret information upon crashing. This appears as an inherent issue in the OpenPGP standard that was not considered by Delta Chat. The draft on OpenPGP "crypto refresh" lists this attack as a security consideration for OpenPGP implementors [57, Section 13.14].

Attack. The attack is straightforward: an attacker with the knowledge of the target's address and public key simply sends an OpenPGP compression quine to the target, encrypted under the target's public key; there is no need for the target to recognize or manually accept the contact.

Consequences. Delta Chat crashes almost immediately upon receiving the message, and the issue persists as long as Delta Chat is connected to the e-mail server. To recover from the attack, the target must manually delete the message from the server, switch to different keys or accounts while offline, or reinstall Delta Chat.

Mitigation. The rPGP library should set a maximum recursion depth for OpenPGP messages. It is also a good idea for rPGP to check against some of the tests in the OpenPGP interoperability test suite.[17] However, without further defenses, the attacker would still able to send a compressed message with an exorbitant compression ratio, also known as a "ZIP bomb", to achieve a similar effect as a compression quine. Therefore, rPGP could consider treating Compressed packets that exceed a maximum compression ratio or contain data that is too large as invalid.

5 Discussion

While it is difficult to estimate the size of Delta Chat's user base, its promotion to users in high-risk contexts makes it a potential target for powerful real-life adversaries. We have shown that attacks are possible under the threat model envisioned by Delta Chat's developers, raising several questions.

Cause of the attacks. Most of the attacks we found leverage deviations from the OpenPGP, Autocrypt, or SecureJoin specifications, rather than attack the protocols or standards themselves. However, the specifications can be unclear or even misleading in some cases, and attacks stemming from cross-protocol interactions can be notoriously difficult to prevent without a comprehensive understanding of the entire system. We believe that some of the attacks could have been found earlier if an attempt to prove the security of the SecureJoin protocols had been made.

The SecureJoin protocols "consider usability, cryptographic and implementation aspects simultaneously, because they constrain and complement each other" [23]. However, balancing security and usability is a hard problem; for users in high-risk contexts, prioritising feature development may increase harm. For example, we found several vulnerabilities related to Delta Chat's multi-device support. Other decentralised messaging applications used in high-risk contexts like Briar[18] do not support multiple devices, thereby limiting their attack surface. Yet, without certain features, users may switch to other applications; indeed, multi-device support was identified as a necessary feature in Delta Chat's interviews with high-risk users [31].

Appropriateness of Delta Chat's threat model. While our attacks fall within the threat model outlined by Delta Chat, it is also important to assess whether this threat model is appropriate in the first place. Prior work [35] has questioned whether opportunistic encryption in the form of Autocrypt should be promoted to users who may not have a full understanding of the implications of its use; on the other hand, Delta Chat has repeatedly incorporated feedback from groups of high-risk users into its development process [31–33], an undertaking that is uncommon but vital for a secure messaging application. It is also useful to contrast Delta Chat's explicit approach to verification with that of Signal, in which users who do not choose the option of verifying safety numbers are participating in *de facto* unverified chats.

The threat model of verified chats, however, omits several categories of attacks such as attacks on privacy, insider attacks, but also attacks that are prevented by other messaging applications as a matter of course. We give a detailed overview of attacks outside of Delta Chat's threat model in Appendix B.

Securing decentralised communications. What could be done to make Delta Chat, or decentralised messaging services more widely, more secure for the future? We argue that more analysis is necessary on multiple levels.

Commercial security audits can increase trust in a particular product by helping to eliminate implementation flaws and insecure configurations. Delta Chat's two cryptographic audits showed overall positive results, having found only two "high-risk" issues. However, the scope of such audits is, by definition, limited. Our results demonstrate that passing a security audit cannot be seen as a security end-goal in itself.

However, neither can analysis such as ours be seen as a definitive stamp of approval. Beyond immediate mitigation, questions arise about the future of open specifications such as Autocrypt and SecureJoin. Formal cryptographic proofs such as [5] can help in gaining a better understanding of the security guarantees given by a particular design; yet, in cases such as Delta Chat, it can be challenging to make formal statements about a design that lacks a protocol specification and whose cryptographic implementation changes frequently. The work on ClaimChain [41] in particular shows that even if a design with stronger security properties exists, circumstances may prevent it being adopted in practice.

We do not intend to contribute to the already abundant discussion on whether OpenPGP should be considered insecure by modern standards. However, our attacks show that one should take great caution when using OpenPGP in non-standard scenarios as well as when validating OpenPGP messages. We believe Delta Chat should limit its usage of OpenPGP to a more secure subset, and consider upgrading to crypto-refresh [57] in the near future.

Instead of further customising the SecureJoin protocols, pushing for and contributing to a specification of Autocrypt Level 2 could provide a way forward for Delta Chat. This was alluded to in the current Autocrypt specification [53] as providing protection against active attackers but work on it never began. However, such an undertaking would require participation from the wider community. In the meantime, the lack of viable alternative tools for secure decentralised messaging makes it a pressing problem for developers and researchers alike.

A Setup Contact Protocol Details

We first introduce the notation and simplified primitives for the Setup Contact protocol (Section 3.2.2):

- $\mathsf{pk} = (\mathsf{pk}_{\mathsf{prim}}, \sigma_{\mathsf{prim}}, \mathsf{pk}_{\mathsf{sub}}, \sigma_{\mathsf{sub}})$: an OpenPGP transferable public key, where $\mathsf{pk}_{\mathsf{prim}}$ is the primary public key for signing, σ_{prim} is a self-signature, $\mathsf{pk}_{\mathsf{sub}}$ is the public subkey for encryption, and σ_{sub} is a binding signature on $\mathsf{pk}_{\mathsf{sub}}$ by the primary key. We ignore fields like the User ID that are irrelevant for the protocol.

- $\mathsf{sk} = (\mathsf{pk}, \mathsf{sk}_{\mathsf{prim}}, \mathsf{sk}_{\mathsf{sub}})$: an OpenPGP secret key, where $\mathsf{sk}_{\mathsf{prim}}$ and $\mathsf{sk}_{\mathsf{sub}}$ are private keys for $\mathsf{pk}_{\mathsf{prim}}$ and $\mathsf{pk}_{\mathsf{sub}}$ in pk respectively.

- $\mathsf{fp} = \mathtt{FP}(\mathsf{pk})$: an OpenPGP key fingerprint, which is a 20-byte SHA-1 digest derived from the primary key $\mathsf{pk}_{\mathsf{prim}}$.

- $\mathtt{Seal}(\mathsf{sk}_A, \mathsf{pk}_B, m)$: the Autocrypt "encrypt" process (sign-compress-encrypt), where the message m is signed with sk_A and encrypted with pk_B.

- $\mathtt{Open}(\mathsf{sk}_B, \mathsf{pk}_A, c)$: the Autocrypt "decrypt" process (decrypt-decompress-verify).

- $\mathsf{From} = (\mathsf{name}, \mathsf{addr})$: a `From` header, where name is a name (e.g. `"Alice"`) and addr is an e-mail address (e.g. `"alice@example.org"`).

- peers: the Autocrypt peer state table, which contains each peer's Autocrypt public key, gossip key, verified key, and the timestamps for the keys (see Section 3.1.4). We use $\mathsf{peers}[\mathsf{addr}]$ to refer to the peer state for the contact with address addr, and use $\mathsf{peers}.\mathtt{lookup}(\mathsf{fp})$ to refer to the peer state whose Autocrypt key fingerprint is fp; both can uniquely identify a peer state in Delta Chat.

- INVITE and AUTH: random tokens in the QR code.

- tokens: the token database. We use $\mathsf{tokens}.\mathtt{top}()$ to denote selecting the most recently created INVITE and AUTH tokens from the token database.

Figure 4 shows a simplified run of the Setup Contact protocol. For the purpose of introducing the protocol, it suffices to treat the internals of OpenPGP as a black box. Alice's invite code contains her fingerprint fp_A, address addr_A, nickname name_A, and two random tokens, INVITE and AUTH, taken from the tokens_A database. These tokens do not expire unless Alice manually revokes the corresponding QR code. According to the SecureJoin document, INVITE and AUTH should each be at least 8 bytes. In Delta Chat, both tokens are random strings of 11 Base64 characters.

B Attacks Outside of the Threat Model

Here we discuss attacks that are outside of Delta Chat's specified threat model. For example, some attacks may require that the attacker be verified to the target, or break some security properties that are not explicitly claimed to hold in Delta Chat. These attacks may or may not be considered as real threats to Delta Chat users. Note that attacks in the previous subsections may be used to gain privileges for some of these attacks.

Missing standard properties. Note that the threat model outlined in Section 2 excludes attacks that would in general prevent making formal security claims standard in the academic literature on messaging but also more fundamentally on key exchange and secure channels. For example, a more robust protocol would be able to prevent reordering, replay[19] and deletion attacks, but also unknown key-share [16] or identity misbinding attacks such as the one below.

Contact misbinding. In the Setup Contact protocol, while Bob's message carries a protected `From` header, Alice's client still accepts the message and ignores the protected `From` if it is different from the outer unprotected `From`. Therefore, a network attacker could perform an identity-misbinding attack between Alice and Bob, where the attacker modifies messages from Bob to Alice as if they were sent from another address controlled by the attacker, and forwards messages intended for the attacker-controlled address to Bob. Upon completion of the Setup Contact protocol, Alice's client would mark the attacker-controlled address as verified with a green checkmark, but still under Bob's public key.

To fix this issue, Delta Chat should ensure that the protected `From` header is present in SecureJoin messages whenever possible, and reject the message with possible warnings to the user if it is missing or different from the unprotected `From`. Note that simply preferring the protected `From` would not be a correct mitigation as it would make spoofing easier for an attacker.

Attacks on privacy. An eavesdropping attacker can easily distinguish Autocrypt traffic by checking the Autocrypt header. The attacker can also distinguish messages from different groups, since the group ID is a part of the plaintext `Message-ID` header. An attacker that can only observe and modify partial network traffic, e.g. a malicious e-mail server, may "taint" Autocrypt keys in order to to learn more about the social graph of the target. The attacker can do this by adding unhashed subpackets to OpenPGP keys in Autocrypt headers found in network messages, which is possible since these fields are not protected by signatures nor contribute to the key fingerprint. Afterwards, the attacker can interact with potential contacts and see from the `Autocrypt-Gossip` header whether they possess the tainted key.

[19] Newer versions of Delta Chat do add limited replay protection by including a `Message-ID` header in the protected payload, see Section 4.2.

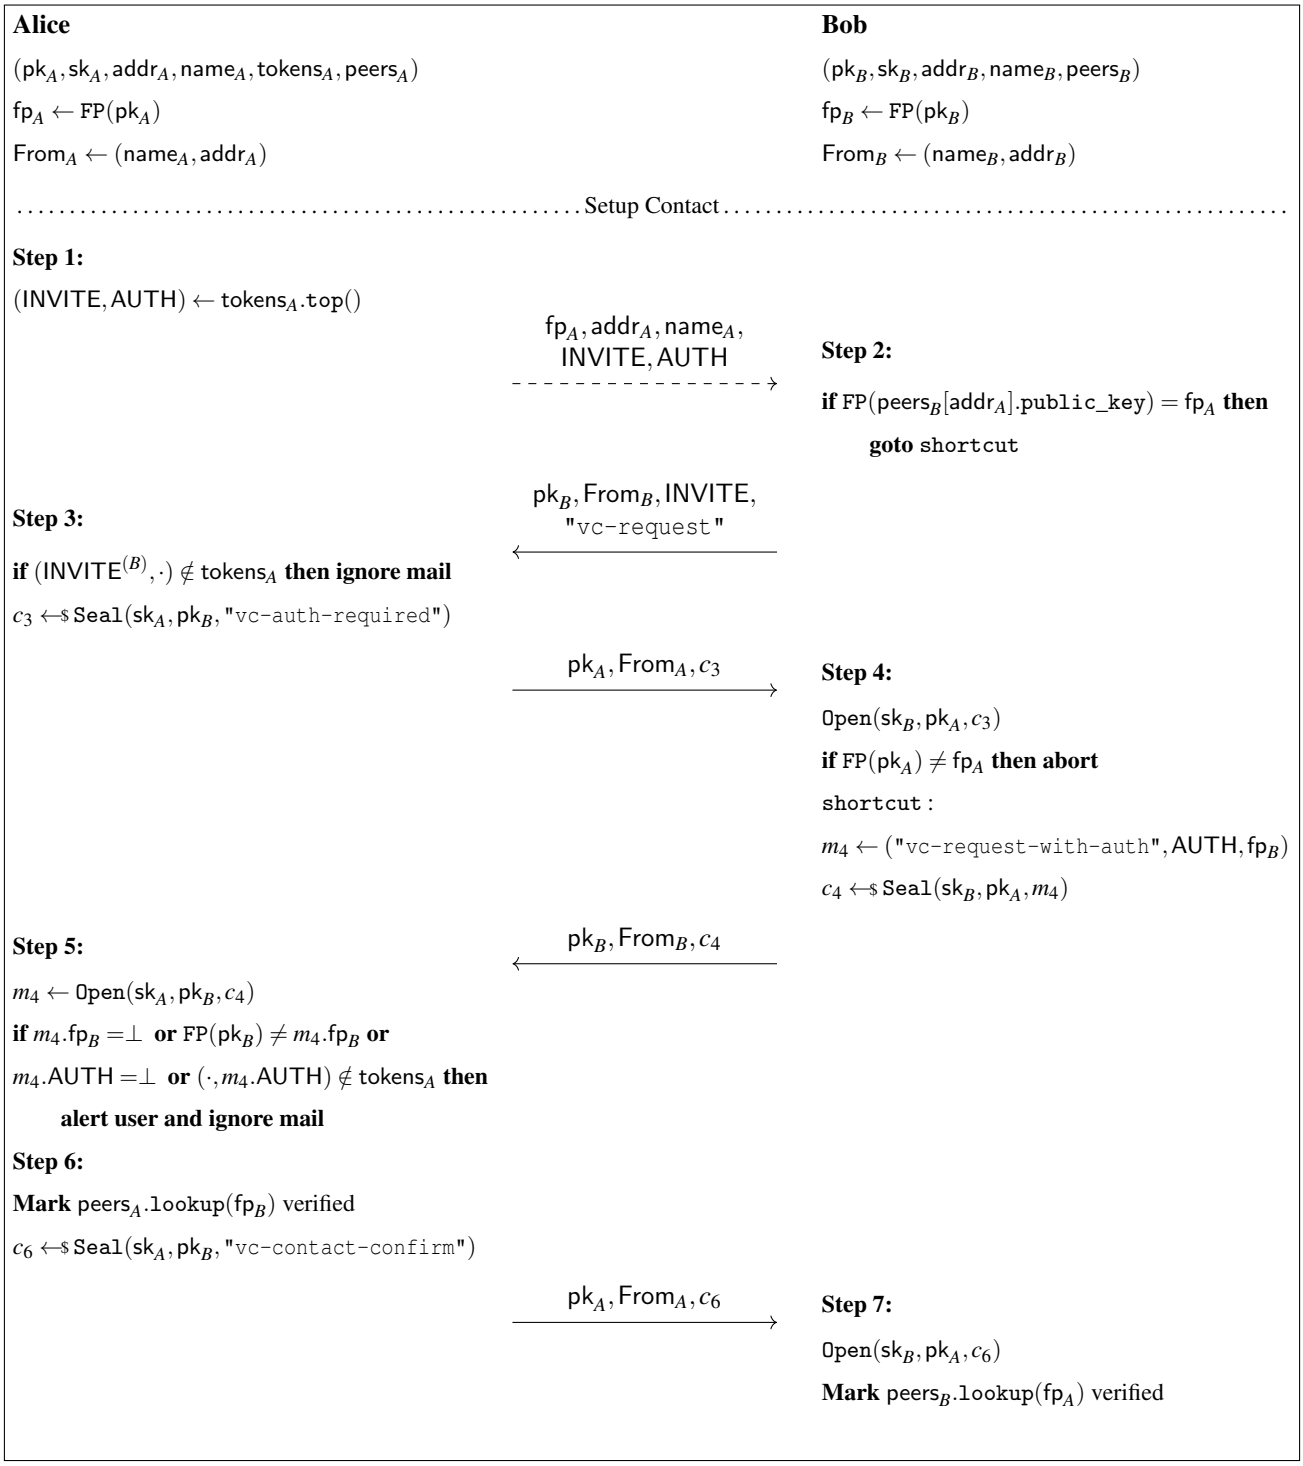

Figure 4: A simplified description of the Setup Contact protocol in Delta Chat. We assume messages on the wire are correctly formatted. Delta Chat checks message labels before possible signature verification and ignores messages with incorrect labels. If `Open` fails on verification, then Alice's client alerts the user and ignores the message, while Bob's client aborts the protocol; for all other `Open` failures, including during decryption and decompression, Delta Chat ignores the message. We do not include fields that are sent by honest participants but are not checked by their peers' clients. We also omit the Autocrypt key update process (Section 3.1), implicitly assuming that the effective dates for outbound messages are increasing for each participant.

ENG25519: Faster TLS 1.3 handshake using optimized X25519 and Ed25519

Abstract

The IETF released RFC 8446 in 2018 as the new TLS 1.3 standard, which recommends using X25519 for key exchange and Ed25519 for identity verification. These computations are the most time-consuming steps in the TLS handshake. Intel introduced AVX-512 in 2013 as an extension of AVX2, and in 2018, AVX-512IFMA, a submodule of AVX-512 to further support 52-bit (integer) multipliers, was implemented on Cannon Lake CPUs.

This paper first revisits various optimization strategies for ECC and presents a more performant X25519/Ed25519 implementation using the AVX-512IFMA instructions. These optimization strategies cover all levels of ECC arithmetic, including finite field arithmetic, point arithmetic, and scalar multiplication computations. Furthermore, we formally verify our finite field implementation to ensure its correctness and robustness.

In addition to the cryptographic implementation, we further explore the deployment of our optimized X25519/Ed25519 library in the TLS protocol layer and the TLS ecosystem. To this end, we design and implement an OpenSSL ENGINE called ENG25519, which propagates the performance benefits of our ECC library to the TLS protocol layer and the TLS ecosystem. The TLS applications can benefit directly from the underlying cryptographic improvements through ENG25519 without necessitating any changes to the source code of OpenSSL and applications. Moreover, we discover that the cold-start issue of vector units degrades the performance of cryptography in TLS protocol, and we develop an auxiliary thread with a heuristic warm-up scheme to mitigate this issue.

Finally, this paper reports a successful integration of the ENG25519 into an unmodified DNS over TLS (DoT) server called `unbound`, which further highlights the practicality of the ENG25519. We also report benchmarks of TLS 1.3 handshake and DoT query, achieving a speedup of 25% to 35% for TLS 1.3 handshakes per second and an improvement of 24% to 41% for the peak server throughput of DoT queries.

1 Introduction

In the TLS 1.3 standard [46] released by IETF in 2018, the elliptic curve cryptographic (ECC) algorithms X25519 [2] and Ed25519 [6] are recommended as the standard key exchange and identity verification algorithms. These two public-key cryptographic (PKC) algorithms are the security-critical and time-consuming steps in the TLS handshake.

In today's society, people are becoming increasingly reliant on online services, such as e-commerce and social media. For these online services, the challenge of slower service responses or even service outages due to increased load is something that service providers have to contend with, especially during times of surging user access. For instance, during events like Black Friday sales, website traffic can surge to levels 30 times higher than usual [51], and social media services can experience crashes due to sudden spikes in user traffic [1, 29]. Additionally, DNS and its privacy-enhanced variant, DNS over TLS (DoT), serving a massive user base, are integral parts of the internet's infrastructure [16].

These online services undoubtedly rely on the TLS protocol to secure communication. However, the TLS handshake, as the core of the entire protocol, involving complex cryptographic computations, poses a potential bottleneck limiting the quality improvements of these online services. This paper aims to address the challenges of mitigating the computational burden introduced by the TLS handshake, especially in high-load server scenarios. This paper takes a bottom-up methodology to solve this problem, starting from optimizing cryptographic algorithms at the lowest level, proceeding to the OpenSSL layer, and ultimately reaching the TLS application layer.

1.1 Motivations

The motivations of this paper, from the lower cryptographic layer to the higher application layer, are as follows:

(1) Previous work has extensively explored the efficient ECC implementation using the advanced Single Instruction

Multiple Data (SIMD) instructions on various CPUs, including NEON instructions on ARM CPUs and AVX2/AVX-512 instructions on Intel CPUs (e.g. [7, 15, 18, 25, 35]). But only a few of them (e.g. [18, 25]) focused on optimizing ECC using the latest AVX-512 on Intel CPUs. Additionally, the existing ECC optimizations using AVX-512 did not maximize the parallelism potential of AVX-512 or utilize the more powerful 52-bit (integer) multipliers in AVX-512IFMA (Integer Fused Multiply-Add). Therefore, we try to fill this gap by utilizing the powerful AVX-512IFMA to speed up cryptographic computations, thus alleviating the computational burden on servers.

(2) While many implementations have sought to improve the efficiency of ECC, they often neglect the integration of optimized ECC into TLS libraries and the broader TLS ecosystem. As a result, the TLS ecosystem cannot actually benefit from these ECC optimizations at large. Therefore, investigating how to integrate the optimized ECC implementation into a TLS application without modifying its source code would enable us to explore the tangible performance enhancements that the low-level ECC optimizations provide for high-level TLS applications. We aim to constitute a systematic study covering not only cryptographic optimization but also the integration into the TLS ecosystem.

(3) When integrating the optimized ECC implementation into the TLS ecosystem, we find that the vector units' (e.g. AVX2 or AVX-512) cold-start issue leads to noticeable performance degradation of cryptographic primitives. Based on our observations, the relevant primitives are even 3.8× slower than usual. This finding motivates us to systematically examine and alleviate the adverse effects of the cold-start issue on real-world TLS applications.

(4) The TLS protocol has become a cornerstone of safeguarding privacy in today's digital landscape. The TLS handshake, as the central component of the TLS protocol, involving complex cryptographic computations, serves as a potential bottleneck, constraining service quality improvements in various contexts like DoT, e-commerce, and social media. This motivates us to address the above-mentioned issues and develop a solution to mitigate the computational burden caused by the TLS handshake.

1.2 Major contributions

Our artifact is available at https://github.com/Ji-Peng/eng25519_artifact. This work has four main contributions.

First, we investigate how to maximize the parallelism potential of AVX-512IFMA and utilize its 52-bit multipliers to speed up the ECC arithmetic, including finite field arithmetic, point arithmetic, and scalar multiplication. To achieve this, we adopt a radix-2^{51} big number representation tailored for the 52-bit multiplier of AVX-512IFMA, we develop an efficient finite field arithmetic implementation, whose correctness is formally verified using the semi-automatic tool CRYPTOLINE. Besides, we show that by adopting the 8-way parallelism in the low-level finite field arithmetic, we can explore more parallelism strategies (see Figure 2 for the overview of our strategies) for the upper layers of ECC. With these optimizations, we achieve new speed records for X25519-KeyGen, Ed25519-Sign, and Ed25519-Verify. However, the X25519-Derive function used to compute the shared secret key is limited by its inherent execution flow and data dependencies; thus, we cannot achieve a faster implementation.

Then, we design and implement an OpenSSL ENGINE called ENG25519 to speed up the TLS ecosystem. The ENG25519 could transparently integrate our optimized cryptographic library into OpenSSL and, ultimately, into TLS applications. We demonstrate the successful integration of ENG25519 into `unbound`, a DNS over TLS (DoT) server, to further illustrate its practicality and conduct a systematic study under the DoT scenario. Compared with other related work ([5, 9]), the ENG25519 is superior to `libsuola` in [9], as an ENGINE template, in integrating ECC implementation to the TLS layer, because it has been verified to successfully reach the TLS application layer.

Then, we evaluate the performance of the cryptographic algorithms in realistic TLS application scenarios rather than just using ideal warm-start benchmark testing. We accomplish this by testing the DoT query scenario, concluding that these cryptographic computations are not warm-started, and performance suffers to varying degrees of degradation compared to the warm-start benchmark. Some subroutines even take 3.8× longer than their warm-start CPU cycles, making the cryptographic implementers "get half the results with twice the effort". To resolve the cold-start issue in realistic TLS application scenarios, we developed an auxiliary thread with a heuristic warm-up scheme for preventing vector units from entering a low-power mode. Besides, our $8 \times$ 1-way X25519-KeyGen is utilized with a focus on cache friendliness and optimal performance. To achieve this, we call the key generation subroutine multiple times when necessary and save the extra keypairs for future use, as the key generation is independent of the communication peer's information and can be precomputed for enhanced cache friendliness[1] and efficiency.

Finally, in the TLS application layer, we achieve a speedup of 25% to 35% for TLS 1.3 handshakes per second and an improvement of 24% to 41% for the peak server throughput of DoT queries. This implies that this paper presents an effective solution to mitigate the computational burden imposed by TLS handshakes for throughput-critical online services. Besides, our study demonstrates that the parallel strategies employed in our ECC implementation, the ENG25519 framework, and the proposed heuristic warm-up scheme for mitigating the cold-start issue of vector units can be extended to related work in this field, and our findings have broad implications and can contribute to parallel computing in ECC and

[1] The cache friendliness involves L1 instruction and L1 data cache of CPU.

other related areas.

2 Background

This section introduces the relevant technical background. In Section 2.1, we briefly introduce the AVX-512 instructions. Next, we describe the algorithmic background of X25519 and Ed25519 in Section 2.2. Finally, we introduce the TLS 1.3 handshake and DNS over TLS (DoT) in Section 2.3.

2.1 AVX-512

As the latest version of the AVX instruction set, AVX-512 provides double-sized vectors compared to AVX2. AVX-512 provides 32 512-bit registers that enable flexible operation for a greater range of parallel data, such as eight 64-bit or four 128-bit lanes.

Apart from the core extension AVX-512F (Foundation), which all AVX-512 implementations require, AVX-512 supports many submodules, such as AVX-512IFMA (Integer Fused Multiply-Add). One of AVX-512IFMA's critical features is the 52-bit integer multiplier, which is the widest multiplier in the SIMD instructions of the current x86-64 series CPUs. Indeed, AVX2 and AVX-512F multiplier have a width of only 32 bits.

AVX-512 introduces new concepts, such as mask operations and broadcasts. The mask operation allows for precise control over the specific behavior of SIMD instructions. The mask instruction specifies the lanes that should be executed or disregarded for a given operand. For more details about AVX-512IFMA instructions, we refer to Appendix A.

2.2 X25519 and Ed25519

X25519 and Ed25519 are constructed from the Montgomery [33] and twisted Edwards [4] curves, respectively. In 2015, RFC 7748 [30] introduced the construction of the Diffie-Hellman protocol based on Curve25519 with 128-bit security, referred to as X25519. X25519 has two stages: key generation (KeyGen) and shared secret calculation (Derive). The core operation of KeyGen is a fixed-point scalar multiplication, and the core operation of Derive is a variable-point scalar multiplication (see [30] for more details).

In 2017, the Edwards-curve Digital Signature Algorithm (EdDSA) named Ed25519, with the same security level as X25519, was introduced in RFC 8032 [28]. It is suggested that Curve25519 is birationally equivalent to Edwards25519, the underlying curve of Ed25519 [6, Sec 2]. Ed25519 consists of three stages: key generation (KeyGen), signature generation (Sign), and signature verification (Verify). The core operation of KeyGen and Sign is a fixed-point scalar multiplication, while the core operation of Verify is a double-point scalar multiplication (see [28] for more details). Later in 2018, RFC 8446 [46] included X25519 and Ed25519 into the cipher suite supported by TLS 1.3.

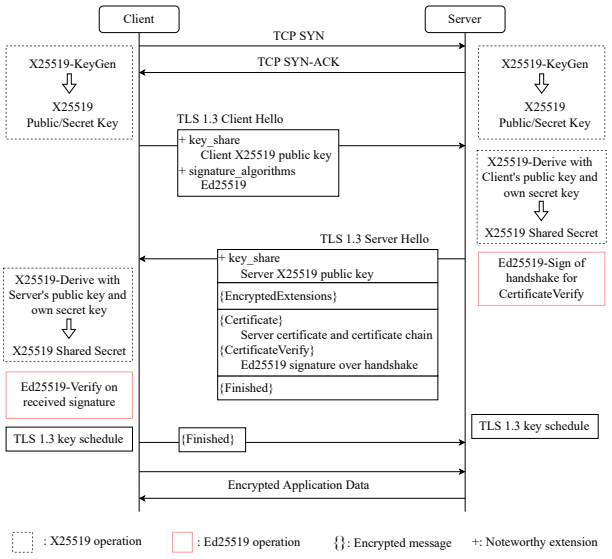

Figure 1: Overview of TLS 1.3 handshake with X25519 for key exchange and Ed25519 for digital signature

The efficient coordinates for implementing the point arithmetic of Edwards25519 are the extended twisted Edwards coordinates [26, Sec 3], which can be expressed as (X,Y,T,Z). Here, T is an auxiliary coordinate that holds $T = XY/Z$. The identity element is $(0,1,0,1)$, and the negative element of (X,Y,T,Z) is $(-X,Y,-T,Z)$.

To avoid confusion among the three terms: Curve25519, X25519, and Ed25519, Bernstein standardized their description in [3], describing "X25519" as the Diffie-Hellman key exchange system on Montgomery curve, "Ed25519" as elliptic curve signature system on twisted Edwards curve, and "Curve25519" as the underlying elliptic curve of X25519/Ed25519.

2.3 TLS 1.3 and DNS over TLS (DoT)

To illustrate the basic flow of the TLS 1.3 handshake, we present a simplified flow chart (see Figure 1) of the TLS 1.3 handshake, assuming that X25519 is used for key exchange and Ed25519 is used for digital signature. The handshake is primarily accomplished through the `Client Hello` and `Server Hello` messages and related extensions. The cryptographic operations performed by the client include X25519-KeyGen, X25519-Derive, and Ed25519-Verify, while the server's cryptographic operations include X25519-KeyGen, X25519-Derive, and Ed25519-Sign. The X25519 public key is transmitted through the `key_share` extension, and the Ed25519 signature is sent via the `CertificateVerify` extension. For more relevant details, we refer readers to the RFC 8446 [46].

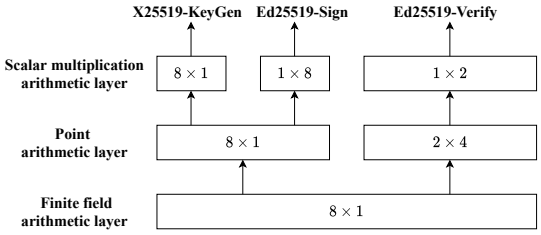

Figure 2: An overview of our ECC implementation. Please refer to Section 3.1 for the meaning of $m \times n$-way operation.

DNS over TLS (DoT) is specified in RFC 7858 [27], which can protect user privacy by encrypting and wrapping DNS queries and responses via TLS. Given the security guarantees of the TLS layer, DoT can impede the monitoring and analysis of DNS traffic. The workflow of DoT is that the client and server establish a TLS connection via a TLS handshake, and then DNS queries and responses are sent and received through this TLS connection. A DoT client can establish a TLS connection with a DoT server via a TLS handshake, only to send a DNS query and close the connection after receiving the corresponding DNS response. In this case, the overhead proportion of the TLS handshake will be more significant, highlighting the role of the handshake's speed optimization.

3 Optimized X25519 and Ed25519 Implementation

This section presents our bottom-up optimized implementation of X25519 and Ed25519. Our optimizations cover all layers of the ECC implementation, including finite field arithmetic, point arithmetic, and scalar multiplication. The finite field arithmetic consists primarily of the basic operations in $\mathbb{F}_p$, such as addition, subtraction, multiplication, square, and inversion modulo p. The point arithmetic includes point addition and point doubling on elliptic curves. The scalar multiplications involves fixed-point, variable-point, and double-point scalar multiplications.

Each layer of ECC implementation has different parallelism strategies. Figure 2 shows an overview of the proposed ECC implementation. To clarify the description, we provide a parallelism hierarchy division method and a vital optimization principle — the MTP principle — in Section 3.1. Overall, we implement the 8×1-way finite field arithmetic with the 52-bit multiplier of AVX-512IFMA in Section 3.2, maximizing its parallelism. Then, we further show that the underlying 8×1-way finite field arithmetic can transfer more parallelism to the upper layer, i.e. 8×1-way and 2×4-way point arithmetic in Section 3.3. Based on these point arithmetic implementations, we further implement the 8×1-way fixed-point scalar multiplication, 1×8-way fixed-point scalar multiplication in Section 3.4, and 2×4-way double-point scalar multiplication in Section 3.5 for X25519-KeyGen, Ed25519-Sign, and Ed25519-Verify, respectively. A comparison with other work is given in Section 3.6.

Key generation is an independent process that does not rely on information from the communication peer during the TLS handshake (see Figure 1). Therefore, one could generate eight different keypairs by calling our 8×1-way X25519-KeyGen subroutine once and save them in the machine. When a new keypair is needed for the next TLS handshake, it can be retrieved directly from the remaining keypairs without executing X25519-KeyGen again. If no keypairs are left, the machine will generate a new batch.

However, X25519-Derive, Ed25519-Sign, and Ed25519-Verify all rely on the message of the communication peer, making their 8×1-way implementation difficult to integrate into the TLS layer. Using an asynchronous programming framework to collect eight requests asynchronously and then perform the 8×1-way operation requires refactoring the TLS applications' source code. This is contrary to the original intention of this paper, namely benefiting the TLS applications from cryptographic optimization without modifying their source code. Thus, integrating other 8×1-way implementations into the TLS layer will be our future work. We only present the optimized 8×1-way X25519-KeyGen, 1×8-way Ed25519-Sign and 1×2-way Ed25519-Verify in this paper.

3.1 Parallelism hierarchy

We use the paradigm "finite field arithmetic" $\rightarrow$ "point arithmetic" $\rightarrow$ "scalar multiplication" to represent our parallelism strategy. For example, our optimized Ed25519-Verify strategy is $8 \times 1 \rightarrow 2 \times 4 \rightarrow 1 \times 2$ (cf. Figure 2), which can also be abbreviated as 1×2-way Ed25519-Verify. X25519-Derive is an exception since the variable-point scalar multiplication (i.e. Montgomery ladder algorithm) is directly contructed on top of the finite field layer. Thus, the paradigm of X25519-Derive is "finite field arithmetic" $\rightarrow$ "Montgomery ladder".

The AVX-512's 512-bit registers allow the 8×64-bit partition (i.e. 8 lanes, each of which holds 64 bits), and these 8 lanes can be used to implement 8×1, 4×2, 2×4, or 1×8-way finite field arithmetic.

- **Interpretation of parallelism**. In the implementation that follows $m \times n$ parallelism, "m" represents the number of independent operations simultaneously executed in parallel within this layer, while "n" refers to the degree of acceleration attained by each independent operation. Taking the 4×2-way finite field implementation as an example, "4" means that four independent finite field operations are executed in parallel, and "2" means that 2-way acceleration is performed inside each finite field operation.
- **Transfer of parallelism.** The "m" indicates the number of independent operations occurring at this layer that

can be transferred to the upper layer; "n" signifies the amount of parallelism digested by this layer. Take the 4×2-way finite field implementation as an example. The four independent arithmetic of the finite field layer can be passed upwards to the point arithmetic layer, namely implementing the point arithmetic in the form of 4×1-way, 2×2-way, or 1×4-way.

- **MTP optimization principle.** We notice that if we digest "n" parallelism in the low-level finite field implementation, we will suffer from performance loss caused by permutation instructions. See Appendix B for a detailed comparison between the 4×2-way and 8×1-way finite field multiplication implementations. In brief, the 4×2-way finite field multiplication needs some awkward permutation instructions to construct the required execution flow, which will suffer a performance penalty due to the high latency of permutation instructions. In contrast, we can naturally construct the execution flow of 8×1-way multiplication, minimizing the permutation performance penalty. We propose the Maximized Transfer Parallelism (MTP) principle which aims to maximize the transfer of SIMD parallelism to the upper layer and avoid wasting parallelism in lower level layer.

3.2 8×1-way finite field arithmetic

Unlike the AVX2 implementation of Cheng et al. [15], which adopts the radix-2^{29} representation to implement their 4×1-way X25519. We employ the radix-2^{51} representation to fully utilize the 52-bit multiply-add instructions in AVX-512IFMA. Note that our method is not a straightforward generalization of [15] because they utilize the 32-bit multiplier of AVX2, while we utilize the 52-bit multiplier of AVX-512IFMA. Therefore, we need to re-design the finite field arithmetic.

The radix-2^{51} method divides the 255-bit elements into five 51-bit limbs and a finite field element f is represented as:

$$f = f_0 + 2^{51} f_1 + 2^{102} f_2 + 2^{153} f_3 + 2^{204} f_4 \tag{1}$$

where $0 \le f_i < 2^{52}$ for $0 \le i < 5$. Among all the finite field arithmetic, modular multiplication is an essential operation. The modular multiplication $f \times g$ consists of two steps: multiplication and modular reduction.

Step 1. Multiplication.

$$\begin{aligned} &h = f \times g = h_0 + 2^{51} h_1 + \cdots + 2^{51\cdot 8} h_8 + 2^{51\cdot 9} h_9, \\ &h_k = \sum_{i+j=k} (f_i g_j)_l + 2 \sum_{i+j=k-1} (f_i g_j)_h, \\ &\quad (0 \le i, j < 5,\ 0 \le k < 10) \end{aligned} \tag{2}$$

Step 2. Modular reduction. Its basic idea is as follows:

$$\begin{aligned} &p = 2^{51\cdot 5} - 19 \ \Rightarrow\ 2^{51\cdot 5} \equiv 19 \mod p \\ &2^{51\cdot 5} h_5 = 19 h_5, \cdots, 2^{51\cdot 9} h_9 = 2^{51\cdot 4} 19 h_9 \\ &h_0 \mathrel{+}= 19 h_5, h_1 \mathrel{+}= 19 h_6, \cdots, h_4 \mathrel{+}= 19 h_9 \end{aligned}$$

Then, the modular reduction can be performed in the following order:

$$\begin{aligned} &①h_5 \to h_6, ②h_6 \to h_7, ③h_7 \to h_8, ④h_8 \to h_9, \\ &⑤19^2(h_9 >> 51) \to h_0|h_1, ⑥19h_5 \to h_0|h_1, \\ &⑦19h_6 \to h_1|h_2, ⑧19h_7 \to h_2|h_3, ⑨19h_8 \to h_3|h_4, \\ &⑩19h_9 \to h_4|h_5, ⑪19h_5 \to h_0 \end{aligned} \tag{3}$$

In step 1, the 52-bit multiplier separates the lower 52-bit and upper 52-bit of the 104-bit product into two registers. In Equation 2, the subscript l and h represents the lower 52-bit and upper 52-bit of the product, respectively. To fit with the radix-2^{51} representation, the upper 52-bit $(f_i g_j)_h$ is converted from $2^{52} 2^{51\cdot(i+j)} (f_i g_j)_h$ to $2^{51\cdot(i+j+1)} 2 (f_i g_j)_h$, and is accumulated to the corresponding limb.

In step 2, the paradigm $h_5 \to h_6$ means replacing (h_5, h_6) with $(h_5 \bmod 2^{51}, h_6 + \lfloor h_5 / 2^{51} \rfloor)$; the paradigm $19^2(h_9 >> 51) \to h_0|h_1$ means replacing (h_0, h_1) with $(h_0 + (19^2(h_9 >> 51))_l, h_1 + 2(19(h_9 >> 51))_h)$. The bit length of $h_i (i = 5, \cdots, 9)$ may exceed 52 before the modular reduction. To utilize the 52-bit multiplier, we must propagate the carry that exceeds 51-bit to the higher limb. After the carry propagation (i.e. ① to ⑤), the modular reduction of ⑥ to ⑪ is performed.

The carry chain has many data dependencies that cause extra latency to the computational process. Therefore, we adjust the carry order and perform it in the following order: ①③⑤②④⑥⑧⑩⑦⑨⑪. Apart from the modular multiplication, the carry propagation of modular addition and subtraction undergoes similar optimization.

In terms of data type, we adopt similar terminology from [15, Sec 3.1]. The fundamental data type used in the 8×1-way finite field arithmetic is the vector set V, which consists of 5 vectors (i.e. 512-bit registers) v_i $(0 \le i < 5)$, and each vector contains 8 limbs from different finite field elements. The vector set V is defined as:

$$\begin{aligned} V &= [a, b, \cdots, g, h] \\ &= \left[\sum_{i=0}^{4} 2^{51i} a_i, \sum_{i=0}^{4} 2^{51i} b_i, \cdots, \sum_{i=0}^{4} 2^{51i} g_i, \sum_{i=0}^{4} 2^{51i} h_i \right] \\ &= \sum_{i=0}^{4} 2^{51i} [a_i, b_i, \cdots, g_i, h_i] = \sum_{i=0}^{4} 2^{51i} v_i \end{aligned} \tag{4}$$

where $v_i = [a_i, b_i, \cdots, g_i, h_i]$, and all of the $a_i, b_i, \cdots, g_i, h_i$ are 51-bit or 52-bit limbs. Each register comprises eight 64-bit lanes, with each lane storing a 51-bit or 52-bit limb. In the 8×1-way finite field arithmetic, eight limbs in one register come from eight different finite field elements. Based on this data structure, we implemented the 8×1-way modular addition, subtraction, multiplication, square, and inversion using AVX-512IFMA.

Formal verification of our finite field implementation The finite field implementation is critical for performance

Algorithm 1 2×4-way point addition.

Input: $[P,J] = [X_P, Y_P, T_P, Z_P, X_J, Y_J, T_J, Z_J]$; $[Q^{pre}, K^{pre}] = [Y_Q - X_Q + 2p, Y_Q + X_Q, 2dT_Q, 2Z_Q, Y_K - X_K + 2p, Y_K + X_K, 2dT_K, 2Z_K]$; P, Q, J, and K are points on Edwards25519; Q^{pre} is the precomputed format of Q, which is generally obtained from a precomputed table.

Output: $[R,S] = [X_R, Y_R, T_R, Z_R, X_S, Y_S, T_S, Z_S]$ such that $R = P + Q$, $S = J + K$.

and security in ECC. Even minor errors in the finite field implementation can lead to severe consequences such as cryptographic attacks or functional failures [8]. We utilize a semi-automatic formal verification tool, CRYPTOLINE [21, 32], to provide mathematical guarantee of its correctness. For more details, see the artifact of this work.

3.3 8×1-way and 2×4-way point arithmetic

X25519-KeyGen is always computed on the Edwards curve, and then the result is converted to the equivalent Montgomery curve. X25519-Derive generally adopts the Montgomery ladder algorithm, and we can not achieve a new speed record. We therefore only focus on the point arithmetic on the Edwards curve. For the point addition formula on twisted Edwards curves, giving $P = (X_P, Y_P, T_P, Z_P)$ and $Q = (X_Q, Y_Q, T_Q, Z_Q)$ in the format of extended twisted Edwards coordinates [26, Sec 3], $R = P + Q = (X_R, Y_R, T_R, Z_R)$ is calculated as follows:

$$\begin{array}{ll} A \leftarrow (Y_P - X_P) \times (Y_Q - X_Q), & B \leftarrow (Y_P + X_P) \times (Y_Q + X_Q), \\ C \leftarrow 2d \times T_P \times T_Q, & D \leftarrow 2Z_P \times Z_Q, \\ E \leftarrow B - A, & F \leftarrow D - C, \\ G \leftarrow D + C, & H \leftarrow B + A, \\ X_R \leftarrow E \times F, & Y_R \leftarrow G \times H, \\ Z_R \leftarrow F \times G, & T_R \leftarrow E \times H. \end{array} \tag{5}$$

By scheduling eight independent point additions (i.e. above formula) into each lane of the 8×1-way finite field arithmetic, we arrive at $8 \times 1 \rightarrow 8 \times 1$. The 8×1-way point doubling follows a similar approach.

Faz-Hernández et al. [18, Alg 4] implemented a 1×4-way point addition based on 4×1-way finite field arithmetic using AVX2 instructions. However, limited by its calculation flow, the point addition cannot be extended to 1×8-way. Consequently, we design a 2×4-way point addition, shown in Algorithm 1, to handle this shortcoming. In Algorithm 1, $+2p$ ensures that the result of subtraction remains within the non-negative range. Whereby the permutation instruction PERM and mask instruction MADD/MSUB are mentioned in Appendix A. The 2×4-way point doubling is computed in a similar manner.

3.4 8×1-way and 1×8-way fixed-point scalar multiplication

We adopt the terminology of searching a point from precomputed tables in [18, Sec 4.1]. For a fixed-point scalar multiplication kP, where P is known beforehand, precomputing several multiples of P can effectively reduce the computational overhead. In this case, the scalar k is a 253-bit[2] integer. Let $t = \lceil 253/\omega \rceil$ with $\omega > 0$. We precompute a set of t tables; each contains $2^{\omega-1}$ points. These tables are defined as $T_u = \{T_u(v) = 2^{\omega u} vP \mid \text{for } 1 < v \leq 2^{\omega-1}\}$ for $0 \leq u < t$. Searching for a point from these tables is defined as:

$$\phi(T_u, v) = \begin{cases} T_u(v), & \text{if } v > 0 \\ -T_u(-v), & \text{if } v < 0 \\ O, & \text{otherwise .} \end{cases} \tag{6}$$

The scalar k is recoded into signed segments $(k_0, \cdots, k_{t-1})$, such that $k = \sum_{j=0}^{t-1} 2^{\omega j} k_j$ and $-2^{\omega-1} \leq k_j < 2^{\omega-1}$ (see [18, Alg 5] for the recoding algorithm). This work employs $\omega = 4$ and $t = 64$ and only precomputes even-indexed tables (i.e. all T_u for even u) to reduce memory consumption. We utilize a secure and constant-time masking technique to search for points from these tables, which avoids secret-key indexing and potential side-channel attacks.

8×1-way implementation for X25519-KeyGen Using the 8×1-way implementation, eight independent scalar multiplications can be computed in parallel based on our 8×1-way point arithmetic. The calculation of each scalar multiplication is as follows.

$$kP = \sum_{j=0}^{31} \phi(T_{2j}, k_{2j}) + 2^4 \sum_{j=0}^{31} \phi(T_{2j}, k_{2j+1}). \tag{7}$$

Such a formula is viewed as a lane in our 8×1-way point addition. When eight independent scalar multiplications are computed in parallel, we arrive at $8 \times 1 \rightarrow 8 \times 1 \rightarrow 8 \times 1$.

[2] 253 is the bit length of the elliptic curve group order ℓ of Curve25519. The scalar is guaranteed to lie within the range of $[0, \ell)$ before executing the scalar multiplication.

Algorithm 2 Optimized double-point scalar multiplication.

Input: (k,l,P,Q), where k and l are 253-bit[4] scalars, P and Q are points on Edwards25519 curve, P is a fixed point, and Q is a variable point. The precomputed table $tableP \leftarrow \{O,P,2P,\cdots,2^{\omega-1}P\}$, where ω is the width of the window, O is the identity element of elliptic curve group, and $tableP$ can be precomputed offline since P is a fixed point.

Output: $R = kP + lQ$.

1: Compute $tableQ \leftarrow \{O,Q,2Q,\cdots,2^{\omega-1}Q\}$ at runtime
2: $(k_0,k_1,\cdots,k_{r-1}) \leftarrow \text{Recoding}_\omega(k)$ ▷ $r = \lceil 253/\omega \rceil + 1$
3: $(l_0,l_1,\cdots,l_{r-1}) \leftarrow \text{Recoding}_\omega(l)$
4: $[M,N] \leftarrow [O,O]$
5: $[A,B] \leftarrow [\pm tableP[|k_{r-1}|], \pm tableQ[|l_{r-1}|]]$ ▷ The sign of the point taken from tables follows the sign of the corresponding scalar fragments (i.e. k_{r-1} and l_{r-1} here).
6: $[M,N] \leftarrow [M,N] + [A,B]$ ▷ Using our 2×4-way point addition.
7: **for** $i \leftarrow r-2$ to 0 **do**
8: $\quad [M,N] \leftarrow 2^\omega [M,N]$ ▷ Using our 2×4-way point doubling ω times.
9: $\quad [A,B] \leftarrow [\pm tableP[|k_i|], \pm tableQ[|l_i|]]$
10: $\quad [M,N] \leftarrow [M,N] + [A,B]$
11: **end for**
12: $R \leftarrow M + N$
13: **return** R

1×8-way implementation for Ed25519-Sign The calculation of kP using our 1×8-way strategy is shown as follows.

$$\begin{aligned} kP = &\sum_{j=0}^{7} \phi(T_{2j}, k_{2j}) + 2^4 \sum_{j=0}^{7} \phi(T_{2j}, k_{2j+1}) \\ &+ \sum_{j=8}^{15} \phi(T_{2j}, k_{2j}) + 2^4 \sum_{j=8}^{15} \phi(T_{2j}, k_{2j+1}) \\ &+ \sum_{j=16}^{23} \phi(T_{2j}, k_{2j}) + 2^4 \sum_{j=16}^{23} \phi(T_{2j}, k_{2j+1}) \\ &+ \sum_{j=24}^{31} \phi(T_{2j}, k_{2j}) + 2^4 \sum_{j=24}^{31} \phi(T_{2j}, k_{2j+1}), \end{aligned} \tag{8}$$

where the eight accumulators are computed in parallel by the 8×1-way point arithmetic and ultimately arrive at $8 \times 1 \rightarrow 8 \times 1 \rightarrow 1 \times 8$.

3.5 2×4-way double-point scalar multiplication

The core operation of Ed25519-Verify is a double-point scalar multiplication, i.e. $kP + lQ$, where k and l are scalars (i.e. 253-bit integers), P is a fixed point, and Q is a variable point.

Faz-Hernández et al. [18, Alg 6] adopted a w-NAF [47] method to compute the double-point scalar multiplication.

Table 1: The number of point addition (PA) and point doubling (PD) of our double-point scalar multiplication with different window widths.

ω	PD	PA	PA+0.97PD[1]
3	257	88	338
4	259	68	320
5	260	57	310
6	267	53	312
7	276	55	323

[1] The proposed 2×4-way point addition and point doubling implementation consume 181 and 176 CPU cycles, respectively in our machine.

Their parallelism strategy is $4 \times 1 \rightarrow 1 \times 4 \rightarrow 1 \times 1$ using AVX2, which shows that the point arithmetic layer digests all the parallelism. It is suboptimal according to the MTP principles. Moreover, they also admit (in [18, Sec 4.2]) that they cannot provide a more efficient strategy due to the inherent sequential pattern of the w-NAF method.

Instead of using the w-NAF method, we design a window-based method to break the parallelism limit. We describe the basic idea of the window-based method [23, Alg 3.41] with a simple example. Calculating scalar multiplication $51P$ with window width $\omega = 3$ and signed encoding is shown as follows. (1) Recode the scalar 51 into signed w-bit segments, i.e. $(1,-2,3)$ such that each value lies within the range of $[-2^{3-1}, 2^{3-1})$ and $1 \cdot 2^{3 \cdot 2} - 2 \cdot 2^{3 \cdot 1} + 3 \cdot 2^{3 \cdot 0} = 51$. (2) Scan segments from left to right and accumulate them. $R \leftarrow O, R \leftarrow R+1P, R \leftarrow 2^3 R, R \leftarrow R+(-2P), R \leftarrow 2^3 R, R \leftarrow R+3P$, where O is the identity element of elliptic curve group, "+" means point addition, and $2^3 R$ is completed by three times of point doublings. $1P$, $2P$, and $3P$ are all obtained from a precomputed table, $-2P$ is obtained by negating $2P$. For a fixed point, precomputation can be performed offline; for a variable point, precomputation has to be run online.

The starting point is to design a window-based method to construct the double-point scalar multiplication. Instead of computing $R \leftarrow R + iP$ solely, we compute $R \leftarrow R + iP$ and $R' \leftarrow R' + jQ$ in parallel for constructing a 2×4-way point arithmetic naturally, where i and j are scalar fragments. Finally, we arrive at $8 \times 1 \rightarrow 2 \times 4 \rightarrow 1 \times 2$. In this way, the finite field layer does not digest parallelism ahead of time. Two parallelisms are passed to the top-most scalar multiplication layer, thus minimizing the permutation performance penalty at the bottom layer.

We present our double-point scalar multiplication in Algorithm 2. The $\text{Recoding}_\omega()$ subroutine in lines 2 and 3 is used to recode a 253-bit scalar k into a series of signed segments such that $k = \sum_{i=0}^{r-1} 2^{\omega i} k_i$, where $r = \lceil 253/\omega \rceil + 1$, ω is the width of the window, and $-2^{\omega-1} \le k_i < 2^{\omega-1}$. See [18, Alg 5] for more details of the $\text{Recoding}_\omega()$ subroutine.

Table 2: The CPU cycles comparison of different X25519 implementations under warm-start conditions. Hisil et al. [25] and Nath et al. [35] only provided optimized X25519-Derive implementation. ISA/ISE stands for Instruction Set Architecture/Extension.

Reference	X25519-KeyGen			X25519-Derive			ISA/ISE
	Cycles	Ratio[1]	Strategy	Cycles	Ratio[2]	Strategy[3]	
OpenSSL [41]	90,809	12.01	$1\times1\rightarrow1\times1\rightarrow1\times1$	90,849	1.47	$1\times1\rightarrow1\times1$	x86-64
Faz-H. [18]	26,420	3.49	$4\times1\rightarrow4\times1\rightarrow1\times4$	71,454	1.15	$2\times2\rightarrow1\times2$	AVX2
Hisil [25]	-	-	-	61,867	1.00	$4\times2\rightarrow1\times4$	AVX-512F
Nath [35]	-	-	-	64,832	1.05	$4\times1\rightarrow1\times4$	AVX2
Cheng [15][4]	70,164	2.32	$4\times1\rightarrow4\times1\rightarrow4\times1$	-	-	-	AVX2
This work	60,479	1.00	$8\times1\rightarrow8\times1\rightarrow8\times1$	-	-	-	AVX-512IFMA

[1] Our 8×1-way X25519-KeyGen can generate eight different keypairs once. The implementation of Cheng et al. is a 4×1-way implementation; others are $1\times n$-way (one keypair once). Therefore, the ratio with Cheng et al. is $(70164/4)/(60479/8)=2.32$. Other calculations are similar to this.

[2] We don't provide a faster X25519-Derive implementation. All comparisons are made with Hisil et al.

[3] The strategy is represented as "finite field" $\rightarrow$ "Montgomery ladder".

[4] Cheng et al. provide a 4×1-way implementation of the X25519-Derive, but as Section 3 said, integrating it into the TLS ecosystem needs to re-engineer the TLS application so we do not present their cycles.

Determines the window's width ω The larger the value of ω, the larger the precomputation overhead of *tableQ* will be, and the number of point addition (PA) and point doubling (PD) in the main loop will be smaller. The computational cost of Algorithm 2 is mainly composed of the precomputation cost of *tableQ* and the main loop cost. The precomputation cost is $(2^{w-3}+1)PD+2^{w-3}PA$. The cost of the main loop is $w(r-1)PD+rPA$. Line 12 is a point addition to calculate the final result. We detail the computational cost for different ω in Table 1, and it is obvious that $\omega=5$ achieves the best performance.

3.6 Comparison

Note that the performance comparison in this section only considers the warm-start case. The cold-start case will be analyzed in Section 4.

Our benchmark machine is an Intel Xeon (Ice Lake) Platinum 8369B with 8 vCPUs and 16 GiB memory[3]. We use GCC 9.2.0 to compile all programs. We did not disable Turbo Boost option for the following reasons: Firstly, and most importantly, we aimed to simulate real-world application scenarios as closely as possible rather than conducting tests under ideal conditions. Secondly, extensive testing revealed that our experimental results remain reproducible even without disabling Turbo Boost, with no significant jitter observed.

The implementations of OpenSSL [40,41], Hisil et al. [25] and Cheng et al. [15], as well as this work are all compiled with the "-O2" flag[4], while the implementations of Faz-Hernández [18] and Nath et al. [35] are compiled with the "-O3" flag. Our experiment shows that the performance difference between "-O2" and "-O3" is negligible.

All performance reported in this section is warm-start performance; we run the subroutine 2,000 times before counting the CPU cycles to avoid the cold-start issue. The reported CPU cycles represent the average time taken to run the subroutine 20,000 times.

Table 2 compares our X25519 implementation with others. Even though OpenSSL's implementation is the slowest one in the table, a comparison with it is still needed. Since none of the previous work has integrated their implementations into OpenSSL, we need to use the OpenSSL implementation as a baseline when comparing metrics related to the TLS handshake. The ratio of CPU cycles of OpenSSL's X25519-KeyGen to our implementation is as high as 12.01; in other words, the throughput (executions per second) of our implementation is 12.01 times that of OpenSSL X25519-KeyGen. The proposed X25519-KeyGen achieves such a significant performance improvement because we pass the 8-way parallelisms of the AVX-512IFMA to the top layer thoroughly according to our MTP principles.

Table 3 provides a comparison of various Ed25519 implementations. Ed25519-Sign and Ed25519-Verify achieve 3.79 and 3.33 times higher throughput than OpenSSL, respectively. We also give the corresponding fixed-point scalar multiplication comparison in Table 4, showing that the throughput of our optimized fixed-point multiplication is 8.06 times and 1.67

[3] Our machine is leased from Alibaba Cloud. The family and instance type are compute optimized type c7 and ecs.c7.2xlarge, respectively. The 8 vCPUs can be approximately understood as 4 physical cores & 8 hyperthreads.

[4] For the implementation of OpenSSL, we need to extract the X25519 and Ed25519 implementation from the huge OpenSSL project to form a new small project for benchmark, so its compilation options are consistent with our implementation. For the implementation of Hisil et al., their compiling script did not work on our machine, so we refactored their project, and its compile options were also consistent with our implementation. Cheng et al. originally used the "-O2" option; they used the Clang compiler by default, and we changed it to GCC for a fair comparison.

Table 3: The CPU cycles comparison of different Ed25519 implementations under warm-start conditions. The comparison of Ed25519-KeyGen is not provided, partly because it is not used in TLS handshake and its performance is close to X25519-KeyGen.

4 Reaching TLS and Application layers

The goal of reaching TLS and the application layers is to explore the performance of cryptographic operations in realistic scenarios, including the impact of the cold-start issue of vector units. In Section 4.1, we implement ENG25519 to transparently integrate our optimized implementation into TLS applications. Section 4.2 explores the cold-start issue and presents our solution for alleviating this issue. We conduct several experiments in Section 4.3 and Section 4.4 to benchmark TLS handshakes and DoT queries, respectively, through the successful integration of ENG25519.

4.1 The ENG25519 ENGINE

We follow the methodology suggested in [49] for incorporating the optimized X25519 and Ed25519 implementation into the OpenSSL ENGINE framework. Interested readers can refer to this paper for more detailed descriptions.

In the OpenSSL framework, an ENGINE acts as a container for implementing cryptographic algorithms. OpenSSL has a built-in ENGINE called "dynamic" that loads other ENGINEs, such as our ENG25519, in the form of a shared library, dynamically at runtime. Thus, through the OpenSSL configuration file, the "dynamic" ENGINE loads ENG25519, and the optimized implementations of X25519 and Ed25519 are transparently integrated into both OpenSSL and TLS applications.

The ENG25519 is built based on `libsuola` [50] in [49] and `engntru`[5] [43] in [5]. However, while `libsuola` provided simple test cases to verify its correctness, it did not reach the TLS ecosystem. When we attempted to reach the TLS layer, we encountered two bugs in `libsuola` (see Appendix C for the fixes). Consequently, our ENG25519 is a better ENGINE template to integrate ECC implementations into the TLS layer than `libsuola`, as ENG25519 has been verified to reach both the TLS and application layers.

Table 5: Detailed configuration of ENG25519.

Subroutine	Implementation
X25519-KeyGen Ed25519-KeyGen	Our $8\times1\rightarrow8\times1\rightarrow8\times1$ impl. *batch-size* $=16$ (Section 3.4)
X25519-Derive	$4\times2\rightarrow1\times4$ impl. of Hisil et al. ([25])
Ed25519-Sign	Our $8\times1\rightarrow8\times1\rightarrow1\times8$ impl. (Section 3.4)
Ed25519-Verify	Our $8\times1\rightarrow2\times4\rightarrow1\times2$ impl. (Section 3.5)

The X25519 and Ed25519 are implemented through the EVP_PKEY_meth and the corresponding EVP_PKEY_ASN1_meth APIs within the OpenSSL framework, which are abstract data types provided by OpenSSL for public key cryptographic algorithms. The former API provides `keygen()` and `derive()` methods for X25519 implementation; provides `keygen()`, `sign()`, and `verify()` for Ed25519 implementation. The latter one provides encoding and decoding methods for the public and secret keys. Table 5 presents the detailed configuration of ENG25519.

To integrate our 8×1-way X25519-KeyGen into ENG25519, we implement a BATCH_STORE structure, as described in [5]. This structure holds a certain number of keypairs, i.e., 128 in our case. The `keygen()` method of X25519 accesses this structure to determine if there are any remaining keypairs. If so, it fetches them directly. Otherwise, it uses our 8×1-way X25519-KeyGen 16 times to regenerate the keypairs and repopulate the structure. We will discuss the design

[5] An OpenSSL ENGINE that can integrate the batched implementation of a post-quantum key exchange scheme, NTRU Prime, into TLS and TLS applications.

Table 6: Warm-start performance vs cold-start performance in the DoT query scenario. CC is the abbreviation of CPU cycles.

Subroutine	Warm-start CC	Cold-start CC (DoT)	Cold-start CC/ warm-start CC	DoT warm CC[3]	DoT warm CC/ warm-start CC
Our X25519-KeyGen[1]	7,560[2]	28,450	3.8	10,315[4]	1.4
Our Ed25519-Sign	24,723	52,157	2.1	28,515	1.2
Our Ed25519-Verify	81,506	239,176	2.9	90,956	1.1
Hisil et al. X25519-Derive [25]	61,867	97,789	1.6	64,395	1.0

[1] Here, we set the batch size to 1 to see the effect of the auxiliary thread more intuitively.
[2] In Table 2, our 8×1-way X25519-KeyGen takes 6,0479 cycles for generating eight keypairs. Here, we report the average cost for generating one keypair.
[3] The performance using our auxiliary warm-up thread for mitigating the cold-start issue.
[4] Part of the overhead is consumed by the `BATCH_STORE` frame.

decisions for *batch-size* $= 16$ later. The `derive()` method is a wrapper around the 1×4-way X25519-Derive implementation by Hisil et al. [25]. The `keygen()` method for Ed25519 is similar to the X25519 case. The `sign()` and `verify()` methods are wrappers of our 1×8-way Ed25519-Sign and 1×2-way Ed25519-Verify implementation, respectively.

4.2 How to mitigate the cold-start issue?

The so-called "cold-start" approach measures the direct running time of the cryptographic algorithm a few thousand times during cryptographic benchmark tests. In contrast, the "warm-start" approach involves an initial warm-up phase where the cryptographic algorithm is executed a few hundred times before measurement. According to [19, Sec 11.9], the processor will set the upper parts of the AVX2/AVX-512 vector units to a low-power mode to save power if the units are not in use for about 675 µs, leading to a warm-up phase of approximately 14 µs (56,000 clock cycles at 4 GHz) when an AVX2/AVX-512 instruction is executed in the low-power mode. During the warm-up phase, the throughput of the related instructions is 4.5 times slower than usual.

After a careful review of the previous implementations with AVX2/AVX-512, we found that the cryptographic implementers tend to report only warm-start performance (e.g. [12, 13, 15, 18, 25, 35] and their software [10, 11, 14, 17, 24, 34]), without considering the adverse effects of the cold-start issue of vector units. Actually, the cold-start issue has never been discussed in previous related work in the cryptographic engineering field. This finding motivates us to explore the actual effect the cold-start issue brings to the ECC implementation with AVX2/AVX-512. Furthermore, as our objective is to incorporate the AVX-512IFMA-optimized ECC implementation into TLS, the vector units could operate in the low-power mode during certain stages of the TLS protocol, which could result in a much worse cold-start performance than what has been observed during warm-start testing.

As a result, we intend to systematically examine and alleviate adverse effects of the cold-start issue on real-world TLS applications. We measured the CPU cycles of cryptographic operations under the DoT query benchmark conditions (cf. Section 4.4). These results are more qualified than the warm-start performance reported in Table 2 and 3 to illustrate the performance of cryptographic operations in realistic TLS applications.

We present the results in Table 6. The "warm-start CC" column is derived from Table 2 and 3. The "Cold-start CC (DoT)" column is measured under DoT query benchmark conditions, and the results show that cryptographic operations are cold-started. The "Cold-start CC/warm-start CC" column indicates the performance degradation of cryptographic operations in the DoT query conditions (i.e. cold-start scenario) compared to the warm-start scenario. The last two columns will be analyzed later. All subroutines suffer from varying degrees of performance degradation; especially the X25519-KeyGen takes 3.8 times longer in the DoT scenario than in the warm-start scenario.

Initially, we hypothesized that the performance degradation was caused by cache misses due to the larger executable file than the L1 cache (as mentioned in [55, Sec 5.1]). However, after careful analysis through the top-down method [54] with `pmu-tools` [39], we concluded that cache misses could not cause such significant performance degradation. Subsequently, we discovered the cold-start issue of vector units, which is also mentioned in [19, 20, 52]. As this is a mechanism inside the CPU without any interface to disable it, we have to find a workaround to mitigate this issue.

The warm-up phase typically lasts around 14 µs (56,000 cycles under 4GHz), after which all vector units are fully activated, as demonstrated in [19, Sec 11.9]. The vector units will enter low-power mode if no vector instructions are executed for approximately 675 µs. To tackle this issue, one can execute a vector instruction 14 µs prior to cryptographic operations to initiate the warm-up phase. However, predicting precisely when a client initiates a TLS handshake with a server is impossible.

To address this problem, we propose an auxiliary warm-up thread that executes a dummy vector instruction every 500 µs to prevent the vector units from entering low-power mode. The time interval is set as 500 µs to allow for timer errors. Nonetheless, continuously preventing the vector units from entering low-energy mode will increase the CPU's power consumption, which contradicts the CPU designer's intentions. Therefore, we propose a heuristic warm-up scheme for the auxiliary thread, which operates as follows: It wakes up every 500 µs, executes a vector instruction if necessary, and then goes to sleep. Otherwise, it goes to sleep directly, resulting in minimal consumption of CPU resources because it sleeps most of the time.

Heuristic warm-up scheme The `unbound` server provides the capability to report statistics [45], allowing us to determine the number of DoT queries within a 60-second period[6], denoted as Q. We record the maximum number of DoT queries that `unbound` can resolve in 60 seconds as Q_{max}, which is approximately 290,000 with ENG25519 support. We classify DoT workload into three categories: high, medium, and low. In high workload scenarios ($Q \geq 120,000$), at least one DoT query is resolved on average every 500 µs, and the auxiliary thread does not require any warm-up actions. For medium workload scenarios ($60,000 \leq Q < 120,000$), the auxiliary thread executes one vector instruction every 500 µs to prevent the vector unit from entering low-power mode. For low workload scenarios ($Q < 60,000$), the auxiliary thread does not need to execute any warm-up actions. Compared to consistently executing a vector instruction every 500 µs to warm up vector units, regardless of the workload scenario, our heuristic warm-up scheme considers the various scenarios' requirements. Unnecessary warm-up actions are removed for high-workload scenarios, periodic warm-up actions ensure faster TLS handshakes for medium-workload scenarios, and for low-workload scenarios, we avoid disrupting the power-saving mechanism inside the CPU. We describe the heuristic warm-up scheme as follows.

$$T = \begin{cases} +\infty, & Q \geq 120,000 \\ 500\,\mu s, & 60,000 \leq Q < 120,000 \\ +\infty, & Q < 60,000 \end{cases} \quad (9)$$

where the time interval T denotes the duration for the auxiliary thread to execute a vector instruction for warm-up vector units, and the symbol $+\infty$ indicates no instruction execution. In our implementation, the thresholds for dividing the three workload cases and the corresponding time intervals are adjustable, enabling the scheme to be expanded to other application scenarios. See Appendix D for the guidelines of parameters adjustment.

The last two columns in Table 6 show the effectiveness of our auxiliary thread. These results are measured after equipping our auxiliary thread with $T = 500\,\mu s$ for both the server and the client. In realistic scenarios, we only equip the server with the auxiliary thread. The client is only equipped with the auxiliary thread in the experiments of Table 6; in all other experiments, the client is not equipped with the auxiliary thread. In practice, requests initiated by clients are scattered and unpredictable. We forgo the performance sweetspot brought by auxiliary threads on the client side to simulate a more realistic scenario. In this way, among the cryptographic operations performed by the client, the batching technique described below can mitigate the cold-start issue of X25519-KeyGen. However, X25519-Derive and Ed25519-Verify will inevitably suffer from the cold-start issue. Benchmarks in Sections 4.3 and 4.4 demonstrate that our configuration (i.e. the server using ENG25519 with our auxiliary thread and the client using ENG25519 without our auxiliary thread) still outperforms other configurations.

[6]The time interval is adjustable in the unbound configuration file.

Table 7: Amortized CPU cycles (CC) to generate a keypair using our 8×1-way X25519-KeyGen with different batch sizes. The data presented here encompasses the memory management overhead introduced by the OpenSSL ENGINE layer.

Batch size	Amortized CC with auxiliary thread	Amortized CC without auxiliary thread
1	10,315	28,450
2	9,903	24,977
4	9,107	19,388
8	9,003	14,108
16	8,980	11,406

Power consumption One might think that using AVX-512 and bypassing energy-saving mechanisms could potentially increase CPU power consumption and even carbon emissions. We argue that our faster cryptographic computations not only don't increase power consumption but actually reduce it due to the overall time reduction. Consider the cryptographic operations in a TLS 1.3 handshake on the server side, i.e. X25519-KeyGen+X25519-Derive+Ed25519-Sign. This work (97.1k CC) achieves an 184% and 31% improvement over OpenSSL (275.3k CC) and Faz-Hernandez (127.1k CC), respectively. Professional power consumption tests [31] indicate that AVX-512 only increases average power consumption by 17% and peak power consumption by 10% compared to AVX2. Additionally, compared to the implementation without any AVX instructions, AVX-512 increases the peak power consumption by 9.6%, but reduces the average power consumption. Considering the efficiency improvement, utilizing AVX-512 remains beneficial in terms of power consumption.

Online-KeyGen and offline-KeyGen We only consider the online KeyGen scenario. The offline-KeyGen pattern is commonly used in scenarios such as TLS/SSL certificate au-

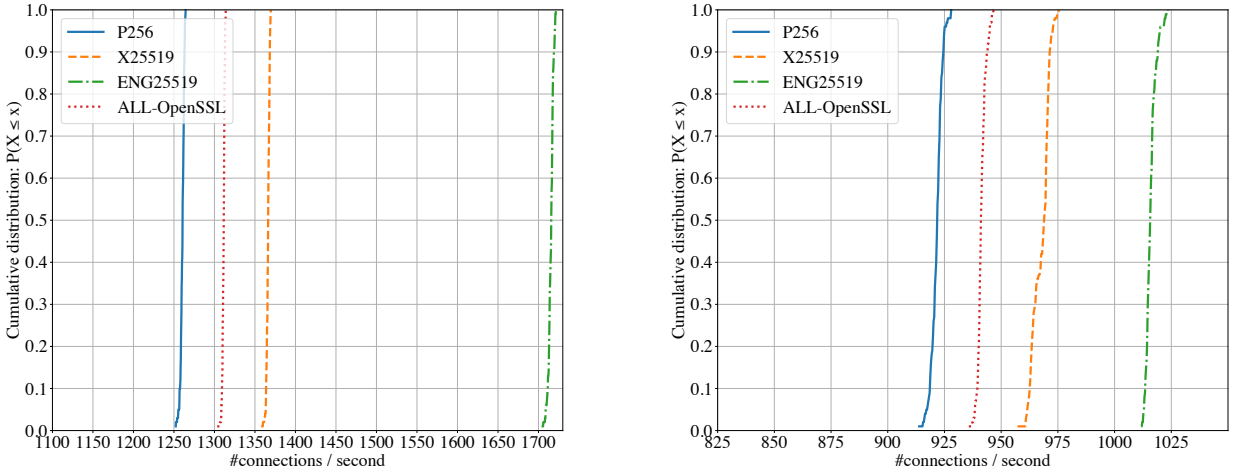
thorities and cryptocurrencies with dedicated security devices for protecting offline keypairs. Our focus is on the online-KeyGen (for X25519 key exchange) scenario. Most server software using the TLS protocol adopts the online-KeyGen mechanism, such as `unbound` and `nginx`. The precomputed keypairs are securely stored in memory, eliminating the need for dedicated security devices. Key management involves simple memory operations at the ENGINE level, which is transparent to the server.

Batch X25519-KeyGen As previously mentioned, X25519-KeyGen can be performed without relying on information from the communication peer. This is the underlying premise that allows our 8×1-way X25519-KeyGen to be utilized. Calling our 8×1-way X25519-KeyGen once generates eight different keypairs. We call it 16 times when needed, denoted as *batch-size* $= 16$, for two reasons. First, when auxiliary thread support is not available, such as on the client side mentioned above, multiple calls can amortize the impact of the cold-start issue. Second, when auxiliary thread support is present, as on the server side, multiple calls are more cache-friendly and can improve performance. Table 7 presents the amortized cost of each keypair under different batch sizes. Compared to *batch-size* $= 1$, the performance improvement of *batch-size* $= 16$ is 13% or 60% with or without our auxiliary thread, respectively. Further increasing *batch-size* beyond 16 yields diminishing returns, so we adopt 16 as our choice. The time taken to generate a batch is approximately 0.22 to 0.33 milliseconds (under 4GHz), which is imperceptible to users.

4.3 Benchmark of TLS handshake

We used two machines with the same configuration as the client and server to benchmark TLS handshake, the same as in Section 3.6. Additionally, the two machines communicate over an internal network with a bandwidth of up to 10Gbps. Our OpenSSL version is `1.1.1q`. Our benchmark method is similar to Bernstein et al. [5, Sec 4.4] in Usenix Security 2022. We ran a generic TLS server on the server side that listens for connections on a given port using TLS via the `openssl s_server` tool [42]. On the client side, we measured handshakes per second using `tls_timer` [44]. In the main loop of `tls_timer`, it records a timestamp, and then performs a certain number of TLS connections, then records another timestamp, resulting in the elapsed time. For each TLS connection, it just performs TLS 1.3 handshake without sending any application data, and then the client properly shuts down the connection. The elapsed time covers the computational overhead of cryptographic operations, the time for the packet to travel over the network, and the time to travel from kernel space to user space.

Our experiments with cumulative distributions are presented in Figure 3a. We used Ed25519 as the signature algorithm for all experiments. As a baseline for comparison, we report results with both client and server using NIST P-256 [36] and X25519 in OpenSSL `1.1.1q` for key exchange, namely "P256" and "X25519" in legend. Both experiments use the cryptographic implementation built into OpenSSL instead of using any ENGINEs. In the setting of the "ENG25519" legend, the server adopts our ENG25519 supported by our auxiliary warm-up thread, and the client adopts our ENG25519 not supported by the auxiliary thread. The "ALL-OpenSSL" legend indicates that the ENGINE is implemented using X25519 and Ed25519 implementation in OpenSSL. When it is compared with the "X25519" configuration, the impact of the ENGINE framework on performance can be known.



On average, the proposed ENG25519 setting (1,707 #connections/second) enables 25% and 35% more handshakes per second than X25519 (1,366) and P256 (1,260), respectively.

4.4 Benchmark of DoT query

We conducted two benchmarking approaches. The first involved end-to-end experiments derived from [5, Sec 4.4] in Usenix Security 2022, allowing us to showcase optimizations on both client and server paths. This approach is in align with users' perception. The second measured the server's peak throughput by bombarding it with a sufficient number of clients, quantified as the number of completed DoT queries per 60 seconds (#queries/min). Large-scale service providers are particularly interested in this metric, as higher throughput can potentially reduce hardware acquisition costs.

End-to-end experiments On the server side, we utilized `unbound` [37] DoT server, which listens for TLS connections on a given port. On the client side, we developed the `dot_timer` tool based on the `tls_timer`. Once the TLS 1.3 handshake is completed, `dot_timer` sends a DNS query to `unbound`, waits for the corresponding DNS response over the established TLS connection, and then properly shuts down the connection. Other configurations remain unchanged from Section 4.3. Compared to `tls_timer`, the elapsed time recorded by `dot_timer` additionally covers the time taken by the client to send the DNS query and receive the DNS response over the TLS connection. Figure 3b visualizes our experimental results, with the same legends as in Section 4.3. Our ENG25519 outperforms all other configurations.

Peak throughput Our ENG25519 configuration achieved a significant improvement, achieving 290,315 #queries/min, which represents a 41% and 24% increase over P256 (206,275) and X25519 (234,875), respectively. This enhancement demonstrates the effectiveness of our optimizations in achieving higher server throughput.

(a) TLS 1.3 handshake performance

(b) DoT query performance

Figure 3: Cumulative distributions of TLS handshake and DoT query performance under different configurations. For each configuration, we collected 100 samples in terms of the average number of TLS connections and DoT queries per second. For each sample, we measure the elapsed time over 10000 sequentially TLS 1.3 handshakes and DoT queries.

5 Security

We confirm that all instructions used in this work are constant-time, and we avoid secret-data-dependent memory access and branches to protect against cache-timing attacks and branch prediction attacks. The implementation of X25519-KeyGen and Ed25519-Sign involves accessing precomputed tables. Our secure table lookup method traverses the entire (sub)table and uses masking techniques to obtain the desired table entry. Attackers cannot observe any useful cache access patterns or expose any secret information. The precomputed keypairs are saved directly into memory. Memory security is ensured through operating system (OS) measures, e.g., virtual memory, access control, and memory isolation. Our X25519 keypairs follow the "one-time pad" pattern, with no secret information being revealed to a specific cache line. Different private keys are generated using random number generation APIs, ensuring no correlations between different keys. Thus, our implementation does not introduce any potential attack surface and does not affect the security assumptions relied upon by cryptographic primitives.

6 Availability and Scalability

The availability of AVX-512IFMA AVX-512IFMA was first implemented in Cannon Lake CPUs in 2018. Since then, it has gained widespread support in high-performance server environments. After 2018, most Intel Xeon series processors, except Cascade Lake (2019) and Cooper Lake (2020), have provided support for AVX-512IFMA. On the client side, AVX-512 support has been somewhat contentious due to power consumption concerns. However, it is important to note that our optimizations are of greater interest to large-scale service providers.

For hardware without AVX-512IFMA support AVX2 enjoys more widespread support compared to AVX-512, with almost all CPUs released after Haswell (2013) supporting AVX2. For hardware that only supports AVX2, one can derive a solution with additional engineering efforts: At the cryptographic primitive layer, employ $4 \times$ 1-way X25519-KeyGen from [15], X25519-Derive from [25], Ed25519-Sign, and Ed25519-Verify from [18]. In the OpenSSL ENGINE layer, our ENG25519 framework (including batching mechanisms for X25519-KeyGen) can be reused with some engineering effort to align with the interfaces of cryptographic primitives. Our auxiliary threads with the heuristic wake-up strategy can also be used to mitigate the cold start issue associated with AVX2.

Scalability of the heuristic warm-up scheme Our implementation of the heuristic warm-up scheme depends on the reporting statistics feature of `unbound`. However, for TLS applications without this feature, the scheme is still available by implementing it at the ENGINE layer.

Scalability of MTP principle for high-end hardware For wider SIMD/vector instruction sets, such as the vector length

supported by the ARM SVE(2) is up to 2,048 bits [48], and supported by the vector extension of RISC-V is up to 16,384 bits [22]. The design concepts proposed in this paper to enhance the parallelism of ECC-related arithmetic from 4-way to 8-way can serve as a valuable guide when contemplating hardware with greater parallelism. For instance, guided by the MTP principle, for a machine that supports 1,024-bit vectors, according to the ideas in this work, the optimization scheme is $16\times1 \to 16\times1 \to 16\times1$ X25519-KeyGen, $4\times4 \to 1\times4$ X25519-Derive, $16\times1 \to 16\times1 \to 1\times16$ Ed25519-Sign, and $16\times1 \to 2\times8 \to 1\times2$ Ed25519-Verify. Then, utilize the methodology similar to this paper to reach the TLS layer and TLS applications.

Application scenarios In addition to the example of DoT provided in this paper, we list here more potential application scenarios that could benefit from this paper: (1) E-commerce, especially during promotional discount periods. During events like Black Friday sales, website traffic can surge to levels 30 times higher than usual [51]. A report by the WTO [53, Sec 7] also mentions that with the rise of e-commerce, network capacity and higher bandwidth services have proved to be crucial. (2) Social media platforms that experience sudden spikes in activity due to major news events can also be vulnerable to performance issues related to the TLS handshake and could experience crashes [1, 29]. (3) Industrial Internet of Things (IoT) servers. It's predicted that by 2025, the number of connected devices per minute will reach 152,000 [38]. For instance, there can be thousands of devices connected to the server at any given time, each requiring a secure TLS handshake. This underscores the critical importance of improving server throughput. The common feature of these scenarios is their strong emphasis on peak throughput because it can even affect hardware resource procurement costs.

Session resumption mechanism This mechanism can effectively expedite TLS handshakes using pre-shared keys. However, to ensure forward secrecy when conducting fast handshakes with this mechanism, ECDHE calculations (i.e., X25519-KeyGen and X25519-Derive in our case) are still required. As mentioned in TLS 1.3 specification [46, Sec 2.2]: "When a client offers resumption via a PSK, it SHOULD also supply a "key_share" extension to the server to allow the server to decline resumption and fall back to a full handshake if needed. The server responds with a "pre_shared_key" extension to negotiate the use of PSK key establishment and can (as shown here) respond with a "key_share" extension to do (EC)DHE key establishment, thus providing forward secrecy." Therefore, this work can also accelerate scenarios where session resumption is used while ensuring forward secrecy.

7 Conclusions

In this study, we redesign and implement all layers of ECC arithmetic to improve the performance of X25519 and Ed25519 using the AVX-512IFMA instruction set. At the OpenSSL level, we proposed ENG25519, based on the OpenSSL ENGINE API and `libsuola`, which can actually benefit the TLS application from the optimized ECC implementations. In the end, we choose TLS handshakes and DoT for application-level benchmarking. During this process, we also uncover and address the cold-start issue of vector units, which, to our knowledge, had not been reported in the field of cryptographic engineering before.

Our solution achieves a speedup of 25% to 35% for TLS handshakes per second and improves peak server throughput for DoT queries by 24% to 41%. This means that our solution is indeed effective in mitigating the computational burden of TLS handshakes for throughput-critical scenarios. Additionally, we discuss the scalability of our solution, which can extend to high-end hardware, low-end hardware, and various CPU architectures. This suggests that our solution offers guidance for complex real-world environments.

A Details of AVX-512IFMA instructions

The 52-bit multiplication instructions One of AVX-512IFMA's critical features is the 52-bit integer multiplier, with corresponding instructions like `vpmadd52luq` and `vpmadd52huq`. For instance, the "`vpmadd52luq a_l, b, c`" and "`vpmadd52huq a_h, b, c`" instructions[7] can multiply the unsigned 52-bit integers in each 64-bit lane of `b` and `c` and produce a 104-bit intermediate result utilizing the 52-bit multiplier. The first instruction gets the low 52-bit result and accumulates it to the corresponding lane of `a_l`. The second instruction gets the high 52-bit result and accumulates it to `a_h`.

Mask addition and subtraction instructions Consider the inline[8] mask addition instruction `_mm512_mask_add_epi64`, abbreviated as VMADD. The syntax of the instruction is as follows:

```
__m512i _mm512_mask_add_epi64(__m512i src,
        __mmask8 k, __m512i a, __m512i b);
```

The instruction adds packed eight 64-bit integers in `a` and `b`, stores the results in `dst` (the return value), and employs an 8-bit mask `k` to determine whether each corresponding lane of `dst` should be a copy of the corresponding lane of `src` or the result of the addition. Specifically, when the mask bit in `k` is 0, the corresponding lane in `dst` is a copy of the corresponding lane in `src`, and when the mask bit is 1, the corresponding lane in `dst` is the sum of the corresponding lanes in `a` and `b`. The mask subtraction `_mm512_mask_sub_epi64`, abbreviated as VMSUB, operates in a similar manner.

Suppose $a = [a_0, a_1, a_2, a_3, a_4, a_5, a_6, a_7]$ and $b = [b_0, b_1, b_2, b_3, b_4, b_5, b_6, b_7]$. In line 2 of Algorithm 1, the mask k is 0x11, which is represented in binary as 00010001. The result of the MADD$(a, 0x11, a, b)$ instruction is $[a_0 + b_0, a_1, a_2, a_3, a_4 + b_4, a_5, a_6, a_7]$. This means that the 0-th and 4-th lanes are the sum of the corresponding lanes in a and b, while the remaining lanes are a copy of the corresponding lanes in a.

Permutation instructions Apart from the mask instructions, the permutation instruction, abbreviated as PERM, is also versatile. With the following syntax, it shuffles the 64-bit integers in `a` within each 256-bit lane using the control bits in `imm8` and stores the results in `dst`.

```
__m512i _mm512_permutex_epi64(__m512i a,
        const int imm8);
```

For example, in line 1 of Algorithm 1, where `imm8` is 0xB1, and its binary representation is 10110001, which is equivalent to "2 3 0 1" in two-bit integers. The result of PERM$(a, 0xB1)$ is $[a_1, a_0, a_3, a_2, a_5, a_4, a_7, a_6]$. Every two-bit integer in "2 3 0 1" is used to index a 64-bit integer in each 256-bit lane of a 512-bit register. The 8-bit values 0xDD, 0x88, and 0x4B in Algorithm 1 follows the same pattern as `imm8`.

B Performance penalty caused by permutation instructions

Using 4×2-way modular multiplication as an example, let $a, b, \cdots, g, h \in \mathbb{F}_p$ where $p = 2^{255} - 19$. The 4×2-way modular multiplication calculates four modular multiplications in parallel, i.e., $a \cdot e, b \cdot f, c \cdot g, d \cdot h \pmod p$. The four elements a, b, c, and d can be represented using three 512-bit registers with the radix-2^{51} representation as $[a_0, a_3, b_0, b_3, c_0, c_3, d_0, d_3]$, $[a_1, a_4, b_1, b_4, c_1, c_4, d_1, d_4]$, and $[a_2, 0, b_2, 0, c_2, 0, d_2, 0]$.

[7] Each of the AVX-512 instruction has a corresponding mask operand to control the specific behavior of the instruction, here we ignore it for the convenience of understanding.

[8] Intel Intrinsics Guide: https://www.intel.com/content/www/us/en/docs/intrinsics-guide/index.html

The elements e, f, g, and h can also be represented in a similar way. We need to construct all the product terms, i.e. $a_i e_j$, $b_i f_j$, $c_i g_j$, and $d_i h_j$ where $i, j = 0, \cdots, 4$, using the following computation sequences:

$$
\begin{aligned}
&[a_0, a_0, b_0, b_0, c_0, c_0, d_0, d_0] \times [e_0, e_3, f_0, f_3, g_0, g_3, h_0, h_3] \\
&[a_0, a_0, b_0, b_0, c_0, c_0, d_0, d_0] \times [e_1, e_4, f_1, f_4, g_1, g_4, h_1, h_4] \\
&[a_0, a_0, b_0, b_0, c_0, c_0, d_0, d_0] \times [e_2,\ 0,\ f_2, 0,\ g_2,\ 0,\ h_2, 0] \\
&\cdots \\
&[a_4, a_4, b_4, b_4, c_4, c_4, d_4, d_4] \times [e_0, e_3, f_0, f_3, g_0, g_3, h_0, h_3] \\
&[a_4, a_4, b_4, b_4, c_4, c_4, d_4, d_4] \times [e_1, e_4, f_1, f_4, g_1, g_4, h_1, h_4] \\
&[a_4, a_4, b_4, b_4, c_4, c_4, d_4, d_4] \times [e_2,\ 0,\ f_2, 0,\ g_2,\ 0,\ h_2, 0].
\end{aligned}
$$

Obviously, we need to use permutation instructions to transform the form $[a_0, a_3, b_0, b_3, c_0, c_3, d_0, d_3]$ (i.e. input form) into the form $[a_0, a_0, b_0, b_0, c_0, c_0, d_0, d_0]$. In addition, permutation instructions are also required when accumulating these product terms. Overall, twenty permutation instructions are used (12 `vpshufd` instructions and 8 `vpblendmq` instructions) in our 4×2-way modular multiplication.

For the 8×1-way modular multiplication, the eight finite field elements can be represented with radix-2^{51} representation as:

$$
\begin{aligned}
&[a_0, b_0, c_0, d_0, e_0, f_0, g_0, h_0] \\
&\cdots \\
&[a_4, b_4, c_4, d_4, e_4, f_4, g_4, h_4].
\end{aligned}
$$

We can construct the execution flow without permutation instructions by adopting a similar computation sequence as 1-way implementation.

The performance penalty caused by awkward permutation instructions in the bottom-level finite field arithmetic will be magnified due to its heavy usage by the upper-level arithmetic (e.g. point arithmetic and scalar multiplication).

C Fixing two bugs in libsuola

The first bug prevents the TLS layer from finding a suitable signature algorithm for the TLS handshake when we want TLS to select Ed25519. During the execution flow of the TLS handshake, OpenSSL checks the digital signature algorithm and its corresponding message digest algorithm. If the check fails, OpenSSL refuses to use the corresponding algorithm, resulting in the failure of the TLS handshake. In the `libsuola` implementation, OpenSSL is told that the message digest scheme for Ed25519 is "mandatory"[9], which makes TLS refuse to use the Ed25519 algorithm, causing the TLS handshake to fail. To fix this issue, our ENG25519 tells OpenSSL that the message digest scheme for Ed25519 is "advisory"[10] instead of "mandatory".

[9] Return value is 2 in https://github.com/romen/libsuola/blob/c055fd0f546b8a257293e7794055886081deddfd/meths/suola_asn1_meth.c#L208-L212

[10] Return value is 1 instead of 2

The second bug resulted from an incorrect `EVP_MD` implementation for Ed25519, causing incorrect signature results. Before calling the `sign()` subroutine during the TLS handshake, OpenSSL copies a temporary `EVP_MD` and uses it to execute `sign()`. The message cached in the original `EVP_MD` is not cleared after the `sign()` subroutine is executed, which leads to residual contents being included in the signed messages. We fix the issue by clearing the message in the original `EVP_MD` after it is copied by OpenSSL.

After fixing these two bugs, our ENG25519 works successfully after integrating it into TLS applications.

D Parameter adjustment guidelines

The parameters used for categorizing three workload cases The configuration of these parameters determines how the workload is categorized into three different cases. We consider $Q \geq 120,000$ as high load because estimates suggest that under such load, there is an average of one DoT request every 500 microseconds, simulating a wake-up operation. Therefore, there's no need for an additional wake-up. The division between medium and low loads is primarily based on empiricism. For medium loads, our default configuration enable wake-up operations to expedite server-side TLS handshake computations, proactively preparing for potential transitions to high load conditions due to sudden user surges. Experienced developers can fine-tune the categorization of the three workload cases based on their own empirical insights. For example, if one aims to accelerate TLS handshake calculations even under low load conditions, it is possible to remove the low load scenario by considering $0 \leq Q < 120,000$ as a medium load condition.

The time interval parameter Recall that for Intel CPUs, if no vector instructions are executed for approximately 675 microseconds, vector units enter a low-power mode. Setting this parameter to 500 microseconds primarily addresses potential timer inaccuracies. If CPUs of other architectures exhibit similar cold-start issues due to internal designs, this parameter should be adjusted based on the distinct cold-start behaviors.

Formal Security Analysis of Widevine through the W3C EME Standard

Abstract

Streaming services such as Netflix, Amazon Prime Video, or Disney+ rely on the widespread EME standard to deliver their content to end users on all major web browsers. While providing an abstraction layer to the underlying DRM protocols of each device, the security of this API has never been formally studied. In this paper, we provide the first formal analysis of Widevine, the most deployed DRM instantiating EME.

We define security goals for EME, focusing on media protection and usage control. Then, relying on the TAMARIN prover, we conduct a detailed security analysis of these goals on some Widevine EME implementations, reverse-engineered by us for this study. Our investigation highlights a vulnerability that could allow for unlimited media consumption. Additionally, we present a patched protocol that is suitable for both mobile and desktop platforms, and that we formally proved secure using TAMARIN.

1 Introduction

The world of entertainment is evolving rapidly. Indeed, Over-the-Top (OTT) platforms, such as Netflix, Amazon Prime Video, and Disney+, have revolutionized the way we consume content. OTT streaming services are websites that consumers use to access their favorite movies. These services, valued at $455 billion in 2022 [25], are accessible on almost all Internet-enabled devices, including smart TVs, computers, laptops, smartphones and tablets. The large distribution of media in user-controlled devices creates challenges for OTT platforms. The main challenge remains piracy; a recent study indicates that 80% of digital piracy is now due to streaming [40]. This is due to the fact that digital video is a set of binary information that represents video content. Bits can be easily copied, transferred, or stored. Therefore, digital video is intrinsically unprotected, *i.e.* digital video can easily be viewed by anybody and be infinitely duplicated. Thus, in some cases, it needs protection, namely access control, under some defined conditions. For instance, many OTT platforms enforce monthly subscription, meaning that customers pay a regular fee to access a catalog of premium video contents defined by the OTT.

Consequently, OTT platforms rely on DRM (Digital Rights Management), which is a technology that aims to protect media from piracy. Modern DRMs ship content in an encrypted form, and then control their decryption through authorized modules on users' devices. A prerequisite to decryption is to process the corresponding license. A DRM license describes the agreement between the OTT, or content providers, and the consumer. A license contains the decryption key, the associated usage rights and consumption policies that the DRM module is authorized to perform with the key. Given their sensitive nature, licenses are protected when delivered to the client's DRM module. The underlying protection mechanisms are proprietary and unique for each DRM system, thereby requiring Web OTT platforms to cumbersomely adapt their websites for each DRM using plugins. For instance, until December 2014, users needed to install some Wine-wrapped Microsoft Silverlight plugin to watch Netflix on Ubuntu [39].

Striving to make the Web an online environment to watch movies, the World Wide Web Consortium (W3C) published Encrypted Media Extensions (EME) as a W3C Recommendation or Web standard [14]. EME is an Application Programming Interface (API) that allows plugin-free playback of encrypted content seamlessly in all major Web browsers. Thus, Web developers no longer have to use proprietary tools required by external plugins. Roughly, the EME protocol abstracts the process of license acquisition and related actions, allowing OTT platforms to develop their Web applications once and to deploy them everywhere on the Web regardless of which DRM system is used. EME adoption was decried [21]; the opponents articulated security and privacy concerns about a "built-in DRM in the Web". Several privacy issues were pointed out by Patat *et al.* [34] that show how to leverage EME to construct unique fingerprints. As for security, we merely find some auto-congratulation messages of W3C members claiming that EME "*brings greater security to the Web*" [43]. This is unfortunate, since, despite being optional, EME is

deployed on all major browsers [7]. Thus, any vulnerability on a given DRM system can leverage the EME promise: implement the exploit once (simply using Javascript) and compromise everywhere. This makes EME a lucrative attack target for piracy.

Problem Statement. Years after its wide integration, we fill this gap by taking a closer look at the security of EME as a protocol. In this paper, we present, to the best of our knowledge, the first in-depth security analysis of the EME API standard covering a rigorous formal analysis of both its workflow and security requirements. A significant challenge in conducting such an analysis is that the EME standard involves various *opaque* messages that depend on the underlying DRM system. It is important to note that the EME specifications do not introduce yet-another DRM system; rather, they abstract browser interaction with pre-existing DRM modules. Therefore, any complete analysis must be contingent on a particular instantiation of EME. We base our analysis on Widevine [16], which is a cross-platform (Windows, Android, Linux and macOS) and cross-browser (Firefox, Edge, Chrome, and all other Chromium-based browser) DRM owned by Google. The scope of other proprietary systems, such as FairPlay [1] and PlayReady [29], would have been more limited. More importantly, each DRM system introduces a plethora of proprietary technical details. We prioritized lucidity in our presentation and longitudinal analysis over completeness, particularly since our conclusions would have remained unaltered: the security of EME is quite brittle and requires formalization to accomplish the associated security goals.

In [22], Heilman introduces the concept of perfect DRM using game theory. A perfect DRM system is one such that content protected by it is not available for further copying; the option of piracy is unavailable to consumers. Therefore, we would like to formally prove the absence of piracy: *i.e.* that EME, when instantiated with a specific DRM system, namely Widevine, satisfies a desired security notion. At a methodological level, piracy can be hard to model because it involves security notions beyond the straightforward confidentiality and integrity of messages. In addition, it should scale well enough to allow us to model the complex EME workflow.

Contributions Summary. We present in this work four main contributions. First, we reverse engineer the EME messages as defined by Widevine. Second, examining the security mechanisms of Widevine, we discover a vulnerability that allows a malicious user to load arbitrary consumption policies for any license, given a plausible behavior of the Widevine client. We propose a mitigation to fix that flaw. Third, we define clear security goals capturing the notion of piracy. Finally, supported by our EME insights and reverse engineering, we formalize Widevine EME and its expected security goals, and perform formal analysis to prove the absence of piracy despite subtle behaviors of Widevine implementations. For our model, we leverage the TAMARIN prover [28], a symbolic protocol analysis tool, to analyze several non-trivial aspects of Widevine EME. One of the challenges in developing our model is that it requires finding middle ground between the EME protocol with its opaque messages, and the proprietary technical details of Widevine. Thus, we needed to identify the core theoretical concerns of EME, and apply them to how Widevine is implemented in practice. We notably identify how updating licenses in EME constitutes a central part causing sophisticated security issues. In fact, the vulnerability we identified was discovered through our formal analysis. We also formally study the mitigation we propose, and prove that it achieves our formalization of Heilman's perfect DRM security. Overall, our work shows that the W3C claims about "greater security" guaranteed by EME cannot be taken for granted; formal analysis is needed to verify them.

Related work. DRM systems have never ceased to be broken by attackers looking for pirated content. However, as breaking DRM is illegal in many countries, few hackers have ever published detailed technical descriptions of their attacks. Some remarkable exceptions are the "Beale Screamer" case [38], and more recently the L3-decryptor against Widevine [19]. Since 2010, Widevine has seen extensive adoption. Unfortunately, little literature was dedicated to the study of its security mechanisms. Patat *et al.* delve into the undocumented Widevine protocol, shedding light on its various cryptographic components on Android in [33]. They also explore the privacy implications of EME Widevine in [34]. Zhao [46] breaks the Trusted Execution Environment-based Android Widevine. These studies offer profound insight into the design of Widevine, yet the integration of Widevine with the W3C EME standard remained until now unstudied. Our work explores this area, examining how Widevine instantiates EME messages. Unlike previous attacks with sophisticated low-level exploits, ours could in principle be exploited by JavaScript code executed in a simple web page.

Other work has formally studied the security of Web standards. Besides EME, the W3C develops Web standards for various security applications, including notably the Web Authentication API [23], the Web Cryptography API [45], and the Web Payment API [24]. Formal methods are generally not used during the standardization process (though it has been suggested *e.g.* by [20]). They have however been applied to several already existing W3C standards [6, 13, 17]. These analyses all uncovered severe, previously unknown attacks, illustrating the power of formal verification techniques. Because of its opaque messages, EME remained without analysis, which our work addresses. Unlike other work, we do not use specialized formal models designed for the Web, such as WebSpi [3] (based on PROVERIF) or the Web Infrastructure Model (WIM) [15]. Indeed, the threat model we consider is ill-adapted to these models, since we suppose that the attacker controls the browser.

Reproducibility and Responsible Disclosure. All our formal models written in TAMARIN are available online [11], for reproducibility purposes, and to assist future work on this

topic. Moreover, we have communicated our draft to the editors of the latest EME draft. On February 13th 2024, they discussed our technical findings in the media WG meeting. The meeting minutes can be found in [44], where our findings were acknowledged. In further discussions, editors suggested a Widevine contact, which we did reach on March 25th, but we have not got any answer. This is unfortunate, since our results concern the particular instantiation of EME by Widevine, even though EME editors mentioned that they would follow on the suggested patch and modify the standard accordingly whenever Widevine reply.

2 Background on DRM

DRM is a set of tools used to protect content from piracy. Today, most large streaming platforms use either Widevine [16] or PlayReady [29] to ensure that only authorized viewers can access protected content.

2.1 DRM Common Architecture

DRM systems are complex, and their design differs depending on the context in which they are used. Here, we only consider DRMs protecting content delivered over the Internet in unicast mode. In this family, all DRMs share at least five common components [36]: (1) a content packager to encrypt content, (2) a content server that delivers the protected media, (3) a content provider that manages subscriptions, (4) a license server that delivers licenses under the control of the content provider, and (5) a client application that enables content consumption. The first two elements are often mapped to a single entity called *Content Delivery Network* (CDN), whereas the content provider and the license server are mapped to an entity called *Over-the-Top* (OTT) media service platform.

We now describe the transactional model of DRM, which details what happens once a subscribed client selects some content to consume. First, the associated CDN delivers the protected content to the client's device. To play back the received content, the DRM client needs the corresponding license. Thus, it requests a valid license from the license server operated by the content provider. A license holds the content's symmetric encryption key, as well as the usage rights granted to the client. Once the license server has verified that the requester fulfills some mandatory conditions, it builds the corresponding license, and cryptographically binds it to the targeted DRM client. When receiving the license, the DRM client is now ready to decrypt the protected content.

2.2 DRM Common Security Model

In [12], Diehl presents a layered security model for DRM based on four main features: content protection, rights enforcement, rights management, and trust management. The *content protection* layer securely seals the content (using *e.g.* symmetric encryption), so that nobody may access it unless explicitly authorized. On the client side, this layer decrypts the content, for the client application, if it receives the associated secret key from its upper neighbor, namely the *rights enforcement* layer. That layer ensures that the content will be used under the conditions indicated by the usage rights, as they were defined by the *rights management* layer. This third layer, on the client side, forwards its decision to its lower counterpart to prevent any unauthorized use. On top, the *trust management* layer ensures that only trustful principals interact, and behave as expected. Trust is enforced via authentication and certificates.

We can map the different DRM elements to this four-layer model. The content packager and content server, namely the CDN, implement the content protection layer. The license server implements the rights enforcement layer, whereas the content provider implements the rights management layer.

2.3 W3C EME Standard

As mentioned in the introduction, in response to the fragmented landscape of DRM solutions, recent technical standards have been defined to solve the interoperability issue. Of particular interest, we focus on the W3C EME standard. It was established to offer a uniform API, allowing web pages to seamlessly interact with browser-supported DRM systems. The primary objective of EME is to enable content providers to work consistently across various browsers, by abstracting a common workflow for license acquisition and usage rights. Although optional, EME has gained support from major web browsers, including Edge, Firefox, Chrome, Safari, Opera, as well as their mobile counterparts [7]. We present below the different components involved in EME, and we detail its API.

EME Components. We list below the main entities as introduced in the standard.

- **CDM**: The Content Decryption Module refers to the DRM system specified in EME. It is responsible for protecting licenses, and enforcing usage rules when decrypting media content on the user's device.
- **User-Agent**: The user-agent, *e.g.* a browser, refers to the entity implementing the EME workflow and API. The EME API is invoked through JavaScript to communicate with a specific CDM.
- **License Server**: License requests generated by the CDM are transmitted to the corresponding license server associated with the specific CDM. This server manages licenses and usage rights for protected content.

The EME design splits the client application, as described in Rosenblatt *et al.*'s architecture [36], into the user-agent (mostly open-source) and the CDM (mostly proprietary).

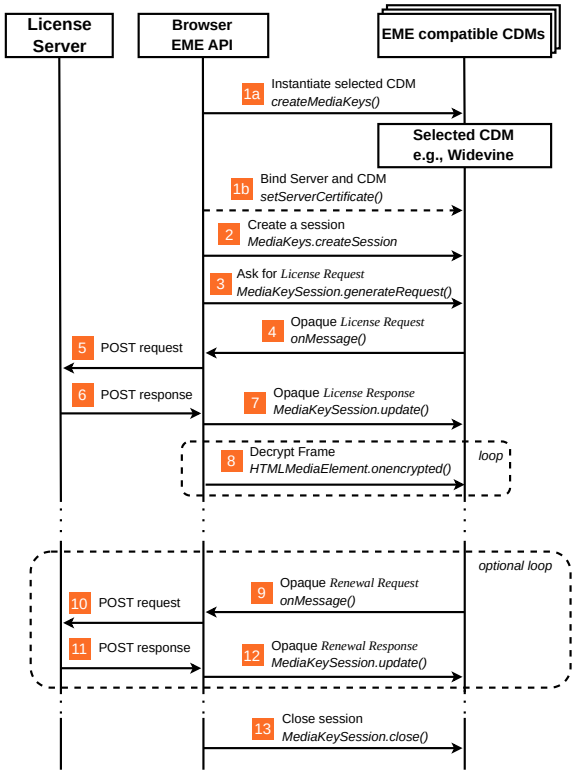

Figure 1: EME Workflow – License Acquisition and Renewal.

Protocol Workflow. EME establishes a standardized API that revolves around acquiring licenses, as in the rights enforcement layer, while abstracting the specificities of the underlying protection techniques. Consequently, the EME API depends on various objects and events to facilitate the implementation of proprietary DRM systems. Note that user authentication by the content provider falls outside the scope of EME. An overview of the protocol is given in Figure 1. We assume that the EME user-agent has already obtained all necessary details about the encrypted media from the CDN, including supported codecs and which DRM system to use.

The execution of the EME workflow begins at step 1a, after gaining access to a KeySystem using `requestMediaKeySystemAccess` method with, as inputs, the requested DRM and configurations for decrypting and decoding the media, an instantiation of a CDM is performed using `createMediaKeys`. At this particular stage, the CDM is accessible and represented by a `MediaKeys` object; however, it is unable to receive any license. Optionally in 1b, the `setServerCertificate` method can be invoked to bind the `MediaKeys` object to a given license server certificate. Then, in step 2, a session is established within the CDM, represented by a `MediaKeySession` object, and is identified by a unique sessionID. The EME standard mandates that sessions be associated with separate key wallets and isolated cryptographic environments. They are used to exchange data, mostly licenses, between the license server and the CDM. When a session is created, its key wallet is empty, and it cannot decrypt any content.

Acquire Licenses. In order to obtain media decryption keys and corresponding usage rights, also known as licenses, media-specific `Initialization Data` is sent to the CDM in step 3. This data is used by the CDM's `generateRequest` method to generate a license request. The specific content of the generated request is entirely dependent on the DRM system being used, as indicated in step 4. It is treated as an opaque message within the EME framework. Upon receiving the opaque license request, the user-agent forwards it to the license server in step 5. The server answers with an opaque license response in step 6. Using the EME API call `update` in step 7, the response is transmitted to the CDM session, and subsequently handled by DRM-specific mechanisms. According to EME, a successful call to `update` implies that the decryption key is now in the CDM memory, and may only be used according to its usage rights. Now that the CDM session possesses at least one license, it is ready to play the encrypted media in the browser through the HTML5 video element in step 8. At this stage, the session can either be closed in step 13, or undergo the renewal process.

Renew Licenses. Following their reception, licenses may or may not be renewed, depending on their usage rights. If permitted, the CDM fires an event to deliver a renewal request to the user-agent. It does so using the `MediaKeyMessageEvent` interface, with its type attribute set to `license-renewal` in step 9. Similar to the initial license acquisition process, this request is forwarded to a license server in step 10. Once the renewal response is received in step 11, the `update` method is invoked in step 12, updating proprietary metadata as needed.

3 Widevine EME

Widevine is a closed-source proprietary DRM developed by Google [16]. Over the years, Widevine has grown into one of the most widely adopted DRM technologies, supporting various formats such as MPEG-DASH, HLS, or CMAF [26,27,31], and is now leveraged by leading OTT platforms, such as Netflix, and Disney+. Widevine is supported on a wide range of devices, including Android devices, smart TVs, game consoles, and desktop browsers on all major operating systems, including Windows, Linux, and macOS. Since its integration as EME CDM in the Chromium project [8] in February 2013 (three months before the release of the EME first public draft), Widevine has been steadily deployed in various browsers. Note that most browsers provide support for only one or two CDM systems, including Widevine in most cases.

The Widevine cross-platform technology had to adapt its CDM implementation, especially its callable API, with respect to the host framework and the required security level.

This adaptation does not come without risk, since Patat *et al.* [33] leverage the abstraction layer defined for Android to break Widevine's security. One might reasonably wonder whether the EME abstraction can also be used somehow to bypass Widevine protection. In other words, is the Widevine instantiation of EME secure enough for streaming services?

To answer this question, we first dissect the different opaque messages instantiated by Widevine during the EME workflow. We also identify the different elements being present in the CDM internal memory during an opened session. Then, we present an attack given the target CDM not enforcing some additional security verification.

3.1 Experimentation Settings

Operating Systems and Browsers. In order to have a broad view of Widevine's EME instantiation, we used Android mobile devices, being the most used OS in the world [41], and desktops implementation of the CDM. For Android, we used Nexus 5/5X and Pixel 1, 3, 4, and 6 from Android versions 6 to 12. On desktop, we used Windows 10/11, macOS Big Sur, and Ubuntu 22.04. Each time, we performed our analysis on major up-to-date browsers with Firefox up to version 122, Chrome version 121, and Edge version 120 [42].

Widevine Ecosystem. For each device and browser, we used the up-to-date CDMs of Widevine, ranging from version 3.1.0 to 16.1.0 for Android, and the desktop version 4.10.2557.0. As for the license server, we set up our environment to communicate with the integration test license server provided by Widevine, to stay as close to the intended server behavior as possible.[1]

Research Methodology. Our approach to analyzing the Widevine EME protocol involves the observation of EME messages and API calls, using reverse engineering techniques and the monitoring of the Widevine CDM activity. To this end, we leveraged various tools, including Frida [35], Ghidra [30], Widevine-dedicated monitoring utilities such as WideXtractor [2], and custom scripts to inspect and manipulate EME interactions. We performed static, dynamic and API reverse engineering techniques to analyze Widevine on both Desktop and Android platforms.

- *Static Analysis:* Using Ghidra, we decompiled Widevine binaries to gain a structural understanding of the implementation and to identify key functions involved during the protocol, such as license acquisition or renewal.

- *Dynamic Analysis:* We leveraged Frida for Android and WideXtractor for EME monitoring on Desktops. These tools enabled us to write hooks for the identified functions and monitor the data processed during typical CDM-Server communications.

- *API analysis:* We manipulated the arguments of identified function calls, by introducing errors, redundancies, and forged parameters, to note all resulting behaviors.

This setup allowed us to intercept all messages between our test devices and the Widevine integration test server, during the decryption and playback of protected media content using the CDM. We documented all message exchanges and API invocations for subsequent analysis, enabling a comparative study across different operating systems and CDM versions. Through static analysis, we gained insights into the structure of opaque messages within EME. This analysis allowed us to better understand Widevine EME, including license acquisition, renewal processes, and cryptographic elements based on prior works [33, 34], but also on our own reverse engineering efforts for Widevine EME message format, security validation, temporal checks, and the management of data within the CDM memory. We also study the CDM behavior when errors occur during an open session.

3.2 CDM Internals

We present the different stages and operations of the Widevine CDM, from the initial state setup to license acquisition and renewal process. A summary of message contents and memory internals are presented in Table 2 and Table 3 of Appendix A.

3.2.1 Initial State

The Widevine CDM is provisioned with a pair of RSA keys, called the Device RSA Key, either in a hardcoded form like in desktop implementations, or on the fly through a provisioning mechanism [33]. With it, the CDM composes a Client ID from the Device RSA Key public part combined with device metadata [34]. Additionally, it possesses a service certificate public key obtained from the remote license server (via `setServerCertificate`), which holds the corresponding private key. Once the EME workflow has started and the necessary information has been retrieved from the license server, a session within the CDM can be initiated, setting the stage for license acquisition.

3.2.2 Acquire Licenses

Client Request. Following a call to `generateRequest`, the CDM creates a nonce in its memory to serve as an anti-replay measure. Using the public key within the service certificate from the license server, the CDM encrypts a freshly generated privacy key, which is used to encrypt, for privacy purposes (as shown in [34]), the Client ID containing the public Device RSA Key. Alongside these elements, the request also includes a randomly generated Request ID, the desired Key ID (KID for short) extracted from the media metadata and used by the license server to retrieve the corresponding key, and the request time T1 which is stored in the CDM memory. The

[1] https://proxy.staging.widevine.com/proxy

whole request is signed using the Device RSA private key of the device and then sent to the license server. Three elements are stored in a session memory of the CDM: the nonce, T1, and the whole request. Our assumptions on server-side request processing are discussed in Section 3.2.4.

License Format. The license consists of two main parts. The first part contains the encryption by the Device RSA public key of a fresh Session Key. Three keys are derived from that Session Key: the Asset Key, the MAC Server Key and the MAC Client Key. The derivation process, detailed in [33], involves some constant values as well as the client request. The derived keys are used to protect the second part of the license, in which we find the previous Request ID, the request time, KID and the license usage rights called policies. Among others, the policies define the license duration Δ_1. Also included in this part are the decryption key, called Content Key, and its KCB (Key Control Block). The KCB contains the request nonce, and is encrypted by the Content Key, which is encrypted by the Asset Key. The integrity of the second part is protected with an HMAC using the MAC Server Key.

License Processing. Upon receiving the license response, the CDM acts in two phases. In the first phase, it decrypts the Session Key using its Device RSA private key, derives the three keys from this Session Key, and stores them in its memory. In the second phase, it verifies the HMAC of the received license and checks the equality of the stored T_1 and the one received in the response. The CDM first retrieves the Content Key, and then decrypts the KCB to extract the nonce. It then checks the nonce, and removes it from its memory. After successful verification, the CDM computes the license expiration time T1 + Δ_1. The CDM loads the Content Key in its memory for use. During our tests, we observed that any failed attempt of a future load does not invalidate the current Content Key in memory; media decryption can still happen.

3.2.3 Renew Licenses

Client Request. If the loaded policies allow the CDM to update its Content Key, an event of type license-renewal is triggered by the CDM. On renewal request creation, a newly generated privacy key is used to encrypt the Client ID as in the original request. Alongside them, the initial Request ID and request time T1 are used with a renewal request time T2, a counter C set to 0, or to the current counter in memory if it is not the first renewal request. The whole request is protected by an HMAC using the MAC Client Key. The CDM may generate multiple queries for the same renewal event identified by the same counter, but with different time. Indeed, EME events and renewal load might be asynchronous, and therefore multiple renewal queries may have been emitted before any successful load. Different queries may point to the same event if they all include the same identifier, *i.e.* counter.

License Format. The renewal license includes the Request ID, T1 and T2, an incremented counter $C = C + 1$, and the updated policies with the new duration time Δ_2. The license is protected with an HMAC using the MAC Server Key.

License Processing. The CDM can now update its Content Key. If the HMAC validation is successful, the new counter value replaces the existing one in memory, only if it is strictly greater than the former value; otherwise, the key update is unsuccessful. The expiration time of the Content Key is updated to T2 + Δ_2 + (T2' - T2). Here, T2' denotes the time indicated in the license response. Since multiple renewal queries with varying T2 values may have been sent, the received T2 might not correspond to the most recent one stored in the CDM.

3.2.4 Other Considerations

Different CDM Instances. Widevine provides different CDM implementations. Here, we highlight one in particular. In Android, during renewal, the KCB of the loaded Content Key is sent through the Client Request. Thus, a nonce is generated by the CDM, that checks its presence in the response as in the original request.

Minimum Viable License Server. In our study, we did not reverse engineer license servers, because we did not have any direct access to them. Indeed, we only experimented with the Widevine test license server to avoid legal issues. Here, we describe what we expect from a license server regarding the different EME stages, in conformance with what was observed from the test server. We assume that all values expected to be random are generated thusly. In addition, during license acquisition, the license server verifies the signature of the client request, and verifies that the Client ID was issued by some trusted certification authority controlled by Widevine. It also stores stateful information about the received license request: Request ID and derived session keys. As for license renewal, the license server verifies the HMAC of the client request, constructs the response, and does not store any state about it. For both cases, we suppose that the license server always replies to a request with a valid format without considering the semantics of the different fields. For instance, we assume that the license server would reply to valid queries with a valid license, even if the request contains times in the future, or a series of renewal requests that do not start with counter 0. This allows us to expand the scope of our work by analyzing the Widevine CDM implementation regardless of any additional non-standardized security mechanisms enforced by proprietary license servers.

3.3 Potential Attack

During our formal analysis of the Widevine EME (see Sections 5 and 6), we found one critical vulnerability which we describe in the following (see Figure 2), along with suggestions on how to fix it.

Attack Requirement. The attack exploits an understated detail while processing licenses of type license-request. Recall

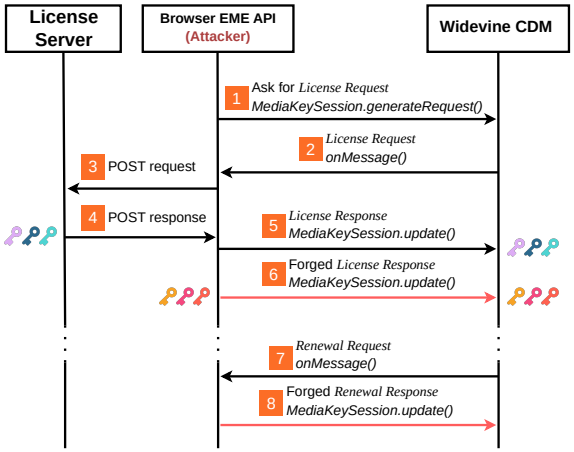

Figure 2: Widevine EME Key Derivation Attack.

that the CDM acts in two phases to load the Content Key and its associated policies. The attack requires that all modifications to the CDM memory during the first phase persist even if the second phase fails. For instance, if a license contains an invalid HMAC tag, and a valid session key encrypted with a valid Device RSA public key, then the derivation process (first phase) succeeds and the newly derived keys are stored in the memory. However, the second phase aborts as the HMAC verification does not succeed. It is important to note that Widevine CDM implementations may behave otherwise. Our hypothesis is supported by the interface of the Android CDM, where, according to [33], the load process involves two different calls: `DeriveKeysFromSessionKey`, followed by `LoadKeys`. However, we did not implement the attack to avoid any legal issues.

Attack Description. The objective of this attack is to allow the attacker, that is a subscribed user, to get more than what they pay for from the content provider, which is the victim. In technical terms, the attacker would like to load arbitrary policies, and hence an indefinitely long expiration time, for any Content Key that can be renewed at least once. To do this, the attacker does not need more than intercepting and making EME calls in the browser (via a plugin for example), on the attacker's device.

The attack scenario consists of three stages. The first stage is to observe the EME inputs and outputs during a successful license acquisition. Of particular interest, the attacker needs the client request, the Request ID and the Device RSA public key. This corresponds to steps 1 to 5 in Figure 2. In the second stage, the attacker forges a new license that attempts to load as a license of type license-request. This license contains a valid encryption of an attacker-generated session key, and some gibberish other values. As shown in step 6, the attacker calls the `update` API, and thus overwrites the Asset and MAC keys of the opened session with other keys that they control. The third stage is to wait for a renewal request that the attacker stops in step 7. Then, in step 8, the attacker forges a new license of type license-renewal leveraging the freshly modified keys. The attacker can, for instance, include any expiration time. The CDM would accept this license, since the attacker knows the derived keys. A similar attack is found even when renewal licenses contain encrypted KCBs.

Attack Mitigation. There are several ways to address this vulnerability, *e.g.* one could force all CDM implementations to commit their memory only when all the license acquisition process succeeds. This solution might not be straightforward to implement, especially when this may involve several API calls for modularity reasons. More broadly, we did not opt for any solution that requires subtle modifications in the behavior of Widevine CDMs. Instead, we suggest the following fix including two modifications. The first one concerns the EME specifications; we propose that an opened session is bound to a read-only server certificate that cannot be changed. Any subsequent call to `setServerCertificate` only impacts future sessions. The second modification concerns the format of license of type license-request. We propose that the license be signed by the private key of the server certificate. Thus, the CDM solely accepts licenses from the same entity for which it has generated the license request. Note that our mitigation suggests making use of the same RSA key pair for both signing and decryption in order to reduce storage requirements and costs for key certification. This practice does not come without risk, and can be a source of insecurity depending on the used signature/encryption schemes [10]. The Widevine CDM uses OAEP for encryption and PSS for signature, as found by Patat *et al.* [33]. Haber and Pinkas have shown that these two schemes are jointly secure; in other words, they can be securely combined using the same key without compromising their security [18].

4 EME Security Requirements

Despite not affecting all implementations of the Widevine CDM, our vulnerability demonstrates how brittle the security of a popular EME instantiation can be. This may be partly explained by the fact that the security objectives of EME are not well understood, or even clearly stated. The EME standard [43] is actually rather brief when it comes to security. It shortly introduces three potential attack vectors: input validation, CDM update frequency, and network. Further security specifications are omitted on the ground that *requirements for security cannot be met without the knowledge of the security and privacy properties of the Key System and its implementation(s)* [43]. In other words, the EME standard suggests that there is no, or very little, common security guarantees for EME to refer to without considering specific CDM implementations. This point of view is unfortunate, for two reasons: (1) the essence of EME is to ensure content security, and a common model might help future DRM systems; (2) a major

part of EME concerns the rights enforcement layer, whose security *has* already been discussed, in [12, 37].

In what follows, we propose some core security properties for EME, when considered as an enforcement layer. Then, we present a high-level description of seven security goals we define, covering all aspects of the EME workflow. We will use these goals later on to perform a complete computer-aided formal verification of the Widevine EME protocol.

As already mentioned in the introduction, the main goal of EME is the interoperability between DRMs. Thus, EME contains unspecified message formats whose instantiations are DRM specific. Even if the exact content of these messages is necessary to perform a complete security analysis, the security goals presented in this section are generic and reusable to continue analyzing other DRMs, e.g. PlayReady or FairPlay.

4.1 EME as an Enforcement Layer

EME defines an enforcement layer that works as follows. The license server encapsulates the secret decryption key (obtained from the CDN), also called the *Content Key* in the Widevine jargon, with the associated usage rights, or *policies* (from the content provider), into a license. This license is forwarded to the CDM that first checks the usage rights before loading the key into its memory for content decryption.

According to [37], the rights enforcement layer has two main roles. First, it protects the usage rights associated with content against tampering: an attacker should not be able to modify the usage rights. Second, it guarantees that usage rights cannot be bypassed: an attacker should not be able to use the content in a way not authorized by the usage rights. The actual enforcement of licenses is proprietary, and rarely studied in literature. Instead, we suggest four main properties:

1. Confidentiality of the decryption key, so that an attacker cannot obtain a digital copy of the content outside the CDM.
2. Integrity of the usage rights, so that an attacker cannot alter the usage rights delivered by the content provider. For instance, an attacker could not extend their rights by altering the license expiration time.
3. Authenticity of the usage rights, so that the CDM enforces the rights strictly as they only were defined by the party related to the owner of the decryption key.
4. Freshness of the license, so that the CDM can only use it once, regardless of its type: license-request or license-renewal.

In the next subsection, we express and expand the above properties as 7 precise security goals. Loosely, property 1 maps to goal 1, properties 2 and 3 map to the two goals 2 and 5, and property 4 maps to goals 3 and 6. As for goals 4 and 7, they are defined to ensure that content will be used only under the conditions defined by the usage rights, notably the expiration time. Strictly speaking, this aspect is part of the rights management layer, but we still decided to consider it, since the EME standard defines an abstraction of the session expiration time.

4.2 EME Security Goals

Recall that the essence of DRM systems is to allow content providers to protect their media from *piracy*. A naive definition for protection from piracy would be: preventing any media from being illegally distributed outside the DRM ecosystem. Here, we go further this vague definition, and propose several security goals depicting EME as an enforcement layer. These goals, although stated in natural language, have a clear meaning and will be formalized in the next sections.

The EME protocol does not deal with trust issues between the content provider, the license server and the CDN. Therefore, our security goals assume all three are trustworthy entities communicating securely. Henceforth, we use the generic term "Over-the-Top" (OTT) platform to refer to them. Decryption keys are not shared between different OTTs. We also assume a trusted authority issuing certificates to *trusted* OTTs and *trusted* CDM modules. Thus, our security goals are stated against an attacker who does not carry any valid certificate, whether acting as an OTT or a CDM. We also assume that the attacker cannot tamper with the CPU clock used by the CDM.

Goal 1. Confidentiality of the decryption key.

The decryption key remains secret.

Only trusted CDMs can acquire the decryption key of media content. Thus, assuming the encryption algorithm used is secure, media contents cannot be obtained by an attacker.

Goal 2. Integrity and authenticity of initial licenses.

The CDM must load licenses of type license-request *as they were generated* by the issuing entity.

This goal implies integrity of both the decryption key and the associated usage rights. It also implies that the CDM accepts licenses only if the included usage rights come from the same entity that owns the decryption key.

Goal 3. Freshness of initial licenses.

A given license of type license-request can be loaded at most once, and only by the CDM generating the corresponding request.

In the EME API, an OTT issues a license of type license-request to reply to a query of type `generateRequest`. This goal mandates that the generated license can only be loaded by the trusted CDM creating the `generateRequest`. It also mandates that a load can only happen once for a given license.

Otherwise, an obvious attack would be to replay licenses to the CDM in an offline mode without validation from the OTT.

Goal 4. Enforcing expiration time of initial licenses.

Before any renewal, the CDM is able to use the decryption key at a given time `T` only if the expiration time specified by the OTT in the initial license is greater than `T`.

The EME standard expects that all licenses are associated with an expiration time. In section 2 of [14], the standard states that "*a key is not usable for decryption if its license has expired*".

Goal 5. Integrity and authenticity of renewal licenses.

The CDM must load licenses of type license-renewal *as they were generated* by the issuing entity.

This goal implies integrity of the included usage rights. It also implies that the CDM accepts license-renewals only if they come from the same entity that issued the associated license of type license-request. In other words, only the OTT owning the decryption key loaded by a CDM can update its usage rights.

Goal 6. Freshness of renewal licenses.

A given license of type license-renewal can only be loaded once after a renewal event, and only by the CDM generating the corresponding request. This must hold even if multiple renewal licenses corresponding to the same renewal event have been emitted.

Similar to Goal 3, this goal mandates that the generated license can only be loaded by the trusted CDM triggering the event for license-renewal. Recall that a renewal event may generate multiple queries all containing the same unique identifier; a counter in the case of Widevine.

Goal 7. Enforcing expiration time of renewal licenses.

After a renewal, the CDM is able to use the decryption key at a given time `T` only if the expiration time specified by the OTT in a renewal license is greater than `T`.

This goal is the counterpart of Goal 4. Note that loading a renewal license on a CDM does not always extend expiration times; it may instead shorten them. The OTT, however, cannot force the CDM to actually load a (potentially shortening) renewal licence, and only knows it has been sent.

4.3 Threat Model

It should be noted that the threat model for DRM is quite different from the traditional threat model for Alice-Bob protocols. The traditional model often assumes that Alice and Bob trust each other. For DRM systems, the threat model cannot assume this symmetry of trust. In most cases, Alice, the content provider, cannot trust Bob, the content user. In fact, Alice cannot distinguish an honest user from a dishonest one. Even if Bob is honest, it does not mean that his computer has not been tampered with. This asymmetry explains why content providers, or license servers, only trust Bob's CDM, and not his browser, *i.e.* his EME user-agent.

Thus, our threat model involves an attacker that can inject calls to the EME API into any page. In addition, calls to the EME API from any page can be intercepted, thereby modifying or injecting arbitrary data in the parameters of method calls. This corresponds to the network attacks as defined in section 10.3 in [14]. We exclude all software-based attacks, based on input sanitization and CDM vulnerabilities. This is due to the fact that all DRM systems can be trivially broken, provided a CDM with software vulnerabilities. Our paper focuses on finding weaknesses on the EME protocol itself, assuming a secure CDM implementation. For instance, the attacker can be a user with valid subscription that installs a malicious browser plugin controlling all calls to EME to extend their rights, even after the end of their subscription.

5 Formal Verification using TAMARIN

We analyzed the Widevine protocol using the protocol verification tool TAMARIN, to determine whether the security goals detailed in Section 4 are satisfied. In this section, after a brief introduction to TAMARIN, we explain our TAMARIN models as well as the difficulties we have encountered in providing a faithful representation of some parts of the API under study.

5.1 TAMARIN in a Nutshell

The TAMARIN prover [28] is a security protocol verification tool that supports both falsification and unbounded verification in the symbolic model. As usual in this setting, messages are represented by terms, and the cryptography is assumed to be perfect, *e.g.* nonces are unguessable, and recovering the content of a ciphertext is only possible when knowing the key. Security protocols are specified as multiset rewriting systems, which makes the tool particularly suitable to model stateful protocols such as APIs for which some contents (*e.g.* key material, counter values) are stored over a long period. This aspect is well-known to be difficult to handle, and despite some recent advances made in PROVERIF [4,5], another well-known symbolic protocol verifier, TAMARIN seemed to be better suited to our case study. In particular, a recent extension introduces subterm-based proof techniques [9], which helps dealing with counters, making it particularly attractive.

TAMARIN relies on multiset rewriting, a formalism that is commonly used to model concurrent systems, since it naturally supports independent transitions. The state of the system, *i.e.* the contents of each agent's memory, the network, and the attacker's knowledge, is globally modeled by a multiset of *facts*. Each fact is a name and a sequence of

terms representing data. For instance, in our models, a fact `!MovieGen($title, ~movie)` stores the information that a `~movie` has been generated, with its `$title` – in TAMARIN, values prefixed with `$` represent publicly known values, and values prefixed with `~` are fresh values, that are *a priori* secret.

A rewrite rule in TAMARIN has a name, *e.g.* **GenMovie**, and three components, each of which is a multiset of facts: the rule's left- and right-hand sides, and its labels. Executing this rule consumes (from the global fact multiset) the facts on the left, produces the facts on the right, and adds the label to the execution trace. Facts prefixed with `!` are *persistent*, *i.e.* they are not consumed, and can thus never be deleted or changed. For instance, the following rule **GenMovie** generates new **!MovieGen** facts with different movies, obtained using a built-in **Fr** fact that produces fresh values.

```
rule GenMovie:  [ Fr(~movie) ]
              -[ LMovieGen($title, ~movie) ]->
                [ !MovieGen($title, ~movie) ]
```

TAMARIN analyzes protocols in the so-called Dolev-Yao model, where the attacker is able to receive, intercept, modify, and forge messages. A built-in fact `K(m)` records that the attacker knows message `m`. TAMARIN has built-in rules for the attacker, that let them perform computations on messages they know, such as encrypting when they know both the plaintext and the key. Two built-in facts, `In(m)` and `Out(m)`, let protocol rules input and output messages from and to the network, which is supposed controlled by the attacker.

Once the protocol is modeled, we express security properties using *lemmas*. These are first-order formulas, written using the facts that label the rewriting rules. They can express properties of the protocol's traces. Execution steps in a trace are identified by indices `#i`, prefixed with `#`. For instance, the lemma below states that for all traces where a `movie` has been generated at step `#i` (label **LMovieGen**, from rule **GenMovie**), at no point `#j` in the trace does the attacker know `movie`. In other words, this expresses that movies are never known by the attacker.

```
lemma movieSecrecy: "∀ #i title movie.
   LMovieGen(title, movie)@#i ⇒ ¬ (∃ #j. K(movie)@#j)"
```

Restrictions are another useful feature of TAMARIN. They are formulas similar to lemmas, except that instead of proof obligations, they are assumptions, *i.e.* they tell TAMARIN to restrict its analysis to traces where they hold. As an example, we may use a restriction to model the fact that the OTT, when renewing a license, may attach a policy to it, marking it as further renewable or not. Assuming that the corresponding rule modeling the OTT features a fact **License**, where the policy field is left unspecified, we can write a restriction to enforce that only traces where the policy is instantiated by `'renewable'` or `'stop'` will be considered in the analysis.

```
restriction LicenseRenewOrStop:
"∀ #i l. License(l)@#i ⇒(l = 'renewable' | l = 'stop')"
```

When provided with a lemma, TAMARIN attempts to prove it, or to find a trace that contradicts it. This trace contains the sequence of rules that are applied and the actions the attacker took to violate the property. As the proof search is undecidable, TAMARIN may also not terminate. In that case, it is possible to use an interactive mode and to prove the property manually by guiding TAMARIN regarding the states to explore. Once the proof is done, or an attack is found manually, it is possible to store it, or to write an oracle that guides TAMARIN during its exploration. The idea is that, even if the security analysis requires some manual guidance at first, it is then possible to reproduce the result automatically.

5.2 Our TAMARIN Models

As explained in the previous section, one difficulty was to write the models themselves. In the absence of a clear, detailed specification, the reverse engineering stage gradually made it possible to clarify various points and obtain a representation as faithful as possible of the protocol to be studied.

We model four variants of Widevine: we analyze both the Android version, where the KCB is part of the renewal request, and the desktop version, where it is not. For each version, we consider both the actual protocol and the patched version, which includes the mitigation we propose. These four TAMARIN studies are rather similar regarding the protocol models, as they share a common basis, with only minor changes to account for the presence of the KCB and patch.

Our model of the Widevine protocol is composed of 18 multiset rewriting rules in total, divided in three sets: 6 rules for the initialization of pre-existing data (movies, content keys, public key infrastructure, *etc.*), 8 rules for the role of the CDM, and 4 rules for the role of the OTT. These rules model an unbounded number of instances of CDMs and OTTs running the protocol in parallel.

As an example, the following rule **CDMGenerateRequest** (simplified for legibility) models the generation of a license request by a CDM.

```
rule CDMGenerateRequest:
  let request = <~rID, ~keyID, %t,
                 enc(clientID, ~kPrivacy),
                 aenc(~kPrivacy, pk(~kOTT)), ~n>
      signReq = sign(request, kDevice)
  in
  [ In(%t), In(~keyID), Fr(~rID), Fr(~n), Fr(~kPrivacy),
   !OTTKey(~kOTT), !CDMSession(~sID, kDevice, clientID)]
 -[ GTime(%t), LCDMGenR(~requestID, ~sID, %t) ]->
  [ Out(<request, signReq>), CDMNonce(~n, ~sID),
   !CDMState(~rID, ~sID, ~kOTT, request, %t),
    CDMKeys(~rID, ~sID, ∅),
    CDMContentKey(~rID, ~sID, ∅, %1) ]
```

In this rule, a CDM session, with a session state `!CDMSession(~sID, kDevice, clientID)` containing a session identifier, a device key, and a client ID, generates a random request ID `~rID`, a nonce `~n` and a privacy

key ~kPrivacy. It uses these values to compute the license request, and signs it with its device key. It outputs the resulting message <request, signReq>, and stores all relevant data in facts CDMNonce, !CDMState, CDMKeys, CDMContentKeys. The role of these facts is further discussed in Section 5.4. The rule is labeled with fact LCDMGenR, recording the request generation. Note that the request contains a value %t, representing the current date, also included in an input and in label GTime: these are used as part of our model of time, which we discuss in Section 5.5.

5.3 Main Assumptions and Limitations

It is worth discussing the faithfulness of our models and analysis. We have attempted to construct a formal model of EME/Widevine that is as close to the real protocol as possible. However, a gap can occur between our model and reality.

Indeed, this mainly comes from the gap between our description of the CDM and its actual implementation. The EME specification, combined with the reverse engineering we performed, gives us a description of the behavior of the CDM. This description is fairly precise – going back and forth between the reverse engineering and formal modeling allowed us to extensively test the CDM to refine it, as described in Section 3.1. Still, we cannot be certain that we perfectly described the CDM: ultimately, we only know about the behaviors we could observe, and there could in principle exist some behaviors of the CDM that are possible but that we were unable to trigger.

Below, we discuss two particular modeling assumptions we made in our Tamarin analysis.

First, when loading a license response, the counter kept by the CDM is in a normal execution still at its initial value (zero). Indeed, in a normal, honest execution of the protocol, only one load is performed in any given CDM session. It is however unclear how that counter would be handled if an attacker was somehow able to cause a second "load" to be successfully executed in a session. We have not been able to test which behavior is implemented in practice, which would have required us to simulate an OTT sending several license responses. We therefore felt that the reasonable way to proceed in our analysis was not to make an arbitrary choice, but rather to discard executions where two loads are successfully performed in the same CDM session. We express this assumption in TAMARIN as a restriction.

It is of note that this restriction is actually in line with the most recent draft of the EME standard [32], which imposes that only one license request is sent by the CDM per session. We were in fact able to prove that, for the desktop version of the CDM, the unicity of the license request implies the unicity of the nonce, and in turn of the license load, per CDM session, *i.e.* to lift that assumption. In the Android version, however, the same argument cannot be made. Since a nonce is also generated for any license renewal request by the CDM to populate the KCB, the unicity of the nonce per session, from which that of the load follows, does not hold. Thus, we kept the unique load assumption for that version of the protocol.

Second, in some implementations, when receiving a license response, a single CDM API function call performs both the derivation of Asset and MAC keys, and then the loading of the license. Providing this function with badly constructed parameters may result in the CDM deriving and storing the keys, and then failing to load the license. That behavior was observed while reverse engineering some CDM implementations. To account for this scenario, we chose in our model to split the handling of a license response into two rules, one for deriving the keys, and the second for loading the license. We however do not require the loading to be performed immediately after the derivation – such restrictions are not easily dealt with in TAMARIN. This gives the attacker slightly more power than is actually possible. That is not an issue: the attack we found does not use this additional power, and we still could prove secure the patched versions of the protocol.

Regarding the OTT, as already mentioned in Section 3, we did not reverse engineer its behavior, and therefore we modeled a "minimal" OTT. Note that the attack we discovered in our analysis does not depend on internal or unspecified behaviors of the OTT: it can be performed with any OTT that replies to normal protocol messages as expected.

5.4 A Stateful API Manipulating Counters

Although EME prescribes the flow of messages between the CDM and OTT in a normal execution of the protocol, the related API provides the browser with methods that can in fact be called in any order. To accurately represent this behavior, we do not impose a sequential order for the rules in our TAMARIN models: any CDM rule can be executed at any point, and updates the CDM's internal state accordingly. This state is modeled using facts that store the relevant information – persistent facts, for data that is set once and never updated, and non-persistent facts for data that can be updated later on. For instance, in rule CDMGenerateRequest described earlier, a persistent fact !CDMState is created to store (among other data) the ~rID and the initial license request, which are stored until the end of a session and never updated. On the other hand, CDMNonce and CDMContentKey are linear facts. They are used to store resp. the nonce sent in a license request, which can later be deleted when loading the matching response, and the memory cell used to store the content key and license policy, which are initially 'null' and can later be updated when loading (renewal) responses. This is rather standard practice when modeling stateful protocols and APIs. It does however complicate reasoning, compared to stateless protocols, as it required us to show invariants on the states, to help TAMARIN in its backwards search.

A notable feature of the CDM state is the presence of a counter identifying an event of license renewal. This counter

is incremented each time a renewal response is successfully loaded. We rely on a recent extension of TAMARIN [9], that is specifically designed to reason about increasing counters.

5.5 The Crucial Role of Time

A major feature of our TAMARIN analysis is the modeling of time. Widevine messages for license and renewal requests include timestamps indicating the date at which requests are generated, and responses contain a time-to-live indicating the duration of the license's validity. TAMARIN has no built-in notion of time – only an ordering of events in an execution trace, which protocol messages do not have access to.

The indices available in TAMARIN are useful to reason about the order of actions, but they cannot express durations, they cannot be used to compute values (e.g. the sum of two indices is meaningless), and they cannot be used as timestamps in messages (an agent sending the index of its action makes no sense). It is sometimes possible to abstract time away, and to write properties at the level of indices. This is usually done for instance when modelling authentication properties stating that when an agent performs an action at $\#i$, then another one has performed a specific action at $\#j$ with $\#j < \#i$.

For that reason, timestamps are usually abstracted away (or simply not modelled at all) when analyzing protocols in TAMARIN. However, in our case some security goals rely heavily on time, and we did not see a way to abstract it. Indeed, timestamps are essential to the security of the system, as they are required to state Goals 4 and 7 (*cf.* Section 4). For that reason, we propose an explicit model of time, accessible to protocol agents, which is to our knowledge the first in TAMARIN.

We model time as a global clock, *i.e.* an integer counter `%t`, representing the current date. Each protocol rule receives, by an input `In(%t)`, the current time from the attacker. That value `%t` can then be used and referred to when writing security lemmas. We let the attacker pick the clock value each rule receives, modeling the fact that they can decide to wait as long as they want before triggering the execution of a rule. We force them however to choose these values in a consistent way: time only goes forward. To do so, we label each rule with an event fact `GTime(%t)`, recording the time at which it is executed, and we consider the following restriction:

```
restriction TimeIncreasing: "∀ #i #j %t1 %t2.
 GTime(%t1)@#i & GTime(%t2)@#j & #i<#j ⇒ %t1<<%t2"
```

We can then use this global time to specify for instance that the CDM only uses a content key (using a rule not depicted here, labeled with fact `LCDMUseKey`) at time `%t` if the expiration date `%t0 %+ %delta` for the license, stored in its state (fact `LCDMContentKey`), has not passed yet. This is expressed by the following restriction (simplified, for clarity):

```
restriction UseKeyLegal:
  "∀ #i requestID sID  k %t %t0 %delta.
     LCDMUseKey(rID, sID, k)@#i
   & LCDMContentKey(rID, sID, k, %t0, %delta)@#i
   & GTime(%t)@#i
  ⇒  %t << %t0 %+ %delta"
```

The reasoning on time is again facilitated by the recent TAMARIN extension for counters [9]. In order to obtain better performance from TAMARIN, we actually only add the timer input and label to the protocol rules that effectively use the current time. Doing so produces the same executions, but greatly reduces the number of `GTime(%t)` facts TAMARIN has to consider, only keeping those that are really useful.

6 Results of the Formal Analysis

We describe here how we proceed to analyze the models presented in Section 5.2. We first explain our methodology in Section 6.1 before summarizing our findings in Section 6.2. In Section 6.3, we give an overview of how TAMARIN reasons by providing some details about the proofs of Goal 2.

6.1 Our Methodology

Initially, we focused on obtaining a faithful model of the protocol in its desktop version. In a second stage, we considered the model for the Android version (*i.e.* with a KCB in the license renewal requests). This only causes some minor changes in our security analysis. We summarize some hands-on details about our TAMARIN model and how to execute it in Appendix B. For each model, we started with some sanity checks to ascertain that models were correct. This is the purpose of the "executability lemma" available in each model. These TAMARIN lemmas express the fact that the normal intended protocol flow can be executed in our models. These lemmas can be found in each of our Tamarin files and are systematically checked before performing the security analysis. While this reduces the risk that modelling mistakes were made, it does not guarantee that our models exactly correspond to the implementation. Though unfortunate, this situation is common when formally verifying protocols.

Then, the security analysis is carried out in 3 stages:

Some basic secrecy properties (including Goal 1). We first state some lemmas to establish secrecy of various keys used in the protocol, in particular the content keys used to protect movies, and the session keys generated by OTTs. These basic properties were easy to prove for TAMARIN, and their proofs were obtained automatically. All these lemmas are marked with flag `[reuse]`, to let TAMARIN know they can and should be used when proving the other security goals.

Analysis of the initial part (i.e. Goals 2, 3, and 4). This part requires the writing of some specific intermediate lemmas, especially to reason about the content of some memory cells, *e.g.* those used to store the Asset and the MAC keys.

Analysis of the renewal part (i.e. Goals 5, 6, and 7). This part is by far the most involved. When trying to prove Goal 5,

TAMARIN led us to the derive attack we presented in Section 3.3. Then, once this issue was resolved by applying the proposed patch, we applied the same methodology as the one for analyzing the initial part.

License policies. When performing a security analysis of a DRM system, it makes sense to check that license policies are respected, *i.e.* that the CDM can load a renewal license only if this is authorized by the policy. This goal cannot be stated at the EME level, as policies are not part of the EME specification. However, we can express it when analyzing Widevine EME, and we therefore decided to consider this extra goal, which we call Goal 8, in our security analysis.

6.2 Summary of our Results

Our findings are summarized in Table 1. While most of the basic secrecy properties were obtained automatically using the autoprove mode of TAMARIN, the proofs of Goals 2 to 8 required some intermediate lemmas. These proofs have thus been obtained at first using the interactive mode of TAMARIN. For reproducibility purposes, we then automated them, relying on the oracle mechanism available in TAMARIN.

	without fix		with fix	
KCB	with	without	with	without
Goal 1	✓	✓	✓	✓
Goal 2	✓	✓	✓	✓
Goal 3	✓	✓	✓	✓
Goal 4	✓	✓	✓	✓
Goal 5	✗	✗	✓	✓
Goal 6	✓	✓	✓	✓
Goal 7	✗	✗	✓	✓
Goal 8	✗	✗	✓	✓

Table 1: Summary of our results. ✓ indicates that the goal is proved automatically by TAMARIN, whereas ✗ means that the goal is false (variants of the derive attack).

All our experiments were performed on a laptop with a 2.30GHz Intel Core i7-1068NG7 CPU and 16GB of RAM. We use version 1.8.0 of TAMARIN. Our models are available for reproducibility purposes [11]. The verification time varies depending on the model, and the goals we are trying to establish. The easiest lemmas are proved in a few seconds, whereas the most difficult ones, *i.e.* Goals 5-8 of the patched Android version, require around 4 minutes.

6.3 Proving the Security Goals

Even if the proofs are done *in fine* in an automatic way, some expertise and manual effort were necessary to obtain them. As an illustration, we present the proof of Goals 2 and 5.

```
lemma Goal2:
"∀ #i1 #i2 rID sID k kAsset kMacS kMacC resp
      title movie ottID keyID.
 Load(rID, sID, k, kAsset, kMacS, kMacC, resp)@#i1
 & Movie(title, movie, ottID, keyID, k)@#i2
⇒ (∃ #j.   #j < #i1
 & OTTLR(rID, ottID, k, kAsset, kMacS, kMacC, resp)@#j)"
```

This lemma states that when the CDM loads a license `resp` for a movie with content key `k`, this license has been generated by an OTT before, *i.e.* at some step `#j` occurring before `#i1`.

The proof of `Goal2` relies on two secrecy lemmas. One establishes the secrecy of the session keys generated by an honest OTT, and the other is actually `Goal1`: secrecy of content keys. We also need an additional lemma, stating that when a command uses the Asset or MAC keys, then these keys have been initialized earlier by a call to the derive command, unless there are still `'null'`.

```
lemma CDMKeysInit[reuse, use_induction]:
 "∀ #i rID sID kAsset kMacS kMacC.
      Keys(rID, sID, kAsset, kMacS, kMacC)@#i
⇒ ( (∃ #j. (#j < #i)
       & Derive(rID, sID, kAsset, kMacS, kMacC)@#j)
   | (kAsset ='null' & kMacS = 'null' & kMacC = 'null'))"
```

This lemma, although not surprising, is not obvious to TAMARIN, and requires a proof by induction, as indicated by the flag `[use_induction]`. The induction step holds, as the memory cells storing those keys are either left unchanged, in most rules, or indeed initialized, in the derive rule.

Using these three lemmas, we are then able to conduct the proof of `Goal2` with TAMARIN. When a load command is successfully executed, the MAC received by the CDM:

- *(i)* either comes from the protocol;
- *(ii)* or has been forged by the attacker.

In the former case, due to the format of the received MAC, it has necessarily been emitted by a license-response command, and thus the claim holds. Indeed, in this case, the agreement on the different keys is clear, as the content key appears in the exchanged message. In the second case *(ii)*, the `CDMKeysInit` lemma tells us that the Asset and the MAC keys are:

- *(ii.a)* either `'null'`;
- *(ii.b)* or have been initialized by a derive command.

In case *(ii.a)*, as the load command also needs a message of the form `senc(k, kAsset)` in input, the branch can be closed: if `kAsset` was equal to `'null'`, then the secrecy of the content key `k` would be violated.

In case *(ii.b)*, the derive rule tells us that the MAC key is `KDF(..., kSession)`. As no rule produces such a term at an extractable/deducible position, the attacker must have built it using their own `kSession`. In that case, the message `senc(k, kAsset)` with `kAsset=KDF(...,kSession)`, needed in input of the Load rule, can either be produced by the OTT, or

constructed by the attacker. The former case contradicts the fact that the kSession keys generated by the OTT are secret (the aforementioned secrecy lemma). The latter case implies that the attacker knows the content key k, leading again to a contradiction.

Implementing this proof strategy in an oracle, we obtain the following result, indicating that TAMARIN succeeds in proving all the lemmas. It also gives us the number of reasoning steps done by TAMARIN for each proof.

```
==============================================
SecrecykSession (all-traces): verified (25 steps)
Goal1 (all-traces): verified (4 steps)
CDMKeysInit (all-traces): verified (43 steps)
Goal2 (all-traces): verified (10 steps)
==============================================
```

Goal 5. The statement for **Goal5** is similar to **Goal2**, except that it concerns the renewal part.

```
lemma Goal5:
  "∀ #i1 #i2 rID sID k kAsset kMacS kMacC
       resp title movie ottID keyID.
  LoadRenew(rID,sID,k,kAsset,kMacS,kMacC,resp)@#i1
  & Movie(title, movie, ottID, keyID, k)@#i2
 ⇒  (∃ #j. #j < #i1
  & OTTRR(rID, ottID, k, kAsset, kMacS, kMacC, resp)@#j)"
```

Regarding its proof, things are a bit different. Actually, we have already seen that **Goal5** does not hold, because of the derive attack (*cf.* Section 3.3). We would like to pinpoint exactly where the previous reasoning fails. Basically, the issue comes from the fact that the content key k is not part of the response processed by the CDM, and thus to ensure agreement on it, more work is needed even in case *(i)*. The case *(ii.a)* and *(ii.b)* are also more complex for the same reason. We can *not* reason on the message senc(k, kAsset), which is not present in a renewal response. Case *(ii.a)* can be handled by showing that kAsset = 'null' implies that the memory cell was not initialized, which is actually not possible (this requires some extra intermediate lemmas). Case *(ii.b)* is more problematic and leads to the derive attack. A way to prove this case would be to ensure that the kSession key as seen by the CDM is secret, and thus the attacker is not able to build KDF(..., kSession). This secrecy property (of kSession from the CDM's point of view) does not hold in the unpatched protocol, but is fixed by the proposed patch.

7 Conclusion

In this paper, we performed the first in-depth and formal analysis of the W3C EME as implemented by Widevine. To the best of our knowledge, our work is the first to provide such analysis of any DRM system for video playback. To enable the analysis, we reverse-engineered various Widevine proprietary details, and we formulated precise security properties that reflect the notion of piracy. Our study indicates that our methodology is effective in automatically finding potential weaknesses. Building on a systematized workflow for the EME API allowed us to consider sophisticated combinations that can be achieved by the attacker in our threat model.

In the future, we aim at keeping our models up to date with upcoming work revealing novel insights about Widevine internals or about other DRM systems. We chose Widevine because of its dominance, but other DRM systems, such as PlayReady and FairPlay, are of course worth analyzing. This requires us to extend our work in two ways. First, we need to reverse-engineer these systems (as we do in Section 3 for Widevine), and also to provide a formal model of them (as we do in Sections 5 and 6 for Widevine). However, the security goals set out in Section 4 will remain unchanged, and we can even imagine that some parts of the formal model (e.g. the way we model time) could be reused.

In addition, there are multiple ways to improve our work, notably by considering a new threat model where valid OTT platforms can be dishonest. Namely, an attacker can successfully perform the setServerCertificate method to interact with the CDM through successfully initialized sessions. Lastly, we believe that it would be insightful to analyze EME through specialized models designed for the Web. Indeed, EME inherently uses many features of the Web, including scripts, origins (and hence, the notion of domains), the windows and document structure of browsers, and HTTPS. Therefore, basing future analysis of EME on a model that supports these features is crucial in order to be able to model EME as implemented by browsers (and not CDMs). Unlike our work, the related threat model is malicious web pages attempting to break privacy, or even to hijack opened sessions by a valid OTT.

A Widevine EME Internals

A summary of Widevine EME message content and Widevine internals are given in Table 2 and Table 3.

B Formal Security Analysis

Size of our TAMARIN models. We summarize some information regarding the size of our models in Table 4. We do not take into account the part of the files concerning the sanity check (executability lemma).

	without fix	with fix
#LoC protocols	510	510
#LoC properties	200	450
#lemmas (secrecy properties)	9	11
#lemmas (initial part)	5	5
#lemmas (renewal part)	_	15

Table 4: Summary regarding the size of our models. #LoC includes the comments, and #lemmas includes the intermediate lemmas stated and proved to establish our 7 main goals.

Command line to run experiment. Each model found in 'widevine.spthy' can be launched via the following command:

```
tamarin-prover --prove  --derivcheck-timeout=0
        --heuristic=O --oraclename='widevine.oracle'
        widevine.spthy -DSecrecy -DGoalInitialPart
```

We explain below the different elements:

- `--prove` means that the tool is launched using its automatic mode (no user interaction);
- `--derivcheck-timeout=0` is there to turn off some sanity checks that are useless once the model is written;
- `--heuristic=O --oraclename='widevine.oracle'` means that the oracle written in the file 'widevine.oracle' will be used to guide the proof search;
- `-DSecrecy -DGoalInitialPart` indicates that only the main part of the file as well as those defined in the macros `DSecrecy` and `DGoalInitialPart` will be taken into account.

Some insights regarding Goal 6 and its proof. Regarding freshness of the license during a load (Goal 3), the situation is rather simple. This property is ensured by the nonce generated by the CDM and consume when the response (which contains also the nonce) is loaded by the CDM. The TAMARIN proof is very easy and done in very few steps. Establishing Goal 6 (freshness of the license during a renewal load) is more involved. The difficulty comes from the fact that the renewal part does not rely on the use of a nonce to ensure freshness of the response that is loaded. The freshness is ensured through the use of a counter that is increased by the CDM each time a renewal response is loaded. We thus have to state and prove some lemmas (by induction) that roughly state that the counter is always increasing, and even strictly increases each time a renewal load is performed. Then, Goal 6 easily follows.

```
==============================================================
CounterIncrease (all-traces): verified (259 steps)
CounterIncreaseStrictly (all-traces): verified (3941
    steps)
Goal6 (all-traces): verified (18 steps)
==============================================================
```

EME Message	EME Method	Widevine EME Message Content
License Request	`generateRequest`	body = {Request ID, nonce, {ClientID}$_{\text{privacyKey}}$, {privacyKey}$_{\text{serviceCertificate}_{\text{pub}}}$, KID, T1}, signature = sign(body, DeviceRSAKey$_{\text{priv}}$)
License Response	`update`	body = {{SessionKey}$_{\text{DeviceRSAKey}_{\text{pub}}}$, response = Request ID, T1, KID, {ContentKey}$_{\text{AssetKey}}$, {KCB}$_{\text{ContentKey}}$, Policies}, hmac = HMAC(response, MAC Server Key)
Renewal Request	`onMessage`	body = {Request ID, {ClientID}$_{\text{privacyKey}}$, {privacyKey}$_{\text{serviceCertificate}_{\text{pub}}}$, T1, T2, counter, *nonce*†}, hmac = HMAC(body, MAC Client Key)
Renewal Response	`update`	body = {Request ID, T1, T2, Updated counter, Updated Policies, *Updated KCB*†}, hmac = HMAC(body, MAC Server Key)

† only on Android.

Table 2: Widevine EME Message Content.

Steps	EME Protocol	EME Method	Widevine Method	Widevine Internal Memory
1	Initial State	`createSession`	OpenSession	InitialKeys = {DeviceRSAKey$_{\text{pub/priv}}$, serviceCertificate$_{\text{pub}}$}, Session ID
2	License Request	`generateRequest`	PrepareKeyRequest	InitialKeys, IDs = {Session ID, Request ID}, nonce, T1, request

Length Leakage in Oblivious Data Access Mechanisms

Grace Jia
Yale University

Rachit Agarwal
Cornell University

Anurag Khandelwal
Yale University

Abstract

This paper explores the problem of preventing length leakage in oblivious data access mechanisms with passive persistent adversaries. We show that designing mechanisms that prevent both length leakage and access pattern leakage requires navigating a three-way tradeoff between storage footprint, bandwidth footprint, and the information leaked to the adversary. We establish powerful lower bounds on achievable storage and bandwidth footprints for a variety of leakage profiles, and present constructions that perfectly or near-perfectly match the lower bounds.

1 Introduction

Cloud services offer scalable, fault-tolerant, and easy-to-manage systems for storing and querying data. However, using (untrusted) cloud services also leads to significant security concerns: data accesses that used to be contained within an organization's trusted domain are now visible to potentially untrusted entities on the cloud. A now-long line of work has shown that, even if offloaded data is encrypted, an adversary can exploit data access patterns to learn damaging information about the data [1–4]. To protect against such access pattern attacks, our community has developed a large and active body of research on oblivious data access mechanisms: on different adversarial settings (*e.g.*, active [5] vs. persistent passive [6]), enabling transactional [7] and asynchronous queries [8, 9], enabling distributed proxy deployments [10, 11], achieving performance scalability [12–19], and identifying performance limits [20–25], to name a few.

This paper explores a complementary problem: preventing length leakage in oblivious data access mechanisms. Specifically, both ORAM-based [5] and PANCAKE-based [6] oblivious data access mechanisms assume that all data objects are of the same size; this is far from realistic in practice—recent studies from real-world production systems have established that data object sizes can vary by multiple orders of magnitude [26]. For such realistic scenarios, it becomes important to design systems that not only enable oblivious data access but also protect against length leakage.

Preventing length leakage in oblivious data access mechanisms raises new challenges: as we will show, it requires navigating a complex three-way tradeoff between the storage used by the mechanism (i.e., its storage footprint), the total amount of access traffic to the storage per query (i.e., its bandwidth footprint), and the precise information leaked to the adversary. To provide some intuition, consider the following two extreme design points. One obvious design is "padding"-based [27]: each object is padded with random bits to the largest object size, say, s_{max} (queries are responded to in an obvious manner); with n objects, this design requires storage footprint equal to $n \cdot s_{max}$, bandwidth footprint proportional to s_{max} per query[1], and informally speaking, leaks information about the number of objects (n) and the largest object size (s_{max}) to the adversary. At the other extreme are more recent "packing"-based designs [28], in particular size-locked indexes [29]: all data objects are packed into one blob (each data access query is responded to by downloading the entire blob). This requires storage and bandwidth footprint equal to the sum of the sizes of the plaintext objects—$\sum_i s_i$; informally, such packing-based designs leak information about the sum of the sizes of the plaintext objects to the adversary. Returning to the three-way tradeoff: the first design has *higher* storage footprint, *lower* bandwidth footprint, and (informally) *less* information leakage than the second design. Thus, depending on the storage budget, bandwidth budget, and/or security goals, either of the two design points may be of interest.

This paper explores fundamental limits *and* achievable design points for preventing length leakage in oblivious data access mechanisms. We focus on passive persistent adversaries, as motivated by the PANCAKE work [6]. We provide details on our system and security model in §2, but briefly, an encryption proxy takes as input a collection of n plaintext objects of sizes $S = \{s_1, s_2, \ldots, s_{max}\}$, and creates encrypted objects that will be stored in an untrusted storage server. The

[1] ORAM and PANCAKE incur $\Omega(\lg(n)) \cdot s_{max}$ and $3 \cdot s_{max}$ bandwidth footprint, respectively.

adversary can observe all the (encrypted) queries/responses between the proxy and storage, but it cannot inject queries; instead, queries are sampled from a distribution π. The encryption mechanism has an estimate of the distribution, and the adversary knows the precise distribution. The adversary "wins" if it can distinguish the sequence of queries from a sequence of uniformly distributed accesses to fixed-sized random bit strings—capturing both access pattern and length leakage. We introduce a formal security framework that captures this setting as real-or-random indistinguishability under chosen distribution and length attack (ROR-CDLA, §7).

1.1 Summary of Key Results

We establish the following results (Table 1):

(1) First, we establish the intuitive result that padding-based schemes [27] applied to oblivious data access mechanisms [6] yield bandwidth-optimal constructions, while providing strong security: leaking only the number of objects (n) and the largest object size (s_{max}) to the adversary. In particular, we establish that any scheme that reveals only n and s_{max} must incur a minimum bandwidth footprint $\alpha \times s_{max}$ per query, where $\alpha \geq 1$ is a constant (independent of n) for any fixed storage footprint; larger storage footprint may enable a smaller α. Furthermore, we establish that padding-based schemes [27] applied to oblivious data access mechanisms [6] achieve an upper bound that precisely matches this lower bound. These results imply that it is possible to design mechanisms that offer strong security at low bandwidth overheads[2] if there is little variance in object sizes (i.e., the average object size is close to the largest) but quite high for use cases where object sizes may vary by orders of magnitude [26]. This motivates the relaxation of security for more storage and bandwidth-efficient schemes.

(2) Second, we establish lower and upper bounds for packing-based designs [28, 29]. Specifically, our lower bound shows that when restricted to minimum possible storage—the sum of all the object sizes—any scheme that reveals n and $\sum_i s_i$ must have a bandwidth overhead of $\sum_i s_i$ (matching the bandwidth overhead of the size-locked index construction [29]). Our lower bound and the construction whose performance meets the lower bound is more general: given even slightly more storage than $\sum_i s_i$, it is possible to dramatically reduce bandwidth footprint, albeit with slightly more leakage than size-locked indexes. In contrast to size-locked indexes that pack all objects into one bin, our generalized construction first bin-packs objects across s_{max}-sized bins and then employs a PANCAKE-based oblivious access mechanism over the bins. This construction achieves our generalized lower-bounds, i.e., if a scheme is allowed to leak the plaintext object sizes (instead of the sum of the object sizes as in the size-locked index construction), its bandwidth footprint lower bound decreases to a smaller multiple of s_{max} (compared to (1)), with the multiple decreasing even faster as the given storage increases. This is particularly useful for datasets with objects of very variable sizes, where bin-packing objects can permit massive reduction of the bandwidth overhead for a given storage footprint.

Leaked information	Bandwidth Lower-bound	Optimal Scheme
n, s_{max} (§3)	$\frac{\lfloor \kappa n \rfloor}{\lfloor \kappa n \rfloor - n + 1} \cdot s_{max}$	Padded PANCAKE
n, S (§4)	$\frac{\lfloor \kappa n \rfloor}{\lfloor \kappa n \rfloor - N_{OPT} + 1} \cdot s_{max}$[3]	Stuffed PANCAKE
n, s_{max}, π (§5)	No closed form	Greedy PANCAKE
n, S, π (§6)	No closed form	MILP

Table 1: **Summary of our results** for n objects with sizes $S = \{s_1, \ldots, s_n\}$ and access distribution π. κ is a parameter that bounds storage to $\kappa \cdot n \cdot s_{max}$, and N_{OPT} is the minimum number of s_{max}-sized bins required to contain all objects.

(3) Third, for the case of leaking the access distribution, we present an improvement over the existing state-of-the-art construction, PANCAKE [6]. Our scheme greedily replicates objects with higher access probabilities and is provably bandwidth-optimal. Since the scheme can leak the access distribution, the bandwidth footprint depends on the distribution and can often be much smaller than those for (1). This is particularly useful for real-world key-value stores where accesses follow well-known Zipfian or bimodal distributions [26, 32].

(4) Finally, for the case of leaking both the individual object sizes and the access distribution, we demonstrate a fundamental limitation in existing constructions in terms of achieving bandwidth optimality. We demonstrate that existing oblivious data access mechanisms perform *uniform* load balancing of requests across object replicas; however, non-uniform load balancing is necessary to achieve optimality. We present a Mixed-Integer Linear Program (MILP)-based construction that performs non-uniform load-balancing to achieve bandwidth-optimality, outperforming all PANCAKE-variants introduced above. Depending on the input object sizes and access distribution across them, this construction can achieve a significantly low bandwidth overhead. However, the MILP approach does not scale beyond a few hundred objects, so we approximate its behavior using a polynomial-time scheme (Greedy Stuffed PANCAKE, §6.2).

In §2.3, we discuss how an adversary can use each leakage profile to extract meaningful information about the data.

Practical implications. We also empirically characterize the three-way tradeoff space for real-world datasets. Figure 1 shows the bandwidth overhead of each of the constructions in Table 1 as a function of their storage overhead.

Figure 1 confirms our results (1)-(4): bandwidth overheads for each scheme decrease with more storage, and given any

[2] A scheme's bandwidth overhead is its bandwidth footprint relative to an insecure baseline's footprint. A similar definition holds for storage overhead.

[3] Bound only holds for $\hat{s} = s_{max}$ and $\hat{s} \geq \frac{\lfloor \kappa n \rfloor}{\lfloor \kappa n \rfloor - N_{OPT} + 1} \cdot s_{max}$.

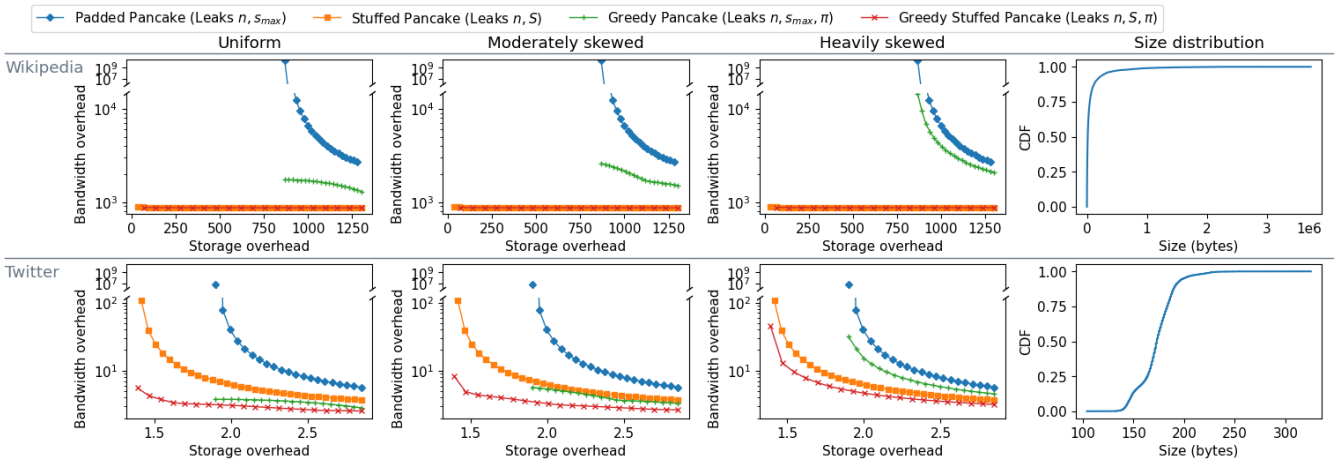

Figure 1: **Bandwidth vs. storage overhead across schemes with different leakage (§1.1).** We use real-world datasets from Twitter [30] (top) and Wikipedia [31] (bottom) (see Appendix for Facebook datasets [26]) and Zipf access patterns with varying skew (left to right). The rightmost column shows the dataset's object size CDF. Bandwidth overheads for schemes that do not leak object sizes start from $n \cdot s_{max}$ (required for security). The y-axes are in log-scale broken between bandwidth overheads 120–$10^6\times$ (Twitter) and 15000–$10^6\times$ (Wikipedia).

fixed storage, bandwidth overheads decrease as more information is leaked. Considering dataset-specific characteristics, we find that since Wikipedia has a large range of object sizes, all schemes observe a minimum of $\sim$1000$\times$ overhead, since hiding each object's identity requires each query to fetch the largest object size, which is 1000$\times$ larger than the average (similar observations have been made in prior work [33]). However, schemes that leak the object lengths (as noted in (2), (4)) incur lower bandwidth overheads, confirming our theoretical results. As such, the bandwidth overhead for such schemes is over 10$\times$ lower than schemes that do not leak object sizes. On the other hand, the Twitter dataset with less variability in object sizes can use schemes that do not leak object sizes for stronger security at a lower bandwidth overhead. Specifically, it observes $<$ 10$\times$ bandwidth overhead with 2–3$\times$ storage overhead, which reduces to 2–3$\times$ bandwidth overhead on leaking object sizes.

For access patterns with varying skew, schemes that do not leak the access distribution have the same bandwidth overhead regardless of skew, as expected; for schemes that leak access distribution, we observe lower bandwidth overheads (as noted in (3), (4)). Bandwidth overheads increase with the access skew since hiding the identity of the most popular object requires injecting more noise for all other objects.

Takeaways. For the problem of simultaneously preventing length leakage and access pattern leakage, our results establish a rich tradeoff space between the storage footprint, bandwidth footprint, and information leakage. Our constructions demonstrate that existing oblivious data access mechanisms can resist length leakage attacks with simple modifications in proxy-side encryption mechanisms. Even so, this paper only takes the first step in laying the intellectual foundation for preventing length leakage in oblivious data access mechanisms. Much more work needs to be done in this space; to that end, we close the paper by outlining several avenues of future research.

2 Overview

We now describe our system and security models.

2.1 System Model

Our setup consists of a key-value (KV) store that supports (single-key) get and put operations on KV pairs (k, v) submitted by one or more clients. Our results can, however, be applied to any data store that supports read and write operations. We focus on a trusted proxy architecture commonly used by encrypted data stores [8, 10–12, 34], which assumes multiple client applications route query requests through a single trusted proxy. The proxy manages the execution of these queries on behalf of the clients, sending queries to the untrusted storage service. We assume all communication channels are encrypted, e.g., using TLS.

2.2 Security Model

We now define our adversary and class of considered schemes.

Threat model. We use a trusted proxy threat model where the client and proxy servers belong to a trusted domain. We model client queries as independent samples from a distribution π over keys, i.e., the probability of access to a key k is $\pi(k)$. This work focuses on settings where the underlying distribution π is static. We discuss how our results may translate to the dynamic setting where π changes over time in §8.

We assume that the untrusted cloud storage service is controlled by a passive persistent adversary. This is typical of secure cloud-deployments [1, 2, 4, 6, 35], where the adversary (usually the cloud provider) can observe the volume (i.e., the number and size) of client queries, as well as the encrypted data stored at and retrieved from the storage service. It cannot, however, access cryptographic keys or change queries, responses, or stored data. The adversary aims to infer any information about individual KV pairs that are accessed. Similar to prior work [6, 9, 10, 12], we do not target hiding the timing of client queries.

Considered schemes. We consider a class of schemes $\mathcal{M}$, where each scheme $\Pi \in \mathcal{M}$ is defined as a pair of algorithms $\Pi = (\mathsf{Init}, \mathsf{Query})$. While we defer the formal security definitions to §7, we focus on an intuitive description here.

Init is an initialization algorithm that takes as input:

- a set KV of n key-value pairs $\{(k_1, v_1), \ldots, (k_n, v_n)\}$,
- a set S of value sizes $\{s_1, \ldots, s_n\}$, where s_i is the size of v_i.
- a distribution π over KV, where $\pi(k_i)$ corresponds to the probability of accessing key k_i, and,
- a storage parameter σ, which decides the total storage capacity available to the scheme.

Init outputs the following:

- a new set EKV of $\hat{n}$ KV pairs $\{(\hat{k}_1, \hat{v}_1), \ldots, (\hat{k}_{\hat{n}}, \hat{v}_{\hat{n}})\}$,
- a mapping P that maps each key k_i in KV to a set of keys in EKV whose values "contain" v_i in a contiguous sequence of s_i bytes. If Keys(KV) and Values(KV) denote the set of keys and values in KV respectively, then:

$$\forall k \in \mathsf{Keys}(\mathsf{KV}), \mathsf{P}(k) = \{\hat{k} \in \mathsf{Keys}(\mathsf{EKV}) \mid \hat{v} \text{ contains } v\}$$

- a set π_r of functions indexed by key k, where $\pi_r[k]$ takes as input $\hat{k} \in \mathsf{Keys}(\mathsf{EKV})$ and outputs the access probability of the copy of k's value contained in $\hat{k}$'s encrypted value [4],
- a distribution π_f over EKV, where $\pi_f(\hat{k})$ denotes the probability of accessing key $\hat{k}$ via "fake" queries or noise,
- the proportion of real queries δ to EKV, and,
- a constant $B \geq 1$ that will be used by Query and determine bandwidth footprint.

The mapping P is stored at the proxy and is hidden from the adversary; so are π_r and π_f. Note that since values of KV are contained in a contiguous sequence of s_i bytes in values of EKV (identified by P), $\mathcal{M}$ implicitly rules out compression or other encoding schemes that increase or decrease the size of data contained in values $v \in \mathsf{Values}(\mathsf{KV})$. Each key-value pair $(\hat{k}, \hat{v})$ in EKV is ultimately encrypted by applying a secretly keyed pseudorandom function (PRF) to the key (*e.g.*, HMAC) to generate a label, denoted $F(\hat{k})$, and symmetrically encrypting the value using authenticated encryption, denoted $E(v')$. These labels and encrypted values are ultimately stored in the storage service, while the secret keys needed for F and E are stored at the proxy and, therefore, hidden from an adversary. Because F is deterministic, the proxy can perform operations for key $\hat{k}$ by instead requesting $F(\hat{k})$[5]. We have omitted the two required cryptographic secret keys in our notation for simplicity. We cryptographically bind labels and value ciphertexts by using the label as associated data with E.

EKV additionally satisfies the following three properties:

Property 1. *Each value $\hat{v}$ in* Values(EKV) *has the same size* $\hat{s} \geq \max_i(s_i)$.

Property 2. *The total storage used by values* Values(EKV) *must be less than σ, i.e., $\hat{s} \times \hat{n} \leq \sigma$.*

Property 3. *Each v_i in* Values(KV) *is "contained" in at least one $\hat{v}_j$ in* Values(EKV)*, i.e., $\forall k_i \in \mathsf{Keys}(\mathsf{KV}), |\mathsf{P}(k_i)| \geq 1$.*

Intuitively, Property 1 ensures protection against length-leakage, while Property 2 bounds the scheme's storage footprint. Finally, Property 3 ensures that all the data in KV is still present in EKV, i.e., the scheme is lossless.

Query is a query algorithm that transforms a query on plaintext keys in Keys(KV) to one or more queries on encrypted keys in Keys(EKV). Query takes as input:

- Init's outputs P, π_r, π_f, δ, B and,
- a sequence of queries $Q = \{\mathsf{q}_1, \ldots, \mathsf{q}_q\}$ on plaintext keys in Keys(KV), where each query q_j is drawn from the distribution π; i.e., $\Pr[\mathsf{q}_j = k_i] = \pi(k_i)$.

Query generates as output:

- a sequence of queries $\hat{Q} = \{\hat{\mathsf{q}}_1, \ldots, \hat{\mathsf{q}}_{\hat{q}}\}$ over encrypted keys in Keys(EKV), where $\hat{q} = q \cdot B$.

The generated sequence of queries satisfies two properties:

Property 4. *All keys in* EKV *are accessed with equal probability, i.e., $\forall i, j,\ \Pr[\hat{\mathsf{q}}_j = F(\hat{k}_i)] = 1/\hat{n}$.*

Property 5. *The expected number of accesses to any key $k \in$* Keys(KV) *is no more than the expected number of accesses to all keys $\hat{k} \in$* Keys(EKV) *that k maps to in* P*:*

$$\forall k \in \mathsf{Keys}(\mathsf{KV}), E(k \in Q) \leq \sum_{\hat{k} \in \mathsf{P}(k)} E(\hat{k} \in \hat{Q}).$$

Property 4 ensures security by requiring protection against access pattern leakage. Property 5 ensures correctness by requiring that all queries in Q are answered in expectation over the randomness in Query's execution. We use "in expectation"

[4] Note that the function $\pi_r[k]$ is *not* a distribution over $\mathsf{P}(k)$, since $\sum_{\hat{k}} \pi_r[k](\hat{k}) = \pi(k)$, i.e., the original access probability of key k and not 1.

[5] There is a negligible probability for two distinct keys $\hat{k}_i, \hat{k}_j$ to have $F(\hat{k}_i) = F(\hat{k}_j)$; we ignore this case for simplicity.

rather than "with high probability" to strengthen our results: since our lower bounds (§3, §4) hold for the more relaxed expectation-based correctness, they must also hold for more stringent probability-based correctness. Property 5 thus excludes from $\mathcal{M}$ any mechanism that achieves security (i.e., Properties 1 and 4) "incorrectly", *e.g.*, by ignoring a large fraction of client queries or responding with incorrect values.

We base our analysis on two key performance metrics:

- The **storage footprint** of Π is defined as σ, the total storage capacity available to the scheme.
- The **bandwidth footprint** of Π is defined as $\beta := B \cdot \hat{s}$, the number of bytes fetched from EKV per query in Q.

2.3 Considered Leakage Profiles

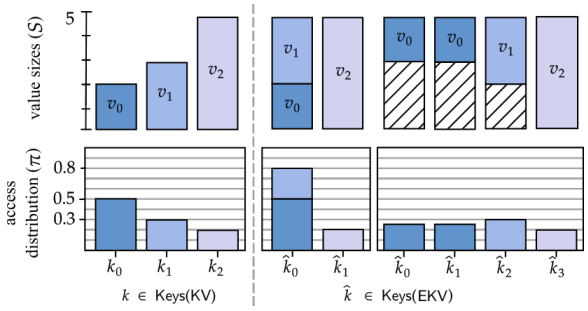
How much information can be leaked about the underlying data store differs by application; we capture these standards in the leakage profile $\mathcal{L}$ atop our considered class of schemes $\mathcal{M}$. Leakage profiles describe an upper bound on what an adversary learns from the execution of some scheme $\Pi \in \mathcal{M}$: any information other than the output of $\mathcal{L}$ must be hidden.

Again, we only provide an intuitive description of the security goal with leakage here and defer a formal simulator-based ROR-CDLA security definition to §7. Given any input store KV with access distribution π, value sizes S, storage footprint σ, and a sequence Q of q queries sampled from π, we consider the "real world" where Π produces a sequence of (encrypted) queries $\hat{Q}$. In contrast, the "ideal world" uses a sequence of $q \cdot B$ accesses generated from a uniform distribution over a set of $\hat{n}$ random bit strings of size $\hat{s}$. For some leakage profile $\mathcal{L}$, a scheme $\Pi \in \mathcal{M}$ is $\mathcal{L}$-secure (or, $\Pi \in \mathcal{ML}$) if the outputs of the real and ideal worlds are indistinguishable. In the ideal world, $\hat{n}$, $\hat{s}$ and B are generated by an algorithm $\mathcal{S}$ that only sees $\mathcal{L}(\mathsf{KV}, S, \pi, \sigma)$. In other words, any adversary's view of Π's execution must be simulatable given only $\mathcal{L}$'s output and no other information about Π's inputs or internal state. In §7, we will show that the real and ideal worlds correspond to ROR-CDLA^0 and ROR-CDLA^1, respectively.

We emphasize that these leakage profiles only relax what information is revealed during the *initialization* of the encrypted store EKV. Any $\Pi \in \mathcal{M}$ must still meet Properties 1-5, ensuring that *for every query, the identity of the accessed key and its associated value are hidden*. Thus, all schemes in our considered class $\mathcal{M}$ resist existing access pattern attacks [1, 36, 37] and length leakage attacks [2, 38, 39], since they rely on leakage due to accesses to the KV store via client queries, i.e., information revealed *after* initialization.

We focus on four leakage profiles that determine whether or not the scheme reveals KV's value sizes or access distribution:

$\mathcal{L}_m$ (§3): $\mathcal{ML}_m$ is the subset of schemes in $\mathcal{M}$ with leakage profile $\mathcal{L}_m$, where $\mathcal{L}_m(\mathsf{KV}, S, \pi, \sigma) = (n, s_{max}, B)$. Intuitively, an adversary only learns the number of keys and the maximum value size in KV, along with the number of encrypted queries Π makes, $q \cdot B$, ensuring protection against both access distribution and length leakage-abuse attacks. Since our considered leakage profiles have the same input and outputs that always contain n, B, we will omit them in our notation.



$\mathcal{L}_S$ (§4): $\mathcal{ML}_S$ denotes the class of schemes in $\mathcal{M}$ with leakage profile $\mathcal{L}_S$, where $\mathcal{L}_S$ outputs (S). For any scheme $\Pi \in \mathcal{ML}_S$, an adversary can observe the sizes of all values in KV S and the output of $\mathcal{L}_m$. This permits, for instance, compression-based attacks in the vein of CRIME [38] and BREACH [39], which leverage the sizes of encrypted values to learn about the plaintext values. As a concrete example, consider two sensitive database tables with noticeably different value size distributions, *e.g.*, flu records in one table (with smaller, less detailed reports) and cancer records in another (with longer, more detailed reports), in a medical database. In this setting, the attacker can distinguish between the tables and identify when a request is for a flu or cancer record. This is analogous to attacks in traffic analysis literature over websites, which distinguish between different websites by observing the sum of packet sizes across its visited webpages [40].

$\mathcal{L}_\pi$ (§5): $\mathcal{ML}_\pi$ denotes the class of schemes in $\mathcal{M}$ with leakage profile $\mathcal{L}_\pi$, where $\mathcal{L}_\pi$ outputs (s_{max}, π). For any scheme $\Pi \in \mathcal{ML}_\pi$, an adversary can identify the access distribution π over KV and the output of $\mathcal{L}_m$. Like in the previous setting, an attacker can distinguish between two database tables by their access distributions, *e.g.*, a table with flu records and uniform access pattern from a table with cancer records and skewed access pattern. Note that $\mathcal{L}_\pi$ still excludes traditional access pattern attacks [1, 2, 36, 37] that exploit the mapping between KV pairs and their access frequencies.

$\mathcal{L}_{S\pi}$ (§6): $\mathcal{ML}_{S\pi}$ denotes the class of schemes in $\mathcal{M}$ with leakage profile $\mathcal{L}_{S\pi}$, where $\mathcal{L}_{S\pi}$ outputs (S, π). For any scheme $\Pi \in \mathcal{ML}_{S\pi}$, an adversary can identify the value lengths S *and* access distribution π. In this setting, attacks on schemes can exploit the leakage of size distribution (i.e., attacks in $\mathcal{L}_S$), access distribution (i.e., attacks in $\mathcal{L}_\pi$), or a combination of the two (*e.g.*, a volume *and* access pattern leakage-abuse attack [41]). Continuing our medical database example, a third table of arthritis records with uniform access patterns and longer reports can be distinguished from the cancer table by value sizes and the flu table by access pattern.

3 $\mathcal{L}_m$: Revealing the largest value size

Under our strictest leakage profile, the adversary may only learn the largest value size (s_{max}) and the number of keys (n). We do not explore stricter profiles that hide even s_{max} since they would yield impractically high bandwidth footprint overheads (even $\mathcal{L}_m$ yields impractical overheads as noted in §1.1). To understand what constructions are possible under this leakage profile, consider a KV with three key-value pairs, with sizes and access probabilities, as shown in Figure 2a.

(a) Example input KV. (b) Packing. (c) Padding + replication.
Figure 2: Sample constructions under $\mathcal{M}$; see §3 for details.

First, since no value size other than $s_{max} = 5$ can be leaked, all values in the output EKV must be at least 5 bytes in size.

It may be tempting to pack the values of keys k_0 and k_1 into a single 5-byte value for space efficiency (Figure 2b); however, this scheme is $\notin \mathcal{ML}_m$. By observing that EKV consumes 10 bytes of storage, the adversary learns a bound on the sum of the value lengths and that at least one value is smaller than s_{max}. As such, for any scheme in $\mathcal{ML}_m$, its storage footprint must be independent of the value sizes S. We, therefore, focus on schemes that pad the values for k_0 and k_1 to size s_{max}.

The second security requirement is a uniform access distribution across keys in EKV. Consider a scheme that injects "fake" accesses to each padded value to equalize the access probabilities of the keys. However, the additional volume of access traffic to EKV reveals information about the original access distribution over the input KV, *e.g.*, an access distribution skewed towards k_0 in Figure 2a requires more fake accesses to k_1 and k_2, while one where all key access probabilities are equal does not require any additional fake accesses. An adversary can distinguish between these two cases by observing the traffic volume to EKV. Thus, the bandwidth footprint of any scheme in $\mathcal{ML}_m$ must be independent of the access distribution π over KV.

Other schemes that naively replicate the key-value pairs or combine replication and fake accesses can still be insecure under $\mathcal{ML}_m$. Consider a scheme that replicates the padded value of k_0 and divides its accesses equally between the copy and the original. This results in four padded values (Figure 2c), and the remaining non-uniformity in access distribution can be smoothed using fake accesses. This scheme can still reveal information about the original access distribution over the input KV: if replication is used to smooth access frequencies based purely on the skew in the input distribution, then the total number of replicas (which is output by Init) leaks this degree of skew. In particular, if π were uniform, no replicas would be needed, and the output EKV would only contain three key-value pairs instead of four replicas in our example. As such, the storage footprint of a scheme in $\mathcal{ML}_m$ must also be independent of the access distribution π.

We formalize these intuitive observations, i.e., a scheme $\Pi \in \mathcal{ML}_m$ must have output storage and bandwidth footprints independent of the value sizes and access distributions over KV, into performance lower bounds for any scheme $\Pi \in \mathcal{ML}_m$ in §3.1. We then show in §3.2 that an adaptation of the PANCAKE algorithm [6] — dubbed Padded PANCAKE or PPC — is a bandwidth-optimal $\mathcal{ML}_m$ scheme.

3.1 Performance Bounds

Any scheme $\Pi \in \mathcal{ML}_m$ must output a EKV that has the same storage footprint ($\hat{n} \cdot \hat{s}$) across all input stores KV of n key-value pairs — otherwise it reveals information about the value sizes S, or at the very least, some information about $\sum_i s_i$. For correctness, all data encoded in KV must also be in EKV (Property 3). An input where all values have size s_{max} requires EKV to store at least $n \cdot s_{max}$ bytes for no information to be lost from KV. Then for any n-key input to Π, the output EKV must always have a storage footprint of at least $n \cdot s_{max}$. Moreover, we find that in minimizing bandwidth footprint, schemes in $\mathcal{ML}_m$ do not benefit from using EKV value size $\hat{s}$ larger than s_{max}. This is because larger EKV values increase the number of bytes transferred per access without reducing the proportion of fake queries required. We generalize these observations to all schemes in $\mathcal{M}$ that do not leak S in the following two lemmas, deferring their proofs to Appendix B.

Lemma 1. *Any $\Pi \in \mathcal{M}$ with leakage $\mathcal{L}$ and $S \notin \mathcal{L}$ requires storage footprint $\sigma \geq n \cdot s_{max}$.*

Lemma 2. *Given storage footprint $\sigma = \kappa \cdot n \cdot s_{max}$, a scheme $\Pi \in \mathcal{M}$ with leakage $\mathcal{L}$ and $S \notin \mathcal{L}$ that incurs the minimum possible bandwidth footprint must use $\hat{s} = s_{max}$.*

In Theorem 3.1, we leverage the above lemmas to show that the minimum bandwidth footprint for any scheme in $\mathcal{ML}_m$ with storage footprint $\sigma = \kappa \cdot n \cdot s_{max}$ ($\kappa \geq 1$) is $\frac{\lfloor \kappa n \rfloor}{\lfloor \kappa n \rfloor - n + 1} \cdot s_{max}$. Since $\mathcal{ML}_m$ schemes do not leak π, their bandwidth footprint must be the same for any π. Intuitively, our proof identifies inputs S and π that maximize any scheme's bandwidth footprint — this happens when all values are as large as possible and access distribution is as skewed as possible. An $\mathcal{ML}_m$ scheme must incur the same bandwidth footprint for any other S and π, so the minimum bandwidth footprint achievable in this worst case is also the lower-bound for any $\mathcal{ML}_m$ scheme.

Theorem 3.1. *Any $\Pi \in \mathcal{ML}_m$ with storage footprint $\sigma = \kappa \cdot n \cdot s_{max}$ ($\kappa \geq 1$) must have bandwidth footprint $\beta \geq \frac{\lfloor \kappa n \rfloor \cdot s_{max}}{\lfloor \kappa n \rfloor - n + 1}$.*

Proof. Suppose for contradiction that Π incurs storage footprint $\sigma = \kappa \cdot n \cdot s_{max}$ and minimum possible bandwidth footprint $\beta = (1 - \delta) \cdot \frac{\lfloor \kappa n \rfloor}{\lfloor \kappa n \rfloor - n + 1} \cdot s_{max}$ for some $0 < \delta < 1$. We will show that the scheme cannot be $\mathcal{L}_m$-secure.

We define an $\mathcal{L}_m$-adversary $\mathcal{A}$ as in Figure 3. The intuition behind $\mathcal{A}$'s attack — and our proof — is that given a heavily skewed access distribution as input, Π does not have enough

$\mathcal{A}_1$: Computing inputs:

$S \leftarrow \{s_{max}, ..., s_{max}\}$
$\pi \leftarrow \{1-\varepsilon, \frac{\varepsilon}{n-1}, ..., \frac{\varepsilon}{n-1}\}$
$\sigma \leftarrow \kappa \cdot n \cdot s_{max}$
$\mathsf{KV} \leftarrow \emptyset$
For i in 1 to n:
  $k_i \leftarrow\$ \{0,1\}^m$
  $v_i \leftarrow\$ \{0,1\}^{S[i]}$
  $\mathsf{KV} \leftarrow\cup (k_i, v_i)$
Return $\mathsf{KV}, S, \pi, \sigma$

$\mathcal{A}_2(\mathsf{EKV}, \hat{Q})$: Computing output bit:

Build histogram of accesses in $\hat{Q}$; Let x be the maximum number of accesses to any $\hat{k} \in \mathsf{Keys(EKV)}$.
If $x > (c+3\sqrt{c})\ln\hat{n}$:
  $b \leftarrow 0$
Else:
  $b \leftarrow 1$
Return b

Figure 3: Real-or-random adversary $\mathcal{A}$ for Theorem 3.1. $\varepsilon \to 0$ is chosen by $\mathcal{A}$ to skew the access distribution.

bandwidth to ensure a uniform access distribution over its output EKV (*e.g.*, by injecting fake accesses). We show this in Step 1 of our proof below. This allows the adversary $\mathcal{A}$ to distinguish between ROR-CDLA^0 and ROR-CDLA^1 by examining the sequence of output queries $\hat{Q}$ and performing a simple statistical test: it simply guesses that it is interacting with the real Π if the maximum number of queries to any key in EKV is above some threshold. The threshold must be carefully chosen such that the probability of exceeding it is low for a uniform distribution of queries but high for the non-uniform distribution of queries that Π would generate with insufficient bandwidth. This forms the basis of Step 2, where we show that the adversary has a non-trivial probability of distinguishing between ROR-CDLA^0 and ROR-CDLA^1 for $\delta > 0$, completing the proof.

The attack assumes that $\hat{Q}$ has a sufficiently large number of queries, specifically $\hat{q} = |\hat{Q}| = c\hat{n}\ln\hat{n}$ queries, where $c > 1/\ln\hat{n}$ is a polynomial in $\hat{n}$, ensuring that $\mathcal{A}$'s attack is polynomial-time. Looking ahead, we set the threshold $\mathcal{A}$ uses to be $\hat{q}/\hat{n} + 3\sqrt{c}\ln\hat{n} = (c+3\sqrt{c})\ln\hat{n}$, and $c = \hat{n}^2$.

Step 1: Given $\mathcal{A}$'s choice of inputs, Π's output EKV has a non-uniform access distribution. To this end, we show that $\exists\hat{k} \in \mathsf{Keys(EKV)}$ with access probability $\Pr[\hat{k}] > \frac{1}{\hat{n}}$.

Recall that in the KV generated by $\mathcal{A}_1$, all n values are of size s_{max}, the most heavily accessed key (which we shall call h) has access probability $1-\varepsilon$, and the remaining $n-1$ keys have access probability $\frac{\varepsilon}{n-1}$. Lemma 2 shows that for Π to incur the minimum possible bandwidth it must use $\hat{s} = s_{max}$. Then the number of values in EKV is $\hat{n} = \lfloor\frac{\sigma}{\hat{s}}\rfloor = \lfloor\kappa n\rfloor$, and each value can contain exactly one value from KV. Now for Π to fulfill Property 5, the sum of accesses to each $\hat{h} \in \mathsf{P}(h)$ in $\hat{Q}$ must be at least the number of accesses to h in Q in expectation. This gives the inequality below:

$$(1-\varepsilon)\cdot q \le \left(\sum_{\hat{h}\in\mathsf{P}(h)} \Pr\left[\hat{h} \in \hat{Q}\right]\right)\cdot q \cdot B$$

$$\text{or, } B \ge \frac{1-\varepsilon}{\sum_{\hat{h}\in\mathsf{P}(h)}\Pr\left[\hat{h}\in\hat{Q}\right]}$$

Since bandwidth footprint is proportional to B, in the best case Π can minimize the bandwidth footprint by splitting the access probability of h uniformly across $\mathsf{P}(h)$, i.e.,

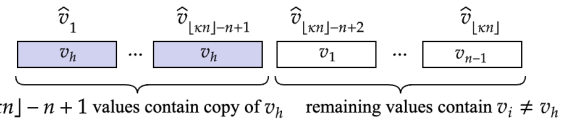


Figure 4: Placement of values $v \in \mathsf{Values(KV)}$ across values $\hat{v} \in \mathsf{Values(EKV)}$ to minimize bandwidth footprint with $\mathcal{L}_m$ leakage. v_h (highlighted) is the value associated with key h in Theorem 3.1.

$$B \ge \frac{1-\varepsilon}{|\mathsf{P}(h)|\cdot p} \tag{1}$$

where p is the probability of accessing any key $\hat{h} \in \mathsf{P}(h)$. Since Π controls $|\mathsf{P}(h)|$, it can minimize B by maximizing $|\mathsf{P}(h)|$. To do so, Π must assign the $n-1$ keys other than h to as few keys in Keys(EKV) as possible, i.e., $n-1$ keys. This allows h to be mapped to the remaining $\lfloor\kappa n\rfloor - n + 1$ values in EKV, i.e., $|\mathsf{P}(h)| = \lfloor\kappa n\rfloor - n + 1$, as shown in Figure 4. Substituting $|\mathsf{P}(h)|$ in (1), we lower bound p:

$$p \ge \frac{1-\varepsilon}{B(\lfloor\kappa n\rfloor - n + 1)}$$

Since Π's bandwidth footprint β is

$$B\cdot\hat{s} = (1-\delta)\cdot\frac{\lfloor\kappa n\rfloor}{\lfloor\kappa n\rfloor - n + 1}\cdot s_{max},$$

Rearranging gives us $\frac{1}{\lfloor\kappa n\rfloor(1-\delta)} = \frac{1}{B(\lfloor\kappa n\rfloor - n+1)}$, which plugs into the above lower bound on p to give:

$$p \ge \frac{1}{\lfloor\kappa n\rfloor}\cdot\frac{1-\varepsilon}{1-\delta} = \frac{1}{\hat{n}}\cdot\frac{1-\varepsilon}{1-\delta}.$$

Since EKV contains a key with access probability $p \ge \frac{1}{\hat{n}}\cdot\frac{1-\varepsilon}{1-\delta}$, we know that $\mathcal{A}$ can choose a ε such that $p > \frac{1}{\hat{n}}$, resulting in a non-uniform distribution over keys in EKV.

At this point, a computationally unbounded adversary can already distinguish the non-uniform distribution over the real Π's output from the uniform distribution over a simulated output by observing a large enough sequence of Π's output queries ($\hat{Q}$). However, ROR-CDLA security employs a polynomial-time adversary $\mathcal{A}$; so, we define $\mathcal{A}_2$ in Figure 3 to use the simple threshold-based test to detect non-uniformity in $\hat{Q}$'s access distribution over EKV, where $|\hat{Q}|$ is polynomial in $\hat{n}$. We then show that this test gives $\mathcal{A}$ non-negligible advantage against Π for all simulator algorithms $\mathcal{S}$.

Step 2: $\mathcal{A}$ has a non-negligible advantage. To show this, we lower-bound $\mathbf{Adv}^{\text{ror-cdla}}_{\Pi,\mathcal{L}_m,\mathcal{A},\mathcal{S}}(\lambda)$ by a function $f(\hat{n},\varepsilon,\delta)$, and show that with $\varepsilon \to 0$ and sufficiently large values of $\hat{n}$, $f(\hat{n},\varepsilon,\delta)$ approaches 1 for $0 < \delta < 1$ and $\varepsilon \to 0$. Since

$$\mathbf{Adv}^{\text{ror-cdla}}_{\Pi,\mathcal{L}_m,\mathcal{A},\mathcal{S}}(\lambda) = |\Pr[\text{ROR-CDLA}^0_{\Pi,\mathcal{L}_m,\mathcal{A},q}(\lambda) = 1] - \Pr[\text{ROR-CDLA}^1_{\Pi,\mathcal{L}_m,\mathcal{A},\mathcal{S},q}(\lambda) = 1]|,$$

We obtain this function by finding (i) an upper bound on $\Pr[\text{ROR-CDLA}^0_{\Pi,\mathcal{L}_m,\mathcal{A},q}(\lambda) = 1]$, and (ii) a lower bound on $\Pr[\text{ROR-CDLA}^1_{\Pi,\mathcal{L}_m,\mathcal{A},\mathcal{S},q}(\lambda) = 1]$. We also note that since

$\mathcal{A}_2$'s test does not leverage $\hat{n}$, $\hat{s}$ and B generated by the algorithm $\mathcal{S}$, $\mathcal{A}$ works against all possible $\mathcal{S}$.

Step 2(i): We upper-bound $\Pr[\text{ROR-CDLA}^0_{\Pi,\mathcal{L}_m,\mathcal{A},q}(\lambda)=1]$, i.e., the probability that $\mathcal{A}$ guesses incorrectly that the queries $\hat{Q}$ it is given are sampled from a uniform distribution rather than generated by Π.

To do so, we focus on the key $\hat{h} \in \mathsf{P}(h)$ with access probability p. $\mathcal{A}_2$ outputs 1 if, for all keys in EKV, the number of queries they receive is less than or equal to $\mathcal{A}$'s threshold. We can, therefore, use the probability that $\hat{h}$ receives $\leq (c+3\sqrt{c})\ln\hat{n}$ queries as an upper bound for $\Pr[\text{ROR-CDLA}^0_{\Pi,\mathcal{L}_m,\mathcal{A},q}(\lambda)=1]$, and compute the same using the one-sided Chebyshev inequality. While we defer its full derivation to Appendix B.1, we state the upper bound below:

$$\Pr[\text{ROR-CDLA}^0_{\Pi,\mathcal{L}_m,\mathcal{A},q}(\lambda)=1] \leq \frac{(1-\varepsilon)(\hat{n}(1-\delta)-(1-\varepsilon))}{(1-\varepsilon)(\hat{n}(1-\delta)-(1-\varepsilon))+\frac{c\ln\hat{n}\left(\frac{1-\varepsilon}{1-\delta}-1-\frac{3}{\sqrt{c}}\right)^2}{\hat{n}(1-\delta)^2}}. \quad (2)$$

Note that $\mathcal{A}$ must choose a small enough ε such that $a>0$, specifically $\varepsilon < 1-(1+3\sqrt{c})(1-\delta)$. Since we also need $\varepsilon > 0$ for the π chosen by $\mathcal{A}$ to be a valid distribution, the attack can only work with $\delta > \frac{3}{3+\sqrt{c}}$.

Step 2(ii): We lower-bound $\Pr[\text{ROR-CDLA}^1_{\Pi,\mathcal{L}_m,\mathcal{A},\mathcal{S},q}(\lambda)=1]$, i.e., the probability that $\mathcal{A}$ guesses correctly that the queries in $\hat{Q}$ are sampled from a uniform distribution.

Once again, $\mathcal{A}$ outputs 1 if all keys receive more than $(c+3\sqrt{c})\ln\hat{n}$ queries, so we represent the number of queries to a key in EKV with a binomial random variable. We then use the Chernoff bound to compute the upper bound of the probability that *all* keys receive $> (c+3\sqrt{c})\ln\hat{n}$ queries, which we subtract from 1 to obtain the desired lower bound on $\Pr[\text{ROR-CDLA}^1_{\Pi,\mathcal{L}_m,\mathcal{A},\mathcal{S},q}(\lambda)=1]$. Again, while its derivation is deferred to Appendix B.1, we have the lower bound:

$$\Pr[\text{ROR-CDLA}^1_{\Pi,\mathcal{L}_m,\mathcal{A},\mathcal{S},q}(\lambda)=1] \geq 1-\hat{n}^{-2}. \quad (3)$$

Finally, we compute $\mathcal{A}$'s advantage using (2) and (3):

$$\begin{aligned}\mathbf{Adv}^{\text{ror-cdla}}_{\Pi,\mathcal{L}_m,\mathcal{A},\mathcal{S}}(\lambda) &= |\Pr[\text{ROR-CDLA}^0_{\Pi,\mathcal{L}_m,\mathcal{A},q}(\lambda)=1] \\ &\quad - \Pr[\text{ROR-CDLA}^1_{\Pi,\mathcal{L}_m,\mathcal{A},\mathcal{S},q}(\lambda)=1]| \\ &\geq \left|1-\frac{1}{\hat{n}^2}-\frac{(1-\varepsilon)(\hat{n}(1-\delta)-(1-\varepsilon))}{(1-\varepsilon)(\hat{n}(1-\delta)-(1-\varepsilon))+\frac{c\ln\hat{n}\left(\frac{1-\varepsilon}{1-\delta}-1-\frac{3}{\sqrt{c}}\right)^2}{\hat{n}(1-\delta)^2}}\right| \\ &= f(\hat{n},\varepsilon,\delta)\end{aligned}$$

giving us our lower-bound function f on the advantage. We let $\mathcal{A}$ set $\varepsilon \to 0$ and $c=\hat{n}^2$, giving us:

$$f(\hat{n},\delta) = \left|1-\hat{n}^{-2}-\frac{\hat{n}(1-\delta)-1}{\hat{n}(1-\delta)-1+\frac{\hat{n}^2\ln\hat{n}\left(\frac{1}{1-\delta}-1-\frac{3}{\hat{n}}\right)^2}{\hat{n}(1-\delta)^2}}\right|$$

Figure 5 shows that for large $\hat{n}$, the bound on $\delta > \frac{3}{3+\sqrt{c}}$ for which $\mathcal{A}$'s attack works becomes vanishingly small, and

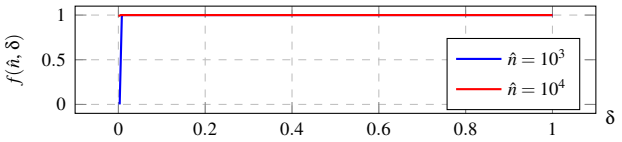

Figure 5: Variation of $f(\hat{n},\delta)$ with δ and $\hat{n}$.

$f(\hat{n},\varepsilon,\delta)$ is a nonzero value that rapidly approaches 1. Since f represents a lower bound on $\mathbf{Adv}^{\text{ror-cdla}}_{\Pi,\mathcal{L}_m,\mathcal{A},\mathcal{S}}(\lambda)$, our adversary $\mathcal{A}$ has a non-zero advantage, completing the proof. □

Observe that as n grows large, the lower-bound converges to $\frac{\kappa s_{max}}{\kappa-1}$, which depends solely on the storage footprint since $\kappa = \frac{\sigma}{n s_{max}}$. This highlights a fundamental trade-off between storage and bandwidth footprints: an optimal $\mathcal{ML}_m$ scheme can leverage more storage to lower the bandwidth footprint.

3.2 Padded PANCAKE: Optimal $\mathcal{ML}_m$ scheme

We now present a $\mathcal{ML}_m$ scheme, Padded PANCAKE (Figure 6), defined as PPC := $(\mathsf{Init}_{\text{PPC}}, \mathsf{Query}_{\text{PPC}})$ and adapted from PANCAKE [6] to the variable-length setting. We begin with a summary of PANCAKE's approach and then describe Padded PANCAKE's key differences.

PANCAKE leverages knowledge of the access distribution π to ensure an adversary observes a uniform access distribution over the encrypted KV pairs. First, it selectively replicates KV pairs with high access probability while ensuring the total number of keys in the encrypted store is exactly $2\cdot n$ (adding fake replicas if necessary). This smoothes out the access distribution over the resulting encrypted KV pairs to some extent; the remaining non-uniformity is removed by injecting fake queries. To this end, it computes a fake access distribution π_f over the replicated encrypted KV pairs required to ensure uniform distribution, assuming the proportion of real queries is δ (set to $1/2$ by default). All encrypted queries are sent in batches of size $B=3$ to ensure that the adversary cannot distinguish fake queries from real ones. PANCAKE thus secures the KV store against access pattern attacks with a $3\times$ bandwidth overhead and $2\times$ storage overhead but assumes that the store contains only uniform-size values.

Padded PANCAKE generalizes PANCAKE to support values of arbitrary sizes. At a high level, it pads every key to the largest value size, s_{max}, and then simply applies PANCAKE to the set of padded KV pairs. More specifically, given a total storage footprint $\sigma = \kappa\cdot n\cdot s_{max}$, its initialization function, $\mathsf{Init}_{\text{PPC}}$, creates $\hat{n} = \lfloor \sigma/s_{max} \rfloor = \lfloor \kappa n \rfloor$ values in the output EKV. Of these values, n contain one of each value $v \in$ KV padded to length s_{max} and encrypted. Of the remaining $\hat{n}-n$ values, some hold padded and encrypted replicas of values in KV that have access probability $> \frac{1}{\hat{n}-n+1}$, while the rest are dummy replicas to ensure that the number of values in EKV is exactly $\hat{n}$. $\mathsf{Query}_{\text{PPC}}$ generates a sequence of $q\cdot B$ real and

fake queries to ensure a uniform access distribution across $\hat{k} \in \mathsf{Keys}(\mathsf{EKV})$.

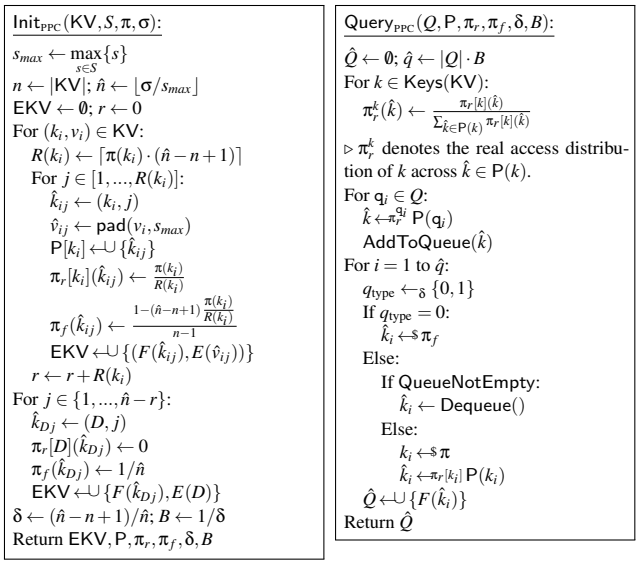

Figure 6: Padded PANCAKE's Init and Query algorithms. The function $\mathsf{pad}(x, s)$ returns string x padded to size s.

Next, we show that PPC is bandwidth-optimal, i.e., it achieves the bandwidth lower bound given by Theorem 3.1.

Theorem 3.2. *For any storage footprint $\sigma = \kappa \cdot n \cdot s_{max}$ ($\kappa \geq 1$),* PPC *is a bandwidth-optimal $\mathcal{ML}_m$ scheme.*

Proof. By construction in Figure 6, $\mathsf{Init}_{\mathrm{PPC}}$ sets $B = \frac{\hat{n}}{\hat{n}-n+1}$, while ensuring π_r, π_f and δ are always valid for any π. As such, PPC has $\beta = B \cdot s_{max} = \frac{\lfloor \kappa n \rfloor \cdot s_{max}}{\lfloor \kappa n \rfloor - n + 1}$, equal to the lower bound given by Theorem 3.1. □

PPC's bandwidth optimality demonstrates the viability of PANCAKE-based solutions in $\mathcal{M}$ — simply padding values in PANCAKE enables an optimal scheme in $\mathcal{ML}_m$ that runs in polynomial time. However, its bandwidth overheads may not be practical for many storage scenarios (*e.g.*, for the Wikipedia dataset with large variance in data sizes, §1.1). We explore relaxed leakage profiles for lower bandwidth footprints next.

4 $\mathcal{L}_S$: Revealing the value sizes

Now we consider the leakage profile $\mathcal{L}_S = (S)$, i.e., the adversary learns the sizes of values in KV. Since schemes in $\mathcal{ML}_S$ do not leak the access distribution (π), their bandwidth and storage footprint must be independent of π. However, leaking S allows us to consider new constructions not in $\mathcal{ML}_m$ — those whose bandwidth and/or storage footprint may depend on S, *e.g.*, the packing example in Figure 2b. We note that it may be possible to leak more information than s_{max} and less than S, *e.g.*, the sum of value sizes ($\sum_i s_i$), as explored in recent work [33]. However, we restrict our focus on leaking S since there are inputs for which $\sum_i s_i$ directly reveals S, *e.g.*, if there are $n-1$ values of size s_{max} and one value of size $s_{max} - 1$, knowing $\sum_i s_i = n \cdot s_{max} - 1$ immediately reveals S. Moreover, our bandwidth lower bounds for leaking S hold for leaking $\sum_i s$. Indeed, our findings complement the recent work, which investigates size-based leakage in greater depth.

4.1 Performance Bounds

The following theorem presents the minimum bandwidth footprint for any scheme $\Pi \in \mathcal{ML}_S$ with storage footprint $\sigma = \kappa \cdot n \cdot s_{max}$. Our proof is similar to that of Theorem 3.1: since a scheme in $\mathcal{ML}_S$ must have the same bandwidth footprint independent of π, we construct a worst-case π to maximize the bandwidth footprint, giving us a lower-bound. However, the relaxed leakage profile allows this lower-bound to be lower than that of Theorem 3.1, depending on how well values in KV can be packed into s_{max}-sized bins.

Theorem 4.1. *Let $N_{OPT} \leq n$ be the minimum number of s_{max}-sized bins needed to bin-pack all values in* KV. *Any $\Pi \in \mathcal{ML}_S$ with storage footprint $\sigma = \kappa \cdot n \cdot s_{max}$ ($\kappa > 0$) and $\hat{s} = s_{max}$ or $\hat{s} \geq \frac{\lfloor \kappa n \rfloor \cdot s_{max}}{\lfloor \kappa n \rfloor - N_{OPT} + 1}$ must have bandwidth footprint $\beta \geq \frac{\lfloor \kappa n \rfloor}{\lfloor \kappa n \rfloor - N_{OPT} + 1} \cdot s_{max}$.*

Proof. Suppose for contradiction that Π has storage footprint $\sigma = \kappa \cdot n \cdot s_{max}$ and bandwidth footprint $\beta = (1 - \delta) \cdot \frac{\lfloor \kappa n \rfloor}{\lfloor \kappa n \rfloor - N_{OPT} + 1} \cdot s_{max}$ for some $0 < \delta < 1$. We will show that the scheme cannot be $\mathcal{L}_S$-secure. Since our proof approach is similar to the proof of Theorem 3.1, we omit common aspects while outlining the salient differences.

Let $\mathcal{L}_S$-adversary $\mathcal{A}$ be defined as in Figure 3 with a single modification: instead of $S \leftarrow \{s_{max}, \ldots, s_{max}\}$, $\mathcal{A}_1$ sets $S \leftarrow \{s_1, \ldots, s_n\}$, which is a list of arbitrary sizes sorted in descending order. The order ensures that the key with the largest value size has access probability $1 - \varepsilon$, which is crucial to $\mathcal{A}$'s approach. We will show that given the large, heavily accessed key and limited range for $\hat{s}$, Π cannot maintain a uniform access distribution over EKV with the assumed bandwidth footprint in Step 1. $\mathcal{A}_2$ can then use the same threshold test from Figure 3 to distinguish between $\text{ROR-CDLA}^0_{\Pi, \mathcal{L}_S, \mathcal{A}, q}(\lambda)$ and $\text{ROR-CDLA}^1_{\Pi, \mathcal{L}_S, \mathcal{A}, \mathcal{S}, q}(\lambda)$ in Step 2.

Step 1: Given $\mathcal{A}$'s choice of inputs, Π's output EKV has a non-uniform access distribution. $\mathcal{A}_1$ generates KV of variable-sized values, where the largest value is also most heavily accessed. The key for this value (say, h) has access probability $1 - \varepsilon$, and the remaining $n-1$ keys have access probability $\frac{\varepsilon}{n-1}$. We will show that one of the keys in EKV that maps to h must have access probability $> 1/\hat{n}$.

Since $\Pi \in \mathcal{M}$, by Property 1, each value $\hat{v} \in \mathsf{Values}(\mathsf{EKV})$ has size $\hat{s}$ and by Property 2, $|\mathsf{EKV}| = \hat{n} \leq \kappa n s_{max} / \hat{s}$. To allow Π to use as much storage as possible, we set $\hat{n} = \lfloor \kappa n s_{max} / \hat{s} \rfloor$. For Property 3, Π maps each $k \in \mathsf{Keys}(\mathsf{KV})$ to a nonempty

set $\mathsf{P}(k) \subseteq \mathsf{Keys}(\mathsf{EKV})$. We focus on the set $\mathsf{P}(h)$ of keys in EKV that h is assigned to; following the same reasoning as Inequality 1 in Theorem 3.1, Property 5 allows us to show:

$$B \geq \frac{1-\varepsilon}{|\mathsf{P}(h)| \cdot p} \tag{4}$$

where p is the equal probability of accessing any key $\hat{h} \in \mathsf{P}(h)$. Again, minimizing bandwidth footprint (which is proportional to B) requires minimizing $|\mathsf{P}(h)|$, and we consider the following two cases for it:

Case 1: $\hat{s} \geq \frac{\lfloor \kappa n \rfloor \cdot s_{max}}{\lfloor \kappa n \rfloor - N_{OPT}+1}$**.** Π's bandwidth footprint is:

$$\beta = B \cdot \hat{s} = \frac{(1-\delta) \cdot \lfloor \kappa n \rfloor \cdot s_{max}}{\lfloor \kappa n \rfloor - N_{OPT} + 1} \tag{5}$$

so we have:

$$B = \frac{(1-\delta)}{\hat{s}} \cdot \frac{\lfloor \kappa n \rfloor \cdot s_{max}}{\lfloor \kappa n \rfloor - N_{OPT} + 1} \leq (1-\delta) < 1$$

violating the constraint $B \geq 1$, making this case impossible.

Case 2: $\hat{s} = s_{max}$**.** Then $\hat{n} = \lfloor \kappa n \rfloor$. Since h has size s_{max}, the values of each $\hat{h} \in \mathsf{P}(h)$ may only contain the value corresponding to h, and nothing else. Then to maximize $|\mathsf{P}(h)|$, Π must minimize the number of values that contain values of the remaining keys $\mathsf{Keys}(\mathsf{KV}) \setminus \{h\}$. This minimum number is equal to the optimal number of s_{max}-sized bins needed to bin-pack the values of $\mathsf{Keys}(\mathsf{KV}) \setminus \{h\}$, which is $N_{OPT} - 1$. Therefore, $|\mathsf{P}(h)| \leq \hat{n} - (N_{OPT} - 1) = \lfloor \kappa n \rfloor - N_{OPT} + 1$. Substituting this into (4), we get:

$$p \geq \frac{1-\varepsilon}{B(\lfloor \kappa n \rfloor - N_{OPT} + 1)}$$

Rearranging (5) gives us $\frac{1}{\lfloor \kappa n \rfloor (1-\delta)} = \frac{1}{B(\lfloor \kappa n \rfloor - N_{OPT}+1)}$ for $\hat{s} = s_{max}$, which simplifies the above lower bound on p to:

$$p \geq \frac{1}{\lfloor \kappa n \rfloor} \cdot \frac{1-\varepsilon}{1-\delta} = \frac{1}{\hat{n}} \cdot \frac{1-\varepsilon}{1-\delta}$$

EKV then contains a key with access probability $p \geq \frac{1}{\hat{n}} \cdot \frac{1-\varepsilon}{1-\delta}$, which is the same result as in Theorem 3.1. While the value of $\hat{n}$ may differ, $\mathcal{A}$ can still choose an ε such that $p > \frac{1}{\hat{n}}$, giving a non-uniform distribution. Once again, a computationally unbounded adversary can distinguish between Π's non-uniform access distribution and a uniform access distribution with a sufficiently-long $\hat{Q}$. However, ROR-CDLA security requires $\mathcal{A}_2$ (Figure 3) to distinguish between the distributions in polynomial time. Specifically, we must show that $\mathcal{A}$ has non-negligible advantage $\mathbf{Adv}^{\text{ror-cdla}}_{\Pi,\mathcal{L}_S,\mathcal{A},\mathcal{S}}(\lambda)$ against Π for all simulator algorithms $\mathcal{S}$. Fortunately, the approach for showing this is identical to Step 2 in the proof of Theorem 3.1, since $\mathcal{A}_2$ uses the exact same threshold-based test; we avoid repeating it for brevity. □

Theorem 4.1 imposes a bandwidth lower bound on $\mathcal{ML}_S$ schemes, but only for $\hat{s} = s_{max}$ and $\hat{s} \geq \frac{\lfloor \kappa n \rfloor \cdot s_{max}}{\lfloor \kappa n \rfloor - N_{OPT}+1}$. The bound does not hold between these two sizes, as values in EKV are large enough to benefit from a more strategic placement of KV values across EKV values. We confirm this intuition with a simple counterexample.

Lemma 3. *There exists a scheme* $\Pi \in \mathcal{ML}_S$ *with* $s_{max} < \hat{s} < \frac{\lfloor \kappa n \rfloor \cdot s_{max}}{\lfloor \kappa n \rfloor - N_{OPT}+1}$ *and input* $(\mathsf{KV}, S, \pi, \sigma)$ *for which* Π *has bandwidth footprint* $\beta < \frac{\lfloor \kappa n \rfloor}{\lfloor \kappa n \rfloor - N_{OPT}+1} \cdot s_{max}$.

Proof. Let $\mathsf{Keys}(\mathsf{KV}) := \{k_1, k_2\}$ with value sizes $S := \{10, 1\}$ and $\sigma = 22$, i.e., $\kappa n = \sigma / s_{max} = 2.2$. The minimum number of s_{max}-sized bins needed to bin-pack the values of KV is $N_{OPT} = 2$, so Theorem 4.1 gives the bandwidth lower bound $\beta = \frac{\lfloor \kappa n \rfloor}{\lfloor \kappa n \rfloor - N_{OPT}+1} \cdot s_{max} = 20$.

Now we give a scheme Π with $10 < \hat{s} < 20$ and bandwidth footprint $\beta < 20$ for all π. Let Π have $\hat{s} = 11$, making $\hat{n} = 2$. Let each value in EKV contain a replica of both values in KV. Then Π can equally divide access probabilities across EKV, i.e., $\forall k \in \mathsf{Keys}(\mathsf{KV}), \forall \hat{k} \in \mathsf{Keys}(\mathsf{EKV}), \pi_r[k](\hat{k}) = \pi(k)/2$, which means both keys in EKV have access probability $1/2$. No additional queries are needed to smooth the access distribution, so Π can set $B = 1$, making $\beta = B \cdot \hat{s} = 11 < 20$. □

In this example, a small increase in $\hat{s}$ above s_{max} vastly improves space utilization. The possibility of this occurrence depends on S, $\hat{s}$, and the corresponding bin-packing. For large n, however, such cases should be rare, and Theorem 4.1's bound should hold for most $\hat{s}$.

Next, we introduce a polynomial-time $\mathcal{ML}_S$ scheme that achieves the bound outlined in Theorem 4.1 for $\hat{s} = s_{max}$.

4.2 Stuffed PANCAKE: Optimal $\mathcal{ML}_S$ scheme

Our proposed scheme in $\mathcal{ML}_S$ exploits revealing S by bin-packing the values in KV into equal-sized bins, and then using PANCAKE to equalize access probabilities across bins.

$\underline{\mathsf{Init}_{\text{SPC}}(\mathsf{KV}, S, \pi, \sigma)}$:
$n \leftarrow |\mathsf{KV}|; s_{max} \leftarrow \max_{s \in S}\{s\}; \mathsf{EKV} \leftarrow \emptyset$
$\hat{s} \leftarrow s_{max}; \hat{n} \leftarrow \lfloor \sigma / \hat{s} \rfloor; \sigma' \leftarrow \hat{n} \cdot \hat{s}$
$\mathsf{KV}', \mathsf{P}' \leftarrow \mathsf{OptBinPack}(\mathsf{KV}, \hat{s})$
For $(k', v') \in \mathsf{KV}'$:
  $\pi_p(k') \leftarrow \sum_{k:k' \in \mathsf{P}'(k)} \pi(k)$
  $S' \xleftarrow{\cup} \{|v'|\}$
$\mathsf{EKV}, \mathsf{P}'', \pi'_r, \pi_f, \delta, B \leftarrow \mathsf{Init}_{\text{PPC}}(\mathsf{KV}', S', \pi_p, \sigma')$
For $k \in \mathsf{Keys}(\mathsf{KV})$:
  $k' \leftarrow \mathsf{P}'[k]$
  $\mathsf{P}(k) \xleftarrow{\cup} \mathsf{P}''[k']$
  For $\hat{k} \in \mathsf{P}''[k']$:
    $\pi_r[k](\hat{k}) \leftarrow \pi(k)/|\mathsf{P}(k)|$
Return $\mathsf{EKV}, \mathsf{P}, \pi_r, \pi_f, \delta, B$

$\underline{\mathsf{Query}_{\text{SPC}}(\ldots)}$:
Return $\mathsf{Query}_{\text{PPC}}(\ldots)$

Figure 7: Stuffed PANCAKE pseudocode. We omit $\mathsf{Query}_{\text{GPC}}$'s arguments since they are the same as $\mathsf{Query}_{\text{PPC}}$'s.

We define Stuffed PANCAKE (Figure 7) as $\text{SPC} := (\mathsf{Init}_{\text{SPC}}, \mathsf{Query}_{\text{SPC}})$, where $\mathsf{Init}_{\text{SPC}}$ first runs an optimal packing algorithm to place n values into $\hat{n}$ bins of size s_{max}. It

then leverages Init_{PPC} with storage footprint $\sigma = \lfloor \kappa n \rfloor \cdot s_{max}$ to generate the final $\text{EKV}, \pi_f, \delta, B$, and post-processes outputs P and π_r to ensure correct mappings from keys in KV to keys in EKV. $\text{Query}_{\text{SPC}}$ simply uses $\text{Query}_{\text{PPC}}$ to generate queries to EKV. Note that while we use $\hat{s} = s_{max}$ in our description of SPC, it can easily use $\hat{s} > s_{max}$. We now show that SPC achieves Theorem 4.1's lower bound.

Theorem 4.2. *For any storage footprint $\sigma = \kappa \cdot n \cdot s_{max}$ ($\kappa \geq 1$), SPC is a bandwidth-optimal $\mathcal{ML}_S$ scheme.*

Proof. In Init_{SPC}, OptBinPack generates KV' containing N_{OPT} values of size s_{max} each. This KV' is then input to Init_{PPC} along with storage $\lfloor \kappa n \rfloor \cdot s_{max}$; since $\text{Query}_{\text{SPC}}$ uses the unmodified $\text{Query}_{\text{PPC}}$, SPC's bandwidth footprint is the same as PPC's, except with $n := N_{OPT}$ and $\sigma := \lfloor \kappa n \rfloor \cdot s_{max}$. Substituting these values into Theorem 3.1, we have that SPC has $\beta = \frac{\hat{n}}{\hat{n} - N_{OPT} + 1} \cdot s_{max} = \frac{\lfloor \kappa n \rfloor}{\lfloor \kappa n \rfloor - N_{OPT} + 1} \cdot s_{max}$, equal to the bound in Theorem 4.1. □

Theorem 4.2 shows that SPC's freedom to leak size distribution permits it to achieve a lower bandwidth footprint compared to PPC for the same storage footprint.

Approximating OptBinPack**.** Optimal bin-packing is an NP-hard problem; however, we can use *near-optimal* approximate algorithms that run in polynomial time, *e.g.*, First-Fit Decreasing (FFD) which uses $\leq \frac{11 N_{OPT} + 6}{9}$ bins [42].

5 $\mathcal{L}_\pi$: Revealing the access distribution

Our next leakage profile is $\mathcal{L}_\pi = (s_{max}, \pi)$. Like $\mathcal{L}_S$, $\mathcal{L}_\pi$ is a relaxation of $\mathcal{L}_m$ but allows new constructions that are distinct from those under both $\mathcal{L}_m$ and $\mathcal{L}_S$. Since schemes in $\mathcal{ML}_\pi$ do not leak value sizes S, their storage and bandwidth footprints must be independent of S; however, they can depend on the access distribution π. For instance, the packing approach of Figure 2b is not in $\mathcal{ML}_\pi$ for the same reason that it is not in $\mathcal{ML}_m$: it reveals information about the value sizes. However, the scheme in Figure 2c is in $\mathcal{ML}_\pi$ because the access distribution can be revealed.

Unlike prior sections, we do not have a closed-form lower-bound on bandwidth footprint for $\mathcal{ML}_\pi$; we instead directly provide a bandwidth-optimal $\mathcal{ML}_\pi$ scheme.

5.1 Greedy PANCAKE: Optimal $\mathcal{ML}_\pi$ scheme

We now present a scheme in $\mathcal{ML}_\pi$ that greedily replicates values with the highest access probabilities, then smooths the access distribution across the replicas with fake queries.

Let Greedy PANCAKE be $\text{GPC} := (\text{Init}_{\text{GPC}}, \text{Batch}_{\text{GPC}})$. Given $\sigma = \kappa \cdot n \cdot s_{max}$ storage, Init_{GPC} starts with an array R of n elements, where $R[i] = |\text{P}(k_i)|$ is the total number of keys $\hat{k} \in \text{Keys(EKV)}$ that key $k_i \in \text{KV}$ is mapped to. The access probability of k_i is split equally across the keys in P, i.e., for all $\hat{k} \in \text{P}, \pi_r[k_i](\hat{k}) = \pi(k_i)/R[i]$. Initially $R[i] = 1$ for all k_i; for each of the remaining $\hat{n} - n$ keys in EKV, the scheme assigns to it the key k_i with the highest split access probability $\pi(k_i)/R[i]$ at that point. Like in previous PANCAKE-based schemes, Init_{GPC} also computes π_f, δ, B to be used in the query algorithm $\text{Query}_{\text{GPC}} := \text{Query}_{\text{PPC}}$.

$\underline{\text{Init}_{\text{GPC}}(\text{KV}, S, \pi, \sigma)}$:
$n \leftarrow |\text{KV}|$; $s_{max} \leftarrow \max_{s \in S}\{s\}$
$\hat{s} \leftarrow s_{max}$; $\hat{n} \leftarrow \lfloor \sigma / \hat{s} \rfloor$
$\text{EKV} \leftarrow \emptyset$; $r \leftarrow 0$; $R \leftarrow [1, ..., 1]$
While $\sum_{i=1}^{n} R[i] < \hat{n}$:
  $h \leftarrow \arg\max_i \pi(k_i)/R[i]$
  $R[h] \leftarrow R[h] + 1$
$\hat{p}_{max} \leftarrow \max_{k_i \in \text{Keys(KV)}} \pi(k_i)/R[i]$
For $i \in [1, ..., n]$:
  For $j \in [1, ..., R[i]]$:
    $\hat{k}_{ij} \leftarrow (k_i, j)$
    $\hat{v}_i \leftarrow \text{pad}(v_i, s_{max})$
    $\text{P}[k_i] \xleftarrow{\cup} \{\hat{k}_{ij}\}$
    $\pi_r[k_i](\hat{k}_{ij}) \leftarrow \pi(k_i)/R[i]$
    $\pi_f(\hat{k}_{ij}) \leftarrow \frac{\hat{p}_{max} - \pi(k_i)/R[i]}{\hat{n} \cdot \hat{p}_{max} - 1}$
    $\text{EKV} \xleftarrow{\cup} \{(F(\hat{k}_{ij}), E(\hat{v}_i))\}$
$\delta \leftarrow 1/(\hat{n} \cdot \hat{p}_{max})$; $B \leftarrow 1/\delta$
Return $\text{EKV}, \text{P}, \pi_r, \pi_f, \delta, B$

$\underline{\text{Query}_{\text{GPC}}(\ldots)}$:
Return $\text{Query}_{\text{PPC}}(\ldots)$

Figure 8: Greedy PANCAKE's Init & Query algorithms. We omit $\text{Query}_{\text{GPC}}$ arguments since they are the same as $\text{Query}_{\text{PPC}}$'s.

Theorem 5.1 shows that Greedy PANCAKE is bandwidth-optimal if the entire storage footprint $\sigma = \kappa \cdot n \cdot s_{max}$ must be used. We defer the proof to Appendix B but summarize our approach here in two steps. First, since the bandwidth footprint of all schemes in $\mathcal{ML}_\pi$ must be independent of S, by Lemma 2, increasing the size $\hat{s}$ of values in EKV beyond s_{max} is not beneficial to reducing bandwidth footprint for schemes in $\mathcal{ML}_\pi$. Second, we show that Greedy PANCAKE using $\hat{s} = s_{max}$ is bandwidth-optimal using the "greedy stays ahead" argument: for each of the $\hat{n} - n$ keys in EKV to which GPC assigns a key from KV, the resulting maximal split access probability $\hat{p}_{max} = \max_{k_i \in \text{Keys(KV)}} \pi(k_i)/R[i]$ is at most that of an optimal algorithm at the same step.

Theorem 5.1. *For any storage footprint $\sigma = \kappa \cdot n \cdot s_{max}$ ($\kappa \geq 1$), GPC achieves the lowest bandwidth footprint β for any $\mathcal{ML}_\pi$ scheme that uses exactly σ storage.*

Intuitively, since GPC can reveal the access distribution, it allocates storage to values proportional to their access probability, maximally utilizing the given storage footprint to minimize bandwidth footprint. A caveat for Greedy PANCAKE, however, is that it is only bandwidth-optimal among schemes that must use all of the storage given, i.e. *exactly* $\kappa \cdot n \cdot s_{max}$ bytes. There are cases when using storage less than $\kappa \cdot n \cdot s_{max}$ results in a lower bandwidth footprint. Consider $\pi = (\frac{1}{5}, \frac{2}{5}, \frac{2}{5})$ and $\sigma = 6 s_{max}$; GPC creates six replicas, i.e., $\beta \geq \sigma \cdot \hat{p}_{max} = \frac{6}{5} s_{max}$. However, one can get a uniform access distribution over EKV with just five replicas: assign 2 replicas each to the keys with

access probability $\frac{2}{5}$ and 1 to the key with probability $\frac{1}{5}$, giving us $\beta = s_{max}$. With this intuition, we can modify GPC to achieve the minimum β for any $\sigma \leq \kappa \cdot n \cdot s_{max}$:

GPC*. We define $\text{GPC}^* = (\text{Init}_{\text{GPC}^*}, \text{Query}_{\text{GPC}})$, where $\text{Init}_{\text{GPC}^*}$ iterates through storage footprints σ from $n \cdot s_{max}$ to $\kappa \cdot n \cdot s_{max}$. For each σ, GPC* runs $(\mathsf{EKV}, \mathsf{P}, \pi_r, \pi_f, \delta, B) \leftarrow \text{Init}_{\text{GPC}}(\mathsf{KV}, S, \pi, \sigma)$ and tracks a running minimum on bandwidth footprint across the outputs from Init_{GPC}, and returns the $(\mathsf{EKV}, \mathsf{P}, \pi_r, \pi_f, \delta, B)$ for the global minimum.

Theorem 5.2. *For any storage footprint $\sigma = \kappa \cdot n \cdot s_{max}$ ($\kappa \geq 1$), GPC* is a bandwidth-optimal $\mathcal{ML}_{\pi}$ scheme.*

Proof. This follows from Theorem 5.1 and GPC*'s use of GPC in its exhaustive search for the optimal bandwidth footprint over storage footprints from $n \cdot s_{max}$ to $\kappa \cdot n \cdot s_{max}$. □

6 $\mathcal{L}_{S\pi}$: Revealing value sizes & distribution

Our last considered leakage profile is $\mathcal{L}_{S\pi} = (S, \pi)$, where the adversary may know both the value sizes S and access distribution π over KV. As the most relaxed leakage profile considered, $\mathcal{L}_{S\pi}$ allows for a much larger solution space than the previous leakage profiles. For instance, both packing (Figure 2b) and replication (Figure 2c) can be used by schemes in $\mathcal{ML}_{S\pi}$. Unfortunately, the search space for a performance-optimal scheme in $\mathcal{ML}_{S\pi}$ is too large, and we currently do not have a polynomial time algorithm that achieves the performance lower-bound. However, we provide a MILP formulation that yields a bandwidth-optimal construction (§6.1), along with Greedy Stuffed PANCAKE (§6.2), a sub-optimal poly-time algorithm in $\mathcal{ML}_{S\pi}$ that is efficient in practice.

6.1 MILP-based optimal $\mathcal{ML}_{S\pi}$ scheme

We formulate the problem of assigning values $v \in \mathsf{Values}(\mathsf{KV})$ and access probabilities to values $\hat{v} \in \mathsf{Values}(\mathsf{EKV})$ to minimize bandwidth footprint as an MILP.

For a key $k \in \mathsf{Keys}(\mathsf{KV})$, let $\hat{p}_{k,\hat{k}}$ be the portion of its real access probability $\pi(k)$ assigned to $\hat{k} \in \mathsf{Keys}(\mathsf{EKV})$; note that if $\hat{k} \notin \mathsf{P}(k)$ then $\hat{p}_{k,\hat{k}} = 0$, and $\sum_{\hat{k} \in \mathsf{EKV}} \hat{p}_{k,\hat{k}} = \pi(k)$. Let $\hat{p}_{\hat{k}} = \sum_{k \in \mathsf{KV}} \hat{p}_{k,\hat{k}}$, i.e., the summed access probabilities of the replicas of keys $k \in \mathsf{Keys}(\mathsf{KV})$ assigned to a key $\hat{k} \in \mathsf{Keys}(\mathsf{EKV})$. Let $\hat{p}_{max} = \max_{\hat{k} \in \mathsf{EKV}} \hat{p}_{\hat{k}}$, and $\hat{k}^*$ be the corresponding key in $\mathsf{Keys}(\mathsf{EKV})$. The objective function for our MILP is given below. We prove that it lower-bounds the bandwidth footprint in Lemma 5 (Appendix B).

$$\textbf{minimize } \hat{n} \cdot \hat{s} \cdot \hat{p}_{max} \tag{6}$$

Our goal is subject to the following constraints:

(a) The real access probabilities must be between 0 and 1.

(b) The real access probabilities across the replicas of a key $k \in \mathsf{KV}$ must sum to k's real access probability.

(c) A key $k \in \mathsf{KV}$ assigned to $\hat{k} \in \mathsf{EKV}$ via P should have non-zero access probability only if $\hat{k} \in \mathsf{P}(k)$.

(d) Sum of value sizes $s_i \in S$ corresponding to keys $k_i \in \mathsf{KV}$ assigned to $\hat{k} \in \mathsf{EKV}$ via P must not exceed $\hat{s}$.

Let $y_{k,\hat{k}} \in \{0,1\}$ be a decision variable that denotes whether or not key $k \in \mathsf{KV}$ mapped to key $\hat{k} \in \mathsf{EKV}$ via P. Then the above constraints can be encoded in the MILP as follows:

$$\forall k \in \mathsf{KV}, \hat{k} \in \mathsf{EKV}, \quad 0 \leq \hat{p}_{k,\hat{k}} \leq 1 \tag{a}$$

$$\forall k \in \mathsf{KV}, \quad \sum_{\hat{k} \in \mathsf{EKV}} \hat{p}_{k,\hat{k}} = \pi(k) \tag{b}$$

$$\forall k \in \mathsf{KV}, \hat{k} \in \mathsf{EKV}, \quad \hat{p}_{k,\hat{k}} \leq y_{k,\hat{k}} \cdot \pi(k) \tag{c}$$

$$\forall \hat{k} \in \mathsf{EKV}, \quad \sum_{k_i \in \mathsf{KV}} y_{k_i,\hat{k}} \cdot s_i \leq \hat{s} \tag{d}$$

The above formulation is not linear: since $\hat{p}_{max}$ is the maximum of $\hat{n}$ linear functions of decision variables, the goal (6) contains a min-max term. However, this term can be linearized through standard techniques [43], making it solvable. Also, since the formulation does not ensure Property 4, we adapt our MILP scheme below to fulfill this requirement.

For each storage capacity $\kappa \cdot n \cdot s_{max}$ and feasible pack size $\hat{s}$ ranging from s_{max} to $s_{tot} = \sum_i s_i$ the $\text{Init}_{\text{MILP}}$ runs a program solver $\mathsf{Solve}(\cdot)$ on the problem formulation. After choosing the bandwidth-optimal pack size, $\text{Init}_{\text{MILP}}$ computes $(\mathsf{EKV}, \mathsf{P}, \pi_r)$ according to the solver output, and (π_f, δ, B) based on Init_{PPC}. Like GPC (§5.1), MILP uses exactly the storage footprint σ given. As with GPC, this has a simple fix: run $\text{Init}_{\text{MILP}}$ for each feasible storage footprint from s_{tot} to σ for a bandwidth-optimal scheme for all $\sigma \leq \kappa \cdot n \cdot s_{max}$. The algorithm definitions are deferred to the full version [44].

Theorem 6.1. *For any storage footprint $\sigma = \kappa \cdot n \cdot s_{max}$ ($\kappa > 0$), MILP is a bandwidth-optimal $\mathcal{ML}_{S\pi}$ scheme.*

Proof. Optimality follows from the objective function of MILP, while feasibility follows from its constraints. □

While the MILP enables an optimal $\mathcal{ML}_{S\pi}$ solution, it is an NP-hard problem. We show a sub-optimal but polynomial-time construction in $\mathcal{ML}_{S\pi}$ next.

6.2 PANCAKE-based poly-time $\mathcal{ML}_{S\pi}$ scheme

Greedy Stuffed PANCAKE (GSPC) is a combination of SPC and GPC*: $\text{Init}_{\text{GSPC}}$ first packs the values of KV into s_{max}-sized bins, then passes the result to $\text{Init}_{\text{GPC}^*}$, while $\text{Query}_{\text{GSPC}}$ is the same as $\text{Query}_{\text{GPC}^*}$ (see the full version [44] for pseudocode). While GSPC runs in polynomial time, it is sub-optimal:

Lemma 4. *There exists a scheme $\Pi \in \mathcal{ML}_{S\pi}$ and input $(\mathsf{KV}, S, \pi, \sigma)$ for which Π has bandwidth footprint β lower than GSPC's.*

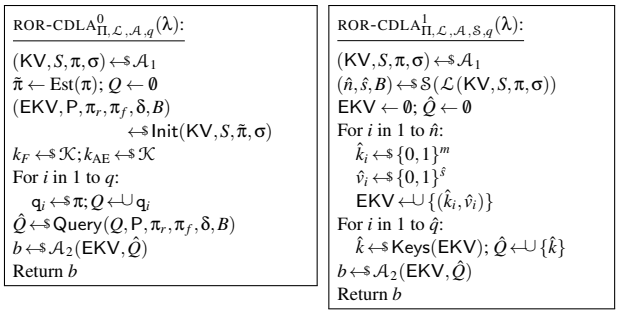

Figure 9: ROR-CDLA security game for key-value store schemes.

Proof. Let the input have sizes $S = \{4,3,2,1\}$, access distribution $(0.1,0.1,0.3,0.5)$, and storage footprint $\sigma = 16$.

First, GSPC sets $\hat{s} = 4$ and bin-packs the values into $N_{OPT} = 3$ bins $(\{4\},\{3\},\{2,1\})$ with access probabilities $(0.1,0.1,0.8)$. GSPC then runs $\mathsf{Init}_{\mathrm{GPC}^*}$, which replicates the last bin, giving $(\{4\},\{3\},\{2,1\},\{2,1\})$ with access probabilities $(0.1,0.1,0.4,0.4)$. Then GSPC sets $B = \hat{n} \times 0.4 = 1.6$ to get $\beta = B \cdot \hat{s} = 6.4$.

Now consider an alternate scheme Π that makes the following assignment, where each tuple (s,p) denotes a value of size s with access probability p, and separate values in EKV are delineated by $\{\}$: $\{(4,0.1)\}$, $\{(1,0.2),(3,0.1)\}$, $\{(1,0.15),(2,0.15)\}$,$\{(1,0.15),(2,0.15)\}$. Since $\hat{p}_{max} = 0.3$, Π can set $B = \hat{n} \times 0.3 = 1.2$ to get $\beta = 4.8 < 6.4$. □

The counterexample highlights the key shortcomings of GSPC: it cannot (i) replicate *individual* values in KV, or (ii) perform *non-uniform* load balancing across replicas. Nevertheless, as shown in §1.1 GSPC is bandwidth-efficient for large n.

7 Formal Security Analysis using ROR-CDLA

We present our new security model ROR-CDLA, which builds on prior work [6] to capture schemes in $\mathcal{M}$ as defined in §2.2. It extends prior work's ROR-CDA model [6], which captures security against access pattern attacks by a passive persistent adversary without accounting for length leakage attacks.

Technical preliminaries. All algorithms including adversaries are assumed to run in time polynomial in the security parameter, denoted λ. A scheme is secure if the advantage gained by any adversary is negligible, i.e., tends to zero faster than the inverse of any polynomial.

Definition 1 (ROR-CDLA with simulator)**.**

Let $\Pi = (\mathsf{Init},\mathsf{Query})$ be an encrypted storage scheme as defined in §2 and let $\mathcal{L}$ be a leakage function. For algorithms $\mathcal{A}$ and $\mathcal{S}$, we define the two games:

ROR-CDLA$^0_{\Pi,\mathcal{L},\mathcal{A},q}(\lambda)$ $\mathcal{A}(1^\lambda)$ picks inputs $(\mathsf{KV},S,\pi,\sigma)$. The game then runs $(\mathsf{EKV},\mathsf{P},\pi_r,\pi_f,\delta,B) \leftarrow\$ \mathsf{Init}(\mathsf{KV},S,\pi,\sigma)$, samples q queries (Q) from π, and runs $\hat{Q} \leftarrow \mathsf{Query}(Q,\mathsf{P},\pi_r,\pi_f,\delta,B)$. It gives $(\mathsf{EKV},\hat{Q})$ to $\mathcal{A}$, which eventually returns a bit that the game outputs.

ROR-CDLA$^1_{\Pi,\mathcal{L},\mathcal{A},\mathcal{S},q}(\lambda)$ $\mathcal{A}(1^\lambda)$ picks inputs $(\mathsf{KV},S,\pi,\sigma)$. The game then runs $(\hat{n},\hat{s},B) \leftarrow\$ \mathcal{S}(\mathcal{L}(\mathsf{KV},S,\pi,\sigma))$ and generates an EKV consisting of $\hat{n}$ random bit strings of size $\hat{s}$. It samples $\hat{Q}$ as $\hat{q} = qB$ queries from a uniform distribution over the keys of EKV, and gives $(\mathsf{EKV},\hat{Q})$ to $\mathcal{A}$, which eventually returns a bit that the game outputs.

We define the ROR-CDLA-$\mathcal{L}$-advantage of $\mathcal{A}$ and $\mathcal{S}$ to be

$$\mathbf{Adv}^{\text{ror-cdla}}_{\Pi,\mathcal{L},\mathcal{A},\mathcal{S}}(\lambda) = |\Pr[\text{ROR-CDLA}^0_{\Pi,\mathcal{L},\mathcal{A},q}(\lambda) = 1] - \Pr[\text{ROR-CDLA}^1_{\Pi,\mathcal{L},\mathcal{A},\mathcal{S},q}(\lambda) = 1]|$$

and we say that Π is ROR-CDLA-$\mathcal{L}$-secure if for all polynomial-time adversaries $\mathcal{A}$ there exists an algorithm $\mathcal{S}$ such that $\mathbf{Adv}^{\text{ror-cdla}}_{\Pi,\mathcal{L},\mathcal{A},\mathcal{S}}(\lambda)$ is negligible.

Note that in the real world, Init for schemes in $\mathcal{M}$ must use an estimate $\tilde{\pi}$ of π, though we define our constructions on input π for simplicity. We will prove that our schemes are secure if the estimate is sufficiently accurate, i.e., $\tilde{\pi}$ is indistinguishable from π with a limited number of samples.

Leakage	ROR-CDA $\Rightarrow \mathcal{ML}_{(\cdot)}$?	$\mathcal{ML}_{(\cdot)} \Rightarrow$ ROR-CDA?
$\mathcal{L}_m$	✗	✓
$\mathcal{L}_S$	✗	✓
$\mathcal{L}_\pi$	✗	✗
$\mathcal{L}_{S\pi}$	✗	✗

Figure 10: **ROR-CDA VS ROR-CDLA.** The second column shows for each leakage profile $\mathcal{ML}_{(\cdot)}$ whether or not any ROR-CDA-secure scheme is in $\mathcal{ML}_{(\cdot)}$. The third column shows whether any scheme in $\mathcal{ML}_{(\cdot)}$ is also ROR-CDA-secure.

Comparison to ROR-CDA. While ROR-CDLA builds on ROR-CDA, it captures a distinct security goal. As shown in Figure 10, no ROR-CDA scheme is ROR-CDLA-secure under any leakage profile: unlike ROR-CDA, ROR-CDLA security requires hiding individual value sizes during access.

For $\mathcal{L}_m$ and $\mathcal{L}_S$, all ROR-CDLA schemes are ROR-CDA-secure as they hide the access distribution π, revealing only value size related information (s_{max} and S respectively) during initialization. The similarity of the definitions means that $\mathcal{L}_m$- and $\mathcal{L}_S$-secure schemes can be derived from an ROR-CDA scheme such as PANCAKE with minor transformations (i.e., to hide value sizes). The opposite holds for π-leaking profiles $\mathcal{L}_\pi$ and $\mathcal{L}_{S\pi}$, as ROR-CDA requires hiding access distribution during both access and initialization. While our secure constructions borrow selective replication and fake querying techniques from PANCAKE, they do not directly use PANCAKE. We prove the security of our constructions across §3.2–§6.2 in the full version of our paper [44].

8 Discussion & Future Work

Our work opens up several directions for future research:

Dynamic distributions. Our analysis focused on data stores with static access patterns and value size distributions. While our lower bounds still hold for dynamic distributions, finding upper bounds is an important next step. For example, an adaptive alternative to MILP would be valuable, as MILP currently requires complete re-initialization should the KV store's access or size distribution change. PANCAKE's [6] adaptations to dynamic access distributions provide a starting point, but additional study is required for dynamic value sizes.

Performance bounds for efficient schemes. In §6.2 we introduced Greedy Stuffed PANCAKE scheme as a polynomial-time approximation of MILP that always finds a feasible, but possibly suboptimal, solution. An analysis of whether its performance is within a bounded factor of the optimal would be interesting for future research.

Completeness of bounds. As Lemma 3 has shown, the lower bound on bandwidth footprint for $\mathcal{ML}_S$ does not hold for $s_{max} < \hat{s} < \frac{\lfloor \kappa n \rfloor}{\lfloor \kappa n \rfloor - N_{OPT} + 1} \cdot s_{max}$. This leaves a gap for which the lower bound on bandwidth footprint, as well as an optimal $\mathcal{ML}_S$ scheme, is unknown. We believe multi-dimensional bin-packing approaches, which take both access probability and value sizes into account, could provide answers for both.

Active adversaries. Our constructions allow us to characterize the storage, bandwidth, and security tradeoff in $\mathcal{M}$. However, $\mathcal{M}$ excludes active adversaries from our threat model. While our lower bounds for passive persistent adversaries also hold for active adversaries, our proposed constructions would require additional protections against injected queries. Applying length leakage analysis to oblivious access schemes designed for this stronger threat model, such as ORAMs, would be a promising direction.

Compression. $\mathcal{M}$ rules out schemes that reduce the value sizes in EKV via compression. However, such schemes may improve throughput at lower storage footprints and even achieve lower bandwidth than our bounds. Extending our analysis to compression schemes will further expand the discussion on the storage-bandwidth-security tradeoff.

9 Conclusion

We explored the problem of hiding length leakage in oblivious data access mechanisms with passive persistent adversaries. We developed novel security models with different leakage profiles and strong lower bounds on achievable storage and bandwidth footprint under them. We also presented provably secure schemes for each profile that are bandwidth-optimal.

Acknowledgments

We thank the anonymous reviewers and the shepherd for their valuable feedback on our paper. We also thank Thomas Ristenpart for many insightful discussions during this work. Our research is supported in part by NSF Awards CNS-2054957, CNS-2047220, CNS-2147946 and CNS-2112562.

A Additional Experimental Results

In addition to the Twitter and Wikipedia datasets, we also apply our key results from §1.1 to two workloads from Facebook's Memcached deployments [26]: (i) the USR workload for user account status information, and (ii) the ETC workload for large-scale, general-purpose KV storage.

Figure 11 remains consistent with our theoretical results: all schemes observe a drop in bandwidth overhead as more storage is provided, and the strongest leakage profile incurs the highest bandwidth overhead.

Facebook-USR has a bimodal distribution of small value sizes that differ by only 5 bytes. This allows all leakage profiles to observe $< 10\times$ bandwidth overheads at a mere $1.3\times$ storage overhead. In fact, the size distribution of this dataset is so extreme that revealing it does not bring performance benefits for data with near-uniform sizes; there is no arrangement of values that better utilizes storage compared to simply padding each value to s_{max}. $\mathcal{L}_m$ and $\mathcal{L}_S$ thus have near-identical bandwidth overheads, as do $\mathcal{L}_\pi$ and $\mathcal{L}_{S\pi}$.

Meanwhile, Facebook-ETC has a long-tailed size distribution like Wikipedia's, and exhibits similar bandwidth overhead trends — the minimum storage overhead for $\mathcal{L}_m$ and $\mathcal{L}_\pi$ leakage settings is over $1200\times$, and the bandwidth overhead for $\mathcal{L}_m$ is more than 10^9. Bandwidth overheads under $\mathcal{L}_S$ and $\mathcal{L}_{S\pi}$ are much lower in comparison but still over $1000\times$, since hiding each value's identity requires fetching for each query s_{max} bytes, which in Facebook-ETC is $> 1000\times$ larger than the average value size. This again confirms our intuition that long-tailed size distributions are more suited to $\mathcal{L}_S$ or $\mathcal{L}_{S\pi}$ leakage settings that avoid the costs of hiding value lengths.

As for access distribution skewness, the results match Figure 1: schemes that do not leak the access distribution (PPC and SPC) observe the same bandwidth overhead regardless of access skew across key-value pairs. For schemes that do leak access distribution (GPC and GSPC), bandwidth overheads increase with the access skew due to noise injection to hide the identity of the most popular key.

B Additional Lemmas & Definitions

We present a bound on B for any scheme in $\Pi \in \mathcal{M}$:

Lemma 5. *For any scheme $\Pi \in \mathcal{M}$, let the sum of the real access probabilities of keys $k \in \mathsf{Keys(KV)}$ contained in key $\hat{k} \in \mathsf{Keys(EKV)}$ be $\hat{p}_{\hat{k}} = \sum_{k \in \mathsf{KV}} \pi_r[k](\hat{k})$. Let $\hat{p}_{max} = \max_{\hat{k} \in \mathsf{EKV}}(\hat{p}_{\hat{k}})$; then $B \geq \hat{n} \cdot \hat{p}_{max}$.*

Proof. Since δ is the proportion of real accesses in $\hat{Q}$ and B is the ratio of the number of queries in $\hat{Q}$ compared to Q, we use δ to give a lower bound on B. For Property 4, Π must choose δ and π_f such that the probability of accessing any $\hat{k} \in \mathsf{EKV}$ is $1/\hat{n}$, i.e.,

$$\delta \cdot \hat{p}_{\hat{k}} + (1-\delta) \cdot \pi_f(\hat{k}) = \frac{1}{\hat{n}}$$

$$\text{or, } \delta \cdot \sum_{k \in \mathsf{KV}} \pi_r[k](\hat{k}) + (1-\delta) \cdot \pi_f(\hat{k}) = \frac{1}{\hat{n}}$$

For the probability $\pi_f(\hat{k})$ to have a valid non-negative value in the above equation for any $\hat{k}$, Π must have $\delta \leq \frac{1}{\hat{n} \cdot \sum_{k \in \mathsf{KV}} \pi_r[k](\hat{k})} \leq \frac{1}{\hat{n} \cdot \hat{p}_{max}}$.

Summing Property 5's inequality over all $k \in \mathsf{Keys(KV)}$:

$$E(\text{real queries in } Q) \leq E(\text{real queries in } \hat{Q})$$

Since all queries in Q are real, and the expected number of real accesses in $\hat{Q}$ is $\delta \cdot |\hat{Q}| = \delta \cdot q \cdot B$, we have $q \leq \delta \cdot q \cdot B$, i.e., $B \geq \frac{1}{\delta} \geq \hat{n} \cdot \hat{p}_{max}$. □

We provide the proofs of Lemmas 1 and 2 (§3.1).

Lemma 1. *Any $\Pi \in \mathcal{M}$ with leakage $\mathcal{L}$ and $S \notin \mathcal{L}$ requires storage footprint $\sigma \geq n \cdot s_{\max}$.*

Proof. Let us consider a scheme Π that has storage footprint $\sigma < n \cdot s_{max}$ when possible, i.e., the sum of its input sizes $\sum_i s_i < n \cdot s_{max}$. Against this scheme, we give an $O(n)$-time adversary $\mathcal{A}$ that, for all algorithms $\mathcal{S}$, has advantage $\mathbf{Adv}^{\text{ror-cdla}}_{\Pi,\mathcal{L},\mathcal{A},\mathcal{S}}(\lambda) = 1/2$.

Now we construct $\mathcal{A}$. $\mathcal{A}_1$ chooses value sizes from one of two distributions: $S_0 = \{s_{max}, ..., s_{max}\}$, i.e., all values have size s_{max}; or $S_1 = \{s_{max}, 1, ..., 1\}$, i.e., only one value has size s_{max}, while the rest are size 1. The two size distributions are chosen such that for S_0 and S_1, Π will output EKV_0 and EKV_1 respectively — while EKV_0 must have storage footprint $\sigma \geq n \cdot s_{max}$ to fulfill Property 3, EKV_1 has a lower storage footprint.

$\mathcal{A}_1$ flips a coin $b \sim \{0,1\}$ and assigns value sizes corresponding to S_b. It then outputs a KV with the chosen size distribution and uniform π. $\mathcal{A}_2$ takes as input EKV and $\hat{Q}$. $\mathcal{A}_2$ ignores $\hat{Q}$, but checks if the storage footprint of EKV is less than $n \cdot s_{max}$ bytes (i.e., $b = 1$) or at least $n \cdot s_{max}$ (i.e., $b = 0$). If the storage footprint matches the coin-flip b, $\mathcal{A}_2$ outputs 1. Otherwise, it outputs 0.

Suppose $\mathcal{A}$ is in $\text{ROR-CDLA}^0_{\Pi,\mathcal{L},\mathcal{A},q}(\lambda)$ interacting with the real Π. If $\mathcal{A}$ chooses S_0, Π always outputs an EKV using $n \cdot s_{max}$ bytes of storage. Similarly if $\mathcal{A}$ chooses S_1, Π always outputs an EKV using less storage, meaning $\Pr[\text{ROR-CDLA}^0_{\Pi,\mathcal{L},\mathcal{A},q}(\lambda) = 1] = 1$.

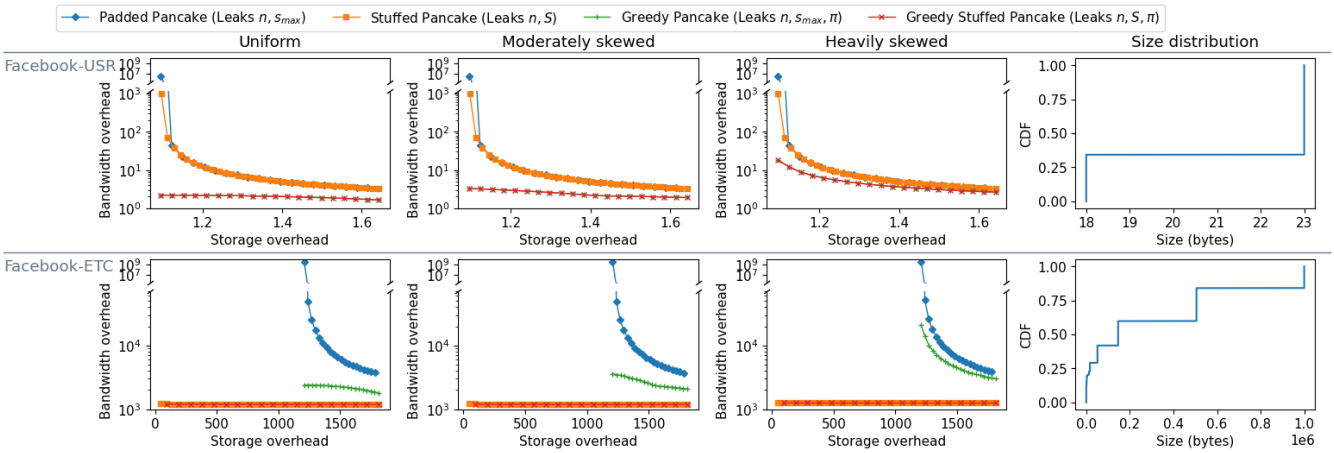

Figure 11: **Bandwidth vs. storage overhead across schemes with different leakage (continued from §1.1).** We use real-world workloads Facebook-USR (top) and Facebook-ETC (bottom) from Facebook Memcached deployments [26], and Zipf access patterns with varying skew (left to right). The rightmost column shows the dataset's object size CDF. Bandwidth overheads for schemes that do not leak object sizes start from the minimum storage footprint required for security, i.e., $n \cdot s_{max}$. The y-axes are in log-scale broken between bandwidth overheads 1200–2e5× (Facebook-USR) and 70000–2e5× (Facebook-ETC).

Now suppose $\mathcal{A}$ is in $\text{ROR-CDLA}^1_{\Pi,\mathcal{L},\mathcal{A},\mathcal{S},q}(\lambda)$ interacting with a simulator $\mathcal{S}$. $\mathcal{S}$ only knows the output of $\mathcal{L}_m$ on the KV given by $\mathcal{A}$, which is n and s_{max}. Without access to b, $\mathcal{S}$ can only *guess* whether $\mathcal{A}$ chose S_0 or S_1, and output pack sizes with the storage footprint that $\mathcal{A}$ expects. $\mathcal{S}$ guesses correctly with probability $\frac{1}{2}$, so $\Pr[\text{ROR-CDLA}^1_{\Pi,\mathcal{L},\mathcal{A},\mathcal{S},q}(\lambda) = 1] = \frac{1}{2}$.

Thus $\mathcal{A}$'s advantage $\mathbf{Adv}^{\text{ror-cdla}}_{\Pi,\mathcal{L},\mathcal{A},\mathcal{S}}(\lambda) = |1 - \frac{1}{2}| = \frac{1}{2}$. □

Lemma 2. *Given storage footprint $\sigma = \kappa \cdot n \cdot s_{max}$, a scheme $\Pi \in \mathcal{M}$ with leakage $\mathcal{L}$ and $S \notin \mathcal{L}$ that incurs the minimum possible bandwidth footprint must use $\hat{s} = s_{max}$.*

Proof. Let Π be given inputs $\mathsf{KV}, S, \pi, \sigma$. Since Π does not leak S, it must incur the same bandwidth footprint for all S. As such, we consider the worst-case $S = \{s_{max}, \ldots, s_{max}\}$.

By Property 1, each value $\hat{v} \in \mathsf{Values(EKV)}$ has the same size, say $\hat{s} = \gamma \cdot s_{max}$ for some $\gamma \geq 1$. Since all the values $v \in \mathsf{Values(KV)}$ are size s_{max}, we can view each value $\hat{v} \in \mathsf{Values(EKV)}$ as a set of γ "slots", where each slot can hold a copy of an s_{max}-sized input value $v \in \mathsf{Values(KV)}$.

By Property 3, each value in KV maps to at least one s_{max}-sized slot in EKV's values. The goal now is to map each key in KV to one or more slots in a manner that incurs at most β bandwidth footprint. Note that since every $v \in \mathsf{Values(KV)}$ is exactly size s_{max}, non-integer values of γ would only result in wasted space in each value $\hat{v}$ and, therefore, wasted bandwidth per access; as such, we only focus on integral γ values. Since EKV uses total storage $\kappa \cdot n \cdot s_{max}$, the number of values in EKV is $\hat{n} = \frac{\kappa n}{\gamma}$.

Let $\hat{p}_{\hat{k}}$ be the sum of the access probabilities of the keys $k \in \mathsf{Keys(KV)}$ assigned to key $\hat{k} \in \mathsf{Keys(EKV)}$, i.e., $\hat{p}_{\hat{k}} = \sum_{k \in \mathsf{KV}} \pi_r[k](\hat{k})$. Let $\hat{p}_{max} = \max_{\hat{k} \in \mathsf{EKV}} (\hat{p}_{\hat{k}})$. Lemma 5 gives us $B \geq \hat{n} \cdot \hat{p}_{max}$, so we have bandwidth footprint:

$$\beta = B \cdot \gamma \cdot s_{max} \geq \hat{n} \cdot \hat{p}_{max} \cdot \gamma \cdot s_{max}$$
$$= \frac{\kappa n}{\gamma} \cdot \hat{p}_{max} \cdot \gamma \cdot s_{max} = \sigma \cdot \hat{p}_{max}$$

As such, minimizing $\hat{p}_{max}$ minimizes β. Note $\hat{p}_{max}$ is monotonically non-decreasing in γ: larger γ would allow more keys $k \in \mathsf{Keys(KV)}$ to be mapped to keys $\hat{k} \in \mathsf{Keys(EKV)}$ and increase $\hat{p}_{max}$. Thus, the smallest possible value $\gamma = 1$ minimizes bandwidth footprint β. □

B.1 Bandwidth Bound of $\mathcal{ML}_m$

We present the full version of Step 2 of Theorem 3.1's proof, including the derivation of the lower bound on the advantage $\mathbf{Adv}^{\text{ror-cdla}}_{\Pi,\mathcal{L}_m,\mathcal{A},\mathcal{S}}(\lambda)$ of adversary $\mathcal{A}$ as defined in Figure 3.

Step 2: $\mathcal{A}$ has a non-negligible advantage. To show this, we lower-bound $\mathbf{Adv}^{\text{ror-cdla}}_{\Pi,\mathcal{L}_m,\mathcal{A},\mathcal{S}}(\lambda)$ by a function $f(\hat{n}, \varepsilon, \delta)$, and show that with $\varepsilon \to 0$ and sufficiently large values of $\hat{n}$, $f(\hat{n}, \varepsilon, \delta)$ approaches 1 for $0 < \delta < 1$ and $\varepsilon \to 0$. Since

$$\mathbf{Adv}^{\text{ror-cdla}}_{\Pi,\mathcal{L}_m,\mathcal{A},\mathcal{S}}(\lambda) = |\Pr[\text{ROR-CDLA}^0_{\Pi,\mathcal{L}_m,\mathcal{A},q}(\lambda) = 1]$$
$$- \Pr[\text{ROR-CDLA}^1_{\Pi,\mathcal{L}_m,\mathcal{A},\mathcal{S},q}(\lambda) = 1]|,$$

We obtain this function by finding (i) an upper bound on $\Pr[\text{ROR-CDLA}^0_{\Pi,\mathcal{L}_m,\mathcal{A},q}(\lambda) = 1]$, and (ii) a lower bound on $\Pr[\text{ROR-CDLA}^1_{\Pi,\mathcal{L}_m,\mathcal{A},\mathcal{S},q}(\lambda) = 1]$. We also note that since $\mathcal{A}_2$'s test does not leverage $\hat{n}$, $\hat{s}$ and B generated by the algorithm $\mathcal{S}$, $\mathcal{A}$ works against all possible $\mathcal{S}$.

Step 2(i): We upper-bound $\Pr[\text{ROR-CDLA}^0_{\Pi,\mathcal{L}_m,\mathcal{A},q}(\lambda) = 1]$, i.e., the probability that $\mathcal{A}$ guesses incorrectly that the queries $\hat{Q}$ it is given are sampled from a uniform distribution rather than generated by Π.

To do so, we focus on the key $\hat{h} \in \mathsf{P}(h)$ with access probability p. $\mathcal{A}_2$ outputs 1 if, for all keys in EKV, the number of queries they receive is less than or equal to $\mathcal{A}$'s threshold. We can, therefore, use the probability that $\hat{h}$ receives $\leq (c+3\sqrt{c})\ln\hat{n}$ queries as an upper bound for $\Pr[\text{ROR-CDLA}^0_{\Pi,\mathcal{L}_m,\mathcal{A},q}(\lambda)=1]$, and compute the same using the one-sided Chebyshev inequality, as we show next.

Let $X_{\hat{h}}$ be the random variable that counts the number of queries to $\hat{h}$ in $\hat{Q}$. $X_{\hat{h}}$ follows a binomial distribution $B(\hat{q},p)$ with mean $\mu=\hat{q}p \geq \frac{\hat{q}}{\hat{n}}\cdot\frac{1-\varepsilon}{1-\delta}$ and variance $\sigma^2 = \hat{q}p(1-p) = \hat{q}\left(\frac{1}{\hat{n}}\cdot\frac{1-\varepsilon}{1-\delta}\right)\left(1-\frac{1}{\hat{n}}\cdot\frac{1-\varepsilon}{1-\delta}\right)$. Since $\hat{q}=c\hat{n}\ln\hat{n}$, we have $\mu = c\ln\hat{n}\left(\frac{1-\varepsilon}{1-\delta}\right)$ and $\sigma^2 = \frac{c\ln\hat{n}(1-\varepsilon)(\hat{n}(1-\delta)-(1-\varepsilon))}{\hat{n}(1-\delta)^2}$.

To compute $\Pr[X_{\hat{h}} \leq (c+3\sqrt{c})\ln\hat{n}]$, we apply the one-sided Chebyshev inequality [45]: $\Pr[X_{\hat{h}} \leq \mu - a] \leq \frac{\sigma^2}{\sigma^2+a^2}$. We set:

$$a = \mu - (c+3\sqrt{c})\ln\hat{n} = c\ln\hat{n}\left(\frac{1-\varepsilon}{1-\delta} - 1 - \frac{3}{\sqrt{c}}\right).$$

Then, substituting into Chebyshev's inequality, we have:

$$\begin{aligned}
&\Pr[X_{\hat{h}} \leq (c+3\sqrt{c})\ln\hat{n}] \\
&\leq \frac{\frac{c\ln\hat{n}(1-\varepsilon)(\hat{n}(1-\delta)-(1-\varepsilon))}{\hat{n}(1-\delta)^2}}{\frac{c\ln\hat{n}(1-\varepsilon)(\hat{n}(1-\delta)-(1-\varepsilon))}{\hat{n}(1-\delta)^2} + c^2\ln^2\hat{n}\left(\frac{1-\varepsilon}{1-\delta}-1-\frac{3}{\sqrt{c}}\right)^2} \\
&= \frac{(1-\varepsilon)(\hat{n}(1-\delta)-(1-\varepsilon))}{(1-\varepsilon)(\hat{n}(1-\delta)-(1-\varepsilon)) + \frac{c\ln\hat{n}\left(\frac{1-\varepsilon}{1-\delta}-1-\frac{3}{\sqrt{c}}\right)^2}{\hat{n}(1-\delta)^2}}.
\end{aligned}$$

This gives us our upper-bound:

$$\begin{aligned}
&\Pr[\text{ROR-CDLA}^0_{\Pi,\mathcal{L}_m,\mathcal{A},q}(\lambda)=1] \\
&\leq \frac{(1-\varepsilon)(\hat{n}(1-\delta)-(1-\varepsilon))}{(1-\varepsilon)(\hat{n}(1-\delta)-(1-\varepsilon)) + \frac{c\ln\hat{n}\left(\frac{1-\varepsilon}{1-\delta}-1-\frac{3}{\sqrt{c}}\right)^2}{\hat{n}(1-\delta)^2}}. \qquad (2)
\end{aligned}$$

Note that $\mathcal{A}$ must choose a small enough ε such that $a>0$, specifically $\varepsilon < 1-(1+3\sqrt{c})(1-\delta)$. Since we also need $\varepsilon > 0$ for the π chosen by $\mathcal{A}$ to be a valid distribution, the attack can only work with $\delta > \frac{3}{3+\sqrt{c}}$.

Step 2(ii): We lower-bound $\Pr[\text{ROR-CDLA}^1_{\Pi,\mathcal{L}_m,\mathcal{A},\mathcal{S},q}(\lambda)=1]$, i.e., the probability that $\mathcal{A}$ guesses correctly that the queries in $\hat{Q}$ are sampled from a uniform distribution.

Once again, $\mathcal{A}$ outputs 1 if all keys receive more than $(c+3\sqrt{c})\ln\hat{n}$ queries, so we represent the number of queries to a key in EKV with a binomial random variable. We then use the Chernoff bound to compute the upper bound of the probability that *all* keys receive $> (c+3\sqrt{c})\ln\hat{n}$ queries, which we subtract from 1 to obtain the desired lower bound on $\Pr[\text{ROR-CDLA}^1_{\Pi,\mathcal{L}_m,\mathcal{A},\mathcal{S},q}(\lambda)=1]$, as we show next.

Let $X_{\hat{k}}$ be the random variable that counts the number of queries to $\hat{k} \in \mathsf{Keys}(\mathsf{EKV})$. Each $X_{\hat{k}}$ has a binomial distribution $B(\hat{q},1/\hat{n})$. To find $\Pr[X_{\hat{k}} \leq (c+3\sqrt{c})\ln\hat{n}]$, we apply the Chernoff bound [46]:

$$\Pr[X_{\hat{k}} \geq (1+a)\mu] \leq \exp\left(\frac{-a^2\mu}{3}\right) \text{ for any } 0<a<1$$

Substituting in $a = 3/\sqrt{c}$:

$$\Pr[X_{\hat{k}} \geq (c+3\sqrt{c})\ln\hat{n}] \leq \exp\left(\frac{-\left(\frac{3}{\sqrt{c}}\right)^2 c\ln\hat{n}}{3}\right) = \hat{n}^{-3}$$

By the union bound, the probability that any key receives more than $(c+3\sqrt{c})\ln\hat{n}$ queries is $\leq \hat{n}(\hat{n}^{-3}) = \hat{n}^{-2}$. Thus,

$$\Pr[\text{ROR-CDLA}^1_{\Pi,\mathcal{L}_m,\mathcal{A},\mathcal{S},q}(\lambda)=1] \geq 1-\hat{n}^{-2}. \qquad (3)$$

B.2 Bandwidth-optimality of GPC

Here we prove that Greedy PANCAKE is bandwidth-optimal.

Theorem 5.1. *For any storage footprint $\sigma = \kappa\cdot n\cdot s_{max}$ ($\kappa \geq 1$), GPC achieves the lowest bandwidth footprint β for any $\mathcal{ML}_\pi$ scheme that uses exactly σ storage.*

Proof. Any $\mathcal{ML}_\pi$ scheme must have the same bandwidth footprint for any input sizes S; as such, Lemma 2 holds for schemes in $\mathcal{ML}_\pi$; GPC already uses $\hat{s}=s_{max}$, satisfying this requirement. We show that GPC with $\kappa\cdot n\cdot s_{max}$ storage achieves the optimal bandwidth footprint for $S := \{s_{max},\ldots,s_{max}\}$, and, by extension, all other S.

Let $R[i] = |\mathsf{P}(k_i)|$ be the number of keys $\hat{k} \in \mathsf{Keys}(\mathsf{EKV})$ mapped to key $k_i \in \mathsf{Keys}(\mathsf{KV})$ by GPC, and let $R^*[i]$ be the number of $\hat{k} \in \mathsf{Keys}(\mathsf{EKV})$ mapped to key $k_i \in \mathsf{Keys}(\mathsf{KV})$ by an optimal algorithm. Let $f(j,R) := \max_{k_i\in\mathsf{Keys}(\mathsf{KV})} \pi(k_i)/R[i]$ after j out of $\hat{n}$ keys in EKV have been assigned a key in KV. By induction on j, we show that $f(j,R) \leq f(j,R^*)$ for $n \leq j \leq \hat{n}$.

Base case: $j=n$. Since each key $k \in \mathsf{Keys}(\mathsf{KV})$ is initially assigned exactly one key $\hat{k} \in \mathsf{Keys}(\mathsf{EKV})$, we have:

$$f(j,R) = f(j,R^*) = \max_{k_i\in\mathsf{Keys}(\mathsf{KV})}\{\pi(k_i)\}$$

Induction. Let $f(j,R) \leq f(j,R^*)$ hold for some $j > n$. Consider the $(j+1)^{th}$ key $\hat{k}_{j+1} \in \mathsf{Keys}(\mathsf{EKV})$ to be assigned a key in $\mathsf{Keys}(\mathsf{KV})$. GPC assigns to it $h = \arg\max_{k_i\in\mathsf{Keys}(\mathsf{KV})} \pi(k_i)/R[i]$, which means before this step, $\forall\hat{k} \in \mathsf{P}(h), \pi_r[h](\hat{k}) = f(j,R)$. Since we know $f(j,R) \leq f(j,R^*)$, the best choice that the optimal algorithm has in minimizing $f(j+1,R^*)$ is to assign its $\hat{k}^*_{j+1}$ to the key h^* for which $\forall\hat{k} \in \mathsf{P}(h), \pi_r[h](\hat{k}) = f(j,R^*)$. Since $f(j,R^*) \geq f(j,R)$, we still have that $f(j+1,R) \leq f(j+1,R^*)$.

We now show that the optimal $f(j+1,R)$ allows GPC to achieve the minimum bandwidth footprint. Assume for the sake of contradiction that there is an optimal R^* that has a lower bandwidth footprint than R. Bandwidth footprint is $\beta = B\cdot\hat{s}$, and by Lemma 5, $B \geq \hat{n}\cdot f(j,R^*)$. Then R^* using less bandwidth than R can only mean that $f(j,R^*) < f(j,R)$ for $j=\hat{n}$ — a contradiction. □

Unbalanced Circuit-PSI from Oblivious Key-Value Retrieval

Abstract

Circuit-based Private Set Intersection (circuit-PSI) empowers two parties, a client and a server, each with input sets X and Y, to securely compute a function f on the intersection $X \cap Y$ while preserving the confidentiality of $X \cap Y$ from both parties. Despite the recent proposals of computationally efficient circuit-PSI protocols, they primarily focus on the balanced scenario where $|X|$ is similar to $|Y|$. However, in many practical situations, a circuit-PSI protocol may be applied in an unbalanced context, where $|X|$ is significantly smaller than $|Y|$. Directly applying existing protocols to this scenario poses notable efficiency challenges due to the communication complexity of these protocols scaling at least linearly with the size of the larger set, i.e., $\max(|X|,|Y|)$.

In this work, we put forth efficient constructions for unbalanced circuit-PSI, demonstrating sublinear communication complexity in the size of the larger set. Our key insight lies in formalizing unbalanced circuit-PSI as the process of obliviously retrieving values corresponding to keys from a set of key-value pairs. To achieve this, we propose a new functionality named Oblivious Key-Value Retrieval (OKVR) and design the OKVR protocol based on a new notion termed sparse Oblivious Key-Value Store (sparse OKVS). We conduct comprehensive experiments and the results showcase substantial improvements over the state-of-the-art circuit-PSI schemes, i.e., $1.84 \sim 48.86\times$ communication improvement and $1.50 \sim 39.81\times$ faster computation. Compared to a very recent unbalanced circuit-PSI work, our constructions outperform them by $1.18 \sim 15.99\times$ and $1.22 \sim 10.44\times$ in communication and computation overhead, respectively, depending on set sizes and network environments.

1 Introduction

In Private Set Intersection (PSI) [20, 23, 32, 34, 42–44, 48, 51], two parties, the client with a set X and the server with a set Y, securely compute the intersection $X \cap Y$, without leaking the information of the items that are not in the intersection. Depending on the output, PSI can be broadly classified into two categories, plain PSI and circuit-based PSI (denoted as circuit-PSI) [28]. Notably, circuit-PSI has garnered significant attention in recent times [10, 45, 51]. Unlike plain PSI, which directly reveals the plaintext of the intersection $X \cap Y$, circuit-PSI offers the capability to securely compute a function f on the intersection and exclusively outputs the result $f(X \cap Y)$ without leaking $X \cap Y$. This expands the applicability of PSI to a broader range of scenarios. Formally, for each element $x \in X$, the two parties acquire secret shares of b, where $b = 1$ if $x \in X \cap Y$ and $b = 0$ otherwise. These shares can then be leveraged to securely compute any desired function using generic secure two-party computation protocols [26, 57]. Recent advancements in circuit-PSI protocols [6, 10, 45, 48, 51] have demonstrated efficient computation and achieved linear communication complexity proportional to the size of the parties' sets.

While circuit-PSI protocols offer notable advantages, their current emphasis is primarily on scenarios where the sets held by the involved parties are of similar size (i.e., the balanced setting). However, practical applications, particularly in client-server scenarios, often demand the execution of circuit-PSI protocols in an *unbalanced* setting. In such situations, the client typically possesses a smaller set, compared to the server's considerably larger set. A relevant example is private contact tracing for infectious diseases [9, 55], where a client aims to privately check if the collected tracing data aligns with traces of diagnosed patients. Achieving this involves computing the cardinality function on the set intersection [55], with only the client gaining knowledge of the count of matching traces. In practical terms, the server may hold a set comprising several million items, vastly outnumbering the client's set, which might only consist of a few hundred items.

Furthermore, Google [29] employed a private application for measuring ad conversion rates, specifically examining the revenues from ad viewers who later engage in related transactions. In this scenario, a client (such as a holder of transaction data) possesses records of customer transactions, while

✉Corresponding author.

a server (like an advertising company) maintains records of customers who have viewed ads. The task involves intersecting identifiers of those who viewed a specific ad with those who completed a transaction, followed by the computation of an aggregation function on the resulting intersection. Notably, the sets involved in this process are highly unbalanced, given that the number of ad impressions typically exceeds the number of transactions by orders of magnitude. Moreover, the transaction records and ad views are privacy-sensitive, potentially containing personal interests, preferences, and even health-related information. Consequently, there is an imperative need for such an unbalanced circuit-PSI protocol.

Nevertheless, the current landscape lacks effective techniques tailored for unbalanced circuit-PSI scenarios. Existing solutions encounter challenges, as they either compromise the confidentiality of private intersections or impose substantial communication overhead. On one hand, some studies have introduced unbalanced PSI protocols [11, 12, 16, 32, 50] addressing scenarios where the server's set is much larger than the client's. Despite their relevance, extending these protocols to unbalanced circuit-PSI settings proves challenging, as they inherently disclose the intersection in plaintext. On the other hand, applying state-of-the-art circuit-PSI protocols [6, 10, 45, 48, 51] directly to unbalanced settings is also problematic. These protocols are specifically designed for parties' sets of similar size. When used in unbalanced settings, these protocols incur at least linear communication complexity on the larger set, leading to a notable performance decline, especially in bandwidth-constrained network environments. Refer to Section 1.3 for more details. The above discussion raises the following natural question:

Can we construct concretely efficient unbalanced circuit-PSI protocols with sublinear communication in the size of the larger set?

1.1 Our Contributions

In this paper, we make an affirmative answer to the above question. Our contributions can be summarized as follows:

- We construct highly efficient unbalanced circuit-PSI protocols, exhibiting communication overhead that scales sublinearly with the size of the larger set. In line with previous works, our protocols are secure against semi-honest adversaries.
- At the heart of our methodology is a newly introduced functionality called Oblivious Key-Value Retrieval (OKVR). We provide its construction based on a novel notion termed sparse Oblivious Key-Value Store (sparse OKVS).
- We implement our protocols alongside state-of-the-art circuit-PSI protocols in a unified framework. The results demonstrate the significant enhancements of our protocols in both communication and computation overhead. Specifically, our protocol achieves a communication cost $1.84 \sim 48.86\times$ lower and a running time $1.50 \sim 39.81\times$ faster compared to the state-of-the-art protocols. Very recently, Son and Jeong [54] also present unbalanced circuit-PSI protocols, and our constructions show reductions in communication and computation overhead by $1.18 \sim 15.99\times$ and $1.22 \sim 10.44\times$, respectively, depending on set sizes and network environments.

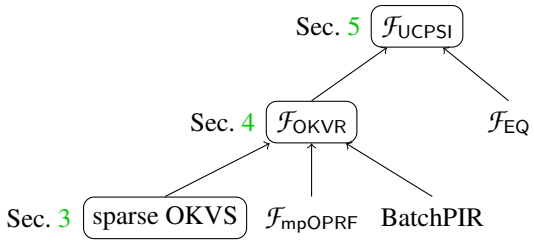

Figure 1: Overview of our unbalanced circuit-PSI framework. Rounded rectangles are contributions of this work.

1.2 Overview of Our Techniques

The main insight driving our framework is that unbalanced circuit-PSI can be formalized as obliviously retrieving the values corresponding to keys from a key-value store[1], followed by an equality test. We elaborate on this insight below. For simplicity, we consider the scenario where the client's set comprises only a single element x and the server's set is represented as $Y = \{y_1, \ldots, y_n\}$. Specifically, the server initiates the process by constructing a key-value store with key-value pairs $\{(y_1, r), \ldots, (y_n, r)\}$, where each item y_i serves as a key and the corresponding value is a randomly sampled r. Subsequently, the client employs x as the query key and obliviously retrieves a value r^* from the server. This retrieved value should satisfy $r^* = r$ if $x \in Y$ and r^* is uniformly random otherwise. Finally, the unbalanced circuit-PSI evaluation concludes with the computation of a secret-shared output, derived from a private equality test conducted on r^* and r. To achieve the fully-fledged construction based on the above insight, we undertake three intermediate steps detailed in Figure 1, and overview them in a bottom-up manner.

1. We introduce a new notion termed sparse Oblivious Key-Value Store (sparse OKVS), designed to encode key-value pairs into a compact representation while supporting efficient retrieval. Within this sparse OKVS abstraction, we identify and detail efficient instantiations that align with our goals.

[1] A key-value store for $\mathcal{K} \times \mathcal{V}$ is a data structure that represents a desired mapping $k_i \to v_i$, where $(k_i, v_i) \in \mathcal{K} \times \mathcal{V}$.

2. We present a new functionality called Oblivious Key-Value Retrieval (OKVR). This serves the purpose of obliviously retrieving the values corresponding to keys from a key-value store. We construct an efficient OKVR protocol, which is facilitated by utilizing the property of sparse OKVS.

3. We construct fully-fledged unbalanced circuit-PSI protocols characterized by sublinear communication complexity in the size of the larger set. The cornerstone of our construction is a specialized padding-free variant of OKVR. This specifically addresses an efficiency concern arising from commonly employed hash-to-bin techniques in circuit-PSI.

Below, we give more technical details to illustrate the above three intermediate steps.

Retrieving key-value pairs efficiently. The central objective of our framework is the efficient and oblivious retrieval of key-value pairs. Thus, the starting point involves transforming the server's key-value pairs into a compact representation conducive to efficient retrieval.

Although this functionality can be accomplished by leveraging Oblivious Key-Value Store (OKVS) [23, 43], a primary challenge lies in that the retrieval efficiency can not be well guaranteed in existing OKVS. Specifically, OKVS comprises two algorithms, namely $(\mathsf{Encode}, \mathsf{Decode})$. The Encode algorithm takes a set of key-value pairs $\{(k_i, v_i)\}_{i\in[n]}$ as input and produces a vector D. The Decode algorithm takes D and any key k as input, providing an output that corresponds to v_i if k matches some k_i used to generate D. In our framework, the Decode algorithm aligns with our retrieval procedure and will be implemented in an oblivious manner. Unfortunately, prior works utilize OKVS instances in a black-box way, e.g., accessing the whole vector D for Decode, causing linear communication complexity in the size of the key-value pairs. This problem stems from the absence of explicit requirements for decoding efficiency in existing OKVS.

We introduce a new OKVS notion, termed *sparse* OKVS, designed to enhance decoding efficiency. A key difference from prior OKVS constructions [23] lies in that the structure of the output D from Encode can be organized as $D_0 \| D_1$ with $|D_0| = \omega(|D_1|)$, and Decode exclusively accesses a constant number (e.g., $2 \sim 3$) of elements within the larger D_0 and an arbitrary number of elements within the smaller D_1. Consequently, we refer to D_0 as the sparse part and D_1 as the dense part. Importantly, accessing a constant number of elements on the larger sparse part is a pivotal property for achieving efficient oblivious key-value retrieval. Later, we will make a large number of retrievals on the dense part nearly cost-free. We identify existing constructions that satisfy the sparse OKVS abstraction, such as Garbled Cuckoo Tables (GCT) [23, 43]. Refer to Section 3 for more details.

Retrieving key-value pairs obliviously. Building upon the efficient retrieval strategy outlined above, our next objective is to facilitate the client to obliviously retrieve the server's key-value pairs with the following security guarantee. The server should remain unaware of which value was retrieved, and the client should not acquire knowledge of other key-value pairs within the server's set.

Unfortunately, it is challenging to achieve the above goal while ensuring concrete efficiency. A possible solution to oblivious key-value retrieval is employing Private Information Retrieval (PIR)[2] [5, 38–40], in which the client privately retrieves the relevant items from the server's OKVS encoding. These retrieved items are used in the decoding for the reconstruction of the corresponding value for the query. However, it requires a substantial number of PIR queries, causing a huge loss of efficiency. Moreover, PIR alone cannot safeguard the privacy of the server's key-value pairs.

We formalize the above objective as a new functionality named Oblivious Key-Value Retrieval (OKVR). In OKVR, the server possesses a large set of key-value pairs denoted as $L = \{(k_1, v_1), \ldots, (k_n, v_n)\}$ and the client holds a smaller query set $Q = \{q_1, \ldots, q_t\}$ with $n \gg t$. After the execution, the client obtains a value z_i for each $q_i \in Q$, where $z_i = v_j$ if q_i matches some k_j and $(k_j, v_j) \in L$. Otherwise, z_i is a uniformly random value. To achieve concretely efficient and asymptotically communication-sublinear OKVR, we present the construction derived from sparse OKVS and a hybrid PIR strategy. Specifically, we first utilize sparse OKVS to encode the server's key-value pairs into $D_0 \| D_1$. Subsequently, PIR is exclusively applied to the sparse part D_0 to retrieve the desired items, while the dense part D_1, owing to its small size, is directly transmitted from the server to the client. This ensures the retrieval of a constant number of items on D_0 via PIR, while the client can locally obtain a considerable number of items in D_1 with minimal cost. To enhance PIR efficiency further, given the requirement of multiple retrievals at once, we exploit recent BatchPIR schemes [5, 40] that substantially reduce communication and computation overhead in batch retrievals. Moreover, similar to prior works [11, 45], we address the PIR's privacy concern regarding the server's key-value pairs by invoking an Oblivious Pseudorandom Function (OPRF) [22] before the execution of sparse OKVS. Refer to Section 4 for more details.

Constructing fully-fledged unbalanced circuit-PSI. We propose an efficient construction of unbalanced circuit-PSI from OKVR, achieving sublinear communication complexity on the size of the larger set.

A key challenge is the PIR efficiency issue in OKVR caused by the commonly employed hash-to-bin technique. In constructing efficient circuit-PSI protocols [10, 45], hash-to-bin techniques are integral for reducing computational costs. Specifically, the client employs Cuckoo hashing [41] to map the set X of size-t into a table T_X of size $m = (1+\varepsilon)\cdot t$, where $\varepsilon > 0$ is a constant. In this mapping, each bin of T_X contains

[2] The communication complexity of PIR is sublinear to the database size.

at most one item. Simultaneously, the server maps its items in Y to a table T_Y of size m using simple hashing, allowing each bin to accommodate multiple items. After that, the client has to conceal the mapped positions by padding dummy points into empty bins of T_X [44,45]. The evaluation of unbalanced circuit-PSI invokes the OKVR functionality, where the client inputs T_X and the server inputs $\{P_i\}_{i\in[m]}$ with $P_i := \{(y', r_i)\}$ for all $y' \in T_Y[i]$ and a random r_i. Nevertheless, these dummy points introduce additional overhead in terms of PIR queries within the OKVR procedure, which dominates the overhead of our unbalanced circuit-PSI protocol.

To mitigate this issue, we introduce a specialized *padding-free* OKVR solution where the client only inputs the key set of size t rather than $(1+\varepsilon)\cdot t$. The key insight here is that, prior to PIR queries, the client is already aware that these dummy points do not belong to the intersection. Consequently, random values are obtained according to the functionality of OKVR. Recall that OKVR outputs a random value when a query is not present in the server's key set. As a result, our padding-free OKVR protocol invokes OKVR solely on the bins of T_X that correspond to the elements of X and locally samples uniformly random values for the dummy points. Notably, the confidentiality of the mapped positions is guaranteed because we take the whole client's query set as input to OKVR. Refer to Section 5 for more details.

1.3 Related Works

We elaborate on existing balanced circuit-PSI protocols as well as related techniques in the unbalanced setting, and further discuss the essential differences between these works and our protocols.

Circuit-PSI. Circuit-PSI was initially introduced by Huang et al. [28], leveraging generic secure computation techniques, i.e., garbled circuits [57]. They employed optimized sort-compare-shuffle circuits to reduce circuit size, resulting in a circuit that contains $O(n\log n)$ comparisons, where n represents the set size. Following this, several subsequent works [15,44,46] aimed to reduce the number of comparisons and hence optimize asymptotic computation and communication complexity. Recently, Pinkas et al. [45] achieved the first circuit-PSI protocol with linear communication complexity by introducing a novel batch Oblivious Programmable Pseudorandom Function (OPPRF) [35]. Similar to an oblivious PRF that provides the sender with a key of PRF and the receiver with the outputs of the PRF on points of his choice, an OPPRF enables the sender to additionally send the receiver a hint that can program the PRF to output specific values on certain input points privately chosen by the sender. The main bottleneck of this protocol is that the computation complexity is super-linear in the size of the server's set [10,45]. This is caused by the expensive polynomial interpolation in their OPPRF construction. Recent works [6,33,48,51] addressed this problem leveraging state-of-the-art OKVS such as Garbled Cuckoo Tables (GCT) [23] that achieves linear computation complexity. Chandran et al. [10] also proposed specialized circuit-PSI protocols with both linear computation and communication complexity. The main technique is a new primitive called relaxed batch OPPRF. Moreover, Chandran et al. [10] and Han et al. [27] presented specialized equality test protocols aimed at further improving the concrete overhead of circuit-PSI.

A potential limitation of the above state-of-the-art circuit-PSI approaches is the communication complexity, which scales at least linearly with the size of the two parties' sets. The fundamental reason is that these circuit-PSI utilize existing OKVS [23] in a black-box way and send the whole encoded vector (i.e., the hint) to the client. In our work, to avoid linear communication, we present sparse OKVS and particularly focus on the decoding efficiency, which could be used to construct sublinear circuit-PSI protocols.

Unbalanced PSI-related works. There are some related PSI protocols in the unbalanced setting. We discuss the main differences between these works and ours. Several works proposed computation and communication efficient schemes for unbalanced PSI [12,16,32,50] and labeled PSI [11,16] from fully homomorphic encryption (FHE). However, these approaches face challenges when extending to our circuit-PSI setting because they focus on directly outputting the intersection to the client. While the work on labeled PSI [11] theoretically discussed the possibility of extending their protocol to unbalanced circuit-PSI, concrete constructions were lacking. Subsequently, Lepoint et al. [36] proposed an unbalanced private join and compute (PJC) scheme for the inner product, achieving sublinear communication cost in the size of the larger set. This scheme focuses on computing the inner product of associated values within the intersection and illustrates how to extend to compute arbitrary functions. However, their construction relies on (garbled) Bloom filters [7,19], which encode n items into a vector of length $O(\lambda n)$ with a statistical security parameter λ. This leads to the communication and computation complexity additionally depending on λ. In comparison, our unbalanced circuit-PSI protocols can realize a $\lambda\times$ improvement on both the computation and communication overhead thanks to our concretely and asymptotically efficient OKVR protocols.

Very recently, Son and Jeong [54] (SJ23) provided two concrete constructions to instantiate the theoretical extension from labeled PSI to unbalanced circuit-PSI [11]. The first construction follows the labeled PSI using FHE on polynomial evaluation along with several optimizations, while the second construction proposes a novel recursive solution. However, their two constructions have a significant trade-off between communication and computation due to balancing the expensive homomorphic multiplication and the number of communicated FHE ciphertexts. Different from their works, we formalize circuit-PSI as obliviously retrieving the value corresponding to a key from a key-value store, and provide

efficient constructions from sparse OKVS and BatchPIR. As shown in Section 6.2, the main advantage is that our protocols are more suitable for the unbalanced setting. Rather, SJ23 works well for relatively large client's set sizes, e.g., at least thousands of elements.

2 Preliminaries

2.1 Notations

We denote the two parties as client $\mathcal{C}$ and server $\mathcal{S}$. We use κ and λ to denote the computational and statistical security parameters, respectively. For two distributions X and Y, we write $X \approx_c Y$ and $X \approx_s Y$ if X and Y are computationally and statistically indistinguishable, respectively. We use $[n]$ to denote the set $\{1,2,\ldots,n\}$ and $D[i]$ to represent the i-th element of a vector D. By $a \leftarrow A$, we denote that a is randomly selected from the set A. $a \leftarrow \mathrm{A}(x)$ denotes that a is the output of the randomized algorithm A on input x, and $a := b$ denotes that a is assigned by b. $\langle x,y \rangle$ denotes the inner product of x and y. $\langle x \rangle_0^B$ and $\langle x \rangle_1^B$ denote Boolean shares of x such that $x = \langle x \rangle_0^B \oplus \langle x \rangle_1^B$. $1\{x=y\}$ outputs 1 if $x=y$ and 0 otherwise.

2.2 Threat Model

Similar to prior circuit-PSI schemes [10,45,48,51,54], in this work, we consider static semi-honest probabilistic polynomial-time (PPT) adversaries. Namely, a PPT adversary $\mathcal{A}$ passively corrupts either the client $\mathcal{C}$ or the server $\mathcal{S}$ at the beginning of the protocol and honestly follows the protocol specification. We use the standard simulation-based security definition for secure two-party computation [25]. Like these previous works, our construction invokes multiple sub-protocols, and we use the *hybrid model* to describe them. By convention, a protocol invoking a functionality $\mathcal{F}$ is referred to as the $\mathcal{F}$-hybrid model. We give the formal security definition as follows.

Definition 1. *Let* $\mathrm{view}_{\mathcal{C}}^{\Pi}(x,y)$ *and* $\mathrm{view}_{\mathcal{S}}^{\Pi}(x,y)$ *be the views (including input, random tape, and all received messages) of* $\mathcal{C}$ *and* $\mathcal{S}$ *in a protocol* Π*, respectively, where* x *is the input of* $\mathcal{C}$ *and* y *is the input of* $\mathcal{S}$*. Let* $\mathrm{out}(x,y)$ *be the protocol's output of both parties and* $\mathcal{F}(x,y)$ *be the functionality's output.* Π *is said to securely compute a functionality* $\mathcal{F}$ *in the semi-honest model if for every PPT adversary* $\mathcal{A}$ *there exists PPT simulators* $\mathrm{Sim}_{\mathcal{C}}$ *and* $\mathrm{Sim}_{\mathcal{S}}$ *such that for all inputs* x *and* y*,*

$$\begin{aligned}\{\mathrm{view}_{\mathcal{C}}^{\Pi}(x,y), \mathrm{out}(x,y)\} &\approx_c \{\mathrm{Sim}_{\mathcal{C}}(x, \mathcal{F}_{\mathcal{C}}(x,y)), \mathcal{F}(x,y)\},\\ \{\mathrm{view}_{\mathcal{S}}^{\Pi}(x,y), \mathrm{out}(x,y)\} &\approx_c \{\mathrm{Sim}_{\mathcal{S}}(x, \mathcal{F}_{\mathcal{S}}(x,y)), \mathcal{F}(x,y)\}.\end{aligned} \tag{1}$$

2.3 Oblivious Key-Value Store

A key-value store [23,43] is simply a data structure that maps a set of keys to the corresponding values. The definition is as follows:

Functionality $\mathcal{F}_{\mathsf{mpOPRF}}$

Parameters: A PRF $F : \{0,1\}^{\kappa} \times \{0,1\}^{\ell} \to \{0,1\}^{\ell}$.

Functionality:

1. Wait for input $\{x_1,\ldots,x_n\} \in (\{0,1\}^{\ell})^n$ from the receiver.
2. Wait for input $\mathsf{k} \in \{0,1\}^{\kappa}$ from the sender.
3. Output $\{F(\mathsf{k},x_1),\ldots,F(\mathsf{k},x_n)\}$ to the receiver.

Figure 2: Ideal functionality for multi-point OPRF

Definition 2. *A Key-Value Store (KVS) is parameterized by a key space* $\mathcal{K}$*, a value space* $\mathcal{V}$*, a set of randomized functions* H*, input length* n *and output length* m*, and consists of two algorithms:*

- Encode_H*: on input key-value pairs* $\{(k_i,v_i)\}_{i\in[n]} \in (\mathcal{K}\times\mathcal{V})^n$*, outputs an object* $D \in \mathcal{V}^m$ *(or an error indicator* $\perp$ *with statistically small probability).*
- Decode_H*: on input* $D \in \mathcal{V}^m$ *and a key* $k \in \mathcal{K}$*, outputs a value* $v \in \mathcal{V}$*.*

Correctness. A KVS is correct if, for all $L \in (\mathcal{K}\times\mathcal{V})^n$ with distinct keys such that $\mathsf{Encode}_H(L) \neq \perp$, it holds that $\mathsf{Decode}_H(\mathsf{Encode}_H(L),k) = v$, where $(k,v) \in L$.

Obliviousness [23]. A KVS is an Oblivious KVS (OKVS) if, for all distinct $\{k_1^0,\ldots,k_n^0\} \in \mathcal{K}^n$ and $\{k_1^1,\ldots,k_n^1\} \in \mathcal{K}^n$, Encode_H does not output $\perp$ on $\{k_1^0,\ldots,k_n^0\}$ and $\{k_1^1,\ldots,k_n^1\}$, and then

$$\begin{aligned}&\{\mathsf{Encode}_H(\{(k_1^0,v_1),\ldots,(k_n^0,v_n)\}) \mid v_i \leftarrow \mathcal{V} \text{ for } i \in [n]\} \approx_s\\ &\{\mathsf{Encode}_H(\{(k_1^1,v_1),\ldots,(k_n^1,v_n)\}) \mid v_i \leftarrow \mathcal{V} \text{ for } i \in [n]\}.\end{aligned} \tag{2}$$

Double obliviousness [48, 51]. An OKVS is doubly oblivious if, for all distinct $\{k_1,\ldots,k_n\} \in \mathcal{K}^n$ and n values $v_1,\ldots,v_n$ each sampled uniformly at random from $\mathcal{V}$ such that Encode_H does not output $\perp$ for $\{k_1,\ldots,k_n\}$, $\mathsf{Encode}_H(\{(k_1,v_1),\ldots,(k_n,v_n)\})$ is statistically indistinguishable from an uniformly random element in $\mathcal{V}^m$. Note that double obliviousness directly implies obliviousness [6,48].

Binary OKVS [23]. An OKVS is binary if, for any k, $\mathsf{Decode}_H(D,k)$ can be expressed as a binary linear combination of D, i.e., $\mathsf{Decode}_H(D,k) := \langle D, h(k) \rangle$ where $h : \mathcal{K} \to \{0,1\}^m$ is some public function defined by H. In this work, we restrict ourselves to binary OKVS schemes.

2.4 Batch Private Information Retrieval

In a Batch Private Information Retrieval (BatchPIR) scheme [5, 13, 30, 37, 40], the client wants to privately download a batch of b entries from the server's dataset D of size n. A

BatchPIR consists of three routines, all taking the computational security parameter κ as an implicit input:

- $\mathsf{Query}(\{i_1,\ldots,i_b\}) \to (qu, st)$: on input a set of distinct indexes $\{i_1,\ldots,i_b\} \in ([n])^b$, outputs a query qu and a private state st including the index set.
- $\mathsf{Response}(D, qu) \to res$: on input the database D and the query qu, outputs a response res.
- $\mathsf{Extract}(st, res) \to \{y_1,\ldots,y_b\}$: given the state st and the response res, outputs a batch of entries $\{y_1,\ldots,y_b\}$.

A BatchPIR protocol should satisfy the following properties:

Correctness. A BatchPIR is correct if for any dataset D and all distinct inputs $I = \{i_1,\ldots,i_b\}$, it holds that

$$\mathsf{Extract}(st, \mathsf{Response}(D, qu)) = D[i_1],\ldots,D[i_b], \quad (3)$$

where $(st, qu) \leftarrow \mathsf{Query}(I)$.

Client query privacy. The client's query should reveal no information about the query indexes. Formally, a BatchPIR scheme satisfies *client query privacy* if, for all PPT adversaries $\mathcal{A}$ and all distinct batch query sets I_1, I_2 with $|I_1| = |I_2|$,

$$\begin{aligned} &\Pr[\mathcal{A}(qu) = 1 \mid (st, qu) \leftarrow \mathsf{Query}(I_1)] \\ -&\Pr[\mathcal{A}(qu) = 1 \mid (st, qu) \leftarrow \mathsf{Query}(I_2)] \le \mathrm{negl}(\kappa). \end{aligned} \quad (4)$$

Note that (Batch)PIR does not aim to protect the privacy of the server's dataset D [5].

2.5 Multi-point Oblivious Pseudorandom Function

An Oblivious Pseudorandom Function (OPRF) [22] is a protocol involving two parties, i.e., the sender and the receiver. The sender inputs the key $\mathsf{k} \in \{0,1\}^\kappa$ of a PRF F and obtains nothing, while the receiver takes $x \in \{0,1\}^\ell$ as input and obtains $F(\mathsf{k}, x) \in \{0,1\}^\ell$. In a multi-point OPRF (mpOPRF) [31], the receiver takes as input $\{x_1,\ldots,x_n\} \in (\{0,1\}^\ell)^n$ rather than a single point and obtains $\{F(\mathsf{k}, x_1),\ldots,F(\mathsf{k}, x_n)\} \in (\{0,1\}^\ell)^n$. The mpOPRF functionality is shown in Figure 2.

2.6 Secret Sharing and Equality Test

Our construction uses 2-out-of-2 boolean secret sharing techniques [53]. The boolean shares of $x \in \{0,1\}$ are $\langle x \rangle_0^B$ and $\langle x \rangle_1^B$, held by the client $\mathcal{C}$ and the server $\mathcal{S}$ respectively, satisfying $x = \langle x \rangle_0^B \oplus \langle x \rangle_1^B$. In our protocols, $\langle x \rangle^B$ denotes that $\mathcal{C}$ and $\mathcal{S}$ hold boolean shares of x. Our construction also invokes a private equality test, which takes as input two ℓ-bit values x, y and outputs the boolean shares of b, where $b := 1\{x = y\}$. We present the functionality in Figure 3. We use the state-of-the-art construction [10] to instantiate this functionality.

Functionality $\mathcal{F}_{\mathsf{EQ}}$

Parameters: Client $\mathcal{C}$ and server $\mathcal{S}$.

Functionality:

1. Wait for input $x \in \{0,1\}^\ell$ from $\mathcal{C}$.
2. Wait for input $y \in \{0,1\}^\ell$ from $\mathcal{S}$.
3. Sample $\langle b \rangle_0^B$, $\langle b \rangle_1^B$ uniformly at random from $\{0,1\}$ such that $b := 1\{x = y\}$.
4. Output $\langle b \rangle_0^B$, $\langle b \rangle_1^B$ to $\mathcal{C}$ and $\mathcal{S}$, respectively.

Figure 3: Ideal functionality for private equality test

2.7 Cuckoo Hashing

Cuckoo hashing [41] uses α random hash functions $h_1,\ldots,h_\alpha : \{0,1\}^* \to [m]$ to map n elements into m bins, where $m = (1+\varepsilon)\cdot n$ with the constant $\varepsilon > 0$. The mapping procedure is as follows. An element x is inserted into the bin $h_i(x)$, if this bin is empty for some $i \in [\alpha]$. Otherwise, we pick a random $i \in [\alpha]$, insert x in $h_i(x)$, evict the item currently in $h_i(x)$ and recursively insert the evicted item. The recursion proceeds until no more evictions are necessary or a threshold number of re-allocations are done. If the recursion stops for the latter reason, it is considered a failure event, meaning there exists at least an element that is not mapped to any bins. Some variants of Cuckoo hashing maintain a set called the stash, to store such elements. Stash-less Cuckoo hashing is where no special stash is maintained. In this work, we only leverage stash-less Cuckoo hashing.

3 Sparse Oblivious Key-Value Store

3.1 Definition

We present a new notion called sparse Oblivious Key-Value Store (sparse OKVS), which incorporates a sparsity property into OKVS introduced in Section 2.3. A formal definition is provided below.

Definition 3. *An OKVS is sparse if (1) the output D of Encode_H can be structured as $D = D_0 \| D_1$ with $|D_0| = \omega(|D_1|)$, and (2) for any k, $\mathsf{Decode}_H(D,k) := \langle l(k) \| r(k), D_0 \| D_1 \rangle$, where two mappings l, r are defined by H such that $l : \mathcal{K} \to \{0,1\}^{|D_0|}$ outputs a sparse binary vector with a constant weight α and $r : \mathcal{K} \to \{0,1\}^{|D_1|}$ outputs a dense binary vector.*

In other words, the sparsity property allows Decode to only access a constant number of elements in large D_0 and an arbitrary number of elements in small D_1. Thus, we refer D_0 and D_1 to the sparse and dense parts, respectively. Besides, the correctness and (double) obliviousness properties follow those

of OKVS in Section 2.3. For convenience in our construction, we use α mappings $\{l_i : \mathcal{K} \to [|D_0|]\}_{i\in[\alpha]}$ to equivalently represent the mapping $l : \mathcal{K} \to \{0,1\}^{|D_0|}$, namely the output of $\{l_i\}_{i\in[\alpha]}$ are α non-zero positions of the mapping l's output. We emphasize that the sparsity property latter will be importantly utilized to facilitate the efficiency of our oblivious key-value retrieval constructions in Section 4.

Compared to OKVS [23], our sparse OKVS has the following technical advantage. Specifically, sparse OKVS encodes key-value pairs into a compact representation for efficient retrieval with a constant number of accesses on the large sparse part. This is an important property for applications in the unbalanced setting. However, many OKVS [23], e.g., polynomial and random matrix-based solutions, do not have this property. Building on sparse OKVS, the unbalanced circuit-PSI in Section 5 achieves asymptotically sublinear communication with the larger server's set. In contrast, existing circuit-PSI protocols based on OKVS suffer from linear communication complexity due to using OKVS in a black-box manner.

3.2 Instantiation

Before giving instantiations that fall within our definition of sparse OKVS, it is crucial to note that many recent instances of OKVS do not meet this criterion. Counterexamples include those based on polynomials or random matrices [23,43], where Decode requires accessing all positions of the output of Encode. Besides, although RB-OKVS [6] and Garbled Bloom Filter (GBF) [19] satisfy the definition of sparse OKVS, they require accessing $O(\lambda)$ positions of the Encode's output. This is concretely inefficient in our following constructions.

In this work, we instantiate sparse OKVS using Garbled Cuckoo Table (GCT) [23,43]. In a GCT, a set of n key-value pairs is encoded into a vector represented as $D_0\|D_1$, where the sparse part D_0 is of size $s = O(n)$ and the dense part D_1 contains very few $d = \lambda + O(\log n)$ items. Generally speaking, for a set of key-value pairs $L = \{(k_1,v_1),\ldots,(k_n,v_n)\}$, the encoding algorithm constructs a matrix A based on the keys $k_1,\ldots,k_n$, where the i-th row of A equals $l(k_i)\|r(k_i)$ for two mappings $l : \{0,1\}^* \to \{0,1\}^s$ with constant weight-α output and $r : \{0,1\}^* \to \{0,1\}^d$. Here, l can be represented by $\{l_i : \{0,1\}^* \to [s]\}_{i\in[\alpha]}$, where α is a small constant (e.g., 2 or 3). Namely, $l(k)$ is 1 only in α positions, i.e., $l_1(k)$, ..., $l_\alpha(k)$. Thus, it holds the sparsity property as defined in the above. The output $D_0\|D_1$ satisfies that $A \cdot (D_0\|D_1)^T = (v_1,\ldots,v_n)$. To solve this equation, there are several novel methods such as Cuckoo graph strategies [23,43] and triangulation-based techniques [48]. We refer the interested readers to their works [23,43,48].

Functionality $\mathcal{F}_{\mathsf{OKVR}}$

Parameters: Client $\mathcal{C}$ and server $\mathcal{S}$. The input sizes of $\mathcal{C}$ and $\mathcal{S}$ are t and n, respectively, where $n \gg t$. The output size of $\mathcal{C}$ is t. The key space $\mathcal{K}$ and the value space $\mathcal{V}$.

Functionality:

1. Wait for input a set of keys $Q = \{q_1,\ldots,q_t\} \in \mathcal{K}^t$ from $\mathcal{C}$.
2. Wait for input a set of key-value pairs $L = \{(k_1,v_1),\ldots,(k_n,v_n)\} \in (\mathcal{K}\times\mathcal{V})^n$ from $\mathcal{S}$.
3. Output $Z := \{z_1,\ldots,z_t\} \in \mathcal{V}^t$ to $\mathcal{C}$, where $z_i = v_j$ if $q_i = k_j$ and $(k_j,v_j) \in L$, otherwise z_i is uniformly sampled from $\mathcal{V}$.

Figure 4: Ideal functionality for oblivious key-value retrieval

4 Oblivious Key-Value Retrieval

4.1 Definition

We propose a new functionality called Oblivious Key-Value Retrieval (OKVR). The formal definition of OKVR is given in Figure 4. Generally speaking, the server has a large set of key-value pairs $L = \{(k_1,v_1),\ldots,(k_n,v_n)\}$ and the client holds a small set of keys $Q = \{q_1,\ldots,q_t\}$, where $n \gg t$. For each $q_i \in Q$, the client wants to obtain the corresponding value v_j if $q_i = k_j$ and $(k_j,v_j) \in L$, and a uniformly random value otherwise. After the protocol execution, neither party should gain any additional information. In particular, the server should not learn which value was retrieved, while the client should not learn the other key-value pairs in the server's set. Moreover, the client even does not know whether the query is in the server's key-value pairs, when the server's values are uniformly random.

A similar functionality is Batch Oblivious Programmable Pseudorandom Function (B-OPPRF) [45]. We explain the differences between our OKVR and B-OPPRF as follows. (1) Unlike B-OPPRF, we particularly focus on the unbalanced setting and aim to achieve sub-linear communication on the larger set. (2) While B-OPPRF requires a specific distribution (e.g., related but uniform distribution) of values, our OKVR functionality supports arbitrary values. Given these features, OKVR itself may be of independent interest and can be employed for key-value retrieval scenarios to ensure privacy for both parties in the client-server setting. We also note that our OKVR can be viewed as a batched variant of symmetric keyword PIR [14] with the following exception: our OKVR requires responding to a random value when the query is not in the key-value pairs, but symmetric keyword PIR returns a special symbol for this situation. Below, we give an efficient construction of OKVR, which is built on sparse OKVS in Section 3 and crucially exploits its sparsity to facilitate

efficiency.

4.2 Construction

We introduce the construction of OKVR in Figure 5 based on sparse OKVS, which achieves *sublinear* communication cost in the size of the server's large set. The core idea of our OKVR protocol is that the server first exploits a sparse OKVS to encode the key-value pairs $L = \{(k_1, v_1), \ldots, (k_n, v_n)\}$ into a compact vector $D_0 \| D_1$. Then, the client employs a Batch Private Information Retrieval[3] (BatchPIR) protocol [5, 40] to secretly retrieve the desirable items from $D_0 \| D_1$ that are used to compute the corresponding values of the query $Q = \{q_1, \ldots, q_t\}$. Note that this requires $t \cdot (\alpha + |D_1|)$ PIR queries, where α is the access number on the sparse part D_0 required for decoding. Such a large number of PIR queries on the dense part D_1, e.g., $|D_1| = \lambda + O(\log n)$ for GCT [23], will dominate the overhead of this solution.

To further improve performance, we present a hybrid PIR strategy exploiting the sparsity property of sparse OKVS. That is the decoding process requires only accessing a small constant number α of positions from the sparse part D_0, while accessing a large number of positions from the dense part D_1 of small size. In our hybrid PIR strategy, the two parties invoke PIR only on D_0, while D_1 is directly sent to the client by the server. As a result, this strategy takes $\alpha \cdot t$ PIR queries in total, significantly saving $t \cdot |D_1|$ PIR invocations.

Besides, to hide information of the server's key-value pairs L, we additionally invoke a multi-point Oblivious Pseudorandom Function (mpOPRF) protocol [31]. It takes the query $Q = \{q_1, \ldots, q_t\}$ from the client and the PRF key k from the server, and returns $F(\mathsf{k}, q_i)$ to the client for $q_i \in Q$. We let the server compute $D_0 \| D_1$ on PRF-masked key-value pairs, denoted as $L' = \{(k_i, v_i + F(\mathsf{k}, k_i))\}_{i \in [n]}$. After PIR, the client can de-mask retrieved items using $\{F(\mathsf{k}, q_i)\}_{i \in [t]}$ to obtain the desired values.

We analyze the asymptotic communication complexity, which consists of three parts. (1) The mpOPRF protocol requires $O(t)$ communication cost. (2) $\alpha \cdot t$ PIR queries on D_0 consume $O(t \cdot \sqrt{n})$ or $O(t \cdot \log n)$ depending on PIR schemes [5,38,40]. (3) Taking GCT as an example, sending D_1 requires $\lambda + O(\log n)$ communication cost. Therefore, the asymptotic communication cost of OKVR scales sublinearly with the server's set size n.

Theorem 1. *Given a BatchPIR scheme with client query privacy and a sparse OKVS algorithm, the protocol in Figure 5 securely computes $\mathcal{F}_{\text{OKVR}}$ in Figure 4 against semi-honest adversaries in the $\mathcal{F}_{\text{mpOPRF}}$-hybrid model.*

Proof. We prove the following two properties.

Correctness. There are two cases for the correctness analysis. (1) In the case $q_i \in \{k_1, \ldots, k_n\}$ and $q_i = k_j$, according to the correctness of mpOPRF, sparse OKVS, and BatchPIR, $z_i = \mathsf{Decode}_H(D_0 \| D_1, q_i) - F(\mathsf{k}, q_i) = \mathsf{Decode}_H(D_0 \| D_1, k_j) - F(\mathsf{k}, k_j) = v_j$ with overwhelming probability. (2) In the case $q_i \notin \{k_1, \ldots, k_n\}$, due to the pseudorandomness of the underlying PRF, $z_i = \mathsf{Decode}_H(D_0 \| D_1, q_i) - F(\mathsf{k}, q_i)$ is pseudo-random.

Security. We exhibit simulators $\text{Sim}_{\mathcal{C}}$ and $\text{Sim}_{\mathcal{S}}$ for simulating the view of the corrupt client $\mathcal{C}$ and server $\mathcal{S}$, respectively, and prove that the simulated view is indistinguishable from the real one via standard hybrid arguments.

Corrupt client. $\text{Sim}_{\mathcal{C}}(Q, Z)$ simulates the view of the corrupt $\mathcal{C}$. It executes as follows:

- $\text{Sim}_{\mathcal{C}}$ samples uniform values $q'_i \leftarrow \mathbb{F}$ for $i \in [t]$. Then, it invokes the mpOPRF receiver's simulator $\text{Sim}^R_{\text{mpOPRF}}(Q, Q')$, where $Q' := \{q'_1, \ldots, q'_t\}$, and appends the output to the view.
- $\text{Sim}_{\mathcal{C}}$ uniformly samples $D_0 \| D_1 \leftarrow \mathbb{F}^s \times \mathbb{F}^d$ such that for $q_i \in Q$, $\mathsf{Decode}(D_0 \| D_1, q_i) = z_i + q'_i$, where $q'_i \in Q'$. Moreover, $\text{Sim}_{\mathcal{C}}$ follows the real protocol to generate qu and computes $\mathsf{Response}(D_0, qu) \rightarrow res$, and appends res and D_1 to the view.

We argue that the view output by $\text{Sim}_{\mathcal{C}}$ is indistinguishable from the real one. We first define three hybrid transcripts T_0, T_1, T_2, where T_0 is the real view of $\mathcal{C}$, and T_2 is the output of $\text{Sim}_{\mathcal{C}}$.

1. Hybrid_0. The first hybrid is the real interaction described in Figure 5. Here, an honest $\mathcal{S}$ uses real inputs and interacts with the corrupt $\mathcal{C}$. Let T_0 denote the real view of $\mathcal{C}$.
2. Hybrid_1. Let T_1 be the same as T_0, except that the mpOPRF execution is replaced by the mpOPRF receiver's simulator $\text{Sim}^R_{\text{mpOPRF}}(Q, Q')$, where Q' has t elements $\{q'_1, \ldots, q'_t\}$, each of which is uniformly sampled from $\mathbb{F}$. The simulator security of mpOPRF and pseudorandomness of the underlying PRF guarantee this view is indistinguishable from T_0.
3. Hybrid_2. Let T_2 be the same as T_1, except that $D_0 \| D_1$ is sampled uniformly from $\mathbb{F}^s \times \mathbb{F}^d$ such that for $q_i \in Q$, $\mathsf{Decode}(D_0 \| D_1, q_i) = z_i + q'_i$, where $q'_i \in Q'$. Moreover, $\text{Sim}_{\mathcal{C}}$ follows the real protocol to generate qu and $\mathsf{Response}(D_0, qu) \rightarrow res$ is executed locally by $\text{Sim}_{\mathcal{C}}$. By the double obliviousness property of sparse OKVS, the simulated $D_0 \| D_1$ has the same distribution as it would in the real protocol. Consequently, both distributions of $D_0 \| D_1$ are randomly uniform with the constraint $\mathsf{Decode}(D_0 \| D_1, q_i) = z_i + q'_i$. Hence, T_1 and T_2 are statistically indistinguishable. This hybrid is exactly the view output by the simulator.

Corrupt server. $\text{Sim}_{\mathcal{S}}(L, \perp)$ simulates the view of the corrupt $\mathcal{S}$. It executes as follows:

[3] Compared to PIR, BatchPIR [5,40] has concretely lower communication and computation overhead when performing batch retrievals.

Protocol Π_{OKVR}

Parameters: Client $\mathcal{C}$ and server $\mathcal{S}$. Functionality $\mathcal{F}_{\text{mpOPRF}}$ for $F : \{0,1\}^\kappa \times \{0,1\}^* \to \mathbb{F}$ in Figure 2. A sparse OKVS scheme $(\mathsf{Encode}_H, \mathsf{Decode}_H)$ with $\mathcal{K} = \{0,1\}^*$ and $\mathcal{V} = \mathbb{F}$ over a field $\mathbb{F}$, where H consists of $\alpha+1$ random mappings $\{l_i : \{0,1\}^* \to [s]\}_{i\in[\alpha]}$ and $r : \{0,1\}^* \to \{0,1\}^d$. A BatchPIR scheme $(\mathsf{Query}, \mathsf{Response}, \mathsf{Extract})$.

Inputs: $\mathcal{C}$ inputs a set of keys $Q = \{q_1, \ldots, q_t\} \in (\{0,1\}^*)^t$. $\mathcal{S}$ inputs a set of key-value pairs $L = \{(k_1, v_1), \ldots, (k_n, v_n)\} \in (\{0,1\}^* \times \mathbb{F})^n$.

Protocol execution:

1. $\mathcal{C}$ and $\mathcal{S}$ invoke $\mathcal{F}_{\text{mpOPRF}}$, in which $\mathcal{C}$ acts as the receiver with the input Q and $\mathcal{S}$ acts as the sender with the input $\mathsf{k} \leftarrow \{0,1\}^\kappa$. Then, $\mathcal{C}$ obtains $Q' := \{q'_1, \ldots, q'_t\}$, where $q'_i := F(\mathsf{k}, q_i) \in \mathbb{F}$ for $i \in [t]$.
2. $\mathcal{S}$ invokes sparse OKVS to compute $D_0 \| D_1 := \mathsf{Encode}_H(L') \in \mathbb{F}^s \times \mathbb{F}^d$, where $L' := \{(k_1, v_1 + F(\mathsf{k}, k_1)), \ldots, (k_n, v_n + F(\mathsf{k}, k_n))\}$.
3. $\mathcal{C}$ computes a set $I := \{l_j(q_i)\}_{i\in[t], j\in[\alpha]}$ of size αt. When there are collisions, I needs to be filled with distinct values to size αt. $\mathcal{C}$ executes $\mathsf{Query}(I) \to (qu, st)$ of BatchPIR and sends qu to $\mathcal{S}$.
4. $\mathcal{S}$ executes $\mathsf{Response}(D_0, qu) \to res$ on the sparse part D_0 and sends res to $\mathcal{C}$. In parallel, $\mathcal{S}$ also sends the dense part D_1 to $\mathcal{C}$.
5. $\mathcal{C}$ invokes $\mathsf{Extract}(st, res)$ to learn $\{D_0[l_j(q_i)]\}_{i\in[t], j\in[\alpha]}$. $\mathcal{C}$ computes and outputs $Z := \{z_1, \ldots, z_t\}$ with $z_i := \mathsf{Decode}_H(D_0 \| D_1, q_i) - q'_i$, where $\mathsf{Decode}_H(D_0 \| D_1, q_i) := \sum_{j\in[\alpha]} D_0[l_j(q_i)] + \langle r(q_i), D_1 \rangle$ over $\mathbb{F}$.

Figure 5: Protocol for oblivious key-value retrieval

- $\text{Sim}_{\mathcal{S}}$ generates a random key k. Then, it invokes the mpOPRF sender's simulator $\text{Sim}^{S}_{\text{mpOPRF}}(\mathsf{k}, \perp)$ and appends the output to the view.
- $\text{Sim}_{\mathcal{S}}$ samples uniformly random $I = \{i_1, \cdots, i_{\alpha t}\} \leftarrow [s]^{\alpha t}$ with distinct values and invokes $\mathsf{Query}(I) \to (qu, st)$. $\text{Sim}_{\mathcal{S}}$ appends qu to the view.

We argue that the view output by $\text{Sim}_{\mathcal{S}}$ is indistinguishable from the real one. We first define three hybrid transcripts T_0, T_1, T_2 where T_0 is the real view of $\mathcal{S}$, and T_2 is the output of $\text{Sim}_{\mathcal{S}}$.

1. Hybrid_0. The first hybrid is the real interaction described in Figure 5. Here, an honest $\mathcal{C}$ uses real inputs Q and interacts with the corrupt $\mathcal{S}$. Let T_0 denote the real view of $\mathcal{S}$.
2. Hybrid_1. Let T_1 be the same as T_0, except that the mpOPRF execution is replaced by its sender's simulator $\text{Sim}^{S}_{\text{mpOPRF}}(\mathsf{k}, \perp)$ where k is uniformly sampled by $\text{Sim}_{\mathcal{S}}$. The security of the mpOPRF functionality guarantees the view is indistinguishable from the real execution.
3. Hybrid_2. Let T_2 be the same as T_1, except that the query index set I is replaced by uniformly random $i_1, \cdots, i_{\alpha t} \in [n]^{\alpha t}$ with distinct values. This hybrid is computationally indistinguishable from T_1 by the client query privacy of the BatchPIR scheme. Specifically, if there is a distinguisher $\mathcal{D}$ that can distinguish T_1 and T_2 with non-negligible probability, then we can construct a PPT adversary $\mathcal{A}$ to break the client query privacy of the BatchPIR scheme as follows: $\mathcal{A}$ sends I_0 and I_1 as the challenge message to the challenger, where I_0 is the query index generated using $\mathcal{C}$'s real inputs and I_1 is uniformly sampled. Then, $\mathcal{A}$ receives the query ciphertext $\mathsf{Query}(I_b) \to qu$ from the challenger, where b is uniformly sampled. Then, $\mathcal{A}$ executes as $\mathcal{C}$ in Hybrid_1 with the corrupt $\mathcal{S}$ except the BatchPIR query generation step. After that, $\mathcal{A}$ invokes $\mathcal{D}$ with $\mathcal{S}$'s view in the above interaction and outputs $\mathcal{D}$'s output. Note that if $qu \leftarrow \mathsf{Query}(I_0)$, the view of the corrupt $\mathcal{S}$ is exactly T_1. If $qu \leftarrow \mathsf{Query}(I_1)$, the resulting view corresponds to T_2. Therefore, $\mathcal{A}$ can break the client query privacy of the BatchPIR scheme with the same advantage as $\mathcal{D}$.

□

5 Unbalanced Circuit-PSI

5.1 Definition

We give the formal definition of the unbalanced circuit-PSI (UCPSI) functionality in Figure 6. This functionality closely follows prior circuit-PSI works [45, 51], except with a particular focus on the unbalanced setting. Generally speaking,

Functionality $\mathcal{F}_{\mathsf{UCPSI}}$

Parameters: Client $\mathcal{C}$ and server $\mathcal{S}$. The input sizes of $\mathcal{C}$ and $\mathcal{S}$ are t and n, respectively, where $n \gg t$. The output size is $m = (1+\varepsilon)\cdot t$ with a constant $\varepsilon > 0$. A function $\mathsf{Reorder} : (\{0,1\}^*)^t \to (\pi : [t] \to [m])$, which on input a set of size t outputs an injective mapping π.

Functionality:

1. Wait for input a set $X = \{x_1, \ldots, x_t\} \in (\{0,1\}^*)^t$ from $\mathcal{C}$.
2. Wait for input a set $Y = \{y_1, \ldots, y_n\} \in (\{0,1\}^*)^n$ from $\mathcal{S}$.
3. Compute $\pi \leftarrow \mathsf{Reorder}(X)$.
4. For $i \in [m]$, sample $\langle b_i \rangle_0^B, \langle b_i \rangle_1^B \in \{0,1\}$ uniformly such that $\langle b_i \rangle_0^B \oplus \langle b_i \rangle_1^B = 1$ if $\exists x_{i'} \in X, y_j \in Y$ s.t. $x_{i'} = y_j$ where $i = \pi(i')$, and $\langle b_i \rangle_0^B \oplus \langle b_i \rangle_1^B = 0$ otherwise.
5. Output $(\{\langle b_i \rangle_0^B\}_{i\in[m]}, \pi)$ to $\mathcal{C}$ and $\{\langle b_i \rangle_1^B\}_{i\in[m]}$ to $\mathcal{S}$.

Figure 6: Ideal functionality for unbalanced circuit-PSI

it allows the client to input a small set X of size t and the server to input a large set Y of size n, where $n \gg t$. After the protocol, the two parties will learn secret shares of whether an element of X lies in the intersection. These secret-shared outputs along with X can then be used in any subsequent secure computation [36, 52].

5.2 Construction

We propose the construction of UCPSI from OKVR in Figure 7. We emphasize that the main difference from previous circuit-PSI works [10, 45, 48, 51] is that our UCPSI achieves sublinear communication complexity on the size of the larger set. Below, we explain our idea by first giving a basic construction from our OKVR functionality, followed by an optimized version employing a *padding-free* OKVR technique tailored to UCPSI.

Basic construction. Following circuit-PSI, we utilize hash-to-bin techniques [44, 45], which reduce the intersection evaluation on all items to only execute on bins with fewer items. The construction contains the following three steps.

(1) *Hash-to-bin.* The hash-to-bin technique employs Cuckoo hashing [41] and simple hashing as follows. Given the set X of size t, the client creates a Cuckoo hash table T_X of size $m = (1+\varepsilon)\cdot t$ with β hash functions $h_1, \ldots, h_\beta : \{0,1\}^* \to [m]$, where $\varepsilon > 0$ is a constant. It ensures that for each $x_i \in X$, $x_i \| j$ is stored at $T_X[h_j(x_i)]$ for some $j \in [\beta]$. Due to $m > t$, there are some empty bins and we require padding these bins with dummy items that are marked as $\perp$. On the other hand, the server constructs a simple hash table T_Y of size m using the same hash functions as the above. Specifically, given the set Y of size n, for each $y_i \in Y$, this table stores $y_i \| j$ at all locations $T_Y[h_j(y_i)]$ for $j \in [\beta]$. In T_Y, each bin may hold more than one item. Unlike other works [16, 36] that pad all bins to a pre-defined maximum size with dummy items, we do not need padding since our protocol will combine the items of all T_Y's bins into a single set for subsequent steps. Obviously, the total number of items in all T_Y's bins is fixed, i.e., βn.

(2) *OKVR.* Since both parties use the same hash functions, our scheme only requires checking whether the item placed in a bin by the client is among the items placed in this bin by the server. We employ our OKVR to accomplish this functionality. Specifically, for each i-th bin, the server samples a random value r_i and constructs a set of key-value pairs $P_i := \{(y', r_i)\}$ for all $y' \in T_Y[i]$. The client and the server invoke the OKVR protocol with input T_X and $\{P_i\}_{i\in[m]}$, respectively. After the protocol, the client obtains r_i^* for $i \in [m]$. Note that r_i^*'s are uniformly random, because in each bin of T_Y the client only queries once.

(3) *Private equality test.* In this step, the client and server check $r_i = r_i^*$, and compute boolean secret shares of b_i that indicates whether the client's i-th element is in the server's set. This operation is achieved by the private equality test (EQ) functionality $\mathcal{F}_{\mathrm{EQ}}$ in Figure 3. This operation causes a small overhead in our unbalanced case since we only require $O(t)$ invocations, where $t \ll n$.

Optimization from padding-free OKVR. The dominant cost of the basic construction stems from the OKVR step, which requires BatchPIR with $m = (1+\varepsilon)\cdot t$ queries on the server's dataset $\{P_i\}_{i\in[m]}$. To reduce this overhead, we propose padding-free OKVR that only consumes t BatchPIR queries. We emphasize this reduction is important, since as shown in Section 6.1, ε is usually chosen as 0.27.

The main insight is that OKVR outputs a random value when a query is not found in the server's key set, which is actually the case for dummy items $\perp$ in the table T_X. In detail, before BatchPIR queries, the client has known that these $\perp$ items are not in the intersection, and hence a random r_i^* will be obtained according to the functionality of OKVR. Therefore, we present an efficient padding-free strategy for invoking OKVR. In particular, let $\pi : [t] \to [m]$ be an injective mapping that maps an element index of X to the position in T_X, i.e., $\pi(i) = h_j(x_i)$ such that $T_X[h_j(x_i)] = x_i \| j$. Then, the client invokes $\mathcal{F}_{\mathrm{OKVR}}$ only with $\{T_X[\pi(i)]\}_{i\in[t]}$ and learns $\{r^*_{\pi(i)}\}_{i\in[t]}$, and for $j \in [m]\backslash\{\pi(i)\}_{i\in[t]}$, r_j^* is sampled uniformly from $\{0,1\}^\ell$ by the client. One may question whether it leaks to the server the mapping of the client's Cuckoo hashing table, which depends on the client's private input set. We note that this is not the case because the client combines all queries into a batch to perform BatchPIR on a single database from key-value pairs of all server's bins. We give the formal description of our UCPSI protocol in Figure 7, and the correctness and security are analyzed below.

Protocol Π_{UCPSI}

Parameters: Client $\mathcal{C}$ and server $\mathcal{S}$. β hash functions $\{h_i : \{0,1\}^* \to [m]\}_{i\in[\beta]}$ used in Cuckoo hashing, where $m = (1+\varepsilon)\cdot t$ with a constant $\varepsilon > 0$. Ideal functionalities $\mathcal{F}_{\mathrm{EQ}}$ in Figure 3 with input bitlength $\ell := \lambda + \log m$ and $\mathcal{F}_{\mathrm{OKVR}}$ in Figure 4.

Inputs: $\mathcal{C}$ inputs a set $X = \{x_1, \ldots, x_t\} \in (\{0,1\}^*)^t$. $\mathcal{S}$ inputs a set $Y = \{y_1, \ldots, y_n\} \in (\{0,1\}^*)^n$.

Protocol execution:

1. $\mathcal{C}$ maps X into a Cuckoo hash table T_X of m bins, such that for any $x \in X$, there exists an $j \in [\beta]$ satisfying $T_X[h_j(x)] = x\|j$. Define a function $\pi : [t] \to [m]$ that maps an element index of X to the position in T_X, i.e., $\pi(i) = h_j(x_i)$ such that $T_X[h_j(x_i)] = x_i\|j$.
2. $\mathcal{S}$ maps Y into a simple hash table T_Y of m bins, such that for any $y \in Y$ and all $j \in [\beta]$, it holds that $y\|j \in T_Y[h_j(y)]$.
3. For $i \in [m]$, $\mathcal{S}$ samples random $r_i \in \{0,1\}^\ell$, and defines $P_i := \{(y', r_i)\}$ for all $y' \in T_Y[i]$.
4. $\mathcal{C}$ and $\mathcal{S}$ invoke $\mathcal{F}_{\mathrm{OKVR}}$ with input $\{T_X[\pi(i)]\}_{i\in[t]}$ and $\{P_i\}_{i\in[m]}$, respectively. $\mathcal{C}$ initializes empty $R^* := \{r_1^*, \ldots, r_m^*\}$ and assigns the output of $\mathcal{F}_{\mathrm{OKVR}}$ to $\{r^*_{\pi(i)}\}_{i\in[t]}$. For $j \in [m]\backslash\{\pi(i)\}_{i\in[t]}$, r_j^* is sampled uniformly from $\{0,1\}^\ell$.
5. For $i \in [m]$, $\mathcal{C}$ and $\mathcal{S}$ invoke $\mathcal{F}_{\mathrm{EQ}}$ with input r_i^* and r_i, respectively. As a result, they learn boolean shares $\langle b_i\rangle_0^B$ and $\langle b_i\rangle_1^B$, respectively, where $b_i = 1$ if $r_i^* = r_i$ and $b_i = 0$ otherwise.

Figure 7: Protocol for unbalanced circuit-PSI

Theorem 2. *The protocol in Figure 7 securely computes $\mathcal{F}_{\mathrm{UCPSI}}$ in Figure 6 against semi-honest adversaries in the $(\mathcal{F}_{\mathrm{OKVR}}, \mathcal{F}_{\mathrm{EQ}})$-hybrid model.*

Proof. We prove the following two properties.

Correctness. There are three cases for the correctness analysis. (1) In the case where $x \in X \cap Y$, there exists a unique j such that $T_X[h_j(x)] = x\|j$ and $y\|j \in T_Y[h_j(y)]$ and $x = y$ with an overwhelming probability according to the statistical analysis of Cuckoo hashing. From the correctness of OKVR, when $\mathcal{S}$ samples r, $\mathcal{C}$ will obtain r^* such that $r^* = r$. From the correctness of EQ, $\mathcal{C}$ and $\mathcal{S}$ obtain secret shares of $b = 1$. (2) In the case where $x \in X \setminus Y$, there exists a unique j such that $T_X[h_j(x)] = x\|j$ but $T_X[h_j(x)] \notin T_Y[h_j(x)]$. According to the correctness of OKVR, $\mathcal{C}$ will obtain a random r^*. The collision may occur namely $r^* = r \wedge x \notin Y$, which violates the correctness. The false positive error probability in each bin equals $2^{-\ell}$. By setting $\ell = \lambda + \log m$, a union bound shows the overall probability of false positive is $2^{-\lambda}$, which is negligible. Due to $r^* \neq r$ with overwhelming probability and the correctness of EQ, $\mathcal{C}$ and $\mathcal{S}$ obtain secret shares of $b = 0$. (3) In the case of dummy points, $\mathcal{C}$ directly samples r^* uniformly at random. The correctness is the same as the second case.

Security. We exhibit simulators $\mathrm{Sim}_{\mathcal{C}}$ and $\mathrm{Sim}_{\mathcal{S}}$ for simulating corrupt $\mathcal{C}$ and $\mathcal{S}$, respectively, and argue the indistinguishability of the produced transcript from the real execution.

Corrupt client. $\mathrm{Sim}_{\mathcal{C}}(X, (\pi, \{\langle b_i\rangle_0^B\}_{i\in[m]}))$ simulates the view of the corrupt $\mathcal{C}$. It executes as follows:

- $\mathrm{Sim}_{\mathcal{C}}$ uniformly samples $R^* := \{r_1^*, \ldots, r_m^*\}$, and invokes the OKVR's client simulator $\mathrm{Sim}^{\mathcal{C}}_{\mathrm{OKVR}}(\{T_X[\pi(i)]\}_{i\in[t]}, \{r^*_{\pi(i)}\}_{i\in[t]})$. $\mathrm{Sim}_{\mathcal{C}}$ appends the output to the view.
- $\mathrm{Sim}_{\mathcal{C}}$ invokes the EQ's client simulator $\mathrm{Sim}^{\mathcal{C}}_{\mathrm{EQ}}(r_i^*, \langle b_i\rangle_0^B)$ for $i \in [m]$, where $r_i^* \in R^*$, and appends the output to the view.

The view simulated by $\mathrm{Sim}_{\mathcal{C}}$ is computationally indistinguishable from the real one by the underlying simulators' indistinguishability. It is worth noting that although for all keys in each set P_i of key-value pairs, the corresponding value is always a uniformly random r_i, the client's output $\{r_i^*\}_{i\in[m]}$ of OKVR is still uniformly random. The reason is that for each P_i, at most one value is retrieved by the client according to the property of Cuckoo hashing.

Corrupt server. $\mathrm{Sim}_{\mathcal{S}}(Y, \{\langle b_i\rangle_1^B\}_{i\in[m]})$ simulates the view of the corrupt $\mathcal{S}$. It executes as follows:

- $\mathrm{Sim}_{\mathcal{S}}$ samples uniformly random $\{r_1, \ldots, r_m\}$ and generates $\{P_i\}_{i\in[m]}$ like Figure 7, and invokes the OKVR's server simulator $\mathrm{Sim}^{\mathcal{S}}_{\mathrm{OKVR}}(\{P_i\}_{i\in[m]}, \perp)$. $\mathrm{Sim}_{\mathcal{S}}$ appends the output to the view.
- For $i \in [m]$, $\mathrm{Sim}_{\mathcal{S}}$ invokes the EQ's server simulator $\mathrm{Sim}^{\mathcal{S}}_{\mathrm{EQ}}(r_i, \langle b_i\rangle_1^B)$ where r_i is sampled as above, and appends the output to the view.

It is straightforward to see that the view simulated by $\mathrm{Sim}_{\mathcal{S}}$ is computationally indistinguishable from the real one by the OKVR and EQ simulators' indistinguishability. □

6 Implementation and Evaluation

We implement our protocols in Java, and run the experiments on a single Intel Core i9-9900K with 3.6GHz and 128GB RAM. All evaluations are performed using 8 threads. We simulate the network connection using the Linux tc command. The simulated network settings include LAN (10Gbps bandwidth and 0.05ms RTT latency) and WAN (50Mbps bandwidth with 80ms RTT latency). Given that we focus on the unbalanced setting, where the client may only have constrained resources (e.g., very low bandwidth), we also test our protocols on a simulated mobile network setting (1Mbps bandwidth and 80ms RTT latency). Our source code is available at https://github.com/alibaba-edu/mpc4j.

6.1 Implementation Details

A unified circuit-PSI framework. We provide a comprehensive circuit-PSI framework that serves as a unified platform for implementing both our proposed protocols and state-of-the-art circuit-PSI schemes. This framework involves a full re-implementation of existing circuit-PSI schemes, such as the general circuit-PSI protocols[4] (PSTY19 [45], CGS22 [10] and RR22 [48]) and the unbalanced circuit-PSI protocol SJ23 [54]. The necessity for a large-scale re-implementation arises from the original implementations being conducted under different underlying protocols and experimental settings. This diversity poses challenges for fair comparisons. Specifically, some prior implementations, like CGS22, focus solely on balanced circuit-PSI, lacking support for unbalanced cases[5]. (2) There are variations in performance evaluations due to different thread settings: PSTY19, CGS22, and SJ23 evaluate their protocols in the single-thread setting, while RR22 employs multi-thread execution. (3) Different protocols instantiate underlying cryptographic primitives. For instance, PSTY19 and CGS22 utilize IKNP OT for the equality test, while RR22 and SJ23 use different silent OT variants, namely Silver OT [18] and Ferret OT [56], respectively. To address these challenges, we provide unified implementations and conduct fair comparisons within our framework. The details are elaborated in the subsequent sections.

Implementation details of our protocols. We set the computational security parameter $\kappa = 128$ and the statistical security parameter $\lambda = 40$. The used dataset is 128-bit random strings. We note that our implementation is generic and the dataset can be set as arbitrary values of any length. Following existing circuit-PSI protocols [10, 45, 48], we set the size of the server's set as $2^{20} \sim 2^{22}$. We choose the smaller size of the client's set as $2^4 \sim 2^{12}$, since the client is defined to use a smaller set in our focused unbalanced setting. To complete our constructions, we implement the following components.

Stash-less Cuckoo hashing. We use stash-less Cuckoo hashing with 3 hash functions that store n elements into $\lceil (1+\varepsilon) \cdot n \rceil$ bins, where $\varepsilon > 0$. Based on the analysis of PSZ18 [47], ε is usually chosen as 0.27, which has been widely used in prior works [10, 45, 51].

Blazing-fast OKVS. We implement the blazing-fast OKVS with clustering as our sparse OKVS, as proposed by RR22 [48], following their open-source code [2] as a reference. The underlying field $\mathbb{F}$ is instantiated as $GF(2^\ell)$. Specifically, the elements are distributed into several buckets through a hash function. Each bucket independently generates an OKVS, and these individual OKVS are subsequently merged. Notably, the OKVS encoding for each bucket operates independently and is amenable to parallel processing, leading to a substantial enhancement in efficiency. The blazing-fast OKVS offers two variants employing 2 or 3 hashing functions, both of which are included in our evaluation for a comprehensive assessment.

BatchPIR. We implement the state-of-the-art vectorized BatchPIR [40], utilizing their open-source code [4] as a reference. We specifically opt for the BatchPIR variant due to its support for batched PIR queries with very low communication costs. We adopt the JNI technique to invoke the BFV homomorphic encryption [8, 21] provided by Microsoft SEAL library v4.1 [3]. Our implementation aligns with the chosen parameter settings and also leverages the modulus switching technique to effectively reduce the size of response ciphertexts.

mpOPRF. We implement OMG-DH-based OPRF [31, 50], enabling the server to encode inputs and initialize PIR protocols in the setup phase (specific details of the setup setting will be elaborated later). For better efficiency, we use Four$\mathbb{Q}$ elliptic curve [17], renowned for its rapid scalar multiplication of random points and an efficient implementation of hash-to-curve operations. We note that existing unbalanced PSI protocols integrate Four$\mathbb{Q}$ and similar techniques to expedite the setup phase [11, 12, 16].

Equality test. We implement the private equality test (EQ) protocol in CGS22 [10]. This protocol has low communication costs and is rooted in the solution to the Millionaires' problem within the CrypTFlow2 framework [49]. It recursively performs equality tests on substrings organized in a tree structure. To conduct tests on leaf substrings, a 1-out-of-2^s OT scheme is employed, where s is a constant and we set $s = 4$, aligning with the choice made in [10]. Our OT implementation utilizes a silent OT variant, namely, Ferret OT [56].

Pre-processing setting. Similar to unbalanced PSI protocols [11, 12, 16], we establish our framework within the pre-processing setting. This configuration allows the server to pre-process its input set during the setup phase, enhancing online performance. Specifically, the pre-processing in our

[4] Bienstock et al. [6] recently propose nearly-optimal OKVS and also apply it in circuit-PSI (called BPSY23). Currently, we do not include this baseline because (to the best of our knowledge) we cannot find a way of supporting multi-thread encoding for their OKVS construction without increasing the encoding rate. Note that BPSY23 has a similar performance as RR22 (Refer to Figure 7 of BPSY23).

[5] See Issue #4 of the CGS22 open-source implementation for details.

protocol encompasses tasks such as hashing the input set into bins, encoding elements within these bins using sparse OKVS, and initializing BatchPIR. Notably, these pre-processing tasks are independent of the client's inputs and can be efficiently completed during the setup phase [12].

Implementation details of baselines. We re-implement state-of-the-art circuit-PSI schemes including PSTY19 [45], CGS22 [10], RR22 [48], and SJ23 [54]. Our implementations and comparisons are fair for the following reasons. (1) All their implementations support multi-thread execution and are compatible with both balanced and unbalanced settings. We test both our protocols and prior works under the same and commonly used experimental setting (e.g., thread numbers and security parameters) and the same 128-bit dataset. (2) We instantiate the underlying building blocks using the same state-of-the-art techniques. For example, all protocols invoke Ferret OT [56] as the OT extension. We also introduce the advanced optimizations in prior works. Below, we give more detailed descriptions.

SJ23. We re-implement the two constructions of SJ23 [54] due to the absence of an available open-source implementation. We set the polynomial degree and modulus coefficient based on the analysis provided by SJ23, while also determining the query power according to APSI parameters [1]. In the case of their first construction, we integrate the noise flooding technique [24], introducing an encryption of zero with 40-bit noise during the response generation phase. For the second construction, we adopt SEAL's default configurations for the ciphertext modulus to ensure a sufficient noise budget for the multiplication of a multiplicative mask. Notably, partition numbers per bin in SJ23 are fixed for specific set sizes. To accommodate arbitrary set sizes, we employ the lookup table method, as identified in the RR22 implementation [2], to estimate partition numbers per bin. This approach allows us to support a broader range of set sizes in our re-implementation.

PSTY19. We re-implement PSTY19 while introducing two crucial optimizations to enhance performance. Firstly, we address the computational bottleneck identified in PSTY19 [10, 45], specifically associated with polynomial interpolation (MegaBin). To mitigate this, we substitute the MegaBin operation with the 3-Hash Garbled Cuckoo Table (3H-GCT) [23]. Secondly, to further optimize communication costs, we incorporate the state-of-the-art equality test protocol from CGS22 into PSTY19 and instantiate it with Ferret OT.

CGS22 and RR22. We re-implement CGS22 and RR22 and adhere to their original experimental settings. A notable adjustment is made by employing the equality test protocol of CGS22, integrated with Ferret OT, to decrease communication costs in our implementations.

6.2 Experimental Results

We compare our protocols with the state-of-the-art balanced circuit-PSI, i.e., PSTY19 [45], CGS22 [10], and RR22 [48], and unbalanced circuit-PSI SJ23 [54], which consists of two constructions, called SJ23-C1 and SJ23-C2. The runtime and communication costs of our constructions and previous works are shown in Tables 1 and 2. Note that in the setup phase, the communication is dominated by sending Galois and relinearization keys of the underlying homomorphic encryption in BatchPIR to the server. As these keys remain independent of the server's set, they can be sent only once and cached for repeated protocol executions [12, 16]. Consequently, this communication cost can be amortized over multiple client requests.

Performance of OKVR. We first test the performance of our main building block, i.e., OKVR, in Table 1. We report the communication and computation costs to show the scalability of OKVR. For example, for the server's set size 2^{22} and the client's set size 2^{12}, it only requires 13.041 MB and 9.313 seconds in the WAN setting. Moreover, we also test the length of the encoded vector and observe that the length of the dense part is much smaller than that of the sparse part. This is consistent with our construction in Section 4. We note that the size of the dense part can be further reduced when utilizing sparse OKVS without clustering. For instance, with

Table 2: Communication and runtime comparison of our protocols with previous works. The best result is marked in green, and the second best result is marked in blue.

the server's set size 2^{20}, the sizes of the dense part are 72 and 56 in our 2-Hash and 3-Hash OKVR protocols, respectively.

Communication comparison. The comparison between our protocols and recent balanced circuit-PSI techniques, i.e., PSTY19, CGS22, and RR22, is reported in Table 2. We can observe that our protocols achieve the lowest online communication cost, outperforming them by $1.84 \sim 48.86\times$. Moreover, our protocols exhibit greater advantages when the difference between the set sizes of the client and server is significant. In addition, when comparing with SJ23, the communication of our constructions is $1.18 \sim 15.99\times$ better than their protocols in the extremely unbalanced setting, e.g., the client set of size 2^4 and 2^8. For the client's set size 2^{12}, our protocols still outperform the second construction of SJ23.

Runtime comparison. As evidenced by Table 2, our protocols consistently outperform balanced circuit-PSI works PSTY19, CGS22, and RR22 across all set sizes and network setups. Specifically, the runtime efficiency of our constructions surpasses these works by $1.50 \sim 39.81\times$. On the other hand, when compared with SJ23, the runtime of our constructions is $1.22 \sim 10.44\times$ better in the extremely unbalanced setting, e.g., the client set of size 2^4 and 2^8. Moreover, we observe that SJ23 works well for relatively large client's set sizes, e.g., 2^{12}, and has a similar high overhead even when the set size decreases. The reason is that SJ23 requires packing a large number of the client's elements into a ciphertext and

amortizing the overhead of expensive FHE operations. Besides, the two SJ23 protocols have varying runtime results between LAN and Mobile settings due to large communication differences, which will affect the performance in bandwidth-limited settings. Rather, our two UCPSI constructions with 2-Hash and 3-Hash have a similar communication cost and particularly perform better in these constraint network settings.

7 Conclusion

In this work, we introduce unbalanced circuit-PSI constructions that achieve sublinear communication complexity in the size of the larger set. The core idea is the functionality and construction of Oblivious Key-Value Retrieval (OKVR), which may be of independent interest. We fully implement our constructions and state-of-the-art circuit-PSI protocols in a unified framework for fair comparisons. We evaluate the efficiency of our constructions and the results show that our scheme achieves up to 48.86× communication improvement and 39.81× runtime reduction over previous works.

Acknowledgments

We would like to express our deepest gratitude for the invaluable help provided by our shepherd as well as all the reviewers for their constructive comments. A Unbalanced Circuit-PSI with Payloads

In some scenarios, each input item of the parties has an associated payload. The task is to compute a function of the payloads of the items in the intersection. In this section, we extend our unbalanced circuit-PSI protocol to support computing functions on the intersection of input sets along with associated payloads.

Formally, the client inputs a small set X of size t along with an associated value set $\tilde{X}$, and the server inputs a large key set Y of size n along with an associated value set $\tilde{Y}$. After the protocol, the two parties will compute a function on the intersection and the corresponding payloads. This construction is significantly built on our unbalanced circuit-PSI protocols in Figures 7 except for the following parts. (1) In step 3 of the unbalanced circuit-PSI protocol, the client samples random r_i, w_i, and defines $P_i := \{(y', r_i \| (\tilde{y} - w_i))\}$, where $y' = y \| j \in T_Y[i]$ for some $j \in [\beta]$ and $\tilde{y}$ is the payload of y. (2) In step 4, the two parties invoke $\mathcal{F}_{\text{OKVR}}$ on this new key-value pairs P_i, and the client obtains $r_i^* \| w_i^*$. After $\mathcal{F}_{\text{OKVR}}$, the generic 2PC functionality will then take as input $(r_i^*, w_i^*, x_i, \tilde{x}_i)$ from the client and (r_i, w_i) from the server.

PEPSI: Practically Efficient Private Set Intersection in the Unbalanced Setting

Abstract

Two parties with private data sets can find shared elements using a Private Set Intersection (PSI) protocol without revealing any information beyond the intersection. Circuit PSI protocols privately compute an arbitrary function of the intersection - such as its cardinality, and are often employed in an *unbalanced* setting where one party has more data than the other. Existing protocols are either computationally inefficient or require extensive server-client communication on the order of the larger set. We introduce Practically Efficient PSI or PEPSI, a non-interactive solution where only the client sends its encrypted data. PEPSI can process an intersection of 1024 client items with a million server items in under a second, using less than 5 MB of communication. Our work is over 4 orders of magnitude faster than an existing non-interactive circuit PSI protocol and requires only 10% of the communication. It is also up to 20 times faster than the work of Ion et al., which computes a limited set of functions and has communication costs proportional to the larger set. Our work is the first to demonstrate that non-interactive circuit PSI can be practically applied in an unbalanced setting.

1 Introduction

Privacy-preserving data analytics operates on the principles that (i) data is accessible and can be analyzed while (ii) ensuring that the user's privacy remains uncompromised. For instance, consider the application of secure contact discovery used in private messengers such as Signal [16, 24]. Users want to connect with their friends without sharing their entire contact list with the server, and the server does not want to disclose the list of all contacts to each user. The revelation of this information by the client (or server) would defeat the very essence of these services.

Private Set Intersection (PSI) protocols offer a solution to this problem. PSI is designed to compute the intersection of two sets while ensuring that nothing beyond the intersection is revealed. A specific form of PSI is *unbalanced* PSI, in which one party, typically the client, has a substantially smaller set than the second party, the server. Moreover, the client is often a resource-constrained device like a mobile phone or an IoT device with limited network connectivity. Consequently, it benefits the client by minimizing network communication, reducing the number of network round trips, and offloading computational tasks to the server.

In some cases, the goal of the client and server is to compute functions of the intersection, rather than to learn the intersection itself. For instance, in the case of COVID-19 exposure applications, a user simply wants to know if they share any randomly generated codes with those stored on the server, indicating potential exposure [17, 36, 37, 39]; who those matches are is irrelevant. Similarly, when gauging the effectiveness of ad campaigns by cross-referencing online advertisements with offline credit card transactions [22], the advertiser is interested in knowing the total sales corresponding to a specific set of credit cards used at certain vendors. Only the total sales amount is of interest, not the individual transactions. *Circuit PSI* is the term used when a function of the intersection is calculated rather than the intersection itself.

In the circuit PSI setting, the work of Kacsmar et al. [23] (referred to as DiPSI) is best suited for the unbalanced non-interactive setting. However, DiPSI still suffers from inefficiency issues. In contrast to DiPSI, the numerous fast state-of-the-art solutions for PSI [7, 14, 34] are limited in terms of being extendable to the circuit PSI setting. Specifically, each state-of-the-art solution is limited in one of the following ways. The first limitation is for solutions that are restricted as to the functions they can compute [22, 28]. They are unable to execute functions beyond a specific predefined set. Despite the fact that protocols designed for specific functions allow targeted optimizations, our evaluation shows that we outperform the state-of-the-art for many specific functions, particularly for large server set sizes. Furthermore, targeted optimizations become obsolete when the function needs to be changed. Second, adapting some solutions to circuit PSI levies a computational and communication burden on the client to compute arbitrary functions, usually in the form of

Table 1: Comparing the properties of different PSI protocols. m and n are the client and server set sizes, respectively. We assume $m \ll n$ in the analysis of works which support the unbalanced setting. DH: Diffie-Hellman. 2PC: two-party computation. PDTE: private decision tree evaluation. *PSI using [22, 30, 42] is done in one round and an extra round is required to compute the sum. Moreover, it can only perform a limited set of functions in only one extra round. **PSI is realized by extending private set membership.

Work	Tools	Unbalanced	Rounds	Comm.	Comp.	PSI	Labelled PSI	Circuit PSI

two-party computation [7, 33]. This communication burden is usually proportional to the larger set [7, 22, 33] or depends on the complexity of the task. Such a burden is not acceptable when designing a non-interactive protocol.

Summary of Contributions. In this work, we propose PEPSI, an efficient, non-interactive circuit PSI protocol using homomorphic encryption. Homomorphic Encryption (HE) is a form of encryption that permits computation on the data while in encrypted form. In PEPSI, the client encrypts its elements using an HE scheme and sends them to the server, which compares the elements homomorphically. The output of each comparison is binary and is used to compute functions. Our approach removes the limitations that are present in existing work. PEPSI does not restrict the function that can be evaluated, there is no communication or computation burden on the client to compute the function, and it only has communication complexity proportional to the smaller client set size.

Our approach also overcomes the impractical runtimes associated with the DiPSI protocol from the literature [23]. We address the slow comparisons by comparing items using the efficient constant-weight equality operator [19], permutation-based hashing, and cuckoo hashing. Altogether this reduces the size of the elements that need to be compared such that PEPSI is over four orders of magnitude faster than DiPSI and requires 90% less communication. For example, PEPSI can compute the intersection of 1024 and one million 32-bit elements in under one second with less than 5 MB of communication.

PEPSI has a runtime and communication cost comparable to other PSI protocols based on HE [10, 14], which cannot extend to circuit PSI. Moreover, the client is required to do much less computational work in PEPSI, making it compatible with use cases where the client does not have much computational power, i.e., the unbalanced setting. We empirically compare PEPSI with state-of-the-art protocols in our experiments, showing that PEPSI is even competitive with PSI protocols which cannot extend to circuit PSI. Our work is the first to show that non-interactive circuit PSI can be efficient up to the point it is practical for use in applications.

2 Related Work

The term *private set intersection* (PSI) was coined by Freedman et al. [21]. In a PSI protocol, two parties compute the intersection of their respective private sets such that no information is revealed except the intersection itself. If the intersection is only revealed to one of the parties, this is known as one-sided PSI. However, one-sided PSI can be extended to two-sided PSI by running the protocol a second time and switching the roles of the client and server.

2.1 PSI with Leakage

In some applications and real-world use cases, such as checking for compromised credentials, the overhead of PSI is high if the client element is compared to all elements. For example, comparing the client credentials to billions of leaked credentials is expensive. To alleviate the overhead, some works propose to only compare the client elements to a subset of the server elements [29, 38]. For example, elements are distributed into buckets by their prefix. To query for a specific element, the client only queries the bucket corresponding to that element instead of the entire set. The server will know that the client's query falls into that specific bucket so such an approach partially leaks information about the client at the cost of better performance. This leakage degrades the security guarantees but may be acceptable in some applications. Thomas et al. [38] predict that the prefix of a user's creden-

tials is common with about 350k-470k other users, assuming each client has one credential in the database.

Our work does not follow this approach and instead offers PSI without leakage. While such an approach requires more computational effort, it offers better security. We note that our protocol could also be combined with bucketization, offering a tunable trade-off between security and performance from the leakage of current protocols [29, 38] to no leakage.

2.2 Unbalanced PSI

Unbalanced PSI is a special case of PSI where one party, which we call the client, has a much smaller set compared to the other party, i.e., the server [1, 2, 10, 11, 14, 17, 24, 29]. This is a common assumption in many applications of PSI. For example, in compromised credentials checking (C3) [24, 29], the client wishes to access a large database containing credentials that are leaked on the web. While the set of client credentials is small, e.g., a few hundred credentials, the database of leaked credentials is in the billions and growing [24, 29]. Moreover, the client is usually bandwidth-constrained and has limited computational power. Hence, protocols with limited network round trips and little client-side computation are preferred. A narrower variant of unbalanced PSI exists, dubbed laconic PSI, with the additional constraint that only the server learns the output of the protocol [1, 2].

While there are many efficient state-of-the-art PSI protocols [7, 30, 32, 34, 35], the communication complexity of these solutions scales with the larger set, making them unsuitable for unbalanced PSI. For example, Pinkas et al. and Chandran et al. propose PSI protocols that compute an oblivious PRF for each element of the server set [7, 35]. Ma and Chow propose to construct a private decision tree from the server set, which is encrypted and sent to the client. The client then obliviously traverses this decision tree using OT [30]. Such solutions are useful in high-bandwidth, low-latency networks but fall short over high-latency networks.

Amongst solutions that have no leakage, the current most efficient non-interactive PSI protocols in the unbalanced case are based on homomorphic encryption [10, 11, 14]. Homomorphic encryption (HE) is a type of encryption that allows computations on data in its encrypted form. Chen et al. [11] were among the first to propose a PSI protocol specifically designed for the unbalanced setting using homomorphic encryption. If $\mathbb{Y}$ represents the server set, the key idea is to construct the polynomial $P(x) = r\prod_{y_i \in \mathbb{Y}}(x - y_i)$, for some random value r. The client sends an encryption of its elements to the server, which then homomorphically evaluates $P(x)$ on the client input. For a certain client element x_0, if $x_0 \in \mathbb{Y}$, then $P(x_0) = 0$, otherwise $P(x_0)$ is a random number. The idea of representing the set as a polynomial had been proposed before [26] and Chen et al. included optimizations to reduce the multiplicative depth of the function that is homomorphically evaluated, thereby enhancing efficiency [11]. Chen et al. [10] and Cong et al. [14] built upon [11], employing a combination of Oblivious Pseudorandom Functions (OPRF) and homomorphic encryption. This improved performance extended the security to the malicious model and also allowed the protocol to extend to elements of arbitrary bitlength.

2.3 Labelled PSI

A specific variant of PSI is *labelled PSI*, where the server has a private label associated with each element in its private set. The server stores pairs in the form of (y_i, ℓ_i) where y_i is the identifier of the element and ℓ_i is the label associated with that element. The two parties compute the intersection of their sets and output all the pairs (y_i, ℓ_i) where y_i is in the intersection of the two sets. Nothing beyond the elements in the intersection and their corresponding labels are revealed to either one of the parties. When the client has only one element, this problem is equivalent to private information retrieval by keywords, first proposed by Chor et al. [12]. In the context of private contact discovery, the client may wish to retrieve the public keys of users in their contact list [16, 24].

Many PSI protocols can be extended to labelled PSI with additional computation and communication costs. For example, Chen et al. [10] and Cong et al. [14] extend their protocol to labelled PSI by evaluating another polynomial which evaluates to the ℓ_i when $x = y_i$. For the protocols of Pinkas et al. [33] and Chandran et al. [7] the extension to labelled PSI can be done without changing the asymptotic complexity, but it does result in doubling the concrete communication and computation cost.

2.4 Circuit PSI

Another variant of PSI is *circuit PSI*, where the objective is to compute a function of the intersection, rather than the intersection itself. One example is PSI-Cardinality, where the parties compute the size of the intersection [23]. Another example is PSI-Sum [22], where the sum of values associated with elements in the intersection is revealed.

One application for PSI-Sum, known as ad-conversion, is assessing the effectiveness of ad campaigns [22]. A company purchasing an ad through an ad service company, such as Google, would like to know the total purchases made by users who have seen their particular ad. If Google can show a client who paid to have an ad displayed through their system that the ad leads to sales, then it is easier to convince the client to purchase more ads in the future. Such ad-conversion computations can be done by linking those who have seen an ad with their credit card transactions. However, credit card vendors are unwilling to disclose their clients' transactions. PSI-Sum is a solution in this scenario.

In the existing approaches [10, 11, 14], every comparison between a client and server element results in an arithmetic

output. An arithmetic output means that if the elements are equal, the output is zero, and the output is a random non-zero number in $\mathbb{Z}_p$, for some p. While using this approach results in fast PSI protocols, computing a function of the intersection is not feasible. To compute a function, the result of each comparison must be converted to a binary output, i.e., one for a match and zero otherwise.

One approach to computing such functions is to use secure two-party computation (2PC) to convert the arithmetic output into a secret-shared binary output. 2PC can then be used to compute any arbitrary function over the binary output. While there is flexibility regarding the functions that can be computed in this approach, the communication complexity of MPC protocols is high. More specifically, the communication complexity depends on the size of both sets and the complexity of the desired function [7, 33].

Another approach is to compare elements from the client and server homomorphically via a homomorphic equality circuit. The output of the comparisons is binary in this case. This is the only non-interactive approach in the literature and is more suitable for the unbalanced setting since it does not require any client interaction. The work of Kacsmar et al. [23], which they call DiPSI, uses this approach. DiPSI achieves asymptotically optimal communication, given that only the client dataset is communicated over the network. The authors use this protocol to compute a differentially private PSI-Sum and other functions. The main problem with DiPSI is the extremely high runtime. PSI-Sum between 1024 client elements and 1 million server elements can take over 600 minutes. This can mainly be attributed to the homomorphic comparison function that they employ. We propose a solution that compares elements homomorphically, similar to DiPSI but is over four orders of magnitude faster.

Some works take a different approach to circuit PSI by designing a protocol that can compute a very specific function very efficiently [22, 28]. This is in contrast to the other approaches where an arbitrary function can be derived. A specialized protocol outperforms generalized protocols in terms of performance but restricts the functions that can be derived and may leak additional information in the process [22].

Ion et al. [22] propose a protocol for PSI-Sum-with-Cardinality. This protocol outputs, to the server, the sum of values associated with elements in the intersection, whilst also revealing the intersection cardinality to the client. Lepoint et al. [28] proposed Private Join and Compute (PJC) which provides PSI-sum, which is the sum of values associated with elements in the intersection, without leakage of the intersection cardinality. However, their protocol cannot compute any function other than the sum and has an expensive offline phase. PSI-Stats follows a similar approach and supports more functions including arithmetic and geometric mean, standard deviation, and approximate composition [42]. However, this protocol is still limited to the functionalities proposed by the authors. A common feature of these works is they require three rounds of interaction and the final results are revealed to the server.

3 Background

3.1 The FV Cryptosystem

The FV cryptosystem [18] permits computation over vectors of numbers using Single Instruction, Multiple Data (SIMD) operators. Plaintexts are vectors of length N where each element is in $\mathbb{Z}_t$. N and t are called the *polynomial modulus degree* and the *plaintext modulus*, respectively. Ciphertexts are vectors of polynomials with coefficients in $\mathbb{Z}_q$, where q is called the *ciphertext modulus* and $\mathcal{C}$ is the ciphertext space. The following operations are permitted in FV:

- Addition: Given $c_X, c_Y \in \mathcal{C}$ which encrypts $X, Y \in \mathbb{Z}_t^N$, respectively, output c_A which encrypts $X+Y$.
- Plain Multiplication: Given $X \in \mathbb{Z}_t^N$ and $c_Y \in \mathcal{C}$ which encrypts $Y \in \mathbb{Z}_t^N$, output c_{PM} which encrypts $X \odot Y$.
- Multiplication: Given $c_X, c_Y \in \mathcal{C}$ which encrypt $X, Y \in \mathbb{Z}_t^N$, respectively, output c_M which encrypts $X \odot Y$.

Note the addition ($+$) and multiplication ($\odot$) operations from FV over vectors in $\mathbb{Z}_t$ are defined element-wise.

3.2 Constant-weight Encoding

A constant-weight code is a collection of binary codewords with the same Hamming weight, i.e., each codeword has a fixed number of bits set to one. Throughout this paper, we denote the common Hamming weight that the codewords share as h. We denote the set of ℓ-bit constant-weight codewords with Hamming weight h by $CW(\ell, h)$.

We use the arithmetic constant-weight equality operator from Mahdavi and Kerschbaum [19] for comparing constant-weight codewords with Hamming weight h. The choice of h impacts the computation cost of the operator and the required communication. This operator does not depend on the operands which it is comparing, and so can be computed using SIMD operations. Algorithm 1 describes this operator. Throughout this paper, we denote $[n] = \{0, 1, ..., n-1\}$ for $n \in \mathbb{N}$.

Algorithm 1 Arithmetic Constant-weight Equality Operator

1: **algorithm** ARITH-CW-EQ(x, y)
2: $\quad h' = \sum_{i \in [\ell]} x_i \cdot y_i$
3: $\quad e = (1/h!) \prod_{i \in [h]} (h' - i)$
4: $\quad$ **return** $e \in \{0, 1\}$

3.3 Hashing Optimizations

We use a collection of hashing techniques to reduce the total number of comparisons and the cost of each comparison.

Hashing-to-Bins. Hashing-to-bins reduces the number of comparisons in a PSI protocol [20, 23, 32, 35]. Elements are distributed into a predetermined number of bins and comparisons are only performed between client and server elements in the same bin; since the bin in which an element is placed is determined using hashes of that element. When using this strategy, note that it is necessary to pad each bin with dummy elements up to a predetermined size to prevent the load of the bins from leaking information about the dataset.

There is a possibility that the number of elements in a bin exceeds the predetermined maximum, which would constitute a failure in the protocol. Thus, it is necessary to employ a strategy that cleverly manages elements that fall into the same bin.

Cuckoo hashing [31, 41] is a strategy for hashing elements into bins such that elements can be ejected from their current bin and placed in another bin after their initial placement. In Cuckoo hashing [31], there are m elements which are placed in $b = \varepsilon m$ bins, for some constant ε. Each bin holds at most one element and the placement of each element is determined using k hash functions, denoted as $H_i : \mathcal{X} \mapsto [b]$ for $i = 1, 2, \cdots, k$.

For each element x, we place x in bin $H_1(x)$. If bin $H_1(x)$ was already occupied by x', such that $H_1(x) = H_i(x')$, we evict x' from the bin. The new placement for x' is bin $H_{i+1 \mod k}(x')$. If that bin is empty, we are done; otherwise, we repeat this process, evicting the current resident of the bin. To ensure the protocol terminates, it is necessary to define an upper bound on the number of evictions permitted. If an empty bin is not found with the permitted number of evictions, the element is placed in a stash with a fixed size. Thus, to locate an element x, it is sufficient to look in bin $H_1(x)$, $H_2(x)$, $\cdots$, $H_k(x)$ or in the stash. When selecting parameters ε, k, and the stash size, please refer to past work analyzing the failure rates of Cuckoo hashing [3, 25, 31, 34].

Permutation-based Hashing Permutation-based hashing (PBH) is a technique to reduce the length of elements [3, 27, 32, 35]. We describe PBH in the following paragraph using the assumption that the number of bins is $b = 2^c$, for some $c \in \mathbb{N}$.

For a λ-bit element x, assume $x = x_H || x_L$ where $||$ is the concatenation operation and $|x_H| = c$ and $|x_L| = \lambda - c$. In the binning procedure, instead of placing x in bin $H(x)$, we place x_L in bin $b_x = x_H \oplus H(x_L)$. Now, if two elements x and y are placed in the same bin and match, this means that $x_L = y_L$ and $b_x = b_y$. From that, we have

$$b_x = b_y \Rightarrow x_H \oplus H(x_L) = y_H \oplus H(y_L) \Rightarrow x_H = y_H$$

Combining $x_L = y_L$ and $x_H = y_H$, we can deduce that $x = y$. Using this technique, we compare $\bar{\lambda}$-bit elements where $\bar{\lambda} = \lambda - c$. Since we can identify matches using only these shorter elements, we will only store elements of length $\bar{\lambda}$ in our bins. Thus, we term $\bar{\lambda}$ the *effective bitlength* and use it as the bitlength parameter throughout our descriptions and analysis of our protocol.

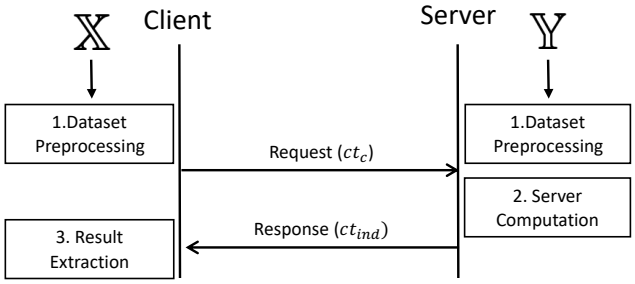

Figure 1: Stages of PEPSI.

4 PEPSI: Practically Efficient PSI

In this section, we describe our protocol PEPSI in detail; specifically, we describe the necessary steps to compute the intersection between a client set of size n and a server set of size m, where each set contains λ-bit elements. PEPSI is a PSI protocol that operates in one round and consists of three stages: Dataset Preprocessing, Server Computation, and Result Extraction. The client sends a *request message* to the server and the server responds with a *response message*. The request and response message constitute the total communication complexity of the protocol. At the end of the protocol, the client learns the intersection and the server learns nothing about the client set.

Figure 1 visualizes the steps of the protocol and the interaction between the client and server. In the base case (no variants), the Server Computation stage simply computes the intersection. This can be extended to other functionalities such as labelled PSI, computing a function on top of the intersection, and laconic PSI. See Section 5 for such variants. Table 2 summarizes all the notations used in the protocol description.

4.1 Dataset Preprocessing

In the first stage, the client and server must asynchronously preprocess their datasets to prepare them for the next stage. Preprocessing the dataset reduces the protocol latency when a client queries a server. This preprocessing is also helpful for the server, which has a large dataset and can reuse the preprocessed dataset for many queries by various clients. Both parties, client and server, preprocess their data in three steps: hashing optimization, encoding elements, and finally, batching (and encryption). Figure 2 visualizes the steps of the preprocessing. Note the actions in each step by a party are dependent on whether they are in the role of client or server. We

Table 2: Summary of notation for algorithm description.

Input Parameters	
$\mathbb{X}$	Client set
$\mathbb{Y}$	Server set
m	Client set size
n	Server set size
λ	Bitlength of elements
α	Maximum Error rate
Cryptographic Parameters	
N	Polynomial modulus degree
q	Coefficient modulus
t	Plaintext modulus
Binning Parameters	
b	Number of bins in T_c and T_s
γ	Client maximum bin load
μ	Server maximum bin load
$\bar{\lambda}$	Effective bitlength (used in PBH)
Constant-weight Code Parameters	
h	Hamming weight of constant-weight code
ℓ	Constant-weight code length
Auxiliary Notation	
T_c	Client table with b bins with γ elements
T_s	Server table with b bins with μ elements
T'_c	T_c with **encoded** elements
T'_s	T_s with **encoded** elements
pt_c	Plaintexts of clients elements
ct_c	Ciphertexts of clients elements
val_c	Ciphertexts of clients values
pt_s	Plaintexts of servers elements
val_s	Plaintexts of server values

provide a high-level overview here with relevant pseudocode in Appendix B.

Hashing Optimization. Our hashing optimization uses a hashing-to-bins strategy in conjunction with permutation-based hashing. Hashing-to-bins reduces the number of elements we need to compare, and permutation-based hashing reduces the size of elements that are inserted in the table (recall $\bar{\lambda} = \lambda - c$ as the effective bitlength from Section 3). The selected hashing-to-bins strategy in PEPSI must insert elements into b bins and does not require a stash. Elements that fall into the stash must be compared with all other elements, which severely diminishes the performance of our protocol. Moreover, permutation-based hashing cannot be used in conjunction with a stash. Hence, for the binning portion of the hashing optimization, we can use known hashing strategies that do not have a stash, such as Cuckoo hashing without a stash [33, 35] or Dual hashing [23].

The client and server have predetermined maximum bin loads, γ and μ, respectively, which are a function of their set sizes and the number of bins. After inserting elements into the bins, each party pad bins with dummy elements up to the maximum load of the bin. If more elements are inserted into a bin than the maximum load, the protocol fails. We denote the client's binning table with b bins and a maximum load of γ as T_c. Similarly, we denote the server's binning table with b bins and a maximum load of μ as T_s.

Encode to Constant-weight Codewords. The client encodes each $\bar{\lambda}$-bit element in T_c as a constant-weight codeword of length ℓ and Hamming weight h. The Hamming weight can be chosen freely but affects the communication-computation tradeoff (see Section 6). We set ℓ as a function of $\bar{\lambda}$ and h such that there is a unique representation for every $\bar{\lambda}$-bit element in T_c. So,

$$\ell = \ell(\bar{\lambda}, h) = \min\left\{\ell \in \mathbb{N} \mid \binom{\ell}{h} \geq 2^{\bar{\lambda}}\right\}. \tag{1}$$

We denote T'_c as the new table which holds the encoded elements. Dummy elements are encoded to the all-zero string of length ℓ. The server constructs T'_s from T_s using the same procedure as the client uses to construct T'_c from T_c.

Batching (and Encryption). In the last step, the client restructures T'_c to obtain a table of plaintexts. Recall that plaintexts are vectors of length N. Each position in $pt_c[i][j]$ corresponds to elements from one of the b bins. More concretely, $pt_c[i][*]$ contains the bits of the i-th encoded element in each of the b bins of T_c. We call this the client's i-th batch. Moreover, this process, which we call *batching*, allows the protocol to perform comparisons in different bins simultaneously. Each shade of red in Figure 2 shows the contents of one plaintext. The client additionally encrypts each plaintext with its secret key. The server constructs plaintexts pt_s in a similar fashion from the contents of T'_s and the server's i'-th batch is defined similarly. The server does not need to encrypt its plaintexts.

We assume $b = N$ in this example to simplify the explanation, but we show how to relax this assumption in relevant steps of the protocol.

4.2 Server Computation

The client sends the ciphertexts it has produced to the server for the next stage. In this stage, the server receives the ciphertexts of the client's elements and performs the set intersection (see Algorithm 2). At a high level, for each $i \in [\gamma]$ and $i' \in [\mu]$, the server compares batch i of the client's dataset with batch i' of the server's dataset. The output of this step is a table of ciphertexts of size $\gamma \times \mu$, which we denote by ct_{eq}. For $i \in [\gamma]$ and $i' \in [\mu]$, $ct_{eq}[i][i']$ denotes the result of comparing elements from batch i from the client and batch i' from the server.

Recall that the arithmetic constant-weight equality operator does not depend on the operands of the comparison. Hence,

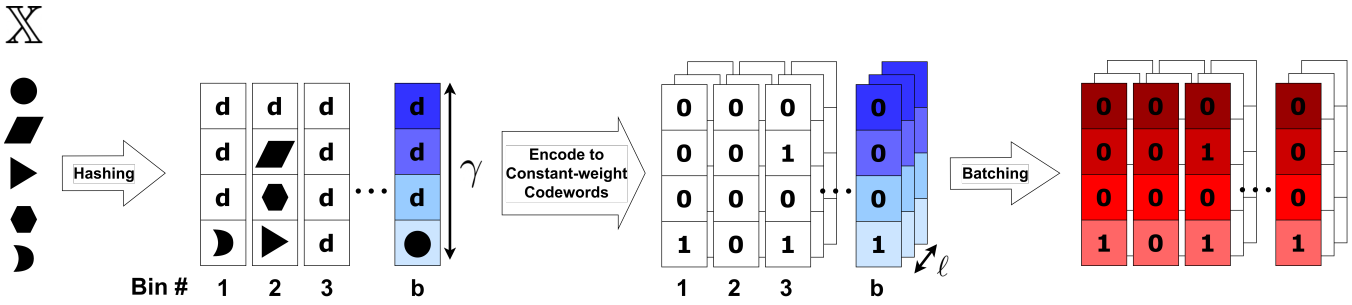

Figure 2: Client Dataset Preprocessing in PEPSI. d indicates dummy elements, b is the number of bins, and γ is the clients maximum bin load. From left to right: symbols represent the real-valued payload that is hashed into bins with a maximum bin load γ. The payload is encoded into bits using our constant-weight codewords, whereby the same color indicates the same payload, and finally encrypted into a ciphertext by batching across bins. The preprocessing outputs $\ell \cdot \gamma$ ciphertexts.

we can use it as a SIMD operator in line 4 of Algorithm 2.

Algorithm 2 Compute intersection of client and server set

1: **algorithm** INTERSECT(ct_c, pt_s)
2: **for each** client batch $i \in [\gamma]$ **do**
3: **for each** server batch $i' \in [\mu]$ **do**
4: $ct_{eq}[i][i'] \leftarrow$ ARITH-CW-EQ($ct_c[i], pt_s[i']$)
5: $ct_{ind}[i] \leftarrow \sum_{i' \in [\mu]} ct_{eq}[i][i']$
6: **return** ct_{ind}

If $b \neq N$, line 4 of Algorithm 2 is repeated $\lceil b/N \rceil$ times.

4.3 Result Extraction

The server sends the ciphertexts from the previous stage to the client for the final stage. In this final stage, the client decrypts the ciphertexts received from the server to obtain the indicator vector. The indicator vector specifies whether there was a match in the server set, for each element in the client set. From that, the client extracts the intersection. Algorithm 3 shows the procedure for this stage.

Algorithm 3 Extract intersection from server output

1: **algorithm** EXTRACTINTERSECTION
2: **for each** client batch $i \in [\gamma]$ **do**
3: $ind[i] \leftarrow \mathsf{Dec}(ct_{ind}[i], \mathtt{sk}_c)$
4: **for each** bin $k \in [b]$ **do**
5: **if** $ind[i][k] = 1$ **then**
6: Add $T_c[k][i]$ to intersection
7: **return** intersection

5 PEPSI Variants

Section 4 describes PEPSI for computing the intersection of two sets of λ-bit elements. However, the algorithm can be adapted for several other scenarios as well. Each adaptation adds extra steps to the protocol to achieve extra functionality or enhance performance. We describe these adaptations in detail in this section.

5.1 Optimization for Large Elements

In some applications, the client and server elements are very large, e.g., file names or 256-bit strings. In these cases, it is inefficient to compare large elements homomorphically. Instead, we map each element to a smaller λ-bit element using a hash function. However, if λ is too small, there may be colliding elements, which results in an incorrect result. Hence, we derive the failure rate of PEPSI if we map m client elements and n server elements to λ-bit elements. Conversely, we choose λ such that the failure rate of PEPSI is less than a given parameter α.

Not all collisions result in failure of the protocol, i.e., an incorrect result. Failure occurs when two unequal elements, one from the server and one from the client, have an identical mapping and are compared to each other by being placed in the same bin. Such an event produces an incorrect result since two unequal elements match. The upper bound on the failure rate is given in Lemma 1. Note that collision between two client elements (similarly, server elements) does not result in an incorrect result since client elements are not directly compared with each other.

Lemma 1. *When hashing m client elements and n server elements to λ-bit strings, the probability of failure in the protocol due to collisions is upper bounded by*

$$\frac{b\gamma\mu}{2^{\lambda}}, \tag{2}$$

where b, γ, and μ are the number of bins, maximum client bin size, and maximum server bin size, respectively.

We prove Lemma 1 in Appendix A. Using Lemma 1, we can see that, to bound the failure rate by $2^{-\alpha}$, we must

choose λ, such that $b\gamma\mu 2^{-\lambda} \leq 2^{-\alpha}$. Hence, we set $\lambda = \alpha + \lceil \log_2(b\gamma\mu) \rceil$.

5.2 Labelled PSI

PEPSI can be adapted to labelled PSI by altering the server computation and the result extraction. Algorithm 4 shows the adapted algorithm. In this algorithm, we denote the server labels as val_s, which is a vector of μ plaintexts. Moreover, the algorithm assumes that the label fits within one plaintext slot, but this can be extended to labels of arbitrary size. We show this extension in Appendix C and the corresponding result extraction procedure in Algorithm 4.

Algorithm 4 Server Computation and Result Extraction for Labelled PSI

1: **algorithm** LABELLEDPSI($ct_c[i]$,$pt_s[i']$)
2: **for each** client batch $i \in [\gamma]$ **do**
3: **for each** server batch $i' \in [\mu]$ **do**
4: $ct_{eq}[i][i'] \leftarrow$ ARITH-CW-EQ$(ct_c[i], pt_s[i'])$
5: $ct_{res}[i] \leftarrow \sum_{i'} val_s[i'] \cdot ct_{eq}[i][i']$
6: Send ct_{res} to the client
7: **algorithm** EXTRACTLABELS(ct_{res})
8: **for each** client batch $i \in [\gamma]$ **do**
9: $val[i] \leftarrow \mathsf{Dec}(ct_{res}[i], \mathtt{sk}_c)$
10: **for each** bin $k \in [b]$ **do**
11: **if** $val[i][k] \neq 0$ **then**
12: Add $val[i][k]$ to intersection labels
13: **return** intersection labels

5.3 Circuit PSI

PEPSI can additionally be extended to compute functions over the intersection. Such functions include PSI-Cardinality, PSI-Sum [23], PSI-Inner-Product [22, 28], and beyond. We introduce additional functionalities in the appendix.

PSI-Sum & PSI-Cardinality. In PSI-sum, the sum of server values associated with the elements in the intersection are output to the client. Algorithm 5 show the modified server computation and result extraction for PSI-sum, respectively. Kacsmar et al. use the same algorithm for securely computing PSI-sum and give proof of correctness and security [23]. PSI-Cardinality, which computes the size of the intersection, is a special case where the server values are equal to one.

PSI-Inner-Product. PSI-sum can be generalized to PSI-Inner-Product [28] as well. Assuming that the encrypted client values are denoted as val_c, we simply replace line 4 of Algorithm 5 with

$$sum \leftarrow \sum_{i' \in [\mu]} val_s[i'] \cdot \sum_i val_c[i] \cdot ct_{eq}[i][i'].$$

Algorithm 5 Server computation and result extraction for PSI-Sum

1: **algorithm** COMPUTEPSISUM(ct_c, pt_s)
2: **for each** client batch $i \in [\gamma]$ **do**
3: **for each** server batch $i' \in [\mu]$ **do**
4: $ct_{eq}[i][i'] \leftarrow$ ARITH-CW-EQ$(ct_c[i], pt_s[i'])$
5: $ct_{sum} \leftarrow \sum_{i' \in [\mu]} val_s[i'] \cdot \sum_i ct_{eq}[i][i']$
6: Sample vector $r \leftarrow [r_0, r_1, \cdots, r_{N-1}]$ s.t. $\sum r_i = 0$
7: $ct_{res} \leftarrow ct_{sum} + r$
8: **return** ct_{res}
9: **algorithm** EXTRACTPSISUM(ct_{res})
10: $res \leftarrow \mathsf{Dec}(ct_{res}, \mathtt{sk}_c)$
11: $ct_{sum} \leftarrow \sum_{k \in [b]} res[i]$
12: **return** ct_{sum}

6 Analysis of PEPSI

In this section, we provide an overview of the security analysis and details on communication and computation complexities. The communication and computation analysis is necessary to choose optimal parameters and enables PEPSI to achieve competitive performance compared to related work.

Security Analysis. The PEPSI protocol operates in the semi-honest model, i.e., the client and server follow the protocol but may try to infer extra information. The client input privacy is guaranteed due to the use of homomorphic encryption. The noise level in the homomorphic ciphertexts can reveal extra information about the server's dataset. Hence, we need a technique to make the noise level of the output ciphertexts indistinguishable from fresh ciphertexts. This is referred to as *circuit privacy* in the literature [5]. Techniques such as noise flooding [4, 9] achieve this property and can also be used in this work. Noise flooding is not implemented in the available homomorphic encryption libraries, so we do not perform that step in our implementation. However, it has a negligible effect on runtime, i.e., at the cost of one extra homomorphic addition, so our experimental results are unaffected. We choose all parameters such that we have 128-bit security.

Extending to the Malicious Model. The malicious security model removes the assumption that adversaries follow the protocol and considers active adversaries behaving arbitrarily. The malicious model for PSI has two limitations: 1) A malicious party may simply substitute its input and learn (parts of) the other party's set once the intersection is revealed, which cannot be prevented in the malicious model. 2) In a one-round protocol, arbitrary behaviour is only possible in the input-carrying first message. Hence, additional information can only be computed from the message (output) received in response to this first message. Using techniques such as input verification [6, 15] and verifiable homomorphic

encryption [40] we can augment our protocol to account for malicious clients and servers. However, we leave a details description of such a protocol for future work.

Notes on Performance Analysis. The communication and computation costs of PEPSI depend on many parameters, the most apparent of which are the set sizes and the bitlength of elements. Two parameters that can be tuned to optimize performance are the binning strategy and the Hamming weight.

The choice of binning strategy and associated parameters has been extensively discussed in previous works [31, 35], and using existing analysis, we can derive the relevant binning parameters b, γ, and μ, given the set sizes. Hence, in this work, we compute the communication and computation cost as a function of γ, μ, and b instead of the set sizes. As a result, our analysis is agnostic to the binning strategy.

The other parameter we can optimize over is the Hamming weight. The Hamming weight h is a parameter of the constant-weight equality operator. Cryptographic parameters depend solely on h as it determines the multiplicative depth. The code length is a function of the bitlength (and effective bitlength) and the Hamming weight, so it does not need to be optimized. In this section, we discuss how the communication and computation of PEPSI are affected by the Hamming weight and the tradeoff between these two metrics.

Analysis for Parameter Selection. Using the analysis from this section, we define strategies for optimally selecting parameters for PEPSI. There are two obstacles to optimizing the parameters in PEPSI. Firstly, there are circular dependencies between the parameters. For example, the cryptographic parameters, N and q dictate the number of bins, which influences the error rate which in turn influences the parameters of the constant-weight code. However, the Hamming weight of the constant-weight code determines the multiplicative depth, which puts a lower bound on the cryptographic parameters. The second obstacle is that there is no precise closed-form formula for the runtime so it requires experimental evaluation. Moreover, in many cases, there is no definitive choice for the parameters that optimize both communication and computation. In such cases, we visualize the communication computation tradeoff to assist in parameter selection. Hence, optimizing the parameters amounts to a non-trivial task that requires experimental evaluation and careful and systemic selection of the parameters.

6.1 Communication Complexity

The total communication complexity of PEPSI consists of the request and response messages. The response message depends on the function that is being evaluated. For example, if the set intersection is returned, the response is as big as the request message. In contrast, if we want the intersection cardinality, the response is only one ciphertext. In all the examples examined in this work, the response is smaller than the request size. Hence, to encompass all of these applications, we analyze and optimize the request size.

Asymptotic Communication Complexity. Theorem 1 derives the asymptotic complexity of the request in PEPSI as a function of the code length, ℓ.

Theorem 1. *The asymptotic complexity of the request message in PEPSI is $O(b \cdot \gamma \cdot \ell)$, where $\ell = \ell(\bar{\lambda}, h)$ as defined in Equation (1).*

Proof. As shown in Section 4, in the request, the encrypted plaintexts containing T'_c are sent to the server. T'_c is a table with dimension $b \times \gamma \times \ell$, with one bit in each cell of this table. Hence, the total communication is $O(b \cdot \gamma \cdot \ell)$. □

Corollary 1.1. *If we use Cuckoo hashing in PEPSI, then the communication complexity can be simplified to $O(m \cdot \ell)$ where m is the client set size and $\ell = \ell(\bar{\lambda}, h)$ as defined in Equation (1).*

Concrete Communication Cost. Theorem 1 only states the asymptotic complexity of the request size, but in practice, the size of the ciphertext must also be considered. Encoded elements in the client's set are put into $\lceil b/N \rceil \cdot \gamma \cdot \ell$ ciphertexts and each ciphertext in the request is approximately $N \cdot q$ bits, where q is the FV ciphertext modulus which is used. So overall, the size of the request in PEPSI is $\lceil b/N \rceil \cdot \gamma \cdot \ell \cdot N \cdot q$ bits (or simply $b \cdot \gamma \cdot \ell \cdot q$ when b is a multiple of N).

Note that the ciphertext modulus depends on the multiplicative depth, which depends only on the Hamming weight. N and q must also satisfy requirements for security which have been outlined in the literature [8]. For each Hamming weight, we select the smallest parameter set, which ensures the correctness of the result while also providing at least 128-bit security. Table 3 shows the polynomial modulus degree and bitlength of the coefficient modulus we use for each h.

Table 3: Polynomial modulus degree and coefficient modulus as a function of the Hamming weight.

h	1	2	3-4	5-8	9-16	17-32	33-64
$\log_2 N$	12	13	13	13	14	14	14
$\log_2 q$	72	144	168	204	240	276	312

Optimizing Communication Cost. The communication cost is derived as a function of the code length. However, the code length itself depends on the Hamming weight and effective bitlength, as shown in Equation (1). Hence, to minimize the communication complexity, we look for the Hamming weight which minimizes $\lceil b/N \rceil \cdot \gamma \cdot \ell \cdot N \cdot q$.

We know that γ does not depend on the Hamming weight so it acts as a constant in our optimization and can be removed.

So we can minimize $\lceil b/N \rceil \cdot \ell \cdot N \cdot q$, where $\ell = \ell(\bar{\lambda}, h)$. The effect of b is more convoluted and must be taken into account in the optimization. For simplicity, we assume $b \leq 4096$, which is less than the smallest possible value for N, so $\lceil b/N \rceil = 1$. We show results for other values of b in the appendix.

Figure 3 plots $\lceil b/N \rceil \cdot \ell \cdot N \cdot q$ with $b \leq 4096$ as a function of the Hamming weight for $\bar{\lambda} = 16, 32, 48$ to demonstrate that a minimum exists. The minimum communication occurs for $h = 8, 8, 23$, respectively.

We plot the optimal Hamming weight for communication for each effective bitlength in Figure 4 assuming $b \leq 4096$. In the case of a tie between two Hamming weights, we choose the smaller Hamming weight since it requires less computation. Generally, as the effective bitlength grows, a larger Hamming weight is required to achieve the smallest communication cost.

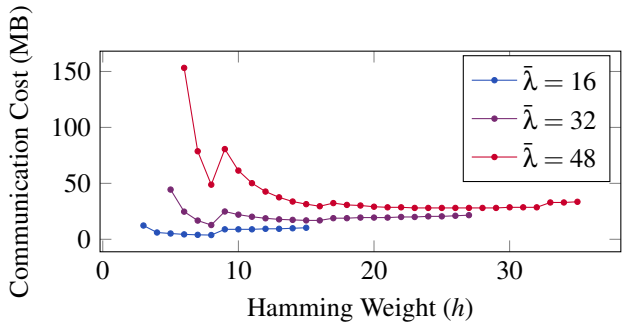

Figure 3: Code length as a function of the Hamming weight for $\bar{\lambda} \in \{16, 32, 48\}$ for $b \leq 4096$. The minimum occurs for a Hamming weight of 8, 8, and 23, respectively.

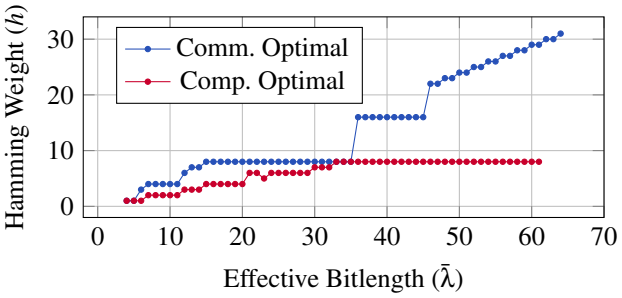

Figure 4: Hamming weight which optimizes communication and computation as a function of the effective bitlength ($\bar{\lambda}$) in blue and red, respectively. We assume $b \leq 4096$ in these graphs.

6.2 Computation Complexity

Amongst the stages of the protocol, the Result Extraction has a small computation overhead and also depends on the specific function that we derive. The data preparation can be done offline. Most of the online computation time is dedicated to the Server Computation stage. Within that stage, the majority of the runtime is dedicated to computing the encrypted indicator vector (Algorithm 2) and is required for any subsequent computation. The server computation algorithms described in Section 5.3 may perform additional operations after the indicator vector is derived, but in all cases, these operations are insignificant compared to calculating the indicator vector. Hence, we base our analysis and parameter selection on Algorithm 2 and calculate and optimize the runtime of this algorithm.

Approximate Server Computation Complexity. We approximate the computational complexity of the Server Computation stage by counting the number of expensive homomorphic operations, i.e., plaintext and homomorphic multiplications.

Theorem 2. *The number of homomorphic operations in Algorithm 2 is* $(\ell \cdot \mathtt{PM} + h \cdot \mathtt{M}) \cdot \lceil b/N \rceil \cdot \gamma \cdot \mu$ *where* PM *and* M *denote plaintext and homomorphic multiplication, respectively, and* $\ell = \ell(\bar{\lambda}, h)$.

Proof. The constant-weight equality operator in line 3 of Algorithm 2 consists of ℓ homomorphic multiplications and h plaintext multiplications [19]. In the general case when the number of bins is larger than N, line 4 of Algorithm 2 is performed $\lceil b/N \rceil$ times. Moreover, this line is repeated in two loops of length γ and μ, hence the total number of operations is $(\ell \cdot \mathtt{PM} + h \cdot \mathtt{M}) \cdot \lceil b/N \rceil \cdot \gamma \cdot \mu$. □

Optimizing Computation Cost. Given that we do not have a closed-form formula for the computation complexity of the homomorphic operators, optimizing the computation complexity is not possible. However, the concrete computation cost of PEPSI can be optimized empirically. Optimization is performed over the Hamming weight since we assumed that the bitlength, b, γ, and μ are given.

The client and server set sizes determine γ and μ, based on the binning strategy. The choice of h does not affect any of these parameters and only influences ℓ. Hence, γ and μ can be treated as constants in the optimization and it suffices to minimize $\left\lceil \frac{b}{N} \right\rceil \cdot (\ell \cdot \mathtt{PM} + h \cdot \mathtt{M})$. Theoretically, optimizing this term is difficult since there are no closed-form formulas for the runtime of homomorphic operations. Instead, we empirically optimize it by trying different Hamming weights. We set $\gamma = \mu = 1$ to eliminate the variance introduced by those parameters and run PEPSI using only one thread.

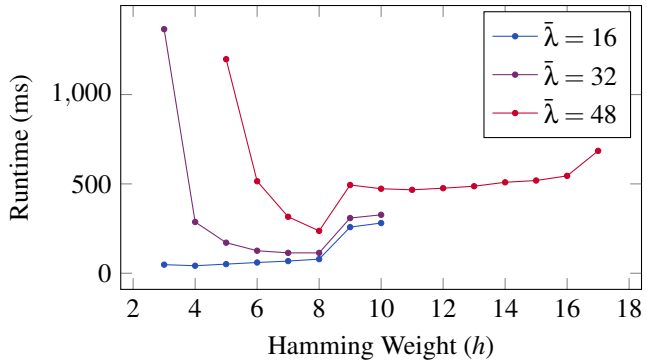

Figure 5: Runtime as a function of the Hamming weight for $\bar{\lambda} \in \{16, 32, 48\}$ for $b \leq 4096$. The minimum occurs for a Hamming weight of 4, 8, and 8, respectively.

Figure 4 shows, in red, the Hamming weights which optimize computation time for each effective bitlength assuming that $b \leq 4096$. Similar to the communication, the optimal Hamming weight for runtime increases as $\bar{\lambda}$ increases.

6.3 Communication/Computation Tradeoff

Note that choosing parameters that optimize the computation would increase communication costs and vice versa. In practice, it may be reasonable to choose parameters that fall somewhere between the two extremes. Figure 6 visualizes the communication/computation tradeoff for the intersection as the Hamming weight varies. We plot the communication/computation tradeoff for $\bar{\lambda} = 16, 24, 32$ assuming that $b \leq 4096$.

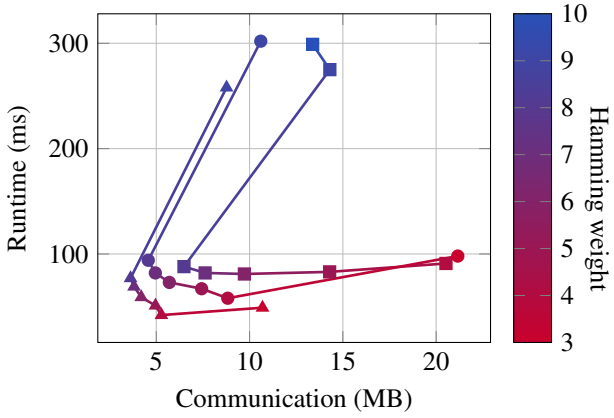

Figure 6: Visualizing the tradeoff between communication cost and runtime in PEPSI for $\bar{\lambda} = 16$ (triangles), $\bar{\lambda} = 24$ (squares), and $\bar{\lambda} = 32$ (circles) with $b \leq 4096$. Each point indicated running PEPSI with a specific Hamming weight which varies from 3 (on the lower right side) to 9 (on the upper left). We set $\gamma = \mu = 1$ in this example to isolate the effect of other parameters.

Notice that in some cases, the communication optimal may incur a high burden on the computation for very little gain, and vice versa. For example, in Figure 3 for $\bar{\lambda} = 48$, the communication cost decreases very slightly (less than 6%) as we increase h from 16 to 23. However, in Figure 5, the computation cost is much lower for $h = 16$ compared to $h = 23$ (over 40%).

7 Evaluation

Experimentation Details. We implement PEPSI in C++ using the Microsoft SEAL[1] library and measure runtime and communication. The SEAL library implements a variant of the FV cryptosystem and supports the operations we use (recall Section 3). Our implementation of PEPSI and the code used in our evaluation is available on Github [2]. We run experiments using two scenarios: 1) 32-bit elements and 2) large elements. 32-bit elements can be used to represent phone numbers in private contact discovery [23, 24]. Large elements are useful for applications such as checking for compromised credentials, where credentials could be strings of arbitrary length [29]. Parameters for these two scenarios are selected as follows:

Parameters for 32-bit Elements. Based on Figure 4, the best Hamming weight we can choose for the communication cost is $h = 8$, which results in $N = 2^{13}$ and $\log_2 q = 192$. As explained in Section 4, we round the number of bins up to a multiple of N for efficiency. Consequently, in our experiments, we have $b = N = 2^{13}$, $\bar{\lambda} = 19$, and $\ell = 24$. For our binning strategy, we use Cuckoo hashing with three hash functions without a stash, so $\gamma = 1$. We choose the parameters of Cuckoo hashing such that the failure rate is less than 2^{-40}. Based on the analysis in the literature [33, 35], the number of bins must be at least $1.27m$. The server bin size depends on the server set size and the number of bins. We use upper bounds for the server bin load found in the literature [31] and confirm the numbers experimentally using a simulation of the binning strategy.

Parameters for Large Elements. We choose the parameters such that the failure rate due to colliding elements is less than $\alpha = 2^{-40}$, so λ changes as the server set size increases. The binning strategy is Cuckoo hashing with three hash functions and no stash, so $\gamma = 1$. As a result, $b = N = 16384, \lambda = 40 + \lceil \log_2(b \cdot \gamma \cdot \mu) \rceil = 40 + \lceil \log_2(b \cdot \mu) \rceil, \bar{\lambda} = 40 + \lceil \log_2(\mu) \rceil$.

7.1 PSI Evaluation and Comparison

Comparison with DiPSI [23]. DiPSI [23] is the most similar work in the literature and operates in one round, similar to PEPSI. While PEPSI uses a homomorphic equality operator, similar to DiPSI, it improves on DiPSI in several aspects. The

[1] https://github.com/microsoft/SEAL
[2] https://github.com/RasoulAM/pepsi

two main differences are the use of a more efficient equality operator and permutation-based hashing. These differences result in significant improvements in concrete runtime and communication costs. Moreover, the advantage is increased by careful optimization of the parameters of PEPSI, as was mentioned in Section 6. Such optimizations are not required in DiPSI given that there is no variable parameter in the equality operator.

Table 1 shows that the asymptotic complexity of DiPSI and PEPSI is identical, but if we include parameters regarding the bitlength of elements, there is a difference. Table 4 displays the asymptotic complexity of the two protocols. The table also shows that the multiplicative depth of PEPSI does not depend on the bitlength, which results from our choice of equality operator.

Protocol	Communication	Computation	Mult. Depth
DiPSI	$O(m\lambda)$	$O(n\cdot\lambda)$	$\log_2\lambda$
PEPSI	$O\left(m\cdot\ell(\bar{\lambda},h)\right)$	$O\left(n\cdot\ell(\bar{\lambda},h)\right)$	$1+\log_2 h$

Table 4: Asymptotic complexity of DiPSI vs PEPSI in the unbalanced case, i.e., $m \ll n$.

All our experiments follow the unbalanced setting where the server has more elements than the client. DiPSI performs the intersection over 32-bit elements, so we do the same for a fair comparison. Cong et al. [14] allows to use elements of arbitrary length so we compare with the variant of PEPSI which can do the same. We measure all messages exchanged as the total communication and for computation, we measure the server's total runtime. We repeat experiments three times and report the average. However, the runtime of DiPSI is prohibitively high, so we take numbers from their paper [23].

Table 5 shows runtime of DiPSI and PEPSI for intersection of sets with 32-bit elements. This table shows that DiPSI is much slower than our work. PEPSI is at least four orders of magnitude faster than DiPSI. Most of this speedup can be attributed to the faster comparison operator, which we use in PEPSI. The communication of PEPSI is much smaller as well, which stems from 1) better parameters for the cryptosystem, 2) permutation-based hashing in conjunction with Cuckoo hashing, and 3) optimal Hamming weight, which minimizes communication. PEPSI requires 90% less communication compared to DiPSI. DiPSI can extend to labelled PSI and circuit PSI as well, which increases the total runtime and communication. We omit DiPSI from the rest of the evaluation due to its low performance.

To summarize, PEPSI is a strict improvement over DiPSI. It is non-interactive, similar to DiPSI, requires strictly less communication, is over three orders of magnitude faster, and is capable of all functionalities that DiPSI offers.

Table 5: Private set intersection over 32-bit elements using DiPSI and PEPSI. The bin size in PEPSI is $b = 8192$ in all cases. DNF indicates experiments which did not finish in less than an hour. * We copied the runtimes and communicating cost for DiPSI from their paper [23]. Note that the runtime of DiPSI is in minutes.

Comparison with Cong et al. [14] Cong et al. [14] is the state-of-the-art amongst non-interactive PSI protocols with only two rounds of interaction. The work of Cong et al. has strictly improved over the work of Chen et al. [10, 11]. Cong et al. denote the time required to compute the OPRF of server elements as *offline* time. We report the offline and online time separately. We use the publicly available implementation of the work of Cong et al. [14], which is published on Github[3] and is called APSI. We use parameters provided with their code for each client and server set size pair. Table 6 compares PEPSI and the work of Cong et al. [14] for intersection of sets with large elements.

The communication cost of PEPSI is more than the work of Cong et al. in PSI and labelled PSI, but the gap narrows as the size of the labels increases. Regarding runtime, most of the server runtime (over 95%) in the work of Cong et al. [14] is spent computing a pseudo-random function for each server element in the offline phase. They state that this step could be computed offline and stored on the server. This is a valid assumption for some applications but does not apply to scenarios in which the server database frequently changes or when we require the overall runtime to be small. In the case of PSI (without labels), for smaller server set sizes, the protocol of Cong et al. has a better total runtime. However, for server sets with over 2^{24} elements, the total runtime of PEPSI is less than the work of Cong et al., with PEPSI requiring less time in the offline phase, but more time in the online phase. Hence, in the case of PSI, PEPSI is preferable for large server sets that frequently change.

7.2 Labelled PSI Evaluation and Comparison

We compare with the work of Cong et al., which is the state-of-the-art in non-interactive labelled PSI. They use the same

[3] https://github.com/microsoft/APSI

Table 6: Private set intersection and Labelled PSI over large elements using the work of Cong et al. and PEPSI. The number of bins is set to $b = 16384$ in PEPSI for all cases.

parameters for the experiment but vary the label size. We choose 32-byte and 288-byte labels in our experiments. The results of this comparison are summarized in Table 6.

However, the work of Cong et al. has a high overhead when extending to labelled PSI instead of PSI. The computation cost of Cong et al. scales with the size of the label. In contrast, our work requires negligible additional server time to compute labelled PSI. The total runtime of PEPSI is consistently less than Cong et al. and the gap widens as the server set size increases, but PEPSI still requires more time in the online phase. So, in summary, in the case of labelled PSI, PEPSI is consistently faster than Cong et al., particularly for large, dynamic server sets and large labels but requires more communication.

7.3 Circuit PSI Evaluation and Comparison

Our evaluation of circuit PSI is focused on non-interactive solutions, which are compatible with the unbalanced setting. Hence, we omit solutions based on 2PC [33, 35], which require interaction between the client and server to compute the function. DiPSI can extend to circuit PSI and evaluate arbitrary functions but has a prohibitively high runtime, as we saw in Table 5. Recall that the work of Chen et al. [10, 11] and Cong et al. [14] cannot extend to circuit PSI. Instead, we compare with the work of Ion et al. [22], which is also a circuit PSI protocol but is limited to only a few functions: PSI-Cardinality and PSI-Sum-with-Cardinality. We use the public implementation[4] which is provided by the authors. PSI-Stats [42] performs the same operations as Ion et al. in the first two rounds of interaction and requires more operations when computing more complex functions. In the case of computing the PSI-Sum, PSI-Stats is identical to the work of Ion et al. Given that there is no publicly available implementation of PSI-Stats, we resort to the measurements from the work of Ion et al.

In our experiments in this section, we set the client set size to be $m \in \{1024, 2048, 4096, 8192\}$ and vary the server set size to observe the effect on communication and computation. The entire communication across all rounds is recorded and

	2048	3380	1240			76.3	33.7
	4096	3120	1250			75.8	33.7
	8192	3140	1250			75.6	33.6

Table 7: PSI-Sum using PEPSI and the work of Ion et al. [22]. Times are reported in seconds, and communication is in MegaBytes. DNF denotes instances which did not finish in under one hour. The number of bins is set to $b = 16384$ in PEPSI for all cases.

the runtime denotes the server runtime. Ion et al. [22] map elements to 256-bit strings using hash functions, so we use the variant of PEPSI with large elements to have a fair comparison. Table 7 summarizes the results of the experiments in this section.

Note that the cardinality is leaked whilst computing the sum in the work of Ion et al. [22]. In contrast, PEPSI does not have such leakage and is advantageous in this regard. Moreover, Ion et al. [22] is very limited in the functions that it can compute. Another observation is that the communication of the work of Ion et al. scales linearly with the server set size [22], whereas the communication cost of PEPSI increases at a much lower rate. For this reason, PEPSI is advantageous in the unbalanced setting and can scale to much larger server set sizes. The runtime of both protocols increases as the server size increases, but PEPSI is over 100x times faster than the work of Ion et al. [22]. One reason that PEPSI is faster than the work of Ion et al. [22] is the low per-element computation cost due to the use of batched homomorphic encryption. In contrast, the work of Ion et al. uses expensive modular exponentiations. The client must also perform expensive modular exponentiations, whereas in PEPSI, the client requires only a small amount of computation.

7.4 Summary of Evaluation

In our evaluation of PSI, we found that PEPSI demonstrates runtime that is comparable with other approaches [10, 14] but requires more communication. However, PEPSI excels particularly when the server size is very large and dynamic. In the context of labelled PSI, PEPSI is consistently faster than existing methods but requires more communication. The advantage of PEPSI increases as the label size increases. For circuit PSI, and specifically for PSI-Sum, PEPSI is faster than existing non-interactive approaches [22, 23], especially when dealing with larger server sets. Additionally, PEPSI has a significant advantage in communication cost, as it only depends on the client set size, making it highly efficient for large server sets. Furthermore, PEPSI offers the flexibility to easily extend to other functions, a capability that is not feasible with related work.

8 Conclusion

We propose PEPSI, a practical non-interactive circuit PSI protocol using homomorphic encryption. Some state-of-the-art PSI protocols cannot extend to circuit PSI. Those extending to circuit PSI require an interactive step with the client to compute the function or have the communication cost proportional to the server set size. These limitations are undesirable in the unbalanced setting. DiPSI, the only solution which does not have these limitations, has impractical runtimes. PEPSI addresses all these problems and proposes an efficient circuit PSI protocol with low communication overhead.

We use multiple techniques, such as constant-weight equality operators and permutation-based hashing that greatly improve the runtime and communication cost of PEPSI and result in a protocol that is competitive with existing work. We achieve competitive runtime and communication through careful optimization of parameters such as the Hamming weight.

PEPSI can compute the intersection of 1024 client elements with one million server elements in less than one second with less than 5 MB of communication. Functions such as sum and cardinality can be computed with negligible additional runtime. PEPSI is over four orders of magnitude faster than DiPSI, and 20x faster than the work of Ion et al. [22].

A Proof of Lemma 1

Lemma 1. *When hashing m client elements and n server elements to λ-bit strings, the probability of failure in the protocol due to collisions is upper bounded by*

$$\frac{b\gamma\mu}{2^{\lambda}}, \tag{2}$$

where b, γ, and μ are the number of bins, maximum client bin size, and maximum server bin size, respectively.

Proof. Let $\mathbb{P}[B]$ denote the probability of failure due to a collision. Let $\mathbb{P}[B_i]$ denote the probability of there existing a collision between any two of the elements of bin i, for $i \in \{1,2,\cdots,b\}$. So we have

$$\mathbb{P}[B] \leq \sum_{i\in[b]} \mathbb{P}[B_i]. \tag{3}$$

We know that, in a given bin, failure only occurs when two unequal elements, one from the server and the other from the client, have an equal constant-weight mapping. We know that the probability of a collision between two distinct elements from the domain is $2^{-\lambda}$, where the probability is in expectation over all perfect hash functions.

Hence, combining the facts stated above, we have that

$$\mathbb{P}[B] \leq \sum_{i\in[b]} \mathbb{P}[B_i] = \sum_{i\in[b]} \gamma\mu 2^{-\lambda} = b\gamma\mu 2^{-\lambda}. \tag{4}$$

25: **return** pt_s

B Data Preparation

The algorithm for server and client data preparation is provided as Algorithm 6. The client's secret key is denoted $\mathtt{sk}_c$, and is used for encryption. The encryption procedure is denoted with Enc. CW-ENCODE is the algorithm for mapping elements to constant-weight codewords. Precisely, we use the perfect mapping [19, Algorithm 3] and the lossy mapping [19, Algorithm 8] from the work of Mahdavi and Kerschbaum in the case of small and large elements, respectively. We refer the reader to the paper for the details of those algorithms.

C Large Labels

Algorithm 4 can be extended to the case where server labels are larger than one plaintext slot. The expensive step of the algorithm, which is matching client and server elements, does not need to be repeated. Instead, we simply repeat line 4 of Algorithm 4 for as many times that is required, depending on the size of the label.

D PSI-kth-Match.

Another function that the server can compute over the intersection is returning only one element in the intersection. This can be used to iteratively return the results of the protocol. For example, a data scientist may wish to see a sample of items in the intersection before deciding whether to recieve the entire intersection.

For simplicity, we only describe the cleartext algorithm for finding the kth match in a vector. The algorithm is designed such that it can be efficiently computed using homomorphic encryption. We include correctness and security proof to show that this algorithm can compute the kth match whilst not revealing any other information about the intersection. The full details on how to implement this algorithm using homomorphic encryption and the FV library are left for future work.

Assume that $I \in \{0,1\}^n$ denotes a vector with ones in some indices. The objective is to compute M such that $M[i_k] = 0$ where i_k is the position of the kth one in I. Algorithm 7 shows the algorithm that can achieve this.

Algorithm 7 Algorithm for kth match

1: **algorithm** ComputePSIkthMatch($I \in \{0,1\}^n, k$)
2: **for each** $i \in [n]$ **do**
3: $r \xleftarrow{\$} \mathbb{Z}_p$
4: $M[i] \leftarrow r \cdot (k \cdot I[i] - 1 - \sum_{i'<i} I[i'])$
5: **return** M

Theorem 3. *Algorithm 7 is correct, i.e., M is zero at the index of the kth one in I, and non-zero in all the indicies.*

Proof. Let $i_1 < i_2 < \cdots < i_s$ be the indicies such that $I[i_1] = I[i_2] = \cdots = I[i_s] = 1$ and $I[i] = 0$ for $i \neq i_j$. If $M[i] = k \cdot I[i] - 1 - \sum_{i' \leq i} I[i']$ then

$$M[i_k] = k \cdot I[i_k] - 1 - \sum_{i'<i_k} I[i'] = k - 1 - (k-1) = 0$$

Moreover,

$$j \neq k \Rightarrow M[i_j] = k \cdot I[i_j] - 1 - \sum_{i'<i_j} I[i'] = k - j \neq 0$$

$$i_j < i < i_{j+1} \Rightarrow M[i] = k \cdot I[i] - 1 - \sum_{i' \leq i} I[i'] = -1 - j \neq 0$$

which proves the theorem. □

The security of this algorithm is proven by showing that M reveals nothing about I other than the position of the kth one in the array.

Theorem 4. *If M is defined as in Algorithm 7, then M reveals nothing about I other than the index of the kth one.*

Proof. As shown in the correctness proof,

$$k \cdot I[i] - 1 - \sum_{i' \leq i} I[y'] \neq 0$$

for $i \neq i_k$. Moreover, due to the multiplication of r, which is uniformly random, $M[i]$ is also uniformly random, for $i \neq i_k$. Hence, $M[i']$ for $i' \neq i_k$ does not reveal any information about I. □

E Optimization for different values of b

Figure 5 showed the relationship between runtime and the Hamming weight for a fixed range of b. While there is not a close formula to show the effect of b, we can see in the graph below that for a larger b, the effect is roughly the same.

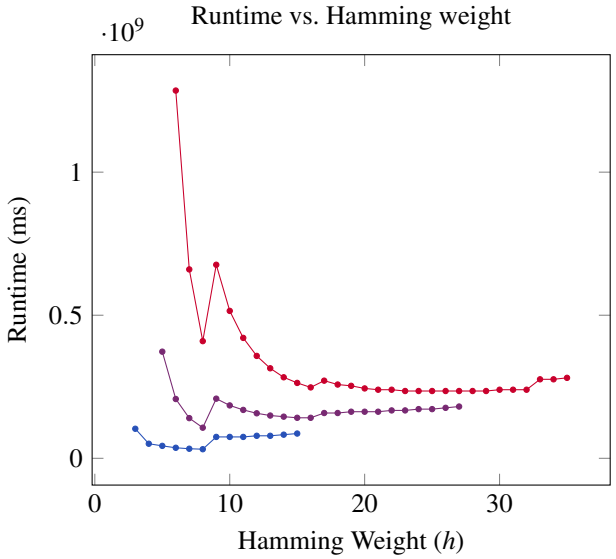

Figure 7: Code length as a function of the Hamming weight for $\bar{\lambda} \in \{16, 32, 48, 64\}$ for $4096 < b \leq 8192$. The minimum occurs for a Hamming weight of 8, 8, and 23, respectively.

Scalable Private Set Union, with Stronger Security

Abstract

Private Set Union (PSU) protocol allows parties, each holding an input set, to jointly compute the union of the sets without revealing anything else. In the literature, scalable PSU protocols follow the "split-execute-assemble" paradigm (Kolesnikov et al., ASIACRYPT 2019); in addition, those fast protocols often use Oblivious Transfer as building blocks. Kolesnikov et al. (ASIACRYPT 2019) and Jia et al. (USENIX Security 2022), pointed out that certain security issues can be introduced in the "split-execute-assemble" paradigm. In this work, surprisingly, we observe that the typical way of invoking Oblivious Transfer also causes unnecessary leakage, and only the PSU protocols based on additively homomorphic encryption (AHE) can avoid the leakage. However, the AHE-based PSU protocols are far from being practical.

To bridge the gap, we also design a new PSU protocol that can avoid the unnecessary leakage. Unlike the AHE-based PSU protocols, our new construction only relies on symmetric-key operations other than base OTs, thereby being much more scalable. The experimental results demonstrate that our protocol can obtain at least 873.74× speedup over the best-performing AHE-based scheme. Moreover, our performance is comparable to that of the state-of-the-art PSU protocol (Chen et al., USENIX Security 2023), which also suffers from the unnecessary leakage.

1 Introduction

In a Private Set Union (PSU) protocol, two players, a sender and a receiver, holding input sets X and Y, respectively, can jointly compute the union $X \cup Y$ as output. To ensure the joint computation is *private*, any additional information except the union $X \cup Y$, is not allowed to be learned by the players. Especially, information about the items in the intersection set $X \cap Y$ should not be learned by the players. Often we consider a simplified version of PSU: Instead of having both players to obtain the same output $X \cup Y$, in the simplified version of PSU, only the receiver obtains the output $X \cup Y$.

Symmetric Key-based PSU protocols. Kolesnikov et al. [21] is the first to only leverage symmetric key techniques to design a PSU protocol, such that their protocol is truly practical and scalable. Multiple followup results then are developed [1,8,13, 19,29,31]. In this work, we observe that all of these symmetric key-based protocols suffer from unnecessary leakage.

Kolesnikov et al.'s "split-execute-assemble" based PSU. Kolesnikov et al. [21] introduce for the first time the "split-execute-assemble" paradigm into the design of scalable PSU protocols: First, the pair of input sets X and Y are **split** into multiple much smaller pairs of subsets, i.e., $\{(X_1,Y_1),(X_2,Y_2),\cdots,(X_\beta,Y_\beta)\}$, where $\beta \in \mathbb{N}$; Here, $|X| = N_1$ and $|Y| = N_2$; for all $i \in [\beta]$, $|X_i| \ll N_1$ and $|Y_i| \ll N_2$. Then, the two parties **execute** β number of PSU protocol instances, as subroutine, and each instance is on pair of subsets (X_i,Y_i). The receiver obtains $Z_i = X_i \cup Y_i$. Finally, the receiver **assembles** the outputs of all subroutine protocol instances, and obtains the output $Z = Z_1 \cup Z_2 \cup \cdots \cup Z_\beta$.

Security concerns in the "split-execute-assemble" based PSU. Applying the above paradigm to the PSU design is a natural and interesting idea. However, as discussed by Kolesnikov et al. [21], in the "split-execute-assemble" paradigm, the receiver can learn if a subset Y_i includes items that are in the intersection $X \cap Y$, which is not allowed in PSU. In order to eliminate the information leakage, Kolesnikov et al. developed a careful *padding strategy* in [21]. Unfortunately, Jia et al. [19] pointed out that this padding strategy is *insufficient* to eliminate the leakage: Roughly, whenever the output $Z_i = X_i \cup Y_i$ is equal to Y_i for the i-th PSU sub-protocol instance, the receiver will be aware that the i-th subset Y_i includes the items in $X \cap Y$ with an overwhelming probability (see Section 3.1 and Appendix A for more details).

In our work, we observe that the leakage pointed out by Jia et al. [19] can actually be deduced from the output $X \cup Y$. In other words, as long as the receiver obtains the output $X \cup Y$, he can learn the leakage. At first glance, the protocol

*Part of the work was done at Shanghai Jiao Tong University.
†Corresponding author.

by Kolesnikov et al. [21] seems to be secure enough. However, we find that the receiver in Kolesnikov et al. [21] can learn the leakage *during the execution*, rather than *after receiving the output*, and we call this leakage as "during-execution leakage". Unlike obtaining leakage only after protocol execution is completed, during-execution leakage may lead the receiver to terminate the protocol upon learning sufficient leakage[1].

OT-based PSU, and its security concerns. The subsequent works [1, 8, 13, 19, 29, 31] do not leverage the "split-execute-assemble" paradigm, but we find that these solutions still suffer from the during-execution leakage. More specifically, for each item in the input set X, the receiver first learns whether it is a member of the set Y, and then obtains the output $Z = X \cup Y$ by invoking the underlying Oblivious Transfer (OT) instances with the membership information. In other words, the OT-based PSU protocols leaks the membership information *before* the execution of the protocol is completed.

AHE-based PSU. The during-execution leakage is not necessary for a PSU protocol, as we observe that the AHE-based protocols can avoid it. Using additively homomorphic encryption (AHE), Frikken et al. [12] construct the first efficient PSU protocols. Later Davidson et al. [10] improve the performance along this line. More concretely, the receiver generates a representation $P(\cdot)$ of his set Y such that if $x \in Y$, then $P(x) = 0$, and sends $\mathsf{Enc}(P(\cdot))$ to the sender. Then, for each $x \in X$, the sender calculates a ciphertext based on $\mathsf{Enc}(P(\cdot))$. Finally, the receiver can obtain the items in $X \setminus Y$ by decrypting the ciphertexts *without* needing extra information in advance. However, the AHE-based PSU protocols are still far from being practical and scalable.

Main question. Based on the discussions so far, we can see that existing provably secure PSU protocols:

(1) either avoid the during-execution leakage but are not scalable, as in AHE-based PSU protocols;
(2) or are scalable but suffer from the during-execution leakage, as in symmetric key-based PSU protocols.

It will be desirable to achieve the "best of the two worlds". Therefore, we have the following research question: *Is it possible to design a provably secure scalable PSU that does NOT suffer from the leakage?*

1.1 Our results

In this paper, we give an affirmative answer to the above question through the following results.

Revisiting the existing PSU protocols. In Section 3, we investigate existing PSU protocols, and find that scalable symmetric key-based PSU protocols suffer from the during-execution leakage, but non-scalable AHE-based PSU protocols do not. To provide a formal analysis, we define a new enhanced ideal functionality for PSU, denoted as $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$ in Section 4, that does not allow the leakage during the execution. The formal analysis is provided in Section 6.

A new PSU protocol. In Section 5, we provide the first PSU protocol which achieves both scalability and the enhanced PSU functionality $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$ *simultaneously*.

Our design: The main difference between the OT-based and the AHE-based PSU lies in the method the receiver uses to obtain items in $X \setminus Y$. In the AHE-based PSU, the receiver obtains the items in $X \setminus Y$ via decryption, without knowing any membership information in advance. Whereas, the receiver in the OT-based PSU needs to use the membership information to obtain the items in $X \setminus Y$ through OTs. To achieve the enhanced PSU functionality $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$ as in the AHE-based PSU, our core idea is to "mimic" the decryption process in the AHE-based PSU: For each item $x \in X$, the sender randomly chooses a secret key r and sends the ciphertext $c = x \oplus r$ to the receiver. Then, if $x \notin Y$, the receiver obtains the identical secret key r; otherwise, the receiver obtains a distinct secret key $r' \neq r$. This way enables the receiver to obtain x by calculating $c \oplus r'$ only when $x \notin Y$.

To this end, we employ the following two steps. First, we transform the problem of "determining whether an item x belongs to a set Y" into the problem of "evaluating the equality of two strings, using Oblivious Programmable PRF (OPPRF)." More concretely, if $x \in Y$, the PRF value t obtained by the sender will be equal to the receiver's PRF value t'. Then, we propose a novel building block, called "Equality-Conditional Random Generation (ECRG)", where the sender inputs (t, r) and the receiver inputs t', then the receiver obtains $r' = r$ if $t' \neq t$, or another random string $r' \neq r$ otherwise. Obviously, through ECRG, the receiver can obtain x only when $x \notin Y$.

A straightforward way to support the general case, where the sender holds multiple items, is to repeat the above process while using a batched ECRG (bECRG). However, this will incur a quadratic cost. To reduce the cost, we use Cuckoo hashing, and the leakage incurred by Cuckoo hashing can be avoided by leveraging Permute+Share. As in the OT-based PSU, our new PSU construction only relies on symmetric-key operations other than base OTs, and is thus significantly more scalable than AHE-based PSU.

Performance comparision: We implement our protocol in C++. The experimental results in Table 2 (see Section 5.5) show that our protocol can obtain *at least* 873.74× *speedup* over the latest AHE-based scheme [10] in a LAN setting, and our communication cost is 5× less than theirs. Moreover, the performance of our protocol is *comparable* to that of the state-of-the-art PSU protocol [31] for large balanced sets, in a LAN setting; Note that the PSU protocol in [31] cannot achieve $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$ due to the during-execution leakage.

[1] In practice, the receiver may be required to pay a fee to the sender after completing the execution. If the execution is terminated, the receiver may not be obligated to pay the fee.

2 Preliminaries

In this section, we briefly recall "generalized Reversed Private Membership Test (g-RPMT)", "Oblivious Transfer (OT)", "Oblivious Programmable PRF (OPPRF)", "Private Equality Test (PET)", "Permute+Share (PS)", simple hashing and Cuckoo hashing.

Generalized Reversed Private Membership Test. Reversed Private Membership Test (RPMT) was first proposed and formalized in [21]. More concretely, the sender P_0 holding an item x and the receiver P_1 holding a set Y. Then, the receiver P_1 can learn a bit b without obtaining any information else about item x; if $x \in Y$, $b = 1$, otherwise, $b = 0$. Meanwhile, the sender P_0 knows nothing about P_1's set Y. Based on the RPMT, a generalized RPMT was proposed in [19] where the sender P_0 inputs a set X, rather than an item x. We give the functionality $\mathcal{F}_{\text{g-RPMT}}$ in Figure 1.

Functionality $\mathcal{F}_{\text{g-RPMT}}$

Parameters:

- Two parties: sender $\mathcal{S}$ and receiver $\mathcal{R}$;
- Set size for sender $\mathcal{S}$ is n_1, set size for receiver $\mathcal{R}$ is n_2.

Functionality:

1. Wait for input $X = \{x_1, \cdots, x_{n_1}\}$ from $\mathcal{S}$, abort if $|X| \neq n_1$;
2. Wait for input $Y = \{y_1, \cdots, y_{n_2}\}$ from $\mathcal{R}$, abort if $|Y| \neq n_2$;
3. For each $i \in [n_1]$, if $X[i] \in Y$, set $b_i = 1$, otherwise, $b_i = 0$;
4. Send $\langle \mathsf{Request} \rangle$ to the simulator Sim;
5. Upon receiving $\langle \mathsf{Response}, \mathsf{OK} \rangle$ from Sim, send $\{b_1, \cdots, b_{n_1}\}$ to $\mathcal{R}$;

Figure 1: Generalized Reversed Private Membership Test Functionality.

1-out-of-2 Oblivious Transfer. 1-out-of-2 oblivious transfer (OT) is a two-party protocol, where party P_0 takes as input two strings $\{x_0, x_1\}$, and the other party P_1 chooses a random bit b and obtains nothing other than x_b while P_0 learns nothing about b. The first OT protocol was proposed by Rabin in [27]. And due to the lower bound in [16], all the OT protocols require expensive public-key operations. To improve the performance, Ishai et al. [17] introduced the concept of OT extension that enables us to carry out many OTs based on a small number of basic OTs. The functionality $\mathcal{F}_{\mathsf{OT}}$ is shown in Figure 2.

Oblivious Programmable PRF. Oblivious Programmable PRF was first proposed and formalized in [20]. Compared to oblivious PRF (OPRF), OPPRF allows the sender P_0 to additionally "program" the PRF values of some inputs, and outputs pseudorandom PRF values everywhere else. More specifically, the sender P_0 inputs $T = \{(x_i, y_i)\}_{i \in [n]}$, which means that the PRF value of x_i is set to be y_i. The receiver P_1 inputs $(q_1, \cdots, q_t)$. After the execution, the sender obtains (k, hint), and the receiver obtains $\{F(k, \mathsf{hint}, q_i)\}_{i \in [t]}$ and hint. Note that if $q_j = x_i$, $F(k, \mathsf{hint}, q_i) = y_i$, otherwise, $F(k, \mathsf{hint}, q_i)$ is pseudorandom. The functionality $\mathcal{F}_{\mathsf{OPPRF}}$ is given in Figure 3.

Functionality $\mathcal{F}_{\mathsf{OT}}$

Parameters:

- Two parties: P_0 and P_1.

Functionality:

1. Wait for input $\{x_0, x_1\}$ from P_0;
2. Wait for input $b \in \{0, 1\}$ from P_1;
3. Send $\langle \mathsf{Request} \rangle$ to the simulator Sim;
4. Upon receiving $\langle \mathsf{Response}, \mathsf{OK} \rangle$ from Sim, send output x_b to P_1.

Figure 2: 1-out-of-2 Oblivious Transfer functionality.

Functionality $\mathcal{F}_{\mathsf{OPPRF}}$

Parameters:

- Two parties: P_0 and P_1;
- A programmable PRF F with function $\mathsf{KeyGen}(\cdot)$;
- Upper bound n on the number of points to be programmed;
- Upper bound t on the number of queries.

Functionality:

1. Wait for input $T = \{(x_1, y_1), \cdots, (x_n, y_n)\}$ from P_0;
2. Wait for input $\{q_1, \cdots, q_t\}$ from P_1;
3. Generate $(k, \mathsf{hint}) \leftarrow \mathsf{KeyGen}(T)$ and $\{F(k, \mathsf{hint}, q_i)\}_{i \in [t]}$;
4. Send $\langle \mathsf{Request} \rangle$ to the simulator Sim;
5. Upon receiving $\langle \mathsf{Response}, \mathsf{OK} \rangle$ from Sim, send $\{F(k, \mathsf{hint}, q_i)\}_{i \in [t]}$ and hint to P_1, and (k, hint) to P_0.

Figure 3: Oblivious Programmable PRF Functionality.

Private Equality Test. Private Equality Test (PET) is used to test whether two strings are equal. More concretely, the two parties P_0 and P_1 hold strings x_0 and x_1 respectively. PET outputs a bit b_0 to P_0 and b_1 to P_1 such that if $x_0 = x_1$, $b_0 \oplus b_1 = 0$, otherwise, $b_0 \oplus b_1 = 1$. The existing works [6, 9, 11] designed efficient PET protocols. We give the functionality $\mathcal{F}_{\mathsf{PET}}$ in Figure 4.

Permute + Share. The $\mathsf{Permute}+\mathsf{Share}$ functionality $\mathcal{F}_{\mathsf{PS}}$ is defined by Chase et al. in [7]. There are two parties P_0 and P_1 in this functionality, where P_0 possesses a set $X = \{x_1, \cdots, x_n\}$ of size n and P_1 picks a permutation π on n elements. The goal of $\mathcal{F}_{\mathsf{PS}}$ is to let P_0 learn the shares

Functionality $\mathcal{F}_{\mathsf{PET}}$

Parameters:

- Two parties: P_0 and P_1;

Functionality:

1. Wait for input x_0 from P_0;
2. Wait for input x_1 from P_1;
3. Generate b_0 and b_1 such that if $x_0 = x_1$, $b_0 \oplus b_1 = 0$, otherwise $b_0 \oplus b_1 = 1$;
4. Send $\langle \mathsf{Request} \rangle$ to the simulator Sim;
5. Upon receiving $\langle \mathsf{Response}, \mathsf{OK} \rangle$ from Sim, send b_1 to P_1, and b_0 to P_0.

Figure 4: Private Equality Test Functionality.

$\{s_{\pi(1)}, s_{\pi(2)}, \cdots, s_{\pi(n)}\}$ and P_1 learn nothing but the other shares $\{x_{\pi(1)} \oplus s_{\pi(1)}, x_{\pi(2)} \oplus s_{\pi(2)}, \cdots, x_{\pi(n)} \oplus s_{\pi(n)}\}$. As mentioned in [7], some earlier works [15, 23] can also be used for securely realizing $\mathcal{F}_{\mathsf{PS}}$. These solutions all have computation/communication complexity $O(n \log n)$. The functionality $\mathcal{F}_{\mathsf{PS}}$ is shown in Figure 5.

Functionality $\mathcal{F}_{\mathsf{PS}}$

Parameters:

- Two parties: P_0 and P_1;
- Set size n for P_0;
- Length of element ℓ.

Functionality:

1. Wait for input $X = \{x_1, \cdots, x_n\}$ from P_0, abort if $|X| \neq n$, or $\exists\ x_i \in X$ such that $|x_i| > \ell$;
2. Wait for input a permutation π from P_1, abort if π is not a permutation on n items;
3. Send $\langle \mathsf{Request} \rangle$ to the simulator Sim;
4. Upon receiving $\langle \mathsf{Response}, \mathsf{OK} \rangle$ from Sim, give output shuffled shares $\{s_{\pi(1)}, s_{\pi(2)}, \cdots, s_{\pi(n)}\}$ to P_0, and another shuffled shares $\{x_{\pi(1)} \oplus s_{\pi(1)}, x_{\pi(2)} \oplus s_{\pi(2)}, \cdots, x_{\pi(n)} \oplus s_{\pi(n)}\}$ to P_1.

Figure 5: Permute + Share functionality.

Simple Hashing. In the simple hashing scheme, there are γ hash functions $h_i : \{0,1\}^* \to [b]$, where $i \in [\gamma]$, used to map n items into b bins $B_1, \cdots, B_b$. An item x will be added into $B_{h_1(x)}, B_{h_2(x)}, \cdots, B_{h_\gamma(x)}$, regardless of whether these bins are empty. The maximum bin size ρ can be set to ensure that no bin will contain more than ρ items except with probability $2^{-\lambda}$ when hashing n items into b bins.

Cuckoo Hashing. Cuckoo hashing was introduced by Pagh and Rodler in [24]. In this hashing scheme, there are γ hash functions $h_1, \cdots, h_\gamma$ used to map n items into $b = \varepsilon n$ bins and a stash, and we denote the i-th bin as B_i. Unlike the simple hashing, the Cuckoo hashing can guarantee that there is only one item in each bin, and the approach to avoid collisions is as follows: For an item x, it can be inserted into any empty bin of $B_{h_1(x)}, B_{h_2(x)}, \cdots, B_{h_\gamma(x)}$. If there are no empty bins in the k bins, randomly select a bin $B_{h_r(x)}$ in these γ bins, and evict the prior item y in $B_{h_r(x)}$ where $h_r(x) = h_r(y)$ to a new bin $B_{h_i}(y)$ where $i \neq r$. The above procedure is repeated until no more evictions are necessary, or until the number of evictions has reached a threshold. In the latter case, the last item will be put in the stash. According to the empirical analysis in [26], we can adjust the values of γ and ε to reduce the stash size to 0 while achieving a hashing failure probability of 2^{-40}. Moreover, the works [22,30] have shown that Cuckoo hashing can theoretically achieve negligible failure probability.

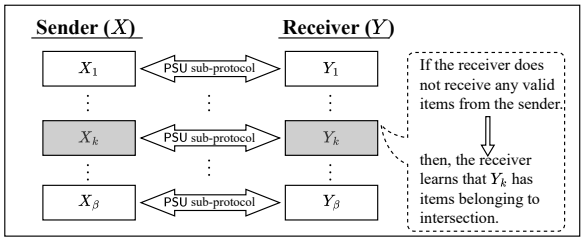

Figure 6: The leakage of protocol in [21].

3 Leakage Analysis

In this section, we thoroughly analyze the leakage in existing PSU constructions. Specifically, we observe that the symmetric key-based PSU constructions [1,8,13,19,21,29,31] suffer from the during-execution leakage, whereas the AHE-based PSU protocols [10, 12] can avoid it.

3.1 Revisiting the Leakage of PSU in [21]

The PSU protocol in [21] is performed in a "split-execute-assemble" paradigm. As shown in Figure 6, the sender and receiver map their input sets X and Y into two simple hash tables respectively, such that the set X (resp. Y) is divided into subsets $X_1, \cdots, X_\beta$ (resp., $Y_1, \cdots, Y_\beta$). Note that each bin of the sender is filled with a special item, and each bin of the receiver is filled with one special item and some dummy items. Then, for each pair of bins, the two parties execute a PSU sub-protocol. We briefly recall the leakage pointed out by Jia et al. [19] in Figure 6; if the receiver does not receive any valid items from the sender in the k-th bin, the receiver can know that there are items belonging to $X \cap Y$ in Y_k with an overwhelming probability once the sub-protocol in this bin is finished. Roughly speaking, there are two cases in which the receiver does not receive any valid items; Case_1 is that $X_k \neq \emptyset \wedge X_k \subseteq Y_k$, and Case_2 is that $X_k = \emptyset$. According to the analysis in [19], the receiver can learn that Case_1 happens

Functionality $\mathcal{F}_{\mathsf{PSU}}^{n_1,n_2}$

Parameters:

- Set size for sender $\mathcal{S}$ is n_1, set size for receiver $\mathcal{R}$ is n_2.

Functionality:

1. Wait for $X = \{x_1, \cdots, x_{n_1}\}$ from $\mathcal{S}$, abort if $|X| \neq n_1$;
2. Wait for $Y = \{y_1, \cdots, y_{n_2}\}$ from $\mathcal{R}$, abort if $|Y| \neq n_2$;
3. Give output $X \cup Y$ to $\mathcal{R}$.

Figure 7: The Original Ideal Functionality for PSU.

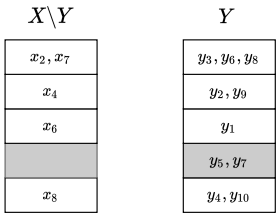

Figure 8: The receiver maps $X \setminus Y$ and Y into two simple hash tables respectively.

with an overwhelming probability, which means that she can know that there are items belonging to $X \cap Y$ in Y_k with the same probability. Please see Appendix A for more details about the leakage.

After reviewing the security proof in [21], we find that the protocol in [21] can indeed securely realize $\mathcal{F}_{\mathsf{PSU}}^{n_1,n_2}$ (recalled in Figure 7), which means that the functionality $\mathcal{F}_{\mathsf{PSU}}^{n_1,n_2}$ actually allows the leakage. Next, we will analyze the leakage from the perspective of ideal functionality.

3.2 Leakage Allowed in $\mathcal{F}_{\mathsf{PSU}}^{n_1,n_2}$

According to $\mathcal{F}_{\mathsf{PSU}}^{n_1,n_2}$, the simulator for the corrupted receiver only obtains the output, i.e., $X \cup Y$, which means that the leakage recalled above can be deduced from $X \cup Y$. Therefore, in any protocols that securely realize $\mathcal{F}_{\mathsf{PSU}}^{n_1,n_2}$, the receiver can obtain the leaked information once receiving *all the items* in $X \cup Y$, which will be explained by the following example:

Assuming the receiver's set $Y = \{y_1, y_2, \cdots, y_{10}\}$ and $X \setminus Y = \{x_7, x_2, x_4, x_6, x_8\}$, the receiver can map $X \setminus Y$ and Y into two simple hash tables respectively as shown in Figure 8. Note that even if the PSU protocol does not use the bucketing technique as in [21], the receiver can choose some hash functions to perform the mapping. We can see that in the left table, no items in $X \setminus Y$ are mapped to the 4th bin marked in gray. Then, according to the analysis in [19], the receiver can learn that items belonging to $X \cap Y$ are in $\{y_5, y_7\}$ with a high probability.

3.3 Leakage Occurring in Symmetric Key-based PSU Protocols

In this section, we further analyze the leakage of PSU protocol in [21] and the subsequent symmetric key-based PSU protocols [1, 8, 13, 19, 29, 31].

PSU Protocol in [21]. As analyzed before, the leakage of PSU protocol in [21] is actually allowed by the functionality $\mathcal{F}_{\mathsf{PSU}}^{n_1,n_2}$. However, we notice that the receiver in [21] can learn the leakage *during the execution*, rather than after receiving *all the items* in $X \cup Y$. We call the leakage occurring in [21] as "during-execution leakage". Recall the example shown in Figure 6, once completing the execution in the k-th bin, the receiver learns with an overwhelming probability that there are intersection items in Y_k.

Intuitively, the during-execution leakage in protocol [21] is incurred by the "split-execute-assemble" paradigm. Therefore, a natural question is *"Do the subsequent OT-based PSU protocols (including [1, 8, 13, 19, 29, 31] and the basic scheme in [21]) avoid the during-execution leakage?"* While these OT-based PSU protocols do not leverage the split-execute-assemble paradigm, we observe the answer is still negative.

OT-based PSU Protocols. We observe that all the OT-based PSU protocols in [1, 8, 13, 19, 29, 31] and the basic scheme in [21] follow the design framework shown in Figure 9. Concretely, the sender first randomly permute his set X. Then, through generalized Reversed Private Membership Test (g-RPMT), the receiver can learn a bit b_i for each item in X; $b_i = 0$ means $x_i \notin Y$, otherwise $x_i \in Y$. The receiver knows no more information about x_i beyond whether it belongs to Y, and the sender learns nothing about Y. At last, the receiver obtains x_i if $b_i = 0$, otherwise, obtains $\perp$. Intuitively, in the design framework shown in Figure 9, the set Y is processed as a whole and the receiver obtains the items in $X \setminus Y$ in random order. Therefore, the receiver in the design framework cannot obtain the leakage shown in Figure 6 during the execution. However, it can be observed that the receiver obtains $\{b_1, \cdots, b_{n_1}\}$ before obtaining the output $X \cup Y$. In other words, even if the receiver does not perform OTs with the sender after executing g-RPMT, the receiver can still learn $\{b_1, \cdots, b_{n_1}\}$. Therefore, $\{b_1, \cdots, b_{n_1}\}$ is also during-execution leakage.

Practical Influence. If any PSU protocol can ensure that the receiver obtains the entire output, it does not matter whether the leakage happens *after* the execution or *during* the execution[2]. However, in practice, many realistic factors (e.g., network interruptions and server failures) may interrupt the execution. Moreover, the receiver may refuse to finish the execution once he obtains sufficient leakage, and leverage the during-execution leakage to launch attacks.

More specifically, in some attacks, the attacker needs to collect information across multiple executions. However, in practice, victims may limit the number of executions for a

[2]Here, we ignore the difference in the time of obtaining the leakage.

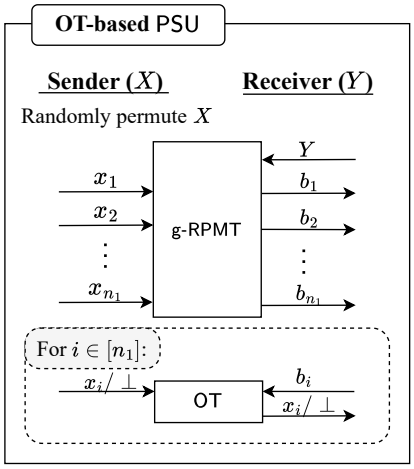

Figure 9: OT-based solutions [1, 8, 13, 19, 21, 29, 31].

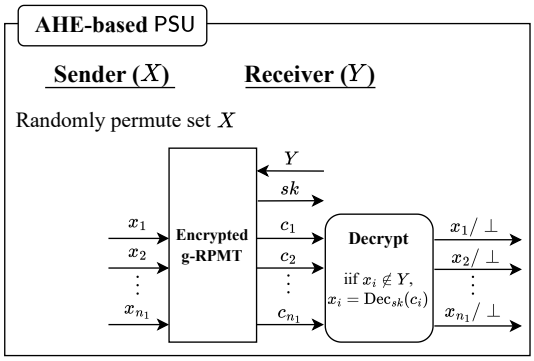

Figure 10: AHE-based solutions [10, 12].

period of time, but they may allow executions to be restarted after interruptions. Therefore, when the protocol suffers from during-execution leakage, the attacker could utilize the during-execution leakage: the attacker interrupts the execution once obtaining the leakage and then initiates a new execution. In this way, the attacker obtains more information within a certain period of time. As an example, we next explain how an attacker can use the during-execution leakage $\{b_1, \cdots, b_{n_1}\}$ in OT-based PSU to launch the attack shown in [14].

Guo et al. [14] launched attacks on protocols that aim to hide intersections but allow leaking intersection sizes, including Private Set Intersection Cardinality (PSI-CA), Private Intersection-Sum with Cardinality (PSI-SUM) and PSU. Specifically, the attacker can leverage the intersection sizes obtained across multiple executions to infer whether some elements are in a set (that is, intersection). They implemented the attack on practical datasets to obtain the tokens of COVID-19 patients, and the interest of the person associated with specific personal_id. The during-execution leakage $\{b_1, \cdots, b_{n_1}\}$ in OT-based PSU actually leaks intersection size. By launching the attack in [14] on the OT-based PSU, the attacker can interrupt the execution upon obtaining $\{b_1, \cdots, b_{n_1}\}$; the attacker can interact with the sender more times, thereby obtaining more intersection sizes to infer intersections.

Guo et al. [14] also mentioned that limiting the number of protocol invocations may be a potential defense. However, if the targeted protocol suffers from the during-execution leakage, only limiting the number of protocol invocations is not enough. Being attentive to interruption events and limiting the number of restarts after interruptions are also necessary.

Given the above example, we know that the during-execution leakage could be exploited by attackers. Fortunately, we observe that the during-execution leakage is *unnecessary*, as the AHE-based solutions [10, 12] can avoid it.

3.4 AHE-based PSU Protocols avoiding the During-Execution Leakage

Different from the symmetric key-based solutions [1, 8, 13, 29, 31] following the design framework shown in Figure 9, the receiver in the AHE-based solutions [10, 12] do not need to first obtain the membership test result (i.e., $\{b_1, \cdots, b_{n_1}\}$) and then interact with the sender to obtain the items in $X \setminus Y$. We give the design framework used by the AHE-based solutions [10, 12] in Figure 10.

More specifically, the two parties in the schemes [10, 12] actually perform a *encrypted* g-RPMT, rather than a g-RPMT. The "encrypted" means that from the output of encrypted g-RPMT, the receiver can obtain a ciphertext c_i for each item x_i in the set X and a decryption key sk. Then, if the receiver can decrypt the ciphertext c_i to obtain a valid item x_i, this means that the corresponding bit $b_i = 0$, otherwise, $b_i = 1$. Note that in the AHE-based solutions [10, 12], the decryption key sk is the secret key of a key pair (pk, sk) chosen by the receiver. It can be observed that in this design framework shown in Figure 10, for an item in the set X, the receiver directly obtains the item itself or $\perp$ without needing to obtain extra information in advance. Therefore, the AHE-based protocols [10, 12] do not suffer from the during-execution leakage.

In summary, we discover that during-execution leakage is prevalent in symmetric key-based PSU protocols, but can be avoided by AHE-based PSU protocols. Given that attackers could exploit during-execution leakage to launch attacks, it is necessary to analyze whether a PSU protocol is susceptible to during-execution leakage when designing it. However, as previously analyzed, in the existing PSU functionality $\mathcal{F}_{\mathsf{PSU}}^{n_1,n_2}$ (see Figure 7), the during-execution leakage is allowed. Therefore, we next in Section 4 define a new PSU functionality in which the during-execution leakage is *not allowed*. In addition, since that the AHE-based PSU protocols are not efficient enough, in Section 5, we design a new symmetric key-based PSU while avoiding the during-execution leakage.

4 Defining a New PSU Functionality $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$

As discussed above, the previous scalable protocols [1, 8, 13, 19, 21, 29, 31] all suffer from the during-execution leakage. However, these protocols have been proven to securely realize the functionality $\mathcal{F}_{\mathsf{PSU}}^{n_1,n_2}$ shown in Figure 7. This means that the functionality $\mathcal{F}_{\mathsf{PSU}}^{n_1,n_2}$ cannot capture the security without during-execution leakage. Therefore, in Figure 11, we define a new enhanced PSU functionality $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$ that can subtly capture the security where the receiver cannot obtain any during-execution leakage before obtaining the output $X \cup Y$.

Functionality $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$

Parameters:

- The functionality interacts with two parties, the sender $\mathcal{S}$ and the receiver $\mathcal{R}$, and the simulator Sim;
- Set size for the sender $\mathcal{S}$ is n_1, and the set size for the receiver $\mathcal{R}$ is n_2.

Functionality:

0. Initialize an ideal state $\mathsf{state}_{\mathsf{U}} = \emptyset$ for party U where $\mathsf{U} \in \{\mathcal{S}, \mathcal{R}\}$; if U is corrupted, the simulator Sim is allowed to access $\mathsf{state}_{\mathsf{U}}$;
1. Upon receiving input $X = \{x_1, \cdots, x_{n_1}\}$ from the sender $\mathcal{S}$, abort if $|X| \neq n_1$; otherwise, update state $\mathsf{state}_{\mathcal{S}} = \langle X \rangle$, and send $\langle \mathsf{Request}, \mathcal{S} \rangle$ to Sim;
2. Upon receiving input $Y = \{y_1, \cdots, y_{n_2}\}$ from the receiver $\mathcal{R}$, abort if $|Y| \neq n_2$; otherwise, update state $\mathsf{state}_{\mathcal{R}} = \langle Y \rangle$, and send $\langle \mathsf{Request}, \mathcal{R} \rangle$ to Sim;
3. Upon receiving $\langle \mathsf{Response}, \mathsf{OK} \rangle$ from Sim, compute $Z = X \cup Y$, and add $\langle \mathsf{Finished} \rangle$ to the sender's state $\mathsf{state}_{\mathcal{S}}$ and $\langle Z \rangle$ to the receiver's state $\mathsf{state}_{\mathcal{R}}$;
4. Output Z to $\mathcal{R}$, and $\langle \mathsf{Finished} \rangle$ to $\mathcal{S}$.

Figure 11: An enhanced ideal functionality for PSU.

Differences from $\mathcal{F}_{\mathsf{PSU}}^{n_1,n_2}$. The main difference from the original PSU functionality $\mathcal{F}_{\mathsf{PSU}}^{n_1,n_2}$ in Figure 7 is that the enhanced functionality $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$ additionally sends an output $\langle \mathsf{Finished} \rangle$ to the sender once the joint computation is completed. We remark that returning $\langle \mathsf{Finished} \rangle$ to the sender is reasonable: in a natural real-world PSU protocol execution, the sender should be aware if the protocol execution has been completed or not; therefore, in the ideal world, the sender should also be informed of the completion. In addition, in the original functionality $\mathcal{F}_{\mathsf{PSU}}^{n_1,n_2}$, the interactions between the functionality and the simulator (i.e., ideal world adversary), are not explicitly described. This presentation is consistent with that in [5], in which the simulator is in charge of the message delivery in the ideal world execution. In this work, to address the subtle issues in existing PSU protocols, we follow Canetti's original formulation [3, 4]; thus, we explicitly present the interactions between the functionality and the simulator. For example, when the PSU functionality receives an input, the simulator must be notified; when a player is corrupted, the simulator must be allowed to "see" the corresponding "ideal state".

During-Execution Leakage Not Allowed in $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$. Next, we take the OT-based design framework shown in Figure 9 as an example to intuitively explain how $\langle \mathsf{Finished} \rangle$ can help us to recognize that a protocol suffers from the during-execution leakage (i.e., a protocol with the during-execution leakage cannot securely realize $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$).

We assume that there is an adversary who corrupts the receiver and that at a certain moment t[3], g-RPMT has finished while OTs have not yet started. Then, the simulator needs to simulate $B = \{b_1, \cdots, b_{n_1}\}$ for the adversary. The simulator only has the two strategies: (1) Do send $\langle \mathsf{Response}, \mathsf{OK} \rangle$ to $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$ immediately; (2) Do not send $\langle \mathsf{Response}, \mathsf{OK} \rangle$ to $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$ immediately.

Following the first strategy, the simulator can simulate $B = \{b_1, \cdots, b_{n_1}\}$, but the sender will forward $\langle \mathsf{Finished} \rangle$ to the environment in the ideal world, while the environment in the real world will not obtain $\langle \mathsf{Finished} \rangle$ since the execution has not been completed in the real world. Therefore, the environment can distinguish the two worlds. On the other hand, if following the second strategy, regardless of whether in the real or ideal world, the environment will not obtain $\langle \mathsf{Finished} \rangle$. However, in the real world, the number of 1 in B is equal to $|X \cap Y|$. Note that the environment knows $|X \cap Y|$, as X and Y are chosen by the environment. Whereas, in the real world, the probability that the simulator does not guess $|X \cap Y|$ successfully is overwhelming. Therefore, the environment can still distinguish the two worlds. The idea of proof can be naturally extended to the protocol of [21] following the split-execute-assemble paradigm. We postpone the rigorous proof to Section 6.1.

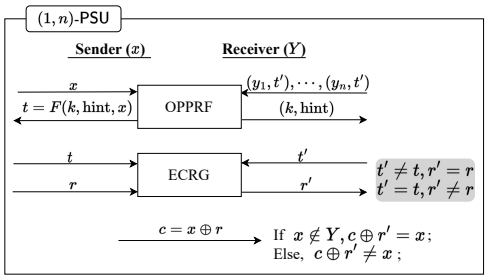
As for the AHE-based protocols following the design framework shown in Figure 10, the simulator for corrupted receiver does not need extra information before simulating the ciphertexts of the encrypted g-RPMT. In order to simulate the ciphertexts, the simulator needs to obtain the output $X \cup Y$ from $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$, which means that the environment will receive $\langle \mathsf{Finished} \rangle$. Note that in the real world, once sending the ciphertexts, the sender completes the execution, so the environment can also obtain $\langle \mathsf{Finished} \rangle$. Therefore, the environment cannot distinguish the two worlds. Please refer to Section 6.2 for more details.

5 A New PSU $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ Realizing $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$

In the previous section, we find that only the protocols following the AHE-based framework shown in Figure 10 can securely realize our new enhanced PSU functionality $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$. However, the AHE-based protocols are not efficient enough in practice, especially for large datasets. In this section, we design a scalable PSU protocol $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ that can securely realize $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$ by using symmetric-key operations. Next, we first give

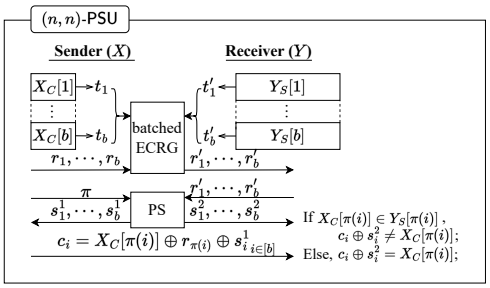
[3] Note that the environment can know the internal state of the adversary, and thus know when the execution starts and when g-RPMT has finished while OTs have not yet started.

an overview of $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$, and then describe two new building blocks Π_{eqOTe} and Π_{bECRG}. Finally, we explain $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ in detail and give a performance evaluation and comparison.



5.1 Overview

We observe that the difference in the way of "transmitting" the items in $X \setminus Y$ can lead to the difference in the security of PSU. More specifically, in the OT-based PSU (see Figure 9), the receiver "picks up" the items in $X \setminus Y$ from the sender's set X by using the information about $X \setminus Y$ obtained in advance. Whereas, the AHE-based PSU (see Figure 10) allows the receiver to directly obtain the items in $X \setminus Y$ by decryption without knowing any information about $X \setminus Y$ in advance, thus achieving $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$. However, the expensive public-key operations result in that the AHE-based PSU is not practical. Therefore, in order to design an efficient PSU protocol achieving $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$, a promising way is to design the "encrypted g-RPMT" only based on symmetric-key operations.



Our core idea is to use one-time pad (OTP) to encrypt the items in $X \setminus Y$, i.e., $c_i = x_i \oplus r_i$ where r_i is the secret key. Then, we need to guarantee that if $x_i \in X \setminus Y$, the receiver can obtain r_i and then learn x_i, otherwise, the receiver will obtain another randomness $r_i' \neq r_i$ such that the receiver cannot recover x_i by calculating $c_i \oplus r_i'$. Moreover, we need to guarantee that r_i and r_i' are pseudorandom, and thus not leaking extra information. Following the core idea, we propose a new design. For the sake of presentation, we first consider a simple case, denoted as $(1,n)-\mathsf{PSU}$, where the sender holds an item x and the receiver holds a set $Y = (y_1, \cdots, y_n)$. The design framework for $(1,n)-\mathsf{PSU}$ is shown in Figure 12a.

Simple case: $(1,n)-\mathsf{PSU}$. We first transfer the problem of testing whether $x \in Y$ to the problem of testing whether two strings t and t' are the same by leveraging "Oblivious Programmable PRF" (OPPRF). More specifically, in OPPRF, the receiver can set the PRF values of all the items in set Y to be a pseudorandom value t', such that the PRF value t of the sender's item would be equal to t' when $x \in Y$. Then, we propose a new protocol called "Equality-Conditional Randomness Generation" (ECRG) as a building block, such that if $t = t'$, ECRG outputs a pseudorandom string r' to the receiver, otherwise, outputs a string r' that is equal to r chosen by the sender. At last, following the above core idea, the receiver can obtain x only when $x \notin Y$.

General case: $(n,n)-\mathsf{PSU}$. It is natural to repeat $(1,n)-\mathsf{PSU}$ (shown in Figure 12a) n times to achieve $(n,n)-\mathsf{PSU}$, i.e., the sender's input set is $X = \{x_1, \cdots, x_n\}$. However, according to the existing OPPRF constructions [6, 25], the size of the hint in OPPRF is $O(n)$ and the corresponding computation cost is at least $O(n)$. Therefore, no matter how we design ECRG, the overall cost would be at least $O(n^2)$, which is not acceptable for large datasets. To reduce the cost, we insert set X and set Y into Cuckoo hashing and simple hashing with $b = \varepsilon n$ bins respectively, by using γ hash functions, such that

(a) $(1,n)-\mathsf{PSU}$. Here, OPPRF and ECRG constitute the "encrypted g-RPMT" in Figure 10 with one element x; r' corresponds to the key sk and $c = x \oplus r$ corresponds to the ciphertext of x.

(b) $(n,n)-\mathsf{PSU}$. Similarly, the OPPRF (to generate t_i and t_i', but omitted here), the batched ECRG and PS constitute the "encrypted g-RPMT" in Figure 10 with input $\{X_C[1], \cdots, X_C[b]\}$; $\{s_1^2, \cdots, s_b^2\}$ corresponds to the key sk and c_i corresponds to the ciphertext of $X_C[\pi(i)]$.

Figure 12: Our new design framework achieving the "encrypted g-RPMT" based on symmetric-key techniques.

OPPRF is performed on small subsets of set Y. We give the design framework for $(n,n)-\mathsf{PSU}$ in Figure 12b.

More specifically, we denote the Cuckoo hash table and the simple hash table after insertion as X_C and Y_S, respectively. Each bin i of the Cuckoo hash table contains only one item $X_C[i]$, and each bin i of the simple hash table contains a subset $Y_S[i]$. Then, we perform an OPPRF to generate (t_i, t_i') for all $i \in [b]$. Note that there are γn items in the simple hash table, and thus the overall cost for generating $\{(t_i, t_i')\}_{i\in[b]}$ is $O(\gamma n)$. Also, we designed a batched ECRG (see Section 5.2) that can generate $\{r_i'\}_{i\in[b]}$ in a batched way and the cost is $O(n)$. At first glance, the sender can directly send $c_i = X_C[i] \oplus r_i$ for all $i \in [b]$, and the receiver can recover $X \setminus Y$ by using $\{r_1', \cdots, r_b'\}$. However, the receiver will learn which bin each item in $X \setminus Y$ is mapped to, which will leak the information about set X (please refer to [21] for more discussions). Furthermore, like in [21], the receiver will know which subsets of the set Y contain items in $X \cap Y$. To achieve the enhanced functionality $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$, we leverage Permute+Share (PS) to share $\{r'\}_{i\in[b]}$ while permuting it by using a random permutation π only known by the sender, i.e., $s_i^1 \oplus s_i^2 = r_{\pi(i)}'$. Finally, the sender calculates $c_i = X_C[\pi(i)] \oplus r_{\pi(i)} \oplus s_i^1$ for all $i \in [b]$, then the

Functionality $\mathcal{F}_{\mathsf{eqOTe}}$

1. Wait for input $\{(x_{1,0},x_{1,1}),(x_{2,0},x_{2,1}),\cdots,(x_{m,0},x_{m,1})\}$ and $\boldsymbol{b}^0=(b_1^0,b_2^0,\cdots,b_m^0)$, where $b_i^0\in\{0,1\}$ and $x_{i,j}\in\{0,1\}^\ell$ from the sender P_0;
2. Wait for input $\boldsymbol{b}^1=(b_1^1,b_2^1,\cdots,b_m^1)$ from the receiver P_1 where $b_i^1\in\{0,1\}$;
3. Send $\langle\mathsf{Request}\rangle$ to the simulator Sim;
4. Upon receiving $\langle\mathsf{Response},\mathsf{OK}\rangle$ from Sim, output $\{x_{i,b_i^0\oplus b_i^1}\}_{i\in[m]}$ to P_1, and $\mathsf{Finished}$ to P_0.

Figure 13: Equality Oblivious Transfer Extension Functionality.

receiver recovers $X\setminus Y$ by using $\{s_1^2,\cdots,s_b^2\}$. Note that the receiver can not learn the corresponding bin of each item in $X\setminus Y$ without knowing the permutation π. Some earlier works [7,15,23] can be used for securely realizing $\mathcal{F}_{\mathsf{PS}}$. These solutions all have computation/communication complexity $O(n\log n)$. Therefore, after optimization, the overall cost of our protocol is $O(\gamma n+n+n\log n)=O(n\log n)$.

We can see that the above process is actually an encrypted g-RPMT as shown in Figure 10. Specifically, the sender uses $r_{\pi(i)}\oplus s_i^1$ as a one-time secret key to encrypt the item $X_C[\pi(i)]$ as a ciphertext c_i, and the receiver can obtain s_i^2 that is equal to $r_{\pi(i)}\oplus s_i^1$ only when $X_C[\pi(i)]\notin Y$, to decrypt c_i.

It is worth mentioning that our protocol does not incur the security issues as in [21], although we leverage bucketing technique. This is because that for each pair of subsets, our protocol just generates intermediate states not leaking extra information, rather than executing a whole PSU sub-protocol where a subset of union is generated.

5.2 New Building Blocks

As mentioned before, our protocol $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ is based on a new building block called "batched Equality-Conditional Randomness Generation (bECRG)". In this section, we define the functionality of bECRG, denoted as $\mathcal{F}_{\mathsf{bECRG}}$. To design protocol Π_{bECRG} that UC-realize $\mathcal{F}_{\mathsf{bECRG}}$, we also propose another new building block called "Equality Oblivious Transfer extension (eqOTe)". Next, we first introduce eqOTe, and then give the functionality and protocol of bECRG.

Equality Oblivious Transfer extension. "Equality Oblivious Transfer extension (eqOTe)" is a variant of OT extension (OTe) [17]. Roughly speaking, the sender holds m pairs $\{(x_{i,0},x_{i,1})\}_{i\in[m]}$ and the receiver holds m bits $\{b_i^1\}_{i\in[m]}$. Through OT extension, the receiver obtains $\{x_{i,b_i^1}\}_{i\in[m]}$ by using only κ base OTs, where $m\gg\kappa$. In eqOTe, the sender additionally holds m bits $\{b_i^0\}_{i\in[m]}$, and the receiver obtains $\{x_{i,b_i^0\oplus b_i^1}\}_{i\in[m]}$. An eqOTe can be easily obtained from an OTe. Specifically, the sender sets $a_{i,b_i^0}=x_{i,0}$ and $a_{i,1\oplus b_i^0}=x_{i,1}$.

Protocol Π_{eqOTe}

Parameters:
- An OT extension protocol Π_{OTe};

Inputs:
- The sender P_0: $\{(x_{1,0},x_{1,1}),(x_{2,0},x_{2,1}),\cdots,(x_{m,0},x_{m,1})\}$ and $\boldsymbol{b}^0=(b_1^0,b_2^0,\cdots,b_m^0)$ where $b_i^0\in\{0,1\}$ and $x_{i,j}\in\{0,1\}^\ell$;
- The receiver P_1: $\boldsymbol{b}^1=(b_1^1,b_2^1,\cdots,b_m^1)$ where $b_i^1\in\{0,1\}$;

Protocol:
1. Sender P_0 sets $a_{i,b_i^0}=x_{i,0}$ and $a_{i,1\oplus b_i^0}=x_{i,1}$;
2. The parties invoke Π_{OTe}, where P_0 acts as the sender with input $\{(a_{i,0},a_{i,1})\}_{i\in[m]}$ and P_1 acts as the receiver with input $\boldsymbol{b}^1$, and P_1 can obtain $\{a_{i,b_i^1}\}_{i\in[m]}$. (If $b_i^0=b_i^1$, $a_{i,b_i^1}=a_{i,b_i^0}=x_{i,0}$, else $a_{i,b_i^1}=a_{i,b_i^0\oplus 1}=x_{i,1}$.)

Figure 14: Equality Oblivious Transfer Extension Protocol.

Then, the two parties perform OTe with $\{(a_{i,0},a_{i,1})\}_{i\in[m]}$ and $\{b_i^0\}_{i\in[m]}$ as inputs, respectively. Obviously, through OTe, if $b_i^1=b_i^0$ (i.e., $b_i^0\oplus b_i^1=0$), the receiver can obtain $a_{i,b_i^1}=a_{i,b_i^0}=x_{i,0}$, otherwise ($b_i^1=b_i^0\oplus 1$), the receiver can obtain $a_{i,b_i^1}=a_{i,b_i^0\oplus 1}=x_{i,1}$. We give the functionality $\mathcal{F}_{\mathsf{eqOTe}}$ and protocol Π_{eqOTe} in Figure 13 and Figure 14, respectively.

Batched Equality-Conditional Randomness Generation. Two parties P_0 and P_1 input strings t and t', respectively, and P_0 additionally inputs r. "Equality-Conditional Randomness Generation (ECRG)" generates another string r' to P_1 such that if $t\neq t'$, $r=r'$, otherwise, r' is a random string. In Figure 15, we give the functionality $\mathcal{F}_{\mathsf{bECRG}}$ of a batched version, where m pairs $\{t_i,t_i'\}_{i\in[m]}$ are as input, and $\{r_i'\}_{\in[m]}$ are output to P_1 based on whether $t_i=t_i'$.

We design protocol Π_{bECRG} (shown in Figure 16) by using $\mathcal{F}_{\mathsf{eqOTe}}$ and $\mathcal{F}_{\mathsf{PET}}$ (see Figure 4) as building blocks. More specifically, for each pair (t_i,t_i'), the two parties P_0 and P_1 invoke $\mathcal{F}_{\mathsf{PET}}$ and obtain b_i^0 and b_i^1 respectively, such that if $t_i=t_i'$, $b_i^0\oplus b_i^1=0$, otherwise, $b_i^0\oplus b_i^1=1$. To realize the functionality $\mathcal{F}_{\mathsf{bECRG}}$ (i.e., if $t_i\neq t_i'$, $r_i'=r_i$, otherwise, r_i' is a random string), P_0 sets $x_{i,0}$ as a random string and $x_{i,1}=r_i$, and the two parties invoke $\mathcal{F}_{\mathsf{eqOTe}}$ such that if $b_i^0\oplus b_i^1=0$, P_0 obtains $x_{i,0}$ (namely, a random string), otherwise, P_0 obtains $x_{i,1}=r_i$. We show the security of Π_{bECRG} in Theorem 5.1.

Theorem 5.1. *The protocol Π_{bECRG} shown in Figure 16) UC-realizes the functionality $\mathcal{F}_{\mathsf{bECRG}}$ (as in Figure 15) in the $\{\mathcal{F}_{\mathsf{PET}},\mathcal{F}_{\mathsf{eqOTe}}\}$-hybrid model, against static, semi-honest adversaries.*

Proof. We will show that for any adversary $\mathcal{A}$, we can construct a simulator Sim that can simulate the view of the corrupted P_0 and the corrupted P_1, such that any PPT environment $\mathcal{E}$ cannot distinguish the execution in the ideal world from that in the real world.

Functionality $\mathcal{F}_{\mathsf{bECRG}}$

Parameters:

- The functionality interacts with two parties, P_0 and P_1, and the simulator Sim;
- Let ℓ_1 be the bit-length of each input items, and ℓ_2 be the bit-length of each output items;

Functionality:

0. Initialize an ideal state $\mathsf{state}_{\mathsf{U}} = \emptyset$ for party U where $\mathsf{U} \in \{P_0, P_1\}$; if U is corrupted, the simulator Sim is allowed to access U's state $\mathsf{state}_{\mathsf{U}}$;
1. Upon receiving input $\{t_1, \cdots, t_m\}$ and $\{r_1, \cdots, r_m\}$ from P_0 where $t_i \in \{0,1\}^{\ell_1}$ and $r_i \in \{0,1\}^{\ell_2}$, update state $\mathsf{state}_{P_0} = \langle \{t_1, \cdots, t_m\}, \{r_1, \cdots, r_m\} \rangle$, and send $\langle \mathsf{Request}, P_0 \rangle$ to the simulator Sim;
2. Upon receiving input $\{t'_1, \cdots, t'_m\}$ from P_1 where $t'_i \in \{0,1\}^{\ell_1}$, update state $\mathsf{state}_{P_1} = \langle \{t'_1, \cdots, t'_m\} \rangle$, and send $\langle \mathsf{Request}, P_1 \rangle$ to the simulator Sim;
3. Upon receiving $\langle \mathsf{Response}, \mathsf{OK} \rangle$ from Sim, if $t_i \neq t'_i$, set $r'_i = r_i$, otherwise, randomly choose $r'_i \xleftarrow{\$} \{0,1\}^{\ell_2}$;
4. Add $\langle \{r'_1, \cdots, r'_m\} \rangle$ to P_1's state_{P_1};
5. Output $\{r'_1, \cdots, r'_m\}$ to P_1.

Figure 15: Batched Equality-Conditional Randomness Generation Functionality.

Corrupted P_0: Simulator Sim simulates a real execution in which P_0 is corrupted. Since $\mathcal{A}$ is semi-honest, Sim can obtain the input $\{t_1, \cdots, t_m\}$ and $\{r_1, \cdots, r_m\}$ of P_0 directly, and externally send $\{t_1, \cdots, t_m\}$ and $\{r_1, \cdots, r_m\}$ to $\mathcal{F}_{\mathsf{bECRG}}$ and then receives $\langle \mathsf{Request}, P_0 \rangle$. When receiving t_i from $\mathcal{A}$, Sim randomly selects $b_i^0 \xleftarrow{\$} \{0,1\}$, and simulates the execution of Π_{PET}. When receiving $\{(x_{i,0}, x_{i,1})\}_{i \in [m]}$ and $\boldsymbol{b}^0$, the input of Π_{eqOTe}, from $\mathcal{A}$, Sim simulates the execution of Π_{eqOTe}. Finally, Sim sends $\langle \mathsf{Response}, \mathsf{OK} \rangle$ to $\mathcal{F}_{\mathsf{bECRG}}$.

We argue that the outputs of Sim are indistinguishable from the real view of P_0 by the following hybrids:

Hyb_0: P_0's view in the real protocol.

Hyb_1: Same as Hyb_0 except that the output of Π_{PET} is replaced by b_i^0 chosen by Sim, and Sim runs the $\mathcal{F}_{\mathsf{PET}}$ simulator to produce the simulated view for P_0. The security of protocol Π_{PET} guarantees the view in simulation is computationally indistinguishable from the view in the real protocol.

Hyb_2: Same as Hyb_1 except that Sim runs the $\mathcal{F}_{\mathsf{eqOTe}}$ simulator to produce the simulated view for P_0. The security of protocol Π_{eqOTe} guarantees the view in simulation is computationally indistinguishable from the view in Hyb_1. The hybrid is the view output by Sim.

Corrupted P_1: Simulator Sim simulates a real execution in which P_1 is corrupted. Since $\mathcal{A}$ is semi-honest, Sim can obtain the input $\{t'_1, \cdots, t'_m\}$ of P_1 directly, and externally send $\{t'_1, \cdots, t'_m\}$ to $\mathcal{F}_{\mathsf{bECRG}}$ and then receives $\langle \mathsf{Request}, P_1 \rangle$. When receiving $\{t'_1, \cdots, t'_m\}$ from $\mathcal{A}$, Sim randomly selects b_i^1, and simulates the execution of Π_{PET}. Once receiving $\boldsymbol{b}^1$, the input of Π_{eqOTe}, from $\mathcal{A}$, Sim sends $\langle \mathsf{Response}, \mathsf{OK} \rangle$ to $\mathcal{F}_{\mathsf{bECRG}}$ and obtains $\{r'_1, \cdots, r'_m\}$. Finally, Sim simulates the execution of Π_{eqOTe} with $\{r'_1, \cdots, r'_m\}$ as output.

Protocol Π_{bECRG}

Inputs:

- P_0: set $\{t_1, \cdots, t_m\}$ and set $\{r_1, \cdots, r_m\}$ where $t_i \in \{0,1\}^{\ell_1}$ and $r_i \in \{0,1\}^{\ell_2}$;
- P_1: set $\{t'_1, \cdots, t'_m\}, t'_i \in \{0,1\}^{\ell_1}$;

Protocol:

- For $i \in [m]$:
  - P_0 and P_1 invoke $\mathcal{F}_{\mathsf{PET}}$ (see Figure 4):
    - P_0 inputs t_i, and P_1 inputs t'_i;
    - P_0 obtains b_i^0, and P_1 obtains b_i^1;
  - P_0 chooses $x_{i,0} \xleftarrow{\$} \{0,1\}^{\ell_2}$ and sets $x_{i,1} = r_i$;
- P_0 and P_1 invoke $\mathcal{F}_{\mathsf{eqOTe}}$ (see Figure 13):
  - P_0 inputs $\{(x_{1,0}, x_{1,1}), (x_{2,0}, x_{2,1}), \cdots, (x_{m,0}, x_{m,1})\}$ and $\boldsymbol{b}^0 = (b_1^0, b_2^0, \cdots, b_m^0)$, and P_1 inputs $\boldsymbol{b}^1 = (b_1^1, b_2^1, \cdots, b_m^1)$;
  - P_1 obtains $\{r'_1, \cdots, r'_m\}$, where $r'_i = x_{i, b_i^0 \oplus b_i^1}$;
- P_1 outputs $\{r'_1, \cdots, r'_m\}$.

Figure 16: Batched Equality-Conditional Randomness Generation Protocol.

We argue that the outputs of Sim are indistinguishable from the real view of P_1 by the following hybrids:

Hyb_0: P_1's view in the real protocol.

Hyb_1: Same as Hyb_0 except that the output of Π_{PET} is replaced by b_i^1 chosen by Sim, and Sim runs the $\mathcal{F}_{\mathsf{PET}}$ simulator to produce the simulated view for P_1. The security of protocol Π_{PET} guarantees the view in simulation is computationally indistinguishable from the view in the real protocol.

Hyb_2: Same as Hyb_1 except that the output of Π_{eqOTe} is replaced by $\{r'_1, \cdots, r'_m\}$ output by $\mathcal{F}_{\mathsf{bECRG}}$ and Sim runs the $\mathcal{F}_{\mathsf{eqOTe}}$ simulator to produce the simulated view for P_1. Regardless of whether r'_i is generated by Π_{eqOTe} or $\mathcal{F}_{\mathsf{bECRG}}$, it would be equal to r_i when $t'_i = t_i$, and be pseudorandom when $t'_i \neq t_i$. The security of protocol Π_{eqOTe} guarantees the view in simulation is computationally indistinguishable from the view in Hyb_1. The hybrid is the view output by Sim. □

5.3 The Details of Protocol $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$

In this section, we detail our PSU protocol $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ (see Figure 17). As explained in Section 5.1, to achieve the enhanced functionality $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$, the core idea of $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ is to design the encrypted RPMT as in the AHE-based PSU: Each item $x_i \in X$ is encrypted by a one-time secret key r_i; if $x_i \in X \setminus Y$, the receiver will obtain r_i, otherwise, the receiver will obtain another random string $r'_i \neq r'_i$, and thus cannot learn x_i. Due to the fact that our $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ only relies on symmetric-key operations other than base OTs, our $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ is much more efficient than the AHE-based PSU.

Protocol $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$

Parameters:

- Hash functions $h_1,\cdots,h_\gamma : \{0,1\}^{\ell_1} \to [b]$;
- A Cuckoo hash table based on $h_1,\cdots,h_\gamma$, with $b = \varepsilon \cdot n_1$ bins, stash size $s = 0$;
- A simple hash table based on $h_1,\cdots,h_\gamma$, with $b = \varepsilon \cdot n_1$ bins and bin size ρ, where $\rho = O(\log(\gamma n_2))$;

Inputs:

- Sender $\mathcal{S}$: set $X = \{x_1,\cdots,x_{n_1}\}, x_i \in \{0,1\}^{\ell_1}$;
- Receiver $\mathcal{R}$: set $Y = \{y_1,\cdots,y_{n_2}\}, y_i \in \{0,1\}^{\ell_1}$;

Protocol:

1. $\mathcal{S}$ inserts set X into the Cuckoo hash table, and fills empty bins with the dummy item d, then denotes the filled Cuckoo hash table as X_C and the item in i-th bin as $X_C[i]$; $\mathcal{R}$ inserts set Y into the simple hash table, then denotes the set of items in the i-th bin as $Y_S[i]$;
2. $\mathcal{S}$ randomly chooses t'_i from $\{0,1\}^{\ell_2}$ for all $i \in [b]$;
3. $\mathcal{S}$ and $\mathcal{R}$ invoke $\mathcal{F}_{\mathsf{OPPRF}}$ (see Figure 3):
   - $\mathcal{S}$ acts as P_1 with input $\{X_C[i]\}_{i\in[b]}$, and $\mathcal{R}$ acts as P_0 with input $\{(Y_S[i][1],t'_i),\cdots,(Y_S[i][\rho],t'_i)\}_{i\in[b]}$;
   - $\mathcal{R}$ obtains $\{k_i\}_{i\in[b]}$ and hint, and $\mathcal{S}$ obtains hint and $\{F(k_i,\mathsf{hint},X_C[i]))\}_{i\in[b]}$ (note that if $X_C[i] \in Y_S[i]$, $F(k_i,\mathsf{hint},X_C[i]) = t'_i$, otherwise, $F(k_i,\mathsf{hint},X_C[i]) \neq t'_i$);
4. $\mathcal{S}$ and $\mathcal{R}$ invoke $\mathcal{F}_{\mathsf{bECRG}}$ (see Figure 15):
   - $\mathcal{S}$ randomly chooses $r_i \xleftarrow{\$} \{0,1\}^{\ell_1}$ for $i \in [b]$;
   - $\mathcal{S}$ acts as P_0 with input $\{F(k_i,\mathsf{hint},X_C[i])\}_{i\in[b]}$ and $\{r_1,\cdots,r_b\}$, and $\mathcal{R}$ acts as P_1 with input $\{t'_1,\cdots,t'_b\}$;
   - $\mathcal{R}$ obtains $\{r'_1,\cdots,r'_b\}$ (if $F(k_i,\mathsf{hint},X_C[i]) = t'_i$, $r'_i \neq r_i$, otherwise, $r'_i = r_i$);
5. $\mathcal{S}$ and $\mathcal{R}$ invoke $\mathcal{F}_{\mathsf{PS}}$ (see Figure 5):
   - $\mathcal{R}$ acts as P_0 with input set $\{r'_1,\cdots,r'_b\}$, and $\mathcal{S}$ acts as P_1 with a random permutation π;
   - $\mathcal{S}$ and $\mathcal{R}$ obtains the shuffled share sets $\{s^1_1,s^1_2,\cdots,s^1_b\}$ and $\{s^2_1,s^2_2,\cdots,s^2_b\}$ respectively, where $s^1_i \oplus s^2_i = r'_{\pi(i)}$;
6. $\mathcal{S}$ performs permutation π on set $\{X_C[1]\oplus r_1, X_C[2]\oplus r_2,\cdots,X_C[b]\oplus r_b\}$ and obtains $\{e_1,e_2,\cdots,e_b\}$ where $e_i = X_C[\pi(i)] \oplus r_{\pi(i)}$;
7. For $i \in [b]$:
   - $\mathcal{S}$ sends $c_i = e_i \oplus s^1_i$ to $\mathcal{R}$;
   - If $c_i \oplus s^2_i \neq d$, $\mathcal{R}$ sets $Z = Z \cup \{c_i \oplus s^2_i\}$;
8. $\mathcal{R}$ outputs $Y \cup Z$, and $\mathcal{S}$ outputs Finished;

Figure 17: A new PSU protocol that can realize $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$ and only relies on symmetric-key techniques (ignoring base OTs).

The sender and receiver first insert their sets X and Y into a Cuckoo hash table and a simple hash table, respectively, and the two filled tables are denoted as X_C and Y_S. Each bin i of the Cuckoo hash table contains only one item $X_C[i]$, whereas each bin i of the simple hash table contains a set $Y_S[i]$. By invoking $\mathcal{F}_{\mathsf{OPPRF}}$, the receiver can set the PRF values of the items in $Y_S[i]$ as the same t'_i. If $X_C[i] \in Y_S[i]$, the sender will obtain $F(k_i,\mathsf{hint},X_C[i]) = t'_i$, otherwise, $F(k_i,\mathsf{hint},X_C[i]) \neq t'_i$. Then, the sender randomly chooses r_i that is used to encrypt $X_C[i]$ for all $i \in [b]$. Through $\mathcal{F}_{\mathsf{bECRG}}$, if $F(k_i,\mathsf{hint},X_C[i]) \neq t'_i$ (i.e., $X_C[i] \notin Y_S[i]$), the receiver can obtain $r'_i = r_i$ and thus learning $X_C[i]$ later, otherwise, the receiver can obtain $r'_i \neq r_i$. By invoking $\mathcal{F}_{\mathsf{PS}}$, $\{r'_1,\cdots,r'_b\}$ are shuffled and shared into $\{s^1_1,\cdots,s^1_b\}$ and $\{s^2_1,\cdots,s^2_b\}$ such that $s^1_i \oplus s^2_i = r'_{\pi(i)}$. Finally, the sender sends $\{X_C[\pi(i)] \oplus r_{\pi(i)} \oplus s^1_i\}_{i\in[b]}$, and the receiver calculates $X_C[\pi(i)] \oplus r_{\pi(i)} \oplus s^1_i \oplus s^2_i$ for all $i \in [b]$. Obviously, only when $r_{\pi(i)} = s^1_i \oplus s^2_i$ (i.e., $X_C[\pi(i)] \notin Y_S[i]$), the receiver can obtain $X_C[\pi(i)]$.

The correctness of $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ shown in Figure 17 is guaranteed unless collisions occur. The collisions can only come from Π_{OPPRF}, i.e., $X_C[i] \notin Y_S[i]$ but $F(k_i,\mathsf{hint},X_C[i]) = t'_i$. By setting the output length ℓ_2 of $F(k,\cdot,\cdot)$ as $\lambda + \log(\varepsilon n_1)$, we can bound the probability of collision happening to $2^{-\lambda}$, where λ is the statistical security parameter. Next, we state the security of $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ in Theorem 5.2.

Theorem 5.2. *The protocol Π_{PSU}^{bECRG} shown in Figure 17 UC-realizes the functionality $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$ (as in Figure 11) in the $\{\mathcal{F}_{\mathsf{OPPRF}},\mathcal{F}_{\mathsf{bECRG}},\mathcal{F}_{\mathsf{PS}}\}$-hybrid model, against static, semi-honest adversaries.*

Proof. We will show that for any adversary $\mathcal{A}$, we can construct a simulator Sim that can simulate the view of the corrupted sender and the corrupted receiver, such that any PPT environment $\mathcal{E}$ cannot distinguish the execution in the ideal world from that in the real world.

Corrupted Sender: Simulator Sim simulates a real execution in which the sender $\mathcal{S}$ is corrupted. Since $\mathcal{A}$ is semi-honest, Sim can obtain the input X of $\mathcal{S}$ directly, and externally send the set X to $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$ and then receives $\langle \mathsf{Request}, \mathcal{S}\rangle$. When receiving $X_C[i]$ from $\mathcal{A}$, Sim randomly selects $t_i \xleftarrow{\$} \{0,1\}^{\ell_2}$ and hint, and simulates the execution of Π_{OPPRF}. Once receiving $\{t_1,\cdots,t_b\}$ and $\{r_1,\cdots,r_b\}$, the input of Π_{bECRG}, from $\mathcal{A}$, Sim simulates the execution of Π_{bECRG}. Upon receiving a permutation π from $\mathcal{A}$, Sim checks if it is a permutation of b items. If so, Sim randomly selects $\{s^1_1,\cdots,s^1_b\}$ where $s^1_i \in \{0,1\}^{\ell_1}$, and simulates the execution of Π_{PS}. After receiving $\{c_1,\cdots,c_b\}$, Sim sends $\langle \mathsf{Response}, \mathsf{OK}\rangle$ to $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$.

We argue that the outputs of Sim are indistinguishable from the real view of $\mathcal{S}$ by the following hybrids:

Hyb_0: $\mathcal{S}$'s view in the real protocol.

Hyb_1: Same as Hyb_0 except that the output of Π_{OPPRF} is replaced by (hint, t_i) chosen by Sim, and Sim runs the $\mathcal{F}_{\mathsf{OPPRF}}$ simulator to produce the simulated view for $\mathcal{S}$. The security of protocol Π_{OPPRF} guarantees the view in simulation is computationally indistinguishable from the view in the real protocol.

Hyb_2: Same as Hyb_1 except that Sim runs the $\mathcal{F}_{\mathsf{bECRG}}$ simulator to produce the simulated view for $\mathcal{S}$. The security of protocol Π_{bECRG} guarantees the view in simulation is computationally indistinguishable from the view in Hyb_1.

Hyb_3: Same as Hyb_2 except that the output of Π_{PS} is replaced by $\{s^1_1,\cdots,s^1_b\}$ chosen by Sim, and Sim runs the $\mathcal{F}_{\mathsf{PS}}$

simulator to produce the simulated view for $\mathcal{S}$. The security of protocol Π_{PS} guarantees the view in simulation is computationally indistinguishable from the view in Hyb_2. The hybrid is the view output by Sim.

Note that after $\mathcal{A}$ sends $\{c_1,\cdots,c_b\}$, $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$ receives $\langle \mathsf{Response},\mathsf{OK}\rangle$ from Sim and outputs $X\cup Y$ to the receiver $\mathcal{R}$. This guarantee that the receiver $\mathcal{R}$ outputs $X\cup Y$ after the sender $\mathcal{S}$ sends $\{c_1,\cdots,c_b\}$ in both worlds.

Corrupted Receiver: Simulator Sim simulates a real execution in which the receiver $\mathcal{R}$ is corrupted. Since $\mathcal{A}$ is semi-honest, Sim can obtain the input Y of $\mathcal{R}$ directly, and externally send the set Y to $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$ and then receives $\langle \mathsf{Request},\mathcal{R}\rangle$. When receiving $\{(Y_S[i][1],t_i'),\cdots,(Y_S[i][\rho],t_i')\}$ from $\mathcal{A}$, Sim randomly selects (k_i,hint), and simulates the execution of Π_{OPPRF}. Once receiving $\{t_1',\cdots,t_b'\}$, the input of Π_{bECRG}, from $\mathcal{A}$, Sim randomly selects $\{r_1',\cdots,r_b'\}$ where $r_i \xleftarrow{\$} \{0,1\}^{\ell_1}$ and simulates the execution of Π_{bECRG}. Upon receiving $\{r_1',\cdots,r_b'\}$ from $\mathcal{A}$, Sim randomly selects $\{s_1^2,\cdots,s_b^2\}$ where $s_i^2\in\{0,1\}^{\ell_1}$, and simulates the execution Π_{PS}. Sim sends $\langle \mathsf{Response},\mathsf{OK}\rangle$ to $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$. After receiving $Z=X\cup Y$ from $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$, Sim calculates $X'=X\setminus Y=Z\setminus Y$ and randomly selects a subset S' of $\{s_1^2,\cdots,s_b^2\}$, where $|S'|=|X\setminus Y|$. For each item $s_i'\in S'$, Sim sets $c_i=X'[i]\oplus s_i'$. Finally, Sim randomly chooses $c_i\xleftarrow{\$}\{0,1\}^{\ell_1}$ for $i\in\{|S'|+1,|S'|+2,\cdots,b\}$ and sends $\{c_1,\cdots,c_b\}$ to $\mathcal{A}$ in random order.

We argue that the outputs of Sim are indistinguishable from the real view of $\mathcal{R}$ by the following hybrids:

Hyb_0: $\mathcal{R}$'s view in the real protocol.

Hyb_1: Same as Hyb_0 except that the output of Π_{OPPRF} is replaced by (hint,k_i) chosen by Sim, and Sim runs the $\mathcal{F}_{\mathsf{OPPRF}}$ simulator to produce the simulated view for $\mathcal{R}$. The security of protocol Π_{OPPRF} guarantees the view in simulation is computationally indistinguishable from the view in Hyb_0.

Hyb_2: Same as Hyb_1 except that the output of Π_{bECRG} is replaced by the $\{r_1',\cdots,r_b'\}$ chosen by Sim, and Sim runs the $\mathcal{F}_{\mathsf{bECRG}}$ simulator to produce the simulated view for $\mathcal{S}$. The security of protocol Π_{bECRG} guarantees the view in simulation is computationally indistinguishable from the view in Hyb_1.

Hyb_3: Same as Hyb_2 except that the output of Π_{PS} is replaced by $\{s_1^2,\cdots,s_b^2\}$ chosen by Sim, and Sim runs the $\mathcal{F}_{\mathsf{PS}}$ simulator to produce the simulated view for $\mathcal{S}$. The corresponding $\{c_1,\cdots,c_b\}$ are also changed according to $\{s_1^2,\cdots,s_b^2\}$. The security of protocol Π_{PS} and the random permutation π guarantee the view in simulation is computationally indistinguishable from the view in Hyb_2. The hybrid is the view output by Sim.

Note that after $\mathcal{A}$ receives $\{s_1^2,\cdots,s_b^2\}$, $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$ receives $\langle \mathsf{Response},\mathsf{OK}\rangle$ from Sim and outputs Finished to the sender $\mathcal{S}$. This guarantees that no matter whether in the ideal world or the real world, the sender $\mathcal{S}$ outputs Finished after completing the interaction with the receiver. □

Table 1: The theoretical complexities of $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$

	Π_{OPPRF}	Π_{bECRG}	Π_{PS}	Ciphertexts
Comp.	$O(\gamma n_2+\varepsilon n_1)$	$O(\varepsilon n_1)$	$O(\varepsilon n_1\log(\varepsilon n_1))$	$O(\varepsilon n_1)$
Comm.	$O(\gamma n_2)$	$O(\varepsilon n_1)$	$O(\varepsilon n_1\log(\varepsilon n_1))$	$O(\varepsilon n_1)$

1. Here, n_1 is the sender's set size and n_2 is the receiver's set size.
2. The Cuckoo hash table and the simple hash table use γ hash functions and εn_1 bins.

5.4 Cost Analysis

We describe the theoretical complexities of our new construction $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ in Table 1; here, we assume that the sender's set size is n_1 and the receiver's set size is n_2. Recall that in $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ (see Figure 17), the sender's set and the receiver's set are initially inserted into a Cuckoo hash table and a simple hash table, respectively, using γ hash functions, and the number of bins is εn_1. After insertion, the Cuckoo hash table contains εn_1 items, and the simple hash table includes γn_2 items. Then, the two parties proceed with the subsequent steps on the two tables, which involve performing Π_{OPPRF}, Π_{bECRG}, Π_{PS}, as well as computing and sending ciphertexts.

We use the batched OPPRF in [6] that can hide the number of items in each bin, to implement Π_{OPPRF}. Thus, padding each bin in the simple hash table up to the maximum bin size, is not required. Specifically, the complexity for hint computation and communication is linear (i.e., $O(\gamma n_2)$) and the sender additionally needs $O(\varepsilon n_1)$ to compute the PRF values. As in Figure 16, our Π_{bECRG} consists of Π_{PET} and Π_{eqOTe}, both exhibiting linear complexity; thus the computation and communication costs of Π_{bECRG} are $O(\varepsilon n_1)$. We use the construction in [23] to implement Π_{PS}, leading to $O(\varepsilon n_1\log(\varepsilon n_1))$ costs. Finally, the sender needs to compute and send a ciphertext for each item in the Cuckoo hash table, and the costs are $O(\varepsilon n_1)$. Overall, the computation and communication complexity of our protocol $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ is $O(n_1\log n_1+n_2)$, making $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ more suitable for balanced sets, i.e., the sizes of the two sets are comparable.

5.5 Performance Evaluation

In this section, we experimentally evaluate our protocol $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ and compare with the previous works.

Benchmarking Environment. We implement our protocol $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ in C++, which is available on GitHub: https://github.com/yanxue820/SecurePSU.git. Our experiments are conducted on a server equipped with two Intel Xeon Silver 4116 CPUs (2.10GHz) and 128GB RAM, running Ubuntu. We evaluate our protocol $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ in two network settings, LAN network with 10Gbps bandwidth and 0.02 ms RTT and WAN network with 100Mbps and 80ms RTT, which are emulated using Linux tc command. We leverage the constructions in [6] to implement Π_{OPPRF} and Π_{PET} (the building block of Π_{bECRG}). We implement Π_{PS} using the

Table 2: Comparisons of total runtime (in seconds) and communication (in MB) between $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ and [10] in WAN (100Mbps bandwidth, 80 ms RTT) and LAN (10Gbps bandwidth, 0.02 ms RTT) settings, where $n_1 = n_2 = n$. The results of [10] and [31] are both sourced from their papers. The implementation of [10] is in Go using 8 threads. The implementation of SKE-PSU [31] is in Java using a single thread; when using the OKVS in [1], the communication and runtime can be improved 2% and 6-9%, respectively. Our protocol $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ is implemented in C++, using a single thread. Setup in our protocol refers to base OTs and generating triples for PET. Our $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ and [10] can achieve the enhanced functionality $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$, while SKE-PSU [31] can not.

code from [19] that is based on Oblivious Switching Network (OSN) [23]. As for OT extension, we use libOTe library [28].

Parameters. We set the computational security parameter $\kappa = 128$ and the statistical security parameter $\lambda = 40$, and item length is 128 bits. We use $\gamma = 3$ hash functions to insert sets X and Y into the Cuckoo hash table and simple hash table, respectively, and ε for Cuckoo hash table is set as 1.27.

Comparisons. We show performance comparisons with the previous works [10, 31] in Table 2. Before our work, only two AHE-based schemes in [10, 12] that can achieve the enhanced PSU functionality, i.e., $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$. The design by Davidson et al. [10] can be seen as an improvement of the one in [12]. Moreover, only Davidson et al. [10] provided experimental results. Therefore, we compare the performance of our $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ with that of the scheme in [10] in Table 2. We can see that, for $n_1 = n_2 = 2^{18}$, our total runtime is 873.74× faster than that of [10] in the LAN setting, while their implementation is in 8 threads and ours is in a single thread; our total communication cost is 5× less than theirs.

Currently, the PSU by Zhang et al. [31] is the state-of-the-art work for large balanced sets, but it can not achieve the enhanced PSU functionality $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$. Zhang et al. [31] gave two designs: (i) SKE-PSU, using symmetric key techniques, and (ii) PKE-PSU[4], using public key techniques. Given that SKE-PSU demonstrates better performance than PKE-PSU when the Internet speed exceeds 100Mbps, we compare the performance of our $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ with that of SKE-PSU in [31] in Table 2. It shows that the performance of our protocol $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ is *comparable to that of SKE-PSU* in the LAN setting. However, the performance of SKE-PSU in the WAN setting is better than ours, due to the less communication cost. In addition, the new OKVS structure designed by Bienstock et al. [1] could be used as a building block to improve the performance of the design in [31]. Specifically, as reported in [1], in a 1Gbps network, the combination can obtain a 16-22% improvement in communication and a 28-40% reduction in runtime compared to PKE-PSU; it also shows a 2% improvement in communication and a 6-9% reduction in runtime compared to SKE-PSU. Nonetheless, it is important to note that the designs in [31] cannot achieve the enhanced PSU functionality $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$, whereas our $\Pi_{\mathsf{PSU}}^{\mathsf{bECRG}}$ can.

To the best of our knowledge, the PSU protocol by Blanton et al. [2] is the only one based on generic MPC techniques, and it can achieve the enhanced PSU functionality $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$. Since its security is guaranteed by the generic MPC techniques, it is out of scope for this work. Nonetheless, here, we still compare the performance of our protocol with that of their scheme. Their paper provided experimental results on small input sets in a three-party and honest majority setting for 32-bit sized elements, using 1Gbps bandwidth. For $n_1 = n_2 = 2^{12}$, their runtime is 24.88s, while ours is 8.42s in the WAN setting. In addition, Kolesnikov et al. [21] calculated the communication cost of [2] for 2PC and 128-bit items; for $n_1 = n_2 = 2^{18}$, its communication cost would be 163208.76MB, which is 282.5× higher than ours.

6 Proofs for Previous Works

In this section, we formally show that the OT-based PSU protocols cannot UC-realize $\mathcal{F}_{\mathsf{ePSU}}^{n_1,n_2}$, whereas the AHE-based PSU protocols can. The proof for OT-based protocols can be naturally extended to the protocol [21] relying on the "split-execute-assemble" paradigm, whose proof can be found in full version [18]. Given that the OT-based design framework is currently mainstream, we define a relaxed PSU functionality $\mathcal{F}_{\mathsf{rPSU}}^{\mathsf{b}}$ to capture its security.

[4] Zhang et al. [31] used PKE-PSU* to represent the version that does not perform point compression.

Protocol $\Pi^{\mathsf{OT}}_{\mathsf{Unified}}$

Inputs:

- Sender $\mathcal{S}$: set $X = \{x_1, \cdots, x_{n_1}\}$, where $x_i \in \{0,1\}^\ell$
- Receiver $\mathcal{R}$: set $Y = \{y_1, \cdots, y_{n_2}\}$, where $y_i \in \{0,1\}^\ell$;

Protocol:

1. The sender $\mathcal{S}$ randomly permutes the set X into the set X^*;
2. The two players $\mathcal{S}$ and $\mathcal{R}$ invoke the "generalized Reversed Private Membership Test" $\mathcal{F}_{\text{g-RPMT}}$ (see Figure 1):
   - $\mathcal{S}$ acts as sender with input set X^*;
   - $\mathcal{R}$ acts as receiver with input set Y;
   - $\mathcal{R}$ obtains output b_i for each $i \in [n_1]$;
3. $\mathcal{R}$ initializes set $Z = Y$;
4. The two players $\mathcal{S}$ and $\mathcal{R}$ **simultaneously**[a] invoke n_1 number of $\mathcal{F}_{\mathsf{OT}}$ (see Figure 2) instances. In the i-th instance, where $i \in [n_1]$,
   - $\mathcal{R}$ acts as receiver with input b_i;
   - $\mathcal{S}$ acts as sender with input $(X^*[i], \perp)$;
   - If $\mathcal{R}$ obtains $X^*[i]$, $\mathcal{R}$ sets $Z = Z \cup \{X^*[i]\}$;
5. $\mathcal{R}$ outputs Z, and $\mathcal{S}$ outputs Finished.

[a] Note that, in practice, the n_1 number of OT instances can be implemented by OT extension [17], so that the receiver can obtain all the items in $X \setminus Y$ at the same time.

Figure 18: The design framework unifying PSU protocols in [1,8,13,19,21,29,31]. Here, the protocol in [21] is the basic scheme without using "split-execute-assemble" paradigm.

6.1 OT-based PSU Protocols

We unify the OT-based protocols [1, 8, 13, 21, 29, 31] into the same framework $\Pi^{\mathsf{OT}}_{\mathsf{Unified}}$ as shown in Figure 18. Next, we show that the protocols unified in Figure 18 cannot UC-realize the new enhanced PSU functionality $\mathcal{F}^{n_1,n_2}_{\mathsf{ePSU}}$. Formally, the security is stated in Theorem 6.1.

Theorem 6.1. *The protocol following the framework $\Pi^{\mathsf{OT}}_{\mathsf{Unified}}$ in Figure 18 cannot UC-realize functionality $\mathcal{F}^{n_1,n_2}_{\mathsf{ePSU}}$ (as in Figure 11) in the $\{\mathcal{F}_{\text{g-RPMT}}, \mathcal{F}_{\mathsf{OT}}\}$-hybrid model, against static, semi-honest adversaries.*

Proof. To complete the proof, we first construct an environment $\mathcal{E}$. Then we show that for any simulator Sim, this constructed $\mathcal{E}$ can tell the difference of the execution in the real world from that in the ideal world, with non-negligible probability.

Construction of environment $\mathcal{E}$. The environment $\mathcal{E}$ chooses sets X and Y as the inputs of the sender and the receiver, respectively. Since the environment $\mathcal{E}$ knows both X and Y, $\mathcal{E}$ of course knows the size of $X \cap Y$, denoted as m. In other words, the environment $\mathcal{E}$ knows the number of 1's in $\{b_1, \cdots, b_{n_1}\}$ is m. The environment $\mathcal{E}$ instructs the dummy adversary $\mathcal{A}$ to corrupt the receiver at the beginning of the protocol execution, and then chooses a time t. Finally, if the number of 1's in $\{b_1, \cdots, b_{n_1}\}$ reported by the dummy adversary $\mathcal{A}$ is m and the message Finished has not been reported by the honest sender $\mathcal{S}$ at the time t, the environment $\mathcal{E}$ outputs 1, otherwise, outputs 0.

The real world execution. In the real world, the Π_{OT} sub-protocol instances will not be executed until the execution of $\Pi_{\text{g-RPMT}}$ sub-protocol instance is finished. Therefore, there is a time t when the receiver obtains $\{b_1, \cdots, b_{n_1}\}$ but not the items in the set $X \setminus Y$. Note that, the receiver is corrupted and under the control by the semi-honest real world adversary $\mathcal{A}$, the bit set $\{b_1, \cdots, b_{n_1}\}$ must be reported to the environment at the time t. Note also that, the protocol execution has not been finished, the honest sender $\mathcal{S}$ is *not supposed to return* the message Finished to the environment $\mathcal{E}$ at the time t.

The ideal world execution. In the ideal world, since the (dummy) receiver is corrupted, the simulator Sim is allowed to access the ideal state $\mathsf{state}_{\mathcal{R}} = \langle Y \rangle$. After receiving from the functionality $\mathcal{F}^{n_1,n_2}_{\mathsf{ePSU}}$ the message $\langle \mathsf{Request}, \mathcal{R} \rangle$, to simulate $\{b_1^{\mathsf{ideal}}, \cdots, b_{n_1}^{\mathsf{ideal}}\}$, the simulator Sim *must* face the following two simulation strategies:

- *Do send $\langle \mathsf{Response}, OK \rangle$ to the functionality $\mathcal{F}^{n_1,n_2}_{\mathsf{ePSU}}$, immediately.* Note that, now the functionality will update the ideal states into $\mathsf{state}_{\mathcal{S}} = \langle X, \mathsf{Finished} \rangle$ and $\mathsf{state}_{\mathcal{R}} = \langle Y, Z \rangle$, and immediately report Finished to the environment $\mathcal{E}$.
- *Do not send $\langle \mathsf{Response}, OK \rangle$ to the functionality $\mathcal{F}^{n_1,n_2}_{\mathsf{ePSU}}$, immediately.* Note that, now the functionality will **not** update the ideal states into $\mathsf{state}_{\mathcal{S}} = \langle X, \mathsf{Finished} \rangle$ and $\mathsf{state}_{\mathcal{R}} = \langle Y, Z \rangle$; of course, no output Finished will be reported to $\mathcal{E}$ immediately.

Security analysis. Now, we can see, if the simulator follows the first simulation strategy, the environment will tell the difference with probability 1, since in the real world, no output Finished will be reported while there is Finished in the ideal world. If the simulator follows the second simulation strategy, the probability that $\mathcal{E}$ outputs 1 in the real world is 1 except negligible probability. However, in the ideal world, the simulator Sim does not know m. The probability that there are m 1's in $\{b_1^{\mathsf{ideal}}, \cdots, b_{n_1}^{\mathsf{ideal}}\}$ is $1/n_1$, which is far less than 1 when n_1 is large enough. Thus, the probability that $\mathcal{E}$ outputs 1 in the ideal world is far less than 1. Therefore, $\mathcal{E}$ can distinguish between the two worlds with non-negligible probability.

Note that, all simulations must follow one of the two strategies. Therefore, for all simulators, our constructed environment can tell the difference between the two worlds with non-negligible probability. This completes the proof. □

We define a relaxed PSU ideal functionality $\mathcal{F}^{\mathsf{b}}_{\mathsf{rPSU}}$ in Figure 19 to capture the security of OT-based design framework, and formally show the security in Theorem 6.2.

Theorem 6.2. *The protocol following the framework $\Pi^{\mathsf{OT}}_{\mathsf{Unified}}$ in Figure 18 UC-realizes the functionality $\mathcal{F}^{\mathsf{b}}_{\mathsf{rPSU}}$ (as in Figure 19) in the $\{\mathcal{F}_{\text{g-RPMT}}, \mathcal{F}_{\mathsf{OT}}\}$-hybrid model, against static, semi-honest adversaries.*

Functionality $\mathcal{F}^{\mathsf{b}}_{\mathsf{rPSU}}$

Parameters:

- The functionality interacts with two parties, the sender $\mathcal{S}$ and the receiver $\mathcal{R}$, and the simulator Sim;
- Set size for sender $\mathcal{S}$ is n_1; set size for receiver $\mathcal{R}$ is n_2.

Functionality:

0. Initialize an ideal state $\mathsf{state}_{\mathsf{U}} = \emptyset$ for party U where $\mathsf{U} \in \{\mathcal{S}, \mathcal{R}\}$; if U is corrupted, the simulator Sim is allowed to access to U's state $\mathsf{state}_{\mathsf{U}}$;
1. Upon receiving input $X = \{x_1, \cdots, x_{n_1}\}$ from the sender $\mathcal{S}$, abort if $|X| \neq n_1$; otherwise, update state $\mathsf{state}_{\mathcal{S}} = \langle X \rangle$, and send $\langle \mathsf{Request}, \mathcal{S} \rangle$ to the simulator Sim;
2. Upon receiving input $Y = \{y_1, \cdots, y_{n_2}\}$ from the receiver $\mathcal{R}$, abort if $|Y| \neq n_2$; otherwise, update state $\mathsf{state}_{\mathcal{R}} = \langle Y \rangle$, and send $\langle \mathsf{Request}, \mathcal{R} \rangle$ to the simulator Sim;
3. Upon receiving $\langle \mathsf{Response}, \mathsf{OK} \rangle$ from Sim, send $\langle \mathsf{Request\_If} \rangle$ to the simulator Sim;
4. Upon receiving $\langle \mathsf{Response\_If}, \mathsf{OK} \rangle$ from Sim, for each $i \in [n_1]$, set $b_i = 1$ if $X[i] \in Y$, otherwise set $b_i = 0$, then record $\{b_1, \cdots, b_{n_1}\}$ to the receiver's state $\mathsf{state}_{\mathcal{R}}$ and send $\langle \mathsf{Request\_Item} \rangle$ to Sim;
5. Upon receiving $\langle \mathsf{Response\_Item}, \mathsf{OK} \rangle$ from Sim, compute $Z = X \cup Y$, and record $\langle \mathsf{Finished} \rangle$ and $\langle Z \rangle$ to the sender's sate $\mathsf{state}_{\mathcal{S}}$ and the receiver's state $\mathsf{state}_{\mathcal{R}}$, respectively;
6. Output Z to $\mathcal{R}$, and Finished to $\mathcal{S}$.

Figure 19: A relaxed PSU ideal functionality leaking **set membership** in advance. Compared to the enhanced PSU functionality $\mathcal{F}^{n_1,n_2}_{\mathsf{ePSU}}$ in Figure 11, $\mathcal{F}^{\mathsf{b}}_{\mathsf{rPSU}}$ additionally adds $\{b_1, \cdots, b_{n_1}\}$ into the receiver's state $\mathsf{state}_{\mathcal{R}}$ as shown in steps 3 - 4.

Proof. To prove this theorem, we will show that for any efficient adversary $\mathcal{A}$, we can construct a simulator Sim to properly simulate the view of the corrupted sender and the corrupted receiver, such that any PPT environment $\mathcal{E}$ cannot distinguish between the execution in the ideal world from that in the real world. In particular, according to the modular design of $\Pi^{\mathsf{OT}}_{\mathsf{Unified}}$ from the sub-protocols $\Pi_{\mathsf{g\text{-}RPMT}}$ and Π_{OT}, the simulator Sim can be constructed by invoking the simulator Sim′ in [1, 8, 13, 19, 21, 29, 31].

Corrupted Sender: Simulator Sim first sends the input set X to $\mathcal{F}^{\mathsf{b}}_{\mathsf{rPSU}}$. After receiving $\langle \mathsf{Request\_If} \rangle$ from $\mathcal{F}^{\mathsf{b}}_{\mathsf{rPSU}}$, Sim first invokes Sim′ to simulate the execution of the sub-protocol $\Pi_{\mathsf{g\text{-}RPMT}}$. Then, Sim sends $\langle \mathsf{Response\_If}, \mathsf{OK} \rangle$ to the functionality $\mathcal{F}^{\mathsf{b}}_{\mathsf{rPSU}}$. Once receiving $\langle \mathsf{Request\_Item} \rangle$ from $\mathcal{F}^{\mathsf{b}}_{\mathsf{rPSU}}$, Sim simulates the execution of sub-protocol Π_{OT} by invoking Sim′. When $\mathcal{A}$ sends items in all Π_{OT} instances, Sim sends $\langle \mathsf{Response\_Item}, \mathsf{OK} \rangle$ to $\mathcal{F}^{\mathsf{b}}_{\mathsf{rPSU}}$ and then obtains $\langle \mathsf{Finished} \rangle$ from the sender's state $\mathsf{state}_{\mathcal{S}}$. Compared to the simulator for corrupted sender in [21], [19], [8], [29] or [13], Sim just additionally receives some request messages and additionally sends some response messages. Moreover, due to the request/response messages, the environment $\mathcal{E}$ will receive the honest receiver's output $X \cup Y$ at the same time in the real and ideal worlds. Therefore, Sim can simulate $\mathcal{A}$'s view such that $\mathcal{E}$ cannot distinguish the two worlds.

Corrupted Receiver: Likewise, simulator Sim first sends the input set Y to $\mathcal{F}^{\mathsf{b}}_{\mathsf{rPSU}}$. After receiving $\langle \mathsf{Request\_If} \rangle$ from $\mathcal{F}^{\mathsf{b}}_{\mathsf{rPSU}}$, Sim first invokes Sim′ to simulate the execution of the sub-protocol $\Pi_{\mathsf{g\text{-}RPMT}}$ except for the last step. To simulate the last step of $\Pi_{\mathsf{g\text{-}RPMT}}$, Sim sends $\langle \mathsf{Response\_If}, \mathsf{OK} \rangle$ to the functionality $\mathcal{F}^{\mathsf{b}}_{\mathsf{rPSU}}$ and then obtains $\{b_1, b_2, \cdots, b_{n_1}\}$. Given $\{b_1, b_2, \cdots, b_{n_1}\}$, Sim can invoke Sim′ to simulate the last step of $\Pi_{\mathsf{g\text{-}RPMT}}$. Once receiving $\langle \mathsf{Request\_Item} \rangle$ from $\mathcal{F}^{\mathsf{b}}_{\mathsf{rPSU}}$, Sim invokes Sim′ to simulate the execution of the sub-protocol Π_{OT} except for the last step (i.e., sending items). Then, Sim sends $\langle \mathsf{Response\_Item}, \mathsf{OK} \rangle$ to $\mathcal{F}^{\mathsf{b}}_{\mathsf{rPSU}}$ and then obtains set Z. By using the items in set $X \setminus Y$, Sim can simulate the last step of each Π_{OT} instance. Compared to the simulator for corrupted receiver in [1, 8, 13, 19, 21, 29, 31], Sim just additionally receives some request messages and additionally sends some response messages. Likewise, due to the request/response messages, the environment $\mathcal{E}$ will receive the honest sender's output Finished at the same time in the real and ideal worlds. Therefore, Sim can simulate $\mathcal{A}$'s view such that $\mathcal{E}$ cannot distinguish the two worlds. □

6.2 AHE-based PSU Protocols

In Figure 20, we show more details on how to achieve encrypted g-RPMT in AHE-based protocols [10, 12]. We can see that if the receiver $\mathcal{R}$ is corrupted, the simulator does not need to simulate anything for $\mathcal{R}$ before simulating $\{c_1, \cdots, c_{n_1}\}$. Therefore, the simulator does not need to obtain information from $\mathcal{F}^{n_1,n_2}_{\mathsf{ePSU}}$ before simulating $\{c_1, \cdots, c_{n_1}\}$. Intuitively, the AHE-based protocols can UC-realize $\mathcal{F}^{n_1,n_2}_{\mathsf{ePSU}}$. The formal security is stated in Theorem 6.3.

Theorem 6.3. *Given an IND-CPA secure AHE scheme, the protocol following the framework $\Pi^{\mathsf{AHE}}_{\mathsf{Unified}}$ in Figure 20 UC-realizes the functionality $\mathcal{F}^{n_1,n_2}_{\mathsf{ePSU}}$ (as in Figure 11), against static, semi-honest adversaries.*

Proof. We will show that for any adversary $\mathcal{A}$, we can construct a simulator Sim that can simulate the view of the corrupted sender and the corrupted receiver, such that any PPT environment $\mathcal{E}$ cannot distinguish the execution in the ideal world from that in the real world.

Corrupted Sender: The simulator Sim for the corrupted sender first sends the input set X to $\mathcal{F}^{n_1,n_2}_{\mathsf{ePSU}}$. After receiving $\langle \mathsf{Request}, \mathcal{S} \rangle$ from $\mathcal{F}^{n_1,n_2}_{\mathsf{ePSU}}$, Sim generates a key pair (pk, sk) and sends pk to $\mathcal{A}$. To simulate the ciphertext c from $\mathcal{R}$, Sim randomly generates a $f_Y(\cdot)$ according to the set size n_2 of Y, then encrypts it to c by using pk and sends c to $\mathcal{A}$. After $\mathcal{A}$ sends back $\{c_1, \cdots, c_{n_1}\}$ to $\mathcal{R}$, Sim sends $\langle \mathsf{Response}, \mathsf{OK} \rangle$ to

Protocol $\Pi^{\mathsf{AHE}}_{\mathsf{Unified}}$

Parameters:

- An AHE scheme includes an encryption algorithm $\mathsf{Enc}_{pk}(\cdot)$ and a decryption algorithm $\mathsf{Dec}_{sk}(\cdot)$.

Inputs:

- Sender $\mathcal{S}$: set $X = \{x_1, \cdots, x_{n_1}\}$, where $x_i \in \{0,1\}^\ell$
- Receiver $\mathcal{R}$: set $Y = \{y_1, \cdots, y_{n_2}\}$, where $y_i \in \{0,1\}^\ell$;

Protocol:

1. The receiver $\mathcal{R}$ generates a key pair (pk, sk) and sends pk to the sender $\mathcal{S}$;
2. $\mathcal{R}$ represents set Y as $f_Y(\cdot)$, generates $c = \mathsf{Enc}_{pk}(f_Y)$ and then sends c to $\mathcal{S}$;
3. $\mathcal{S}$ randomly permutes set X to X^*;
4. $\mathcal{R}$ initializes set $Z = \emptyset$;
5. For each $i \in [n_1]$, $\mathcal{S}$ chooses a uniformly random value r_i, then generates $c_i = (\mathsf{Enc}_{pk}(r_i f_Y(X^*[i])), \mathsf{Enc}_{pk}(r_i X^*[i] f_Y(X^*[i])))$ based on the additive homomorphic property; $\mathcal{S}$ sends $\{c_1, \cdots, c_{n_1}\}$ to $\mathcal{R}$;
6. For each $i \in [n_1]$, $\mathcal{R}$ decrypts c_i to get (d_i^1, d_i^2); if $d_i^1 \neq 0$, $\mathcal{R}$ obtains $X^*[i] = d_i^2/d_i^1$ and sets $Z = Z \cup \{X^*[i]\}$, otherwise $\mathcal{R}$ obtains nothing;
7. $\mathcal{R}$ outputs Z, and $\mathcal{S}$ outputs Finished.

Figure 20: The design framework unifying PSU protocols in [10, 12]. Note that $f_Y(\cdot)$ in [12] is a polynomial $P(x) = \prod_{i=1}^{n_2}(x - y_i)$ such that $P(x^*) = 0$ if $x^* \in Y$, and $f_Y(\cdot)$ in [10] is an inverted Bloom Filter B where Y is inserted by using hash functions $h_1, \cdots, h_\gamma$ such that $\sum_{i=1}^{\gamma} B[h_i(x^*)] = 0$ if $x^* \in Y$ (the "inverted" means that each bit value of the Bloom Filter containing Y is flipped).

$\mathcal{F}^{n_1,n_2}_{\mathsf{ePSU}}$. We can see that the only difference between the ideal world and the real world is that $f_Y(\cdot)$ is randomly generated in the ideal world while $f_Y(\cdot)$ is generated based on Y in the real world. The IND-CPA security of AHE scheme guarantees that any PPT environment $\mathcal{E}$ cannot distinguish between the real world from the ideal world.

Corrupted Receiver: The simulator Sim for the corrupted receiver first sends the input set Y to $\mathcal{F}^{n_1,n_2}_{\mathsf{ePSU}}$ and then receives $\langle \mathsf{Request}, \mathcal{R} \rangle$. Sim will receive a public key pk and a ciphertext c from $\mathcal{A}$. To simulate $\{c_1, \cdots, c_{n_1}\}$, the simulator sends $\langle \mathsf{Response}, \mathsf{OK} \rangle$ to $\mathcal{F}^{n_1,n_2}_{\mathsf{ePSU}}$ and obtains the union $Z = X \cup Y$. Then for $i \in \{1, 2, \cdots, |Z \setminus Y|\}$, Sim randomly picks α_i and generates $c_i = (\mathsf{Enc}_{pk}(\alpha_i), \mathsf{Enc}_{pk}(\alpha_i x_i))$, where $x_i \in Z \setminus Y$. After that, for all $i \in \{|Z \setminus Y| + 1, \cdots, n_1\}$, Sim generates $c_i = (\mathsf{Enc}_{pk}(0), \mathsf{Enc}_{pk}(0))$ by using pk. After randomly permuting the set $\{c_1, \cdots, c_{n_1}\}$, the simulator Sim sends the ciphertexts to $\mathcal{A}$. In both the ideal world and the real world, if $x_i \in X \setminus Y$, the corresponding c_i is a pair of ciphertexts for two messages α_i and $\alpha_i x_i$, otherwise it is the encryption of 0's. Moreover, $\mathcal{A}$ receives the items in $X \setminus Y$ in a random order in both worlds. Therefore, the ideal world and the real world are indistinguishable. □

7 Conclusion

In this work, we conduct a thorough analysis of the leakage in the typical PSU protocols. We identify a prevalent form of leakage in current PSU designs, called "during-execution leakage", which is implied by the output but can be obtained before the complete output is received. In addition, we find that the commonly used functionality $\mathcal{F}^{n_1,n_2}_{\mathsf{PSU}}$ cannot capture the security without during-execution leakage. Therefore, we define a new enhanced functionality $\mathcal{F}^{n_1,n_2}_{\mathsf{ePSU}}$ to capture it.

Concretely, our investigation reveals that although symmetric key-based PSU constructions offer scalability, they are vulnerable to the during-execution leakage. On the other hand, only AHE-based PSU solutions can avoid the during-execution leakage, but their performance falls short of meeting practical requirements. To bridge the gap, we design a new PSU protocol $\Pi^{\mathsf{bECRG}}_{\mathsf{PSU}}$ that is the first scalable PSU protocol to UC-realize the enhanced PSU functionality $\mathcal{F}^{n_1,n_2}_{\mathsf{ePSU}}$ in the semi-honest setting, by using a new building block Π_{bECRG}. Like OT-based PSU protocols, our $\Pi^{\mathsf{bECRG}}_{\mathsf{PSU}}$ only relies on symmetric key operations other than base OTs, obtaining significant performance improvement over AHE-based protocols.

A The leakage in Kolesnikov et al.'s design [21]

In order to improve the performance, Kolesnikov et al. [21] proposed to optimize their protocol by using the bucketing technique, as shown in Figure 21. More specifically, the sender and receiver in [21] first assign their items in X and in Y, into two simple hash tables with the same number of bins, and the maximum bin sizes are assumed to be ρ_1 and ρ_2, respectively. Then they perform the (ρ_1,ρ_2)-PSU sub-protocol on the items of each bin separately. As pointed out by Kolesnikov et al. in [21], however, *the bucketing technique will leak the information "which bins contain items in $X \cap Y$" to the receiver.* To avoid this leakage, in [21] the receiver is required to put a special item $\perp$ into each bin, and to pad the bins with different dummy items d, while the sender pads his bins with the special item $\perp$. For example, in Figure 21, the items $\{x_6, x_2, x_{10}\}$ of X are mapped to the first bin of the sender's simple hash table, and the items $\{y_3, y_8\}$ of Y are mapped to the first bin of the receiver's hash table. Without the special item $\perp$, if $x_2 = y_3$, the receiver can learn that an item belonging to $X \cap Y$ is in $\{y_3, y_8\}$ after executing the (ρ_1,ρ_2)-PSU. By adding the special item $\perp$ to both sides, if the receiver learns that an item from the sender belongs to $\{y_3, \perp, y_8, d\}$, it seems that the receiver cannot know whether the item is a real item (namely, in X) or the special item $\perp$. Unfortunately, Jia et al. [19] pointed out that this strategy is insufficient to avoid the leakage incurred by the bucketing technique, and the detailed analysis is given below.

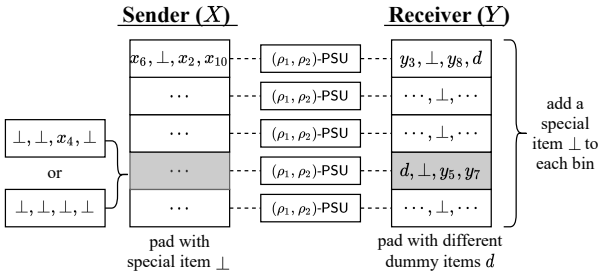

Figure 21: The bucketing technique in [21].

For ease of exposition, we take the 4th (ρ_1,ρ_2)-PSU sub-protocol in Figure 21 as an example to explain why the optimization in [21] fails to hide the intersection information. After the execution of the sub-protocol over the 4th bins, if the receiver does not obtain any items from the sender (that is, all items in the sender's 4th bin belong to the subset in the receiver's 4th bin i.e., $\{d, \perp, y_5, y_7\}$), then the receiver could obtain additional information about the intersection. Concretely, one of the following will occur:

- Case_1: all the real items that are mapped to the sender's bin (say x_4 in Figure 21) belong to $\{y_5, y_7\}$;
- Case_2: no real items are mapped to the sender's bin (i.e., all items are special item $\perp$).

The probabilities that Case_1 and Case_2 occur are denoted as $\Pr[\mathsf{Case}_1]$ and $\Pr[\mathsf{Case}_2]$, respectively. Clearly, if the receiver is able to determine that Case_1 occurs with certain (high) probability, she will know that items belonging to $X \cap Y$ are in $\{y_5, y_7\}$ with the same probability. According to the parameters in [21], Jia et al. [19] estimated $\Pr[\mathsf{Case}_2]$. Note that $\Pr[\mathsf{Case}_1] = 1 - \Pr[\mathsf{Case}_2]$, and the probability $\Pr[\mathsf{Case}_2]$ is very small. For example, when the set size is $n = 2^{20}$, $\Pr[\mathsf{Case}_2] = 5.778 \times 10^{-8}$. This means that when the receiver finds that all items in a bin belong to the intersection, she can learn that this bin has at least one real item with probability $1 - 5.778 \times 10^{-8}$, and that her corresponding bin contains at least an item in $X \cap Y$ with the same probability. Hence, their approach is insufficient to avoid the leakage incurred by the bucketing technique.

O-Ring and K-Star: Efficient Multi-party Private Set Intersection

Abstract

Multi-party private set intersection (mPSI) securely enables multiple parties to know the intersection of their sets without disclosing anything else. Many mPSI protocols are not efficient in practice. In this paper, we propose two efficient mPSI protocols that are secure against an arbitrary number of colluding parties. In the protocol *O-Ring*, we take advantage of the ring network topology such that the communication costs of the party with the largest workload can be cheaper than other mPSI protocols with a star topology. In the protocol *K-Star*, we take advantage of the star topology to support better concurrency such that the protocol can run fast. K-Star is suitable for applications with a powerful centralized server. Different from KMPRT (CCS'17) and CDGOSS (CCS'21) that rely on *Oblivious Programmable PRF* primitive, we simply utilize the cheaper Oblivious PRF (OPRF) and a data structure Oblivious Key-value Store (OKVS). We further propose two fine-grained optimizations for OKVS and OPRF in multi-party cases to improve runtime performance.

After extensive experiments, we demonstrate that both protocols run the fastest and achieve the lowest total communication costs compared with the state-of-the-art counterparts in most settings. Specifically, O-Ring/K-Star is respectively $1.6\times \sim 48.3\times$ and $4.0\times \sim 39.8\times$ (except one setting) cheaper than KMPRT (CCS'17) and CDGOSS (CCS'21) in the total communication costs. For the total running time, K-Star can be respectively $1.4\times \sim 9.0\times$ and $1.0\times \sim 15.3\times$ as fast as them in the LAN setting.

1 Introduction

Two-party private set intersection (PSI) allows two parties (i.e., a receiver and a sender), each of them has a set, to secretly know the intersection of their sets without disclosing anything else. Specifically, a receiver gets the intersection without disclosing any item of its set to the sender; the sender discloses no more than the intersection to the receiver. Different from two-party PSI, multi-party PSI (mPSI) extends the number of parties to $n \geq 3$, which makes it more challenging. Two-party PSI does not need to consider collusion attacks. However, the attack becomes more complicated when it comes to multiple parties. Given n parties, the number of colluding parties can be any t out of them. This explains that though there are many efficient two-party PSI protocols, there are relatively fewer mPSI protocols (e.g., [2, 4, 17]).

mPSI have many applications, e.g., medical data integration [19, 20], cache sharing in edge computation [22], network intrusion attack detection [13], and highly risky individual identifications in the spread of disease [1]. Among the proposed mPSI protocols, some of them are not concretely efficient because of using expensive cryptographic primitives, e.g., homomorphic encryption [6, 12, 15, 18]. CDGOSS'21 [4] is efficient, but it can only work when the number of colluding parties t is smaller than $n/2$. KMPRT'17 [17] can be secure against an arbitrary number of colluding parties. However, it is not sufficiently efficient in both the running time and the communication costs. In KMPRT'17 [17], though the authors also proposed an optimized 3-party PSI protocol, it is insecure. Therefore, proposing an efficient mPSI protocol that can be secure against an arbitrary number of colluding parties is of great significance.

1.1 The high-level idea of our protocol

In this paper, we first propose an efficient mPSI protocol called *O-Ring*. We show a simple example of O-Ring with three parties. For parties P_1, P_2, and P_3, each one has a set (e.g., $X_1 = \{x_1, x_3, x_4\}$, $X_2 = \{x_1, x_2, x_3\}$, and $X_3 = \{x_1, x_2, x_4\}$). The core idea is to utilize a data structure called *oblivious key-value store* (OKVS) to build a ring to filter out non-common items. An OKVS is a data structure that encodes m key-value pairs into a table T. Because of the *oblivious* property, T hides the keys if the values are random. Now, P_1 can respectively generate three random values $\{v_1, v_3, v_4\}$ for $X_1 = \{x_1, x_3, x_4\}$ and encode $\{(x_1, v_1), (x_3, v_3), (x_4, v_4)\}$ into an OKVS table T_1. Upon receiving T_1 from P_1, P_2 decodes to get the values $\{v_1 = Decode(T_1, x_1), v_2' = Decode(T_1, x_2), v_3 =$

$Decode(T_1, x_3)\}$. Here, since $x_2 \notin X_1$, the decoded value v_2' is random. After the transition, P_2 keeps the common key-value pairs $(x_1, v_1), (x_3, v_3)$ but filter out the non-common value v_4. P_2 encodes $(x_1, v_1), (x_2, v_2'), (x_3, v_3)$ into another OKVS table T_2 and sends T_2 to P_3. Then P_3 decodes and gets $\{v_1 = Decode(T_2, x_1), v_2' = Decode(T_2, x_2), Decode(T_2, x_4)\}$. Now, v_3 will also be filtered out because $x_3 \notin X_3$. Finally, P_3 encodes $(x_1, v_1), (x_2, v_2'), (x_4, Decode(T_2, x_4))$ into a table T_3 and returns it to P_1. After decoding, P_1 will know the intersection $I = \{x_1\}$ by checking $v_1 = Decode(T_3, x_1)$, $v_3 \neq Decode(T_3, x_3)$, and $v_4 \neq Decode(T_3, x_4)$.

The above idea is simple, but not secure. First, it is vulnerable to the brute-force attack when the item domain is small. In the above example, if P_1 enumerates all items including x_2 in the domain, P_1 will easily find that $x_2 \in X_2 \cap X_3$ by checking $Decode(T_1, x_2) = Decode(T_3, x_2)$. To thwart this attack, we utilize a cryptographic primitive *oblivious pseudorandom function* (OPRF). It is commonly used in two-party PSI protocols [16, 26], such that the sender with a private PRF key can send the OPRF values to the receiver without disclosing non-common items.

Second, the design is insecure against the collusion attack, which is the greatest challenge in mPSI. For example, if P_1 colludes with P_3, after receiving T_2 from P_2, P_1 and P_3 can easily know $X_1 \cap X_2 = \{x_1, x_3\}$ by checking $v_1 = Decode(T_2, x_1)$, $v_3 = Decode(T_2, x_3)$, but $v_4 \neq Decode(T_2, x_4)$. Ideally, a secure mPSI protocol only discloses the intersection $I = X_1 \cap X_2 \cap X_3$ to the colluding parties. To be secure against an arbitrary number of colluding parties [17], we further exploit the OPRF. Assuming the maximum number of colluding parties is t, in the OKVS chain (or ring) $P_1 \to P_2 \to \cdots \to P_n \to P_1$, we select t parties $P_{n-t+1}, P_{n-t+2}, \cdots, P_n$, each of whom performs OPRFs with the other $n-1$ parties by acting as a common OPRF sender. Also, we select the protocol receiver P_1 to share PRF keys with the remaining $n-t-1$ parties. The idea is that there must be at least one honest party among the $t+1$ selected parties. Then for each item x_j with a value v_j in a party, v_j can be masked by $F_k(x_j)$ or $F_s(x_j)$ such that the colluding parties cannot identify x_j from an obfuscated value $v_j \oplus F_k(x_j)$ or $v_j \oplus F_s(x_j)$, where k is the common sender's OPRF key, s is P_1's PRF key, and F is a PRF. More details can be found in section 5.

1.2 Ring vs star topology

Most of previous protocols (e.g., [2, 4, 9, 12, 17]) are based on a star topology, in which the central party (denoted as *leader*) takes a much heavier burden in communication and computation costs than other parties (denoted as *clients*). Our ring-based protocol can share a part of the central party's costs among the other parties, thus reducing leader's costs. This is motivated by real-world applications in which the communication and computation resources of the leader are limited. Different topologies may be suitable for different applications. For applications without a powerful leader, the ring topology may be more suitable. In contrast, star topology is suitable for applications in which the leader has powerful resources (e.g., a cloud server). In the star topology, the leader can concurrently execute the protocol with different clients, such that the protocol can be faster.

1.3 Our contributions

In this paper, we propose two mPSI protocols, O-Ring and K-Star, tailored for different application scenarios. O-Ring is designed by utilizing a ring topology, while K-Star has a traditional star topology. Briefly, we make the following contributions.

1. O-Ring has three advantages. First, the communication costs of the bearer in O-Ring are cheaper than other mPSI protocols. The *bearer* is the party with the largest workload. Compared with the state-of-the-art protocols KMPRT'17 [17] and CDGOSS'21 [4], O-Ring can be respectively $1.6\times \sim 48.3\times$ and $1.9\times \sim 27.5\times$ as cheap as them in the bearer's communication costs. Therefore, O-Ring is suitable for applications in which the bearer has limited resources. Second, the total communication of O-Ring is low. O-Ring is respectively $1.6\times \sim 48.3\times$ and $4.0\times \sim 39.8\times$ (except one setting) as cheap as them in the total communication costs. Third, O-Ring runs fastest in most settings. For the total running time, in the LAN setting, O-Ring can be respectively $1.4\times \sim 6.0\times$ and $1.2\times \sim 12.9\times$ as fast as them in most of the settings; in the WAN setting, the ratios are respectively $1.2\times \sim 18.1\times$ and $1.1\times \sim 2.7\times$.

2. By modifying O-Ring into a star topology, we further propose another protocol K-Star. K-Star also has three advantages. First, K-Star runs the fastest in most settings. Compared with O-Ring, it is $13.6\% \sim 19.3\%$ faster when $n = 10$ in LAN. The reason is that O-Ring needs to run sequentially among the parties by using the OKVS ring, while K-Star can runs concurrently by using the star topology. Also, compared with KMPRT'17 [17] and CDGOSS'21 [4], in the LAN setting, K-Star can be respectively $1.4\times \sim 9.0\times$ and $1.0\times \sim 15.3\times$ as fast as them; in the WAN setting, the ratios are respectively $1.2\times \sim 18.9\times$ and $1.0\times \sim 4.4\times$ in most of the settings. Second, K-Star gains the same lowest total communication costs as O-Ring. Third, for the bearer's communication costs, K-Star can be $3.0\% \sim 63.4\%$ more expensive than O-Ring but is still much cheaper than KMPRT'17 [17] and CDGOSS'21 [4]. K-star is suitable for applications in which the central party is powerful.

3. We further make two fine-grained optimizations when we implement the OKVS and OPRF in O-Ring and K-Star. In the first optimization, we divide the encoding

scheme of the OKVS [8] into a peeling phase and an unpeeling phase. The peeling phase is only related to each party's items and can be done offline and parallelly by all parties. By applying this optimization in the OKVS chain, it can be 6.3% $\sim$ 52.5% faster. In the offline phase of OPRF protocol [26], a receiver needs to encode item-value pairs into an OKVS table. For each item x, its value is generated by a public cryptographic hash function $H(x)$ and is only related to the item itself. Having this observation, instead of simply invoking n' OPRFs for a party who acts as a common OPRF receiver, we optimize by only encoding the item-value pairs once for this party. After applying this optimization, it saves 1.0% $\sim$ 24.0% computation costs than naively invoking n' OPRFs. More details can be found in subsection 6.1.

4. We identify insecurity in previous efficient mPSI works KMPRT [17] and NTY [21]. Specifically, the augmented semi-honest protocol and the specially optimized three-party PSI protocol in KMPRT [17] are insecure for the collusion attacks. Also, the semi-honest and malicious protocols ($t > 1$) in NTY [21] are prone to the collusion attacks. More details can be found in section 6.4.1.

2 Related work

In this section, we introduce the related mPSI protocols. The computation and communication complexities of these protocols and our protocols are shown in Table 1. More descriptions of the related protocols with ours are as follows.

KMPRT'17 [17]. Kolesnikov et al. [17] proposed the Oblivious Programmable Pseudorandom Function (OPPRF) for their mPSI protocols. In OPPRF, the sender owns an item-value set $\{(x_j, v_j)\}_{\forall j\in[m]}$ and the receiver owns an item set Y, where m is the set size. After OPPRF, the receiver gets the correct value v_j of an item $y \in Y$ if $y = x_j$; otherwise, the value is random to the receiver. After designing their OPPRF protocol, they presented their mPSI protocols. In their first semi-honest mPSI protocol, each party P_i ($i = 1, 2, \cdots, n$) randomly generates n zero shares for each item x_j^i (i.e., $\beta_j^{i,1} \oplus \beta_j^{i,2} \oplus \cdots \oplus \beta_j^{i,n} = 0$). Then P_i invokes an OPPRF with another party P_u who owns a set $X^u = \{x_j^u\}_{\forall j\in[m]}$, by taking $\{(x_j^i, \beta_j^{i,u})\}_{\forall j\in[m]}$ as P_i's item-value set. This phase is called conditional *zero-sharing*. In the next phase, one party P_1 acts as the 'dealer' of the protocol to receive each item's shares from other $n-1$ parties. It is obvious that if an item is in the intersection, its corresponding share sum is 0; otherwise not.

Their second protocol turns the conditional zero-sharing into an unconditional zero-sharing. Specifically, P_i ($i = 1, 2, \cdots, n$) shares a PRF key $s^{i,j}$ to P_j ($j = i+1, i+2, \cdots, n$). If P_i and P_j have a common item x, both of them will have the same PRF value $F_{s^{i,j}}(x)$; then their value sum will be 0 (i.e., the pairwise property). After the unconditional zero-sharing, the protocol receiver P_1 acts as a common OPPRF receiver and respectively invoke an OPPRF instances with P_i ($\forall i \in [2, n]$) who inputs an item-value set $\{(x_j^i, \bigoplus_{u=1}^{i-1} F_{s^{u,i}}(x_j^i) \oplus \bigoplus_{u=i+1}^{n} F_{s^{i,u}}(x_j^i))\}_{\forall j\in[m]}$. Given the pairwise property, if x is in the intersection, its value sum that P_1 computes will be 0. Though the authors claimed that this protocol was secure in the *augmented semi-honest* model, it is prone to collusion attacks. More details are shown in 6.4.1.

To optimize the performance of their semi-honest protocol, the authors also proposed a three-party PSI protocol. However, this protocol is also insecure for the collusion attacks. The detailed analysis is shown in subsection 6.4.1.

CDGOSS'21 [4]. To design a mPSI protocol, Chandran et al. [4] first introduced a functionality *weak private set membership* (wPSM), which can be directly instantiated by the OPPRF in [17]. In their protocol, first, the dealer P_1 hashes all items into a cuckoo hashing table and the other parties hash their items by using the same hash functions. Then each party does wPSM with the dealer P_1 by acting as a sender, such that all parties can get the corresponding value shares for each item. After getting the value shares, all parties need to use a primitive *ConvertShares* (in which a secret sharing scheme is used) to generate the linear shares for the items. As a result, if the majority of parties are honest, the dealer can get the intersection. An interesting point about their work is that the performance of their protocol is independent of the number of colluding parties t by using the primitives. Their protocol can be more efficient than KMPRT'17 [17]. Concretely, their protocol has $6(t+2)/5\times$ less communication costs and is up to $5\times$ (resp. $6.2\times$) faster in LAN (resp. WAN) settings. However, an obvious drawback of their protocol is that their protocol can only work when $t < n/2$. Ideally, a protocol should support an arbitrary number of colluding parties.

NTY'21 [21]. Nevo et al. [21] proposed their mPSI protocols by using an OKVS and OPPRF. To ensure the security of their mPSI protocol, they exploited a zeroXOR protocol based on the augmented semi-honest protocol in KMPRT'17 [17] by changing the input from an item set to an item-value set. A party in zeroXOR needs to sum each item's input value with the PRF value sum before the OPPRF interaction. When $t = n-1$, the input item's value is set as 0 in zeroXOR and their mPSI is almost the same as the augmented semi-honest protocol in KMPRT'17 [17], which is subjected to the attack in subsection 6.4.1. When $t < n-1$, the n parties in the mPSI protocol can be divided into three parts: non-zeroXOR parties $P_2, \cdots, P_{w-1}$, a pivot P_w, and zero-XOR parties $P_{w+1}, P_{w+2}, \cdots, P_n, P_1$, where $w = n-t+1$. In the first step, P_i ($\forall i \in [2, w-1]$) respectively sends a PRF key $s^{i,u}$ to P_u ($u = w+1, w+2, \cdots, n, 1$). Then P_i ($i \in [w+1, n] \cup \{1\}$) can compute the value $\bigoplus_{u=2}^{w-1} F_{s^{u,i}}(x_j^i)$ of each item $x_j^i \in X_i$. P_i ($i \in [2, w-1]$) can compute an item x_j^i's value $F_{s^{i,1}}(x_j^i) \oplus \bigoplus_{u=w+1}^{n} F_{s^{i,u}}(x_j^i)$ and encode these item-

Table 1: The communication and computation complexity of different mPSI protocols. 'semi' indicates semi-honest. 'augmented' indicates augmented semi-honest. λ and κ are respectively the statistical and computational security parameters. m is the set size of all parties. 'Concrete efficient' indicates whether the protocol is efficient in practice.

value pairs into an OKVS table T_i, which is sent to the pivot P_w. Then the pivot can also compute each item x_j^w's value as $\bigoplus_{i=2}^{w-1} Decode(T_i, x_j^w)$. Now, all P_w and $P_{w+1}, P_{w+2}, \cdots, P_n, P_1$ have got their items' values and they can input these item-value pairs into the zeroXOR protocol to get the intersection. Their protocol is still insecure when $1 < t < n-1$. More discussions are in subsection 6.4.2.

Others. Garimella et al. [8] proposed a malicious mPSI protocol based on the augmented semi-honest protocol in KMPRT'17 [17]. In their work, they proved that their protocol was secure in the malicious model but not in the semi-honest model by introducing a random oracle model. However, their protocol is still prone to collusion attacks as KMPRT'17 [17].

Inbar et al. [13] also designed their protocols in both semi-honest and augmented semi-honest security models. Their building primitives are Oblivious Transfer (OT) and an OKVS called Garbled Bloom filter (GBF). The core idea of their protocols is the GBF-based two-party PSI protocol from Dong et al. [7]. In [7], the sender first builds a GBF from his/her set. For an item x, its λ shares are stored in the bins of the GBF by using λ hash functions. The receiver also constructs a Bloom filter [3] by using the same hash functions. In the Bloom filter, if a bin is hashed, then this bin is set as '1'; otherwise '0'. Then the receiver invokes OTs with the sender. If the bin is '1', the receiver gets the correct share in the sender's GBF; otherwise, the receiver can only get a random share. After all OTs, the receiver can check whether the sum of an item's λ corresponding shares equals this item to get the intersection. Inbar et al. [13] extended the work of Dong et al. [7] to multi-party case. In the mPSI protocol, each party works as an OT receiver to query the value shares of other parties. After getting these shares, each party sums these shares and sends the share sums to one party who computes the intersection by reconstructing the share sum of each item.

Ben-Efraim et al. [2] followed Inbar et al. [13]'s work to propose a malicious mPSI protocol. Similar to Dong et al. [7], they aimed to limit the number of '1's one party uses in the OT interactions. To achieve this, they exploited K-out-of-N OT in [25]. A similar work extending [25] can be found in [27]. Another work combining GBF and OPRF can be found in [14]. In addition, some works used additive homomorphic encryption [6,12,15,18], which is expensive and makes the protocols not efficient. Ghosh and Nilges [9] replaced the homomorphic encryption with oblivious polynomial evaluation, which is also expensive [21].

3 Preliminaries

3.1 Notations

Notations	Comments
n	The number of parties
t	The number of colluding parties
P_i	Party i, $i = 1, 2, \cdots, n$
m	The set size of each party P_i
X_i	The set of party P_i, i.e., $X_i = \{x_1^i, x_2^i, \cdots, x_m^i\}$
T_i	The OKVS table of P_i. $T_{i,j}$ is the jth bin
ℓ	The output bit length
λ	The statistical security parameter
κ	The computational security parameter

In addition to the above notations, $\oplus$ is the bitwise XOR; $\bigoplus_{i=1}^n x_i$ denotes $x_1 \oplus x_2 \oplus \cdots \oplus x_n$. $\bigcap_{i=1}^n X_i$ denotes $X_1 \cap X_2 \cap \cdots \cap X_n$. $[m]$ denotes the set $\{1, 2, \cdots, m\}$. $[a, b]$ denotes the set $\{a, a+1, \cdots, b\}$. For any notation with a superscript, e.g., x^i, the superscript i indicates the party index (not the power in math operation).

3.2 Multi-party PSI

The ideal functionality of mPSI is shown in Figure 1. In this functionality, each party P_i inputs a set X_i; P_1 is the only receiver who gets the intersection.

> **Parameters:** The number of parties n, the number of corrupted parties $t < n$, and the set size of each party m. The bit length of each item σ.
> **Inputs:** Each party P_i inputs a set $X_i = \{x_j^i\}_{\forall j \in [m]}$ for $i \in [n]$, and $x_j^i \in \{0,1\}^\sigma$.
> **Outputs:** P_1 gets the intersection $I = \bigcap_{i=1}^n X_i$. The other parties receive $\perp$.

Figure 1: The ideal functionality of mPSI $\mathcal{F}_{m-psi}$.

A computation protocol in the real world is said to be secure with respect to certain adversarial behavior if the possible real executions with such an adversary can be simulated in the corresponding ideal world [10]. In the ideal world, a trusted third party performs the computation after giving the inputs and returns the outputs. To prove the security, one needs to prove the view of the adversary in the real world is indistinguishable from the view of the simulator in the ideal world. Usually, there are two types of security models: semi-honest model and malicious model. In the semi-honest model, the parties follow the protocol strictly but are curious to know extra information beyond their outputs. In the malicious model, the malicious parties can arbitrarily deviate from the protocol. In this paper, we only focus on the semi-honest security model.

mPSI is a special multi-party secure computation. Different from two-party PSI, the greatest threat for the mPSI is the collusion attack. In two-party PSI, only the receiver is allowed to learn the intersection, while the sender learns nothing. Keeping consistent with the two-party security requirement, in mPSI, with an arbitrary number of colluding parties (i.e., $t < n$), if the receiver is in the colluding parties, the colluding parties can learn only the intersection $I = \bigcap_{i=1}^n X_i$; otherwise, the colluding parties learns nothing. In other words, even $t = n-1$ and the receiver is in the colluding parties, they can only know $I = \bigcap_{i=1}^n X_i$ from the honest party. If the receiver is not colluded, the colluding parties know nothing about the receiver's items. It is noted that the colluding parties can know the set information about their own sets, e.g., the intersection of their own sets.

3.3 OKVS

An Oblivious Key-Value Store (OKVS) is a data structure to store key-value pairs. Specifically, given m key-value pairs $S = \{(x_1, v_1), (x_2, v_2), \cdots, (x_m, v_m)\}$, an OKVS encodes them into a table T, which denotes as $T = Encode(S)$. For decoding, one can query to get each key x's corresponding value $Decode(T, x)$. If $x = x_i$, then $Decode(T, x) = v_i$; otherwise, $Decode(T, x)$ is pseudorandom.

Definition 1. *Obliviousness* [8]. If the values in set $\{v_1, v_2, \cdots, v_m\}$ are uniform, then $T_1 = Encode(S_1)$ and $T_2 = Encode(S_2)$ are computationally indistinguishable, where $S_1 = \{(x_1^1, v_1), (x_2^1, v_2), \cdots, (x_m^1, v_m)\}$ and $S_2 = \{(x_1^2, v_1), (x_2^2, v_2), \cdots, (x_m^2, v_m)\}$.

In OKVS, the expansion rate η shows that one only needs a table with size $m\eta$ for encoding. Pinkas et al. [24] proposed an OKVS *PaXoS* with linear computation costs and low expansion rate of $\eta = 2.4$. Later, Garimella et al. [8] proposed *3H-GCT* based on PaXoS to reduce the expansion rate to $\eta = 1.3$. In this paper, for simplicity, we denote an OKVS as its stored table T. In PaXoS/3H-GCT, there are two phases in the encoding: peeling and unpeeling. In the peeling phase, the encoder exploits the keys to find an ordering sequence. Then in the unpeeling phase, the encoder assigns the values based on the ordering sequence. For more details about PaXoS/3H-GCT, one can refer to [8, 24].

3.4 OPRF

Oblivious Pseudorandom Function (OPRF) allows the receiver to obliviously get the PRF values $\{F_k(x_1), F_k(x_2), \cdots, F_k(x_m)\}$ after inputting a set $\{x_1, x_2, \cdots, x_m\}$, where $F_{(\cdot)}(\cdot)$ is a common pseudorandom function (PRF), and the key k is the sender's output. The ideal functionality of OPRF is depicted in Figure 2.

> **Parameters:** The set size m of the receiver. A PRF $F_{(\cdot)}(\cdot)$.
> **Inputs:** The receiver inputs the sets $\{x_i\}_{\forall i \in [m]}$.
> **Outputs:** The receiver gets the PRF outputs $\{F_k(x_i)\}_{\forall i \in [m]}$. The sender gets a pseudorandom secret key k.

Figure 2: The ideal functionality of OPRF $\mathcal{F}_{oprf}$.

OPRF can be utilized to realize a two-party PSI (e.g., [5, 8, 16, 26]). After running the OPRF, the sender gets the OPRF key k and computes the PRF values $V = \{F_k(y_i) | \forall y_i \in Y\}$. Then the sender directly sends V to the receiver. The receiver gets the intersection $I = \{x | F_k(x_i) \in V, \forall i \in [m]\}$. To securely get the intersection, the core idea is to compare the OPRF values of the sender and the receiver. The workflow of a two-party PSI by utilizing OPRF can be found in Figure 3. The security goes that all $\{F_k(y_i) | y_i \in Y \backslash I\}$ are pseudorandom to the receiver. Hence, the receiver learns only the intersection. Here, for security, it is noted that *only the sender can send the OPRF values to the receiver; the receiver cannot send the ORPF values to the sender*. Therefore, it is unidirectional. Once the receiver sends $\{F_k(x_1), F_k(x_2), \cdots, F_k(x_m)\}$ to the sender, it is possible for the sender to get the items of the receiver since the sender holds the key k, especially when the item domain is small.

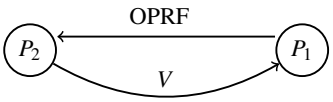

Figure 3: The workflow of two-party PSI by using OPRF. The start and the end of the OPRF arrow line respectively represent the OPRF receiver P_1 and OPRF sender P_2. P_2 returns its OPRF value set V to P_1 after OPRF invocation.

In the above flow, the sender can also return an OKVS table T that encodes $\{(y_i, F_k(y_i))\}_{\forall i\in[m]}$ to the receiver rather than the set V. Then the receiver gets the intersection $I = \{x|F_k(x_i) = Decode(T, x_i), \forall i \in [m]\}$. By returning an OKVS table, the output bit length of $F_k(\cdot)$ can be reduced by $\log_2(n)$ [23] because the receiver no longer needs to compare n OPRF values for each item's OPRF value to know whether it is in the intersection. In this paper, for simplicity, the sender returns an OKVS table encoding the item-value pairs to the receiver.

4 Our protocol without collusion

In this section, we propose a simple and efficient semi-honest mPSI protocol without collusion by only using OKVS and OPRF. The general idea is to reduce the mPSI to the two-party PSI. The receiver P_1 and the last party P_n run as the two-party PSI in Figure 3. All parties run in an OKVS chain.

4.1 A simple but insecure protocol

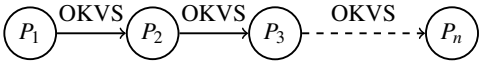

Figure 4: The workflow of an OKVS chain.

We first introduce a protocol called *OKVS chain*. The workflow of an OKVS chain is shown in Figure 4. In the OKVS chain, each party P_i has an item-value pair set $S_i = \{(x_j^i, v_j^i)\}_{\forall j\in[m]}$ and needs to transit the XOR value sum of the common items. Specifically, the first party P_1 encodes his/her item-value pairs $S_i = \{(x_j^i, v_j^i)\}_{\forall j\in[m]}$ into an OKVS table T_1 and transits it to P_2. The intermediate party P_i $(i = 2, 3, \cdots, n)$ receives an OKVS table T_{i-1} from its previous party P_{i-1}. Then P_i decodes each item $x_j^i \in X_i$ to get its corresponding value $Decode(T_{i-1}, x_j^i)$ and encodes to get the next OKVS table $T_i = Encode\{\{(x_j^i, v_j^i \oplus Decode(T_{i-1}, x_j^i))\}_{\forall j\in[m]}\}$. After receiving T_{n-1} from P_{n-1}, P_n computes $v_j^n \oplus Decode(T_{n-1}, x_j^n)$ for each item x_j^n and the transition stops.

In the transition, each party transits the value XOR sum of the intersection items. The obliviousness of the OKVS chain inherits from the OKVS. For P_2, if an item $x_j^2 \notin X_1$, then $Decode(T_1, x_j^2)$ is pseudorandom and P_2's updated value $v_j^2 \oplus Decode(T_1, x_j^2)$ for x_j^2 will be randomized. Then P_2 keeps only the correct value sum for the items in $X_1 \cap X_2$. For P_3, if $x_j^3 \notin X_1 \cap X_2$, its updated value sum $v_j^3 \oplus Decode(T_2, x_j^3)$ will also be randomized. The transition continues until P_n keeps the correct value sum for all items in the intersection $X_1 \cap X_2 \cap \cdots \cap X_n$; otherwise, their value sums are randomized. From another angle, the OKVS chain is a filter to filter out non-common items by randomizing their corresponding values. In the above transition, it is noted that P_i $(i = 2, 3, \cdots, n)$ cannot simply compute $T_i = T_{i-1} \oplus Encode(\{(x_j^i, v_j^i)\}_{j\in[m]})$ because of a possible false positive issue. If doing so, although the common items remain, the non-common items also remain. Then P_i cannot filter out the non-common items. Therefore, P_i has to decode to get the corresponding values from T_{i-1}.

By utilizing the OKVS chain, one can trivially design a mPSI protocol. First, P_1 can generate m random values $\{v_j^1\}_{\forall j\in[m]}$ for his/her m items to input m key-value (item-value) pairs in the chain. The other parties simply input their items with associated values as 0s. After the intersection value transition, P_n will get an updated value set V and send it to P_1. P_1 includes an item into the intersection if its associated value v_j^1 is in V. This protocol is very simple. However, there are two security concerns. First, it is vulnerable to the brute-force attack when the item domain is small. It is noted that P_1 sends out an OKVS table T_1 and receives the value set from P_n. If P_1 simply brute-forces the item domain to get all the associated values by decoding on T_1. Then it is easy to know the intersection of all other parties (i.e., $\bigcap_{i=2}^n X_i$) by intersecting the full domain values with the received value set. Second, it is vulnerable to the collusion attack. For example, if P_3 colludes with P_1, it is easy for them to attack P_2 to know $X_1 \cap X_2$ because P_3 receives the intersection information from P_2 in the chain. It is noted that the input value v_j^i for each item x_j^i are set depending on the specific protocol needs. In the above protocol, $v_j^2, v_j^3, \cdots, v_j^n$ are set as 0. In late sections, they will be set differently.

4.2 O-Ring(t=1): a secure protocol without collusion

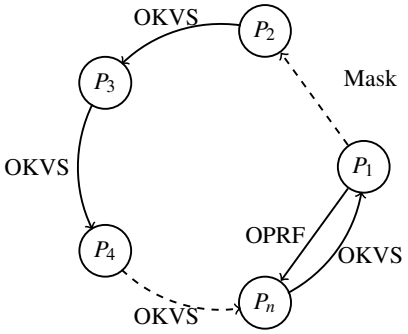

Figure 5: The workflow of our mPSI protocol O-Ring ($t = 1$) without collusion.

Since we do not consider the collusion attack in this section, we put our focus on handling the brute-force attack by combining with an OPRF primitive. The workflow of our protocol is shown in Figure 5. One can easily find that our design combines the OKVS chain with the two-party PSI in Figure 3. When there are only two parties, it simply becomes the two-party PSI. In the flow, 'Mask' indicates that P_1 shares a PRF key with P_2. The full protocol is shown in Figure 6. The correctness goes that if x is in the intersection, the PRF and OPRF value sum will be 0 because PRF and OPRF values are in pairs. Otherwise, the probability that the value sum is 0 will be negligible. For the security, because of the OPRF between P_1 and P_n, P_1 can no longer has the brute-force attack against the other parties because he/she does not have the OPRF key. Due to the page limit, we put the formal security proof of this protocol in Appendix A.1.

Parameters: The number of parties n and set size m. The item's bit length σ. An OKVS scheme $Encode(\cdot)$, $Decode(\cdot,\cdot)$. A PRF $F_{(\cdot)}(\cdot) : \{0,1\}^\kappa \times \{0,1\}^\sigma \mapsto \{0,1\}^\ell$.
Inputs: Each party P_i inputs a set $X_i = \{x_j^i\}_{\forall j \in [m]}$ for $i \in [n]$, and $x_j^i \in \{0,1\}^\sigma$.
Protocol:

1. **[Initiation]**. P_1 sends a PRF key s to P_2. Also, P_1 invokes $\mathcal{F}_{oprf}$ with P_n, where P_1 and P_n respectively act as the receiver and sender. Then P_n receives an OPRF key k and computes an item-value set $S_n = \{(x_j^n, F_k(x_j^n))\}_{\forall j \in [m]}$. P_1 and P_2 respectively compute $S_1 = \{(x_j^1, F_s(x_j^1) \oplus F_k(x_j^1))\}_{\forall j \in [m]}$ and $S_2 = \{(x_j^2, F_s(x_j^2))\}_{\forall j \in [m]}$.
2. **[Transition]**. P_2 starts the OKVS transition by inputting S_2 in the OKVS chain $P_2 \to P_3 \to \cdots \to P_n \to P_1$. In the transition, P_i inputs $\{(x_j^i, 0)\}_{\forall j \in [m]}$ $(i = 3, 4, \cdots, n-1)$ and P_n inputs S_n.
3. **[Intersect]**. P_1 computes the intersection $I = \{x_j^1 | F_s(x_j^1) \oplus F_k(x_j^1) \oplus Decode(T_n, x_j^1) = 0, \forall j \in [m]\}$, where T_n is the P_1's received OKVS table from P_n.

Figure 6: O-Ring ($t = 1$): mPSI without collusion.

5 Our protocol with arbitrary collusion

In the above section, we have designed an elegant mPSI protocol without collusion (i.e., $t = 1$) by utilizing OKVS and OPRF. In this section, we continue to design a mPSI protocol that can thwart $1 < t < n$ colluding parties.

5.1 O-Ring(P_1 honest): a naive protocol

In the mPSI protocol, P_1 is the only one who receives the intersection. In Figure 5, we also observe that P_1 is the end node of the ring, which indicates that P_1 plays a different role from others in the protocol. If P_1 is honest, we utilize its special role to design a mPSI protocol with arbitrary collusion. Specifically, P_1 sends a secret key $s^{1,i}$ to each non-OPRF party P_i respectively $(i = 2, 3, \cdots, n-1)$. Then each of the non-OPRF parties can use this secret PRF key to mask its items' decoded values, thus making it random to other parties. It is noted that there is no need for P_1 to do masking with P_n because they have already invoked an OPRF instance. The general workflow is shown in Figure 7. In this flow, the masked parties P_i $(i = 2, 3, \cdots, n-1)$ can utilize these PRF keys to mask their items' values by updating the value v as $v \oplus F_{s^{1,i}}(x)$, thus keeping it pseudorandom to the other parties.

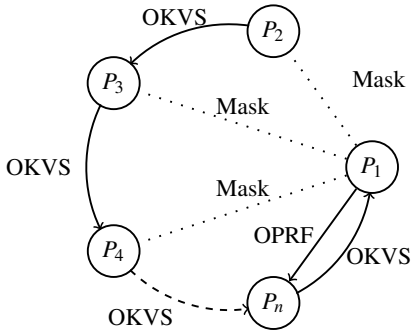

Figure 7: The workflow of our mPSI protocol with arbitrary collusion when P_1 is honest.

5.2 Identifying an honest party

The above protocol assumes that P_1 is honest and does masking between P_1 and the other parties such that the protocol can be secure against an arbitrary number of colluding parties. However, if P_1 joins the collusion, the protocol will be insecure. Therefore, assuming that P_1 is not honest, we need to find an honest party to ensure the security of the protocol.

In addition to having masking between P_1 and the other parties in Figure 7, we follow the masking idea to assume that P_n is honest and try to do the masking between P_n and P_i with PRF keys $s^{n,i}$ $(i = 2, 3, \cdots, n-1)$ to thwart the colluding attack. Unfortunately, there will be a colluding attacks even after masking. If P_1 joins the collusion with a masked party P_i $(i \in [2, n-1])$, they will know extra information beyond the intersection. Specifically, assuming P_1 has an item x but P_i does not, they can know if the other $n-2$ parties have x. P_1 and P_i can simply check if $Decode(T_n, x) \oplus Decode(T_{i-1}, x) = Decode(T_i, x) \oplus F_{s^{n,i}}(x)$[1] if $i > 2$. Here P_i has T_i, T_{i-1}, and $s^{n,i}$; P_1 has T_n. Based on the property of OKVS chain, if $P_2, P_3, \cdots, P_{i-1}, P_{i+1}, \cdots, P_n$ has x, we have $Decode(T_{i-1}, x) = \bigoplus_{j=2}^{i-1} F_{s^{n,j}}(x)$ and $Decode(T_n, x) = Decode(T_i, x) \oplus \bigoplus_{j=i+1}^{n-1} F_{s^{n,j}}(x) \oplus$

[1] For simplicity, we do not consider PRF values between P_1 and the other parties. If consider, P_1 and P_i should check $Decode(T_n, x) \oplus Decode(T_{i-1}, x) = Decode(T_i, x) \oplus F_{s^{n,i}}(x) \oplus \bigoplus_{j=2}^{n} F_{s^{1,j}}(x) \oplus F_{s^{1,i}}(x)$.

$\bigoplus_{j=2}^{n-1} F_{s^{n,j}}(x) = Decode(T_i,x) \oplus \bigoplus_{j=2}^{i-1} F_{s^{n,j}}(x) \oplus F_{s^{n,i}}(x)$. Then it is easy to know $Decode(T_n,x) \oplus Decode(T_{i-1},x) = \bigoplus_{j=2}^{i-1} F_{s^{n,j}}(x) \oplus Decode(T_i,x) \oplus \bigoplus_{j=2}^{i-1} F_{s^{n,j}}(x) \oplus F_{s^{n,i}}(x) = Decode(T_i,x) \oplus F_{s^{n,i}}(x)$. Now, P_i knows x is in the intersection of the other $n-2$ parties' sets, which should not be allowed because x is not in the intersection of all parties. If $i = 2$, P_2 and P_1 can simply check if $Decode(T_n,x) = Decode(T_2,x) \oplus F_{s^{n,2}}(x)$.

The reason why P_i and P_1 can have the collusion attack is that masking by sharing PRF keys is symmetric. Namely, both P_i and P_n know the PRF key $s^{n,i}$. By using this key, P_i can compute the PRF value $F_{s^{n,i}}(x)$ for x to do the checking even he/she does not have x. To thwart the colluding attack, instead of using masking, the asymmetric OPRF can be used. Specifically, P_n can invoke an OPRF instance with P_i by acting as a sender who holds the OPRF key $k^{n,i}$. Then if P_i does not have x, he/she cannot compute $F_{k^{n,i}}(x)$ to finish the checking. Since $i \in [2,n-1]$, P_n needs to do OPRF with $P_2,P_3,\cdots,P_{n-1}$. Taking P_1 into attack, P_n still needs to do OPRF with P_1 by acting as a sender. As a common OPRF sender to the other $n-1$ parties, if one colluding party P_i who acts as an OPRF receiver does not have x, then its OPRF value $F_{k^{n,i}}(x)$ of P_n will be pseudorandom to P_i and the colluding parties, thus ensuring the security of P_n. For an honest party P_j, $j \in [2,n-1]$ who is an OPRF receiver, his/her OPRF value $F_{k^{n,j}}(x)$ is also pseudorandom to other parties because the honest P_n holds the key $k^{n,j}$. Therefore, it is also secure for P_j.

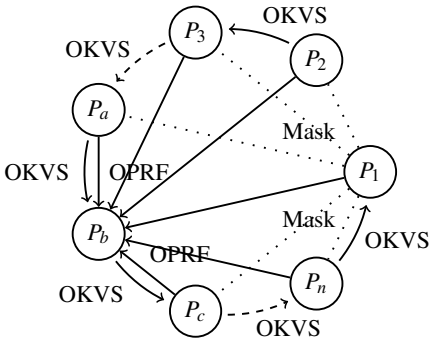

Figure 8: The workflow of a protocol that assumes P_b is honest. P_a and P_c are respectively the previous party and posterior party of P_b in the OKVS chain.

Having the above analysis, we know that if P_n (who acts as a common OPRF sender to the other $n-1$ parties) is honest, the protocol is secure against the collusion attack. In a general discussion, let us assume P_b is honest, the protocol workflow is shown in Figure 8. In this workflow, P_b acts as the common OPRF sender to the other $n-1$ parties and the protocol receiver P_1 shares PRF keys with the other parties except for P_b. It is noted that P_b has already done OPRF with P_1 and there is no need for P_1 to do the masking with him/her. In the OKVS chain, P_b's input key-value pair set in the OKVS chain is $\{(x_j^b, \bigoplus_{i=1}^{b-1} F_{k^{b,i}}(x_j^b) \oplus \bigoplus_{i=b+1}^{n} F_{k^{b,i}}(x_j^b))\}_{\forall j \in [m]}$. From the value sum, one can know that if x_j^b is not in common, at least one of the OPRF values will be pseudorandom to the other parties and the encoded value in T_b is also pseudorandom.

5.3 O-Ring($t > 1$): a protocol against arbitrary collusion

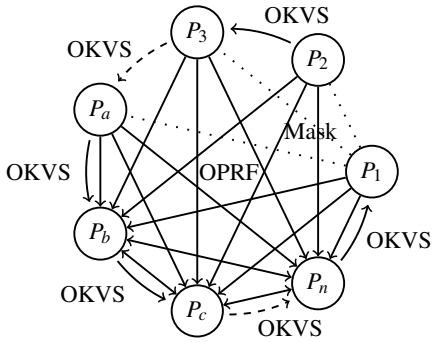

Figure 9: The workflow of O-Ring ($t > 1$). P_i ($\forall i \in [b,n]$) is a common OPRF sender for the other parties $P_1,\cdots,P_{i-1},P_{i+1},\cdots,P_n$. When $t < n-1$, P_1 still needs to share PRF keys with $P_2,P_3,\cdots,P_{b-1}$. The bidirectional arrow line indicates that the two parties invoke two OPRF instances with switched OPRF roles.

After the discussion about the honest party P_b in the above subsection, we design the mPSI protocol *O-Ring* in which there are at most t colluding parties. The workflow of O-Ring ($t > 1$) is shown in Figure 9. In this Figure, we set $b = n-t+1$ and make P_i ($\forall i \in [b,n]$) as a common OPRF sender to the other $n-1$ parties. From subsection 5.1, if P_1 is honest, it is easy to know the protocol is secure. Assuming P_1 is a colluder, there must be at least one honest party among the t parties $P_b,P_{b+1},\cdots,P_n$ because the number of colluders is at most t.

The full protocol is shown in Figure 10. In the protocol, there are three phases: share distribution, share collection, and share transition. In the share distribution phase, P_i ($\forall i \in [b,n]$) has OPRFs with other parties and P_1 shares PRF keys with P_j ($\forall j \in [2,b-1]$). Since the OPRF values and masking values are pairwise, the XOR value sum for a common item will be zero. In other words, each OPRF value or masking value is a share of 0 for the common items. After share distribution, each party P_i collects the shares it distributes and receives for each item from other parties in the OKVS chain by XOR these shares. After preparing the items' corresponding values (i.e., the share sum), all parties input their key-value (i.e., item-value) sets into the OKVS chain and start the intersection value sum transition. Given the property of OKVS chain, the end party P_1 will get the correct value sum of all the parties for each item x_j^1 if $x_j^1 \in X_2 \cap X_3 \cap \cdots \cap X_n \cap X_1$; otherwise not. The correctness of our protocol is obvious because both

Parameters: The number of parties n. The number of colluding parties t. The set size m. The statistical and computational security parameter λ and κ. The item's bit length σ. An OPRF functionality $\mathcal{F}_{oprf}$. A PRF $F_{(\cdot)}(\cdot) : \{0,1\}^{\kappa} \times \{0,1\}^{\sigma} \mapsto \{0,1\}^{\ell}$.
Inputs: Each party P_i ($i \in [n]$) inputs a set $X_i = \{x_j^i\}_{\forall j \in [m]}$.
Protocol:

1. **[Share distribution]**. Denote $b = n - t + 1$.
   (a) **[OPRF]**. P_i ($\forall i \in [b,n]$) respectively invokes an instance of $\mathcal{F}_{oprf}$ with P_j ($\forall j \in [1,n] \backslash \{i\}$) to get $\{Q^i(x_u^i) = \bigoplus_{j=1}^{i-1} F_{k^{i,j}}(x_u^i) \oplus \bigoplus_{j=i+1}^{n} F_{k^{i,j}}(x_u^i)\}_{\forall u \in [m]}$ and $\{F_{k^{i,j}}(x_u^j)\}_{\forall u \in [m]}$, where $k^{i,j}$ is the common OPRF sender P_i's OPRF key.
   (b) **[Mask]**. If $b > 2$, P_1 respectively sends a random PRF key $s^{1,j}$ to P_j ($\forall j \in [2, b-1]$).
2. **[Share collection]**.
   - $b > 2$. P_i ($\forall i \in [2, b-1]$) computes $v_j^i = F_{s^{1,i}}(x_j^i) \oplus \bigoplus_{u=b}^{n} F_{k^{u,i}}(x_j^i)$ ($\forall j \in [m]$). P_i ($\forall i \in [b,n]$) computes $v_j^i = Q^i(x_j^i) \oplus \bigoplus_{u=b}^{i-1} F_{k^{u,i}}(x_j^i) \oplus \bigoplus_{u=i+1}^{n} F_{k^{u,i}}(x_j^i)$ ($\forall j \in [m]$). P_1 computes $v_j^1 = \bigoplus_{u=2}^{b-1} F_{s^{1,u}}(x_j^1) \oplus \bigoplus_{u=b}^{n} F_{k^{u,1}}(x_j^1)$ ($\forall j \in [m]$).
   - $b = 2$. P_i ($\forall i \in [1, b-1]$) computes $v_j^i = \bigoplus_{u=b}^{n} F_{k^{u,i}}(x_j^i)$ ($\forall j \in [m]$). P_i ($\forall i \in [b,n]$) computes $v_j^i = Q^i(x_j^i) \oplus \bigoplus_{u=b}^{i-1} F_{k^{u,i}}(x_j^i) \oplus \bigoplus_{u=i+1}^{n} F_{k^{u,i}}(x_j^i)$ ($\forall j \in [m]$).
3. **[Share transition]**.
   - For O-Ring, in the OKVS chain (i.e., $P_2 \to P_3 \to \cdots \to P_n \to P_1$), each party P_i has $\{(x_j^i, v_j^i)\}_{\forall j \in [m]}$. P_2 starts the transition and P_1 gets the transition value $v_j^1 = v_j^1 \oplus \bigoplus_{i=2}^{n} v_j^i$ for each item x_j^1. P_1 gets the intersection: $I = \{x_j^1 | v_j^1 = 0, \forall j \in [m]\}$.
   - For K-Star, P_i ($i = 2, \cdots, n-1$) builds an OKVS table T_i by encoding $\{(x_j^i, v_j^i)\}_{\forall j \in [m]}$ and sends it to P_n. Upon receiving these tables, P_n also builds an OKVS table T_n by encoding $\{(x_j^n, v_j^n \oplus \bigoplus_{u=2}^{n-1} Decode(T_u, x_j^n))\}_{\forall j \in [m]}$ and sends it to P_1. Then P_1 gets the intersection: $I = \{x_j^1 | v_j^1 \oplus Decode(T_n, x_j^1) = 0, \forall j \in [m]\}$.

Figure 10: O-Ring and K-Star ($t > 1$): our mPSI protocols against $\leq t$ colluding parties.

masking and OPRF enable pairwise sharing. If an item is common, both parties will receive the same mask value and OPRF value. XORing the same value twice will get 0.

Theorem 1. *Our O-Ring ($t > 1$) in Figure 10 realizes the functionality $\mathcal{F}_{m-psi}$ against $\leq t$ colluding semi-honest adversaries in the $\mathcal{F}_{oprf}$ hybrid model.*

Proof. (Sketch). Due to the space limitation, we only sketch the security proof. Dividing the n parties into two groups C and O, which are respectively the coalition of corrupt parties and honest parties. If the protocol receiver P_1 is honest, the protocol is secure (see subsection 5.1 for related analysis). Now, assuming P_1 is a colluder in C, there must be at least one common OPRF sender (say it P_i) among the t common OPRF senders $P_b, P_c, \cdots, P_n$. If $|O| = 1$ (i.e., only P_i in O), it is easy to know the protocol is secure. If $|O| > 1$, denoting P_j as another honest party, then the OPRF values of P_i and P_j are pseudorandom to C because the honest P_i holds the secret OPRF key $k^{i,j}$. Then P_i and P_j's encoded values in step 3 is also pseudorandom. When P_i and P_j both have an item x and they are adjacent, their OPRF value sum by using $k^{i,j}$ will be 0, which is not pseudorandom. However, assuming $x \notin I$, there must be one party in C who does not have x, say P_u. Then $F_{k^{u,j}}(x)$ is pseudorandom to C and it is an XOR share of P_i's value sum in step 2. Then x's encoded value in step 3 is also pseudorandom for C. Since all honest parties' encode values in step 3 are pseudorandom to C, the protocol is secure. More details are in Appendix A.3. □

5.4 K-Star: a protocol with star topology

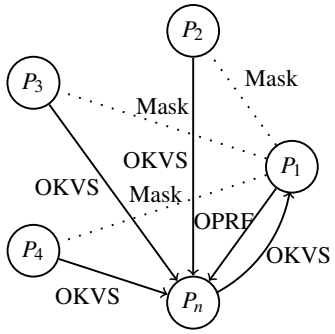

Figure 11: The workflow of K-Star when $t = 1$.

In O-Ring, there is no central party. We notice that many previous works [2, 17, 21] used the star topology to design their protocol. In their works, one party needs to carry the workload much larger than the other parties, especially when n is large and t is small. This cannot be avoided because the star structure requires one party to handle the shares from other parties. In real-world applications, this central party can

be a server with strong computation power and is willing to pay more communication costs.

Based on the ring design, we also proposed a star design *K-Star*. The full protocol of K-Star when $t > 1$ is shown in Figure 10. The only difference between O-Ring and K-Star is in the last step. Instead of transiting the shares via the OKVS chain in O-Ring, the parties $P_2, P_3, \cdots, P_{n-1}$ simply send the value shares to the center P_n via the OKVS tables. Then P_n transits the collected shares to the protocol receiver P_1 such that P_1 can compute the intersection. The security of K-Star ($t > 1$) is the same as O-Ring ($t > 1$).

Theorem 2. *Our K-Star ($t > 1$) in Figure 10 realizes the functionality $\mathcal{F}_{m-psi}$ against $\leq t$ colluding semi-honest adversaries in the $\mathcal{F}_{oprf}$ hybrid model.*

Proof. (Sketch). In O-Ring ($t > 1$), the share distribution and share collection steps by using OPRF and masking ensure the security of the protocol. Specifically, having OPRF enables each item's encoded value in step 3 is pseudorandom to the colluded parties. K-Star and O-Ring only differs in the share transition step. Therefore, if O-Ring ($t > 1$) is secure, K-Star ($t > 1$) is also secure. More analysis are in Appendix A.4. □

We also illustrate the working flow of K-Star when there is no collusion (i.e., $t = 1$) in Figure 11. In the flow, P_1 first sends PRF keys to P_i ($\forall i \in [2, n-1]$) and has an OPRF instance with P_n by acting as an OPRF receiver. Then each party collect their shares. Parties $P_2, P_3, \cdots, P_{n-1}$ directly send their values to the center P_n via OKVS tables. Finally, P_n sends the collected shares to P_1 via an OKVS table to compute the intersection. The full protocol is shown in Figure 12. We put the security proof for this protocol in Appendix A.2.

6 Experiments and evaluations

The benchmark machine is with 32-core Intel(R) Xeon(R) Gold 6226R CPU @ 2.90GHz and 236G RAM. The network is simulated by the localhost network as other mPSI works [4, 17]. The bandwidth and the latency are controlled by the Linux *tc* command. There are two network settings: for the LAN setting, the bandwidth is 10Gbps and the round-trip latency is 0.06ms; for the WAN setting, the bandwidth is 200Mbps and the round-trip latency is 96ms.

To implement our protocols (O-Ring and K-Star), we utilize the OPRF protocol in [26], which is composed of a primitive VOLE and an OKVS. We utilize the OKVS *3H-GCT* [8] with an expansion rate about 1.3. The statistical and computational security parameters are respectively set as $\lambda = 40$ and $\kappa = 128$. The item bit length is $\sigma = 128$. As [17], the item's share bit length is $\ell = \lambda + \log_2(m)$. For each party, we run it by using a single thread as previous works [4, 17]. For each setting, we run 10 times and take the average as [17]. Our protocols are written in C++ as [4, 17]. Our source codes are at https://github.com/private-panda/oring.

Parameters: The number of parties n and set size m. The statistical security parameter λ and the computational security parameter κ. The item's bit length σ. An OKVS scheme $Encode(\cdot)$, $Decode(\cdot,\cdot)$. A PRF $F_{(\cdot)}(\cdot) : \{0,1\}^\kappa \times \{0,1\}^\sigma \mapsto \{0,1\}^\ell$.
Inputs: Each party P_i inputs a set $X_i = \{x_j^i\}_{\forall j \in [m]}$ for $i \in [n]$, and $x_j^i \in \{0,1\}^\sigma$.
Protocol:

1. **[Initiation]**. P_1 sends a PRF key $s^{1,i}$ to P_i ($i = 2, 3, \cdots, n-1$). Also, P_1 invokes $\mathcal{F}_{oprf}$ with P_n, where P_1 and P_n respectively act as the receiver and sender. Then P_n receives an OPRF key k and computes an item-value set $S_n = \{(x_j^n, F_k(x_j^n))\}_{\forall j \in [m]}$. P_1 and P_i ($i \in [2, n-1]$) respectively compute $S_1 = \{(x_j^1, v_j^1 = \bigoplus_{i=2}^{n-1} F_{s^{1,i}}(x_j^1) \oplus F_k(x_j^1))\}_{\forall j \in [m]}$ and $S_i = \{(x_j^i, F_{s^{1,i}}(x_j^i))\}_{\forall j \in [m]}$.
2. **[Transition]**. P_i ($i = 2, 3, \cdots, n-1$) encode S_i into an OKVS table T_i and sends T_i to P_n. Then P_n encodes $\{(x_j^n, F_k(x_j^n) \oplus \bigoplus_{i=2}^{n-1} Decode(T_i, x_j^n)\}_{\forall j \in [m]}$ to get an OKVS table T_n and sends it to P_1.
3. **[Intersect]**. P_1 computes the intersection $I = \{x_j^1 | v_j^1 \oplus Decode(T_n, x_j^1) = 0, \forall j \in [m]\}$.

Figure 12: K-Star ($t = 1$): mPSI without collusion.

6.1 Optimizations

There are two fine-grained optimizations when we implement the OKVS and OPRF. For the OKVS, there are two phases: peeling and unpeeling. The peeling phase is only related to the keys and the unpeeling phase is to assign the values for the keys. Our first optimization is to do the peeling for each party (by taking the items as the keys) before interactions with other parties. Then each party can immediately do the unpeeling (rather than peeling and unpeeling) upon receiving the values from other parties, thus supporting better concurrency. Having this optimization, the running time of the OKVS chain can be 6.3% $\sim$ 52.5% faster, as is shown in Table 2.

$m \backslash n$	3	10
2^{12}	33/46 (27.3%)	169/216 (22.1%)
2^{16}	429/699 (38.6%)	2883/3078 (6.3%)
2^{20}	10412/15001 (30.6%)	29823/62766 (52.5%)

Table 2: The running time (in ms) comparisons for OKVS chain with/without our optimization. In each cell, the left and right data of '/' are respectively for our optimization and the naive one; the data in '()' is the improvement percentage.

In the OPRF invocations, each receiver needs to do the OKVS encoding before interactions with multiple senders. Specifically, an OPRF receiver P_i needs to do

$Encode(\{(x_j^i, H_1(x_j^i))\}_{\forall j\in[m]})$, which is independent with other senders. Here $H_1(\cdot) : \{0,1\}^\sigma \mapsto \{0,1\}^\ell$ is a random oracle. Therefore, there is no need for an OPRF receiver P_i to repeatedly do the encoding for multiple times. In our second optimization, we only do $Encode(\{(x_j^i, H(x_j^i))\}_{\forall j\in[m]})$ once for each OPRF receiver, thus saving computation costs. In Table 3, we compare the running time by utilizing this optimization with that by having n' naive OPRF invocations. From this table, we can find that one can save $1.0\% \sim 24.0\%$ running time for $n' = 2, 9$ and $2^{12} \le m \le 2^{20}$ after optimization. We call our optimization as a multi-sender OPRF. More details are in Appendix B.

$m \backslash n'$	2	9
2^{12}	49/51/113 (3.1%)	95/113 (16.1%)
2^{16}	363/367 (1.0%)	659/867 (24.0%)
2^{20}	9093/9336 (2.6%)	14565/15555 (6.4%)

Table 3: The running time (in ms) comparisons between our optimization (by having an OPRF receiver with n' OPRF senders) with naive n' OPRF invocations. In each cell, the left and right data of '/' are respectively for our optimization and the naive one; data in '()' is the improvement percentage.

6.2 Performance comparisons

We respectively compare the running time and communication costs of O-Ring and K-Star after the above optimizations with other state-of-the-art mPSI protocols [4, 17] in Table 4 and 6. The comparisons are made in the same benchmark environment (i.e., same machine and bandwidth) by running their source codes. In both tables, the client is the party with the lowest workload; the *bearer* is the party with the largest workload[2]. For our K-Star and O-Ring, the *bearer* is P_n and the client is P_2.

6.2.1 K-Star *vs* O-Ring

The difference between O-Ring and K-Star lies in the last step in Figure 10. The ring-based design O-Ring distributes the transition costs to all parties. However, the star-based design K-Star assigns the costs to the bearer P_n. Therefore, P_n gets larger computation costs and communication costs.

In Table 4, we do not show the running time of P_n. The running time of P_n is slightly smaller than the total running time of P_1. For other star-based protocols [4, 25], the running time is the central party's running time. When $n = 3$, O-Ring and K-Star have the same topology, thus having the same performance. Since the star structure gains better concurrency, K-Star runs faster than O-Ring in other settings. For example, when $n = 10$, K-Star runs $13.6\% \sim 19.3\%$ faster in the LAN setting. For the client running time, K-Star and O-Ring are close. O-Ring can share a part of the bearer's cost in K-Star to the other parties, especially the communication costs. From Table 6, we can find that O-Ring has the lowest communication costs for the bearer P_n, which is $3.0\% \sim 63.4\%$ lower than K-Star except for the case when $n = 3$. For the client P_1 in both protocols, the only difference is that P_1 sends an OVKS table to P_2 in O-Ring and sends an OKVS table to the bearer P_n in K-Star, thus having the same communication costs. Though the topology of K-Star is different from O-Ring, the total communication costs do not change. For theoretical communication costs, we put them in Table 5.

From the above analyses, one can find that O-Ring is more suitable than K-Star in applications where the bearer has relatively limited communication and computation resources. In contrast, if the bearer's resources are sufficient, K-Star is preferable because it runs faster.

After comparing O-Ring and K-Star, we continue to make comparisons between them with [4, 17]. Compared with these protocols, O-Ring and K-Star run the fastest and achieve the lowest communication costs in the most of the settings. More details are as follows.

6.2.2 Comparisons with KMPRT'17 [17]

We compare K-Star and O-Ring with the semi-honest protocol in [17] under the same collusion security model, i.e., supporting an arbitrary $t \in [1, n-1]$. Kolesnikov et al. [17] proposed their mPSI protocol by using an OPPRF primitive. Their OPPRF protocols are built upon the OPRF primitives, thus more expensive than OPRF protocol. We build our protocols by using OPRF. Considering $t = n-1$, in their protocol, each party first needs to have $n-1$ OPPRF invocation with other parties and have another invocation with the bearer. Therefore, the total number of invocations is $n \times (n-1) + (n-1) = (n+1)(n-1)$. In comparison, our O-Ring and K-Star only needs $n \times (n-1)$ invocations of the OPRF functionality. When $t < n-1$, they need $(t+1) \times n + (n-1)$ OPPRF invocations. In comparison, we need $t(n-1)$ OPRF invocations. Additionally, we need $n-1$ OKVS encoding and decoding. The cost of OKVS can be very small [8][3]. Therefore, our protocols are theoretically more efficient than [17].

From Table 4, in the LAN setting, O-Ring is respectively $1.5\times \sim 13.2$ and $1.4\times \sim 6.0\times$ as fast as KMPRT'17 [17] in the client running time and the total running time (except for one setting $(n,t,m) = (10,1,2^{20})$). The exception is because O-Ring takes a ring design while KMPRT'17 [17] has a star structure. in the WAN setting, we also observe one exceptions in the settings $(n,t,m) = (10,1,2^{12})$, in which O-Ring is 25.5% and 11.1% slower in the total running time. In other

[2] Here, we do not use *leader* as the traditional mPSI protocols that are based on a star topology. The reason is that we do not have such a central party in O-Ring that is based on a ring topology.

[3] In [8], one can encode $m = 2^{20}$ key-values pairs for 7.13s and decode $m = 2^{20}$ keys for 1.09s with a table size about $1.3m$.

Protocol	Client	Bearer	Total
O-Ring ($t=1$)	ϕ	$2\phi+\omega$	$\phi'+\omega$
O-Ring ($t>1$)	$\phi+t\omega$	$2\phi+(n-1)\omega$	$\phi'+(n-1)t\omega$
K-Star ($t=1$)	ϕ	$\phi'+(n-1)\omega$	$\phi'+\omega$
K-Star ($t>1$)	$\phi+t\omega$	$\phi'+(n-1)\omega$	$\phi'+(n-1)t\omega$

Table 5: The theoretical communication costs (in bits) for O-Ring and K-Star. $\omega = 1.3\kappa m + \ell m + 2^{13}\kappa m^{0.13}$ is the OPRF cost [26]. $\phi = (1.3m+\lambda+0.5\log(m))\ell$ is the OKVS table bit size [8]. $\phi' = (n-1)\phi$.

settings, O-Ring is $1.2\times \sim 18.1\times$ as fast as theirs. Our O-Star has the same star structure as KMPRT'17 [17]. From Table 6, in the LAN setting, K-Star is $1.6\times \sim 12.7\times$ and $1.4\times \sim 9.0\times$ as fast in the client running time and the total running time. in the WAN setting, the ratios for the client running time are $2.0 \sim 26.2\times$ with two exceptions in the settings $(n,t,m) = (10,4,2^{12}), (10,9,2^{12})$. In these two exceptions, K-Star is respectively 22.7% and 8.5% slower. As for the total running time, K-Star is $1.2\times \sim 18.9\times$ as fast with one exception in the setting $(n,t,m) = (10,4,2^{12})$. In this exception, K-Star runs 11.1% slower. In communication, O-Ring and K-Star are respectively $1.4\times \sim 82.6\times$ and $1.6\times \sim 48.3\times$ as cheap as KMPRT'17 [17] in the client's costs and the total costs. For bearer's communication costs, O-Ring and K-Star are respectively $1.4\times \sim 26.9\times$ and $1.4\times \sim 14.4\times$ as cheap.

In KMPRT'17 [17], the authors specially proposed an optimized protocol for $n = 3$. However, when $(n,t) = (3,2)$, their protocol is insecure. More details are in subsection 6.4.3. Therefore, we do not report their data in this setting in Table 4 and 6. In [17], the authors also proposed another protocol that gained better performance based on a weaker security model, i.e., the augmented semi-honest security model. In this paper, we only focus on the semi-honest model. Also, their augmented semi-honest protocol is prone to the collusion attack, which will be also elaborated in subsection 6.4.1.

6.2.3 Comparisons with CDGOSS'21 [4]

Chandran et al. [4] proposed their protocol based on their proposed functionality called wPSM, which was instantiated by the OPPRF protocols in [17]. Additionally, after the OPPRF invocations between the center P_1 and the other $n-1$ parties, they need other multi-party functionalities, e.g., the *ConvertShares* that can exploit (n,t) secret sharing to generate shares. One drawback of their protocol is that their protocol is limited in $t < n/2$. Therefore, we only provide the performance data for $t < n/2$ in Table 4 and Table 6.

From Table 4, for the client running time, O-Ring is respectively $1.7\times \sim 57.1$ and $1.0\times \sim 10.0\times$ as fast as CDGOSS'21 [4] in the LAN and WAN settings. For the total running time, except for two setting $(n,t,m) = (10,1,2^{20}), (10,4,2^{20})$, O-Ring is respectively $1.2\times \sim 12.9\times$ as fast as CDGOSS'21 [4] in the LAN setting. In the WAN setting, except for one setting $(n,t,m) = (10,4,2^{12})$, O-Ring is $1.1\times \sim 2.7\times$ as fast. For K-Star, for the client running time, it is respectively $1.7\times \sim 55.5\times$ and $1.0\times \sim 8.7\times$ as fast as CDGOSS'21 [4] in the LAN and WAN settings. In the total running time, K-Star is $1.0\times \sim 15.3\times$ as fast in the LAN setting. Except for one setting $(n,t,m) = (10,4,2^{12})$, K-Star is $1.0\times \sim 4.4\times$ as fast. In this exception, CDGOSS'21 [4] is $1.5\times$ as fast as K-Star. In communication, O-Ring is respectively $1.2\times \sim 69.9\times$ and $2.0\times \sim 67.8\times$ as cheap as CDGOSS'21 [4] in the client costs and the bearer's costs. For the total costs, except for the setting $(n,t,m) = (10,4,2^{12})$, O-Ring is $4.0\times \sim 39.8\times$ as cheap as theirs. In $(n,t,m) = (10,4,2^{12})$, CDGOSS'21 [4] is $1.1\times$ as cheap as O-Ring. In the bearer's costs, K-Star is $1.9\times \sim 27.5\times$ as cheap as CDGOSS'21 [4].

Table 6: The communication cost (in MB) comparisons between our protocols with other mPSI protocols. The best results are marked in bold. Cell with '-' indicates that the setting is not supported. The *bearer* is the party with the largest workload.

In addition to the above experiment results, we also compare the total theoretical communication costs. From CDGOSS'21 [4], the total communication cost of their protocol is $m(n-1)(4.5\kappa+35\ell+140)$ bits (i.e., in $O(mn)$), which is independent with the number of parties t and linear with n. However, O-Ring and K-star need $(n-1)(1.3m+\lambda+0.5\log(m))\ell+(n-1)t(1.3\kappa m+\ell m+2^{13}\kappa m^{0.13})$ bits (i.e., in $O(mnt)$). Therefore, when t is large (e.g., $t=n/2-1$), their protocol is expected to have better performance than O-Ring and K-Star. For example, in Table 4, when $m=2^{12}$ and $(n,t)=(10,4)$, their protocol needs 17.65 MB in total, which is 5.3% cheaper than O-Ring and K-Star. However, for a large set size $m=2^{20}$, even when we increase n to 54[4], their protocol still needs more communication costs than O-Ring and K-Star. Specifically, their protocol needs 50320.7 MB, while O-Ring and K-Star only need 31573.2 MB, which is 37.3% cheaper. As for the total running time, from Table 4, when $(n,t,m)=(10,4,2^{12})$ in the WAN setting, their protocol can already run 32.1% faster. For a large set size $m=2^{20}$ in the LAN setting, when increasing n to 11 and set the largest $t=5$, their protocol can also run faster. Specifically, their protocol runs in 24.1 seconds, which is 9.8% faster than K-Star.

6.3 Application: secure medical data integration

In [11], Gon et al. showed that integrating medical records between different institutions was useful to investigate the correlation between stroke and cancer. In privacy-preserving medical data integration [19,20], multiple institutions aim to integrate their patient databases without violating the patient or commercial privacy. To achieve this, Miyaji et al. [20] proposed a mPSI protocol by using Bloom filter and exponential ElGamal homomorphic encryption (exElGamalHE) [5].

To test the efficiency of our protocols for secure medical data integration, we set the largest number of institutions $n=16$ and the largest database size $m=2^{14}$ as [20]. For the number of colluding parties, we also consider $t=n-1$ as theirs. The bandwidth is also the same as their (i.e., 2 Gbps). As a result, our O-Ring and K-Ring respectively run in 1.5 seconds and 1.2 seconds, which are cheap. In comparison, their protocol needs >1044 seconds [6], which are expensive. In communication costs for the client and the bearer, O-Ring (resp. K-Star) needs to take 22.7 MB (resp. 22.7 MB) and 22.9 MB (resp. 24.9 MB). For the total communication cost, both O-Ring and K-Star need 177.6 MB. The communication costs are very low. In comparison, the protocol in [20] respectively needs to take 1731.2 MB, 22159.8 MB, and 42934.6 MB for the client, the bearer, and the total cost, which are respectively $>76.2\times$, $>890.0\times$, and $>365.1\times$ as expensive as O-Ring and K-Star.

6.4 Insecurity of prior protocols

6.4.1 Augmented semi-honest protocol [17]

In section 2, we have introduced the augmented semi-honest protocol in [17]. Though it gets good performance, it is prone to the collusion attack when the protocol receiver P_1 joins the collusion. One can first check the case for $t=n-1$. Since the PRF keys sharing is symmetric, if $t=n-1$, all the PRF keys are known to the colluding parties, thus bringing no security benefit. Assuming P_i $(i>1)$ is the non-colluding party and its PRF keys are $s^{i,j}$ $(\forall j\in[n]\backslash i)$, then the share of each item $x^i\in X_i$ is $v^i=\bigoplus_{j=1}^{i-1}F_{s^{i,j}}(x^i)\oplus\bigoplus_{j=i+1}^{n}F_{s^{i,j}}(x^i)$. With the collusion between the receiver with the other $n-2$ parties, the receiver P_1 knows all $s^{i,j}$ $(\forall j\in[n]\backslash i)$. After the OPPRF invocation between P_i, it is easy for P_1 to know the intersection

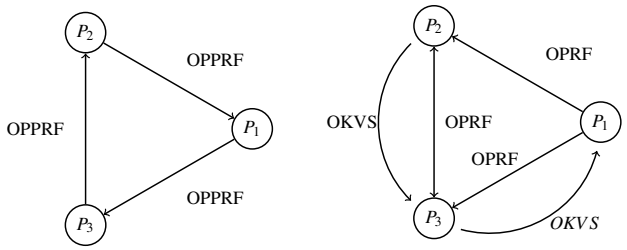
[4] For a larger set size, their program simply crashes.

[5] In [19], the authors directly used the mPSI protocol in [20]. Therefore, we do not put it into analysis in this paper.

[6] Their protocol is very time-consuming. In our implementation of their protocol, only encrypting the Bloom filter by using exElGamalHE takes 1044 seconds. There are also other expensive operations, e.g., computing the sums of the encrypted Bloom filter.

$X_1 \cap X_i$ by comparing the OPPRF value of each item $x^1 \in X_1$ with v^1. If they are equal, then x^1 is in the intersection; otherwise not. As a consequence, the colluding parties know extra information beyond the intersection $\bigcap_{i=1}^{n} X_i$, which is not allowed. In fact, one can further generalize the above collusion attack for $t < n-1$ such that the colluding parties can know $X_1 \cap \bigcap X_i$, where $\bigcap X_i$ is the intersection of the $n-t$ non-colluding parties. Since there are $t-1$ parties who are colluding with the protocol receiver P_1, P_1 can know all the PRF keys between them with the $n-t$ honest parties. Now, after the OPPRF between these $n-t$ honest parties, for each item $x^1 \in X_1$, P_1 simply checks whether its OPPRF value sum is equal to the PRF value sum by using the PRF keys that are known to colluding parties. If there is a match, it indicates that x^1 is in $X_1 \cap \bigcap X_i$. It is noted that none of colluding parties except for P_1 needs to use their sets in the above attack.

6.4.2 ZeroXOR [21]



In section 2, we have introduced the zeroXOR protocol and mPSI protocol in [21]. When $t = n-1$, their mPSI protocol becomes the zeroXOR protocol in which all items' values of the n parties are 0s and their mPSI protocol is almost the same as the augmented semi-honest protocol [17], thus it is also prone to the collusion attack.

When $1 < t < n-1$[7], their mPSI protocol is also insecure. Specifically, the pivot P_w can collude with the protocol receiver P_1 to know information beyond the intersection $\bigcap_{i=1}^{n} X_i$. After receiving an OKVS table T_i from a non-zeroXOR party P_i, P_w decodes and computes each item x_j^w's associated value $v_j^w = Decode(T_i, x_j^w) \oplus v'_j$ and performs OPPRF with the protocol receiver P_1 by inputting $\{(x_j^w, v_j^w)\}_{\forall j \in [m]}$, where v'_j is the PRF value sum in the zeroXOR. If the final value sum of $x_j^1 \in X_1$ is 0, then P_1 will include x_j^1 into the intersection. Now, assuming all the other parties have an item x except for the pivot party P_w. Then P_w and P_1 can collude to know if P_i has x. Specifically, P_w can decode T_i by using x and compute $v'' = Decode(T_i, x) \oplus v'$, where v' is the PRF value sum in the zeroXOR. P_w shows v'' to P_1. If v'' is matched, it indicates that P_i has x. It is noted that P_w can compute any PRF value sum including v' because he/she has the shared PRF keys with the other t parties in the zeroXOR. Therefore, their protocol is also insecure when $1 < t < n-1$.

6.4.3 Optimized three-party protocol [17]

In addition to their augmented protocol and semi-honest general protocol, the authors [17] also specially proposed an optimized three-party PSI protocol. In this protocol, the protocol receiver P_1 and P_2 first invoke an OPPRF instance, in which P_1 acts as the sender and P_2 acts as the receiver. Then P_2 interacts with P_3 by acting as the OPPRF sender. Finally, P_3 interacts with P_1 by acting as the OPPRF sender. One can find the working flow in sub-Figure 13a.

[7] In [21], the authors also specially proposed a protocol when there is no collusion (i.e., $t = 1$), which is secure by using a two-party PSI primitive.

(a) KMPRT [17] (b) O-Ring

Figure 13: Three-party PSI protocol workflow comparisons.

However, their proposed three-party PSI protocol is also insecure. As the sender, P_1 knows the OPPRF key and can get the key-value pairs in the full item domain. Then P_3 will also know $X_2 \cap X_3$ by colluding with P_1. Actually, P_1 is not supposed to act as a sender in any OPPRF (or OPRF) interaction with other parties in case that he/she launches the brute-force attack when the input domain is small. In another collusion attack, P_2 and P_1 can collude to know if P_3 has an item x even $x \notin I$. Specifically, assuming P_1 and P_3 both have x, then P_1 can get the correct value v from P_3. For P_3, v is got from P_2. If P_2 does not have x, P_3 will get the incorrect v and then give v to P_1 and P_1's colluding party P_2. Since P_2 has the OPPRF key, he/she can have the brute-force attack for the input domain until he/she finds x. Or a more simple way of P_2 is to compute the OPPRF values of P_1's items until he/she finds v and knows x. Now, P_2 and P_1 knows P_3 has x even $x \notin I$. Intuitively, it is insecure for an OPPRF receiver to disclose its OPPRF values to the OPPRF sender.

In comparison, our three-party design can thwart the above collusion attacks because both P_2 and P_3 are a common OPRF sender to the other two parties. The working flow of our three-party protocol is shown in sub-Figure 13. It is noted that O-Ring and K-Star share the same topology when $n = 3$. In the first step of our protocol, P_1 invokes the multi-sender OPRF instances with P_2 and P_3 by acting as the receiver. As the receiver of the multi-sender OPRF, only the intersection items' values can be correctly distributed. P_1 cannot know the item-value pairs in the item domain because he/she does not have the OPRF key. P_2 and P_3 both act as a common OPRF sender to the other parties. For an item x of P_2 or P_3, if it is not in common, at least one of its two OPRF values will be pseudorandom to the other parties because he/she holds the OPRF keys. Then the sum of the three OPRPF values (i.e., two values as an OPRF sender and one value as an OPRF receiver) will also be pseudorandom to the other parties, thus disclosing nothing to them. In the above second collusion attack, if P_2 does not have x, the OPRF value for x of P_3 will be pesudorandom to P_2 because P_3 is an OPRF sender (to P_2) who holds the key.

7 Conclusion and Future work

In this paper, we propose two protocols to achieve mPSI. Both protocols can be secure against an arbitrary number of colluding parties. Our first protocol O-Ring is ring-based and has the minimum bearer communication costs. Our second protocol is star-based and can run the fastest in the most of the settings. Both O-Ring and K-Star can achieve the lowest communication costs in the most of the settings. Technically, we utilize the OKVS and OPRF. To better support concurrency and save computation costs, we make find-grained optimizations when we implement the OKVS and OPRF in our protocols. We believe these optimizations can be utilized in other applications where a party needs to have multiple OPRF invocations with other parties by acting as a common OPRF receiver.

In this paper, we only focus on the semi-honest security model. Though Garimella et al. [8] has proved that their malicious mPSI protocol is not secure in the semi-honest model, there are also other works that focus on the malicious security model (e.g., [2,9]). By introducing a random oracle, Garimella et al. [8] designed their malicious mPSI protocol on top of the augmented semi-honest protocol in KMPRT'17 [17]. We believe using a random oracle is also helpful to make our protocols maliciously secure. We keep it as a future work.

A Security proof of O-ring and K-Star

A.1 O-Ring (t=1)

Theorem 3. *Our protocol in Figure 6 realizes $\mathcal{F}_{m-psi}$ against a semi-honest adversary in the $\mathcal{F}_{oprf}$-hybrid model.*

Proof. For the security, the receiver can no longer brute-force the full input domain even if it is small because of OPRF. Without OPRF between P_1 and P_n, P_1 can have the brute-force attack to know $\bigcap_{i=2}^{n}$ by checking P_n's OKVS table T_n. To check if an item x is in $\bigcap_{i=2}^{n} X_i$, P_1 can simply check $Decode(T_n, x) = F_s(x)$ even when $x \notin X_1$ because P_1 has the PRF key s. If yes, then x is in $\bigcap_{i=2}^{n}$. Having the OPRF, as an ORPF receiver, P_1 cannot know $F_k(x)$ if $x \notin X_1$ because P_n holds the key k. Therefore, P_1 cannot know $\bigcap_{i=2}^{n} X_i$. Here we also provide formal security proof.

- **Corrupt** P_2. In the protocol, P_2 receives an PRF key from P_1. Therefore, P_2's view can be simulated by returning a random seed. This view is indistinguishable.
- **Corrupt** P_i ($i \in [3, n-1]$). P_i receives an OKVS table T_{i-1} from its previous party in the protocol. P_i's view can be simulated by returning a random table with the same size. Given the oblivious property of OKVS, this view is also indistinguishable.
- **Corrupt** P_n. P_n receives an OKVS table T_{n-1} from P_{n-1} in the protocol and gets an OPRF key k from $\mathcal{F}_{oprf}$. T_{n-1} and k are independent. P_n's view can be simulated by returning a random table with the same size as T_{n-1} in

the real protocol and a random key. Given the oblivious property of OKVS and the security of OPRF, this view is also indistinguishable.

- **Corrupt** P_1. P_1 receives an OKVS table T_n from P_n and an OPRF set $\{F_k(x_j^1)\}_{\forall j\in[m]}$ from $\mathcal{F}_{oprf}$. The simulator can observe P_1's output set I. P_1's view can be simulated by returning an OKVS table T_n'. Here T_n' is encoded by $\{(x_i', v_i')\}_{i=1,2,\cdots,m-|I|} \cup I'$, where $\{x_i'\}_{m-|I|}$ are non-common items, $\{v_i'\}_{m-|I|}$ are randomly sampled values, and I' are item-value pairs that correspond to the common items and each common item x's value is $Decode(T_n, x)$. Given the obliviousness of OKVS and the security of OPRF, this view is indistinguishable.

□

A.2 K-Star ($t = 1$)

Theorem 4. *Our K-Star ($t = 1$) in Figure 12 realizes $\mathcal{F}_{m-psi}$ against a semi-honest adversary in the $\mathcal{F}_{oprf}$-hybrid model.*

Proof. The correctness is the same as O-Ring ($t = 1$). For security, similar to O-Ring ($t = 1$), because of the OPRF between P_1 and P_n, P_1 cannot have the brute-force attack to know $\bigcap_2^n X_i$ even the input domain is small. The view of a corrupt party can be simulated as follows:

- **Corrupt** P_2. Same as O-Ring ($t = 1$).
- **Corrupt** P_i ($i = 3, 4, \cdots, n-1$). Same as P_2.
- **Corrupt** P_n. Similar as O-Ring ($t = 1$), P_n's view can be simulated by returning $n-2$ random OKVS tables with the same size as T_i in the read protocol and a random key. Given the oblivious property of OKVS and the security of OPRF, this view is also indistinguishable.
- **Corrupt** P_1. Same as O-Ring ($t = 1$).

□

A.3 O-Ring ($t > 1$)

Proof. Dividing the n parties into two groups C and O, which are respectively a corrupt one in which the parties collude and an honest one in which all parties are honest. If the protocol receiver P_1 is honest, the protocol is secure because P_1 discloses nothing about his/her set to the other parties and the values of each other party is obfuscated by P_1's shared values. Now, we assume P_1 is a colluder in C. Then C and O can be taken as two large parties in the protocol. C can be the protocol receiver who gets the intersection and O can be the protocol sender who sends messages to the receiver such that the receiver can compute the intersection. Since the OPRF are the security building block of the protocol. O is supposed to an OPRF sender to C. Since there must be at least one common OPRF sender (say it P_i) among the t common OPRF senders $P_b, P_c, \cdots, P_n$ and all other parties in O are connected with P_i, O can be taken as an OPRF sender to C. Specifically, we consider the following cases:

1. $|O| = 1$. In this case, there is only one party P_i is O. Since P_i is a common OPRF sender to the others, if $x^i \in X_i$ is not in common, its OPRF value sum v^i in step 2 of the protocol is pseudorandom to C. Then C's view can be simulated by returning an OKVS table T_i' (in step 3) in which x^i's value is randomly sampled. This view is indistinguishable. Therefore, the protocol is secure when $|O| = 1$.
2. $|O| > 1$. In this case, denoting P_j as another honest party, for an item x of C, there are two further cases to be considered:
   (a) $x \in X^i \cap X^j$. If x is common in C, C will know x is in the intersection, which is allowed. If not, assuming P_u does not has x, then $F_{k^{i,u}}(x)$ is pseudorandom to P_u and P_i's value sum in step 2 is pseudorandom to C. Since the honest P_i holds the key $k^{i,j}$, P_j's OPRF value $F_{k^{i,j}}(x)$ is also pseudorandom to C and P_j's value sum v^j in step 2 of the protocol is also pseudorandom to C. If P_i and P_j are adjacent, C's view can be simulated by returning an OKVS table $T'_{\max(i,j)}$ in which x's value is randomly sampled. This view is indistinguishable because the pseudorandom $F_{k^{i,u}}(x)$ is an XOR share of $P_{\max(i,j)}$'s value sum $Decode(T_{\min(i,j)}, x) \oplus v^{\max(i,j)}$ in step 3. It is noted that P_i and P_j cannot rely on the security of their key $k^{i,j}$ when they are adjacent because the XOR sum of their OPRF values by using this key is 0. If P_i and P_j are not adjacent, C's view can simulated by returning two OKVS tables T_i' and T_j' in which x's value are randomly sampled. This view is indistinguishable because $F_{k^{i,u}}(x)$ and $F_{k^{i,j}}(x)$ are pseudorandom to C.
   (b) $x \notin X^i \cap X^j$. In this case, $F_{k^{i,j}}(x^i)$ and $F_{k^{i,j}}(x^j)$ are both pseudorandom to C because P_i has the OPRF key $k^{i,j}$, where $x^i \in X_i$, $x^j \in X_j$, and $x^i \neq x^j$. Since $F_{k^{i,j}}(x^i)$ and $F_{k^{i,j}}(x^j)$ are respectively an XOR share of v^i and v^j, the value sums $Decode(T_{i-1}, x) \oplus v^i$ and $Decode(T_{j-1}, x) \oplus v^j$ are also pseudorandom to C. If P_i and P_j are adjacent, C's view can be simulated by returning an OKVS table $T'_{\max(i,j)}$ in which x's value is randomly sampled. This view is indistinguishable because $F_{k^{i,j}}(x^i)$ is pseudorandom and it is an XOR share of $Decode(T_{\min(i,j)}, x) \oplus v^{\max(i,j)}$ in step 3. It is noted that $Decode(T_{\min(i,j)}$ is also pseudorandom based on the property of OKVS when $x^i \neq x^j$. However, we do not rely its security because of the possible brute-force attack (see subsection 4.1 for related analysis). If P_i and P_j are

not adjacent in step 3, C's view can be simulated by returning two OKVS tables T_i' and T_j' in which both x^i's value and x^j' value are randomly sampled. This view is indistinguishable because $F_{k^{i,j}}(x^i)$ and $F_{k^{i,j}}(x^j)$ are pseudorandom to C.

From above analyses, C cannot distinguish the above two cases. Therefore, O-Ring is also secure when $|O| > 1$.

□

A.4 K-Star ($t > 1$)

Proof. In O-Ring ($t > 1$), the share distribution and share collection steps by using OPRF and masking ensure the security of the protocol. Specifically, having OPRF enables each item's value that is encoded in step 3 is pseudorandom to the colluded parties. If P_1 is honest, having masking can also ensure the encoded values are pseudorandom. K-Star ($t > 1$) shares the same OPRF and masking steps (i.e., step 1 and step 2), thus having the same security. K-Star and O-Ring only differ in the share transition step. In K-Sar, there is a center P_n. In the simulation, if the common OPRF sender P_i is P_n, P_i and P_j will be adjacent. The view of C can be simulated by returns an OKVS table T_n' in which an item x's value is randomly sampled. This view is indistinguishable. If P_i is not P_n, P_i and P_j are not adjacent. The view of C can be simulated by returning two OKVS tables T_i' and T_j' in which x's values are randomly sampled. This view is also indistinguishable. □

B Multi-sender OPRF

Parameters: The number of senders n', the set size of each sender m_i and the receiver m_r. The bit length of each item σ. A PRF $F_{(\cdot)}(\cdot)$ and a function $Q_{(\cdot)}(\cdot)$.
Inputs: The receiver has a set $X = \{x_j\}_{\forall j\in[m_r]}$. The n senders respectively have n sets $Y_i = \{y_j^i\}_{\forall i\in[m_i]}$ for $i \in [n]$, and $x_j, y_j^i \in \{0,1\}^\sigma$.
Outputs: The receiver gets an item-value set $\{(x_j, Q_k(x_j)\}_{\forall j\in[m_r]}$ and the n' senders respectively get an item-value set $\{(y_j^i, F_{s^i}(y_j^i))\}_{\forall j\in[m_i]}$ $(i \in [n'])$, where s_i is the i-th sender's PRF key, $k = (s_1, s_2, \cdots, s_{n'})$. If $x_j \in X \cap \bigcap_{i=1}^{n'} Y_i$, then its corresponding value $Q_k(x_j) = \bigoplus_{i=1}^{n'} F_{s^i}(y_*^i))$, where $*$ is the index of an item $y_*^i \in Y_i$ equaling to x_j; otherwise, $Q_k(x_j)$ is pseudorandom to the receiver.

Figure 14: The ideal functionality of multi-sender OPRF $\mathcal{F}_{ms-oprf}$.

We propose the notation of multi-sender OPRF in Figure 14. In multi-sender OPRF, if an item $x \in X \cap \bigcap_{i=1}^{n'} Y_i$, the receiver gets its OPRF value $Q_k(x)$ and each sender gets a share of $Q_k(x)$. Before describing our construction, we first review the Vector Oblivious Linear Evaluation (VOLE) [26], which is a building block for our construction. The ideal functionality of VOLE is shown in Figure 15.

Parameters: The set size m. The computational security parameter κ.
Inputs: Both the receiver and the sender input nothing.
Outputs: The sender receives $\Delta \in \{0,1\}^\kappa$, $B \in m \times \{0,1\}^\kappa$. The receiver receives $A \in m \times \{0,1\}^\kappa$ and $C = \Delta A + B$.

Figure 15: The ideal functionality of VOLE $\mathcal{F}_{vole}$.

We design a multi-sender OPRF protocol in Figure 16. The correctness of this protocol is obvious. If an item x_j is common, we can get $Decode(B_i + \Delta_i A_i' - \Delta_i H_1(y_*^i), y_*^i) = Decode(C_i, y_*^i) = Decode(C_i, x_j)$, where $y_*^i \in Y_i$ equals to x_j. Then the XOR sum of the senders for y_*^i equals the PRF value of the receiver for x_j. More details and security proof for a single OPRF can be found in [26]. In this protocol, the receiver only needs to build the OKVS once when interacting with the n' senders. In the OPRF protocol [26], the OKVS encoding time costs are much larger than VOLE. Therefore, our optimization can save many computation costs compared with simply invoking n' instances of the OPRF protocol, especially when n' is large.

Parameters: The number of senders n'. The statistical and the security parameter are respectively λ and κ. The item's bit length σ. Two random oracles $H_1(\cdot) : \{0,1\}^\sigma \mapsto \{0,1\}^\kappa$ and $H_2(\cdot,\cdot) : (\{0,1\}^\kappa, \{0,1\}^\sigma) \mapsto \{0,1\}^\ell$. An OKVS scheme $Encode(\cdot)$, $Decode(\cdot,\cdot)$. A VOLE primitive $\mathcal{F}_{vole}$. Two PRFs $Q_\cdot(\cdot)$, $F_\cdot(\cdot) : \{0,1\}^\kappa \times \{0,1\}^\sigma \mapsto \{0,1\}^\ell$.
Inputs: The receiver has a set $X = \{x_j\}_{\forall j\in[m_r]}$. Each one of the n' senders has a set $Y_i = \{y_j^i\}_{\forall j\in[m_i]}$ $(i \in [n'])$.
Protocol:

1. **[Initiation]**. The i-th sender samples a random $\omega_i^s \in \{0,1\}^\kappa$ and sends $H_1(\omega_i^s)$ to the receiver.
2. **[OKVS]**. The receiver encodes to get an OKVS table $T = Encode(\{(x_j, H_1(x_j))\}_{\forall j\in[m_r]})$.
3. **[VOLE]**. The i-th sender and the receiver invoke $\mathcal{F}_{vole}$ to respectively get (Δ_i, B_i) and $(A_i, C_i = \Delta_i A_i + B_i)$, where B_i, A_i, C_i are vectors with size m_r, and Δ_i is a constant. The receiver sends $A_i' = A_i + T$ and a random $\omega^r \in \{0,1\}^\kappa$ to the i-th sender.
4. **[PRF valuing]**. For the i-th sender, he/she computes $F_{s^i}(y_j^i) = H_2(Decode(B_i + \Delta_i A_i', y_j^i) - \Delta_i H_1(y_j^i) + \omega^s + \omega^r, y_j^i)$ $(\forall j \in [m_i])$. The receiver computes $Q_k(x_j) = \bigoplus_{i=1}^{n} H_2(Decode(C_i, x_j) + \omega^s + \omega^r), x_j)$ $(\forall j \in [m_r])$, where $k = (s_1, s_2, \cdots, s_{n'})$.

Abstract

Obtaining the authorization of users (i.e., *data owners*) prior to data collection has become commonplace for online service providers (i.e., *data processors*), in light of the stringent data regulations around the world. However, it remains a challenge to uphold the principle of *purpose limitation*, which mandates that collected data should only be processed for the purpose that the data owner has originally authorized. In this work, we advocate *algorithm specificity*, as a means to enforce the purpose limitation principle. We propose ALGOSPEC, which obscures data to restrict its usability solely to an authorized algorithm or algorithm group. ALGOSPEC exploits the nature of *polynomial approximation* that given the input data and the highest order, any algorithm can be approximated with a unique polynomial. It converts the original authorized algorithm (or a part of it) into a polynomial and then creates a list of alternatives to the original data. To assess the efficacy and efficiency of ALGOSPEC, we apply it to the entropy method and Naive Bayes classification under datasets of different magnitudes from 10^2 to 10^6. ALGOSPEC significantly outperforms cryptographic solutions such as fully homomorphic encryption (FHE) in efficiency. On accuracy, it achieves a negligible Mean Squared Error (MSE) of 0.289 in the entropy method against computation over plaintext data, and identical accuracy (92.11%) and similar F1 score (87.67%) in the Naive Bayes classification.

1 Introduction

In recent years, there has been a notable increase in the stringency of data regulations worldwide, such as European Union General Data Protection Regulation (GDPR) [11] and California Consumer Privacy Act (CCPA) [8]. This proactive stance on user data regulation is a response to the growing concerns surrounding user data privacy and security. As a direct consequence, most online service providers (i.e., *data controllers* or *data processors*[1]) are mandated to obtain explicit consent from users (i.e., *data owners*) before initiating data collection. This approach ensures a heightened degree of transparency and accountability during data collection. For instance, Meta now requests explicit user consent before using their personal data for targeted advertising or content personalization [15]. Similarly, Amazon seeks permission from users to collect and store their browsing and purchase history for personalized recommendations [6]. All these shifts underscore the global commitment to safeguarding user privacy and granting data owners control over their personal data.

Despite the commendable strides made in ensuring transparency of data collection, the implementation of another crucial data regulation principle, i.e., the *purpose limitation principle* [13], continues to present challenges. This principle is another cornerstone in data protection, which stipulates that collected data must be utilized *exclusively* for the purpose that the data owner has originally authorized. This is particularly significant in the context of online data processing, which is the backbone of contemporary online services. Two typical scenarios are listed below.

Scenario #1. An online service provider collects user data through its mobile or web client, with its intended purpose disclosed in the associated privacy policy document. The client-side data processing is relatively transparent as it is more or less auditable (e.g., by reverse engineering the client-side software). A noticeable shift occurs once the data reaches the backend, where the data processing becomes nontransparent from the users. This places the users in an unfair position, as they lose visibility and control over how their data is handled.

Scenario #2. A financier collects personal data from individuals who apply for a loan. As part of its evaluation process, it engages a *third-party* credit assessment agency, e.g., Equifax, to assess the credit of the applicants. While the financier can certainly be transparent about its data collection and sharing practices, it still enforces its trust in the credit assessor onto the applicants.

Some existing techniques, such as FHE [32, 51, 54] and differential privacy (DP) [30, 34, 49], can be adapted for purpose limitation. They may fall short in some specific contexts

[1]Both are referred to as *data processors* without causing ambiguity.

though. FHE is effective at safeguarding the original data, but cannot prevent the data processor from performing unauthorized algorithms on the encrypted data. In certain situations when the processor possesses the encryption key (e.g., in ***Scenario #1***), it is feasible for them to reveal the results of unauthorized algorithms. On the other hand, DP enhances privacy by adding perturbations to the original data, but the perturbations may inadvertently compromise the accuracy of the intended algorithms.

Our work. In this work, we propose a novel approach named ALGOSPEC (standing for *algorithm specificity*), which obfuscates the data *exclusively* for the intended algorithm. ALGOSPEC targets to achieve two goals, i.e., algorithm specificity (***Goal #1***) and confidentiality of the original data (***Goal #2***). First, only the intended algorithm can lead to correct results, and no meaningful results can be obtained by unauthorized algorithms. Second, it is infeasible for an adversary operating in polynomial time to recover the original data from the obfuscated version.

The core technique to construct ALGOSPEC is to fit the entire or the core of the intended algorithm using *polynomial approximation*, leveraging its inherent feature that given the input data and the highest order, any algorithm can be accurately approximated using a distinctive polynomial representation (***Goal #1***). ALGOSPEC determines the highest order n based on the discrete logarithm problem, and then the coefficients and the constant term of the polynomial are uniquely determined. The polynomial is combined with the original data to obtain the obscured list M that can hide n and the original data (***Goal #2***) by blurring the non-constant and constant terms of the polynomial through predefined *patterns*.

We conduct comprehensive theoretical and empirical studies on ALGOSPEC to investigate its security, accuracy, and scalability. We prove that n is confidential, M is indistinguishable and finally the original data ℓ is unrecoverable using code-based game-playing with the discrete logarithm problem and the decisional Diffie-Hellman problem. Based on that, the two desired goals of ALGOSPEC can be reduced to the indistinguishability of the original data against the chosen-plaintext attack.

We then experimentally benchmark ALGOSPEC against two typical data protection approaches, i.e., FHE and DP, on two widely-used algorithms in sensitive statistical analysis, i.e., the entropy method and Naive Bayes classification. The results show that ALGOSPEC significantly outperforms FHE in terms of efficiency, with nearly 13 times faster on the entropy method and 4 times faster on Naive Bayes classification. For the accuracy evaluation, we set a baseline by performing direct computation on the original data. ALGOSPEC can achieve an MSE of 0.289 compared with the baseline on entropy method, and identical test accuracy and similar F1 to the baseline on Naive Bayes classification. These findings highlight ALGOSPEC's effectiveness in preserving data privacy without compromising the data analysis. To further evaluate the scalability, we assess it with large-scale datasets with sizes up to 10^6. Its performance remains stable even as the dataset size increases, demonstrating that it is a practical and reliable data protection approach for real-world applications.

Contributions. Our main contributions can be summarized as follows.

- **Purpose limitation beyond legal regulation.** We emphasize the pressing necessity of practical mechanisms that go beyond mere legal manners to ensure purpose limitation, thereby safeguarding individuals' privacy rights and mitigating data misuse or abuse. For data owners, it is imperative that they possess *genuine* control over how their data is to be used. For data processors, they can retain verifiable evidence to demonstrate that the data is processed exclusively for the stated purposes.
- **A practical solution for purpose limitation.** We propose ALGOSPEC, a novel, efficient, and accurate method specifically designed for purpose limitation. It leverages polynomial approximation to fit the intended algorithm into a polynomial, and the original data then can be secured with polynomial-specific computation patterns.
- **A comprehensive study and evaluation.** We conduct a theoretical study on ALGOSPEC to formally prove its security against polynomial time attacks. We also conduct comprehensive experiments to study its performance, in terms of accuracy, efficiency, and scalability, demonstrating its practical applicability.

2 Problem Formulation

2.1 System settings

We define three participants in our problem settings, i.e., the user as the *data owner*, the *data processor*, and the *third party*, representing most of real-world scenarios in online services. The data processor collects user data, and determines and discloses the purpose of processing user data. It seeks to demonstrate to the user that their original data has been used *only* for the disclosed purpose. The data processor may involve a third party to perform (part of) the data processing. The data has to be obfuscated to accommodate *only* the disclosed purpose, before it is outsourced to the third party. We further elaborate and generalize these two scenarios as illustrated in Figure 1.

Scenario #1. In this scenario (Figure 1.(a)), the data processor consists of the client and the server. Data collection is performed by the client, where the intended purpose disclosed, e.g., through the associated privacy policy document. As the client runs on the user device, client-side data processing is transparent and auditable. In contrast, the server-side processing is nontransparent to the user, once the collected data reaches server side. Since the client and server both belong to the data processor, the algorithm is known to the client.

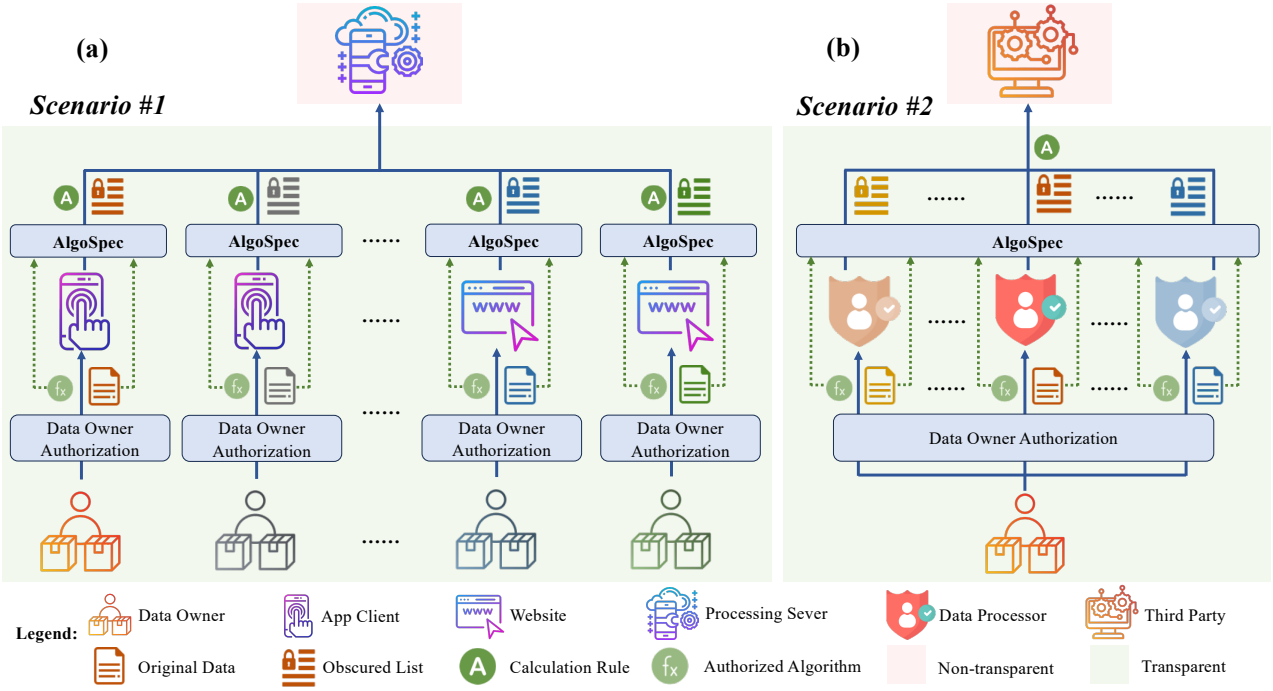

Figure 1: Two typical application scenarios of ALGOSPEC.

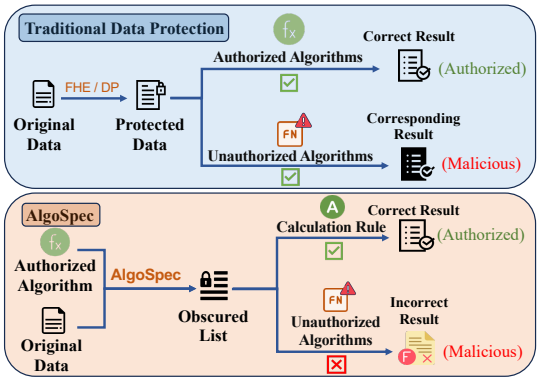

Figure 2: A comparison between the work models of ALGOSPEC and FHE/DP-based approaches.

Scenario #2. In this scenario (Figure 1.(b)), the data processor collects the original data and involves a third party for data processing. Recalling the financier and credit assessor example, the third party (i.e., credit assessor) owns more data than the individual data processor, e.g., the transaction history of a single user among multiple financiers.

Work model of ALGOSPEC. To position ALGOSPEC, we show the difference between its work model and FHE/DP-based approaches in Figure 2, explaining how it achieves the algorithm specificity. It combines the original data with authorized algorithms during the obfuscation. This ensures that the original data can be efficiently computed and analyzed exclusively under the umbrella of authorized algorithms. In contrast, FHE/DP-based approaches focus solely on modifying the original data, such that the resulting data can be processed under any algorithm.

2.2 Goals and Threat Model

ALGOSPEC is designed to align with the purpose limitation principle, which is commonly incorporated by major data regulations around the world, such as GDPR (Article 5, Chapter 2; Article 18, Chapter 3) [12], CCPA (1798.110; 1798.121) [8], The Privacy Act (Content 3, Chapter 6) [14]. In particular, we define two main security goals of ALGOSPEC below.

Goal #1. Algorithm specificity. This is to ensure that only executing the authorized algorithms can obtain correct results.

Goal #2. One-way obfuscation. This is to ensure the polynomial time adversary (PTA) cannot recover the original data.

Consistent with the setup of other related studies [17, 27], we assume the PTA as the attacker. The server of data processor in ***Scenario #1*** or the third party in ***Scenario #2*** is an honest-but-curious attacker, which attempts to recover the original data or perform unauthorized algorithms on the obtained obfuscated data. The attacker has both authorized and unauthorized algorithms.

3 Approach

In this section, we delve into the internals of ALGOSPEC. Figure 3 illustrates its general workflow, and the detailed

Table 1: Key notations used in this paper

Notations	Descriptions
$\mathbb{D}$	original dataset
$\mathbb{D}_f^{(s)}$	value of $\mathbb{D}$ at s^{th} row, f^{th} column
ℓ	unspecified value in dataset
Fx	authorized algorithm
F	polynomial approximation of Fx
n	highest order of F
Fn	malicious algorithms
M	obscured list
N	the number of elements in M
A	calculation rule
d	exponent adjustment factor
λ	coefficient adjustment factor
γ	the number of distances
Γ	distance list
r	result by ALGOSPEC
R	result by applying Fx on $\mathbb{D}$
G	cyclic group
$<\mathcal{G}>$	cyclic group generated by $\mathcal{G}$
$\mathcal{G}$	cyclic group generator
g	random generator
$\mathcal{P}$	possibility

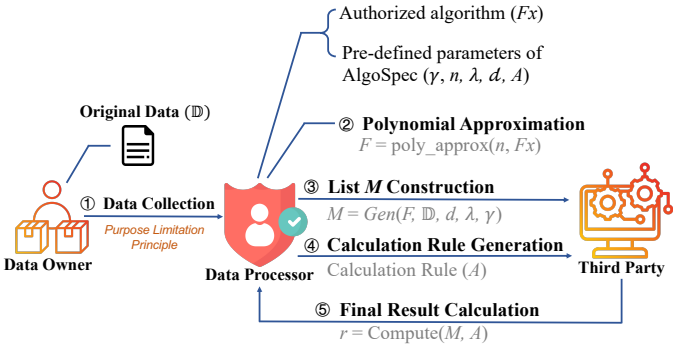

Figure 3: Overall workflow of ALGOSPEC.

algorithm is presented in Appendix A.1. Table 2 provides a step-by-step procedure of using ALGOSPEC. In the remaining of this section, we explain the key techniques of ALGOSPEC. To facilitate understanding, Table 1 lists key notations used.

3.1 Polynomial Approximation

A polynomial consists of variables (also known as indeterminates) and coefficients, combined using addition, multiplication, and non-negative integer exponents [38]. In its most general form, a polynomial can be expressed as Eq. 1.

$$P(x) = \alpha_n x^n + \alpha_{n-1} x^{n-1} + \ldots + \alpha_2 x^2 + \alpha_1 x + \beta, \quad (1)$$

where x is the variable, $\alpha_i x^i$s are the non-constant terms, α_is are coefficients, β is the constant term, and the non-negative integer n represents the highest order of x in the polynomial, which is called the degree of the polynomial.

Polynomial approximation has been proposed to represent a complex function with a polynomial using the target dataset

Table 2: Step-by-step Procedure of ALGOSPEC (***Scenario #2***)

Setup (Data Owner)
• Data owner authorizes data processor to collect data with the desired purpose disclosed.
Setup (Data Processor)
• Data processor obtains authorization for data collection, and discloses the desired algorithm Fx to be applied to the collected data.
• Data processor collects original data from data owner.
• Data processor determines n of the polynomial.
• Data processor converts Fx to polynomial F by polynomial approximation.
• Data processor acquires several components from ALGOSPEC, including d (exponent adjustment factor), λ (coefficient adjustment factor), γ (the number of distances), *pairs* (the pairs selected following distances), and *times* (times that pairs are used).
Setup (Third Party)
• Third party sets up execution environment.
Processing
• ALGOSPEC generates obscured list M using $\mathbb{D}$, F, d, λ, γ.
• When M is generated, calculation rule A is generated automatically.
• Data processor sends M and A to third party.
• Third party computes the result r through M and A.
• Third party sends r to data processor.

[31]. It is based on the foundation established by Mhaskar et al. [41] that the fitted polynomial can be used as an alternative to the original algorithm to obtain almost identical results on the given dataset. This ensures that ALGOSPEC sacrifices minimal precision loss during the obfuscation.

ALGOSPEC adopts polynomial fitting [48], a typical machine learning technique, for the approximation. It defines the range of original data and proceeds to uniformly select a specific number of data points within this range. These selected data points are then processed using the authorized algorithm, producing corresponding output values. The input-output pairs are then used for a polynomial fitting with Mean Squared Error as the loss function, given a specific degree n (determination of n is discussed soon). This is essentially a machine learning process, and it ends up with a polynomial with its uniquely determined coefficients and the constant term. ALGOSPEC works on the entire algorithm in general, but data processors can select core components of the algorithm to approximate. For example, some simple operations like normalization and addition can be excluded during the approximation to retain efficiency without losing accuracy.

The algorithm specificity (***Goal #1***) of ALGOSPEC stems from the *uniqueness* of the polynomial with respect to the degrees used for polynomial approximation. Funaro et al. [31] prove that, given an algorithm, the approximation with different degrees leads to different coefficients and the constant term. Once a polynomial has been derived to represent the authorized algorithm based on the given degree n, computing this polynomial will only yield the same result as applying

the authorized algorithm to the original data.

Determining and hiding n. Revealing n could enable the attacker to fit a polynomial of the authorized algorithm, potentially allowing them to recover the original data from the final result (i.e., r in Figure 3) by solving a high-order equation. In Section 5.3, we present an analysis on the complexity of this attack. By default, ALGOSPEC still keeps n confidential. It leverages the decisional Diffie-Hellman problem (DDH) to generate n (detailed in Section A.2), and constructs the obscured list M to hide it (detailed soon in Section 3.2).

3.2 Obscured List Construction

Based on the polynomial derived, ALGOSPEC proceeds to create an obscured list M, designed to conceal n. The idea is to break down the calculation of the polynomial into a large number ($\gg n$) of basic units. This involves dealing separately with the non-constant terms (Section 3.2.1), i.e., $\alpha_i x^i$ in Eq. 1, and the constant term (Section 3.2.2), i.e., β, capitalizing on the polynomial's inherent properties.

3.2.1 Processing of non-constant terms $\alpha_i x^i$

ALGOSPEC transforms those non-constant terms into a list M', which contains $2n$ elements denoted as m spanning from m_1 to m_{2n}. The intuition behind this is to split the sensitive value into segments, such that the value can be revealed only when merging all segments. To this end, ALGOSPEC introduces two essential factors for each term $\alpha_i x^i$, i.e., a coefficient adjustment factor λ_i, and an exponent adjustment factor d_i, which adjust the coefficient and the exponent, respectively. They compose two vectors of size n, which are denoted as λ and d. Below we explain how each m in M' is constructed.

For m_1 in M', ALGOSPEC sets $m_1 \leftarrow \frac{\alpha_n}{\lambda_n} x^{n-d_n}$, meaning that the first non-constant term depends on λ_n and d_n. Specifically, we divide the coefficient α_n by the corresponding adjustment factor λ_n, and subtract the order n of x from the value of the corresponding position d_n in the exponent adjustment vector. For m_2 in M', we set $m_2 \leftarrow \lambda_n x^{d_n}$ with the same λ_n and d_n as what have been used in constructing m_1. By doing so, the first non-constant term of the polynomial $\alpha_n x^n$ can be obtained by simply multiplying m_1 with m_2. We therefore organize m_1 and m_2 as a pair (m_1, m_2). This process is repeated for the remaining m_i, till the last pair (m_{2n-1}, m_{2n}) where we set $m_{2n-1} \leftarrow \frac{\alpha_1}{\lambda_1} x^{1-d_1}$ and $m_{2n} \leftarrow \lambda_1 x^{d_1}$. Consequently, we have the list M' containing $2n$ ms, i.e., n pairs.

After constructing the list M', ALGOSPEC obtains the way of calculating the result of the polynomial without the constant term β. By computing $m_1 \times m_2 + ... + m_{2n-1} \times m_{2n}$, the result being equal to the calculation of $\alpha_n x^n + \alpha_{n-1} x^{n-1} + ... + \alpha_1 x$ can be derived, i.e.,

$$m_1 \times m_2 + ... + m_{2n-1} \times m_{2n} = \alpha_n x^n + ... + \alpha_1 x. \quad (2)$$

The two vectors λ and d mainly serve to construct the two factors of a term, while also introducing randomness into the distribution of m_is. An extremely large or small λ may lead to precision loss in calculations, so we constrain $\lambda_i \in (0, 1)$ following Gaussian distribution in ALGOSPEC's implementation. We also set $d_i \in [1, 9] \cap \mathbb{Z}$, ensuring efficient computation of m_{2i}. They are adjustable in the actual deployment of ALGOSPEC.

Next, ALGOSPEC provides the way of processing the constant term β, to obtain the completed obscured list M.

3.2.2 Processing of constant term β

ALGOSPEC decomposes β into another list B which has the same pair-wise format as M'. B is of size $N - 2n$ ($N \gg 2n$ and N is an even number), such that the obscured list M of size N can be assembled by concatenating B with M'. We denote the elements in B from m_{2n+1} to m_N. Similar to M', when we design B, we guarantee that computing $m_{2n+1} \times m_{2n+2} + ... + m_{N-1} \times m_N$ achieves the result being equal to β as Eq. 3, i.e.,

$$m_{2n+1} \times m_{2n+2} + ... + m_{N-1} \times m_N = \beta. \quad (3)$$

To ensure that the final computation result matches the desired β, ALGOSPEC utilizes the last two ms to make necessary adjustments. Thus, the initial step involves the random generation of $(N - 2n - 2)$ ms in the list B. We construct the pairs in B to be indistinguishable from those in M', so that the adversary cannot learn n from their distribution patterns defined below.

Definition 1. *(Pattern). A pattern refers to the distribution of the distance* $\lfloor \log \frac{m_i}{m_{i+1}} \rfloor$*, where i is odd and m_is are the elements in M'.*

ALGOSPEC follows five steps to construct B.

Step 1: ALGOSPEC creates adequate new distances[2] and puts them into the list Γ. The number of distances in Γ is denoted as τ. Following each distance in Γ, it builds a list Θ containing τ pairs, i.e., (θ_1, θ_2),..., $(\theta_{2\tau-1}, \theta_{2\tau})$.

Step 2: ALGOSPEC finds the distance with the highest number of occurrences from M', and selects a random number K greater than this maximal occurrence. Then, by leveraging Γ, it adds new distances such that all distances end up with an occurrence number close to K. To achieve this, $(m_{2n+1}, m_{2n+2}), \cdots, (m_{N-3}, m_{N-2})$ is generated, where each m_i follows Gaussian distribution, i.e., $m_i \sim \mathcal{N}(0, \theta_i)$.

Step 3: ALGOSPEC constructs m_{N-1} in B by selecting a pair, such as (θ_i, θ_{i+1}), from Θ and makes $m_{N-1} \sim \mathcal{N}(0, \theta_i)$.

Step 4: For m_N, ALGOSPEC needs a value to ensure that Eq. 3 can be satisfied. Therefore, it sets m_N as

$$m_N = \frac{\beta - (m_{2n+1} \times m_{2n+2} + ... + m_{N-3} \times m_{N-2})}{m_{N-1}}. \quad (4)$$

[2]The number of new distances should not be less than ρ which is the number of distance within n pairs, and we prove its security in Section A.2.

Step 5: ALGOSPEC shuffles all the tuples (m_{2n+1}, m_{2n+2}), ..., (m_{N-1}, m_N), and then reassigns the elements in all tuples to B following the new order.

The generation of list B is a direct outcome of the progression from Step 1 to Step 5. By combining Eq. 2 and Eq. 3, we can derive a new equation

$$\begin{aligned} &m_1 \times m_2 + \ldots + m_{2n-1} \times m_{2n} + \ldots + m_{N-1} \times m_N \\ &= \alpha_n x^n + \ldots + \beta. \end{aligned} \tag{5}$$

During this entire process, the calculation rule A is automatically formulated as follows.

Calculation rule A. The third party can compute the final result using M and A. Specifically, they apply the calculation rule in Eq. 6 to obtain the final result r of the authorized algorithm. The value of r should closely resemble the actual result R obtained when the original authorized algorithm is executed directly, i.e., $r = R + \eta$, where η is a negligible value signifying the margin of error.

$$r = m_1 \times m_2 + \ldots + m_{2n-1} \times m_{2n} + \ldots + m_{N-1} \times m_N. \tag{6}$$

Here, the data processor can delegate part of the complex calculation of M to the third party. Specifically, for those m_is where i is odd, which entail high exponent calculations, the processor can select a relatively small k_i and compute $x_i^{k_i}$ locally, denoted as X_i. Then it can request the third party to compute $X_i^{(i-d_i)/k_i}$ to construct m_i. The third party is not able to recover the original x_i in an efficient way from X_i and $(i-d_i)/k_i$, guaranteed by the discrete logarithm problem [46].

4 Case Studies

We demonstrate the application of ALGOSPEC with two widely-used algorithms, i.e., the entropy method and the Naive Bayes classification. We select them in our study primarily due to the diverse mathematical operations involved in their computation steps. Beyond primitive arithmetic operations, they encompass operations such as logarithmic operations, floating point operations, and probabilistic calculations. These operations have proven challenging for existing cryptographic algorithms designed to operate on ciphertexts [18].

4.1 Entropy Method

The entropy method (EM) is a multi-criteria decision analysis commonly used in measuring value dispersion in many practical cases [23]. The detailed operation of the EM can be summarized by the following steps.

$$x_{ij}^{'} = \frac{x_{ij} - \min(x_{ij})}{\max(x_j) - \min(x_j)}, \tag{7}$$

$$p_{ij} = \frac{x_{ij}^{'}}{\sum_{i=1}^{m} x_{ij}^{'}}, \tag{8}$$

$$e_j = -\frac{1}{\ln(n)} \sum_{i=1}^{m} p_{ij} \ln(p_{ij}), \tag{9}$$

$$W_j = -\frac{1 - e_j}{\sum_{j=1}^{n}(1 - e_j)}, \tag{10}$$

where i represents the i^{th} sample, j represents the j^{th} feature and m represents the number of samples.

Entropy method with ALGOSPEC. Data processor firstly normalizes the data using Z-Score based on the Eq. 7, and then computes p for each value using Eq. 8. Next, according to Eq. 9, data processor applies polynomial approximation on $p_{ij}\ln(p_{ij})$ in order to generate obscured lists from M_1 to $M_{(i\times j)}$, where $i \times j$ is the total number of items in the dataset. The data processor then dispatches Ms to the third party and meanwhile requests them to proceed with the remaining calculations following the calculation rule A. Upon receiving Ms and A, the third party can compute the entropy value e for each feature based on Eq. 9. Finally, the third party computes the weight W for each feature using Eq. 10, and then transmits the results back to the data processor.

4.2 Naive Bayes Classification

Naive Bayes classification serves as a data mining algorithm that is often used for binary classification tasks under supervised learning [37]. The key point of using Naive Bayes classification is to apply attribute conditional independence assumption [52]. If a dataset has d_f features, the conditional independence assumption can be described as

$$p(x_i|y) = \prod_{j=1}^{d_f} p(x_{ij}|y), \tag{11}$$

where i represents the i^{th} sample and j represents the j^{th} feature in the dataset. In this paper, we mainly focus on the application of Naive Bayes classification on continuous values, a common assumption of which is the continuous values conditioned on the label follow a univariate Gaussian distribution [37]. For simplicity of representation, we assume that the data x has only one dimension, and let μ_k denote the mean and σ_k^2 denote the Bessel corrected variance of the values in x associated with class C_k, respectively. That is,

$$\mu_k = \frac{1}{n_k} \sum_{x_i \in C_k} x_i, \tag{12}$$

where n_k represents the number of samples of class C_k, and

$$\sigma_k = [\frac{1}{n_k - 1} \sum_{x_i \in C_k} (x_i - \mu_k)^2]^{\frac{1}{2}}. \tag{13}$$

Suppose there is a new sample v, so the probability density of v given a class C_k can be computed as follows.

$$p(x = v|C_k) = \frac{1}{\sqrt{2\pi\sigma_k^2}} e^{-\frac{(v-\mu_k)^2}{2\sigma_k^2}}. \tag{14}$$

Finally, the category *pred* with the highest probability of occurrence of new sample v is selected, i.e.,

$$pred = \arg\max_{C_k}(p(x = v|C_k)) \tag{15}$$

Naive Bayes classification with ALGOSPEC. The data processor computes μ_k of each feature first using Eq. 12. Then, according to Eq. 13, $(x_i - \mu_k)^2$ is a part of the equation that is viable to apply polynomial approximation. The data processor can have $M_{(i\times j)}$ with the same number as the items in training data and then multiple Ms will be sent to the third party.

When receiving the Ms, the third party computes σ_k for each feature. Then, they calculate the probability of occurrence of each sample under each given category C_k. The third party calculates the probability of occurrence of each sample under different categories by using Eq. 11 and 14, and then sends all computation results to data processor, because data processor needs to estimate the accuracy of the classification.

When the data processor receives the results of $p(x = x_i|C_k)$, they can find the category with the maximum probability of occurrence for each sample, and compare it with its true label. If the accuracy and F1 are satisfactory, the third party can proceed to perform the prediction for new data samples.

Assume the new data sample is v. Similarly, the data processor constructs Ms to represent $(v - \mu_k)^2$ of each feature and sends them to the third party again. Once the third party receives the Ms, $p(x = v|C_k)$ can be calculated by σ_k and sent back. Finally, the data processor finds the category with the highest probability of occurrence of new sample v using Eq. 15.

5 Security Analysis

To establish the security (***Goal #2***) of ALGOSPEC, we leverage a combination of code-based games [20] and decisional Diffie-Hellman (DDH) problems [22]. In this section, we demonstrate how ALGOSPEC maintains the security of the original data against various potential attack scenarios.

5.1 Definitions

ALGOSPEC's selection of n depends on the decisional Diffie-Hellman (DDH) problem, which is a computational problem that arises in the field of cryptography and is often used to assess the security of protocols and systems [22].

Definition 2. *(Decisional Diffie-Hellman problem). The advantage of an adversary* $\mathbf{Adv}^{ddh}_{\mathcal{G},k}(\mathcal{A})$ *in solving the DDH problem relative to* $\mathcal{G}$ *can be defined as the difference between the probability that* $\mathbf{Exp}^{ddh-0}_{\mathcal{G},k}(\mathcal{A})$ *outputs* `true` *and the probability that* $\mathbf{Exp}^{ddh-1}_{\mathcal{G},k}(\mathcal{A})$ *outputs* `true`[3]*, i.e.,.*

$$\begin{aligned}\mathbf{Adv}^{ddh}_{\mathcal{G},k}(\mathcal{A}) = |&\mathcal{P}(\mathbf{Exp}^{ddh-0}_{\mathcal{G},k}(\mathcal{A}) = \texttt{true}) \\ &- \mathcal{P}(\mathbf{Exp}^{ddh-1}_{\mathcal{G},k}(\mathcal{A}) = \texttt{true})|.\end{aligned} \tag{16}$$

In the DDH problem, a finite cyclic group $G = <\mathcal{G}>$ is generated by a generator $\mathcal{G}$, and a random generator $g \xleftarrow{R} \mathbb{G}$ as well as random integers $a, b \xleftarrow{R} \mathbb{Z}^*_p$ are selected uniformly. The goal for the adversary is to distinguish (g, g^a, g^b, g^{ab}) from (g, g^a, g^b, g^c), where c is chosen at random from $\mathbb{Z}^*_p$ [22, 35]. Concretely, adversary will receive g, X, Y and Z, where $X = g^a$, $Y = g^b$ and $Z = g^{ab}$ or $Z = g^c$. If the adversary believes $Z = g^{ab}$, `true` is returned, and `false` otherwise.

The discrete logarithm problem (DLP) is a fundamental mathematical problem with significant applications in scheme security, number theory, and cryptography [40]. ALGOSPEC leverages the inherent computational complexity of the DLP within polynomial time to safeguard the original data during the obfuscation process, ensuring its unrecoverability.

Definition 3. *(Discrete logarithm problem). The DLP is also called Diffie-Hellman key exchange [24]. It is usually defined in the context of finite cyclic groups. In the group* $<\mathcal{G}>$*, given* $x = g^a$ *and* $y = g^b$*, the DLP is to calculate* $g^{ab \bmod p}$ *in polynomial time (PT) [46]. Problems that can be solved in polynomial time are generally seen as tractable, while those that require exponential time or worse are often considered intractable and computationally challenging [19].*

The complexity of solving the DLP relies on the chosen group and its parameters. When the group parameters are appropriately chosen, solving DLP becomes computationally infeasible in PT for prime numbers p. This hardness property is the basis for the security of many security systems.

Definition 4. *(Chosen-plaintext attack). A chosen-plaintext attack (CPA) is a type of cryptographic attack where an adversary has the capability to choose and process specific plaintexts of their choice and then observe the corresponding processed text [9].*

The goal of a CPA is to gain insights into the scheme's security, particularly its vulnerability to various attacks. ALGOSPEC assumes a CPA, which represents a powerful threat model where the adversary has significant control over the inputs, ensuring that the adversary gains no meaningful information about the plaintext from the obfuscated data.

Definition 5. *(Indistinguishability). For an encryption scheme to be considered indistinguishable, for any two plaintexts* m_0 *and* m_1 *chosen by the attacker,* $\mathcal{P}(Enc(m_0) = c) - \mathcal{P}(Enc(m_1) = c) \leq \varepsilon$ *holds, where* m_0 *and* m_1 *are two different plaintexts,* c *is the ciphertext produced by encrypting either one of them and* ε *is a negligible function.*

The most common type of indistinguishability is the *indistinguishability under chosen-plaintext attack* (IND-CPA),

[3] $\mathbf{Exp}^{ddh}_{\mathcal{G},k}(\mathcal{A})$ is the name of a code-based game, and "*ddh*-0" means $c = ab$ in the game, while "*ddh*-1" means $c \xleftarrow{R} \mathbb{Z}^*_p$ in the game.

which is widely used to evaluate the security of cryptographic schemes [25]. IND-CPA assesses the ability of a scheme to protect the confidentiality of plaintext messages in the presence of an active adversary [21]. It provides a strong security guarantee for security schemes and is a critical consideration in the design and evaluation of secure systems.

5.2 *Goal #2* of AlgoSpec

In Section 3.1, we discuss how AlgoSpec can achieve algorithm specificity (***Goal #1***). In this section, we establish that the original data is unrecoverable, in alignment with ***Goal #2***. Two strategies can be used for the attacker to recover the original data. One is to solve an n^{th}-order polynomial based on its degree n, and the other is to analyze the elements in obscured list M and try to recover the original data. We show that when data is obfuscated by AlgoSpec, the attacker cannot effectively recover the original data either way. We list the Theorems to achieve ***Goal #2*** as follows.

Theorem 1. *(Confidentiality of n). Under a CPA, n is not recoverable either from M or the initialization step.*

The proof of Theorem 1 lies in proving that n is confidential at initialization and unrecoverable from M. The former is ensured with generating n based on DDH (Definition 2), and for the latter, AlgoSpec uses a large number (i.e., N) of m_i to hide n. We present the detailed proof based on game playing in Appendix A.2.

Theorem 2. *(Indistinguishability of M). Given M_1 and M_2 that are generated from different degrees n_1 and n_2, respectively, M_1 and M_2 are indistinguishable when given a large N ($N \gg n_1, n_2$).*

Theorem 1 demonstrates that M reveals no information for the adversary to infer n. We utilize this to establish the validity of Theorem 2. Our proof is based on two sub-games of generating M, one using the real n and the other using another degree that is randomly generated. We prove that the difference of the probabilities that the attacker successfully differentiates M in this two sub-games is a negligible function. The detailed proof is listed in Appendix A.3.

Main Theorem. *(Unrecoverability of ℓ). Under a CPA, the original data ℓ is not recoverable by analyzing M or solving the polynomial by obtaining the degree n.*

The main theorem is also proved using code-based game playing. We define a challenge representing the obscured list M that is known by the attacker, and construct a game which asks the attacker to guess whether this challenge represents M or a randomly generated list. The constructed game comprises four sub-games under IND-CPA, and each pair of adjacent sub-games are initialized with difference in only one setting. We generate the challenge C in the first sub-game using the real ℓ, and generate another challenge C' in the last sub-game using a randomly generated ℓ'. By demonstrating that consecutive sub-games satisfy $|\mathcal{P}(G_i(\mathcal{A})=1) - \mathcal{P}(G_{i+1}(\mathcal{A})=1)| \leq \varepsilon$, ($i \in [0,2]$), the first and last sub-games also satisfy $|\mathcal{P}(G_0(\mathcal{A})=1) - \mathcal{P}(G_3(\mathcal{A})=1)| \leq \varepsilon$. The detailed proof is presented in Appendix A.4.

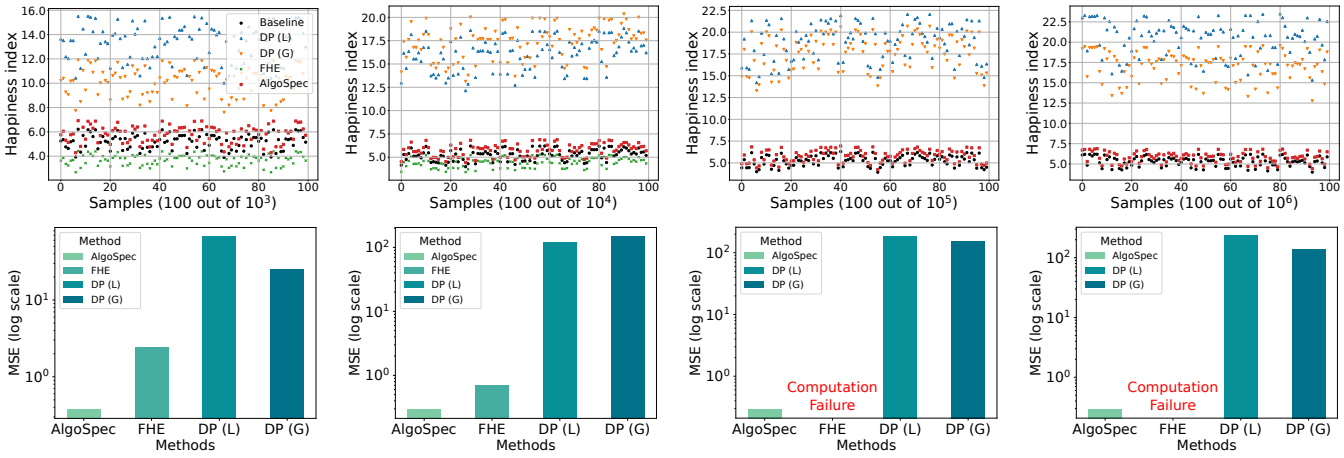
5.3 Discussion on n's Confidentiality



We have proved that ℓ is unrecoverable when n is sufficiently large through code-based game-playing. However, even when n is not exceptionally large, the protection for ℓ can still be ensured. The only way for the adversary to get ℓ is to solve the high-order polynomial as discussed in Section 3.1. When the highest order of the polynomial is greater than 4, solving such a high-order polynomial is an NP-hard problem [44]. Importantly, the adversary must solve high-order polynomials for all ns they selected, which means they face a plethora of NP-hard problems. Therefore, a relatively small n is sufficient in practical use. We empirically find that an n greater than 500 can lead to a precise approximation of complicated algorithms.

6 Evaluation

To evaluate the performance of AlgoSpec, we apply it to the entropy method and Naive Bayes classification. We conduct benchmarking and scalability analysis, to provide a comprehensive assessment of its capabilities.

6.1 Experimental Settings

Datasets. We mainly use the breast cancer [1], heart disease [2], 2021 world happiness report [5], and hypertension [10] datasets to assess the efficacy of AlgoSpec. To provide a thorough evaluation of our methodology across varied dataset sizes, we expand our initial dataset. This allows us to analyze data magnitudes spanning from 10^2 to 10^6. The details of the datasets used in our evaluation is presented in Table 3.

(a) scale of 10^3 dataset (b) scale of 10^4 dataset (c) scale of 10^5 dataset (d) scale of 10^6 dataset

Figure 4: Accuracy and MSE of each method on entropy method through different scales of datasets from 10^3 to 10^6.

Running environment. Our evaluation is conducted on a workstation of Ubuntu 22.04.3 LTS x86_64 as the operating system, and AMD Ryzen Threadripper PRO 5965WX with x86_64 architecture, 48 cores, and 3.800GHz CPU.

Settings. To evaluate the performance of ALGOSPEC side-by-side, we compare it to the baseline, FHE, and DP, where their settings are presented as follows.

Baseline. The baseline is calculated using the authorized algorithm directly, without encryption or preprocessing.

FHE. FHE is a widely-used privacy protection method and has a similar threat model to ALGOSPEC. Despite its limitations in fully addressing the purpose limitation issue, it holds relevance in ***Scenario #2*** (Figure 1.(b)), where the third party can apply any algorithm on the cipher, but has no decryption key to see the computation results. Therefore, FHE is applied to compare with ALGOSPEC.

We choose the currently dominant Python homomorphic encryption library, pi-HEaaN [7], as the main framework, and use Taylor expansion for the non-linear part of an algorithm. To eliminate the computational noise through FHE, we set the scale factor as $\frac{1}{9}$ due to its best performance.

DP. DP is another widely-used privacy-preserving method. It is known for the efficiency due to the lightweight additive noise strategy. Therefore, we select it to benchmark the efficiency of ALGOSPEC. When using DP, we employ two noise mechanisms, i.e., the Laplace mechanism and the Gaussian mechanism. For Laplace mechanism, we set both ε_{dp} and sensitivity to 1.0; for Gaussian mechanism, we set ε_{dp}, δ_{dp}, and sensitivity all to 1.0.

Secure function evaluation (SFE). SFE [33] allows two parties to jointly conduct computation. Thus, we also explore applying SFE for algorithm specificity. We apply two widely-used libraries, namely the garbled-circuit [4] and TenSEAL [3], to the entropy method and the Naive Bayes classification. However, the former fails to split the raw data into two Yao's circuits, as it necessitates the design of intricate circuits to represent logarithmic operations as well as probabilistic calculations. The latter runs into the out-of-memory exception due to the computational complexity. Thus, the results on SFE are not reported in this paper.

6.2 Benchmarking

We benchmark the performance of ALGOSPEC on entropy method and Naive Bayes classification against baseline, FHE, DP with Laplace mechanism, and DP with Gaussian mechanism. The scale of the dataset we use is controlled at 10^4 on entropy method and 10^3 on Naive Bayes classification.

Entropy method. To compare ALGOSPEC's accuracy against others on the entropy method, we first compute the output of the 2021 World Happiness Report ep2, producing the Happiness Index as the accuracy indicator. The results are illustrated in Figure 4.(b). Notably, ALGOSPEC (■) significantly outperforms DP with Laplace or Gaussian mechanism (▲, ▼), and is closer to the baseline (●) than FHE (×), as reflected by the distances from the baseline. To quantify the distance, we utilize the Mean Squared Error (MSE) as an evaluation metric, as illustrated in the four figures at the bottom of Figure 4. Overall, ALGOSPEC excels on the entropy method in terms of accuracy. Unsurprisingly, both DP mechanisms exhibit relatively high MSE, exceeding 100, as the noise added undermines the accuracy of the algorithm. The MSE of FHE is also much higher than ALGOSPEC, because the intermediate noise produced by FHE during computation can significantly affect the classification task, specifically the process of operating the `argmax` function [36].

Next, we evaluate the efficiency of ALGOSPEC. For all methods, we gauge the total computation time, which encompasses the duration from data retrieval to the completion of

Table 4: Efficiency of different scale datasets from 10^3 to 10^6 on entropy method.

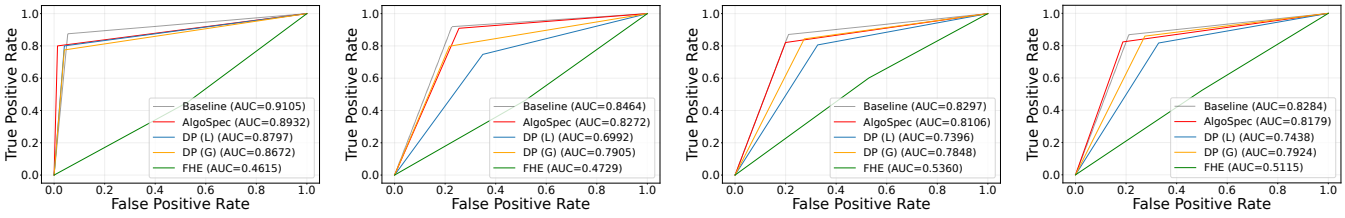
AlgoSpec	0.824	0.833	0.921	0.877	0.812	0.829	0.818	0.832

result computation. Given the involvement of a data processor and a third party in our setup, we further break down the total time into processing time and execution time. Processing time signifies the time the data processor takes on data manipulation. DP's processing time includes the duration of adding noise. FHE's processing is the data encryption and key generation. AlgoSpec 's processing encompasses polynomial approximation and obscured list construction. On the other hand, execution time corresponds to the duration the third party dedicates to carrying out calculations for the final results. The first segment (benchmark) of Table 4 offers insights into the time taken by different methods during the execution of the entropy method, enabling a comprehensive assessment of efficiency. The baseline method requires no data processing, and hence, there is no processing time associated with it. Regarding the processing time, AlgoSpec requires slightly more time due to its preprocessing of both the original data and the intended algorithm. Concerning execution time, our approach falls between DP and FHE but is significantly faster than FHE, completing the task about 487 times shorter. Similarly for the total time, our method also significantly outperforms FHE (nearly 13 times faster).

Naive Bayes classification. We use the heart disease dataset to evaluate the performance of AlgoSpec on Naive Bayes classification. We take test accuracy and test F1 scores as performance indicators for the evaluation. The first segment (benchmark) of Table 5 illustrates the performance of each method. By using the baseline as the reference, and comparing the accuracy and F1 of DP, FHE, and our method, we observe that AlgoSpec exhibits the closest accuracy and F1 to the baseline, with both metrics decreasing by less than 0.02. DP, regardless of the noise mechanism used, lags behind AlgoSpec in terms of both accuracy and F1. FHE performs the poorest, displaying the lowest test accuracy and F1. To illustrate the performance comparison, we use the receiver operating characteristic (ROC) curves and calculate the area under the ROC curve (AUC). Figure 5.(a) presents these curves and AUC values for each method. The red line represents the ROC curve for AlgoSpec, which boasts the closest AUC to the baseline at 0.8272. It is evident that the AUC of our method encompasses those of the other methods, establishing our method as the top performer on accuracy.

Moving on to the efficiency evaluation, we continue to divide the total time into processing time and execution time. Regarding efficiency comparison, which is illustrated in the lead-in segment (benchmark) of Table 6, our results align with those from the entropy method. Although AlgoSpec requires slightly longer processing time, its execution and total time are significantly superior, nearly 7 times and 4 times faster than FHE, respectively.

AlgoSpec demonstrates superior performance in terms of accuracy, as evaluated on both the entropy method and Naive Bayes classification, surpassing other mainstream privacy-preserving approaches. For efficiency, AlgoSpec is between FHE and DP, but given that neither DP nor FHE can maintain a consistent accuracy rate, we believe that it is worthwhile to sacrifice a certain amount of efficiency for a stable and high accuracy of our method.



6.3 Scalability

To explore whether AlgoSpec performs effectively across datasets of various scales, we assess its scalability by utilizing datasets ranging from 10^2 to 10^6.

Table 6: Efficiency of different scale datasets from 10^2 to 10^5 on Naive Bayes classification.

	Heart Disease (10^3)			Breast Cancer (10^2)			Hypertension (10^4)			Hypertension ep (10^5)		
	PT	ET	TT	PT	ET	TT	PT	ET	TT	PT	ET	TT
Baseline	0.000	0.513	0.513	0.000	0.467	0.467	0.000	2.735	2.735	0.000	9.088	9.088
DP (L)	0.082	0.575	0.657	0.104	0.544	0.648	2.034	2.362	4.396	7.750	8.016	15.766
DP (G)	0.059	0.576	0.635	0.077	0.545	0.622	1.421	2.316	3.737	5.448	7.446	12.894
FHE	0.040	9.980	10.020	0.269	3.097	3.366	0.243	196.428	196.672	0.909	788.161	789.070
AlgoSpec	1.432	1.520	2.952	2.011	1.645	3.656	35.915	41.415	77.330	143.045	175.288	318.333

PT: Processing Time **ET**: Execution Time **TT**: Total Time

(a) Heart disease (10^3) (b) Breast cancer (10^2) (c) Hypertension (10^4) (d) Hypertension ep (10^5)

Figure 5: ROC curve and AUC of each method on Naive Bayes classification through different scales of datasets from 10^2 to 10^5.

Entropy method. We use datasets ranging from 10^3 to 10^6 for the entropy method. Figure 4 displays the computation of the happiness index by each method and the Mean Squared Error (MSE) between each method's results and the baseline for datasets of different sizes. Table 4 provides an overview of the efficiency of each method on datasets of varying scales. Notably, as the dataset size exceeds 10^4, FHE encounters computational challenges due to the complexity of its intermediate generated noise. In contrast, AlgoSpec exhibits exceptional scalability, making it capable of handling large-scale datasets.

Naive Bayes classification. We choose the scale of datasets from 10^2 to 10^5 on Naive Bayes classification. Table 5 shows the test accuracy and test F1, while Figure 5 illustrates the ROC curve and AUC of each method on different scales of datasets. We also compare each method's time efficiency across various dataset scales, as shown in Table 6.

AlgoSpec is highly scalable since it can operate on datasets of different sizes ranging from 10^2 to 10^6, which is ideal for our settings of the threat model.

7 Discussions

In this section, we present a discussion on AlgoSpec's generalization for simple and complex algorithms, as well as the challenges of deploying AlgoSpec in practice.

Generalization. Given the target application scenarios of AlgoSpec, the algorithms are typically not simplistic. AlgoSpec could also apply an alleviation for simple algorithms, by covering the simple algorithm with random calculation at an invalid input range. Taking $y = x^2$ as an example, after determining the range of the input (Section 3.1), it keeps the segment of $y = x^2$ within this range. For the remaining, it generates a random complex calculation and combines it with the kept segment. This solution allows AlgoSpec to keep a high degree of n for simple algorithms. For complex algorithms such as neural networks, AlgoSpec faces challenges during the iterative backpropagation. It requires model parameters from previous iterations to approximate new polynomials for the current iteration, meaning that its approximation has to be parameterized. We take the extension of AlgoSpec for parameterized algorithms as future work.

Deployment. When deploying AlgoSpec in real-world scenarios, it entails the client (in ***Scenario #1***) and the data processor (in ***Scenario #2***) to own a certain level of computational capabilities for the polynomial approximation and the obscured list construction. The obscured list generated by AlgoSpec enlarges the original data into an N dimension vector, causing increased storage and network communication costs from $O(1)$ to $O(N)$.

8 Related Work

There are several data protection methods [30, 43, 45, 53, 54] that data processors could use to protect the original data and attempt to meet the purpose limitation principle when sending the data to third parties. We categorize the current mainstream data protection methods into three groups, including *cryptography-based*, *noise-based*, and *algorithm-based*. In this section, we summarize each of them.

Cryptography-based data protection. The cryptography-based data protection that can be used for purpose limitation is fully homomorphic encryption (FHE). Popescu et al. [45]

propose a way of encrypting rational numbers using FHE by decomposing the rational numbers to various polynomials with the order from "0" to "$-n$", which protects rational number data in the medical field. Mukherjee et al. [43] develop a multi-key FHE scheme, which is a framework that allows different participants to use different encryption keys following a fixed computation method, to finally generate the results. Zhao et al. [54] give a solution to the big data privacy problem by deploying FHE to cloud computing, which enables third parties to execute relatively large-scale operations. Although FHE has strong data protection capabilities, it cannot achieve algorithm specificity, particularly, in ***Scenario #1***. Furthermore, its computational complexity is extremely high, requiring a large number of computational units to perform otherwise simple operations [16].

Noise-based data protection. Adding noise or perturbations to the original data is another approach to obfuscate data. One of the widely used noise-based methods is differential privacy (DP), which adds noise via the Laplace mechanism or Gaussian mechanism [30]. DP controls the intensity of the noise by setting different privacy loss parameters, i.e., ε_{dp} and δ_{dp}, as well as sensitivity. In general, the larger the values of ε_{dp} and δ_{dp}, the less noise is added to the data and the weaker the protection. In order to achieve satisfactory computational results with the protection of data security, the values of sensitivity, ε_{dp}, and δ_{dp} are set to 1.0. Cheu et al. [26] propose a scalable and robust protocol with DP by randomizing a set of user-supplied information through anonymous channels, to hide the sensitive information of private data. Wang et al. [50] present a DP method that improves the application of using local differential privacy to multidimensional data collection, so that complex computation can be performed on high-dimensional data. DP is easy to apply, but it may lead to sharp accuracy loss to the intended algorithm.

Algorithm Specificity. Limited research has been dedicated to purpose limitation, resulting in a limited number of methods capable of achieving algorithm specificity. Two recent studies might be adapted to the purpose limitation principle these days. Zhang et al. [53] add targeted noise to images to make them work only for specific tasks, thus protecting them from misuse and unauthorized online searches. Syed-Winkler et al. [47] present a system model for enforcing purpose limitation based on data tagging and attribute-based encryption, ensuring access control based on the purpose of a service. However, although these existing data protection methods can protect the data owners' original data to a certain extent, none of them can really satisfy algorithm specificity under the purpose limitation principle. Thus, to the best of our knowledge, we are the first to discover how to achieve algorithm specificity and provide a novel solution, AlgoSpec, through the lens of algorithm level.

9 Conclusion

We propose AlgoSpec, a solution of algorithm specificity that implements the purpose limitation principle. AlgoSpec's approach is based on the properties of polynomial approximation and complex mathematical problems, so as to convert the intended algorithm and the original data into an obfuscated format. It ensures two crucial goals for the purpose limitation principle. The original data are not recoverable by polynomial time attacks, and the obfuscated data can only be computed with authorized algorithms to generate desired results. We provide a formal proof on the security of AlgoSpec, and experimentally evaluate its accuracy and efficiency performance on the entropy method and Naive Bayes Classification. Our studies demonstrate that AlgoSpec balances computational efficiency with a high level of accuracy. Additionally, its high scalability also enables its applicability in a great range of scenarios and applications. We hope our study can attract more attention to the purpose limitation principle, going beyond the transparency principle that has become common practice nowadays.

A Appendix

A.1 Main Algorithm of AlgoSpec

We represent the workflow of AlgoSpec in Algorithm 1.

A.2 Proof of Theorem 1

We prove Theorem 1 by proving the correctness of Lemma 1 and Lemma 2.

Lemma 1. *(n is initialized indistinguishable). Let $\boldsymbol{Exp}_{\mathcal{G},k}^{ddh}(\mathcal{A})$ be a code-based game-playing. $\boldsymbol{Exp}_{\mathcal{G},k}^{ddh-0}(\mathcal{A})$ and $\boldsymbol{Exp}_{\mathcal{G},k}^{ddh-1}(\mathcal{A})$ are the sub-games in $\boldsymbol{Exp}_{\mathcal{G},k}^{ddh}(\mathcal{A})$, which is illustrated in Table 7. In Proc Initialize (k) of both sub-games, the only difference is $z \xleftarrow{R} xy \bmod p$ in $\boldsymbol{Exp}_{\mathcal{G},k}^{ddh-0}(\mathcal{A})$ and $z \xleftarrow{R} \mathbb{Z}_p^*$ in $\boldsymbol{Exp}_{\mathcal{G},k}^{ddh-1}(\mathcal{A})$. In proc Finalize (β'), the adversary guesses if $Z = g^{\log_g X+Y}$ and returns $\beta' = 1$ if the answer is yes, otherwise $\beta' = 0$ in the two sub-games. We have that n is indistinguishable if*

$$\mathbf{Adv}_{\mathcal{G},k}^{ddh}(\mathcal{A}) = |\mathcal{P}(\boldsymbol{Exp}_{\mathcal{G},k}^{ddh-0}(\mathcal{A}) = 1) - \mathcal{P}(\boldsymbol{Exp}_{\mathcal{G},k}^{ddh-1}(\mathcal{A}) = 1)| \leq \varepsilon, \tag{17}$$

where ε is negligible.

Proof of Lemma 1. The degree n of the polynomial is generated based on DDH (Definition 2), which can be considered as DLP [28, 39] (Definition 3). Let $G = <\mathcal{G}>$ be the finite cyclic group; p is the prime order; $k = |p|$ be the security parameter; $g \xleftarrow{R} G^*$ be the generated element. We generate n by $x \xleftarrow{R} \mathbb{Z}_p^*$, $y \xleftarrow{R} \mathbb{Z}_p^*$, $z \xleftarrow{R} xy \bmod p \Rightarrow n = g^z$.

To prove that n is indistinguishable, we construct a code-based game-playing $\boldsymbol{Exp}_{\mathcal{G},k}^{ddh}(\mathcal{A})$. Table 7 shows the entire game consisting of game $\boldsymbol{Exp}_{\mathcal{G},k}^{ddh-0}(\mathcal{A})$ and game $\boldsymbol{Exp}_{\mathcal{G},k}^{ddh-1}(\mathcal{A})$. Each sub-game contains two processes, the initialization process *Proc Initialize* (k) and finalization process *Proc Finalize* (β'), where β' is a flag that can be set to 1 or 0 based on the adversary guess.

We first design *Proc Initialize* (k) of the two sub-games. It generates a cyclic group G with prime order p using group generator $\mathcal{G}$. Then, it randomly selects a random generator g from G^* and x, y from $\mathbb{Z}_p^*$, and sets $X \xleftarrow{R} g^x$ as well as $Y \xleftarrow{R} g^y$. The only difference between $\boldsymbol{Exp}_{\mathcal{G},k}^{ddh-0}(\mathcal{A})$ and $\boldsymbol{Exp}_{\mathcal{G},k}^{ddh-1}(\mathcal{A})$ is illustrated by the red rectangle. In $\boldsymbol{Exp}_{\mathcal{G},k}^{ddh-0}(\mathcal{A})$, z is the real $z \xleftarrow{R} xy \bmod p$ that we use to generate n, while in $\boldsymbol{Exp}_{\mathcal{G},k}^{ddh-1}(\mathcal{A})$, z is randomly selected from $\mathbb{Z}_p^*$. Then we set $Z \xleftarrow{R} g^z$ and return (G, g, X, Y, Z) in both sub-games. In the *Proc Finalize* (β'), the adversary ends the game by guessing whether $Z = g^{\log_g X+Y}$. If the adversary guesses $Z = g^{\log_g X+Y}$, they set $\beta' = 1$, otherwise they set $\beta' = 0$.

In the *Proc Initialization* (k), there is a DLP. By giving g, X, Y and Z, one cannot distinguish whether $z \xleftarrow{R} xy \bmod p$ or $z \xleftarrow{R} \mathbb{Z}_p^*$. Thus, in both sub-games, based on the returned (G, g, X, Y, Z), the adversary is not able to find the relationship between Z and X, Y, which means when given $Z = g^{\log_g X+Y}$ and $Z \neq g^{\log_g X+Y}$, the adversary can only randomly select one, namely a random guess. As a result, the advantage $\mathbf{Adv}_{\mathcal{G},k}^{ddh}(\mathcal{A})$ of the adversary to win the game $\boldsymbol{Exp}_{\mathcal{G},k}^{ddh}(\mathcal{A})$ is negligible.

Lemma 2. *(n is unrecoverable from M). Let F be a polynomial with the degree n. Let M denote a list containing $\frac{N}{2}$ pairs ($N \gg 2n$) with almost evenly distribution, which follows γ distances. γ is well-designed by $\gamma = \rho + \omega$, where ρ is the number of distances of n pairs and ω is the new distances to be created ($0 \leq \omega \leq \frac{N}{4} - \rho$). Let A denote the calculation rule in AlgoSpec. The CPA is unable to discern n of the polynomial when provided with M.*

Table 8: Code-based game-playing $\boldsymbol{Exp}^{ddh}_{\mathcal{G},k,Gen()}(\mathcal{A})$ to prove M is indistinguishable

To facilitate the proof, we present a supporting claim that formulates Lemma 2 in a mathematical way. n in the claim represents the degree of the polynomial; $\frac{N}{2}$ are exactly the number of pairs in M; following the construction of pattern, we set γ (almost evenly distributed) distances in the claim with the same ρ and ω. Subsequently, we establish the correctness of Lemma 2 by demonstrating the validity of Claim 1.

Claim 1. *Given n pairs following ρ distances and $\left(\frac{N}{2}-n\right)$ pairs that are constructed to follow $\gamma=\rho+\omega$ distances, $\frac{N}{2}$ pairs that are evenly distributed can compose a list M, such that despite the attacker possessing M, n remains indistinguishable.*

Proof of Claim 1. Given $\frac{N}{2}$ pairs and γ distances ($n \ll \gamma < \frac{N}{2}$), there must be at least one distance containing multiple pairs, according to the pigeonhole principle. Therefore, the range of distance in n pairs is $\rho \in [1,n]$ Additionally, we introduce λ and d to adjust the number of distances, ensuring an almost uniform distribution within each distance. M comprises $\frac{N}{2}$ pairs distributed across γ patterns. Considering $\rho \in [1,n]$ and $\omega \in [0, \frac{N}{4}-\rho]$, it follows that $\gamma \in [1, n+\frac{N}{4}-\rho]$. In practical scenarios, where $\frac{N}{2} \gg n \geq \rho$, if $\gamma \leq n$ meaning that $\gamma \in [1,n]$, the adversary needs to attempt $(\frac{N}{2}-\gamma+1)$ times to determine n; if $\gamma > n$ meaning that $\gamma \in (n, n+\frac{N}{4}-\rho]$, the adversary needs to attempt $(\gamma-1)$ times. However, due to the even distribution, the adversary remains unaware of whether $\gamma < n$ or $\gamma > n$, necessitating $\frac{N}{2}$ $(\frac{N}{2}-\gamma+1+\gamma-1)$ attempts, which is impossible within PT. Consequently, even if M is disclosed, n remains unrecoverable.

A.3 Proof of Theorem 2

Table 8 shows the code-based game playing $\boldsymbol{Exp}^{ddh}_{\mathcal{G},k,Gen()}(\mathcal{A})$ used in our proof. Its construction follows the intuition that two Ms generated using different n are indistinguishable. $\boldsymbol{Exp}^{ddh-0}_{\mathcal{G},k,Gen()}(\mathcal{A})$ and $\boldsymbol{Exp}^{ddh-1}_{\mathcal{G},k,Gen()}(\mathcal{A})$ are the sub-games. In $\boldsymbol{Exp}^{ddh-0}_{\mathcal{G},k,Gen()}(\mathcal{A})$, n is set by $n \xleftarrow{R} g^{xy \bmod p}$; in $\boldsymbol{Exp}^{ddh-1}_{\mathcal{G},k,Gen()}(\mathcal{A})$, n is set by $n \xleftarrow{R} \mathbb{Z}_p^*$. Both sub-games return M with their corresponding n in *Proc Initialize*(k,ℓ,F). The adversary is not able to distinguish which M is generated from the real n. M is indistinguishable if

$$\begin{aligned}\mathbf{Adv}^{ddh}_{\mathcal{G},k,Gen()}(\mathcal{A}) = |\mathcal{P}\left(\boldsymbol{Exp}^{ddh-0}_{\mathcal{G},k,Gen()}(\mathcal{A})=1\right) \\ -\mathcal{P}\left(\boldsymbol{Exp}^{ddh-1}_{\mathcal{G},k,Gen()}(\mathcal{A})=1\right)| \leq \varepsilon\end{aligned} \tag{18}$$

The *Proc Initialize*(k,ℓ,F) of the two sub-games is designed to generate M. Their only difference is marked with red rectangles. In $\boldsymbol{Exp}^{ddh-0}_{\mathcal{G},k,Gen()}(\mathcal{A})$, n is the real one generated by $n \xleftarrow{R} g^{xy \bmod p}$, whereas in $\boldsymbol{Exp}^{ddh-1}_{\mathcal{G},k,Gen()}(\mathcal{A})$, n is generated randomly. In the *Proc Finalize*(β), once the adversary has the Ms returned by the two games, they need to determine which M is generated by the real n. In other words, they have to guess whether $n = g^{xy}$[4] or not based on the returned Ms. If they believe $n = g^{xy}$, they set $\beta' = 1$, otherwise they set $\beta' = 0$. Since n is indistinguishable, the adversary has to make a random guess here. Thus, the advantage $\mathbf{Adv}^{ddh}_{\mathcal{G},k,Gen()}(\mathcal{A})$ of the adversary to win the game is a negligible function.

A.4 Proof of Main Theorem

We utilize the IND-CPA framework (Definition 4 and 5) to demonstrate the unrecoverability of the original data ℓ. We devise a game denoted as $\boldsymbol{G}(\mathcal{A})$, depicted in Table 9. $\boldsymbol{G}(\mathcal{A})$ comprises four sub-games, namely, $\boldsymbol{G}_0(\mathcal{A})$, $\boldsymbol{G}_1(\mathcal{A})$, $\boldsymbol{G}_2(\mathcal{A})$, and $\boldsymbol{G}_3(\mathcal{A})$. There is only one distinction between every two consecutive sub-games, highlighted by the red rectangles, and the green rectangles indicate the sole difference between $\boldsymbol{G}_0(\mathcal{A})$ and $\boldsymbol{G}_3(\mathcal{A})$. Each sub-game comprises three processes: *Proc Initialize* (k, ℓ, F), *Proc LR* (ℓ, ℓ'), and *Proc Finalize* (β').

A.4.1 Game Settings

Proc Initialize(k, ℓ, F). In *Proc Initialize* (k, ℓ, F), all four sub-games generate the real M and return (G, γ, g, X). *Proc LR* (ℓ, ℓ'), where LR stands for Left-Right, denoting a procedure aimed at responding to queries posed by an adversary during the game [42]. In *Proc LR* (ℓ, ℓ'), each of the four sub-games supplies the adversary with an additional ℓ', referred to as a challenge message [29], which aids in facilitating the determination of whether ℓ is the original data.

[4] $g^{xy} = g^{xy \bmod p}$ by Lagrange's theorem.

Return (β')	*Return* (β')	*Return* (β')	*Return* (β')

Proc LR($\mathscr{d}$, $\mathscr{d}'$). During *Proc LR*($\mathscr{d}$, $\mathscr{d}'$), in $\boldsymbol{G}_0(\mathcal{A})$, the y is generated by $y \xleftarrow{R} \mathbb{Z}_p^*$, which is the same as the y generated in *Proc Initialize*(k, $\mathscr{d}$, F). Notably, generating y is an intermediate step in the derivation of n. Different y values yield distinct z values, consequently leading to different n. In $\boldsymbol{G}_1(\mathcal{A})$, distinguished from $\boldsymbol{G}_0(\mathcal{A})$, we generate w, a value distinct from y, by $w \xleftarrow{R} \mathbb{Z}_p^*$. As a result, $C1$ and n' differ between $\boldsymbol{G}_0(\mathcal{A})$ and $\boldsymbol{G}_1(\mathcal{A})$, following $C_1 \leftarrow g^y$, $n' \leftarrow X^y$ in $\boldsymbol{G}_0(\mathcal{A})$ and $C_1 \leftarrow g^w$, $n' \leftarrow X^w$ in $\boldsymbol{G}_1(\mathcal{A})$ respectively. It is evident that in $\boldsymbol{G}_0(\mathcal{A})$, $C_1 = Y$ and $n' = n$, whereas in $\boldsymbol{G}_1(\mathcal{A})$, $C_1 \neq Y$ and $n' \neq n$. When examining $\boldsymbol{G}_1(\mathcal{A})$ and $\boldsymbol{G}_2(\mathcal{A})$, the sole difference lies in C_2 generated by *Proc LR*($\mathscr{d}$, $\mathscr{d}'$). In $\boldsymbol{G}_1(\mathcal{A})$, we utilize the original data $\mathscr{d}$ as a parameter of $Gen()$ to generate C_2, i.e., $C_2 \xleftarrow{R} Gen(\mathscr{d},n',N,\gamma,F)$, but in $\boldsymbol{G}_2(\mathcal{A})$, C_2 is generated by the challenge message $\mathscr{d}'$, i.e., $C_2 \xleftarrow{R} Gen(\mathscr{d}',n',N,\gamma,F)$. Therefore, the C_2's in $\boldsymbol{G}_1(\mathcal{A})$ and $\boldsymbol{G}_2(\mathcal{A})$ are different. The difference between $\boldsymbol{G}_2(\mathcal{A})$ and $\boldsymbol{G}_3(\mathcal{A})$ is that we replace $w \xleftarrow{R} \mathbb{Z}_p^*$ in $\boldsymbol{G}_2(\mathcal{A})$ with $y \xleftarrow{R} \mathbb{Z}_p^*$ in $\boldsymbol{G}_3(\mathcal{A})$. In $\boldsymbol{G}_3(\mathcal{A})$, the y in *Proc LR*($\mathscr{d}$, $\mathscr{d}'$) is the same as the y in *Proc Initialize*(k, $\mathscr{d}$, F), so $C_1 = Y$ and $n' = n$. After understanding the differences between two neighboring games, we examine the distinction between $\boldsymbol{G}_0(\mathcal{A})$ and $\boldsymbol{G}_3(\mathcal{A})$, illustrated by the green rectangle. The only difference noted is that in $\boldsymbol{G}_0(\mathcal{A})$, C_2 is generated by $C_2 \xleftarrow{R} Gen(\mathscr{d},n',N,\gamma,F)$, whereas in $\boldsymbol{G}_3(\mathcal{A})$, C_2 is generated by $C_2 \xleftarrow{R} Gen(\mathscr{d}',n',N,\gamma,F)$. This achieves the intended distinction in the game $\boldsymbol{G}(\mathcal{A})$, where whether or not the original data is used to generate C_2 becomes the sole difference. All four sub-games in *Proc LR*($\mathscr{d}$, $\mathscr{d}'$) return (C_1, C_2) before *Proc Finalize*(β').

Proc Finalize(β'). In *Proc Finalize*(β'), the adversary initially checks if $C_1 = Y$, followed by verifying if $C_2 = M$, resembling a conditional probability distribution. Given the returned (G, γ, g, X) in *Proc Initialize*(k, $\mathscr{d}$, F) for the four sub-games, the adversary lacks the information to deduce Y. Therefore, they cannot ascertain whether $C_1 = Y$ when provided with $y \xleftarrow{R} \mathbb{Z}p^*$ and $w \xleftarrow{R} \mathbb{Z}_p^*$. Consequently, in the four sub-games, the probability that the adversary to guess $C_1 = Y$ is almost equal to the probability that they guess $C_1 \neq Y$, meaning a random guess. Subsequently, in determining whether $C_2 = M$, there are two scenarios. One is where the adversary assumes $C_1 = Y$ and believes $C_2 = M$, and the other is where they assume $C_1 \neq Y$ and then believe $C_2 = M$.

A.4.2 Proof

According to the conditional probability distribution, we can express the probability of the adversary guessing $C_2 = M$ in the four sub-games as from Eq. 19 to Eq. 22.

Game $\boldsymbol{G}_0(\mathcal{A})$. We start with Eq. 19.

$$\begin{aligned} \mathcal{P}(G_0(\mathcal{A}) = 1) = \mathcal{P}(C_1 = Y) \times \mathcal{P}\left(\boldsymbol{Exp}_{\mathcal{G},k}^{ddh-0}(\mathcal{A}) = 1\right) \\ \times \mathcal{P}\left(\boldsymbol{Exp}_{\mathcal{G},k,Gen()}^{ddh-0}(\mathcal{A}) = 1\right) + \mathcal{P}(C_1 \neq Y) \\ \times \mathcal{P}\left(\boldsymbol{Exp}_{\mathcal{G},k}^{ddh-1}(\mathcal{A}) = 1\right) \times \mathcal{P}\left(\boldsymbol{Exp}_{\mathcal{G},k,Gen()}^{ddh-0}(\mathcal{A}) = 1\right) \end{aligned} \tag{19}$$

With the premise that $\mathcal{P}(C_1 = Y)$ is a random guess, the probability that the adversary believes $n' = n$ can be considered as the game $\boldsymbol{Exp}_{\mathcal{G},k}^{ddh-0}(\mathcal{A})$, because if $C_1 = Y$, n' is equal to n. Similarly, the adversary guessing $C_2 = M$ can be considered as $\boldsymbol{Exp}_{\mathcal{G},k,Gen()}^{ddh-0}(\mathcal{A})$, given that M is indistinguishable

(Theorem 2) and the adversary is provided with the real ℓ in $\boldsymbol{G}_0(\mathcal{A})$. The success of the adversary's guess depends on whether $n = n'$, making it a conditional probability. Thus, the first case that the probability the adversary returns $\beta' = 1$ can be expressed as $\mathcal{P}(C_1 = Y) \times \mathcal{P}\left(\boldsymbol{Exp}^{ddh-0}_{\mathcal{G},k}(\mathcal{A}) = 1\right) \times \mathcal{P}\left(\boldsymbol{Exp}^{ddh-0}_{\mathcal{G},k,Gen()}(\mathcal{A}) = 1\right)$.

The second case is similar to the first one, with the difference that the adversary considers $C_1 \neq Y$. With this premise, the adversary believes $n' \neq n$, which can be considered as the game $\boldsymbol{Exp}^{ddh-1}_{\mathcal{G},k}(\mathcal{A})$. Thus, the second case that the probability that adversary returns $\beta' = 1$ can be expressed as $\mathcal{P}(C_1 \neq Y) \times \mathcal{P}\left(\boldsymbol{Exp}^{ddh-1}_{\mathcal{G},k}(\mathcal{A}) = 1\right) \times \mathcal{P}\left(\boldsymbol{Exp}^{ddh-0}_{\mathcal{G},k,Gen()}(\mathcal{A}) = 1\right)$. Finally incorporating the two cases, we obtain the probability of the adversary returning $\beta = 1$ shown as Eq. 19.

Game $\boldsymbol{G}_1(\mathcal{A})$. The adversary's guess that $C_2 = M$ in $\boldsymbol{G}_1(\mathcal{A})$ can be descirbed in Eq. 20.

$$\begin{aligned}\mathcal{P}(G_1(\mathcal{A}) = 1) &= \mathcal{P}(C_1 = Y) \times \mathcal{P}\left(\boldsymbol{Exp}^{ddh-0}_{\mathcal{G},k}(\mathcal{A}) = 1\right) \\ &\times \mathcal{P}\left(\boldsymbol{Exp}^{ddh-1}_{\mathcal{G},k,Gen()}(\mathcal{A}) = 1\right) + \mathcal{P}(C_1 \neq Y) \\ &\times \mathcal{P}\left(\boldsymbol{Exp}^{ddh-1}_{\mathcal{G},k}(\mathcal{A}) = 1\right) \times \mathcal{P}\left(\boldsymbol{Exp}^{ddh-1}_{\mathcal{G},k,Gen()}(\mathcal{A}) = 1\right)\end{aligned} \tag{20}$$

The analysis of game $\boldsymbol{G}_1(\mathcal{A})$ is similar to $\boldsymbol{G}_0(\mathcal{A})$. The only difference is that w is no longer the value y in *Proc Intitialize(k, ℓ, F)*, leading to $C_1 \neq n$, which can be considered as the game $\boldsymbol{Exp}^{ddh-1}_{\mathcal{G},k,Gen()}(\mathcal{A})$.

Game $\boldsymbol{G}_2(\mathcal{A})$. The probability of the adversary guessing $C_2 = M$ in $\boldsymbol{G}_2(\mathcal{A})$ is described in Eq. 21. The analysis closely resembles that of game $\boldsymbol{G}_1(\mathcal{A})$ except for the utilization of ℓ' instead of ℓ in *Proc LR*(ℓ, ℓ'). Therefore, we refrain from reiterating the explanation.

$$\begin{aligned}\mathcal{P}(G_2(\mathcal{A}) = 1) &= \mathcal{P}(C_1 = Y) \times \mathcal{P}\left(\boldsymbol{Exp}^{ddh-0}_{\mathcal{G},k}(\mathcal{A}) = 1\right) \\ &\times \mathcal{P}\left(\boldsymbol{Exp}^{ddh-1}_{\mathcal{G},k,Gen()}(\mathcal{A}) = 1\right) + \mathcal{P}(C_1 \neq Y) \\ &\times \mathcal{P}\left(\boldsymbol{Exp}^{ddh-1}_{\mathcal{G},k}(\mathcal{A}) = 1\right) \times \mathcal{P}\left(\boldsymbol{Exp}^{ddh-1}_{\mathcal{G},k,Gen()}(\mathcal{A}) = 1\right)\end{aligned} \tag{21}$$

Game $\boldsymbol{G}_3(\mathcal{A})$. We formulate the probability of the adversary guessing $C_2 = M$ in $\boldsymbol{G}_3(\mathcal{A})$ as presented in Eq. 22.

$$\begin{aligned}\mathcal{P}(G_3(\mathcal{A}) = 1) &= \mathcal{P}(C_1 = Y) \times \mathcal{P}\left(\boldsymbol{Exp}^{ddh-0}_{\mathcal{G},k}(\mathcal{A}) = 1\right) \\ &\times \mathcal{P}\left(\boldsymbol{Exp}^{ddh-0}_{\mathcal{G},k,Gen()}(\mathcal{A}) = 1\right) + \mathcal{P}(C_1 \neq Y) \\ &\times \mathcal{P}\left(\boldsymbol{Exp}^{ddh-1}_{\mathcal{G},k}(\mathcal{A}) = 1\right) \times \mathcal{P}\left(\boldsymbol{Exp}^{ddh-0}_{\mathcal{G},k,Gen()}(\mathcal{A}) = 1\right)\end{aligned} \tag{22}$$

In $\boldsymbol{G}_3(\mathcal{A})$, we set $y \xleftarrow{R} \mathbb{Z}^*_p$ again in *Proc LR*(ℓ, ℓ') identical to the settings in $\boldsymbol{G}_0(\mathcal{A})$. Consequently, the task of determining whether $C_2 = M$ can be regarded as $\boldsymbol{Exp}^{ddh-0}_{\mathcal{G},k}(\mathcal{A})$. Following the integration of the two cases discussed in $\boldsymbol{G}_0(\mathcal{A})$, we have Eq. 22.

Advantage to win $\boldsymbol{G}(\mathcal{A})$. As there is only one difference between the neighboring sub-games, so we consider the two neighboring sub-games as $\boldsymbol{Exp}^{ddh}_{\mathcal{G},k}(\mathcal{A})$ (Section A.3). The advantage of the adversary $\mathbf{Adv}^{ind-cpa}_{\mathcal{G},k,Gen()}(\mathcal{A})$ to win each $\boldsymbol{Exp}^{ddh}_{\mathcal{G},k}(\mathcal{A})$ can be expressed as from Eq. 23 to Eq. 25. Specifically, for $\boldsymbol{G}_0(\mathcal{A})$ and $\boldsymbol{G}_1(\mathcal{A})$, we have

$$\begin{aligned}&|\mathcal{P}(G_0(\mathcal{A}) = 1) - \mathcal{P}(G_1(\mathcal{A}) = 1)| \\ &= |\, 0.5 \times \left[\mathcal{P}\left(\boldsymbol{Exp}^{ddh-0}_{\mathcal{G},k}(\mathcal{A}) = 1\right) + \mathcal{P}\left(\boldsymbol{Exp}^{ddh-1}_{\mathcal{G},k}(\mathcal{A}) = 1\right)\right] \\ &\quad \times \mathcal{P}\left(\boldsymbol{Exp}^{ddh-0}_{\mathcal{G},k,Gen()}(\mathcal{A}) = 1\right) - 0.5 \\ &\quad \times \left[\mathcal{P}\left(\boldsymbol{Exp}^{ddh-0}_{\mathcal{G},k}(\mathcal{A}) = 1\right) + \mathcal{P}\left(\boldsymbol{Exp}^{ddh-1}_{\mathcal{G},k}(\mathcal{A}) = 1\right)\right] \\ &\quad \times \mathcal{P}\left(\boldsymbol{Exp}^{ddh-1}_{\mathcal{G},k,Gen()}(\mathcal{A}) = 1\right)| \\ &= |\mathcal{P}\left(\boldsymbol{Exp}^{ddh-0}_{\mathcal{G},k,Gen()}(\mathcal{A}) = 1\right) - \mathcal{P}\left(\boldsymbol{Exp}^{ddh-1}_{\mathcal{G},k,Gen()}(\mathcal{A}) = 1\right)| \\ &= \mathbf{Adv}^{ddh}_{\mathcal{G},k,Gen()} \leq \varepsilon\end{aligned} \tag{23}$$

For $\boldsymbol{G}_1(\mathcal{A})$ and $\boldsymbol{G}_2(\mathcal{A})$, based on Eq. 20 and Eq. 21, we have

$$|\mathcal{P}(G_1(\mathcal{A}) = 1) - \mathcal{P}(G_2(\mathcal{A}) = 1)| = 0 \leq \varepsilon \tag{24}$$

For $\boldsymbol{G}_2(\mathcal{A})$ and $\boldsymbol{G}_3(\mathcal{A})$, we can derive

$$\begin{aligned}&|\mathcal{P}(G_2(\mathcal{A}) = 1) - \mathcal{P}(G_3(\mathcal{A}) = 1)| \\ &= |\, 0.5 \times \left[\mathcal{P}\left(\boldsymbol{Exp}^{ddh-0}_{\mathcal{G},k}(\mathcal{A}) = 1\right) + \mathcal{P}\left(\boldsymbol{Exp}^{ddh-1}_{\mathcal{G},k}(\mathcal{A}) = 1\right)\right] \\ &\quad \times \mathcal{P}\left(\boldsymbol{Exp}^{ddh-1}_{\mathcal{G},k,Gen()}(\mathcal{A}) = 1\right) \\ &\quad - 0.5 \times \left[\mathcal{P}\left(\boldsymbol{Exp}^{ddh-0}_{\mathcal{G},k}(\mathcal{A}) = 1\right) + \mathcal{P}\left(\boldsymbol{Exp}^{ddh-1}_{\mathcal{G},k}(\mathcal{A}) = 1\right)\right] \\ &\quad \times \mathcal{P}\left(\boldsymbol{Exp}^{ddh-0}_{\mathcal{G},k,Gen()}(\mathcal{A}) = 1\right)| = |\mathcal{P}\left(\boldsymbol{Exp}^{ddh-1}_{\mathcal{G},k,Gen_0}(\mathcal{A}) = 1\right) \\ &\quad - \mathcal{P}\left(\boldsymbol{Exp}^{ddh-0}_{\mathcal{G},k,Gen()}(\mathcal{A}) = 1\right)| \\ &= \mathbf{Adv}^{ddh}_{\mathcal{G},k,Gen()} \leq \varepsilon\end{aligned} \tag{25}$$

In each $\boldsymbol{Exp}^{ddh}_{\mathcal{G},k}(\mathcal{A})$, the adversary's advantage is a negligible function. Summarizing Eq. 23, 24, and 25 based on the triangle inequality theorem, we can obtain Eq. 26, which is the advantage of the adversary to win the game $\boldsymbol{G}(\mathcal{A})$.

$$\begin{aligned}&\mathbf{Adv}^{ind-cpa}_{\mathcal{G},k,Gen()}(\mathcal{A}) = |\mathcal{P}(G_0(\mathcal{A}) = 1) - \mathcal{P}(G_3(\mathcal{A}) = 1)| \\ &\leq |\mathcal{P}(G_0(\mathcal{A}) = 1) - \mathcal{P}(G_1(\mathcal{A}) = 1)| \\ &\quad + |\mathcal{P}(G_1(\mathcal{A}) = 1) - \mathcal{P}(G_2(\mathcal{A}) = 1)| \\ &\quad + |\mathcal{P}(G_2(\mathcal{A}) = 1) - \mathcal{P}(G_3(\mathcal{A}) = 1)| \leq \varepsilon\end{aligned} \tag{26}$$

$\mathbf{Adv}^{ind-cpa}_{\mathcal{G},k,Gen()}(\mathcal{A})$ is a negligible function for PTAs. Therefore, ℓ is unrecoverable under PTAs.

DVSorder: Ballot Randomization Flaws Threaten Voter Privacy

Abstract

A trend towards publishing ballot-by-ballot election results has created new risks to voter privacy due to inadequate protections by election technology. These risks are manifested by a vulnerability we discovered in precinct-based ballot scanners made by Dominion Voting Systems, which are used in parts of 21 states and Canada. In a variety of scenarios, the flaw—which we call DVSorder—would allow attackers to link individuals with their votes and compromise ballot secrecy. The root cause is that the scanners assign pseudorandom ballot identifiers using a linear congruential generator, an approach known since the 1970s to be insecure. Dominion attempted to obfuscate the generator's output, but we show that it can be broken using only pen and paper to reveal the order in which all ballots were cast. Unlike past ballot randomization flaws, which typically required insider access to exploit or access to proprietary software to discover, DVSorder can be discovered and exploited using only public information.

In addition, the election sector's response to our findings provides a case study highlighting gaps in regulations and vulnerability management within this area of critical infrastructure. Although Dominion released a software update in response to DVSorder, some localities have continued to publish vulnerable data due to inadequate information sharing and mitigation planning, and at least one state has deferred addressing the flaw until after the 2024 presidential election, more than two years following our disclosure.

1 Introduction

The secret ballot is a crucial election security mechanism that helps ensure people can vote their conscience without being bribed or coerced. Its protections, which are guaranteed in the constitutions of 44 states [21], have taken on increased importance amidst an alarming rise in voter intimidation [23].

Modern election technology creates new challenges for ballot secrecy, because computerized voting systems are capable of generating ballot-by-ballot results, i.e., data that describes the selections on each individual ballot. Recently, some election officials have started to publish such data in the belief that it bolsters voter confidence, and several states have passed [22] or are considering [2] laws that mandate its publication. Many more localities have released ballot-level data in response to a wave of lawsuits [37] and Freedom of Information Act requests [24] following the 2020 presidential election.

To prevent voters from being associated with their ballots, ballot-level data needs to be anonymized, but deployed election technology has repeatedly failed to do this securely. In 2004, the first academic study of an electronic voting machine found that it used a broken random number generator to shuffle ballot-level data [34], and in the two decades since, researchers have identified similar flaws that could compromise voter privacy in a variety of other election systems (see Section 7). Despite this concerning pattern, there has been little effort to systematically address this class of vulnerabilities, perhaps because access to ballot-level data was historically limited to election insiders. Yet the current trend towards publishing ballot-level data has transformed the nature of the threat: now anyone can potentially exploit such flaws.

To understand how this threat affects contemporary voting technology, we examined ballot-level data from recent U.S. elections. Using only public information, we uncovered a serious privacy flaw in products from Dominion Voting Systems, the country's second-largest voting equipment maker. Due to a flaw in the ballot randomization algorithm used by Dominion precinct-based ballot scanners, anyone can unshuffle ballot-level data produced from affected machines and determine the order in which the ballots were cast. We named the vulnerability DVSorder ("*devious order*"), and it was assigned CVE-2022-48506. Unlike most prior ballot privacy flaws, DVSorder can be identified and exploited by the public—it does not require malicious actions by insiders, compromise of or access to voting machines, or participation by voters themselves—and exploitation cannot be detected by election officials. At the time of discovery, parts of 21 states and Canada used the affected systems [60], and at least 11 states had released vulnerable data that was available online [44, 51, 64].

We reported the vulnerability to Dominion, which created updated software in response. Unfortunately, such a patch can

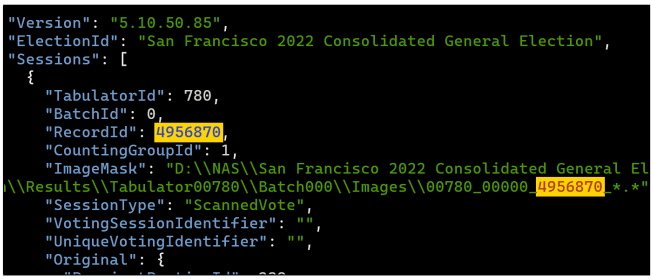
only protect voters in future elections, and vulnerable data that has already been published will remain exploitable.

Since the design, testing, and operation of election technology is a heavily regulated area of critical infrastructure, one might expect flaws like DVSorder to be caught and corrected quickly. Instead, the vulnerability persisted for years, across at least 11 versions of three Dominion products, which were repeatedly certified by multiple regulators at the federal and state levels. This points to gaps in the testing and certification processes used for election equipment, especially with respect to voter privacy. We discuss these issues in Section 8.

Evidence of other kinds of gaps emerged as we carried out disclosure, which provided a rare test case for the election sector's security information sharing and vulnerability management practices (Section 6). Neither Dominion nor the responsible federal agencies effectively notified the local jurisdictions that operate the equipment, leading such major municipalities as San Francisco to continue releasing vulnerable data well after we made our findings public. Once notified, some jurisdictions promptly patched or otherwise addressed the problem, but others have not. One state—Georgia—has announced, citing logistical difficulties, that it will defer mitigation until after the 2024 presidential election, leaving voters at risk more than two years after we disclosed the flaw [61]. These challenges underscore the need for further maturation of security processes throughout the election ecosystem.

Additional information about DVSorder, as well as a data sanitization tool and other recommended mitigations for election officials, can be found online at DVSorder.org.

2 Background

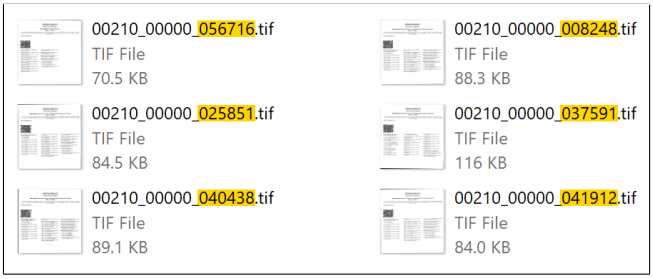


Many modern voting systems produce ballot-level data. In well implemented systems, this data is safe for public release. When systems do not include appropriate safeguards, however, such data can reveal how individuals voted.

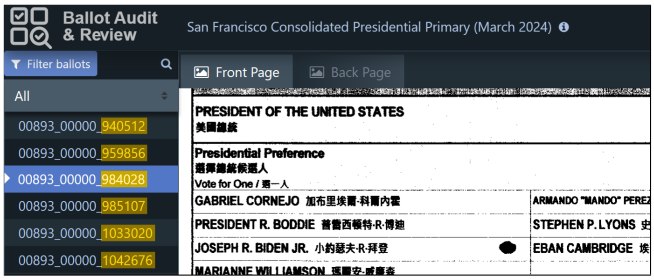
2.1 Ballot-Level Data

Modern ballot scanners produce two main types of ballot-level data that are intended to be public facing. The first, *cast vote records* (CVRs), are the choices selected on an individual ballot along with metadata about the ballot. This metadata identifies the precinct and the tabulator that processed the ballot and includes an ID that uniquely identifies the ballot among those in the election. Dominion systems can export CVRs in CSV or JSON format, as shown in Figures 1a and 1b.

Scanners also produce a second form of ballot-level data, *ballot images*, which are digital scans of each ballot. These image files are typically associated with the same ID as the corresponding CVRs to allow cross comparison. Figure 1c shows an example of a set of ballot images from a Dominion system.



A growing number of jurisdictions publish one or both forms of ballot-level data, sometimes even making them available in interactive forms, such as the online tool in Figure 1d. Although these digital artifacts have limited value for verifying the integrity of an election outcome in the face of electronic tampering [6] (which would require inspection of the original physical ballots, e.g., in a risk-limiting audit), many public officials consider releasing them to be a beneficial "open government" practice that enhances public trust.



(a) JSON-format cast vote records

TabulatorNum	BatchId	RecordId	CountingGroup	PrecinctPortion
987	0	546984	Election Day	City of Detroit, P

Figure 1: Ballot-level data from Dominion systems. Jurisdictions increasingly publish ballot-by-ballot election data in the form of cast vote records (descriptions of the votes recorded from each ballot) or ballot images (scans of each ballot). The most common formats of this data for Dominion systems are shown here. Each associates votes with the ballot's record ID (*highlighted*), the source of the DVSorder vulnerability.

2.2 Dominion Voting Systems

Dominion has been the subject of prominent conspiracy theories concerning fraud in the 2020 U.S. presidential election that have no evidentiary basis [1, 27]. However, researchers have recently shown that some of the company's products really do suffer from serious security problems [18, 27, 29].

Dominion produces a line of equipment it calls Democracy Suite, which includes election management system (EMS) software and both batch-fed and hand-fed ballot scanners, among other components. The company offers three models of hand-fed scanners: the ImageCast Precinct (ICP), ImageCast Precinct 2 (ICP2), and ImageCast Evolution (ICE). These machines are typically used as *precinct tabulators*: that is, they are deployed at polling places, and voters feed in their own marked ballots, which are counted and deposited into an integrated ballot box. When voting is complete, workers use removable memory cards to transfer ballot-level data to a central EMS computer, which aggregates results from tabulators throughout the jurisdiction to generate the official totals.

In order to track data about voted ballots, Democracy Suite uses three fields: *tabulator ID*, *batch ID*, and *record ID*.[1] The combination of these IDs uniquely identifies a ballot within an election, and they are used together to label CVRs and ballot image files, as seen in Figure 1.

Dominion tabulators assign a numeric record ID to every ballot sheet as it is scanned. Typically, these consist of six digits, which are chosen to be unique within a batch. When ballots run across multiple sheets of paper, higher-order digits are added to indicate the sheet number, so that records of a given sheet sort together. For present purposes, we can ignore the sheet number and consider the record IDs mod 1,000,000.

To protect privacy, the record IDs must not reveal the order in which the ballots were cast. Otherwise, for instance, anyone in the polling place could note that someone was the nth voter to use the scanner and later identify their ballot in the data. (We discuss variations of this threat, including attacks that can be performed retrospectively, in Section 4.) To address this, Dominion's hand-fed scanners assign the six low-order digits using a random number generator,[2] which the company asserted in contracts with state governments "ensur[es] the ballot images are de-coupled from voter order" [54, p. 187].

3 The DVSorder Vulnerability

> . . . The moral of this story is that *random numbers should not be generated with a method chosen at random.*
>
> — Donald E. Knuth, 1969 [33, p. 5]

We determined that Dominion ICP, ICP2, and ICE scanners draw their ballot record IDs sequentially from a fixed cycle of possible values that is shared across all machines of the same model. The only unpredictable element is the starting point in the cycle, which each scanner chooses at the start of the election (see Figure 2). Using only publicly available information, we managed to reconstruct the complete cycles for all three scanner models, which turn out to be the obfuscated output of a linear congruential generator. With knowledge of the cycles, anyone can perfectly determine the order the ballots were cast from their record IDs, as shown in Figure 3.

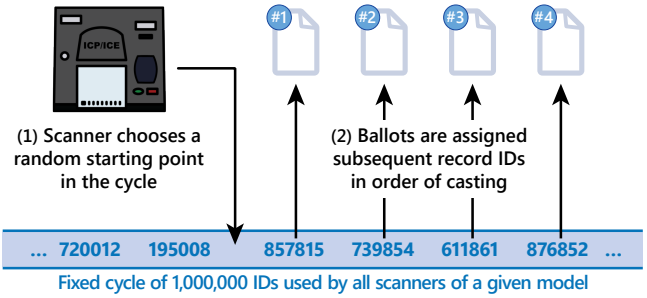

Figure 2: Flawed ballot ID generation. Dominion scanners assign record IDs to ballots as they are cast by following a fixed cycle of one million values. The only unpredictable feature is the starting point.

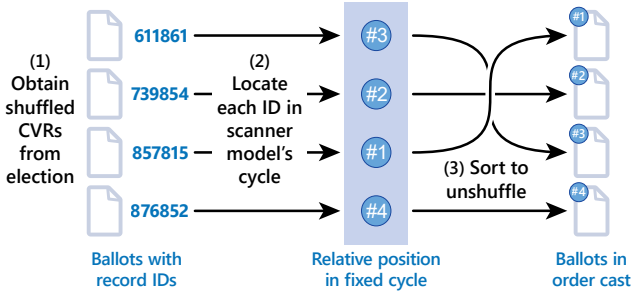

Figure 3: Ballot order can be reconstructed from public data. Record IDs from ballot images or CVRs can be matched to their positions in the fixed cycle. The ballots in a batch will map to consecutive positions, which correspond to the order in which they were cast.

The remainder of this section details the process we used to reconstruct the cycles. It is instructive, because it reveals how readily Dominion's privacy protections can be defeated.

3.1 Reversing the ICP Generator

Our starting point was an unusual public dataset that contained a copy of the memory cards from a jurisdiction's ICP scanners. Raw data from these cards is not typically published, since it is unsafe to do so, but in 2021 card data from a single county was openly distributed by a third party, and we obtained a copy.

When the Dominion system exports ballot-level data for public consumption, it presents the ballots from each batch in a shuffled order to conceal the order of casting, but we found that the raw data from the memory cards contained CVRs in voted order. We determined this by comparing the sequence of ballot styles from the CVRs to the sequence of styles that were cast during the election, as recorded chronologically in log files stored on the cards. These matched exactly.

[1] For a precinct tabulator, all voted ballots are usually assigned batch ID 0.

[2] In contrast, Dominion's batch-fed scanners, which are typically used to count mail-in ballots, assign record IDs sequentially. This is safe under the assumption that mail-in ballots will be adequately shuffled before scanning.

Using the data from one card, we extracted approximately 500 record IDs in voted order. This relatively small sequence was sufficient for us to reverse the full cycle of one million IDs shared across all ICP tabulators. Of course, any election worker with access to the equipment could obtain an ordered ID sequence even more easily by simply scanning a deck of numbered ballots and inspecting the resulting ballot images.

However an initial sample of the generator's output is obtained, the function is weak enough that it can be reversed using only pen and paper through the process described below.

Identifying the Sequence as Nonrandom Closely inspect the following sequence of record IDs (in column-major order):

850934	262494	959507	765067
437941	043481	331519	147059
614932	900792	516506	804866
079948	225788	173513	721853
486435	597795	388000	696860

There are obvious patterns in this sequence. For instance, the digits in the ten-thousands place (*blue*) follow a cycle with period 10. Inspecting a longer sequence would show that the digits in the hundreds place (*red*) follow a cycle with period 100. These cycles, combined with the output domain, suggested that a linear congruential generator (LCG) with modulus 1,000,000 might be in use.

An LCG is defined by the recurrence relation [46]:

$$x_{n+1} = a \cdot x_n + b \mod m.$$

To use an LCG in such an application would be a mistake. Researchers identified patterns in LCG output as early as 1968 [38] and used these patterns to "crack" such generators in cryptographic contexts as early as 1977 [50]. It has been known since 1982 that the outputs of an LCG with unknown parameters can be efficiently predicted with knowledge of just a few consecutive elements from the sequence [46].

If the ICP used a simple LCG with modulus 1,000,000, we would expect the least-significant digit to exhibit a cycle with period at most 10, the second-least-significant digit to exhibit a cycle with period at most 100, and so on. This is because the last decimal digit of the term x_{n+1} may only be affected by the last decimal digit in a, x_n, and b when m is a multiple of 10. Since a and b are constants, the last digit of x_n is the only piece of state affecting the last digit of x_{n+1}. There are only ten possible values for the state, which means the last digit can have a period of at most ten. This logic can be generalized to the other digits in the generator's output.

Identifying the First Obfuscation That cycles of lengths 10 and 100 appear, but in different digit positions than expected, suggests that the order of the digits is being permuted to obfuscate the generator's output. To test this theory, we can set aside the other digits and restore the two digits with known periods to their suspected positions in the underlying state.

We now see the following consecutive terms:

95	46	55	06
93	44	53	03
91	70	51	80
97	72	57	82
48	79	08	89

These terms are not consistent with an LCG, since the numbers remain close together for several sequential terms then jump significantly in a repeated pattern. This suggests that another digit-level obfuscation may be present.

Identifying the Second Obfuscation We intuit that the second obfuscation may be a substitution cipher. To determine the rule of substitution, we observe that the digit now in the tens place changes once for every three or four changes in the ones place. This pattern matches what we would expect when counting by threes. We hypothesize that each term of underlying state differs from the state of the previous term by three.

Next, we observe the four sequential terms 95, 93, 91, 97. Note that the digit in the tens place does not change. This is true when counting by threes only if the numbers in the ones place are $0, 3, 6$, and 9. This suggests that $5, 3, 1$ and 7 correspond to $0, 3, 6$, and 9 respectively. We can extend this pattern further and conclude that the sequence's next term must have a 2 in the ones place, followed by a 5, and so on. This allows us to derive a substitution rule covering each digit.

Completing the Reversal Applying the substitution and permutation rules to the original IDs yields the following terms for the underlying state, where the digits in parenthesis are in uncertain order:

(2138) 70	(4478) 85	(7719) 00	(9059) 15
(8986) 73	(1326) 88	(3667) 03	(6907) 18
(5834) 76	(7174) 91	(0515) 06	(2855) 21
(1782) 79	(4022) 94	(6363) 09	(9603) 24
(8530) 82	(0970) 97	(3211) 12	(5551) 27

This is consistent with our intuition that the underlying state in the two least-significant digits is counting by threes, and confirms that we are on the right track. We now must determine which digit is the third-least-significant of the underlying state. We observe that the least-significant digit of the original record IDs, after applying the substitution rule, switches from pattern $8, 6, 4, 2, 0$ to pattern $9, 7, 5, 3, 1$ when the two least significant digits of the state roll over from 97 to 00; in other words, it happens precisely when we would "carry the one." This suggests that the least-significant digit of the ID is the third-least-significant digit of the underlying state, and that our state increments by $b \equiv 803 \mod 1000$ at each iteration.

We now know the substitution rule and the permutation of the three least-significant digits of the underlying state, as well as the three least-significant digits of the incrementing constant b. We also know that the multiplicative constant satisfies $a \equiv 1 \mod 1000$, and we hypothesize that it is simply 1.

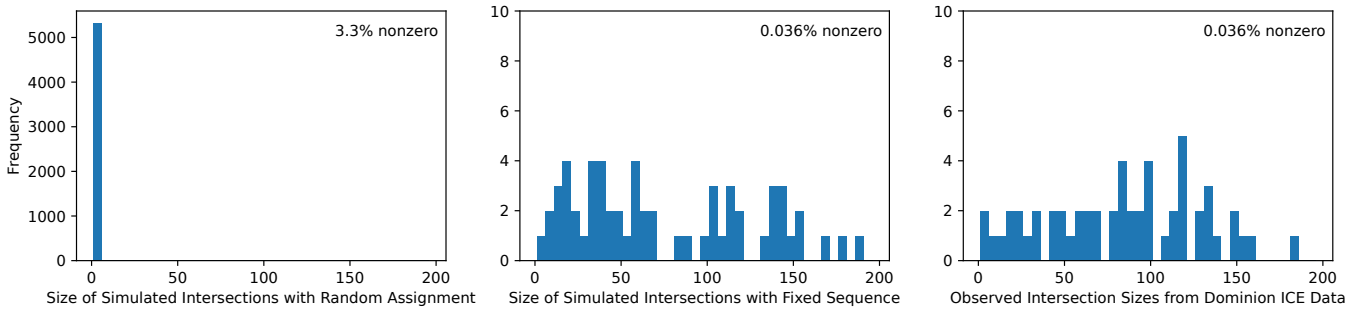

Figure 4: Statistical detection of the flawed RNG. Sets of record IDs chosen by different scanners sometimes overlap. For an election with 571 scanners, we show representative simulations of the intersection sizes obtained if IDs are assigned randomly (*left*) or by picking random starting places in a fixed cycle (*middle*). The latter closely matches the observed distribution in public data from ICE scanners in San Francisco (*right*).

To determine the permutation and incrementation constant of the rest of the state, we refer to the following three terms:

$$(583)\ 476 \qquad (178)\ 279 \qquad (853)\ 082$$

To identify which digit is the next-least-significant in the underlying state, we observe the change in value for each digit between sequential terms. We observe that the first digit increases under the modulus by 6, then by 7. The second digit increases by 9, then by 8. The third digit increases by 5, and again by 5. We note that we would expect to "carry a one" from the less-significant digits whose order we know for both incrementations, so the change in the digit's value should be consistent between the three terms. Thus, the third digit of the unordered tuple must be the third digit of the state, and we must be incrementing by 4803 at each iteration.

To determine the order of the two final digits, we observe that we would expect to carry a one from the digit we just placed on the second incrementation of the state, but not on the first. This is consistent with the change in value for the first digit of our unordered pair, but not of the second. Thus, we conclude that the two remaining digits are swapped.

The ICP Generator The reasoning above lets us derive the complete record ID generation algorithm used by the ICP. Starting from an unknown initial seed, for each subsequent ballot, the ICP iterates the state of the following LCG:

$$x_{n+1} = x_n + 864803 \mod 1000000.$$

It then transforms the LCG's output with a substitution cipher

$$[0,1,2,3,4,5,6,7,8,9] \longrightarrow [5,0,8,3,2,6,1,9,4,7]$$

and permutes the digits such that 123456 becomes 261534. Thus obfuscated, the value becomes the ballot's record ID. This generator has a period of one million and seems to have been used with identical constants across all ICP scanners.

In effect, all ICPs followed the fixed cycle of one million record IDs produced by this function. Each chose an apparently random starting point, then assigned sequential IDs from the cycle to ballots in the order they were cast.

3.2 Reversing the ICE and ICP2 Generator

Dominion's other precinct-based scanners, the ICE and ICP2, do not follow the record ID cycle derived above. We initially had no data known to be in voted order for these models, so we applied a different strategy to determine the generator.

Record ID Intersections First, we determined that these other scanner models use a similar ID generation algorithm to the ICP by comparing the record IDs used in different batches of ballots in public data. If the machines drew IDs uniformly at random, we would expect the magnitude of the intersections between batches to be governed by the birthday paradox. This means we would expect a relatively large number of non-zero intersections with a small number of shared IDs in each. If the machines used a fixed cycle of IDs, however, we would expect non-zero intersections that were rarer but larger. Public CVR data matched the fixed-cycle hypothesis (see Figure 4).

The specific intersections between sets of IDs from different tabulators place constraints on the cycle. When two batches intersect, the IDs in the intersection must be consecutive, and so must the IDs in the union, as illustrated below:

By sourcing public data from many elections and analyzing these intersections, we could potentially reconstruct the complete cycle. The problem of reconstructing a full sequence based on many unordered subsequences is closely related to genome reconstruction algorithms in the field of computational biology (see, e.g., [45]) and would be interesting to pursue, but we applied a simpler method, described below.

Determining Parameters Since the ICE appeared to follow a fixed cycle like the ICP, we conjectured that their RNGs used the same algorithm with different parameters (i.e., permutation and substitution rules and constants a and b). To constrain the space of possibilities, we analyzed public data from San Francisco and identified batches from two ICEs that shared four record IDs in common. By the analysis above, these IDs must appear consecutively (in some order) in the ICE cycle. We exhaustively tested for parameters that

would cause the generator to satisfy this condition, yielding two equivalent generators producing such a cycle and two more that followed the same cycle in the opposite direction. Appendix A explains why such equivalent generators exist.

One of these generators used parameters nearly identical to the ICP's. The only difference was the permutation, which, in the new generator, transformed 123456 to 342615. The constants for the LCG and substitution cipher were unchanged.

Such similarity suggested that this generator followed the cycle in the correct direction. For confirmation, we used scanner log files from an ICE published by San Francisco. The logs allowed us to identify the indices at which overvoted ballots were cast, and we verified that the ballot images the generator placed in these positions were indeed overvoted.

Finally, we located public data produced by ICP2 tabulators and confirmed that the record IDs in each batch were consecutive under the ICE's cycle. This indicated that the same generator was shared by both models.

Code To aid experimenters, the following compact Python program generates the full cycles for all three scanner models:

```
generate_cycle = lambda b,s,p:[sum(s[b*n//
   10**(6-p[i])%10]*10**(5-i) for i in range(6))
   for n in range(10**6)]
b,s = 864803, [5,0,8,3,2,6,1,9,4,7]
icp = generate_cycle(b, s, [2,6,1,5,3,4])
ice = generate_cycle(b, s, [3,4,2,6,1,5]); icp2=ice
```

3.3 Validation and Scope

To further confirm that the generators we derived were correct, and to determine the scope of the vulnerability, we attempted to locate and analyze public ballot-level data from as many jurisdictions as possible that used the affected scanners.

It is straightforward to check if a dataset uses the generators. If it does, we expect the record IDs within each batch of ballots to be consecutive (or nearly so) under one of the cycles. This was the case for every ICP, ICP2, and ICE dataset we encountered. Note that the machines skip ID 0, and on rare occasions one or a few IDs may be missing from otherwise-consecutive batches, which likely correspond to provisional ballots that were scanned but removed from the tally. We created a test tool (available at DVSorder.org) that imports CVRs or ballot images and reports whether they are vulnerable.

Ultimately, we found vulnerable data published online from parts of 11 states [44, 51, 64]: Alaska, Arizona, California, Georgia, Iowa, Michigan, New Jersey, New Mexico, Ohio, Tennessee, and Wisconsin. Twenty-one states (shown in Figure 5), Puerto Rico, and Canada used the vulnerable scanner models in at least some localities as of November 2022 [60].

The datasets we confirmed to be vulnerable were produced in jurisdictions running 11 versions of Democracy Suite: 5.2, 5.4-NM, 5.5, 5.5-A, 5.5-B, 5.5-C, 5.5-D, 5.7-A, 5.10, 5.10A, and 5.15. As of June 2024, we have yet to encounter any dataset with record IDs produced by ICP, ICP2, or ICE scanners that is not affected by the vulnerability.

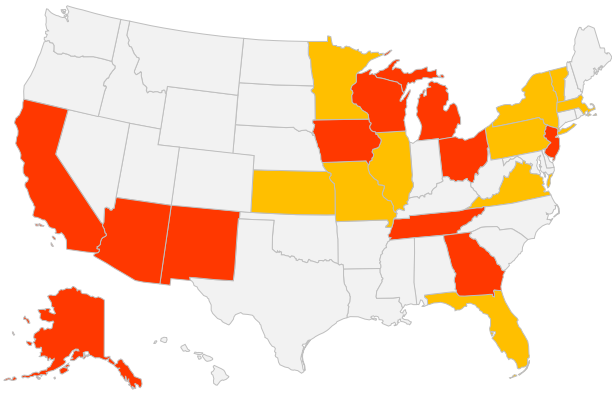
4 Risks and Exploitation

With knowledge of the fixed record ID cycles—or the ability to derive them from public data—one can trivially unshuffle CVRs or ballot images produced by the affected tabulators. This does not require any malicious action by election insiders, access to election equipment, advanced technical capabilities, or participation by voters. Since the vulnerability can be exploited passively using only publicly available information, exploitation carries little potential risk for attackers.

Given the ability to unshuffle ballot-level data, there are several ways that an attacker can learn how specific people voted. Some require making deliberate observations during the election, while others can be performed retrospectively (perhaps years later) if certain side information is available.

Public Counters In most jurisdictions, precinct-based scanners continuously display a public counter that shows how many ballots they have recorded thus far during the election (see Figure 6a). The counter value is equivalent to the index in the unshuffled ballot sequence of the most recently cast ballot. Anyone near the machine—such as poll workers, other voters, or, depending on the layout of the polling place, public observers—can note the counter value after a victim votes in order to later identify that person's ballot. Of the many threats this facilitates, one noteworthy example is spousal coercion. Suppose a man uses a scanner immediately after his wife. The value of the counter before he scans his ballot tells the man the index of his wife's ballot, which lets him learn how she voted if vulnerable ballot-level data becomes public.

Election Observers Poll workers or election observers could also keep a complete ordered record of who uses the scanner, which would allow them to deanonymize all ballots cast at the polling location or to target public figures or specific people they know. In many states, the right of partisan poll watchers to observe inside polling places and to note the identity of voters is enshrined in law (see, e.g., [39, 48]). Organized



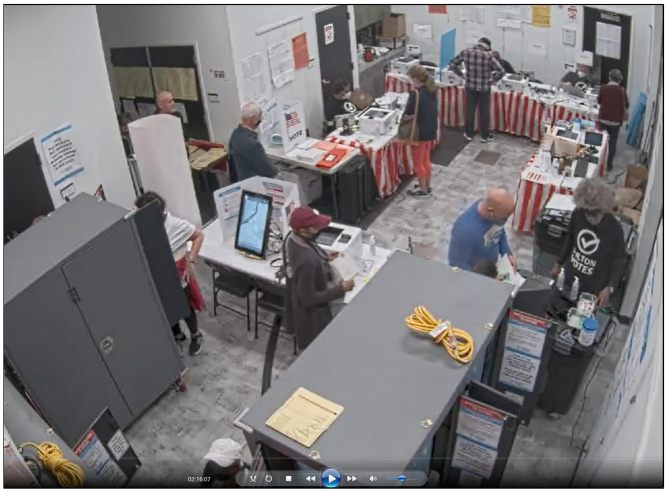


Figure 5: States vulnerable to DVSorder. Parts of 21 U.S. states (*red/amber*) used the vulnerable Dominion scanners as of Nov. 2022, as did Puerto Rico and some Canadian localities. We found vulnerable data published online from recent elections in 11 states (*red*).

(a) Public counter ("ballots cast") displayed by ICP scanner

(b) Video from polling place showing voter using ICP scanner (blue shirt)

Figure 6: Exploiting voted order to deanonymize ballots. An attacker can identify who cast which ballot by making observations during the election or, after the fact, using side information. For example: (*a*) Other voters or poll workers can note the scanner's public counter when victims vote. (*b*) Some localities record video of everyone who uses the scanner, such as this footage from Georgia obtained via a public records request.

political machines could exploit these rights to deanonymize ballots as part of efforts to buy votes or intimidate voters.

Poll Books When a ballot is issued, the voter's identity is typically recorded in a digital or paper-based log called a "poll book" to ensure they do not vote again later. Depending on the design of these poll books, they sometimes record the time at which individual voters received their ballots. This provides a strong proxy to the order in which voters cast their ballots and could reveal many voters' choices, especially during slow parts of the day when voters are widely spaced in time.

Scanner Log Files Some localities publish log files from their ballot scanners. In the Dominion system, these logs by themselves pose little risk to privacy, but they can be combined with DVSorder to determine the exact time that each ballot was cast (subject to the accuracy of the scanner's clock). To exploit this, attackers could infer the time a particular individual used the scanner based on the time they leave the polling place. This could be gathered by watching from outside the building during the election or even after the fact from mobile geolocation data. As another example, journalists sometimes film or photograph candidates and other public figures as they vote. Such media is typically timestamped, which, combined with scanner log files, could be used to deanonymize those individuals' ballots even long after the election.

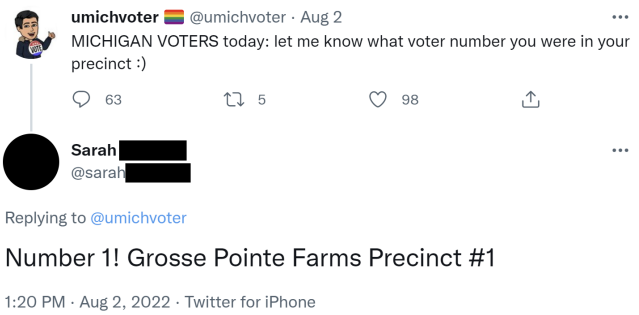

Figure 7: Some voters publicly disclose their voting locations and voter numbers, as in this thread from Twitter (which we have redacted). This is sufficient information to identify the unsuspecting voter's ballot if vulnerable CVRs or ballot image files are available.

Disclosures by Voters Some voters publicly reveal their polling places and voter numbers, as in the Twitter thread shown in Figure 7. As long as the voter has accurately stated their position in the ballot sequence, this lets anyone determine their exact set of votes from vulnerable ballot-level data. For most voters who reveal such information, this is an unexpected violation of privacy, but voters could also disclose this information deliberately (in public or private) in response to vote buying or coercion. Sharing one's voter number before the ballot-level data becomes public provides a mechanism for a voter to "claim" a specific ballot, thereby allowing them to prove how they voted to third parties with some confidence.

Surveillance Footage Some localities record surveillance video inside polling places. For instance, Figure 6b is from a day-long video filmed by a county in Georgia that was obtained by others via a public records request prior to our work. The footage shows everyone who used the scanner, in order. If a jurisdiction where such footage is a public record also releases vulnerable CVRs or ballot images, anyone could unshuffle the data and associate each ballot with *video of the voter casting it*. Attackers could then identify people in the video whom they recognized or use commercially available facial recognition systems to identify voters en masse.

5 Mitigation and Prevention

Correcting DVSorder is simple in theory: modify the scanners to assign record IDs securely at random. This would ensure that ballot-level data cannot be unshuffled and prevent all attack scenarios we have described. In practice, the solution is more complicated: only Dominion can issue new scanner firmware, deploying it requires action by many states and localities, and third-parties cannot fully validate any purported fix without access to Dominion's proprietary source code.

5.1 Dominion's Software Update

Following our disclosure, Dominion did issue a new software version, Democracy Suite 5.17, that, according to certification documents, incorporates an "[i]mproved pseudo random number algorithm" [49, §1.1.2]. The software achieved federal certification in March 2023, clearing the way for use in most states [58]. However, 5.17 includes a host of other changes, making it a major upgrade rather than a focused patch; this adds to the cost and complexity of deployment. As discussed in Section 6, many jurisdictions continue to use older, vulnerable versions more than a year after 5.17 became available.

Dominion has not shared any details about the new PRNG. We do not have access to the new software, and we have been unable to locate any ballot-level data produced by it, so we cannot confirm whether 5.17 adequately addresses DVSorder. Considering the incomplete and potentially misleading guidance that Dominion initially gave its customers following our disclosure (Section 6.3), some skepticism may be warranted.

5.2 Sanitizing Ballot-Level Data

Until corrective scanner firmware is deployed, we recommend that election officials sanitize ballot-level data prior to making it public. This can be done with one of two strategies: either completely remove the record IDs and randomly shuffle the records, or securely rerandomize the record IDs and sort the records. If correctly performed, these approaches will prevent DVSorder from being exploited with the published data.

Remove Record IDs and Randomly Shuffle This strategy is comparatively easy for jurisdictions to implement, so long as they only publish CVRs. (It does not work for ballot images, since removing the record IDs from their filenames causes many images to have the same name.) For CSV-format CVRs, officials should remove the "RecordId" and "CvrNumber" columns. For JSON-format CVRs, officials should remove the "RecordId" and "ImageMask" fields (see Figure 1a).

On its own, deleting these fields is insufficient to reliably guard against exploitation; officials must also randomly shuffle the records. This is because Dominion CVR data sometimes contains batches of ballots that are sorted by record ID. For these batches, an attacker can restore the deleted record IDs using the following attack. Typically, a batch of ballots will contain a mix of ballot *styles* corresponding to populations who vote in different sets of contests. An adversary can learn the sequence of ballot styles that were voted, in order, either from the scanner log files (if available) or by stationing an observer in the polling place. For a large batch of ballots, only one starting part in the scanner's cycle will result in record IDs that map the observed sequence of ballot styles to the sequence contained in the CVRs. Using a brute-force search over the 1,000,000 cycle starting positions, the attacker can infer the deleted record IDs and unshuffle the ballots. To prevent this, it is essential to randomly shuffle the CVRs.

A downside of removing the record IDs is that it can disrupt some desirable uses of public election data. For instance, without record IDs, it is impossible to reliably associate ballot images with the corresponding CVRs to confirm that the choices were correctly interpreted by the scanner. Likewise, if a jurisdiction releases multiple versions of a dataset, it is impossible to precisely determine which records have changed.

Rerandomize Record IDs and Sort To preserve the intended utility of the record ID field while preventing the attack, officials can replace the IDs with new random identifiers that are consistent across all public datasets from the election. This maintains the association between sanitized ballot images and their corresponding sanitized CVRs, and it facilitates review of incrementally published data. Sorting the records by their new IDs will also remove any residual information in their order. Special consideration is required for archives of ballot images, which should be recreated to ensure that the original order of the data is destroyed.

To help officials apply this strategy, we created a free and open-source sanitizer tool, available at DVSorder.org. Our tool supports all common forms of Dominion ballot-level data. To rerandomize the record IDs, it chooses a random key and replaces each ID with a truncated form of its AES ciphertext. If there are multiple datasets from an election, they can be processed with the same key to ensure that records about any given ballot will always be assigned the same ID. Although this might seem like an ideal application for format-preserving encryption [5], we instead designed the tool to change the format of the IDs so as to make sanitized and unsanitized data easily distinguishable and reduce the risk of accidental release.

Neither of these mitigation strategies is perfect. Even if CVRs and ballot images are fully sanitized before publication, election workers will continue to have access to the unsanitized data and so retain the ability to deanonymize ballots. Unsanitized data could also potentially be stolen in a data breach and used to compromise privacy.

5.3 Protections for Raw Scanner Data

To fully address the risk of ballot-ordering attacks, Dominion needs not only to change its record ID generation algorithm but also to correct the fact that its scanners store ballot images [29] and CVRs (Section 3.1) in voted order on their memory cards. To safeguard privacy against attackers who have access to such raw scanner data, Dominion and other voting system vendors should shuffle ballots in-memory using an appropriate randomized data structure (e.g., [41]).

6 Disclosure

Our experience disclosing DVSorder is instructive, as it exposed challenges to security information sharing and widespread gaps in vulnerability management practices within the elections sector. The following narrative highlights opportunities to improve coordination and remediation processes so as to better ensure that future vulnerabilities in election equipment are corrected before they can affect voters.

6.1 Ethical Considerations

Disclosure of a serious vulnerability in an election system requires a careful balance of the equities involved. One of the most consequential decisions we faced was when and how to make information about the vulnerability public, particularly given that we discovered the flaw only a few months prior to the November 2022 U.S. general election.

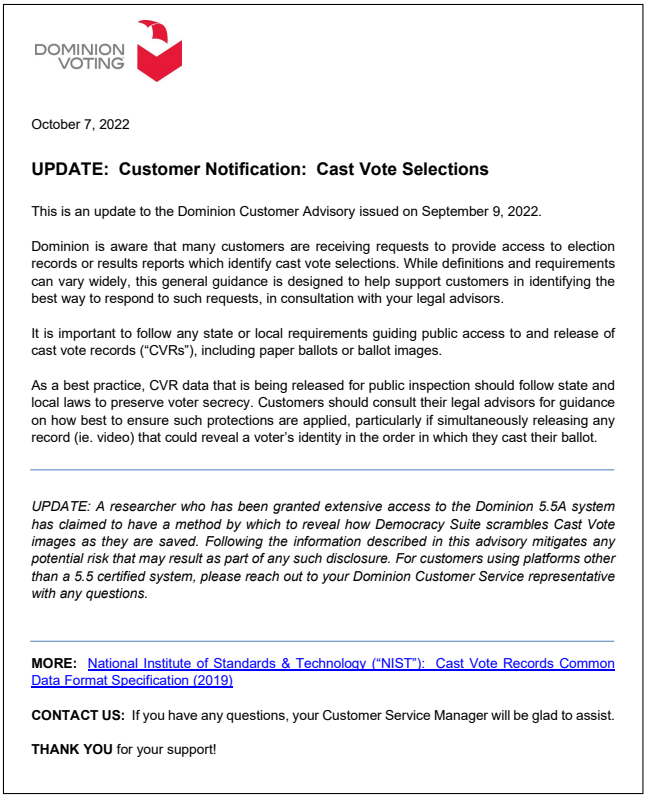
In weighing our options, we saw our foremost obligation as protecting voters. Completely protecting against DVSorder would require officials to patch their election equipment, but patching election systems often takes years, and ballot-level data released in the meantime would remain vulnerable to deanonymization forever. There was also a risk that malicious parties might already have discovered the flaw, since we had been able to do so using only public information. In light of these considerations, we judged that the best way to protect voters would be to disclose the vulnerability to state and local governments as soon as possible, before further data from affected systems would be released. Arming election officials with information about DVSorder, even in the absence of a patch, would allow them to prevent public exploitation by choosing to release less data or by appropriately sanitizing it.

We quickly realized that there was no viable route to notifying the responsible officials without effectively making the vulnerability public. U.S. election administration is decentralized, and the vulnerable equipment is operated by many hundreds of local municipal governments. None of our potential partners—federal agencies and Dominion—appeared to be prepared to privately inform these jurisdictions about the flaw. Even if they were, sanitizing ballot-level data would involve publicly visible changes to datasets that were under intense scrutiny from election skeptics [24], so any such change would require public justification. We concluded that public disclosure prior to the November election would be necessary.

Another central consideration was the effect of our disclosure on public trust. Many prominent election conspiracy theories concerned Dominion, and publishing information about a real vulnerability in the company's products could fan these flames. Yet withholding true vulnerability information would also be harmful to trust in elections. If we had reported the flaw to Dominion and government officials but collaborated to conceal it from the public, that might seem to validate claims of a conspiracy. After considering these risks, we concluded that transparency about the problem had the least potential for harm and was the best course of action.

6.2 Disclosure Process

We discovered the vulnerability in early July 2022. Within days, we contacted the Cybersecurity & Infrastructure Security Agency (CISA), the arm of the Department of Homeland Security responsible for election infrastructure [17]. CISA operates a coordinated vulnerability disclosure (CVD) program that assisted researchers with two earlier election security disclosures by interfacing with the vendors and providing guidance to election officials [18, 53]. We hoped that CISA's CVD program would be an effective way to notify all responsible parties about the problem ahead of the November election. However, on July 22, CISA informed us that it declined to coordinate disclosure for DVSorder and advised us to work directly with Dominion. This caused a lengthy delay, as, in light of Dominion's recent high-profile defamation lawsuits, we sought a careful legal review before approaching them.[3]



We began disclosure to Dominion on August 22 (day zero) with a call to the company's CEO, followed the next day with a letter (available at DVSorder.org) that detailed the flaw and offered our assistance in understanding and mitigating it. Given the short time before the November election, we told Dominion that we intended to make the information public as soon as 30 days later. The company acknowledged receipt of our letter on August 29 (+7 days) but did not further communicate with us about the issue, and we determined that we would have to notify election officials without their help.

On September 2 (+11 days), we sent formal notifications to CISA and to the U.S. Election Assistance Commission (EAC), the federal agency that oversees testing and certification of election equipment [15]. Dominion had not yet informed either agency about the flaw. We requested their assistance in communicating our disclosure to localities that operated affected equipment. EAC informed us that it did not have a comprehensive list of who used the scanners, as not all states require EAC certification for their equipment. CISA initially offered to put us in contact with state-level officials from affected states, but, on September 19 (+28 days), provided only a link to a public contact page on the National Association of State Election Directors website [42], adding further delay.

The lack of infrastructure for coordinated disclosure made identifying and contacting every affected locality nearly impossible, so we directed our notifications to the officials at the state level who were best positioned to communicate the problem and its mitigations to local officials. On October 10 (+49 days), 29 days before the November election, we sent notifications to the state election directors of the 21 states where at least some localities used affected machines according to data from the nonprofit organization Verified Voting [60].[4]

[3] Although Dominion maintains a vulnerability disclosure policy that offers a legal safe harbor for good-faith research, the company reserves the right "to change any aspect of our coordinated disclosure process at any time without notice, and to make exceptions to it on a case-by-case basis" [19].

[4] Due to an oversight, we neglected to notify authorities in Puerto Rico or Canada. This underscores the difficulty of conducting a disclosure of this complexity without the assistance of the vendor or a coordinating authority.

October 7, 2022

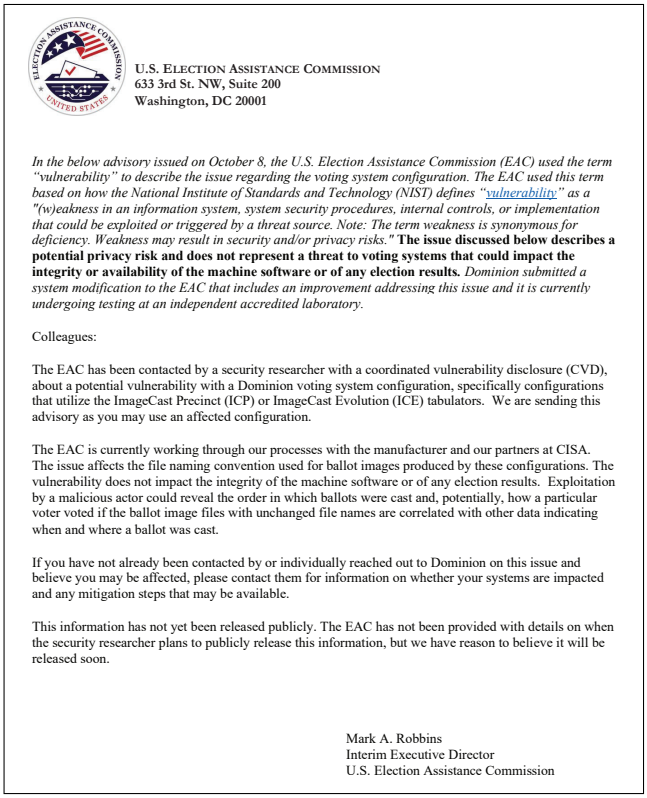
UPDATE: Customer Notification: Cast Vote Selections

This is an update to the Dominion Customer Advisory issued on September 9, 2022.

Dominion is aware that many customers are receiving requests to provide access to election records or results reports which identify cast vote selections. While definitions and requirements can vary widely, this general guidance is designed to help support customers in identifying the best way to respond to such requests, in consultation with your legal advisors.

It is important to follow any state or local requirements guiding public access to and release of cast vote records ("CVRs"), including paper ballots or ballot images.

As a best practice, CVR data that is being released for public inspection should follow state and local laws to preserve voter secrecy. Customers should consult their legal advisors for guidance on how best to ensure such protections are applied, particularly if simultaneously releasing any record (ie. video) that could reveal a voter's identity in the order in which they cast their ballot.



UPDATE: A researcher who has been granted extensive access to the Dominion 5.5A system has claimed to have a method by which to reveal how Democracy Suite scrambles Cast Vote images as they are saved. Following the information described in this advisory mitigates any potential risk that may result as part of any such disclosure. For customers using platforms other than a 5.5 certified system, please reach out to your Dominion Customer Service representative with any questions.

THANK YOU for your support!

(a) Dominion Notification (Oct. 7, 2022)

U.S. Election Assistance Commission
633 3rd St. NW, Suite 200
Washington, DC 20001

In the below advisory issued on October 8, the U.S. Election Assistance Commission (EAC) used the term "vulnerability" to describe the issue regarding the voting system configuration. The EAC used this term based on how the National Institute of Standards and Technology (NIST) defines "vulnerability" as a "(w)eakness in an information system, system security procedures, internal controls, or implementation that could be exploited or triggered by a threat source. Note: The term weakness is synonymous for deficiency. Weakness may result in security and/or privacy risks." **The issue discussed below describes a potential privacy risk and does not represent a threat to voting systems that could impact the integrity or availability of the machine software or of any election results.** *Dominion submitted a system modification to the EAC that includes an improvement addressing this issue and it is currently undergoing testing at an independent accredited laboratory.*

Colleagues:

The EAC has been contacted by a security researcher with a coordinated vulnerability disclosure (CVD), about a potential vulnerability with a Dominion voting system configuration, specifically configurations that utilize the ImageCast Precinct (ICP) or ImageCast Evolution (ICE) tabulators. We are sending this advisory as you may use an affected configuration.

The EAC is currently working through our processes with the manufacturer and our partners at CISA. The issue affects the file naming convention used for ballot images produced by these configurations. The vulnerability does not impact the integrity of the machine software or of any election results. Exploitation by a malicious actor could reveal the order in which ballots were cast and, potentially, how a particular voter voted if the ballot image files with unchanged file names are correlated with other data indicating when and where a ballot was cast.

If you have not already been contacted by or individually reached out to Dominion on this issue and believe you may be affected, please contact them for information on whether your systems are impacted and any mitigation steps that may be available.

This information has not yet been released publicly. The EAC has not been provided with details on when the security researcher plans to publicly release this information, but we have reason to believe it will be released soon.

Mark A. Robbins
Interim Executive Director
U.S. Election Assistance Commission

(b) EAC Advisory (Oct. 8, 2022)

Figure 8: Dominion and EAC issued these advisories without coordinating with us. Dominion's stopped short of confirming the flaw and inaccurately suggested that only 5.5-series products were affected. EAC's mentioned only ballot images. Neither provided effective mitigations.

Finally, on October 14 (+53 days), we disclosed the vulnerability publicly at DVSorder.org. In designing this website, we sought feedback from a range of subject matter experts to help ensure that it clearly explained the issue to voters and election officials without creating unwarranted fear or providing fodder for conspiracy theories. Our public messaging stressed that DVSorder was a *privacy* flaw that *could not directly change votes*, and that there were actions officials could take to prevent exploitation in the upcoming election. We also provided a pair of software tools to help officials do that: our test tool, which checks whether a particular dataset is vulnerable (Section 3.3) and our data sanitizer tool (Section 5.2).

6.3 Responses by Dominion and the EAC

While we were working to notify jurisdictions, Dominion issued a pair of one-page "customer notifications" related to our findings. The company did not provide copies to us, and we only learned about them weeks after they were distributed.

Dominion's initial notification was dated September 9 (+18 days). While it discussed ballot-level data and privacy, it *did not mention* that the scanners had a vulnerability that revealed the order ballots were cast. This left customers to rely on Dominion's earlier, inaccurate assertions that the scanners securely randomized ballot-level data. Instead, the notification merely directed officials to "follow any state or local requirements guiding public access to and release of cast vote records" and to "consult their legal advisors for guidance on how best to ensure that [voter secrecy] protections are applied, particularly if simultaneously releasing any record (i.e., [sic] video) that could reveal a voter's identity in the order in which they cast their ballot."

Dominion issued a revised notification (shown in Figure 8a) on October 7 (+46 days), three days before we notified states. In a one-paragraph "update" appended to the original text, the company acknowledged our claims but stopped short of confirming the flaw. Oddly, the document says that it offers a way to "mitigate[] any potential risk", even though the only action it directs jurisdictions to take is to consult their lawyers. It also appears to suggest that only 5.5-series versions of Dominion products were affected, when in fact every version for which we were able to locate ballot-data was vulnerable. These omissions and potentially misleading statements likely contributed to instances where jurisdictions failed to mitigate the flaw.

On October 8 (+47 days), the EAC issued its own advisory, also without informing us. This notice (Figure 8b) described the flaw only as affecting ballot images, which likely compounded state and local officials' confusion, as Dominion's notice from the day before had seemed to focus on CVRs.
