Meanwhile, the main checker acts as the control unit, orchestrating the overall verification process. For each proof step, ZKSMT relies on a fixed-length array of formulas to store premises associated with the current step, functioning much like instruction operands. Furthermore, temporary storage is needed for a derived conclusion, a pointer to the next proof step, etc. The expression table, similar to the memory in CPU architecture, is read-only in this context. Our main philosophy is to develop a flexible VM that can efficiently encode and verify SMT refutation proofs when the underlying VM is instantiated using ZK protocols. This way, we can plug in any suitable ZK protocol for ZKSMT and bring in optimizations in CPU design. Below we introduce our VM's encoding for formulas and proofs and its execution strategy.

3.1 Encoding Formulas and Proofs

We first explain how ZKSMT represents SMT formulas and checks that particular formulas can be proved from others according to the rules of a logical theory. ZKSMT's encoding of SMT formulas, and the complex terms that they may contain, critically enables it to prove formulas in theories beyond what existing techniques can support.

Encoding Formulas in an Expression Table Every formula is constructed from an operator applied to a finite collection of smaller formulas or terms; thus, it can be represented naturally as an AST. In particular, if we view formulas as being defined by the BNF grammar from Sec. 2.1, we can think of every individual production option used to produce a formula as a node in the formula's AST. The sub-productions are the node's children. Note that even semantically equivalent formulas can have distinct ASTs (e.g., False and ¬True).

ZKSMT stores the ASTs for all formulas involved in the proof in a read-only table M_e, called the *expression table*. We refer to entries in the table as *expressions*. Each expression represents an individual node within the AST of a formula. A node of an AST has three fields: the node ID (NodeID), the immediate addressing list (ImmAddr), and the indirect addressing list (IndAddr). NodeID specifies the operator being employed, such as Eq or Mul. ImmAddr is used to identify constants and immediate values, like an immediate value of an operand in a CPU. We also consider the names of variables as immediate values. AST nodes with children store the indices of their children within the expression table under the IndAddr field. Most expressions, such as logical negation (Not) and equality (Eq), have a fixed number of children. Others, including Boolean conjunction (And), disjunction (Or), and applications of uninterpreted functions (Apply), can have a variable number of entries within IndAddr.

Note that not all nodes in the table are formulas: some entries simply represent parts of other rows' formulas. A row that encodes a term or formula can have multiple other rows pointing to it if the term/formula appears in different formulas (which can even come from different theories). For example, in Table 1, i has only one entry even though it appears within $i = g(a,x)$, $0 \leq i$, and multiple other formulas.

Example 3.1. Table 1 shows a portion of the expression table for the proof in Table 2. The entry with address &14 in Table 1 represents the formula $i < l(a)$, whose NodeID is Lt (less than). The values indicated within the IndAddr field represent the indices for the sub-expression children of $i < l(a)$; specifically, the indices of i (entry &2) and $l(a)$ (entry &5). The sub-expression $l(a)$ (entry &5) is a term rather than a formula and has one sub-expression child a (&3) and the label l as an immediate value stored in ImmAddr.

Encoding Proof Steps A proof step in a theory T consists of an application of a rule, labeled with an identifier with a fixed arity n to formulas $\varphi_0, \ldots, \varphi_n$ to conclude a formula φ (Sec. 2.1). The steps of a theory T of interest are checked in ZKSMT by a finite set of step *checking instructions*, each one checking steps identified by a corresponding rule of T. An occurrence p of a checking instruction has four fields:

- StepID: the position of the step in the execution order.
- RuleID: the identifier of the applied theory rule. The rule identifier r of theory T is identified as the pair (R,T).
- Premises: a list of the StepID's of $\varphi_0, \ldots, \varphi_n$. Each StepID points to a previous step, whose derived formula is a premise of p.
- Result: an index into the expression table to identify the conclusion φ of the current proof step.

Addr.	NodeID	ImmAddr	IndAddr	Meaning
&1	Var	ONE	{}	ONE
&2	Var	i	{}	i
&3	Var	a	{}	a
&4	Var	x	{}	x
&5	Apply	l	{&3}	$l(a)$
&6	Apply	g	{&3,&4}	$g(a,x)$
&7	Mul	0	{&1}	$0 * \texttt{ONE}$
&8	Mul	-1	{&1}	$-1 * \texttt{ONE}$
&9	Eq		{&2,&6}	$i = g(a,x)$
&10	Eq		{&7,&7}	$0 = 0$
&11	Leq		{&7,&8}	$0 \leq -1$
&12	Not		{&11}	$\neg(0 \leq -1)$
&13	Leq		{&7,&2}	$0 \leq i$
&14	Lt		{&2,&5}	$i < l(a)$
&15	And		{&13,&14}	$0 \leq i \wedge i < l(a)$
&16	Not		{&15}	$\neg(0 \leq i \wedge i < l(a))$

Table 1: Part of the expression table M_e for the proof of the safety of `find_and_replace`. We use & to denote the addresses of expressions.

StepID	RuleID	Premises	Result
#2	Assume		&**9**: $i = g(a,x)$
#3	Assume		&**13**: $0 \leq i$
#4	Assume		&**16**: $\neg(0 \leq i \wedge i < l(a))$
...			
#7	Res	{#5,#6}	$0-(-1)=1$
#8	Farkas	{#7}	&**12**: $\neg(0 \leq -1)$
...			
#10	Cong		$\neg((0 \leq i) = (0 \leq -1)) \vee \neg(0=0) \vee \neg(i=-1)$
#11	Res	{#9,#10}	$\neg(0=0) \vee \neg(i=-1)$
#12	Refl		&**10**: $0 = 0$
#13	Res	{#11,#12}	$\neg(i=-1)$
...			
#16	Res	{#14,#15}	&**15**: $0 \leq i \wedge i < l(a)$
#17	Res	{#4,#16}	False

Table 2: Part of the proof step array M_p for the proof of the safety of `find_and_replace`. Not all conclusions' addresses are shown. We use # to denote the IDs of proof steps.

A set of instructions $\mathtt{T}$ is a *T-logical unit* if there is a bijection from rule identifiers of T to instructions in $\mathtt{T}$ such that each instruction succeeds if and on if it is executed in a machine state in which it points encoding of premises and a conclusion that can be derived using its corresponding rule in T.

Size Parameters Five parameters bound the resources used by a ZKSMT instance. **(1)** π is the maximum number of proof steps. It parallels the concept of program size in CPU design and defines the extent of the proof structure that can be examined in a manner similar to how the size of a program in a CPU determines the number of instructions it can execute. **(2)** χ is the maximum number of expressions the proof can use, analogous to the size of the CPU's memory. **(3)** μ is the maximum number of premises in any rule, analogous to the number of registers in a CPU. **(4)** α is the maximum argument list size of any expression, where the argument list size of an expression e is defined as $|e.\mathsf{ImmAddr}| + |e.\mathsf{IndAddr}|$; it is analogous to the bit width of memory entries. **(5)** ρ is the number of distinct rules used in the proof, analogous to the size of the architecture's instruction set. The set of ZKSMT machines over checking instructions $\mathtt{T}$ on particular size parameters is denoted $\mathsf{ZKSMT}[\mathtt{T}](\pi,\chi,\mu,\alpha,\rho)$.

To define the necessary components of the machine, we often use the bit widths of these numbers: $\ell_p = \lceil \log(\pi) \rceil$, $\ell_e = \lceil \log(\chi) \rceil$, and $\ell_r = \lceil \log(\rho) \rceil$.

Example 3.2. Some of the entries of M_e and M_p for the refutation of the formula in Sec. 2.3 are shown in Table 1 and Table 2, respectively. The proof applies rules from EUF and LIA as well as rules for Boolean connectives. Most of the 1,041 steps in the proof are omitted, and some of the steps that we show are simplified. For example, we do not show the steps for adding and removing singleton disjunctions.

3.2 Machine Specification and Execution

Once the encodings are specified, we can build the VM on top of them. We show the overall architecture in Fig. 1.

Machine Specification ZKSMT has five main components:

- pc: the *proof counter*, an ℓ_p-bit integer.
- $\{r_i\}, \{t_i\}$: the list of *registers* that store information for the proof step currently being examined. The machine has $2\mu+2$ registers in total: r_0 stores the conclusion, $r_1, \ldots, r_\mu$ store the premises, and r_{rule} stores the rule ID. The first $\mu+1$ registers are of size ℓ_e, and r_{rule} is of size ℓ_r. The registers $\{t_1, \ldots, t_\mu\}$ store the addresses of $r_1, \ldots, r_\mu$. The main checker uses them when fetching the premises of a proof step from M_e. Each t_i is of size ℓ_e.
- M_e: the *expression table*, a read-only array of size χ that contains all expressions used in the proof, using the encoding system that we explained in Sec. 3.1.
- M_p: the *step table*, a read-only array of size π that contains all the proof steps used in the proof.
- D: the checking order of the proof. The checking order is the order in which proof steps are validated during execution. If $\mathsf{D}[i] = j$, then the validation of the j^{th} proof step occurs on the i^{th} iteration of the main verification loop.

Machine Execution to Validate a Proof As mentioned above, ZKSMT's proof validation process closely resembles how a machine program is executed in the Von Neumann architecture (using a CPU, memory, etc.). To provide more flexibility in VM execution, we distinguish two orderings: the logical ordering and the checking ordering. The logical ordering is the original ordering of the proof as outlined in Sec. 2: a proof step should not use a result proven in a step that occurs

Algorithm 1: ZKSMT$[\mathtt{T}](\pi,\chi,\mu,\alpha,\rho)$'s execution

```
   Output: True, False
1  D ← [0,...,0];
2  for pc = 0 to π − 1 do
3  |  Proof Step Fetch:
4  |  (StepID, RuleID, Res, ClArgs) ← M_p[pc];
5  |  r_rule ← RuleID;
6  |  Conclusion Fetch:
7  |  r_0 = M_e[Res];
8  |  Premise Fetch:
9  |  t_1,...,t_μ ← M_p[ClArgs_0],...,M_p[ClArgs_{μ−1}];
10 |  r_1,...,r_μ ← M_e[t_1.Res],...,M_e[t_μ.Res];
11 |  Rule Checking:
12 |  CheckingInstrs[r_rule](r_0, {r_1,...,r_μ});
13 |  Cycle Checking:
14 |  for j = 1 to μ do
15 |  |  assert(t_j.StepID < StepID);
16 |  D[i] ← StepID ;
17 assert(PermuteCheck(D, [0,...,π − 1]));
18 TypeCheck(M_e);
```

later in the logical ordering. The StepID of each proof step is its logical ordering. However, the checking order, which is the order in which proof steps are validated during the VM's execution, does not need to have any relationship with the logical ordering other than the former being a permutation of the latter. Allowing the two orderings to differ helps us to hide the structure of a proof when we instantiate the VM in ZK (Sec. 5.2).

Algorithm 1 provides an overview of ZKSMT's algorithm, which iterates over the set of all proof steps (line 2). Each proof step is verified over five phases: proof step fetching, conclusion fetching, premise fetching, rule checking, and cycle checking. In the fetching phases (lines 3–10), ZKSMT fetches the relevant elements for that step from the tables M_p and M_e based on the values in the fields Result and Premises and stores them in $r_0,\ldots,r_\mu$. Next, the checker determines the checking instruction to execute by examining the value specified in RuleID (lines 11–12). It delegates the responsibility of validating the proof step to the selected instruction and asserts the success of the validation (line 12). Formulas must be proven before being used as premises. Since StepID represents the logical ordering of a derived formula, we can confirm that in cycle checking that the StepID of every formula in Premises for a rule is strictly smaller than the StepID of the rule's conclusion. This is checked by iterating over all rule premises (lines 13–15). To conclude the iteration, the checker assigns StepID to $D[i]$ (line 16).

To address the potential discrepancies between orderings, we need to perform one more check. Every proof step needs to be verified at some point. The array D keeps track of which proof steps have been validated. When the main loop finishes execution, the main checker verifies that D is a permutation of the list $[0,\cdots,\pi-1]$ (line 17). If it is, then every step in the refutation proof has been verified.

Well-Formed Expressions The soundness of ZKSMT also relies on the well-formedness of expressions in the table M_e. This can be ensured by a process analogous to proof validation. In particular, we type-check each expression according to a set of type rules, which work similarly to proof rules and are provided as public configurations of ZKSMT. To forbid cyclic expressions, ZKSMT also checks for cycles in M_e, similarly to the check for cycles in proof steps.

3.3 Soundness and Completeness

The following are key properties of ZKSMT that establish that it produces exactly valid SMT formulas. Both theorems are defined over an arbitrary theory T and T-logical unit $\mathtt{T}$, formula φ, and size parameters π,χ,μ,α,ρ (Sec. 3.1).

In this context, we say that φ is *boundedly verifiable* if it has a derivation in $\mathcal{T}$ containing at most π steps, χ distinct expressions with at most α arguments, and using ρ rules which all have at most μ premises.

Theorem 1 (Soundness)**.** *A VM in* ZKSMT$[\mathtt{T}](\pi,\chi,\mu,\alpha,\rho)$ *validates* φ *only if* φ *is boundedly verifiable.*

Theorem 2 (Completeness)**.** *If* φ *is boundedly verifiable, then some VM in* ZKSMT$[\mathtt{T}](\pi,\chi,\mu,\alpha,\rho)$ *validates it.*

Proofs of Thm. 1 and Thm. 2 appear in App. B.

4 Instantiating ZKSMT on Practical Theories

In this section, we explain how to instantiate ZKSMT on propositional logic, equality with uninterpreted functions (EUF), and linear integer arithmetic (LIA). We discuss **(1)** the encoding of expressions in each theory, **(2)** the theories' proof rules, and **(3)** the implementations of the checking instructions for an illustrative selection of each theory's rules. Table 3 shows all of the rules that we cover in this section, along with a few others that we discuss later.

4.1 Checking Propositional Logic

We have implemented in ZKSMT an instruction unit that checks applications of the rules of propositional logic. We now describe implementations of checking instructions for selected example rules (Sec. 2.2.1).

ExclMid When the unit instruction that checks applications of ExclMid (the rule formalizing the law of the excluded middle) receives the conclusion expression r_0 from the main checker, it first confirms that r_0's NodeID is Or. Next, the checking instruction retrieves the first two entries a_0 and a_1 from list r_0.IndAddr and confirms that **(1)** the NodeID of a_0 is Not; and **(2)** the expression table index of a_0's child is the same as the expression table index of a_1. In general, the same technique is implemented by all checking instructions that must check that two expressions are identical: the instructions

RuleID	Side Condition	Premises	Conclusion
Boolean			
Resolution	$\exists p.p \in \langle\!\langle A \rangle\!\rangle, \neg p \in \langle\!\langle B \rangle\!\rangle,$ $\langle\!\langle A \rangle\!\rangle \subseteq \langle\!\langle C \rangle\!\rangle \uplus \langle\!\langle p \rangle\!\rangle, \langle\!\langle B \rangle\!\rangle \subseteq \langle\!\langle C \rangle\!\rangle \uplus \langle\!\langle \neg p \rangle\!\rangle$	$\bigvee A, \bigvee B$	$\bigvee C$
DeDup	$\forall a \in \langle\!\langle A \rangle\!\rangle.\ a \in \langle\!\langle B \rangle\!\rangle$	$\bigvee A$	$\bigvee B$
ExclMid			$\bigvee \{\neg a, a\}$
EUF			
Congruence	$\exists A, B, f.(fA = fB) \in C, \lvert A \rvert = \lvert B \rvert,$ $\forall i \in \{0, \ldots, \lvert A \rvert - 1\}.\neg(A_i = B_i) \in C$		$\bigvee C$
LIA			
MulDist			$c * (\sum_{i=0}^{n} d_i * x_i) = \sum_{i=0}^{n} c d_i * x_i$
Flatten	$\exists \langle\!\langle C \rangle\!\rangle, \langle\!\langle D \rangle\!\rangle.\ \langle\!\langle C \rangle\!\rangle \uplus \langle\!\langle \sum D \rangle\!\rangle = \langle\!\langle A \rangle\!\rangle, \langle\!\langle C \rangle\!\rangle \uplus \langle\!\langle D \rangle\!\rangle = \langle\!\langle B \rangle\!\rangle$		$\sum A = \sum B$
Farkas	$\forall i \in \{0, \ldots, n\}.\ m_i \geq 0$ either $c > 0$, or $c = 0$ and $\exists j.\ \leq_j$ is $<$	$\sum_{i=0}^{n}(m_i * a_i) +$ $(-m_i * b_i) = c$	$\bigvee_{i=0}^{n}\{\neg(a_i \leq_i b_i)\}$

Table 3: A selection of ZKSMT's rules for Boolean logic, EUF, and LIA that we cover in Sec. 4, Sec. 5, and Sec. 7. Tables 4 and 5 in the appendix show all of the proof rules omitted here.

check the equality of indices in the expression table, instead of traversing the expressions' complete ASTs.

Many rules of propositional logic, as in the case of ExclMid, do not have premises. Instead of interacting with the results of previous steps, they introduce simple tautologies that other Boolean rules can use as premises later; the checking instructions for such rules need only to pattern-match the rules' conclusions. However, in general, an instruction may need to validate non-trivial *side conditions* imposed by a rule on the terms matched to its conclusion and premises (similar to the LFSC framework [46]). One example of such a rule is Resolution, whose checking instruction we now describe.

Res The checking instruction for Res (the formalization of unit resolution) checks properties of the *multisets* of propositions that may be in each of its premise clauses. To describe the instruction's implementation, we employ the notation $\langle\!\langle A \rangle\!\rangle$ (or $\langle\!\langle a \rangle\!\rangle$) to represent the multiset containing the elements of a list A (or single element a). Also, $\uplus$ is multiset union.

The checking instruction interprets r_0.IndAddr, from the conclusion r_0, as a multiset $\langle\!\langle C \rangle\!\rangle$ and interprets r_1.IndAddr and r_2.IndAddr, from the premises r_1 and r_2, as multisets $\langle\!\langle A \rangle\!\rangle$ and $\langle\!\langle B \rangle\!\rangle$, respectively. After checking that r_0, r_1, and r_2 are Or nodes, the instruction identifies the expression p, locates p within $\langle\!\langle A \rangle\!\rangle$, and locates $\neg p$ within $\langle\!\langle B \rangle\!\rangle$. Finally, the instruction checks the side conditions $\langle\!\langle A \rangle\!\rangle \subseteq \langle\!\langle C \rangle\!\rangle \uplus \langle\!\langle p \rangle\!\rangle$ and $\langle\!\langle B \rangle\!\rangle \subseteq \langle\!\langle C \rangle\!\rangle \uplus \langle\!\langle \neg p \rangle\!\rangle$. Note that p can be provided as an *extended witness* so that the checking instruction does not need to search for it.

In general, checking instructions for all propositional rules that have premises, as in the case of Res, must perform pattern matching on both the conclusion r_0 *and* the premises $r_1, \ldots, r_k$ that they receive from the main checker.

Remark 4.1 (Extended witnesses)**.** In the context of zero-knowledge proofs, determining the value of p for the checking instruction for Resolution can be computationally expensive. To reduce the runtime cost, the proof itself can cache the value of p and provide it for the checking instruction directly. This value serves as an *extended witness*. When it receives an extended witness, the checking instruction only needs to test the side condition on the cached value of p rather than checking all possible options. Multiple other rules use extended witnesses for the same purpose.

DeDup It is straightforward to implement a checking instruction for applications of the de-duplication rule DeDup as presented in Sec. 2.2.1: the instruction simply checks that its conclusion and premise are Or nodes, that the children of the conclusion's node occur in the premise, and that the children of the premise at corresponding positions are identical. However, checking DeDup strictly as presented would unfortunately require a proof to apply it multiple times to remove disjuncts that occur more than twice, and apply another rule formalizing the associativity of disjunction to arrange the premise in an expected form.

Instead, DeDup's actual checking instruction effectively checks repeated applications of such a rule in one step by checking that each distinct element in $\langle\!\langle A \rangle\!\rangle$ is also in $\langle\!\langle B \rangle\!\rangle$, where A is the argument list for the proof step's premise and B is the argument list for its conclusion.

4.2 Checking Equalities with Functions

We have instantiated ZKSMT to refute proofs that use the theory of equality with uninterpreted functions (EUF; Sec. 2.2.2). To check applications of a Congruence$_i$ rule, we model an alternative formulation, easily shown to be logically equivalent to the standard formalization, which derives a disjunction from no premises. The checking instruction for Congruence begins by confirming that the NodeID of the conclusion r_0 is Or. Next, it retrieves the set of expressions indexed by r_0.IndAddr, identifies the pair of function applications, and verifies that the other disjuncts match the corresponding argu-

ments of the function applications.

4.3 Checking Linear Integer Arithmetic

We now describe ZKSMT's representation of expressions from linear integer arithmetic (LIA; Sec. 2.2.3). Then, we discuss implementations of checking instructions in ZKSMT for two LIA rules: MulDist and Farkas.

Expression Representation In ZKSMT's representation of LIA, addition is an n-ary operation, just like $\wedge$ and $\vee$. Singleton sums are allowed, and so are empty sums. The entries in a sum can be arbitrary integer-valued expressions, including other sums. Multiplication in LIA is shorthand for the repeated addition of an expression to itself. A multiplication node always has exactly one child, which can be an arbitrary integer-typed expression. It stores its scaling factor in the ImmAddr field, as we show in entries &7 and &8 in Table 1. The value of the scaling factor can be any integer, positive or negative. We store integer constants in M_e as multiples of a special variable `ONE` that represents 1. This representation enables checking instructions for rules such as MulDist to assume that the sums in their conclusions contain only Mul nodes rather than having a separate case for integer constants.

Multiplication Distribution MultDist's checking instruction can validate an application of MultDist by combining a bounded AST traversal and simple numerical computations with expression equality checks, implemented as checks for reference equality. Specifically, it first checks that the conclusion node r_0 is an Eq node whose children are **(1)** a Mul node with scaling factor denoted **(1.1)** and child denoted **(1.2)** and **(2)** an Add node. It then iterates over the children of nodes **(1.2)** and **(2)** in lockstep, checking that each child of node **(2)** is a Mul node with the same child as the corresponding Mul node in **(1.2)** and a scaling factor that is the product of **(1.1)** and the scaling factor of the same Mul node.

Farkas' Lemma Although Farkas' Lemma formalizes a somewhat subtle law of linear arithmetic, its application as a formal rule can be checked efficiently within ZKSMT's design. The instruction checks that **(1)** its conclusion operand is a node with operation Or whose children are negated inequalities, **(2)** its premise operand is a node with operation Eq whose children are a linear term matching the pattern given in the conclusion and a nonnegative constant, and **(3)** the sub-expressions of the linear term in the premise match the children of the inequalities in the disjuncts of the conclusion.

5 Zero-Knowledge Support

In this section we describe the technical details of ZKSMT's instantiation in ZK. Recall that the prover needs to demonstrate to the verifier that it knows a refutation proof of a formula without revealing the proof (or even the formula) to the verifier. We first explain how to commit ZKSMT's encoding of a refutation proof in Sec. 5.1. We discuss the details of how ZKSMT validates a committed refutation proof in ZK in Sec. 5.2. Finally, in Sec. 5.3, we explain the checking instruction protocols that have some non-trivial design component for the ZK setting, continuing our focus on the theories covered in Sec. 4.

5.1 Refutation Proof Commitment

Recall that a refutation proof consists of a set of clauses and a sequence of proof steps. Both the clauses and proof steps can be committed as fixed-length vectors of integers. In detail, for a k-bit integer, we commit each bit individually (i.e., $\mathbb{F}_2^k$) and they can be converted to an extension binary field element (i.e., $\mathbb{F}_{2^k}$) for free thanks to the structure of the VOLE commitment [20]. Let I, $\mathcal{A}_{\text{imm}}$, and $\mathcal{A}_{\text{ind}}$ denote the set of all possible NodeID values, elements in ImmAddr, and elements in IndAddr, respectively. Given three injective functions $\varepsilon_I : I \to \mathbb{N}$, $\varepsilon_{\mathcal{A}_{\text{imm}}} : \mathcal{A}_{\text{imm}} \to \mathbb{N}_{>0}$, and $\varepsilon_{\mathcal{A}_{\text{ind}}} : \mathcal{A}_{\text{ind}} \to \mathbb{N}_{>0}$, an expression e specified by the tuple (NodeID, ImmAddr, IndAddr) can be mapped to the following vector of integers:

$$\{\varepsilon_I(\mathsf{NodeID})\} \| \{\varepsilon_{\mathcal{A}_{\text{imm}}}(\mathsf{ImmAddr})\} \| \{\varepsilon_{\mathcal{A}_{\text{ind}}}(\mathsf{IndAddr})\}$$

Here, $\varepsilon_{\mathcal{A}_{\text{imm}}}$ and $\varepsilon_{\mathcal{A}_{\text{ind}}}$ are applied element-wise on the two respective lists. Given concrete encoding schemes ε_I, $\varepsilon_{\mathcal{A}_{\text{imm}}}$, and $\varepsilon_{\mathcal{A}_{\text{imm}}}$, an expression can be committed by committing its integer vector element-wise. These encoding schemes are made known by both the prover and the verifier.

An expression's NodeID should be kept private. Different NodeIDs take different numbers of operands. To avoid revealing an expression's NodeID from the size of its ImmAddr and IndAddr, we can pad both ImmAddr and IndAddr to the length α that is the upper bound of their size (Sec. 3.1).

Each proof step can be committed in a similar way. Recall that a proof step is encoded by four fields: StepID, RuleID, Result, and Premises which are either integers or lists of integers serving as pointers. The list Premises has its size bounded by μ. Hence, any proof step can be committed as a list of $\mu+3$ integers.

5.2 Machine Execution in Zero Knowledge

We discuss how machine execution, i.e., the main checker, can be instantiated in ZK. Recall that the main checker performs three key operations:

1. **Fetching essential clauses and expressions.** To verify SMT proofs, we need to read entries from M_e and M_p using committed addresses. We can achieve this by instantiating M_e and M_p with any read-only memory (ROM) protocol [17, 20, 30] in ZK that is compatible with the commitment scheme we use.

2. **Guaranteeing the proof is acyclic.** The proof can be regarded as a DAG with proof steps ordered by their logical order. Proving a graph is a DAG reduces to proving magnitude relationships between pairs of committed integers.

3. **Invoking the corresponding checking instructions.** To ensure the privacy of a proof, the proof rule employed by each proof step should be kept private. This can be achieved generically by multiplexing all checks, but that incurs a high cost and leads to a large overhead. Instead, ZKSMT uses *group checking*, as we will explain next.

Group Checking ZKSMT groups the verification of the proof steps with the same proof rule, where the real checking instruction is the *only* checking instruction that will be called. There is no multiplexing, and no other checking instructions are executed. For instance, all proof steps employing the Resolution rule are verified consecutively, and only the checking instruction of Resolution is invoked on them.

The RuleID of a proof step, which identifies the specific step being validated within a particular checking group, is private to the prover. The StepID of every step that has been verified so far appears in D. The array D is append-only, and at the end of each proof step, the step's committed StepID is appended to it. D can be implemented using a standard array containing commitments when ZKSMT is instantiated in ZK.

The soundness of ZKSMT relies on the permutation checking between D and $\{0,1,\ldots,\pi-1\}$ (see Algorithm 1, line 17). Permutation checking ensures that every proof step is validated. When D contains committed values, the Schwartz-Zippel lemma allows for efficient permutation checking.

Remark 5.1 (Leakage and Optimization)**.** By group checking, we reveal the number of applications of each proof rule in the input proof. On the other hand, grouping checking for identical proof rules over different premises and conclusions offers a chance for optimization by using a ZK protocol optimized for batch proofs (i.e., single instruction multiple data (SIMD) optimizations), such as [52].

5.3 Checking Instructions in Zero Knowledge

Some checking instructions for Boolean, EUF, and LIA rules consist of only reading operations over the expression table and comparisons, such as ExclMid (Sec. 2.2.1). All necessary ZK operations are already needed by the main checker, and the same operations suffice for handling these simple rules.

The instantiation of checking instructions becomes complex when the side condition of the proof rule involves traversing the IndAddr. In Sec. 4, we explain how these side conditions can be represented using the language of multisets. This level of abstraction further enables us to leverage the polynomial commitment scheme when instantiating these checking instructions in ZK. Next, we explain how to check two relations, subset and subset$_d$, between multisets using a polynomial commitment scheme. Following this, we will illustrate our implementations of the DeDup and Resolution checking instructions as examples.

Checking Multiset Relations To enable compact representation and efficient operations simultaneously, our protocol encodes multisets as polynomials over a finite field.

For the checking instructions we consider, we focus on two relations: subset and subset up to the number of occurrences (subset$_d$). The subset relation takes multiplicities into account. The multiset $\langle\!\langle A \rangle\!\rangle$ is a subset of the multiset $\langle\!\langle B \rangle\!\rangle$ if the multiplicities of all elements in $\langle\!\langle A \rangle\!\rangle$ are less than or equal to their multiplicities in $\langle\!\langle B \rangle\!\rangle$. On the other hand, $\langle\!\langle A \rangle\!\rangle$ is a subset$_d$ of $\langle\!\langle B \rangle\!\rangle$ if all distinct elements of $\langle\!\langle A \rangle\!\rangle$ also appear in $\langle\!\langle B \rangle\!\rangle$.

Checking the subset relation between two multisets is based on encoding multisets as univariate polynomials. Let Σ be a finite set, and $\mathbb{F}$ a finite field such that $|\mathbb{F}| > |\Sigma|$. Let $\langle\!\langle \Sigma^* \rangle\!\rangle$ be the set of all possible multisets over Σ. Given an injective function $\psi : \Sigma \to \mathbb{F}$, we define an encoding $\gamma_\psi : \langle\!\langle \Sigma^* \rangle\!\rangle \to \mathbb{F}[X]$ of a multiset as univariate polynomials over $\mathbb{F}$ such that for each multiset $\langle\!\langle \ell \rangle\!\rangle$, the images under ψ of the Σ-elements ℓ_i in $\langle\!\langle \ell \rangle\!\rangle$ are the roots of the image of $\langle\!\langle \ell \rangle\!\rangle$ under γ_ψ:

$$\gamma_\psi(\langle\!\langle \{\ell_0,\ldots,\ell_d\} \rangle\!\rangle) = (X-\psi(\ell_0))\ldots(X-\psi(\ell_d))$$

To check the subset relation between two multisets $\langle\!\langle \ell^{\text{sub}} \rangle\!\rangle$ and $\langle\!\langle \ell^{\text{sup}} \rangle\!\rangle$, the prover commits their polynomial encodings, and the verifier checks that $\gamma_\psi(\langle\!\langle \ell^{\text{sub}} \rangle\!\rangle)$ divides $\gamma_\psi(\langle\!\langle \ell^{\text{sup}} \rangle\!\rangle)$ by attesting that $\gamma_\psi(\langle\!\langle \ell^{\text{sub}} \rangle\!\rangle) \cdot W = \gamma_\psi(\langle\!\langle \ell^{\text{sup}} \rangle\!\rangle)$. Here, W is a private polynomial committed by the prover as an extended witness. We use bivariate polynomials to verify the subset$_d$ relation between two multisets, leveraging an observation from [21]. Let $\bar{\ell}^{\text{sub}}$, $\bar{\ell}^{\text{sup}}$ and $\bar{\ell}$ be permuted versions of ℓ^{sub}, ℓ^{sup} and $\ell = \ell^{\text{sub}} \uplus \ell^{\text{sup}}$ respectively with the d' being the size of $\bar{\ell}^{\text{sub}}$ and d being the size of $\bar{\ell}^{\text{sup}}$. Given the same ψ we use for subset checking, define the following two polynomials:

$$\begin{aligned}\alpha_\psi(\langle\!\langle \bar{\ell}^{\text{sub}} \rangle\!\rangle, \langle\!\langle \bar{\ell}^{\text{sup}} \rangle\!\rangle) := (1+X)^{d'} \cdot \Pi_{i=0}^{d'-1}(Y+\psi(\bar{\ell}_i^{\text{sub}})) \\ \cdot \Pi_{i=0}^{d-2}(Y\cdot(1+X)+\psi(\bar{\ell}_i^{\text{sup}})+X\cdot\psi(\bar{\ell}_{i+1}^{\text{sup}})) \\ \beta_\psi(\langle\!\langle \bar{\ell} \rangle\!\rangle) := \Pi_{i=0}^{d'+d-1}((1+X)\cdot Y+\psi(\bar{\ell}_i)+\psi(\bar{\ell}_{i+1})\cdot X)\end{aligned}$$

It is proved that $\alpha_\psi(\langle\!\langle \bar{\ell}^{\text{sub}} \rangle\!\rangle, \langle\!\langle \bar{\ell}^{\text{sup}} \rangle\!\rangle)(X,Y)$ equals $\beta_\psi(\langle\!\langle \bar{\ell} \rangle\!\rangle)(X,Y)$ if and only if **(1)** $\langle\!\langle \bar{\ell}^{\text{sup}} \rangle\!\rangle$ is a subset$_d$ of $\langle\!\langle \bar{\ell}^{\text{sup}} \rangle\!\rangle$; and **(2)** $\bar{\ell}^{\text{sub}}$, $\bar{\ell}^{\text{sup}}$ and $\bar{\ell}$ are order-consistent[1]. A set of lists is order-consistent if values appear in the same order across all lists in the set. Putting it all together, to check if the subset$_d$ relation between $\langle\!\langle \ell^{\text{sup}} \rangle\!\rangle$ and $\langle\!\langle \ell^{\text{sub}} \rangle\!\rangle$ holds, the verifier attests the following relation between polynomials:

$$\begin{aligned}\alpha_\psi(\langle\!\langle \bar{\ell}^{\text{sub}} \rangle\!\rangle, \langle\!\langle \bar{\ell}^{\text{sup}} \rangle\!\rangle) &= \beta_\psi(\langle\!\langle \bar{\ell} \rangle\!\rangle) \\ \gamma_\psi(\langle\!\langle \bar{\ell}^{\text{sub}} \rangle\!\rangle) &= \gamma_\psi(\langle\!\langle \ell^{\text{sub}} \rangle\!\rangle) \\ \gamma_\psi(\langle\!\langle \bar{\ell}^{\text{sup}} \rangle\!\rangle) &= \gamma_\psi(\langle\!\langle \ell^{\text{sup}} \rangle\!\rangle) \\ \gamma_\psi(\langle\!\langle \bar{\ell} \rangle\!\rangle) &= \gamma_\psi(\langle\!\langle \ell^{\text{sup}} \rangle\!\rangle) \cdot \gamma_\psi(\langle\!\langle \ell^{\text{sub}} \rangle\!\rangle)\end{aligned}$$

Here, the prover computes and commits $\bar{\ell}$, $\bar{\ell}^{\text{sub}}$ and $\bar{\ell}^{\text{sup}}$ using some proper order over Σ.

Resolution Recall that the side condition of Resolution on premise clauses $\bigvee A$, $\bigvee B$ and conclusion clause $\bigvee C$ is

[1] See Claim 3.1 [21] and its proof.

that $\langle\!\langle A \rangle\!\rangle \subseteq \langle\!\langle C \rangle\!\rangle \uplus \langle\!\langle p \rangle\!\rangle$ and $\langle\!\langle B \rangle\!\rangle \subseteq \langle\!\langle C \rangle\!\rangle \uplus \langle\!\langle \neg p \rangle\!\rangle$. Here, A, B, and C are lists of addresses of the expression table and p is an address. Given that the size of the expression table is bounded by χ, we can restrict the co-domain of ε_I to $\mathbb{N}_{\leq\chi}$, i.e., $\varepsilon_I : I \to \mathbb{N}_{\leq\chi}$. We further fix an injective function $\psi_I : \mathbb{N}_{\leq\chi} \to \mathbb{F}$ for a given proof. Then the checking instruction of the resolution rule can be implemented by verifying the subset relation between multisets $\varepsilon_I(\langle\!\langle A \rangle\!\rangle)$, $\varepsilon_I(\langle\!\langle C \rangle\!\rangle \uplus \langle\!\langle p \rangle\!\rangle)$[2] and between $\varepsilon_I(B)$ and $\varepsilon_I(\langle\!\langle C \rangle\!\rangle \uplus \langle\!\langle \neg p \rangle\!\rangle)$ using the approach mentioned above, with ψ concretized by ψ_I. By applying ε_I to the multisets, we mean element-wise application.

DeDup The side condition of DeDup asserts that for all $a \in \langle\!\langle A \rangle\!\rangle$ it holds that $a \in \langle\!\langle B \rangle\!\rangle$ given the premise clause $\bigvee A$ and the conclusion clause $\bigvee B$. This side condition can be validated by checking if $\langle\!\langle A \rangle\!\rangle$ is a subset$_d$ of $\langle\!\langle B \rangle\!\rangle$. Using the same encoding scheme as is used for the Resolution rule, we can implement the checking instruction of the DeDup rule by checking the subset$_d$ relation between $\varepsilon_I(\langle\!\langle A \rangle\!\rangle)$ and $\varepsilon_I(\langle\!\langle B \rangle\!\rangle)$. This relation checking can be achieved using the protocol we explain at the beginning of this section.

6 Implementation

We implement our protocol using the EMP-toolkit [50] for ZKP operations (circuits, polynomials, read-only memory access). We instantiated the arithmetic field as the extension field $\mathbb{F}_{2^{128}}$, under which field operations (and their ZK counterparts) can be efficiently implemented. The indices of proof steps are 32-bit integers, which support refutation proofs with more than one billion steps. In addition, as a performance optimization, we use an array M_a known as the *expression list table* to store argument lists for expressions that can take variable numbers of children. Expressions that take a fixed number of children (which is always 1 or 2 for the theories that we cover) store pointers to their children directly in M_e, but nodes that take variable numbers of children store a pointer to an entry in M_a that contains pointers to the expression's children. It allows us to keep the individual entries of M_e small and to avoid the cost of scanning a variable-length argument list for nodes like Not and Eq. We use η to denote the number of lists in M_a. This is not to be confused with α, which is the maximum length of an individual list within M_a.

7 Evaluation

We evaluate ZKSMT to compare our protocol with the prior state of the art. We intend to answer three key questions:

Q1 Does our protocol efficiently validate SMT formulas that formalize the safety and security of practical software?

Q2 Does our protocol scale well in response to increases in proof size?

Q3 Is ZKSMT more efficient than a zkVM running a commodity SMT proof validator?

The results of our experiments allow us to report an affirmative answer for all three questions. For all benchmarks, we ran ZKSMT on AWS instances of type `r5b.4xlarge` with 128 GB of memory, 16 vCPUs, and a 10 Gbps network connection between the prover and verifier. However, the underlying ZK protocols that we use only consume about 100 Mbps bandwidth. We also configured ZKSMT to use 8 threads. Our methodology and results for Q1, Q2, and Q3 appear in Sec. 7.1, Sec. 7.2, and Sec. 7.3, respectively.

7.1 Verifying Practical Software

To answer Q1, we collected a set of SMT formulas whose validity formalizes program correctness. Specifically, the SMT formulas were generated by the Boogie verification toolchain [5]. The Boogie toolchain contains an intermediate language for expressing low-level programs annotated with function requirements and guarantees, along with compilation passes to an intermediate language from high-level languages including C, Spec#, and Dafny [39]. Boogie generates verification conditions from the annotated intermediate programs in the SMT-LIB 2.0 format, which can be validated by SMT solvers like Z3 [16]. We ran Boogie on its test suite to collect the corresponding SMT formulas, and we validated the SMT formulas using the solver SMTInterpol [14, 32] to generate proof certificates that ZKSMT can process.

Fig. 2 shows the runtime of ZKSMT versus the number of proof steps used in each of the SMT statements in the Boogie test suite. ZKSMT is able to verify most of the test suite SMT statements in ZK within a few seconds, but the largest benchmark takes 39 seconds. We also observe a general linear trend between the running time and the number of steps, which is expected. The fluctuation is due to the use of different rules in each instance, since some rules are more costly than others.

7.2 Scalability

To determine how our protocol scales in response to increases in proof size (Q2), we microbenchmark various aspects of ZKSMT while varying the size of input SMT statements.

Proof Breakdown To assess the relative time consumption of different parts of our protocol, we run three of our Boogie benchmarks and separate the timing results into three phases: type checking, Resolution, and all other proof rules. We place Resolution in a phase of its own because, for each of the examples, it takes more time than checking all of the other rules combined. Fig. 3 shows the performance decomposition for the three benchmarks. All of them are related to program safety verification: Lock is a Boogie benchmark for verification of a lock, Houdini is a benchmark on modular contract checking [37], and McCarthy is an adaptation of a standard benchmark for verification of recursive functions [43].

[2] When verifying equivalences that involve the combination of multisets through union operations, we compute the product of the two corresponding polynomials.

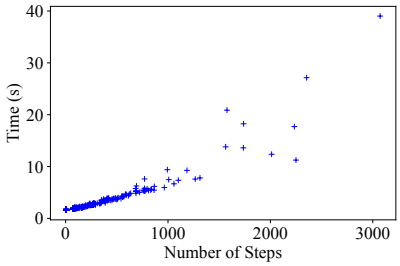

Figure 2: Step counts and time costs for validating SMT statements from the Boogie test suite in ZKSMT.

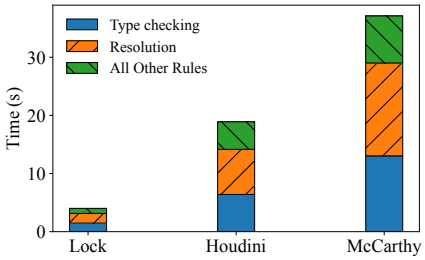

Figure 3: Time cost decomposition for Lock, Houdini, and McCarthy benchmarks.

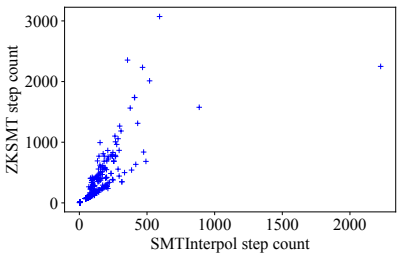

Figure 4: Relative step counts of ZKSMT's proofs and the original SMTInterpol proofs.

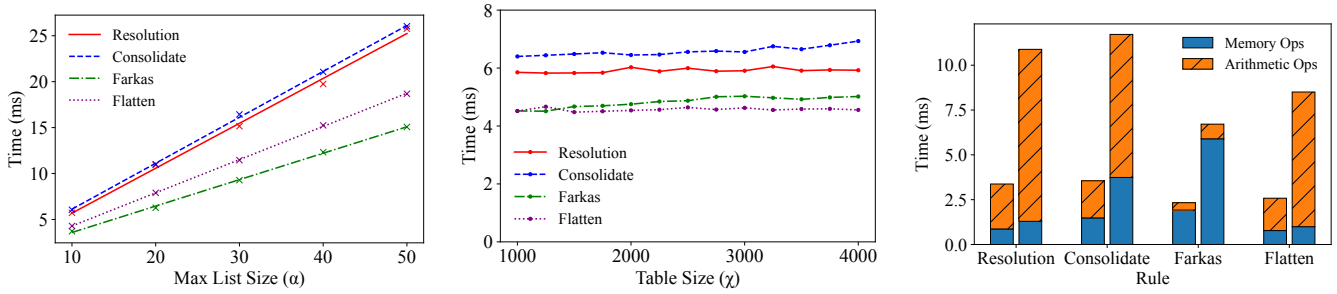
We observe that type checking can be as time-consuming as the main checking loop itself. This is due to the fact that ZKSMT needs to fetch every entry of every list in M_a at least once to confirm that its type fits with the list's type.

Max List Size To understand how α, the maximum list size, affects the running time of our rules, we benchmark the running time of our individual proof rules in isolation. To find the amortized cost of each rule, we run the rule 1,000 times and average the result. Most of our rules are simple, so we present the results for only our four most performance-intensive rules: Resolution, Consolidate, Farkas, and Flatten.

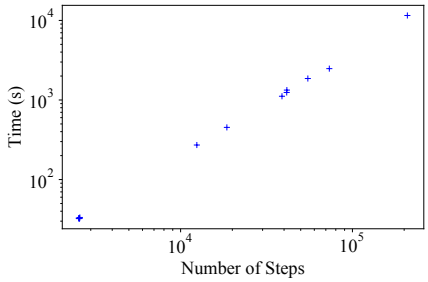
The results of varying α with values ranging from 10 to 50 are presented in Fig. 5a. We ran a linear regression and determined that all four rules scale linearly, with R^2 values above 0.99. This occurs because all four rules contain loops or procedures which iterate $O(\alpha)$ times.



Many of ZKSMT's rules are affected by the size of the longest list in the proof because all argument lists are padded to be the same size. The worst-case scenario for ZKSMT would be a proof that operates mainly on short lists but contains one extra-long list that forces all list-traversing rules to perform a large number of iterations. Fortunately, our benchmarks demonstrate that this degenerate case does not appear in practice. In the future we plan to mitigate the effect of α on a proof's overall running time by breaking down list-based rules into smaller pieces, which will improve runtime even more by eliminating the impact of large maximum list sizes.

Table Size Next, we consider how χ, the size of M_e, affects the running time of our four main rules. For each trial, we ran 10,000 instances of a rule with an α value of 10, which was a common value among our benchmarks, an η value of 1,000, and a π value of 10 while varying the value of χ to between 1,000 and 4,000. The results are plotted in Fig. 5b. Unlike our results for α, the running time does not change appreciably. This is because the main operation in these rules that is affected by a change in table size is the cost of accessing an element from ROM, for which the amortized access time does not depend on the number of elements. For similar reasons, changing the value of η does not change the running time significantly.

Rule Breakdown We also consider which operations make up the running time of our four main rules. With α values of 5 and 21, we divide the running times for each rule into the time taken for memory operations (retrieving entries from M_e or M_a) and the time taken for arithmetic operations (everything else). 5 is a small but still realistic value for α, and 21 is the highest value of α that appears in our Boogie benchmarks. The results appear in Fig. 5c. Arithmetic operations dominate the running time for Resolution, Consolidate, and Flatten, but memory operations dominate the running time for Farkas. This makes sense because, unlike the other three rules, Farkas does not perform any multiset equivalence or containment checks. Multiset checks can work directly with expressions' addresses, but Farkas needs to fetch every entry in its premise and conclusion to pattern-match their NodeIDs and arguments.



Original Proof Size Our work uses a compiler to convert the output of SMTInterpol to the format accepted by ZKSMT. To enable evaluation in zero knowledge, some rules in SMTInterpol, particularly the LIA rules, must be broken down into simpler rules. This increases the proof size. A comparison between the number of proof steps in SMTInterpol and ZKSMT is given in Fig. 4 for the Boogie test suite. The proof size increases by a factor from 1 to 7, which is not problematic because ZKSMT is still vastly more efficient than the generic zkVM solution (Sec. 7.3).

Stress Test To stress test ZKSMT, we ran it against a series of larger tests from the Wisconsin Safety Analyzer [2] benchmark suite found in the official SMT-LIB benchmarks repository [1]. The benchmarks from the Wisconsin Safety Analyzer represent correctness and security properties for commercial off-the-shelf software. The resulting running times are plotted in Fig. 6a. The largest test which passed uses 200K steps, 380K expressions, and a maximum list size α of 97. This verified in about 3 hours, requiring more than 22.9 billion $\mathbb{F}_2$ multiplications and 336 million $\mathbb{F}_{2^{128}}$ multiplications. Larger tests ran out of memory. This demonstrates that ZKSMT can scale up to proofs of a larger size, and gives insight into ZKSMT's current limitations.

(a) (b) (c)

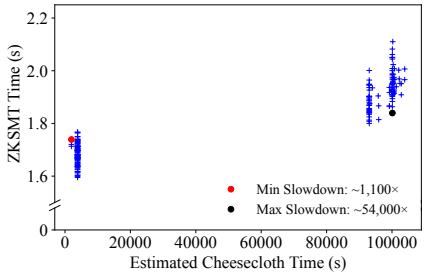


Figure 5: Scalability and rule breakdown of our protocol. Fig. 5a and Fig. 5b contain the running times of a single proof step across different rules for changing values of max list size α and expression table size χ, respectively. Fig. 5c shows the time cost decomposition across the four rules with max list size $\alpha = 5, 21$.

7.3 Comparison with Alternative Protocols

Instead of developing a custom ZK protocol to validate SMT formulas, a simpler approach would be to take a commodity SMT proof validator and compile it to a ZK statement using a ZK virtual machine (zkVM). We benchmark the performance of ZKSMT against such a zkVM to determine whether the benefits of a custom ZK protocol are worth the effort (Q3).

In our evaluation, we used Cheesecloth [15] and Diet Mac'n'cheese [6, 22] as the baseline zkVM. Cheesecloth is a general-purpose tool for generating zero-knowledge proof statements that verify the execution of LLVM programs. Diet Mac'n'cheese is an interactive VOLE-based zero-knowledge proof backend, capable of verifying ZK statements.

We developed a cleartext C++ version of ZKSMT that verifies SMT statements, and we used Cheesecloth and Diet Mac'n'cheese to verify the shortest Boogie benchmark (with only 6 steps) in ZK. The results in Fig. 6b demonstrate that ZKSMT is significantly faster than the baseline, taking seconds instead of hours to verify it. With a 3,330× reduction in runtime, it is clear that ZKSMT provides a significant improvement over the zkVM approach in enabling SMT validation for program verification in ZK.

For a fuller comparison, we ran Cheesecloth to output the number of zkVM cycles required for 190 of our 440 Boogie benchmarks. Cheesecloth failed to process 28 of the benchmarks, and the remaining 222 benchmarks timed out after 5,000,000 zkVM cycles. From the zkVM cycle count, we estimate the ZK running time of Cheesecloth and Diet Mac'n'cheese, which scales linearly relative to cycle count[3]. Fig. 6c compares this estimated running time with ZKSMT's. At best, Cheesecloth's estimated running time is approximately 1,100 times slower than ZKSMT's running time for the same benchmark. At worst, Cheesecloth's estimated running time is more than 54,000 times slower. We highlight the two extremes in the figure.

The wide gap in running time improvements is due to the fact that Cheesecloth can handle only the smaller benchmarks in our suite. Because we focus on small benchmarks, ZKSMT's running times in Figure 6c are dominated by the fixed startup time of EMP-toolkit, which ranges from 1.5 to 1.7 seconds on our evaluation machine. On the largest benchmarks, this startup time is less than 0.1 percent of the overall running time. Cheesecloth does not have a comparable startup cost, but it is significantly slower than ZKSMT in general. We estimate that, if Cheesecloth could run on larger benchmarks, ZKSMT's speedup rate would stabilize at

[3] A single zkVM cycle corresponds to approximately 0.021 seconds of running time.

an even larger number. Still, ZKSMT is much faster than a conservative estimation of Cheesecloth's performance.

8 Related Work

Vulnerability Proofs Prior research on ZK proofs has focused on protocols for proving the existence of bugs and vulnerabilities in programs [15, 27, 31]. With ZKSMT, we work towards the opposite goal of proving that a program is free of bugs and vulnerabilities. Specifically, ZKSMT efficiently proves the unsatisfiability of SMT formulas, which is the first step in a pipeline for safety proofs about programs.

Safety Proofs ZKSMT is not the first ZK protocol to encode refutation proofs. ZKUNSAT [42] is a ZK protocol for validating proofs in propositional logic. Among existing ZK protocols, ZKUNSAT is the most similar to ZKSMT, but ZKSMT is more versatile than ZKUNSAT. ZKUNSAT requires SAT formulas to be in conjunctive normal form, while ZKSMT supports arbitrary AST structures in its more expressive SMT formulas. Also, ZKUNSAT supports only one proof rule, namely resolution. In contrast, ZKSMT's implementation supports dozens of distinct proof rules, and the protocol itself generalizes to any suite of first-order proof rules.

A concurrent work that addresses a similar problem is zkPi [38]. Unlike ZKSMT and ZKUNSAT, zkPi encodes proofs written in interactive theorem provers, primarily Lean. The proofs encoded by zkPi can contain algebraic data types, lambda calculus terms, and induction. ZKSMT differs from zkPi in that it prioritizes efficiency for large-scale first-order proofs that encode formalisms like integer arithmetic directly rather than as part of a broader framework.

General-Purpose ZK Protocols General-purpose ZK protocols emulate program executions in ZK. These protocols are much less efficient than ZKSMT since they must support arbitrary computations while obliviously concealing a program's control flow. When Cheesecloth [15] and TinyRAM [7] execute a program in ZK, they multiplex over all CPU instructions and simulate read, write, malloc, and free operations for the program's memory. Likewise, Pantry [11] and Buffet [49] model programs with memory operations and mutable states. ZKSMT does not incur the same performance costs as Cheesecloth, Pantry, and Buffet because it efficiently checks SMT rules instead of arbitrary computations.

9 Conclusion

This paper introduces ZKSMT, an efficient protocol for validating SMT formulas in ZK. This work sets up exciting future work in multiple directions. First, protocols can be developed for other theories that model practical verification problems but are not currently supported, including the theory of arrays and the theory of bit-vectors [23]. Arrays and bit-vectors are commonly used by symbolic execution engines that execute low-level code [12]. Second, the core logic itself can be extended to validate formulas that contain universal and existential quantifiers. Prominent program verification toolchains often produce quantified formulas as output [5, 39].

Another direction for further research is the combination of ZKSMT's proofs with other proofs about program safety. ZKSMT is a protocol for validating proofs about programs written in a high-level language. For a full ZK program verification pipeline, the prover would also need to demonstrate that a compiled and distributed binary version of the program is observationally equivalent to the high-level program whose correctness proof is covered by ZKSMT. The construction and representation of such proofs is the subject of translation validation [45, 47] and verified compilers [41]. Validating these proofs in ZK is an exciting direction for future work.

A Proof Rule Tables

Tables 4 and 5 show our full set of proof rules for Boolean logic, EUF, and LIA. Table 4 contains the simple rules that have no premises or side conditions, and Table 5 contains the more complex rules.

B Proofs

We now prove that ZKSMT is sound and complete. The proofs are independent of the theories on which ZKSMT is instantiated. A proof Π of a formula φ exists in ZKSMT's format under a theory T if and only if a corresponding proof Π' exists for φ in T outside ZKSMT.

B.1 Proof of VM Soundness

Let Π be a proof in ZKSMT's format that derives φ. Assume that Algorithm 1 succeeds for Π. Our goal is to convert Π into a derivation tree Π' that derives φ. Π' needs to follow the structure defined in Section 2.1.

Let T be the theory used for Π. We can use the exact same theory for Π', so the logical structure of the proof can stay the same. We can simply translate all of the proof steps from Π verbatim to create a proof tree for Π'. No new proof steps

Table 4: ZKSMT's rules that have no premises or side conditions, grouped by theory.

need to be created for Π', but some steps from Π may need to be duplicated. In ZKSMT's format, the conclusion of a proof step can be used as a premise for any number of other proof steps. However, in ordinary proof trees, each step's conclusion can be used only once. If a proof step's conclusion is ever used as a premise for multiple other steps in Π, we can duplicate that proof step in Π' for every place where it is used.

If a proof step is duplicated for Π', then all of its premises need to be duplicated as well. This can lead to a cascading effect where duplicating a proof step requires even more steps to be duplicated as a consequence, but the process is guaranteed to terminate eventually. There are only finitely many steps in Π, each original step takes only finitely many premises, and there are no cycles. An infinite chain of expansions would violate one of those three properties of Π, so we can always find a finite value for π to confirm that φ is boundedly verifiable.

The expression table M_e in Π stores terms and formulas together, but we need to distinguish between terms and formulas for Π'. Recall that ZKSMT's format includes typing constraints (Sec. 3.2). There is a type for formulas, and it does not overlap with the types used for terms in ZKSMT's format, so we can always distinguish between terms and formulas when creating Π'. In Π, the premises and conclusion of every proof step have the type of formulas. We can interpret all expressions of that type as formulas for Π' and treat everything else as a term. We can unfold every term and formula in M_e into a full AST because we forbid M_e to contain cycles. All terms and formulas must be well-formed because they satisfy the typing rules in Π that are based on T.

One minor issue for the conversion from Π to Π' is the fact that functions in Π can behave as predicates. We need to distinguish between functions and predicates for Π', so we can treat functions from Π as either functions or predicates in Π' depending on whether their output type is the type of formulas. Each function in Π has only one permitted output type, so there can be no ambiguity in the conversion.

Every proof step in Π is checked exactly once, so each step in Π' must be valid according to T. We know that every step in Π is checked once because of the permutation check on line 17 of Algorithm 1. A proof tree is valid if every individual step in the tree is valid, and every step in Π' is a copy of a step in Π, so Π' must be a valid derivation of φ.

All that remains to be shown is that we can fix size parameters for Π'. We already covered π. χ can be the same as it is for Π because no new expressions have been created, only copies of existing ones. μ can be the same as it is for Π because every proof step in Π' takes as many premises as it does in Π. α can be the same as it is for Π because no argument lists have been changed. ρ can be the same as it is for Π because every rule has the same premises in Π' as it does in Π. This covers all five size parameters, so φ is boundedly verifiable, and ZKSMT is sound.

B.2 Proof of VM Completeness

For the reverse direction, we will start with a valid derivation tree Π' and produce a valid proof Π in ZKSMT's format. To convert Π' into Π, we can perform some of the same conversions that we performed for the soundness proof in reverse. We can let Π use the same theory T that Π' uses. Every proof step in Π' can become a valid proof step in Π without being altered. Likewise, every term and formula in Π' that is well-typed becomes a well-typed expression in Π. It is possible that Π' contains groups of identical proof steps, but there is no need to consolidate identical proof steps for Π.

We can construct the expression table M_e by giving every distinct AST node in Π' its own entry. It is important that M_e does not contain any duplicates. Whenever two terms or formulas are identical, they should have the same entry in M_e. This is what allows equality checks to work in instances of ZKSMT. The order of the entries in M_e is unimportant. We can add a type for formulas and preserve all of the distinctions between types for terms. We can treat predicates as formula-typed functions.

To finish the construction of Π, we need to define the size parameters π, χ, μ, α, and ρ. Let π be the number of proof steps in Π'. We copied the structure of Π' without adding or removing any steps, so π is also the number of proof steps in Π. Let χ be the number of distinct AST nodes in the terms and formulas in Π'. This is also the number of expressions in Π because of our definition of M_e. Let μ be the maximum number of premises that any proof step in Π' takes. There must be a maximum because Π' is a finite proof, and this is

Table 5: ZKSMT's rules that have premises or side conditions, grouped by theory. Capital letters represent argument lists for n-ary operations, and lowercase letters represent individual expressions.

also the maximum number of premises for Π because we did not modify the proof steps. Let α be the maximum number of arguments taken by any AST node in Π'. Again, this maximum must exist because Π' is finite, and it applies equally well to Π. Lastly, let ρ be the number of distinct proof rules used in Π'. Π uses the same suite of proof rules as Π', so ρ is also the number of distinct proof rules in Π.

We need to confirm that Π passes the checks in Algorithm 1. The rule check on line 12 of Algorithm 1 will always pass because Π and Π' use the same theory. The cycle checks in Algorithm 1 must pass because Π' does not contain any cyclic terms, formulas, or proof steps. The type checking must pass because every term and formula in Π' is well-formed. The permutation check on line 17 must succeed because π is defined as the number of steps in Π' and every step from Π' is copied into Π. There are no other checks that can cause Algorithm 1 to fail, so Π must be a valid instance of ZKSMT. Therefore, ZKSMT is complete.

SoK: What Don't We Know? Understanding Security Vulnerabilities in SNARKs

Abstract

Zero-knowledge proofs (ZKPs) have evolved from being a theoretical concept providing privacy and verifiability to having practical, real-world implementations, with SNARKs (Succinct Non-Interactive Argument of Knowledge) emerging as one of the most significant innovations. Prior work has mainly focused on designing more efficient SNARK systems and providing security proofs for them. Many think of SNARKs as "just math," implying that what is proven to be correct and secure *is* correct in practice. In contrast, this paper focuses on assessing end-to-end security properties of real-life SNARK *implementations*. We start by building foundations with a system model and by establishing threat models and defining adversarial roles for systems that use SNARKs. Our study encompasses an extensive analysis of 141 actual vulnerabilities in SNARK implementations, providing a detailed taxonomy to aid developers and security researchers in understanding the security threats in systems employing SNARKs. Finally, we evaluate existing defense mechanisms and offer recommendations for enhancing the security of SNARK-based systems, paving the way for more robust and reliable implementations in the future.

1 Introduction

Zero-Knowledge Proofs (ZKPs) have undergone a remarkable evolution from their conceptual origins in the realm of complexity theory and cryptography [47, 48] to their current role as fundamental components that enable a wide array of practical applications [36]. Originally conceptualized as an interactive protocol where an untrusted prover could convince a verifier of the correctness of a computation without revealing any other information (zero-knowledge) [47], ZKPs have, over the past decade, transitioned from theory to practical widely used implementation [15, 17, 31, 67, 70, 77, 82, 84].

On the forefront of the practical application of *general-purpose* ZKPs are Succinct Non-interactive Arguments of Knowledge (SNARKs) [26, 40, 44, 50, 75]. SNARKs are non-interactive protocols that allow the prover to generate a succinct proof. The proof is efficiently checked by the verifier, while maintaining three crucial properties: completeness, soundness, and zero-knowledge. What makes SNARKs particularly appealing is their general-purpose nature, allowing any computational statement represented as a *circuit* to be proven and efficiently verified. Typically, SNARKs are used to prove that for a given function f and a public input x, the prover knows a (private) witness w, such as $f(x,w) = y$. This capability allows SNARKs to be used in various applications, including ensuring data storage integrity [82], enhancing privacy in digital asset transfers [67, 84] and program execution [15, 17], as well as scaling blockchain infrastructure [60, 78, 79, 85]. Their versatility also extends to non-blockchain uses, such as in secure communication protocols [61, 96] and in efforts to combat disinformation [54, 56]. Unfortunately, developing and deploying systems that use SNARKs safely is a challenging task.

In this paper, we undertake a comprehensive analysis of publicly disclosed vulnerabilities in SNARK systems. Despite the existence of multiple security reports affecting such systems, the information tends to be scattered. Additionally, the complexity of SNARK-based systems and the unique programming model required for writing ZK circuits make it difficult to obtain a comprehensive understanding of the prevailing vulnerabilities and overall security properties of these systems. Traditional taxonomies for software vulnerabilities do not apply in the case of SNARKs; hence, we provide the seminal work that addresses this gap by providing a holistic taxonomy that highlights pitfalls in developing and using SNARKs. Specifically, we analyzed 141 vulnerability reports spanning nearly 6 years, from 2018 until 2024. Our study spans the entire SNARK stack, encompassing the theoretical foundations, frameworks used for writing and compiling circuits, circuit programs, and system deployments. We systematically categorize and investigate a wide array of vulnerabilities, uncovering multiple insights about the extent and causes of existing vulnerabilities, and potential mitigations.

Contributions.

- **SNARKs system and threat models:** We provide the first framework for reasoning about systems built using SNARKs, analyzing interactions between different components, defining adversaries and their knowledge, and discussing potential implementation-level vulnerabilities and their impact.
- **Study of vulnerabilities:** We present the first systematic study of known vulnerabilities in systems using SNARKs. We gathered 141 vulnerabilities from 107 audit reports, 16 vulnerability disclosures, as well as a number of bug trackers of popular SNARK projects. When it comes to SNARKs, this is the first study of this scale in the literature. Further, because of the breadth of our coverage, we believe our findings to be representative of the entire SNARK space.
- **Vulnerabilities taxonomy:** We introduce a taxonomy for classifying vulnerabilities in SNARKs, highlighting unique vulnerabilities and common pitfalls in the SNARK stack that help researchers and practitioners better understand important threats in the SNARK ecosystem.
- **Analyzing defenses:** We analyze the main defense techniques proposed by the research and practitioner communities and highlight some notable gaps.

Key Findings. We find that developers seem to struggle in correctly implementing arithmetic circuits that are free of vulnerabilities, especially due to most tools exposing a low-level programming interface that can easily lead to misuse without extensive domain knowledge in cryptography. In detail, we find the following flaws to be most pressing: *(i) Implementation bugs across SNARK systems' layers*, including classic vulnerabilities like input validation errors and over/underflows. These can undermine SNARKs' core properties: completeness, soundness, and zero-knowledge. *(ii) The unique programming model for SNARK circuits poses challenges, often leading to under-constrained circuits*. This category emerges from overlooking constraints or misinterpreting logic into circuits. The low-level nature of SNARK Domain Specific Languages (DSLs), such as Circom, exacerbates vulnerabilities due to a lack of common high-level programming features such as basic types. *(iii) Design and implementation errors in proof systems* are critical yet often overlooked vulnerabilities. These errors may originate from the frameworks implementing the proof systems, like an implementation error in Gnark's Plonk verifier, or from the theoretical foundations themselves. An example is the "Frozen Heart" vulnerability, attributed to incomplete descriptions in the original proof system papers, leading to significant implementation errors [32].

It is important to highlight that ZK systems are *not* "just math" — they are complex, "compositional" systems where cross-layer interactions can introduce complex vulnerabilities. This paper attempts to cover the entire gamut of erroneous possibilities in the ZKP space.

2 Background on SNARKs

A ZKP enables an entity to prove that a statement is true, without disclosing anything besides the veracity of the statement. A ZKP is termed a ZK-SNARK if the proof size and verification time are sublinear in the statement to be proven, the communication between prover and verifier is non-interactive, and security holds against a computationally bounded prover. Common ZK-SNARKs are targeting the problem of *circuit satisfiability*, where the statement is represented as an arithmetic circuit. Hence, general-purpose SNARKs prove a fixed NP relation $\mathfrak{R}$, and allow the prover to convince a verifier that for the public input x they know a witness w such that $(x,w) \in \mathfrak{R}$. *Pre-processing SNARKs* [26], which are the focus of this work, additionally introduce a *setup* phase that encodes the relation being proven into a succinct representation.

In summary, a SNARK is composed of three algorithms:
$Setup(pp) \rightarrow (pk, vk)$. Given public parameters pp as input, output proving and verification keys pk and vk.
$Prove(pk, x, w) \rightarrow \pi$. Given the proving key pk, the public input x, and the witness w, output a proof π.
$Verify(vk, x, \pi) \rightarrow \{0,1\}$. Given the verification key vk, the public input x, and the proof π, output 1 if the proof is valid and 0 otherwise.

A ZK-SNARK satisfies the following security properties:
Knowledge Soundness. A dishonest prover cannot convince the verifier of an invalid statement, except with negligible probability.
Perfect Completeness. An honest prover can always convince the verifier of the veracity of a valid statement.
Zero Knowledge. The proof π reveals nothing about the witness w, beyond its existence.

For an in-depth introduction of ZKPs and SNARKs from a theoretical perspective, we refer the reader to [88].

3 System and Threat Models for SNARKs

We introduce a four-layer system model, showing how SNARKs are implemented in practice. Based on our system model, we provide a holistic threat model defining SNARK vulnerabilities, adversaries, and their potential impact.

3.1 System Model

Figure 1 depicts the system architecture of an application based on SNARKs for circuit satisfiability, i.e., argument systems that let the prover show that given a public input x, it knows a witness w such that the circuit satisfies $\mathcal{C}(x,w) = y$. In our system model, we refer to four distinct layers. First,

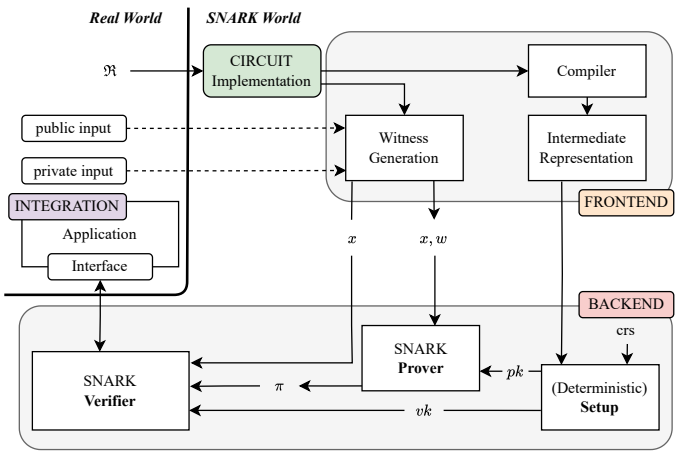

Figure 1: System model of an application based on SNARKs.

```
type Circuit struct {
   X frontend.Variable `gnark:",private"`
   C frontend.Variable `gnark:",public"`
   Y frontend.Variable `gnark:",public"`
}
func (circuit *Circuit) Define(api frontend.API) error {
  outputs := api.Compiler().NewHint(hint.SqrtHint, 1, circuit.X)
  squareRoot := outputs[0]
  api.AssertIsEqual(api.Mul(squareRoot, squareRoot), circuit.X)
  result := api.Mul(squareRoot, circuit.Const)
  api.AssertIsEqual(circuit.Y, result)
  return nil
}
```

Figure 2: Example circuit written in the eDSL gnark [16]. Lines highlighted in gray add constraints in the circuit.

the developer specifies the circuit in the *Circuit Layer*, according to the specification of the statement to be proven. The *Frontend Layer* enables the compilation of the circuit to a SNARK-friendly representation. The *Backend Layer* consumes this representation, and provides the concrete implementation of the proof system. The *Integration Layer* is the application logic that interacts with the proof system. We proceed to introduce the key components in each layer.

(i) CIRCUIT LAYER. SNARKs targeting circuit satisfiability require the computational statement to be represented as an arithmetic circuit. Most SNARKs work over elements in a finite field $\mathbb{F}_p$, and hence each wire in the arithmetic circuit is represented as an element in $\mathbb{F}_p$. Note, that there are also SNARKs employing Ring arithmetic [42], with the purpose of achieving more efficient operations over $\mathbb{Z}_{2^{64}}$ to match native execution on standard CPUs. When developing a ZK system, there are several considerations at different levels of the stack that must be taken into account by developers: *(i)* determining what inputs and outputs of the computation are exposed publicly, *(ii)* encoding the application logic as an arithmetic circuit in $\mathbb{F}_p$, and *(iii)* specifying how applications should compose with the circuit (e.g. by ensuring that public inputs are well-formed before verifying a proof). Specifying circuits correctly is unintuitive, as arithmetic circuits do not natively support non-arithmetic operations. Moreover, developers face challenges in translating conventional programming logic into circuit formats while simultaneously addressing the dual requirements of value assignment for witnesses and applying constraints to check the validity of solutions. The prover is responsible for assigning these values (i.e., witness assignments in the circuit), but the verifier has to check that these assignments adhere to the constraints (i.e., constraints in the circuit). Crucially, developers must remember that a malicious prover might manipulate witness values, bypassing circuit logic. Therefore, it is vital to rigorously constrain the witness within the circuit to only validate legitimate solutions. If the constraints are not sound, then there is the risk of exploitation (see Section 5). For example, expressing $X \neq 0$ is trivial in a "normal" programming language, whereas encoding it in a custom circuit is non-trivial. By Fermat's Little Theorem, one can check $X^{p-1} = 1$, but this would cost $O(logp)$ constraints [71]. An alternative is to have the prover provide a *hint* $H = X^{-1}$, the multiplicative inverse of X, to check $X \cdot H = 1$. Since all nonzero elements in $\mathbb{F}_p$ have a multiplicative inverse, this constrains X to be nonzero by deduction [57]. We provide a concrete example of a circuit leveraging a hint in gnark for efficiently computing the square root in Figure 2. In practice, developer tools employ differing approaches to ease circuit specification in high-level programming interfaces:

Circuit Domain Specific Languages. Domain Specific Languages (DSLs) are specialized programming languages designed to address specific problem domains. In the case of SNARKs, they offer a tailored syntax to efficiently express constraints in an arithmetic circuit [3,11,28,33,71,75]. Learning a DSL might be challenging, especially for developers not familiar with SNARKs.

Circuit Embedded Domain Specific Languages. An Embedded Domain Specific Language (eDSL) is a type of domain-specific language that is embedded within a host general-purpose programming language. For developing SNARKs, several eDSLs have emerged in recent years, embedded as libraries in Golang [16], Rust [37,81,95], and TypeScript [69]. eDSLs can seamlessly interact with other code written in the host language, allowing easy integration with existing libraries. At the same time, they require developers to actively distinguish between in-circuit and out-of-circuit operations, which requires domain expertise to ensure correct implementation.

ZK Virtual Machines. Circuit DSLs and eDSLs allow developers to specify circuits in a manner similar to *application-specific integrated circuits* (ASIC). Zero-Knowledge Virtual Machines (ZK-VMs) follow a different programming model,

where the arithmetic circuit represents the loop of fetching instructions from memory and successively executing them (similar to the fetch-decode-execute cycle as observed in a general-purpose CPU). Common ZK-VMs target existing Instruction Set Architectures [4,18,60,79,85]. For example, ZK-EVMs target the primitive instructions (i.e., "opcodes") of the Ethereum Virtual Machine [60,79,85], and RISC Zero [18] and Jolt [4] operate on the RISC-V instruction set. Similarly, there are ZK-VMs for custom ISAs that are optimized for proving in a SNARK [46,78]. Some ZK-VMs, such as the Cairo ZK-VM [46], provide a DSL to specify programs for the ZK-VM. ZK-VMs can be beneficial as they operate on existing instruction sets and can leverage existing tooling. Writing circuits directly, while more error-prone, can be more efficient due to access to low-level optimizations.

(ii) FRONTEND LAYER: The frontend of a SNARK for circuit-satisfiability compiles the high-level program written by the developer to a representation (i.e., *arithmetization*) which is amenable for the proof system in a backend. Frontends are agnostic to proof systems, as in they can provide a compilation of high-level programs to differing arithmetizations. At runtime, the frontend assigns all intermediate wires in the circuit in order to generate the public and private parts of the *witness*. We introduce the components in detail as follows:

Arithmetization. An arithmetization is a representation of the constraint system in a mathematical form, typically a set of algebraic equations, that can be efficiently processed by the argument system, i.e., the backend of a SNARK. Common arithmetizations include rank-1 constraint systems (R1CS) [44], variations of Plonkish arithmetization [40], Arithmetic Intermediate Representations (AIR) [13] and Customizable Constraint Systems (CCS) [86]. Different arithmetizations result in a different cost profile for the respective proof system that relies on them, and notably, they introduce different limitations with respect to how the circuit is defined. For example, R1CS does not support constraints that have a polynomial degree larger than two, and AIR requires circuits to be uniform. Notably, Setty et al. provided CCS, a constraint system that generalizes Plonkish, AIR, and R1CS arithmetizations [86].

Circuit Compiler. The circuit compiler in a SNARK implementation compiles the circuit specified in a high-level DSL or eDSL to the respective arithmetization. Note, that not all compilers target the compilation of high-level languages to specific arithmetizations. For example, high-level programs can first be compiled to VampIR [1] and ACIR [2], which are intermediate representations that allow compilation to, e.g., R1CS or some form of Plonkish arithmetization and aim to ease the support of multiple backends. Similarly, zkLLVM provides a compiler from the LLVM IR to different arithmetizations, allowing users to prove the execution of, e.g., native Rust, Golang, or C++ [3].

Witness Generation. The main task of the witness generator is to calculate the intermediate wires for a given circuit C, given the assignment of public and private inputs. Note that the concept of a separate witness generator is not necessarily implemented by every frontend. Often, the circuit code can be executed to either produce constraints at compile time (e.g., the line highlighted in grey in Figure 2) or to produce witness values at runtime/proving (e.g., the hint in Figure 2). When an auxiliary "witness generator" exists, instructions are generated on how to fill a symbolic witness table and the witness generator is a binary generated at compile time.

(iii) BACKEND LAYER. Given the arithmetic circuit and witness, the backend specifies the algorithmic implementation of proof systems (e.g., Groth16 [50], Plonk [40], Stark [13], Marlin [26]). At a high level, the backend algorithms follow the API as in Section 2.

Setup. In pre-processing SNARKs, the *setup* algorithm generates the prover and verifier keys (*pk* and *vk*) by encoding the circuit relation, with the primary goal of succinct verification and optimized proving. However, different SNARKs have vastly differing properties with regard to trust assumptions, which in turn also impact their performance. Some SNARKs require a *trusted setup*, i.e., a randomized setup phase that introduces a trapdoor either per circuit (i.e., non-universal) [50] or in a universal setup phase [40]. The *randomized* part of the setup involves public parameters and random input to generate a common reference string (CRS) [68], which can be used to derive *pk* and *vk* in the deterministic part of the setup for a concrete circuit instantiation. The trapdoor needs to be discarded after the setup proccess is done, as anyone who has knowledge of the trapdoor can forge proofs. SNARKs that do not employ a trapdoor in the setup phase are commonly coined *transparent* [13]. Note, that this introduces a trade-off in verifier efficiency — transparent SNARKs only have poly-logarithmic-time verification as compared to constant-time for SNARKs with trusted setup [88].

Prover & Verifier. The prover consumes the values generated by the frontend, where the circuit is represented in a specific arithmetization. At a high level, the prover of a pre-processing SNARK (aside from Groth16 [50]) utilizes a *polynomial commitment* to commit to the satisfying witness, and successively engages with the verifier in an interactive protocol to evaluate the correctness of assignments with regard to the circuit relation. This "recipe" leads to a SNARK if the verifier is public-coin [76], and the prover can hash the transcript of the interactive proof to render the protocol *non-interactive* (a process commonly denoted as applying the "Fiat-Shamir heuristic"). Different proof systems choose different combinations of polynomial commitments and interactive proofs,

[1] https://github.com/anoma/vamp-ir
[2] https://github.com/noir-lang/acvm
[3] https://github.com/NilFoundation/zkLLVM

resulting in differing properties for the respective target applications. The most popular approaches include Plonk [40], which employs a constant-round polynomial interactive oracle proof (IOP) with the KZG commitment [55]. Halo2 [95] uses the Plonk IOP with the Bulletproofs polynomial commitment [19]. Another class of protocol combines a polynomial commitment based on Merkle hashes with a *low-degree test*, resulting in a protocol that does not demand for a trusted setup or operations in elliptic curve groups [12], at the cost of non-constant verification time and a larger proof size [35]. Plonky2 [81] uses the FRI-based polynomial commitment scheme and combines it with the Plonk IOP. Groth16 [50], the SNARK with the shortest proof size, is based on probabilistically checkable proofs (PCP) [44] and pairings over elliptic curves for proof verification. For an in-depth taxonomy, we refer readers to [88]. Some applications leverage one of the above SNARKs without the *zero-knowledge* property, solely relying on non-interactivity and succinctness (e.g zk-EVMs [79, 85]). In most SNARKs, zero-knowledge can be obtained cheaply with minor modifications.

(iv) INTEGRATION LAYER. In our system model, we collectively term any application-specific implementation that doesn't directly relate to the circuit layer, frontend layer, or backend layer, the *integration layer*. This includes source code interacting with any of the other layers, application logic that may impact the overall security of employing SNARKs, as well as composition and aggregation of proofs.

Code Interacting with SNARK Components. A SNARK application requires code that interacts with the functions exposed by the prior layers. Typically, developers use Solidity, JavaScript, or any other language to perform API calls to the frontend or backend. For performance reasons, many applications reduce circuits to their minimal size to fulfill a specific functionality, outsourcing operations, like range-checks for certain input values, to native application code.

Complementary ZKP Logic. An application might employ complementary logic beyond the SNARK itself to ensure its security properties. For example, nullifiers are commonly used as private values that "nullify" a specific object upon its use to ensure that specific operations are only executed once. Consider the use of nullifiers in Tornado Cash [77]. A user deposits a token in a smart contract and associates a secret nullifier with it. When a user wants to withdraw, the contract checks that the nullifier has not been used before to prevent double-spending. The user additionally generates a SNARK proof, which proves that the nullifier is associated with a deposit, without revealing the exact deposit to achieve anonymity.

Proof Delegation, Aggregation, Recursion & Composition. In some applications, proofs can be too computationally expensive to be generated on end-user devices. To achieve proof generation on computationally restricted devices, one may delegate the proof generation to an untrusted party [64]. Similarly, one may require a fast prover (linear in the size of the statement) *and* a fast verifier (constant in the size of the circuit). In this case, common projects employ a recursive composition of proofs, i.e., they first leverage a SNARK with a fast prover and successively prove the verification in a SNARK with a fast verifier. For example, Polygon ZK-EVM [79] composes a FRI-based SNARK with a Groth16 to obtain the succinct proof size and verification for cheap verification of proofs in a smart contract, whilst benefiting from the faster prover time and decreased size of the reference string required for Groth16. Note that in this case, the trust assumption reduces to the weakest component, i.e., Groth16 still requires a trusted setup. There are several other works that employ a similar strategy to obtain efficient SNARK constructions through aggregation or recursive composition [34, 41, 59, 83, 92, 93].

3.2 Threat Model Taxonomy

We consider any usage of a SNARK that violates the intended behavior of one of the previously discussed layers as a SNARK vulnerability. In this section, we first define the scope of vulnerabilities at each layer, outline the roles an adversary can take that may lead to a specific adversarial impact throughout our system model.

Scope of Vulnerabilities. In the *(i) circuit layer*, vulnerabilities may result from coding mistakes on the implementation of circuits that can lead to having inconsistent or weak constraints that break the soundness and/or completeness of the system. A primary reason for this is mistranslation due to developers not being used to writing in a differing programming model that introduces surprising pitfalls. In the circuit layer, we exclude logic bugs that are not necessarily associated with writing SNARK circuits, and focus on issues that arise from the use of SNARK software specifically. In the *(ii) frontend layer*, vulnerabilities may primarily arise due to bugs in compiling from high-level source code to a specific arithmetization. In the *(iii) backend layer*, vulnerabilities may occur in the prover, where adversarial provers attempt proof forgery. For SNARKs requiring a trusted setup, applications might use an MPC-ceremony for generating the reference string trustlessly. Vulnerabilities in the MPC-ceremony are considered out of scope, as they do not directly pertain to SNARKs. Vulnerabilities in the *(iv) integration layer* resemble any issue in the software components that interact with a SNARK. For example, circuits can have implicit constraints that ought to be checked in the integration layer. We exclude traditional vulnerabilities, such as reentrancy for smart contracts, as they are not unique to systems using SNARKs.

(i) ADVERSARIAL ROLES: Throughout this work, we assume that adversaries are rational agents aiming to attack systems utilizing SNARKs. We outline the knowledge an adversary can obtain given its role in our system model in Table 1:

Adversarial Role	Public Input	Private Input	Circuit	Public Witness	Private Witness	Arithmetization	CRS	Prover Key	Verifier Key	Proof
R_1 - Network Adversary	☆	✘	✔	✔	✘	☆	✔	☆	☆	✔
R_2 - Adversarial User	✔	✔	✔	✔	✔	☆	✔	☆	☆	☆
R_3 - Adversarial Prover	✔	☆	✔	✔	☆	✔	✔	✔	☆	✔

Table 1: Categorization of adversarial roles by the knowledge they can obtain and utilize. A *network* adversary can observe existing proofs and reuse them with different inputs to exploit malleability vulnerabilities. The *user* can delegate proof generation to a proving service, while the *prover* can generate and has complete control over proof generation. Typically, soundness vulnerabilities due to circuit bugs can exploited only by the prover. Adversary has "✔" knowledge, "✘" no knowledge, "☆" maybe knowledge.

R1 - Network Adversary. A network adversary can observe the public values transmitted between participants in the SNARK application. Hence, it can obtain knowledge about the public witness x, the public common reference string, and the proof π sent from the prover to the verifier. A network adversary may attempt to exploit weak simulation extractability of certain proof systems that can render a proof malleable [45].

R2 - Adversarial User. In some SNARK applications, users are not involved in proof generation or proof verification at all. For example, ZK-EVMs provide a service that leverages SNARKs primarily to minimize transaction costs. In this case, an adversarial user has oracle access to the prover, i.e., it can submit an arbitrary number of public inputs (or private inputs, in case of privacy-preserving delegated proof generation [27]), with the aim of successfully performing Denial-of-Service (DoS) attacks. Further, an adversarial user may exploit circuit issues, where the circuit is defined by the prover (i.e., the service provider) to whom the user delegates the proof.

R3 - Adversarial Prover. An adversarial prover has knowledge of all input values, including the verifier key, and may attempt to break the underlying cryptographic primitives or exploit misconfigurations in the setup phase. The adversarial prover can easily exploit soundness vulnerabilities in the verifier, such as under-constrained bugs discussed in Section 5. To mitigate this risk, systems, including ZK-rollups, may temporarily adopt permissioned provers, where only authorized entities can generate and submit proofs to the verifier (typically a smart contract acting as the verifier). This approach reduces the risk of adversaries exploiting soundness vulnerabilities, although it does not eliminate the possibility of the permissioned prover exploiting such vulnerabilities.

(ii) VULNERABILITY IMPACT: We categorize the impact of a vulnerability into the following categories:

I1 - Breaking Soundness. The vulnerability allows a prover to convince a verifier of a false statement; that is, it allows the creation of a proof for an incorrect statement that is nonetheless accepted as valid.

Layer	Security audits	Vulnerability disclosures	Bug Tracker	Total
Integration	8	1	4	13
Circuit	86	10	3	99
Frontend	0	0	6	6
Backend	7	5	11	23
Total	**101**	**16**	**24**	**141**

Table 2: Origins of vulnerability reports.

Impact	Soundness	Completeness	Zero Knowledge
Integration	11	2	0
Circuit	94	5	0
Frontend	2	4	0
Backend	17	3	3
Total	**124**	**14**	**3**

Table 3: Impact of SNARK vulnerabilities.

I2 - Breaking Completeness. The vulnerability allows a prover to submit proofs of a true statement that leads to an invalid verification by a verifier. Further, it can be the case that valid proofs are rejected by an honest verifier.

I3 - Breaking Zero-Knowledge. The vulnerability allows an adversary to break the zero-knowledge property, i.e., it allows information leakage about the private witnesses. If an adversary exploits such a vulnerability, they could gain access to sensitive data, such as secret keys or private inputs, leading to privacy violations and potentially further exploits based on the information gained.

4 Methodology

Exploring the security vulnerabilities across the entire SNARK stack presents a complex challenge for several reasons. Firstly, the unique programming model required for developing SNARK circuits means that a significant number of potential security issues are difficult to identify and understand. Secondly, the tools used for SNARK development are themselves non-standardized and heterogeneous, each offering different interfaces. The relative novelty of SNARK technology contributes to a lack of comprehensive documentation and standards, further complicating the analysis of these tools. Moreover, instances of vulnerabilities being actively exploited are rare. There are no incidents of blackhat attacks publicly disclosed related to SNARKs. Furthermore, in applications that leverage the zero-knowledge property of SNARKs, it can be especially challenging to determine if an attack has occurred due to the privacy-preserving nature of these systems. To cope with these challenges, we apply the following methodology.

Analyzed SNARK Implementations. Our examination fo-

cuses on widely deployed SNARK systems, including ZK-rollups for blockchain scalability (e.g., zkSync Era [60], Polygon ZK-EVM [79] Scroll [85]),[4] privacy-centric blockchains (e.g., Zcash [84], Aztec [6], and decentralized privacy applications (e.g., Tornado Cash [77]). We also assess key circuit libraries and SNARK frameworks (e.g., Circom and halo2) [35]. Our analysis further extends to inspecting the underlying proof systems for known bugs. This comprehensive approach ensures that we cover a broad spectrum of real-world SNARK applications and the various layers of technology they rely on.

Data Sources. In our comprehensive study of security vulnerabilities related to SNARK systems, we have utilized an extensive range of data sources to ensure a thorough analysis. Our primary source includes critical and high-impact vulnerabilities identified in 107 security audit reports of systems employing SNARKs. Among these, 75 reports specifically highlighted vulnerabilities directly related to SNARKs, while the remaining reports detailed other types of vulnerabilities, such as common smart contract deficits. Additionally, we have incorporated vulnerabilities from public bug bounty programs and vulnerability disclosures. Our search for disclosures included those from prominent projects like Zcash, Aztec Connect, and TornadoCash, disclosures by security firms and researchers specializing in ZKPs, and comprehensive web searches targeting ZKP vulnerabilities. We reviewed Web3 bug bounty programs like Immunefi, though we found no ZKP-related disclosures there. Additionally, we consulted closely with top audit firms focusing on ZKPs to ensure we didn't miss any critical disclosures. These sources provide real-world examples of how vulnerabilities have impacted operational systems as well as the measures taken to address them. Furthermore, we delved into bug trackers of popular GitHub projects related to SNARKs. Our focus here has been specifically on security-related bugs, filtering out non-security-related issues. Table 2 in our paper depicts these varied data sources, collectively forming the foundation of our study of SNARK security.

Classification. We classify vulnerabilities by determining the layer that they occur in with respect to our system model (cf. Section 3.1). Successively, we asses the vulnerability type (e.g., over-constrained), identify its root cause, and assess whether it impacts soundness, completeness, or zero-knowledge when exploited (cf. Table 3). We provide a full classification of all vulnerabilities as an open-source dataset as a reference for practitioners.[5]

Threats to validity. Our investigation into vulnerabilities within SNARK systems faces several challenges that could affect the validity of our findings. Firstly, the absence of proof-of-concept exploits for many bugs raises questions about their actual exploitability. We try to mitigate this by excluding non-security vulnerabilities from our dataset. Secondly, while our classification of vulnerabilities was rigorously reviewed by multiple researchers and iteratively refined, the possibility of misclassification cannot be entirely ruled out. Our reliance on publicly available reports means our analysis may be skewed towards more commonly detected vulnerabilities, potentially overlooking others that are less apparent but equally prevalent.

[4] Notably, ZK-rollups have more than 1B USD in accumulated value locked in them according to L2BEAT https://l2beat.com/scaling/summary

5 Circuit Issues

Vulnerabilities at the circuit layer represent the most prevalent threat to systems using SNARKs (c.f. Table 2). The primary challenge for developers lies in adapting to a different level of abstraction, coupled with the need to optimize circuits for efficiency, as they significantly influence the cost of using a SNARK. This section initially highlights the three primary vulnerabilities encountered in the circuit layer, followed by outlining the root causes that lead to these vulnerabilities (see Table 4). In total, 95 circuit vulnerabilities led to soundness issues and 4 led to completeness issues (c.f. Table 3).

5.1 Vulnerabilities

V1. Under-Constrained: The most frequent vulnerability in ZK circuits arises from insufficient constraints. This deficiency causes the verifier to mistakenly accept invalid proofs, thus undermining the system's soundness or completeness.

V2. Over-Constrained: Although less common than under-constrained issues, circuits can be over-constrained, leading to the rejection of valid witnesses by honest provers or benign proofs from honest verifiers. This issue stems from extra constraints in the circuit, where legitimate solutions cannot be proven or verified, leading to DoS issues. Nevertheless, over-constrained bugs should not be confused with redundant constraints that add no additional value but do not lead to any issues other than introducing computational inefficiencies.

V3. Computational/Hints Error: Occurs when the computational part of a circuit is erroneous, often leading to complete-

ness issues where for correct inputs, the witness generation either fails or produces wrong results. Note that completeness issues can often be transient, meaning that you can fix the underlying issue without having to update the circuit and recompute the prover and/or the verifier keys. Computational issues may also result in soundness issues if the constraints are applied using the same erroneous logic.

5.2 Root Causes

R1. Assigned but not Constrained: A frequent issue in ZK circuit design lies in distinguishing between assignments and constraints. While constraints are mathematical equations that must be satisfied for any given witness for the proof to be valid, assignments allocate values to variables during the witness generation process. The problem arises when variables are assigned values based on correct computations but lack corresponding constraints. This oversight can lead the verifier to erroneously accept any value for these variables.

R2. Missing Input Constraints: Developers sometimes neglect to apply constraints on input variables in reusable circuits. This omission occurs either (i) unintentionally or (ii) because they anticipate these constraints will be enforced at a different interface level (i.e., caller circuit or integration layer), thus omitting the constraints for optimization reasons. However, the absence of clear documentation or fully constrained inputs in these circuits can lead to severe vulnerabilities. Note that this issue is particularly common in low-level circuit DSLs, such as Circom, which lack user-defined types.

R3. Unsafe Reuse of Circuit: In ZK circuit design, particularly when using DSLs like Circom, the practice of reusing circuits (such as templates in Circom or gadgets in halo2) can introduce vulnerabilities if not handled correctly. This primarily occurs in two scenarios: *(i) Implicit Constraints in Sub-Circuits*, occurred when circuits are reused without appropriately constraining their inputs or outputs based on the assumption that the user will apply these constraints on call-site. *(ii) Insecure Circuits Instantiation* when circuits are meant to be used for specific setups (e.g., specific curves). An example is the Sign template from circomlib, which was designed solely for the BN254 curve field.[6]

R4. Wrong translation of logic into constraints: Translating computations for ZK circuits presents a unique set of challenges, primarily due to the distinct programming model of ZK circuits compared to traditional CPU-targeted code. A significant issue arises when translating logic that involves types and operations available in conventional programming languages but are either absent or must be re-implemented in ZK frameworks (e.g., fixed-point arithmetic). This often leads to the need for creative but error-prone solutions, such as using multiplexers for conditional logic. Developers might inadvertently omit essential constraints or simplify the logic to reduce the number of constraints, potentially missing critical corner cases. This can leave variables under-constrained, allowing them to accept multiple or any values under certain conditions, thus deviating from the developer's intent and introducing vulnerabilities.

R5. Incorrect Custom Gates: In implementations following the TurboPLONK model, such as Halo2, circuit constraints are defined by using custom gates applied to specific rows and cells of a table that constitute the Plonkish representation of the circuit. However, this approach can lead to bugs when custom gates are incorrectly handled. Errors may arise from inaccurately determining the appropriate offsets, resulting in misalignment with the intended behavior of the circuit.

R6. Out-of-Circuit Computation Not Being Constrained: Out-of-circuit computation refers to computations within the code that do not directly impact the witness generation yet play a crucial role in the overall functionality. In DSLs like Circom, certain functions operate outside the circuit logic. Similarly, in eDSLs, standard code (e.g., vanilla Rust) is used for various computations that do not affect witness generation. For instance, computations like division, are typically performed out-of-circuit to optimize circuit efficiency. This method involves executing the computation externally and then witnessing the result back into the circuit where it is constrained to ensure correctness. Issues arise when these out-of-circuit computations lead to missing assignments or when constraints necessary for the circuit's integrity are overlooked. A specific manifestation of this issue is the *boomerang issue*, where a variable, initially constrained within the circuit, is temporarily moved out-of-circuit and then reintegrated without the necessary reapplication of constraints.

R7. Arithmetic Field Error: Working with field arithmetic in ZK circuits can be challenging, especially as developers might overlook the nuances of computations within a finite field. The most common issues in this context are arithmetic overflows and underflows. We categorize the primary types of overflows and underflows in ZK circuits as follows: (i) *Native Field Arithmetic Over/Underflow*, occurs when circuit computations exceed the finite field's limits, causing values to loop back within the field's range due to modulo arithmetic. (ii) *Overflows in Transformed Formats*, risks of overflows arise when numbers are transformed into bit representations for specific operations (e.g., range checks) or for emulating non-native arithmetics like fixed-point arithmetics. This is particularly problematic when multiple bit representations remain within the field's overflow limits, leading to under-constrained vulnerabilities.

R8. Bad Circuit/Protocol Design: Circuit design issues in SNARKs often stem from fundamental flaws in how circuits are conceptualized, potentially leading to unintended behaviors or the violation of protocol properties. A common manifestation of this problem is the incorrect categorization of

[6] https://github.com/iden3/circomlib/blob/master/circuits/sign.circom#L23

Root Cause	PDE	PCE	PUD	ZKPCLE	Total
Integration Design Error	1	2	0	0	3
Missing Validation Input	0	0	9	1	10
Total	**1**	**2**	**9**	**1**	**13**

Table 5: Integration vulnerabilities. PDE: Proof Delegation Error, PCE: Proof Composition Error, PUD: Passing Unchecked Data, ZKPCLE: ZKP Complementary Logic Error

variables – such as designating a variable as private when it should be public. These issues can significantly impact the functionality and security of the protocol.

R9. Other Programming Errors: This category encompasses a range of common programming errors that do not fit neatly into other specific vulnerability categories but still have significant implications for the integrity of SNARK systems. These errors include, but are not limited to, API misuse, incorrect indexing in arrays, and logical errors within the computational parts (i.e., witness generation) of the circuit that are not directly related to constraint application.

Countermeasures. To address circuit layer vulnerabilities in SNARK systems, especially the common issue of underconstrained vulnerabilities, several straightforward yet effective strategies are recommended. Firstly, adding missing constraints, particularly range checks, is crucial to ensure the integrity and robustness of the circuits. In-depth documentation of circuit design and SNARK system specifications can significantly aid in preventing misunderstandings and oversights during development and auditing. Additionally, adopting DSLs, whenever possible, that support modern programming features, such as abstractions and basic types, enhances the development process by providing clearer guidelines and reducing the likelihood of errors. Lastly, the use of specialized security tools designed for ZK circuits, as detailed in Section 8, can detect some vulnerabilities during the developing phase, further securing SNARK systems against vulnerabilities.

6 Integration Layer Issues

Besides circuit-related problems, numerous vulnerabilities in systems employing SNARKs originate from the integration layer. These vulnerabilities often stem from improper interactions between the application/system and the prover or verifier, or from design flaws within this layer that compromise the inherent properties of SNARKs. Table 5 categorizes all analyzed bugs into distinct categories and root causes.

6.1 Vulnerabilities

V4. Passing Unchecked Data: This vulnerability manifests when implicit constraints on the public inputs expected by the circuit are not enforced by the application's verifier. It can result in both soundness and completeness issues. While unchecked data can be input in the circuit directly or indirectly (by hashing it), the failure to enforce these implicit constraints at the integration layer can compromise the integrity of the entire system.

V5. Proof Delegation Error: In scenarios where proof generation is delegated to an untrusted prover, there's a risk of malicious activities. For example, a bad design could lead to the leaking of personal or secret data. This issue underlines the need for secure and trusted channels in proof delegation and decentralized proving services [43].

V6. Proof Composition Error: This issue arises when the logic is distributed across multiple proofs, but the intended behavior is not adequately enforced by the verifier who is expected to glue parts of certain proofs with parts of others. The lack of coherence and coordination between different proofs can lead to undefined behaviors in the application.

V7. ZKP Complementary Logic Error: This category encompasses vulnerabilities in the integration layer arising from the flawed implementation of logic that operates in conjunction with ZKPs. An illustrative example of such a flaw is the poor management of protocol-specific mechanisms like nullifiers. Consider a privacy-preserving application like Tornado Cash (TC), where users aim to dissociate deposits from withdrawals. TC employs ZKPs alongside a nullifier scheme; each deposit involves generating a nullifier and a secret, which, when hashed, are appended in a Merkle tree in TC.[7] Upon withdrawal, the user submits the nullifier and employs a SNARK to prove knowledge of the corresponding secret without revealing it, thus unlinking the withdrawal from the deposit. However, a critical check within the integration layer is required to ensure the unique use of each nullifier. Without this check, the system is vulnerable to exploitation, allowing a user to repeatedly withdraw funds, thus draining TC. This class of bugs, crucially, is not due to a flaw in the circuit's design or implementation but stems from an oversight in auxiliary mechanisms that are integral to the secure and correct application of ZKPs.

6.2 Root Causes

R10. Missing Validation Input: This root cause involves inadequate validation checks on data before its input into the circuit or before computations that affect data used later by the circuit. It arises when the integration layer does not properly validate input data or when the circuit itself lacks necessary checks. This oversight can lead to the acceptance of inappropriate data, potentially getting an application stuck, or worse, compromising the circuit's computations.

[7] For more information on how TC works we refer the reader to the official documentation https://docs.tornadoeth.cash/generals/how-does-tornado-cash-work

Layer	Vulnerability	# Bugs
Frontend	Incorrect Constraint Compilation	3
	Witness Generation Error	3
	Total	**6**
Backend	Setup Error	1
	Prover Error	6
	Unsafe Verifier	16
	Total	**23**

Table 6: Summary of frontend and backend bugs.

R11. Integration Design Error: Design flaws in the integration code that lead to undesired behavior or break protocol properties, such as not checking for duplicate nullifiers, are critical. Furthermore, designing privacy-enhanced applications poses a significant challenge. It is not straightforward to create ZK applications with privacy as a core property, and developers may inadvertently leak information without realizing it. This issue isn't about the proof system or constraints; it is about the inherent difficulty in designing an application that doesn't subtly leak data. This underscores the complexity and importance of carefully considering privacy aspects in the design phase of ZK applications. Fixes often require a high-level redesign rather than a simple programming correction.

7 Frontend/Backend Issues

The compilation of ZK circuits (frontend), along with proving a witness and verifying it (backend), rely on the correctness of the underlying software that implements the compilation process as well as the algorithms that underpin the proof system. Table 6 provides an overview of vulnerabilities that can occur within these components. Vulnerabilities in either the frontend or backend layers pose a significant risk, even if the circuits have been formally verified or if the proof system is theoretically secure; any defects in these layers could render the entire system insecure for end-users.

7.1 Frontend Vulnerabilities

V8. Incorrect Constraint Compilation: This type of vulnerability emerges from deficiencies in the compilation phase, specifically in the enforcement of constraints defined in the ZK circuit. Specifically, such issues may stem from the arithmetization process or overly aggressive optimization routines that unintentionally excise vital constraints. Any missteps in these processes can result in an inaccurate or incomplete translation of the original constraints at the circuit layer. Consequently, this could permit a verifier to erroneously accept an invalid proof or, conversely, to reject a legitimate one. At its core, this vulnerability mirrors a classical compiler bug, wherein the compiler erroneously interprets high-level DSL code.

V9. Witness Generation Error: This issue arises during the witness generation phase, where errors in the compilation can produce invalid witnesses or cause crashes, potentially leading to a denial of service. Typically, such errors occur due to misinterpretation of the circuit code, or due to the generation of bogus witness generators in target languages.

7.2 Backend Vulnerabilities

V10. Setup Error: This vulnerability arises during the setup phase, where the generation of public parameters occurs. Incorrect or easily compromised parameters can significantly undermine the system's integrity.

V11. Prover Error: Issues within the prover of the proof system fall into this category. These vulnerabilities can lead to the prover mistakenly rejecting valid witnesses, accepting invalid ones, or breaking the zero-knowledge property.

V12. Unsafe Verifier: This category includes vulnerabilities resulting from inadequate checks on the verifier's inputs, missing checks during verification, or bogus mathematical operations, risking the proof system's integrity. Vulnerabilities can emerge regardless of whether the verifier is manually implemented or generated by a framework.

7.3 Root Causes

Frontend and backend vulnerabilities can stem from a variety of root causes, ranging from basic programming errors to configuration issues or deviations from the specifications of proof systems. These can be as simple as missing validation checks for proofs or as complex as informational leaks that expose sensitive data. Additionally, the use of poor-quality or predictable randomness sources can compromise crucial ZKP properties. Adherence to proof system specifications is critical in preventing vulnerabilities. A common issue is the incorrect implementation of the Fiat-Shamir transformation, where a critical component is omitted during the hashing process of the transcript.

8 Defenses For SNARKs

This section presents an overview of defense mechanisms aimed at mitigating the SNARK vulnerabilities detailed in the previous sections. Table 7 compiles, to our best knowledge, all publications and tools associated with SNARK security. A filled bullet in the table indicates that the referenced technique provides at least one defensive measure against the issues indicated by the corresponding row's header. Notably, in addition to SNARK-specific strategies, conventional security tools (e.g., fuzzing) have been utilized in audits, although they typically fall short in preventing most vulnerabilities due to the oracle problem [9]. For example, fuzzing might be

	Vulnerability	Defenses

Table 7: An overview of papers and tools offering defense mechanisms for addressing vulnerabilities in SNARK-based systems. While numerous techniques are concentrated on circuit-layer security, they often face challenges in scalability or possess limited functionality tied to specific DSLs. The last column represents traditional security tools (e.g., AFL and property-based testing) employed by auditors in audit reports. Note that these tools typically have limited capabilities for detecting SNARK-related bugs. We excluded the integration layer from the table as no defense detects bugs in that layer.

useful in detecting completeness bugs, but it often falls short of finding soundness issues. In the following, we delve into the current defensive measures for each layer, suggest future steps for preventing SNARK vulnerabilities, and review the tools employed in the audits we examined.

Circuit Layer Defenses. The circuit layer emerges as the most prominent layer for SNARK vulnerabilities, leading to the development of various techniques like static analysis and symbolic execution, particularly targeting under-constrained bugs. Tools such as Circomspect [89] and ZKAP [91] employ static analysis using predefined rules to identify under-constrained issues in Circom circuits. Similarly, Korrect [87] utilizes static analysis and SMT solvers to spot common pitfalls in Halo2 circuits. SNARKProbe [38] leverages fuzzing and SMT solvers to test circuits written using R1CS-based libraries. Picus [74], on the other hand, adopts a more advanced symbolic execution approach to verify that Circom circuits are not under-constrained. CIVER [53] uses a modular technique based on the application of transformation and deduction rules to verify properties of Circom circuits using pre- and post-conditions. In a different approach, DSLs like Coda [64] and Leo [29, 30] support formal verification of circuits, aiding developers in creating more secure circuits.

Despite these initial strides in tool development for ZK circuits, significant limitations remain. Tools relying on SMT solvers, like Picus and Korrect, face challenges due to limited support and efficiency in handling finite field arithmetic, leading to performance bottlenecks [51, 72]. Static analysis tools are often restricted in the range of vulnerabilities they can detect and tend to be specific to certain languages. CirC [71] compiler represents a step towards language-agnostic tooling, allowing various DSLs to compile into an Intermediate Representation, which can then be analyzed for potential vulnerabilities. Another promising direction is the creation of more secure DSLs, like Aleo [28], noname [8], and Noir [9], or eDSLs such as o1js [69], which incorporate strong typing and improved abstractions to prevent common issues.

Additionally, differential testing [65] against a reference implementation could be a viable method to identify computational issues. We anticipate that proper compilation of DSL to an IR could enable more general static analysis to uncover SNARK vulnerabilities in a DSL-agnostic way. Furthermore, applying hardening techniques to automatically patch circuits with missing range checks could enhance security. Complementary to existing approaches, compositional verification techniques could be applied to verify ZK circuits. Lastly, advanced fuzzing techniques that generate slightly incorrect witnesses might prove effective in detecting under-constrained vulnerabilities, while providing counterexamples. Finally, there is a growing demand for more advanced testing frameworks in the field. Such frameworks would greatly assist developers in creating their own unit and integration tests, which could be instrumental in identifying and rectifying many easily detectable vulnerabilities prior to deployment.

Integration Layer Defenses. Table 7 highlights a notable gap: there are currently no specific defenses developed for vulnerabilities in the integration layer of SNARK systems. However, traditional security methods like property-based fuzzing or formal verification could be applicable if there's a comprehensive specification detailing the expected system behavior and its interactions with SNARK components. A promising direction for future development is the creation of

[8] https://github.com/zksecurity/noname
[9] https://aztec.network/aztec-nr/

security frameworks designed to rigorously test the integration between client-side code (such as Solidity and JavaScript) and circuit code. We suggest exploring multi-layer testing and verification techniques targeting both these components simultaneously. An example could be a combined testing of Circom and Solidity applications. Additionally, having a detailed specification of the entire system, including how different components interact, can significantly enhance the effectiveness of manual code inspection.

Frontend/Backend Layers Defenses. The infrastructure layer, comprising the frontend and backend of SNARK systems, has largely been overlooked by security researchers. Ozdemir et al. [73] acknowledged that a flaw in a ZKP compiler could undermine the integrity of a ZKP, and took initial steps to mitigate such risks by partially verifying a key compiler pass in the CirC compiler [71]. SNARKProve [38] implements a fuzzing framework that can be configured with custom files (i.e., *ideal files*) to test specific cryptographic properties of the backends and frontends. In its initial version, it has been successful in detecting issues in the Setup phase of the backend. Moreover, practitioners have employed fuzzing tools like AFL to identify bugs in these layers. However, these tools are somewhat limited in scope, typically only capable of detecting crashes, potentially missing more subtle but critical vulnerabilities such as miscompilations.

As the field progresses with more complex optimizations in the compilation stage being enabled and the introduction of more advanced proof systems, it is likely that more vulnerabilities will emerge at the infrastructure layer of SNARKs. Consequently, there is a pressing need for the development of more sophisticated testing methodologies for the infrastructure layer. Overcoming the oracle problem and generating effective test cases are key challenges in this area. Insights from the extensive body of work on testing conventional compilers [23, 24, 62, 94] could be valuable in devising strategies for more effectively testing SNARK compilers.

Tools Applied on Audits. Our analysis of the 75 audit reports we reviewed revealed that SNARK-related tools were utilized in only 5 instances. Specifically, Picus was employed in 4 audits, while ZKAP, Ecne, and Circomspect were each used once. Interestingly, one audit incorporated differential testing against a reference implementation to identify computational issues in the circuits. Moreover, traditional security tools like AFL, Semgrep, and property testing were used in 10 audits, primarily for detecting bugs at the circuit and infrastructure levels. This highlights a significant need for enhanced tooling for both the frontend and backend layers of SNARK systems.

Multi-Provers as a Defense Mechanism. SNARK proofs are often used in safety-critical contexts, yet, with the current state of technology, guaranteeing that a complex SNARK system is bug-free and safe remains an elusive goal. The multi-prover design enhances safety by introducing redundancy at the proof system level. A multi-prover system utilizes multiple proof systems besides the primary SNARK, such as alternative SNARK proofs or trusted-execution environment (TEE) based proofs [21], and primary proofs are accepted only if the secondary ones agree with it. This design trades off liveness with more safety, as a dispute will potentially bring the system to a halt. Such systems require a dispute resolution mechanism to handle potential disagreements. In practice, some ZK-Rollup projects [85], arguably one of the most complex categories of SNARK systems today, are already experimenting with multi-provers.[10]

9 Issues in Proof Systems

While the focus of earlier sections was on implementation and design vulnerabilities across the four layers introduced in Section 3.1, vulnerabilities can also exist within the theoretical foundations of SNARKs' proof systems. This includes the formal descriptions and security proofs of protocols. Such vulnerabilities are less common but carry significant implications, potentially affecting all implementations of a given proof system. For example, the "Frozen Heart" vulnerability within the Plonk proof system (c.f. Appendix **??**) led to standard implementations of Plonk being compromised. The discovery of such flaws could severely impact the SNARK ecosystem, especially protocols that depend on these systems. Vulnerabilities in the proof system generally stem from two main sources: errors in the original proof system description, including missing or incorrect security proofs or incomplete descriptions that could lead developers to introduce significant vulnerabilities during implementation.

The primary method for evaluating proof systems currently is peer review, where researchers assess security proofs, supplemented by occasional manual audits. Beyond cryptanalysis, employing tools like EasyCrypt [10] and other computer-aided cryptographic proof software [8] offers a promising avenue for formalizing and verifying the security properties of zero-knowledge protocols, as exemplified by Firsov et al.'s work [39]. It is crucial for every proof system to be accompanied by exhaustive security proofs and to undergo rigorous review before production use to prevent potential bugs.

Universal Composability. The universal composability (UC) framework by Canetti [20] is widely considered as the "gold standard" for proving the security of cryptographic primitives. The reason for the popularity of the UC model is that it can guarantee strong security against adaptive adversaries and further allows for modular reusability of cryptographic primitives in greater, high-level protocol designs. Arguing UC security for a SNARK, or a SNARK-based protocol, is non-trivial, as SNARKs commonly use techniques that are not realizable in the UC model [49], and result in SNARKs that are not formally non-malleable. Recent work aims to close this gap by studying compilers that render common

[10] https://scroll.io/blog/scaling-security

SNARKs UC-secure by encrypting the witness and including it in the argument, which results in an overhead that renders the SNARK non-succinct due to the unbounded size of the witness [1, 2, 7, 58]. Most recent work proves that initial SNARK constructions [14, 66] that *do* utilize random oracles are UC-secure [25].

In practice, we observe that UC security is often not considered, and non-UC-secure protocols, like Groth16 [50], are applied without further ado. However, we are not aware of any protocol that claims UC-security and successively got exploited due to erroneous analysis, i.e., an underspecified ideal functionality or incorrectly claiming that the real-life model can be simulated in the ideal process model.

10 Discussion

In the following, we extract insights on the current state of SNARK security, highlight key findings, discuss their implications and make recommendations for future research.

1) Insight – Under-constrained bugs pose a significant threat to SNARK deployments. Under-constrained bugs emerge as the most prevalent vulnerability class within ZK circuits. Unlike typical vulnerabilities, their root causes span from straightforward programming errors to challenges inherent in SNARK DSLs, including the complexity of translating logic to constraints efficiently. As developers navigate these peculiarities, ensuring circuits are thoroughly constrained remains crucial for maintaining system integrity and security.
RQ: *What tools and methodologies can be developed to better identify and mitigate under-constrained bugs in ZK circuits? Which techniques are the most efficient in detecting such bugs?*

2) Insight – Soundness bugs affecting SNARK verifiers lead on average to high severity bugs. Particularly when soundness bugs are exploitable, typically due to under-constrained circuits, they can lead to significant security breaches. Their potential to compromise system security has led to suboptimal strategies, such as employing multi-provers and permissioned provers, alongside significant bug bounties, sometimes reaching up to $500k for a single vulnerability. [11] These measures underscore the critical nature of soundness in maintaining the trustworthiness of SNARK-based systems.
RQ: *What are effective strategies to detect and prevent soundness bugs in SNARKs? Can we formally verify the verifiers, as their scope is limited?*

3) Insight – Low-level circuit DSLs are easy-to-misuse leading to many vulnerabilities. Crafting efficient ZK circuits often necessitates using low-level ZK DSLs such as Circom and Gnark, reminiscent of early assembly and C programming, where common high-level programming features such as abstractions and basic types are absent. This complexity not only steepens the learning curve for developers but also increases the likelihood of introducing vulnerabilities into the circuits. The prevalent use of such DSLs highlights a regression to an era with bugs due to the absence of modern programming safeguards, underscoring an urgent need for more user-friendly DSLs that offer better abstractions and safety features, thereby mitigating the main shortcomings and reducing the vulnerability surface of SNARK applications.
RQ: *How can more user-friendly DSLs be designed to reduce the vulnerability surface of SNARK applications?*

4) Challenge – The added complexity of SNARKs present challenges for developers and auditors. The inherent complexity of SNARKs introduces significant challenges for both developers and auditors, compounded by the abstraction levels of ZK circuits and the low-level intricacies of most DSLs. Developers often find themselves navigating the task of integrating critical cryptographic operations—such as digital signatures, commitment schemes, and Merkle trees—within the ZK circuits. This combination of complex cryptographic code with the unique paradigm of SNARKs places a considerable burden on ensuring accuracy and security, particularly when such code underpins the most vital or privacy-sensitive parts of an application. Hence, not only must developers acquire the technical depth of cryptographic programming within these new frameworks, but auditors must also adapt their methodologies to effectively scrutinize these sophisticated systems.
RQ: *What educational and tooling resources can assist developers and auditors in navigating the complexities of using SNARKs? How useful can specifications (formal or informal) be towards detecting vulnerabilities in systems using ZKPs?*

5) Insight – Compiler and proof system implementation bugs can undermine major protocols. Infrastructure bugs in compilers and proof system implementations can critically undermine the security of major SNARKs. Even when circuits are verified and audited, vulnerabilities in the underlying infrastructure or proof systems can jeopardize the entire application, emphasizing the importance of holistic testing approaches for the infrastructure layer of the SNARKs.
RQ: *How can the reliability and security of compilers and proof system implementations for SNARKs be ensured? Which testing or verification techniques can be applied?*

6) Challenge – Preliminary security tools show promising results but also limitations. Recent developments in tools for securing ZK circuits show promise but face scalability issues and are often limited to specific DSLs or types of vulnerabilities. The complexity of SNARK systems makes manual code inspection necessary, pointing to a significant need for better security tools and educational resources. This combination of advanced tooling and increased knowledge is crucial for improving the security of the SNARK ecosystem.
RQ: *What improvements are needed in security tools to effectively scale and cover a broader range of vulnerabilities? What are the limitations of formal verification tools?*

7) Insight – Insecure Proof System Instantiation. The selection of cryptographic curves and fields for SNARK instantia-

[11] https://aztec.network/blog/aztec-connect-postmortem/

tion is a critical decision that can significantly impact system security. Insecure choices can expose the system to potential brute force attacks similarly to other cryptographic protocols, underscoring the necessity of careful selection to ensure the overall security and integrity of SNARK applications.
RQ: *What is the security of SNARKs instantiation given specific curves and fields? How many bits of security does each SNARK have when using specific configurations?*

8) Challenge – SNARK undetectable exploits. In privacy-preserving blockchains, such as ZCash, coins enter a privacy pool (a.k.a. shielded value pool) where they can be transferred without revealing the amount or recipient address. The transaction validation mechanism relies on SNARKs and a soundness bug can enable the adversary to print infinite coins inside the privacy pool. Note that such attacks can remain undetected as long as, at any point, the amount of coins that exited the pool is smaller or equal to coins that have entered the pool previously. A partial defense against these attacks is *turnstile enforcement*, adding a consensus check to reject blocks violating pool balance, ensuring exits don't exceed entries. This highlights the need for privacy-focused SNARK systems with exploit detection and prevention mechanisms.
RQ: *How can we develop detection mechanisms or heuristics for exploits in privacy-preserving SNARK systems?*

11 Related Work

SNARK Vulnerabilities. This paper introduces a four-layer system model, defines threat models along with a detailed taxonomy of vulnerabilities and root causes across each layer in SNARK systems. Prior works have identified specific vulnerabilities within SNARKs; for example, Wen et al. [91] highlighted common vulnerabilities in Circom circuits, while others [38, 53, 74, 87, 90] have focused mainly on under-constrained vulnerabilities and proposed countermeasures. Ozdemir et al. [73] shed light on potential issues during the SNARK compilation phase. For security tools related to SNARK vulnerabilities, Table 7 offers a comprehensive overview. Additionally, the community maintains a bug tracker dedicated to ZKP-related vulnerabilities.[12] Our research complements these efforts by systematizing knowledge from the examination of 141 vulnerabilities and enriching the understanding of SNARK security.

Security of Integrity-Preserving Technologies. Integrity-preserving computation encompasses a variety of technologies, each presenting unique security challenges. Similar to our work, Cerdeira et al. [21] examined 124 CVEs within TEE-based systems and proposed a vulnerability taxonomy for TrustZone-assisted TEE Systems. Blockchain smart contracts represent another avenue for integrity-preserving computation; Praitheeshan et al. [80] identified common software and Ethereum smart contract vulnerabilities, focusing on issues prevalent at the smart contract layer. Homoliak et al. [52] introduced a multi-layered security model, systematically addressing vulnerabilities, threats, and countermeasures for blockchains. Atzei et al. [5] explored Ethereum's security vulnerabilities, offering a classification of common programming pitfalls. Zhou et al. [97] developed a five-layer model and a comprehensive taxonomy of threat models to analyze and compare incidents in DeFi. Further, Chaliasos et al. [22] used the dataset from [97] to evaluate state-of-the-practice smart contract security tools against real-world vulnerabilities. In a similar way, future work could leverage our findings to assess the efficacy of emerging security tools for SNARKs against the vulnerabilities detailed in our dataset.

12 Conclusions

In this work, we present comprehensive system and threat models for SNARK systems' security, a detailed study, and a taxonomy of 141 vulnerabilities, demonstrating that security breaches can affect every layer of systems employing SNARKs, jeopardizing completeness, soundness, and zero-knowledge properties. Our work reveals the intricate and unique security challenges inherent to SNARKs, indicating that defense mechanisms focusing on SNARK security have significant limitations. By highlighting key insights and potential advancements in security practices, we underscore the urgency for continued research and enhanced defenses within the SNARK ecosystem. As SNARKs become increasingly pivotal in cryptographic applications, our study emphasizes the necessity for progressive and fortified security measures to ensure the robustness of these systems.

SECURITYNET: Assessing Machine Learning Vulnerabilities on Public Models

Boyang Zhang Zheng Li Ziqing Yang Xinlei He Michael Backes Mario Fritz Yang Zhang

CISPA Helmholtz Center for Information Security

Abstract

While advanced machine learning (ML) models are deployed in numerous real-world applications, previous works demonstrate these models have security and privacy vulnerabilities. Various empirical research has been done in this field. However, most of the experiments are performed on target ML models trained by the security researchers themselves. Due to the high computational resource requirement for training advanced models with complex architectures, researchers generally choose to train a few target models using relatively simple architectures on typical experiment datasets. We argue that to understand ML models' vulnerabilities comprehensively, experiments should be performed on a large set of models trained with various purposes (not just the purpose of evaluating ML attacks and defenses). To this end, we propose using publicly available models with weights from the Internet (public models) for evaluating attacks and defenses on ML models. We establish a database, namely SECURITYNET, containing 910 annotated image classification models. We then analyze the effectiveness of several representative attacks/defenses, including model stealing attacks, membership inference attacks, and backdoor detection on these public models. Our evaluation empirically shows the performance of these attacks/defenses can vary significantly on public models compared to self-trained models. We share SECURITYNET with the research community[1] and advocate researchers to perform experiments on public models to better demonstrate their proposed methods' effectiveness in the future.

1 Introduction

Machine learning (ML) has been gaining momentum in multiple fields and achieving success in real-world deployments. However, in recent years, researchers have shown that ML models are vulnerable to various security and privacy risks, such as membership inference [50], model stealing/extraction [53], and backdoor [21]. Quantifying and mitigating ML models' vulnerabilities thus become increasingly important topics.

Currently, most of the research in this field focuses on proposing different attacks and countermeasures. To evaluate these methods, the common practice is that the researchers train models by themselves and treat these models as potential victims' models (target models) in the experiments. Based on some of the well-known papers on two popular attacks against ML models, including membership inference and model stealing [10, 25, 28, 32, 36, 38, 44, 46, 52, 55, 61], we find that all of them conduct experiments on target models trained from scratch by the authors.

This practice, however, faces several limitations. The behavior of the models can vary greatly on different architectures and different datasets. Since training state-of-the-art ML models is resource-intensive and time-consuming, the target models used in machine learning security and privacy research tend to be limited to the most popular architectures trained on the common and approachable experiment datasets (e.g., CIFAR-10 [1], CIFAR-100 [1], and SVHN [2]). Also, the number of models used in the evaluation is often small.

Furthermore, even with the same model architecture and dataset, different procedures and hyperparameters used for training can still drastically alter the model's behavior. For state-of-the-art models, huge efforts are dedicated to fine-tuning hyperparameters to find the best training procedures, thus maximizing the chosen model architecture's potential on the target task. Since research in security and privacy tends to focus on developing attacks and countermeasures, it is unrealistic for the researchers to have a similar level of dedication to training their victim models. Subsequently, the victim model in the experiments might not be adequately trained, whereby the model's performance on the target task is lower than the given architecture's best result (we show evidence in Section 2).

Publishing models with weights on the Internet (*public models*) is becoming a common practice in the machine learning community to increase research reproducibility and pro-

[1] We publish SECURITYNET at https://github.com/SecurityNet-Research/SecurityNet.

vide benchmarks on different ML tasks. These public models cover a wide variety of model architectures and datasets. Moreover, many of these public models are already integrated into companies' products deployed in the real world. For instance, certain transformer models on Hugging Face[2] have been integrated into Amazon SageMaker.[3] *To fully assess the effectiveness of different attacks and defenses on machine learning models, we argue that the experiments should be conducted on such public models when possible.*

1.1 Our Contributions

In this work, we take the first step towards conducting ML models' security and privacy vulnerability evaluation on public models. We collect a large-scale dataset of public models, namely SECURITYNET, to evaluate three popular attacks/defenses in this field, including membership inference attack, model stealing attack, and backdoor detection. We omit the popular topic of evasion attacks due to existing benchmarks [16, 24], but we do include baseline results and discussion in Appendix C. Note that we focus on image classification models as they have been extensively studied by the trustworthy machine learning research community.

SECURITYNET. We build a public model database SECURITYNET by collecting a large number of public models used for image classification from multiple open-source platforms on the Internet, such as Paper with Code [3], Kaggle [4], and GitHub [5]. Many of our public models come from machine learning libraries that contain models with various architectures trained on multiple datasets. These models are usually trained for performance benchmarks, so they have as high as possible prediction accuracy on the target task (of the given architectures). We refer to such models as *benchmark models*. We further manually search for publicly available models from research papers published in top-tier security, machine learning, and computer vision conferences. Among these models from the research papers, we refer to those related to the topic of machine learning security and privacy as *security models*, and the rest are considered as part of the benchmark models. We notice that most of the security models are used for adversarial example research. In general, benchmark and security models will be the main focus of our analysis.

SECURITYNET comprises 910 models covering 42 different datasets. For each model in SECURITYNET, we further annotate its relevant information from three dimensions, namely dataset (e.g., sample size, split ratio, topic category, class fidelity, etc.), model (e.g., number of parameters, FLOPs, architecture type, etc.), and metadata (e.g., publisher type, published year, venue, model purpose, etc.). We hope this information can help security researchers find appropriate public models promptly. Also, we will continue enlarging SECURITYNET with newer models to monitor whether ML models are more or less susceptible to the attacks investigated over time. We plan to share SECURITYNET with the research community to facilitate the research in machine learning security and privacy.

Evaluation Results. With the help of SECURITYNET, we are able to perform an extensive analysis of model stealing, membership inference, and backdoor detection on a large set of public models. To the best of our knowledge, this has not been done before. Our experiments confirm some known results from the literature (but on a much larger number of models), uncover some new insights, and show that attacks and defenses can behave differently on public models than on researchers' self-trained models.

For model stealing on benchmark models from SECURITYNET, we find using a larger and more complex surrogate model architecture to limit the difference between the surrogate and victim models does not improve the attack performance, which differs from previous results [41]. Also, we observe a negative correlation between the attack performance and the victim model's target task performance. Such a negative correlation has been observed in [27] previously; our experiments on a much larger number of (public) models further confirm this. In addition, if the target model is too complex (we test model stealing on a RegNetY-320 model [45] with 145 million parameters for the first time), model stealing is ineffective. The public models trained for security and privacy research (security models) typically perform much worse on their target tasks than the benchmark models. Interestingly, for the low-performing security models, we observe a positive correlation between the attack and the target task performance (the opposite of our observation on benchmark models). All these new insights demonstrate the benefits of performing model stealing experiments on public models.

For membership inference, we evaluate two types of attack methods, namely metric-based attacks [51] and MLP-based attacks [39, 46, 50]. We empirically confirm some results shown in previous works [50], e.g., the attack performance positively correlates with the model's overfitting level on the target task on the large-scale public models. On the other hand, we also discover that the attack methods can be dataset-dependent. For instance, previous works show that the MLP-based attack using full posteriors as its input has the same performance as using the top-k (e.g., top-3) posteriors [46]. However, on datasets with a large number of classes, e.g., 1,000 classes (ImageNet-1k [17]), we show that using top-3 posteriors as inputs achieve much better performance than full posteriors (on average, the attack AUC increases by 5.1%). Some of the security models with lower performance on their target tasks appear to be less vulnerable to membership inference attacks than benchmark models, even when they share a similar overfitting level. We do not make the same observation on security models that achieve similar target task performance as benchmark models.

[2] https://huggingface.co/.
[3] https://aws.amazon.com/machine-learning/hugging-face/.

Finally, we examine three backdoor detection techniques on the public models from SECURITYNET: Neural Cleanse [56], Strong Intentional Perturbation (STRIP) [18], and NEO [54]. Assuming all the benchmark models collected are non-backdoored, we discover that Neural Cleanse has high false positive rates on benchmark models trained on CIFAR-10 and SVHN (20.9% and 13.7%, respectively). By manually checking the generated trigger images, we confirm that the detected triggers are indeed falsely identified. On the other hand, both STRIP and NEO are more robust. They successfully avoid labeling any clean inputs as backdoored samples on CIFAR-10 and SVHN models in our experiments. This again shows the necessity of evaluating attacks and defenses on public models.

Implications. This work aims to provide a more realistic overview of the landscape of machine learning attacks and defenses. We also want to point out that some of the current evaluation results on researchers' self-trained models might not generalize to public models. We advise researchers to examine their proposed methods on at least a few public models for more comprehensive evaluations in the future. Hence, we will share SECURITYNET. We hope our annotations and experiment results on baseline attacks/defenses will greatly minimize the effort for researchers to find appropriate public models for their purpose.

2 SECURITYNET

One of the main contributions of our work is SECURITYNET, a database containing publicly available models with weights. We focus on one of the most popular machine learning tasks, image classification, as it is also typically used to demonstrate the effectiveness of attacks and defenses on ML models.

2.1 Model Collection

Datasets to Models. Our main model collection process, namely datasets to models, consists of two steps, namely dataset searching and model collection. In a nutshell, we first find a diverse set of datasets and then collect public models trained on these datasets.

For dataset searching, we focus on image datasets that are mainly used for classification tasks. Note that we also plan to extend to other types of tasks in the future. The diversity of the datasets is critical. We consider two sources for dataset collection, namely Paper with Code [3] and Kaggle [4]. Paper with Code is a website that provides open-source content, including machine learning papers, codes, datasets, methods, and evaluation results. The website's collection of datasets covers the majority of datasets commonly used for machine learning research. Kaggle is a crowd-sourcing platform that is popular in the data science community. It is well-known for hosting data science competitions and challenges in cooperation with many companies and research institutes. The datasets used in these competitions have a huge variety and typically differ from the experiment datasets collected from Paper with Code.

After collecting a variety of datasets, we then use these datasets as a starting point to search for publicly available models trained on these datasets. Our search can be summarized in a few directions. First and foremost, pre-trained model libraries are some of the most valuable sources, such as PyTorch's official torchvision library.[4] They typically contain a wide range of popular models that are trained to have high performance on the target tasks. We refer to these models as *benchmark models*. Models from reputable sources also provide high confidence in their qualities. These qualities, including no additional data used, a proper partition of training and test data, no malicious data (e.g., backdoor triggers), etc., are especially important for our later analysis. These model libraries, however, also suffer some downsides. Specifically, these libraries typically contain only well-established architectures and benchmark experiment datasets.

Furthermore, we extend our benchmark model collection to other sources, such as models from Kaggle competitions and Paper with Code. These sources provide a much wider range of models in several dimensions, such as model variety, purpose, and quality. We emphasize here that due to the wide range of sources in our model collection, the quality of the models cannot be guaranteed in the same way as with reputable sources (e.g., the Pytorch torchvision library). However, this variation in model quality yields a valuable comparative dimension to our analysis.[5]

Additionally, there are models that we do not include in the database. We exclude models with corrupted weights that cannot be loaded properly or have extremely low performance. Moreover, the same model can appear on multiple platforms. We also exclude these duplicates to avoid over-representation of the same model.

Academic Papers to Models. Furthermore, to obtain an overview of the current models used in research, we manually search for image classification models provided by authors of papers published in recent top-tier conferences. We consider the following security & privacy, machine learning, and computer vision conferences in the last four years: IEEE S&P, USENIX Security, ACM CCS, NDSS, NeurIPS, ICML, ICLR, CVPR, ICCV, and ECCV. To simplify the process, for machine learning and computer vision conferences, we directly search on GitHub for the corresponding repositories (e.g., using keywords "CVPR 2022"). Considering the popularity of GitHub, we believe we capture the majority of the published models in those venues. Meanwhile, for security conferences, we manually check all papers to obtain the models.

[4] https://github.com/pytorch/vision.

[5] For simplicity, these models are also considered as benchmark models in SECURITYNET.

(b) Top Benchmark Model Types

(c) Top Security Model Types

(d) Top Countries Regarding Model Type

(e) Top Venues Regarding Model Type

(f) Top Benchmark Models' Datasets

Figure 1: SECURITYNET statistics.

We also especially focus on models from papers on the topic of trustworthy machine learning from all the conferences considered and refer to them as *security models*. During our collection process, we noticed that the majority of the security models are derived from papers on adversarial example studies. Unfortunately, we cannot find any public models on model stealing and membership inference.[6] Overall, the addition of these models will allow us to conduct a more comprehensive analysis in Section 4. Note that the models from research papers that are not related to security and privacy are considered benchmark models as well.

2.2 Annotation

Once having collected the models, we then annotate their relevant information.[7] The annotation serves two purposes. First, it provides a guideline for our analysis of the current landscape of security and privacy attacks/defenses. Second, it serves as a valuable source for future research.

The annotation for models in SECURITYNET includes quantitative information about their training sets, such as the number of classes, size, image dimensions, etc. Furthermore, we record qualitative information, such as topic categories. Our models' datasets cover a broad range of topics, including natural scenery, medical scans, traffic signs, satellite images, and more. Within each topic category, we further distinguish the dataset's class granularity. For example, while ImageNet-1k and CUB-200-2011 are both categorized as natural scenery, ImageNet-1k includes multiple types of objects ranging from different animals to cars and park benches. We label datasets like ImageNet-1k as coarse-grained datasets. CUB-200-2011 only contains images of different types of birds. Therefore, it is labeled as a fine-grained dataset.

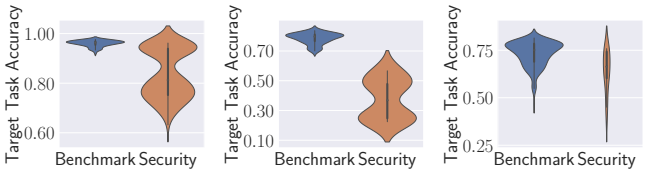
Besides models' datasets, we further annotate their intrinsic properties and metadata. Intrinsic model properties include the number of parameters, FLOPs, architecture type, presence of certain elements (e.g., dropout, batch normalization), etc. We also annotate the models' metadata, such as publishing venues (for research-based models), number of authors, etc. Given the large number of models we have collected, we can analyze different attacks and defenses from the metadata dimension, which, to our knowledge, has not been done before. Appendix A in the appendix provides the complete list of categories annotated by us for SECURITYNET.

2.3 Summary

In total, SECURITYNET contains 910 public models, of which 665 are benchmark models and 245 are security models. These models are trained over 42 different datasets from 13 categories. The models cover an extensive set of 220 architectures (e.g., ResNet-18 [23], ResNet-50, DLA-169 [58], BagNet-33 [7], etc.) based on 60 different model types (ResNet, DLA, BagNet, etc.). The oldest model type included was first introduced in 2012 [30] and the latest one [37] in 2022. Note that for benchmark models, we record the year when the model type was first introduced instead of the trained models' publishing time. Figure 1 shows some general statistics of the models in SECURITYNET.

Model collection for SECURITYNET will be a continuous

[6] Note that for backdoor attacks, our goal is to apply the current backdoor detection methods to the public models. Thus, we do not include the backdoored models published with backdoor-related research papers in our database.



[7] We explain our annotation process in detail in Appendix A.

process. We plan to update SECURITYNET on a bi-annual basis to add new publicly available ML models. This allows us to keep tracking ML models' security and privacy vulnerabilities over time. We will also make SECURITYNET easily accessible to the research community.

Security Models vs. Benchmark Models. Based on the models collected, we first observe that the majority of the security models are trained on small experiment datasets, such as CIFAR-10, CIFAR-100, and SVHN. Only a small amount of the papers include results on more complex datasets like ImageNet-1k. These four datasets also cover the majority of the papers on security and privacy research that we have found. Besides, the model architectures used in security models are also limited, e.g., the majority of the architectures are the simpler and popular ones, such as ResNet-18, VGG-16, etc. Figure 2 shows the model performance difference between the benchmark models and the security models trained on CIFAR-10, CIFAR-100, and ImageNet-1k. We only use benchmark models that share similar architectures with the security models so that the inherent differences in model architectures do not affect the comparison. For CIFAR-10 and CIFAR-100 (too few models for ImageNet-1k), we notice that there are two distinct clusters of models, and both have lower performance than benchmark models. From Figure 3, we can observe the overfitting gaps between benchmark models and security models are not too different for CIFAR-10 and ImageNet-1k models, while CIFAR-100 security models have a lower overfitting level in general. Note that the security models here are for adversarial example research, and we cannot find any published target models for model stealing and membership inference. Nevertheless, some of the membership inference and model stealing papers' reported target task accuracy is still lower than the benchmark models' accuracy in SECURITYNET. For instance, CIFAR-100 models from the popular papers in Section 1 have an average accuracy of 69.0%, compared to our benchmark models' average accuracy of 78.5%. Additionally, we find the performance gap still exists in recently published papers (CIFAR-10: 79% [13]; CIFAR-10: 77%, CIFAR-100: 20% [57]). We believe these security models are not trained to the architecture's maximum "potential" due to limited hyperparameter tuning efforts. For simplicity, previous works [6, 36] in the security/privacy domain only use one set of batch size, learning rate, optimizer, etc., without further hyperparameter fine-tuning. In conclusion, the above results demonstrate that some security models are not adequately trained compared to benchmark models.

3 Attack Methodology and Evaluation Setup

In this paper, we study three types of attacks/defenses on machine learning models, namely model stealing attack, membership inference attack, and backdoor detection. They are among the most well-explored subjects in the field of machine learning security and privacy. In the future, we plan to extend our analyses to other types of attacks/defenses with models from SECURITYNET.

(a) CIFAR-10 (b) CIFAR-100 (c) ImageNet-1k

Figure 2: The model's target task performance with respect to benchmark models and security models.

(a) CIFAR-10 (b) CIFAR-100 (c) ImageNet-1k

Figure 3: The model's overfitting level with respect to benchmark models and security models.

3.1 Model Stealing

Threat Model. In this attack, the adversary aims to build a surrogate model that mimics the target model's behavior. Following one of the most popular attacks [53], we consider an adversary with black-box access to the target model that outputs the full posterior. The adversary also has access to an auxiliary dataset for querying the target model. Note that the auxiliary dataset does not necessarily come from the same distribution as the original training set.

Methodology. The adversary first initiates a surrogate model which can adopt a different architecture than the target model [41]. Then, the adversary queries the samples from their auxiliary dataset to the target model and gets the output posteriors. In the end, the adversary trains their surrogate model leveraging the posteriors as ground truth.

In our experiments, we adopt ResNet-18 to initiate the surrogate models. We further show in Section 4.1 that a more complex surrogate model does not increase the attack performance. We consider two settings for the auxiliary datasets, i.e., partial training set[8] from the target model's training set (default setting) and a large out-of-distribution dataset (specifically, a subset of ImageNet-1k). We train ResNet-18 for 30 epochs using an SGD optimizer with a learning rate of 0.01.

Metrics. We adopt two most widely-used metrics, namely attack accuracy and attack agreement [27], in the evaluation.

[8] We use 50% of the total training data. We evaluate how different query budget affects the attack performance in Appendix B.

Accuracy measures the performance of the surrogate model on the original task, while agreement calculates the prediction agreement between the surrogate model and the target model.

3.2 Membership Inference

Threat Model. The adversary aims to determine whether a given sample is used to train a target model [50]. Following the existing work [36, 39], the adversary is assumed to hold a small subset of the training data which is used as member samples[9] and an auxiliary dataset that represents non-member samples. Note that we use the test set of the corresponding dataset as this auxiliary dataset. For instance, when experimenting on models trained on ImageNet-1k, the auxiliary dataset is ImageNet-1k's test set. The adversary also has access to the black-box target model that outputs full posteriors.

Methodology. We use two popular attacks, namely metric-based [51] and MLP-based [46, 50] attacks. The former distinguishes member (training) samples from non-member (auxiliary) samples based on behavioral differences in prediction statistics, such as prediction correctness and modified prediction entropy [51]. For MLP-based attacks, the adversary feeds the member and non-member samples to the target model and gets the output posteriors. The adversary then trains an attack model (i.e., a binary classifier) based on the posteriors. In our experiments, the attack model is assembled with one layer of 64 neurons and one layer of 32 neurons using the ReLU activation function. We train the attack model for 50 epochs using the Adam optimizer with a learning rate of 0.01.

Metrics. We use AUC to evaluate the attack performance. The higher the AUC, the better the performance is. Concretely, 0.5 represents random guessing, and 1.0 is a perfect prediction.

3.3 Backdoor Detection

In backdoor attacks, the adversary injects the backdoor into the target model without degrading its original performance [12]. Generally, there are two types of backdoor attacks, i.e., untargeted and targeted. Untargeted attacks aim to misclassify triggered images, while targeted attacks misclassify triggered images to one specific class. There exist various types of defenses against backdoors [11, 15, 18, 22, 26, 34, 35, 54, 56]. Since the backdoor injection occurs during training and models in SECURITYNET are already trained, we choose to evaluate backdoor detection methods on these models.

[9] In many membership inference research, such as [39, 46, 50], the adversary is assumed to have a shadow dataset to train their shadow model. To conduct experiments, the researchers split a dataset into four equal parts: two are used as the target model's training and test sets, and the other two are for the shadow model. We cannot follow the same setting here as the models in SECURITYNET are all trained. Thus, we make a stronger assumption for the adversary having access to a partial training set of the target model [36, 39]. Such a stronger assumption also allows us to assess the worst-case scenario of membership leakage threat.

Methodology. We evaluate three popular backdoor detection methods: Neural Cleanse [56], Strong Intentional Perturbation (STRIP) [18], and NEO [54]. The three cover two types of approaches: model inspection and input filtering.

Neural Cleanse is a model inspection approach that aims to detect targeted backdoor attacks. The key idea of this method is to find the minimal trigger needed to misclassify all samples into each label and leverage an outlier detection method to detect if any trigger candidate is smaller than all the other candidates. If such an outlier exists, the model is potentially backdoored, and the trigger can be returned for further analysis. We run Neural Cleanse for 50 epochs and use their default threshold value for detecting outliers.

STRIP is an input-filtering approach. The key idea is that triggered inputs are less affected by perturbations than normal inputs. By overlaying various images on the incoming input, the detector examines the randomness (prediction entropy) of the model's prediction on the overlaid input. The detection considers the model is backdoored if the prediction entropy is low. We use 2,000 images for testing and the default number of 10 images for overlaying input.

NEO is another input-filtering approach. The key idea is that triggers within the input contribute the most to the prediction. The detection first calculates the dominant color of the image, then randomly selects a small region in the input image and replaces it with the dominant color. If the new prediction differs from the original one, NEO assumes the selected region contains a potential trigger and then superimposes it onto the test set. If most of the test sets have different predictions after adding the potential trigger, the current input image is labeled as a backdoored image, and the model is also identified as a backdoored model. We use 200 sampled 4×4 regions (for 32×32 images) and 3 K-means clusters for calculating the dominant color; 0.8 is adopted as the threshold.[10] We use 2,000 images from the test set for evaluation.

Metrics. As the models in SECURITYNET are supposedly free of backdoors, we adopt the false positive rate to evaluate whether these detection methods can falsely recognize clean models as backdoored ones.

4 Experiment Results

4.1 Model Stealing

We now evaluate the performance of model stealing attacks on public models from SECURITYNET.

The Effect of Target Model's Training Set. For our evaluation, we primarily use 389 benchmark models trained on CIFAR-10, CIFAR-100, SVHN, ImageNet-1k, and CUB-200-2011 datasets. These models cover a wide variety of architectures that allow us to make more comprehensive observations

[10] If more than 80% of the images are misclassified after adding the trigger, the trigger is then confirmed.

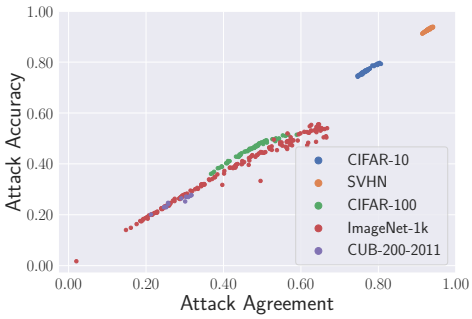


Figure 4: The relationship between the attack agreement and the attack accuracy for model stealing on benchmark models across multiple datasets.

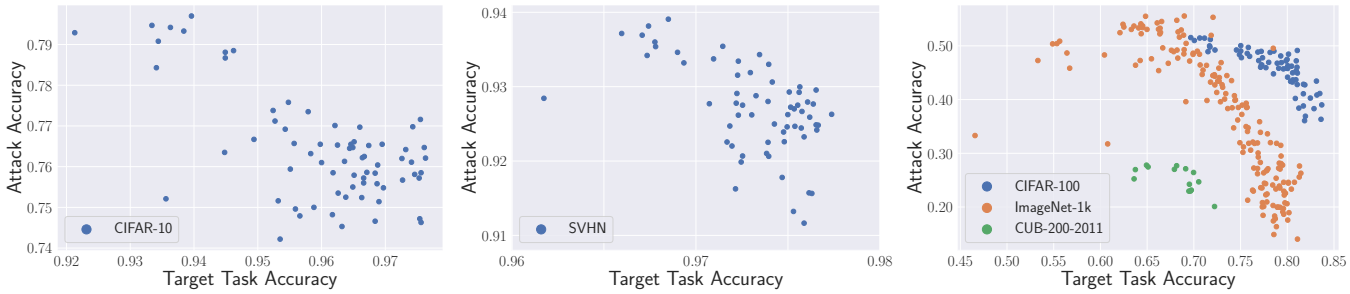
on attack behaviors. First, as seen in Figure 4, we observe a strong positive correlation between the two evaluation metrics (with a 0.991 Pearson correlation coefficient), i.e., the attack agreement (see Section 3) and the attack accuracy on all 389 models. Due to the page limit, we mainly use attack accuracy as the metric for model stealing in the following analysis. Secondly, Figure 5 shows that the attack achieves exceptionally high performance on datasets with a small number of classes and abundant training data, such as CIFAR-10 and SVHN. For more complex datasets like ImageNet-1k, CIFAR-100, and CUB-200-2011, however, the attack performance significantly deteriorates. For instance, the average attack accuracy for ImageNet-1k models is 36.3% while the average target models' accuracy is 73.1%, i.e., the ratio of the two is 0.496. Meanwhile, the corresponding ratios for CIFAR-10 and SVHN models are 0.796 and 0.953. In addition, we find that while the target task performance of CUB-200-2011 models is similar to that of ImageNet-1k models, the attack accuracy on CUB-200-2011 models is significantly lower.[11] Note that ImageNet-1k has more classes in total, but CUB-200-2011 has higher class granularity, which means the two datasets have comparable classification complexity. These results indicate that the model stealing attack is especially ineffective on some outlier datasets, which, to our knowledge, has not been shown previously.

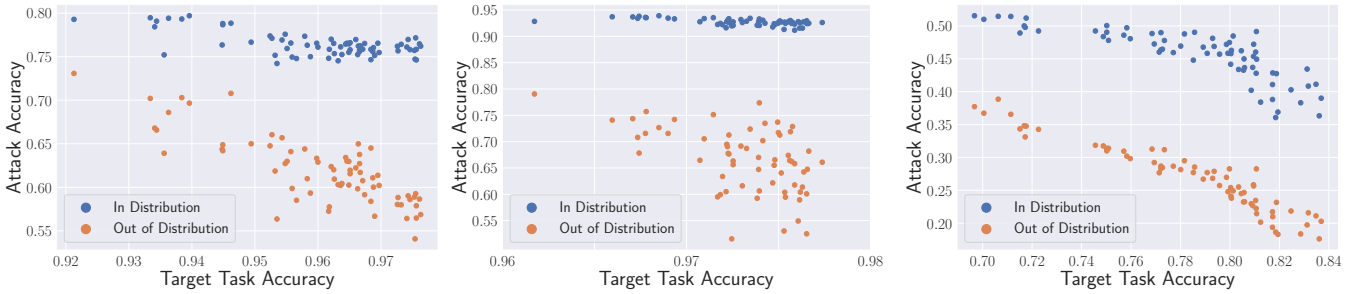
Out-Of-Distribution Auxiliary Dataset. While by default, we assume the adversary has access to a partial training set as the auxiliary dataset, we now consider another scenario where the adversary uses an out-of-distribution dataset to initiate their attack. More concretely, we leverage a subset of the large and diverse ImageNet-1k dataset as the auxiliary dataset to steal benchmark models trained on CIFAR-10, SVHN, CIFAR-100, and CUB-200-2011. Figure 6 shows the attack performance deteriorates across a large number of benchmark models when using the out-of-distribution auxiliary dataset. In addition, we find that the attack performance on SVHN models decreases more significantly than on CIFAR-10 models. For instance, the average attack accuracy decreases by 27.8% on SVHN and 19.0% on CIFAR-10, respectively. We suspect this is due to the fact that the images in ImageNet-1k are more similar to the images in CIFAR-10 than to the images in SVHN.[12] Further, on a more complex dataset, the attack performance can suffer even greater, e.g., with an average degradation of 41.7% on CIFAR-100. For the previous poor-performing CUB-200-2011 models, the attack accuracy also decreases by 21.4%, even though the auxiliary dataset contains many classes similar to the original dataset (e.g., bird species), and overall has more samples than the original partial training set (100k vs. 5k). In summary, we find that using out-of-distribution data as the auxiliary dataset does not benefit model stealing.



The Effect of Target Model's Performance. From the perspective of target models' inherent properties, we mainly study the relation between their target task performance and the corresponding model stealing attacks' performance. Figure 5 shows a distinct negative correlation between the two. While the correlation is clear on both smaller datasets, such as CIFAR-10 (-0.693) and SVHN (-0.603), it is more evident on larger and more complex datasets, like ImageNet-1k (-0.844) and CIFAR-100 (-0.873). We present the Pearson correlation coefficients in the parenthesis. This negative correlation has been observed by Jagielsk et al. [27] previously. Our finding, however, differs in magnitude. Due to the wide range and variety of benchmark models, we find that the attack is largely likely to fail on high-performing models. For example, on most ImageNet-1k models with target task accuracy above 75%, the attack accuracy does not surpass 40%. In a more concrete example, our model stealing attack on RegNetY-320 [45] with 146 million parameters only achieves 25.6% attack accuracy. This implies that the model stealing performing well on simpler architectures does not guarantee success on complex and high-performing models.

More Complex Surrogate Model. All results above are done using the ResNet-18 architecture as the surrogate model. Previous work [41] has shown that using a more complex surrogate model can improve model stealing performance. We now conduct the attack with a larger surrogate model, i.e., WRN-50 [59], to evaluate whether similar observations can be made on benchmark models as well. Figure 7 shows the attack performance actually deteriorates on all three datasets. Specifically, for the SVHN, CIFAR-10, and CIFAR-100 models, the attack accuracy degrades by an average of 5.8%, 29.0%, and 47.3%, respectively. In contrast to previous work, our experiments show that larger and more complex surrogate models do not improve model stealing performance on SECURITYNET.

Benchmark vs. Security Models. As mentioned in Section 2, we also extensively search for public models used in security/privacy research (named security models). Here, we exam-



[11] Note that the model stealing performance on CUB-200-2011 in [41] is higher than ours, this is because the authors fine-tune their surrogate model and target model on base models pre-trained with ImageNet-1k.

[12] Previous work [41] makes similar observations.

ine whether the attack behaves differently on security models compared to the benchmark models above.

Recall that the security models trained on CIFAR-10 can be divided into two clusters in terms of target task performance (see Figure 2). Both Figure 8 and Figure 9 show the cluster of high-performing security models behave very similarly to the benchmark models, where the two evaluation metrics have a high agreement, and the attack performance is negatively correlated (-0.362) with model's target task performance. Interestingly, the low-performing cluster shows drastically different behavior. First, many of these models have high attack agreement while the attack accuracy varies. Secondly, the correlation between the attack accuracy and target task accuracy is distinctively positive (0.998). We find models used for studying model stealing attacks in previous works [36] exhibit similar behavior.[13] This drastic change in correlation indicates that when the target model is not trained to its maximum "potential," the attack can behave differently.

[13]We can infer the same positive correlation from the negative correlation between their models' overfitting level (the difference between training and test accuracy) and the model stealing performance since all of their models have 100% training accuracy.

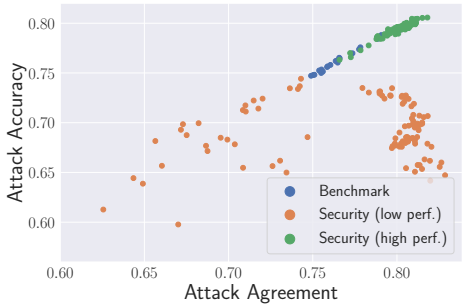

Figure 8: The relationship between the attack agreement and the attack accuracy for model stealing on CIFAR-10 benchmark and security models.

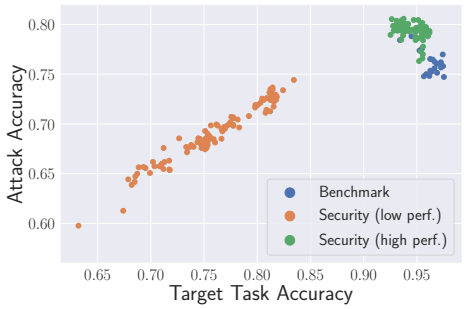

Figure 9: The relationship between the model stealing performance (attack accuracy) and the target model's task accuracy on CIFAR-10 benchmark and security models.

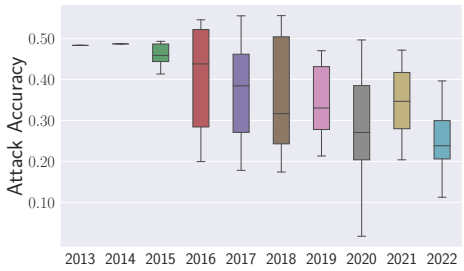

Figure 10: The model stealing performance (attack accuracy) with respect to the publication year.

For future research on the security and privacy of machine learning models, we advise the researchers to use benchmark models when possible or train the target models to high performance.

Metadata. Next, we examine how some metadata relates to the attack performance using public models trained on ImageNet-1k. On the time dimension, Figure 10 shows the model stealing attack is generally less effective on newer models, which may be due to the higher performance of the newer models, see Figure 11. Besides, as the violin plot shows in Figure 12, the distribution of the CV domain is much wider than that of other domains, which means that computer vision conferences are the more popular venue for publishing new

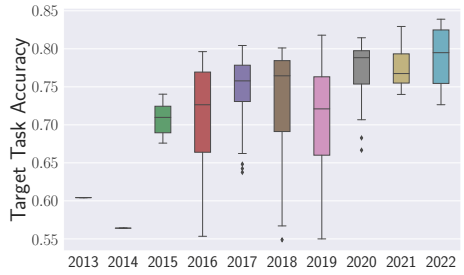

Figure 11: The model's target task performance with respect to the publication year.

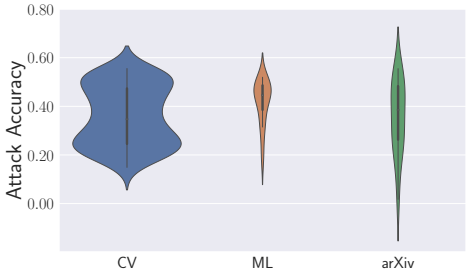

Figure 12: The model stealing performance (attack accuracy) with respect to the conference type.

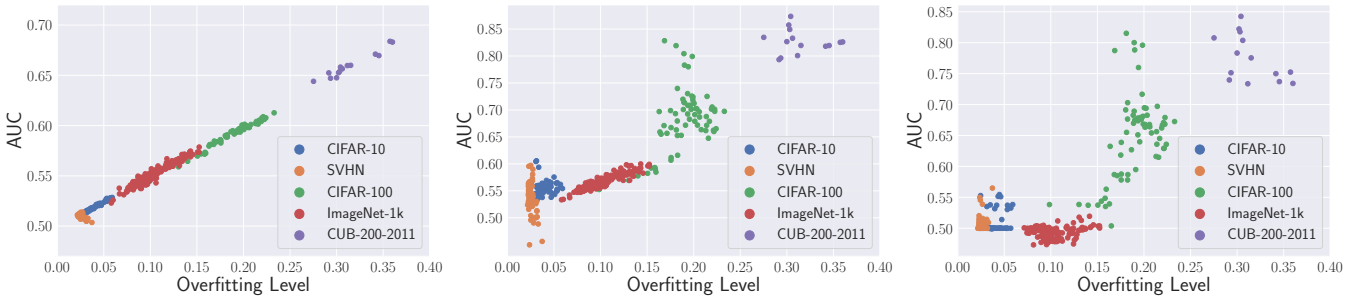
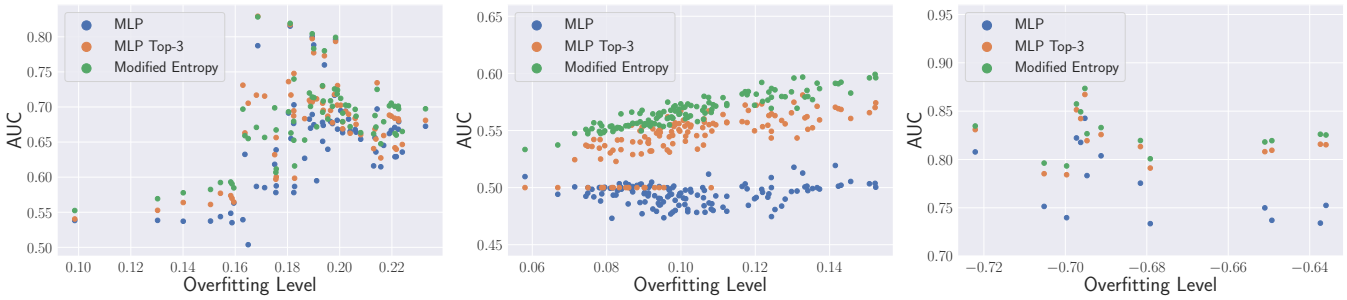


model architectures. However, the attack shows no significant difference between different types of publishing venues.

4.2 Membership Inference

We next evaluate the performance of membership inference attacks on public models from SECURITYNET.



The Effect of Target Model's Overfitting Level. Similar to the previous section, we compare the attack performance on benchmark models trained on several different datasets. First of all, we evaluate the membership inference attack performance on benchmark models with respect to their overfitting level. Here, the overfitting level means the difference between training and test accuracy on models' original datasets [36]. As shown in Figure 13, we make similar observations as in many previous works [36, 50], where membership inference achieves better performance on victim models with a higher overfitting level. We can still find such an association even when the overall attack is not very effective. For instance, the correlation is still present on CIFAR-10 (0.204) and ImageNet-1k (0.247) models, even though the AUC is generally lower than 0.6. This correlation is expected since the attack relies heavily on the different distributions of posterior probabilities between member and non-member samples.

The Effect of Target Model's Training Set. We also compare the membership inference attack performance from the perspective of the target model's training set. For models trained on simpler datasets with a small number of classes and sufficient training data, the attack performs poorly, as seen

(a) Prediction Correctness (b) Modified Entropy (c) MLP Full Posterior

Figure 13: The performance (AUC) of different membership inference attacks with respect to the target model's overfitting level.

(a) CIFAR-100 Models (b) ImageNet-1k Models (c) CUB-200-2011 Models

Figure 14: The performance (AUC) of MLP-based and metric-based membership inference attacks with respect to the target model's overfitting level.

in Figure 13. More concretely, for the SVHN and CIFAR-10 models, the average attack performance is only slightly better than random guessing, with an AUC around 0.565 for the modified entropy attack, and not better than random guessing in most cases for the MLP-based attack. However, many previous works [46, 50] evaluate their attack performance using these two datasets and achieve much higher performance than random guessing, which is quite inconsistent with our observations on benchmark models. This is likely due to the higher prediction accuracy and the lower overfitting level of the benchmark models in SECURITYNET compared to the self-trained ones in previous works.

For more complex datasets, e.g., CIFAR-100 and CUB-200-2011, the attack performance is significantly better than the previous two simple datasets. For instance, the modified entropy attack can achieve higher than 0.8 AUC on almost all CUB-200-2011 models. These results indicate that even these heavily fine-tuned benchmark models cannot achieve the low overfitting level as the ones on simpler datasets.

Interestingly, the membership inference attack does not achieve high performance on the benchmark ImageNet-1k models, even though the overfitting level is not as low as that of the ones trained on simpler datasets. We suspect the large and diverse training set for these benchmark models makes the task of membership inference more difficult. To our knowledge, this observation has not been made previously.

Different Attack Methods' Effectiveness. As mentioned in Section 3.2, we evaluate three attack methods, namely prediction correctness (metric-based) attack, modified entropy (metric-based) attack, and MLP-based attack. Our experiments demonstrate that the modified entropy attack and MLP-based attack show varying degrees of success and correlation with overfitting level, depending on the training set of the victim model, as previously seen in Figure 13. The prediction correctness attack, unlike the other two, strictly follows the model's overfitting level across all datasets evaluated,[14] which implies its better transferability to unknown models and datasets. This method, however, achieves only limited success even on models with high overfitting levels and generally performs worse than the other two methods.

We also observe that the MLP-based method yields poor performance on ImageNet-1k models, given the relatively high overfitting level of these models. We suspect that the dimensions of the full posterior inputs commonly used in these models are too large for the MLP-based attack. To accommodate the large input dimension, we select only the top-3 largest posteriors as input to make the attack model more sensitive to important information in the posterior. Different from observations in previous work [46], Figure 14 shows the MLP-based attack improves significantly on ImageNet-1k models and reaches similar performance as the modified

[14] SVHN models' overfitting levels are too low for the attack to be stable.

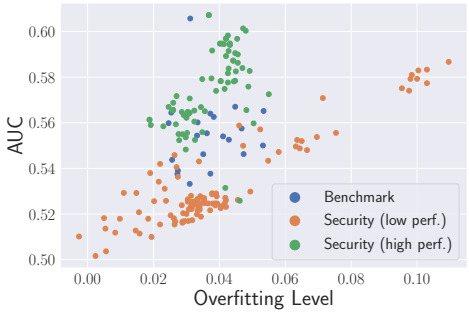


Figure 15: The membership inference performance (AUC) with respect to the target model's overfitting level on CIFAR-10 benchmark and security models.

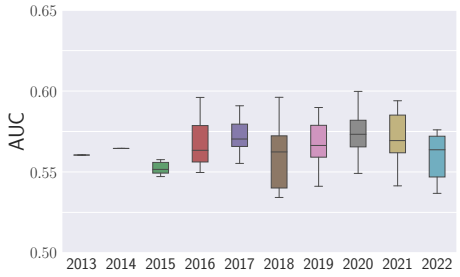

Figure 16: The membership inference performance (AUC) with respect to the publication year.

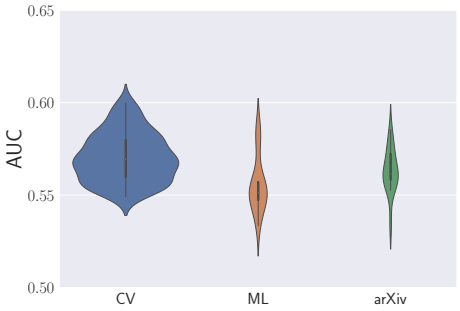

Figure 17: The membership inference performance (AUC) with respect to the conference type.

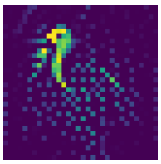
entropy attack. The improvement is less prominent in the CIFAR-100 and CUB-200-2011 models, where the target datasets have a smaller number of classes. This means that the attack performance of the developed methods may vary significantly when evaluated on more complex datasets. While it can be resource-intensive to conduct experiments on more complex datasets, researchers can consider using a few trained benchmark models for attack evaluation in the future.

Benchmark vs. Security Models. Similar to our model stealing analysis, we also compare the membership inference attack performance between benchmark and security models. Figure 15 shows the performance of the modified entropy attacks. We first observe that both types of models generally show a similar positive correlation (0.609) with the overfitting level, indicating that the overfitting level, indeed, is the primary indicator of membership vulnerability. Moreover, we find that the two clusters of security models, which have relatively high and low target task performance, respectively (see Figure 2), also react differently to membership inference attacks. The low-performing security models appear less vulnerable to the attack than both the high-performing ones and benchmark models despite having a similar overfitting level. As a result, the models that are not trained adequately on the target tasks can potentially appear to be less vulnerable and lead to underestimated risks in evaluation.

Metadata. For membership inference, we also examine the correlation between the attack performance (modified entropy) and two types of models' metadata, publishing time and conference type, using ImageNet-1k benchmark models. Figure 16 shows that, unlike model stealing attacks, newer models are not more (or less) secure to membership inference attacks compared to older ones. Meanwhile, in Figure 17, we also do not observe significant performance differences in membership inference on models from different venues.



4.3 Backdoor Detection

We next focus on backdoor detection on the public models. We first emphasize that while it is crucial for the backdoor detection techniques to identify the backdoored model accurately, the techniques' practicality also depends on having an acceptable low false positive rate. Thus, we examine the false positive rate of three widely-used backdoor detections on models from SECURITYNET. Note that since these methods rely on finding easily misclassified labels/images iteratively, the computation cost can be very high. Therefore, we only conduct evaluations on CIFAR-10 and SVHN models. Furthermore, since we aim to examine the false positive rate of these techniques, we only consider benchmark models. The reason is that these benchmark models are (almost) unlikely to contain backdoors.

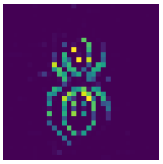


Table 1: Backdoor detection performance (false positive rate) on CIFAR-10 and SVHN models. Runtime is from CIFAR-10's ResNet-18 model.

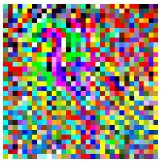
Detection Method	CIFAR-10	SVHN	Runtime
Neural Cleanse	20.9%	13.7%	802.1s
STRIP	0.0%	0.0%	32.1s
NEO	0.0%	0.0%	18.0s



Model Inspection. For the model inspection method, Neural Cleanse has very high detection rates, specifically 20.9% for CIFAR-10 models and 13.7% for SVHN models, shown in Table 1. To determine whether the detection is false positive, we examine the trigger patterns. The method provides trigger patterns generated through optimization and shows both a trigger image and a mask image of the trigger location.

(a) Trigger Mask CIFAR-10

(b) Trigger Mask SVHN

(c) Trigger Image CIFAR-10

(d) Trigger Image SVHN

Figure 18: The trigger masks (a and b) and patterns (c and d) generated by the backdoor detection method Neural Cleanse.

The mask area is selected as an outlier through the detection process, i.e., much smaller than others to cause misclassification. Figure 18 shows two examples detected by Neural Cleanse. The examples, however, do not resemble any trigger patterns. More specifically, the mask area is still too large and generally covers the key areas in the current class of images. For example, the SVHN trigger mask clearly shows the digit 8, which means almost all of the area has to be altered to cause misclassification and is, therefore, not a true trigger. The CIFAR-10 example similarly shows the outline of a bird (which is the label of the class). We can confirm that the detected triggers are indeed all false positives. The false positive rates on these public models greatly exceed the results on their experiment models presented in the original work [56]. The generated trigger patterns do help users eliminate the false positive samples easily, yet they require manual intervention.

Besides, since Neural Cleanse iteratively optimizes the trigger pattern and evaluates the change in prediction results, the run time on our GPU cluster (an NVIDIA DGX-A100 server) is at least 25 times longer than the other two methods. The current run-time evaluation actually benefits Neural Cleanse by evaluating a model with a simple architecture (ResNet-18) trained on a small dataset (CIFAR-10). The detection algorithm's run time will scale with not only the model's computation complexity but also the number of classes in the dataset. For datasets with more classes, such as ImageNet-1k, the method will become infeasible since the run time will become at least 100 times more than the current setting, even if we assume the time cost for each label's iteration remains the same. This significant resource requirement can hinder the method's practicality in the real world.

Input Filtering. For the input filtering methods, i.e., STRIP and NEO, we adopt a subset of the test set for evaluation. Since we choose the images ourselves, we can ensure there is no backdoor, and thus, the method should correctly identify the images as clean. Our experiments show that the two methods are effective in terms of low false positive rates. None of the models is detected as having backdoors. Noticeably, both methods have detection values that are much lower than their respective thresholds, which further indicates the method is effective in avoiding over-detection. The computation cost is also significantly lower compared to Neural Cleanse and realistically allows real-world deployment.

4.4 Result Summary

Thanks to SECURITYNET, we are able to perform an extensive evaluation for model stealing, membership inference, and backdoor detection on a large set of public models, which, to the best of our knowledge, has not been done before. Our analyses confirm some results from previous works but on a much larger scale, discover some new insights, and show some of the previous results obtained from researchers' self-trained models can vary on public models.

First of all, we find that the model stealing attack can perform especially poorly on certain datasets, such as CUB-200-2011, in contrast to target models (with the same architecture) trained on other datasets. Using an out-of-distribution auxiliary dataset also does not improve the attack on our public models. Furthermore, we demonstrate that the model stealing performance negatively correlates with the model's target task performance and is too low to be effective on some modern high-performing models. Unlike previous works [41], we find using a more complex surrogate model does not improve the attack performance. These observations imply that the proposed methods, which perform well under experimental conditions, can become inadequate on public models.

As for membership inference, we make a similar observation, as shown in previous works, that the attack performance positively correlates with the victim model's overfitting level. Additionally, we find methods that perform well on experiment datasets do not guarantee similar performance on more difficult datasets. In contrast to previous work's [46] results, the MLP-based attack performs differently on models trained with data that contains a large number of classes (e.g., ImageNet-1k) when using different input methods.

Additionally, for both model stealing and membership inference, we compare the behavior of security models to that of benchmark models. We notice the security models with low target task performance can react drastically differently to both attacks. More concretely, model stealing attack positively correlates with the target model's performance, and membership inference is less effective given a similar overfitting level. The two observations cannot be made on security models with similar target task performance as benchmark models, and thus, we suspect the training level mainly causes the different attack behavior. We hope to emphasize the necessity of training the target or victim models "properly," i.e., close to the architecture's maximum performance on the target task or using public models as target models for evaluation.

Finally, for backdoor detection, we evaluate the methods'

false positive rates on a large number of public models. This allows us to report our observation on the high false positive rate of Neural Cleanse with more confidence, which may be difficult to conclude from just a few test models. The resource requirement or run time of the detection method should also be taken into account when developing detection methods.

5 Related Works

Model Stealing. Several previous works have shown that machine learning models can be vulnerable to model stealing attacks [8, 27, 29, 40, 41, 48, 49, 53, 55, 60]. In general, model stealing attacks focus on either extracting the target model's parameters [8, 27, 53] or functionalities [27, 29, 41, 48, 49, 60]. Tramèr et al. [53] propose the first model stealing attacks against black-box ML models with prediction API. Orekondy et al. [41] develop Knockoff Nets that can steal the functionality of the given target model and leverage a reinforcement learning approach to improve the query sample efficiency. Model stealing attacks have been applied to different machine learning applications such as BERT-based APIs [29], Graph Neural Networks (GNNs) [49], and Contrastive Learning [48].

Membership Inference. Existing works on membership inference rely heavily on self-trained models to ensure membership information. Shokri et al. [50] develop the first membership inference attacks against ML models. Salem et al. [46] relax such assumptions of [50] by using only one shadow model to establish the attack. Nasr et al. [39] further investigate the membership leakage via the white-box access to the target model. Song and Mittal [51] observe that metric-based attacks can have similar or even better performance than previous attacks that leverage ML-based attack models. Label-only attacks [14, 32] have been proposed for a more difficult scenario where the adversary can only obtain predicted labels instead of the posteriors from the target model.

Backdoor Detection. Chen et al. [12] propose the first backdoor attack and, more specifically, the first targeted backdoor attack using data poisoning. Recently, numerous works have introduced detection methods for both targeted and untargeted backdoored models. Similar to Neural Cleanse [56] examined in this paper, many previous works detect backdoors by inspecting the models [11, 22, 26, 34, 35]. Others such as Cohen et al. [15] detect trigger inputs at inference time like STRIP [18] and NEO [54].

Public Model Analysis and Evaluations. There is not much work on analyzing public models' behaviors, especially from the security and privacy angle. Gavrikov and Keuper [19] analyze the properties of the distribution of 3x3 convolution filter kernels from hundreds of trained models. Schürholt et al. [47] present a dataset of 50,360 systematically generated neural network models for future model property research. This collection of trained models focuses more on providing diverse training trajectories through different combinations of hyperparameters, and thus, models do not necessarily reflect the ones publicly available online.

Large-Scale Evaluation of ML Security and Privacy. Another related topic is the measurement study on the security and privacy risks of machine learning models. Liu et al. [36] examine four inference attacks using five model architectures trained on four datasets. Pang et al. [42] develop TrojanZoo, an open-source platform for evaluating backdoor attacks/defenses. For evasion attacks, a selection of previous works [16, 33, 43] propose security analyses and benchmark platforms for generating and defending adversarial examples. These works, however, aim at developing the toolbox for future risk assessment but do not include evaluation analyses on a large set of public models.

6 Conclusion

In this paper, we collect and annotate an extensive database of public models, namely SECURITYNET, for privacy and security research in machine learning. We examine these public models with model stealing, membership inference, and backdoor detection. Compared to the results in previous works obtained from researchers' self-trained models, we discover some new insights on ML attacks/defenses with SECURITYNET. We will share SECURITYNET with the community and recommend future researchers include experiments on public models to demonstrate their methods' efficacy.

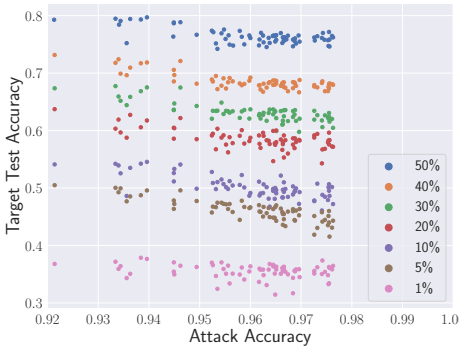

Figure 19: The relationship between the target task accuracy and the attack accuracy for model stealing on CIFAR-10 models when using different query budgets.

Appendix

A Annotating SECURITYNET

To annotate relevant information about the models in SECURITYNET, we utilize a two-step iterative coding process, which has been widely adopted in various fields such as usable security, social computing, and psychology [9, 31]. Concretely, 5 researchers first traverse all models and their relevant information and independently assign initial codes about the categories. They then work together to discuss the initial codes and their interconnections. Disagreement is solved through discussion and a majority vote. After agreeing on a final codebook (see Table 2), they code the entire database again. Our results show high inter-coder agreement (Cohen's kappa = 0.915).

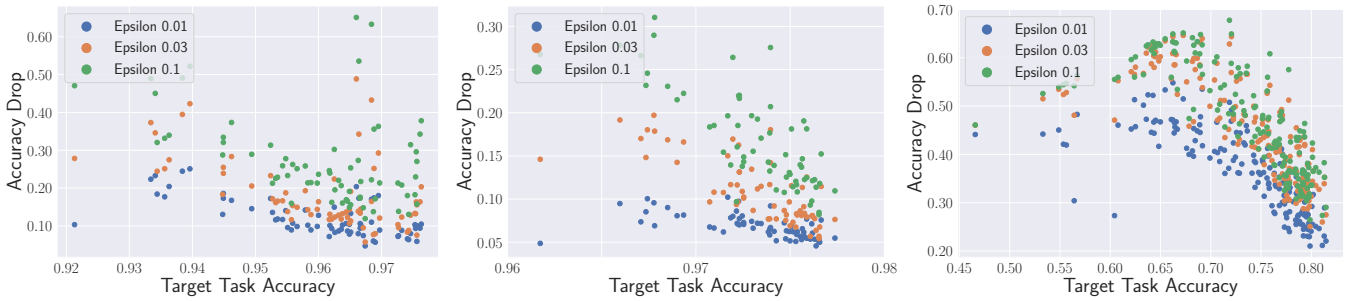
B Model Stealing Query Budget

When using the partial training set to steal target models, we assume the attacker has 50% of the original training data. We also evaluate how different query budget affects the attack performance on CIFAR-10 models. Similar to previous works [41, 53], we find positive correlations between the size of training data and attack performance, as shown in Figure 19.

C Evasion Attacks

Although evasion attacks is not the focus of this paper, we still include some baseline results for the benefit of future researchers in this domain. We examine the standard FGSM [20] attack in white-box and black-box settings. In the white-box setting, the adversary has full access to the model and generates adversarial noise directly. While in the black-box setting, the adversary cannot obtain the gradient from the target model directly but uses an auxiliary model (ResNet-18 trained on the same data) to generate the noise.

We present the accuracy drop on the target task in three different noise levels with epsilon at 0.01, 0.03, and 0.1 in Figure 20. We find there is a negative correlation between the attack effectiveness and the model's original target accuracy (e.g., the Pearson correlation coefficient is -0.491 on ImageNet-1k models). The method becomes ineffective on large models, even in the white-box setting with relatively large noise. For instance, the CIFAR-10 ResNet-1202 model only suffers an accuracy drop of 0.161 in the white-box setting with epsilon 0.1, compared to the much larger 0.491 that of ResNet-20 from the same model family. Under the black-box setting, shown in Figure 21, the effectiveness is very limited, but the negative correlation is still present. At a low noise level (epsilon 0.01), the accuracy drop of the attack is generally lower than 0.05. The negative correlation implies that the method that works on smaller models does not necessarily work as effectively on larger ones. Future researchers should consider selecting a few public models in SECURITYNET that are particularly ineffective with baseline attacks to demonstrate the effectiveness and improvement of the proposed method.



D Limitation

Our project is not without some limitations. When searching for models from academic papers, we focus on papers from top-tier conferences and thus potentially omit some models. We believe models from top conferences are more likely to be adopted by the community. Our analysis is also conducted with PyTorch models only. In later updates, we hope to include models from other platforms, such as TensorFlow. Given the large number of models, we still believe the result is representative even with these biases.

Using pre-trained models can limit the evaluation of some attacks against ML models. To ensure thorough analysis, membership inference attacks usually require control over the training process. However, we advocate for including a few case studies with public models to show that the proposed methods indeed perform similarly on larger models.

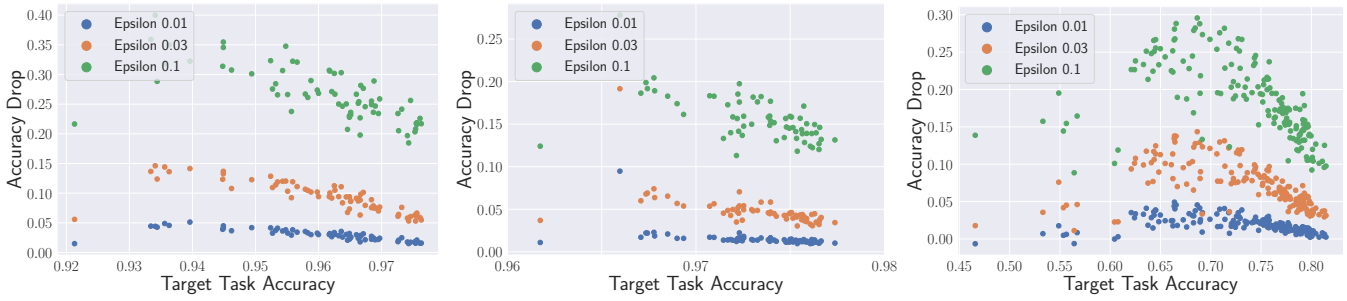


Table 2: The final codebook for SECURITYNET annotation.

Code	Description	Examples
Task Type	The type of tasks the model designed to perform	classification, detection, segmentation
Dataset	The dataset used to train the model	CIFAR-10, ImageNet-1k
Topic Category	The types of subjects in the given dataset	natural scenery, medical scans, satellite images
Training Set Size	The number of samples in the training data	50000, 5994, 1281167
Number of Classes	Number of classes in the dataset	10, 200, 1000
Input Image Dimensions	The image size and number of channels	28×28×1, 32×32×3, 224×224×3
Publishing Venues	The conference or journal where the paper that first introduced the model is published (if applicable)	CVPR, ICCV, NeurIPS
Venue Type	The type/topic of the conference/journal	computer vision, machine learning, preprint
Publishing Year	The year of the publication for the paper (models can be released online later)	2013, 2017, 2020
Number of Authors	The number of authors appeared on the paper that published the given model architecture	2, 3, 8
Affiliation	The author's affiliation	Stanford University, Google, Max Planck Institute
Affiliation Type	The types of affiliation	Companies, Research Institutions, Universities
Country	The country of where the authors' affiliations are established	USA, Germany, China, UK

How does Endpoint Detection use the MITRE ATT&CK Framework?

Apurva Virkud, Muhammad Adil Inam, Andy Riddle, Jason Liu, Gang Wang, Adam Bates
University of Illinois Urbana-Champaign
{avirkud2, mainam2, rriddle2, jdliu2, gangw, batesa}@illinois.edu

Abstract

MITRE ATT&CK is an open-source taxonomy of adversary tactics, techniques, and procedures based on real-world observations. Increasingly, organizations leverage ATT&CK technique "coverage" as the basis for evaluating their security posture, while Endpoint Detection and Response (EDR) and Security Indicator and Event Management (SIEM) products integrate ATT&CK into their design as well as marketing. However, the extent to which ATT&CK coverage is suitable to serve as a security metric remains unclear— *Does ATT&CK coverage vary meaningfully across different products? Is it possible to achieve total coverage of ATT&CK? Do endpoint products that detect the same attack behaviors even claim to cover the same ATT&CK techniques?*

In this work, we attempt to answer these questions by conducting a comprehensive (and, to our knowledge, the first) analysis of endpoint detection products' use of MITRE ATT&CK. We begin by evaluating 3 ATT&CK-annotated detection rulesets from major commercial providers (Carbon Black, Splunk, Elastic) and a crowdsourced ruleset (Sigma) to identify commonalities and underutilized regions of the ATT&CK matrix. We continue by performing a qualitative analysis of unimplemented ATT&CK techniques to determine their feasibility as detection rules. Finally, we perform a consistency analysis of ATT&CK labeling by examining 37 specific threat entities for which at least 2 products include specific detection rules. Combined, our findings highlight the limitations of overdepending on ATT&CK coverage when evaluating security posture; most notably, many techniques are unrealizable as detection rules, and coverage of an ATT&CK technique does not consistently imply coverage of the same real-world threats.

1 Introduction

It is difficult to overstate the influence of the MITRE Corporation's ATT&CK knowledge base [79] on how we conceptualize today's threat landscape. ATT&CK catalogues the observed real-world behaviors (*Procedures*) of hundreds of sophisticated threat groups. It then systematizes these procedures by assigning them to a known adversarial *Technique*, an explanation of "how" the attacker is attempting to achieve an operational goal. Techniques are themselves grouped into *Tactics* that explain the "why" of that goal, supplanting prior notions of a cyber "kill chain" [35]. The end result is a hierarchical taxonomy that bridges the gap between high-level attack objectives and concrete activities on targeted systems.

MITRE ATT&CK is invaluable as a means of systematizing seemingly-disparate attack behaviors and provides much needed context for threat alerts. The US Cybersecurity & Infrastructure Security Agency advises the use of mapping raw data to ATT&CK techniques as a means of enriching threat intelligence and cybersecurity advisories [17]. By annotating low-level threat intelligence with ATT&CK, experts and non-experts alike can situate a threat in the broader context of possible adversary actions and objectives. Today's threat detection products, most notably EDR's and SIEM's, annotate nearly every threat detection rule with ATT&CK techniques (e.g., [21,78,86]). Thus, when an alert occurs, analysts benefit from not only a specific description of the detection query, but also an explanation for how the event fits into the bigger picture of an attack pattern.

However, the applications of MITRE ATT&CK go beyond systematization and explainability – detection products (and the organizations that employ them) are now regularly evaluated on their ability to "cover" each of the ATT&CK techniques. A 2020 survey of security professionals finds that 57% of respondents also use ATT&CK to evaluate the efficacy of deployed security products [9]. Digital forensics and incident response consultants now regularly conduct audits of their clients' coverage of the ATT&CK framework (e.g., [65]). Soon, organizations' cyber insurance premiums may even consider ATT&CK coverage [5]. Unsurprisingly, it is also now commonplace for vendors to actively tout their coverage of ATT&CK in marketing materials (e.g., [15, 31, 70, 87]). However, despite its importance, little attention has been paid to how endpoint detection products actually employ MITRE

ATT&CK, or whether the hype around ATT&CK coverage as a security metric is justified.

In this work, we conduct an independent analysis of MITRE ATT&CK's use in endpoint detection products. *We emphasize that our intent is to evaluate the suitability of MITRE ATT&CK coverage as a security metric, rather than the products themselves.* Analyzing the rule sets of 3 major products, we answer the following research questions:

RQ1: How do products use ATT&CK? We conduct an empirical analysis of how endpoint detection rules are annotated with ATT&CK and examine the overall ATT&CK coverage of popular products. We find that products do not attempt to cover all ATT&CK techniques, with coverage ranging from 48% to 55%. Further, we observe that the available level of coverage is inflated by the presence of low risk and low severity rules that are less likely to be prioritized in practice. Filtering out low and medium risk rules, technique coverage drops to 25%–26%, approximately half of the original coverage. Finally, in addition to the total coverage of techniques between products being fairly consistent, we find that the products have similar preferences for which ATT&CK techniques to cover with statistical significance.

RQ2: Why don't products detect all of ATT&CK? Many ATT&CK techniques (53, 27.7%) were not implemented in any of the commercial products. To understand why, three authors performed open coding on the descriptions of these unimplemented techniques and come to a consensus for all codes. The identified reasons are (1) ineffective detection methods, many of which MITRE explicitly mentions will exhibit high false positive rates and other difficulties; (2) unsuitable target infrastructure, such as techniques that target non-host systems or social media; and (3) techniques that require knowledge of the client enterprise environment.

RQ3: How consistently is ATT&CK applied? Finally, we examine how consistently different vendors perform ATT&CK labeling when attempting to detect the same threats. For this comparison, we identify malicious entities (e.g., malware, CVEs, threat actors) across the rule sets by matching rule metadata against a known list of malicious entities from the rule descriptions. Examining 37 malicious entities that are explicitly referenced in at least two rulesets, we find that vendors are applying ATT&CK technique labels in equally-valid but inconsistent ways. We identify cases of rules that overlap in detected behavior but differ in the annotated ATT&CK techniques and tactics, such that a security analyst may reach different conclusions about the same threats depending on which product they are using.

In addition to three commercial products, we augment our analysis by replicating RQ1 for a large *crowdsourced* ruleset. As crowdsourced rules may not be subject to a uniform quality control process, we report these results in Appendix A. While the coverage of MITRE ATT&CK techniques (79%) is higher than the commercial rulesets, we observe similar trends in the rankings of covered techniques (with statistical significance) as well as the presence of low-criticality rules that may artificially inflate ATT&CK coverage.

To our knowledge, this work marks the first independent analysis of how MITRE ATT&CK is integrated into real-world endpoint detection products. We emphasize that the coverage of ATT&CK is already used as a metric for assessing these types of systems and thus has impacts on real world security. We conclude by discussing the implications of our findings for the enterprise security ecosystem at large. We find that ATT&CK, while useful for explanation purposes, is a poor measure of the detection capabilities of an endpoint detection product. This observation was supported by discussions with one of the surveyed product vendors during our disclosure process. In light of this, we advise stakeholders in the security ecosystem to approach coverage-based evaluations of organizations and products with caution and nuance. Finally, we advise MITRE to take a more active role in guiding how the ATT&CK framework is employed to mitigate future misuse. We open-source our code and analysis at [84] to support future work in the area.

2 Background

MITRE ATT&CK. MITRE ATT&CK is a hierarchical knowledge base that systematizes real-world observations of adversary *procedures* into general *techniques* and high-level *tactics* [79]. Techniques classify an observed procedure from a given threat group into a common offensively-oriented action (the "how"), while Tactics identify the associated attacker objective(s) (the "why"). Procedures can be associated with one or more techniques, and techniques can be associated with one or more tactics. Techniques can also be divided into sub-techniques that describe more granular behavior.[1] As of Version 11, the enterprise ATT&CK matrix that we use in this work is comprised of 14 tactics and 191 techniques. While best known for its taxonomy of tactics and techniques, ATT&CK also indexes additional information including verified threat groups, adversarial campaigns, detection/mitigation strategies, telemetry data sources, and software.

Endpoint Detection Products. Today's enterprises employ a variety of products for threat detection and remediation [39]. Endpoint Detection and Response (EDR) systems are a critical component of enterprise security [24, 26]. EDRs capture and examine endpoint telemetry data for evidence of potentially malicious activity. Security Indicator and Event Management (SIEM) software (e.g., [78]) ingest a variety of telemetry streams, including endpoint events, to centralize analyst operations. SIEMs also typically provide additional detection capabilities over endpoint events, making them functionally equivalent to EDRs for the purposes of this work.

While machine learning (ML) is increasingly integrated

[1] We do not consider sub-techniques in this work because it was not common practice for the surveyed EDRs to annotate rules with sub-techniques.

into products, endpoint detection functions are still largely *rule-based* (i.e., *heuristic-based*) [24, 26], in which an analyst explicitly defines a search query that describes a known adversary behavior. Rule-based detection, as opposed to anomaly-based or other ML approaches, enjoys the advantages of being fully *explainable* because every detection rule is annotated with metadata that explains the intended detection behavior. Today, this metadata often includes annotations linking a rule to one or more techniques enumerated by the MITRE ATT&CK framework. Typically, security analysts will annotate rules with ATT&CK techniques manually based on individual judgement. Rule-based detection also allows operators to tune the detection behavior on a rule-by-rule basis; if a rule is causing many false alarms in an organization, it can be disabled or deprioritized. Products also provide investigation features that allow analysts to triage alerts and examine the telemetry that caused them to fire, as well as response features such as automatic quarantine or malicious process removal.

Detection Rules. To further understand how detection rules work, we demonstrate the syntax and general detection strategy of three exemplar endpoint detection products – Carbon Black [86], Splunk [78], and Elastic [21].

```
process_name:wevtutil.exe
and process_cmdline:cl*
and -process_cmdline:clicktorun*
and -process_cmdline:AnyConnect\.evtx*
```

This Carbon Black rule, obtained from [1], searches for evidence that an attacker is using the Windows Event Utility `wevtutil.exe` to destroy application or system logs. The rule also checks that certain commandline strings are *not* present with the negation operator to tune out common legitimate use cases where an administrator is clearing logs. The rule is tagged with the ATT&CK technique `T1070`, Indicator Removal, which links to the Defense Evasion `TA0005` tactic.

```
(Processes.process_name="RDPWInst.exe"
  OR Processes.original_file_name= "RDPWInst.exe")
AND Processes.process IN ("* -i*", "* -s*",
    "* -o*", "* -w*", "* -r*")
```

This Splunk rule, obtained from [78], searches for `RDPWInst.exe`, which is a Remote Desktop Protocol wrapper library tool that can be abused for remote access. The rule is tagged with the ATT&CK technique `T1021`, Remote Services, which links to the Defense Evasion `TA0005` tactic.

```
event.category : (network or network_traffic)
and network.transport:tcp
and (destination.port: 26
     or (event.dataset:zeek.smtp
         and destination.port: 26))
```

This Elastic rule, obtained from [21], searches for Simple Mail Transfer Protocol (SMTP) traffic on the (non-default) port 26. While legitimate mail transfer agents may use port 26 to deconflict with other agents, it is also used by the BatPatch malware family for command and control traffic. This rule is tagged with the ATT&CK technique `T1048`, Exfiltration Over Alternative Protocol, which links to the Command and Control (`TA0011`) and Exfiltration (`TA0010`) tactics.

Stats	CB	Splunk	Elastic	Sigma
# ATT&CK Tagged Rules	867	911	473	2,195
# Unique Techniques	105	100	92	151
% Technique Coverage	55%	52%	48%	79%
Tactic Coverage	13/14	14/14	13/14	14/14

Table 1: **Dataset Overview:** Detection rules annotated with MITRE ATT&CK technique labels in each product out of all rules present in the head of the main branch of the rule repository (or, for Carbon Black, the customer-visible watchlists).

Marketing with ATT&CK. Beyond the product, MITRE ATT&CK is used extensively in marketing. We identify no less than 19 security vendors that have appealed to ATT&CK in advertisements [12–16, 18, 31, 34, 36, 37, 42, 45, 50, 53, 57, 62, 70, 73, 74]. Notably, 12 of these sources are specifically advertising performance in the MITRE Engenuity sponsored ATT&CK Evaluations. While MITRE Engenuity's guidelines recommend investigating low-level detection details to determine a system's performance, these promotional materials report high-level metrics like ATT&CK coverage. In this work, we investigate the validity of using ATT&CK coverage as a measure of product efficacy.

3 Dataset

We collect data from four popular rule engines and analyze how they make use of the MITRE ATT&CK framework to cover different attack tactics and techniques. We consider detection rules from three popular industry endpoint detection systems: VMware Carbon Black (CB) [86], Splunk Security Content [78], and Elastic [21]. Splunk and Elastic's rulesets are fully open-sourced, available on GitHub. Carbon Black shares hundreds of rules with their customers in the form of curated watchlists that can be enabled for their deployment. We received access to the Carbon Black Cloud product via an Educational license and received their permission to use their name and ruleset in this paper. Carbon Black was reported to be one of the top EDR solutions in multiple 2023 market reports [24, 26], while both Splunk and Elastic are popular SIEM products [59]. Additionally, we include an open and crowd sourced rule repository curated by Sigma [72], also available on GitHub. The ruleset uses a vendor agnostic format and has downstream users including other industry systems such as IBM QRadar. We select these systems due to their wide deployment. Because a crowdsourced ruleset may not have uniform processes to verify the quality of rules, we report on Sigma separately in Appendix A. Our intention is not to evaluate the quality of individual products, but instead to use these products to gain insight into how MITRE ATT&CK is integrated into endpoint detection.

Table 1 summarizes the key statistics of the dataset, which was captured by taking a snapshot of each ruleset in October

Data Field	CB	Splunk	Elastic	Sigma
Name of Attack	✓	✓	✓	✓
Description	✓	✓	✓	✓
ATT&CK Technique(s)	✓	✓	✓	✓
Known False Positives	✓*	✓	✓	✓
Confidence	✓*	✓		
Risk Score		✓	✓	
Severity Score	✓		✓	
Keywords	✓		✓	
References		✓	✓	✓

Table 2: **Metadata from Carbon Black (CB), Splunk, Elastic, and Sigma:** Metadata fields that appear in more than one ruleset, indicated by a checkmark. The asterisk (*) indicates that the field was extrapolated from another field.

2022. We filtered a single crowdsourced watchlist containing 68 rules from the Carbon Black ruleset because these may not undergo quality verification from Carbon Black itself. We also filtered rules that were not annotated with ATT&CK techniques. Finally, we omit rules from the three commercial systems (all except Sigma) that are marked as deprecated or in development, as either indicates that they are not currently endorsed by the product vendor. We refrain from describing statistics of the filtered rules in detail so as to avoid benchmarking the rulesets of the different systems; this is not our objective. Broadly, the majority of rules from all four products are annotated with ATT&CK technique tags, with the exception being rules that are simple IP blocklist rules (e.g., Tor exit nodes). In total, we identify 867 Carbon Black, 911 Splunk, 473 Elastic, and 2,195 Sigma rules.

Our analysis is also informed by the rule metadata, shown in Table 2, made available by each vendor. While all four rulesets include a name, description, and ATT&CK technique tags for each rule, fields begin to diverge subtly beyond this basic information. Splunk, Elastic, and Sigma all contain explicit fields to denote known sources of false positives for each rule, while Carbon Black sorts its rules into recommendation lists based in part on the likelihood of false positives for a given rule. Carbon Black also implicitly describes confidence[2] in these list descriptions, while Splunk has an explicit score, and Elastic has no confidence indicator at all. Only Splunk and Elastic have risk scores[3] while only Carbon Black and Elastic have severity scores,[4] etc.

4 How do products use ATT&CK?

Using this dataset, we analyze how endpoint detection products use the MITRE ATT&CK framework. In this section we will focus on the three commercial rulesets—Carbon Black, Splunk, and Elastic. The corresponding results on the crowdsourced ruleset Sigma can be found in Appendix A.

More specifically, we are interested in understanding which ATT&CK techniques or tactics have corresponding rules implemented, and the coverage of the rulesets. As of Version 11, ATT&CK contains 14 *tactics* that describe the high-level goals of the different phases of the attack and 191 *techniques* that describe the specific attacker actions and methods under these tactics. As shown in Table 1, while all three rulesets cover the vast majority of the tactics (at least 13/14), their overall technique coverage is 48%–55%. In particular, there are 53 techniques (27.7%) that do not have a corresponding rule in any of the three rulesets. Our analysis below shows that different tactics and techniques receive uneven attention or coverage across different products. Certain techniques are consistently under-covered by all three rule engines.

ATT&CK Technique Coverage. Figure 1 reports technique

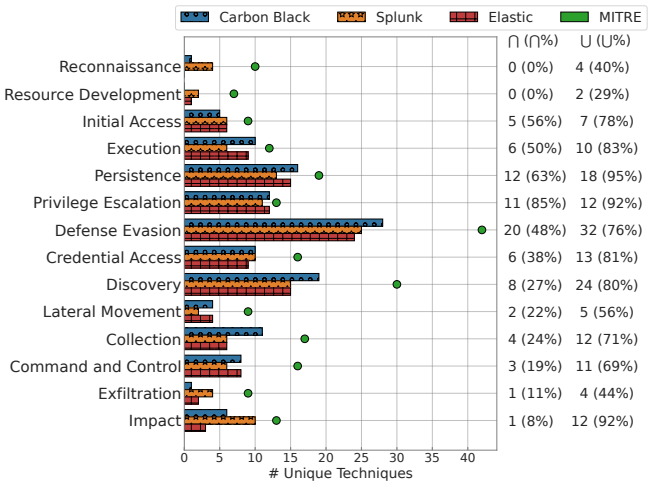

Figure 1: **Technique Coverage under Each Tactic:** The y-axis shows the 14 ATT&CK tactics ordered by the phase of attack (e.g., reconnaissance is typically the first step). The green dots represent the total number of techniques under each tactic in ATT&CK and the bars represent the number of covered techniques by each ruleset. The number and % of covered techniques in the intersection (∩) and union (∪) of all rulesets are shown on the right side.

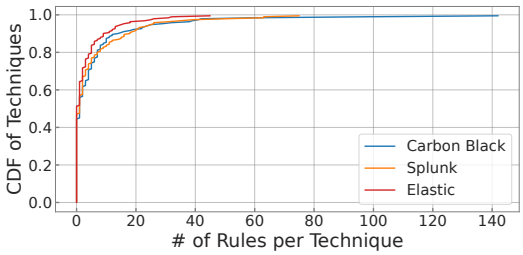

Figure 2: **Rules Per Technique:** Cumulative distribution of the number of rules per technique for each endpoint detection system.

[2]Confidence is the likelihood that an alert is indicative of an attack.
[3]Risk scores are a composite of confidence and severity measures.
[4]Severity scores reflect the potential damage should the attack occur.

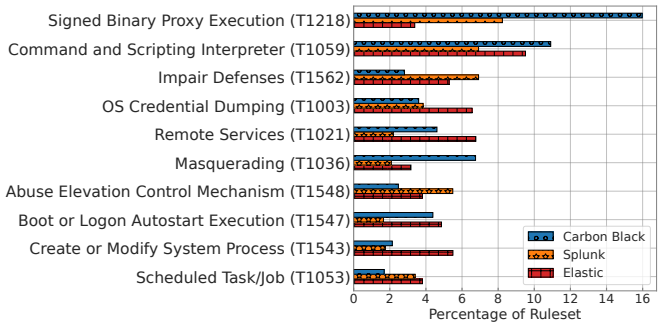

Figure 3: **Top ATT&CK Techniques:** Top 10 techniques ranked based on the sum of associated rules from the three engines. The x-axis shows the % of the rules for a given technique in each engine (e.g., 16% of Carbon Black rules are tagged with `T1218`).

coverage, by tactic, for the three products. The green dot denotes the total number of ATT&CK techniques under each tactic and the bars represent the number of techniques with associated rules in each product. Interestingly, we observe that tactics with more ATT&CK techniques also receive more attention/coverage from the product. More specifically, *defense evasion*, *discovery*, and *persistence* are among the most frequently appearing tactics across all three products. They are also the tactics with the highest number of techniques in the ATT&CK framework. However, certain tactics are consistently under-covered by all three engines. For example, *resource development* only has 2 techniques covered (no coverage by Carbon Black) and *reconnaissance* only has 4 techniques covered (no coverage by Elastic). We suspect these techniques describe offline activities for which it is difficult to implement rules, a hypothesis we explore further in §5.

In Figure 1, we also report the intersection ($\cap$) and union ($\cup$) of the techniques covered by the three products. We observe that the intersection on average covers 32% of the techniques under a given tactic, while the union of the three engines can boost the coverage on average by 38%. The exception is *privilege escalation* where the intersection coverage is already high (85%) and the union can only boost the coverage to 92%. This kind of multi-product analysis of MITRE ATT&CK coverage forms the basis of org-level evaluations of security posture (e.g., [65]); a security consultant evaluating an organization that only licensed one of these products might argue that the organization could improve its security by licensing another of the three products.

ATT&CK Technique Density. We also observe differences not only in the coverage of techniques, but also in their frequency, as shown in Figure 2. We see that 9.9%-13.1% of techniques only have one associated rule, while 29.8%-32.5% techniques have 1 to 5 rules. A small fraction of techniques (1.6%-2%) have more than 50 associated rules implemented. An extreme example is `T1218` (System Binary Proxy Execution) for which Carbon Black has implemented 142 rules to

Metric	Filter	Carbon Black	Splunk	Elastic
Baseline	No Filter	55%	52%	48%
Risk	>= Med.	/	43%	42%
	>= High	/	25%	26%
Severity	>= Med.	52%	/	42%
	>= High	46%	/	26%
Confidence	>= Med.	/	51%	/
	>= High	/	46%	/

Table 3: **Impact of Risk/Severity/Confidence on ATT&CK Technique Coverage:** We observe that technique coverage drops drastically when only considering the rules with the highest operational value. "/" means metadata is not available.

detect this threat. The general trend is consistent across the three products.

Figure 3 lists the top 10 techniques aggregated across all three rulesets. While all 10 techniques have a high coverage by the three engines, there is some variation per ruleset. For example, `T1218` (Signed Binary Proxy Execution) is the predominant technique in Carbon Black and Splunk, but it is not the most frequent in Elastic. To further measure the per-ruleset variation, we calcuate the Spearman's rank correlation coefficient [20, 75] between the ranked lists of techniques for each pair of rulesets. The Spearman coefficient is calculated as $\rho_{R(A),R(B)} = \frac{cov(R(A),R(B))}{\sigma_{R(A)}\sigma_{R(B)}}$ where lists of covered techniques A and B have rank variable representations $R(A)$ and $R(B)$ (in this case, techniques are mapped to the percentage of the ruleset they cover), *cov* is the covariance, and σ is the standard deviation. The coefficient value ρ ranges from -1 to 1 and a positive value closer to 1 indicates more similar ranking for our variables. We also conduct a t-test to determine if ρ is significantly different than 0.

Interestingly, we observe a high level of consistency among the three products in terms of techniques with implemented rules. More specifically, the Spearman coefficient between any given pair of ranked lists is always positive: 0.634 for Carbon Black and Splunk, 0.744 for Carbon Black and Elastic, and 0.639 for Splunk and Elastic. The p-value is < 0.001 for all tests, indicating a statistically significant similarity between the technique rankings of each pair of products. Collectively, it means that, even though different ATT&CK techniques have received uneven attention, the three engines have a similar preference in terms of which techniques to cover.

Risk, Severity, Confidence, and their Impact on ATT&CK Coverage. To provide further context for the implemented rules, we analyze the quantitative metrics assigned to the rules, including confidence, risk, and severity scores. These metrics are supposed to help security analysts to triage alerts. We note that these metrics are assessments made by the developers who work on the rules and are not necessarily universal across endpoint products. However, they serve as an approximation for how the developers believe the rule should be used in

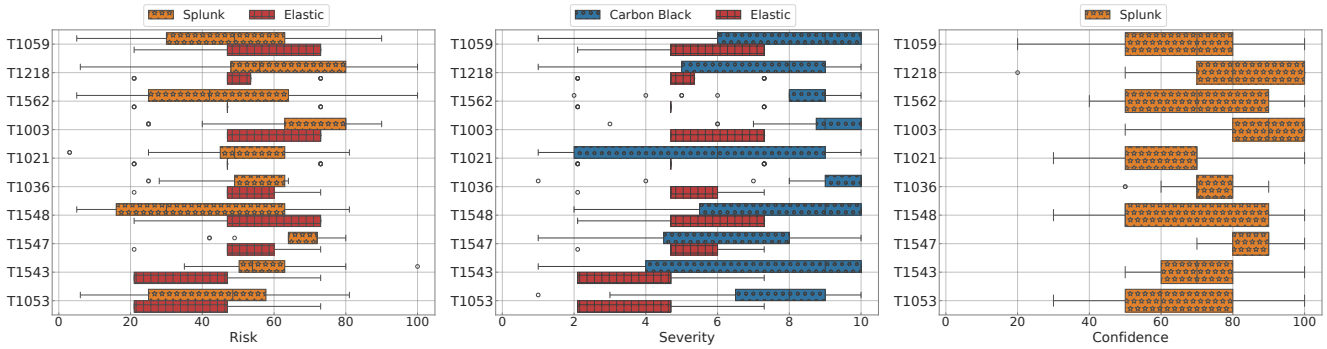

Figure 4: **Risk, Severity, and Confidence For Top Techniques:** The risk, severity, and confidence scores are not available in all three rulesets (see Table 1). We report the available scores for the top 10 techniques ranked by the number of associated rules (see Figure 3).

Metric	Filter	Carbon Black	Splunk	Elastic
Baseline	No Filter	13	14	13
Risk	>= Med.	/	14	12
	>= High	/	13	12
Severity	>= Med.	12	/	12
	>= High	12	/	12
Confidence	>= Med.	/	14	/
	>= High	/	14	/

Table 4: **Impact of Risk/Severity/Confidence on ATT&CK Tactic Coverage:** There are in total 14 tactics in the framework. "/" means metadata is not available to support the filtering.

deployment. Intuitively, rules with high values are likely to be prioritized. On the contrary, rules with low risk/severity/-confidence scores may have low operational value in practice. Splunk confirmed this intuition in their documentation on how risk scores are calculated [77], while Carbon Black confirmed to us internally that this is their intended usage. In Appendix B, we have provided some examples of rules that are likely to have false positives and have lower values in these metrics. By considering these metrics for rules of the same techniques *under the same product*, we examine how each engine interprets the risk of these techniques. For any given metric, the rulesets consistently report scores either with a range of (0, 10) or (0, 100), so we do not need to normalize the metric across products.

Figure 4 shows the risk, severity, and confidence score distributions for each of the top 10 techniques. Recall that all scores are not available in all three rulesets (see Table 1). For example, only Splunk and Elastic report the risk score.

The leftmost plot shows that, for the same technique, there is a *high variance* in terms of the risk scores for the associated rules within each engine. A possible explanation is that there is a wide spectrum of behaviors under the same ATT&CK technique that have different risk levels. The same observation applies to the center plot, reporting severity for Carbon Black and Elastic, indicating that each ATT&CK technique has a large room for different interpretations in terms of the risk/-severity even within an individual product. In other words, the technique itself does not necessarily indicate the perceived risk or severity of the attack. For confidence (rightmost plot), only Splunk has reported this score. While most of the rules have a confidence score over 50 (out of 100), their variance under individual ATT&CK techniques is also high.

Finally, we investigate how the risk, severity, and confidence metrics affect the overall MITRE ATT&CK coverage. The intuition is that rules with lower levels of these metrics have lower operational value and are unlikely to be prioritized by analysts during attack investigation. Therefore, we re-examine ATT&CK coverage after filtering out rules with lower operational values. More specifically, NIST defines the Common Vulnerability Scoring System (CVSS, v3.0) [55] which maps quantitative values (ranging from 0.0 to 10.0) to qualitative severity categories: "None", "Low", "Medium", "High", and "Critical". Considering that the risk and confidence metrics are closely related to the severity score, and all metrics have a (0, 10) or (0, 100) range, we apply the same CVSS mapping for all three metrics (as an approximation).

In Table 3 and Table 4 we report the technique coverage and tactic coverage by considering rules with at least "medium" score (or "high" score). Notably, for both risk and severity, we observe that the ATT&CK technique coverage is halved for Splunk and Elastic when only considering rules with "high" or "critical" levels (i.e., the coverage drops from 52% and 48% to 25% and 26%, respectively).

For tactics, we observe that Elastic loses coverage of "resource development" when eliminating low risk rules, while Splunk loses coverage of "reconnaissance" when eliminating low and medium risk rules. A similar effect is observed for severity: when eliminating low severity rules, Elastic loses coverage of "resource development" while Carbon Black loses coverage of "reconnaissance". This indicates that rulesets do not have effective coverage of these two earliest stages of attack development.

Rules with Multiple ATT&CK Techniques. While the vast majority of rules are annotated with a single technique (84.5%), we find that 349 rules across the three rulesets

(15.5%) have multiple technique annotations. This may be because that the rule broadly detects different system activities, or because the activity can be employed at multiple phases of attack. The breakdown of rules with multiple techniques in each ruleset can be found in Appendix Figure 10. Rules with 2 technique annotations are somewhat common, but rules with 3 or more techniques account for only 1.2%–3.1% of the rules in each ruleset. We investigate an example to understand why a rule may be annotated with multiple techniques.

```
(Processes.parent_process_name=wmiprvse.exe
  OR Processes.parent_process_name=services.exe
  OR Processes.parent_process_name=svchost.exe
  OR Processes.parent_process_name=wsmprovhost.exe
  OR Processes.parent_process_name=mmc.exe)
(Processes.process_name=powershell.exe
  OR (Processes.process_name=cmd.exe
    AND Processes.process=*powershell.exe*)
  OR Processes.process_name=pwsh.exe
  OR (Processes.process_name=cmd.exe
    AND Processes.process=*pwsh.exe*))
```

This rule from Splunk [78] is annotated with six techniques, shown in Appendix Table 7.

This rule detects parent processes that are commonly used in lateral movement behavior and spawn Powershell child processes. In this case, the multiple technique annotations are due to the breadth of the detection. Depending on which parent process is detected, Windows Management Instrumentation (T1047) or Remote Services (T1021) may apply. The detected behavior is also utilizing command line (T1059) and trusted system processes (T1218, T1543). We observe that these techniques are in total associated with five unique tactics, indicating that the system behavior may be applicable at different phases of an attack.

Sigma. We replicate the above analysis on the Sigma ruleset and briefly discuss the results. The full analysis can be found in Appendix A. First, we compare the techniques ranked by coverage in Sigma to the technique rankings in each of the other three rulesets and find that the Spearman coefficient is always moderately positive with statistical significance. Thus, despite Sigma's higher overall technique coverage (79%, see Table 1), the techniques that are covered are prioritized similarly to the commercial rulesets. The distribution of rules per technique is also similar to the commercial rulesets with a long tail of techniques that each represent less than 0.5% of the total rules. Sigma is also similar to the commercial rulesets in that filtering out low and medium criticality level rules drops the coverage of MITRE ATT&CK techniques.

5 Why don't products detect all of ATT&CK?

So far, our results show that endpoint detection products are not using all of the MITRE ATT&CK techniques to construct their detection rules, with coverage ranging from 48% to 55%. In particular, there are 53 ATT&CK techniques (27.7%) that are not implemented by any of the three commercial products. To understand *why* products may not implement corresponding rules for these techniques, we perform a *qualitative analysis* on the textual description of ATT&CK techniques.

Label	Techniques	Example
Ineffective Detection Method	21 (39.6%)	T1480
Targeting Non-Host Infrastructure	13 (24.5%)	T1584
Client-specific	9 (17.0%)	T1528
Vague Detection Method	9 (17.0%)	T1602
Targeting Third Parties	8 (15.1%)	T1591
Provenance-based Detection	4 (7.5%)	T1578
Involving Low-level Behavior	3 (5.7%)	T1200
Involving Removable Media	3 (5.7%)	T1025
Involving Human Factors	1 (1.9%)	T1598
Reason Unknown	2 (3.8%)	T1217
Total Unique Techniques	53	

Table 5: **Qualitative Labels for Unimplemented Techniques:** We label the 53 techniques that are not implemented in any of the three endpoint detection rulesets. Note that one technique may have multiple labels.

5.1 Qualitative Analysis Method

Our analysis is focused on the textual technique description as well as the listed detection strategies in the MITRE ATT&CK framework. To extract the high-level reasons (and a code book), three coders independently analyze (with open coding) the 53 ATT&CK techniques that do not have corresponding rules in any of the three commercial products. All coders are active researchers in the area of intrusion detection and are familiar with the MITRE ATT&CK framework. After independently coding the same subset of techniques, two of the coders meet and discuss their codes to decide upon common terminology and code definitions. Then these two coders continue to independently code the rest of the techniques and refine the codebook. To verify soundness of the coding results, a third coder first independently performs open coding on the techniques to confirm that no new codes emerge and then maps those codes to the existing codebook. Eventually, the three coders code all of the 53 ATT&CK techniques that are not implemented by any product. After independently coding, the coders discuss each technique to verify codes and resolve any disagreements, coming to a consensus on all codes. Since all technique codes are collaboratively reviewed by multiple researchers, we do not report inter-rater reliability [46].

5.2 Annotation Results

As shown in Table 5, we are able to attribute potential reasons behind the lack of implementation for 51 out of 53 techniques (96.2%). Note that one technique may have multiple associated reasons. We are unable to attribute reasons for two

techniques (marked as "reason unknown" in Table 5), which will be further discussed below.

Ineffective Detection Method. 21 techniques (39.6%) have ineffective detection methods, which is the most predominant reason. Among them, MITRE explicitly mentions that the suggested detections are ineffective for 14 techniques. For example, T1480 (Execution Guardrails) refers to attackers using guardrails to only execute an attack when their desired environment conditions are fulfilled (to evade detection). MITRE ATT&CK suggests monitoring for suspicious processes and command executions that gather system information, but MITRE also specifies that this behavior can be difficult to detect since it depends on how the attacker implements their guardrail (i.e., easily producing false positives). For the remaining 7 techniques, detection methods are assessed to be ineffective by the coders. One example of such a technique is T1594 (Search Victim-Owned Websites), which refers to attackers searching websites owned by the victim for information that can be used during targeting. The detection suggestion is to look for suspicious network traffic, which again can lead to high rates of false positives.

Targeting Non-Host Infrastructure. 13 techniques (24.5%) target non-host systems that are part of the target organization's infrastructure. For example, T1584 (Compromise Infrastructure) refers to threats from compromised infrastructures such as cloud servers and remote repositories. The suggested detection is active Internet scanning to identify such compromises. Since the target is not the end-point machine, endpoint products may not be best suited for detection.

Client-specific. 9 techniques (17.0%) are client-specific, which are dependent on the specific services/applications on the clients' hosts. For example, T1528 (Steal Application Access Token) depends on specific applications on hosts. Products may not implement rules for these techniques because they require knowledge of specific services or parameters that customers use.

Vague Detection Method. 9 techniques (17.0%) have detection methods that are labeled as too vague. For example, the detection for T1602 (Data from Configuration Repository) suggests monitoring network traffic for anomalies but does not include specific heuristics. This type of detection may be more difficult to implement by an endpoint detection system.

Targeting Third Parties. 8 techniques (15.1%) involve behavior on third-party platforms that are outside of the target organization's infrastructure (e.g., open websites). For example, T1591 (Gather Victim Org Information) involves searching an organization's social media and largely takes place outside the control of the endpoint product defenses.

Provenance-based Detection. 4 techniques (7.5%) use detection methods requiring provenance tracing, such as T1578 (Modify Cloud Compute Infrastructure), and suggest viewing events as a chain of behavior. Such capability is often not yet available for rule-based detection systems.

Involving Low-level Behavior. 3 techniques (5.7%) involve low-level behavior (e.g., in hardware or firmware) that are not detectable by endpoint detection. An example is T1200 (Hardware Additions).

Involving Removable Media. techniques (5.7%) involve removable media such as USBs, where an endpoint detection product may not be able to determine the correct mount path to monitor (e.g., non-C: drives on Windows). For example, T1025 (Data from Removable Media) concerns data collection from such sources.

Involving Human Factors. 1 technique (1.9%) involves human factors: T1598 (Phishing for Information). We assume that indicators resulting from human involvement would be difficult to encode in a rule.

Reasons Unknown. We were unable to determine why 2 techniques have not been implemented. For example, T1217 (Browser Information Discovery) covers behavior that should be visible within system logs. The second case is T1615 (Group Policy Discovery), where the detections provide examples of system-level signatures associated with abnormal active directory access. It is possible that endpoint products do not implement rules for these techniques because they are not prevalent in real-world settings or the perceived risk of such behavior is relatively low (but we are unable to confirm).

In summary, we find that many techniques are difficult (if not impossible) to implement as effective detection rules due to vague descriptions of attack behaviors or ineffective detection strategies, or because the attacker actions are outside the scope of a typical endpoint detection product. The implication is that ATT&CK coverage may not be a sound security metric since covering all these ATT&CK techniques could mean sacrificing the quality of the detection rules.

6 How consistently is ATT&CK applied?

After investigating techniques that are not implemented by products, we now focus on the *implemented rules* and examine whether products have applied MITRE ATT&CK consistently to tag the rules. As a comprehensive knowledge base, ATT&CK provides a common language for describing and communicating security threats between different vendors/-parties in the community. For rules created to detect the same threat (attacker action), we expect them to be tagged with the same ATT&CK techniques such that people can effectively link and compare rules from different vendors. Note that we are not considering the *process* of how analysts annotate rules with ATT&CK; rather, we aim to analyze the resulting annotations. For this analysis, we first search for rules that are created to detect the same malicious entities across the three products, and empirically assess the consistency of their tagged ATT&CK techniques.

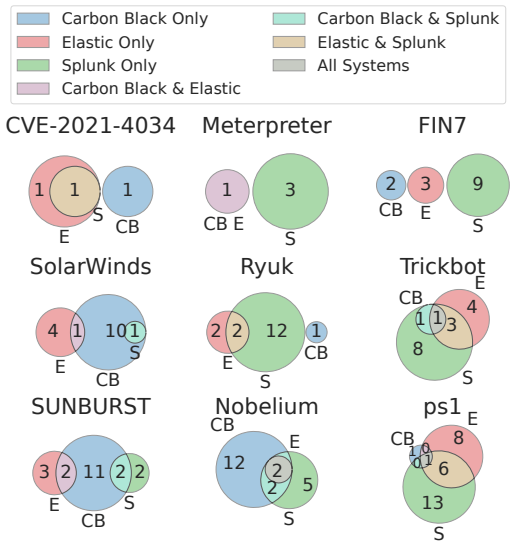

Figure 5: **Comparing ATT&CK Technique Labels for Endpoint Detection Rules Designed for the Same Malicious Entities:** These 9 malicious entities have dedicated rules in all three rule sets. ATT&CK label agreement for each entity is generally poor, suggesting there may exist multiple valid interpretations for the same threat, and it is difficult to use the ATT&CK framework to tag the threat consistently across products.

6.1 Grouping Rules across Products

To identify rules created for the same attack behavior across products, we first group rules based on their *rule metadata*. More specifically, rules are often created to counter specific malware, vulnerabilities (CVE), malicious campaigns, or threat groups (threat actors), which are usually mentioned in the rule description. We consider these specific threats to be "malicious entities". Take this description from an Elastic rule as an example: "*The malware known as SUNBURST targets the SolarWind's Orion business software for command and control. This rule detects post-exploitation command and control activity of the SUNBURST backdoor.*" Here the description references two malicious entities: the "SUNBURST backdoor" and the attack campaign against "SolarWinds" discovered in December 2020 [22].

As such, we construct a list of *malicious entities* (i.e., keywords associated with specific procedure-level threats) and perform preliminary grouping of the rules. We determine the malicious entities that a rule is associated with in the following ways. First, from the MITRE ATT&CK framework, we obtain a list of common threat groups (135), software names (718), and campaign names (14), as these often serve as reasons for rule creation. "Threat groups" in MITRE ATT&CK are typically used to refer to threat actors; MITRE also keeps track of the multiple names of the same threat actor (assigned by different security vendors). Then, we augment the list of threat groups and software names using data from the Malpedia library [25]. In total, the concatenated list contains 3,920 items. Using this item list, we search the rule metadata for potential matches. Finally, to identify additional items that are not tracked by MITRE ATT&CK or Malpedia, we further extract keywords from each rule's description field using a popular keyword extraction tool called KeyBERT [44].

Analyzing the matched entities, we note that not all of the listed items (from MITRE, Malpedia or KeyBERT) are necessarily malicious. For example, there are benign softwares such as "Reg" and "Net" that have known patterns of misuse from adversaries as well as legitimate uses by administrators and pen testers. The list also contains popular benign software such as "powershell" that is often the target of malicious attacks. To this end, we *manually* go through the results to verify that the matched items and keywords are correct, and filter to only include those that we consider "malicious entities."

Across all three rulesets, we identified and verified 191 malicious entities. These include 62 malware names and 30 threat actors (explicitly matched with the MITRE/Malpedia list), 49 CVEs, and 50 additional malicious entities from our keyword extraction (KeyBERT). This corresponds to 100 (11.5%) rules in Carbon Black, 429 (47.1%) rules in Splunk, and 84 (17.8%) rules in Elastic. Note that a rule may be associated with multiple malicious entities. For example, 34 rules are labeled with both *nobelium* and *sunburst*. This is because the Nobelium threat group used the SUNBURST backdoor in their 2020 attacks against SolarWinds [49].

Overlapping Malicious Entities. Appendix Figure 6 visualizes the overlap of dedicated rules from the three products for detecting each of the malicious entities we identify. We observe that there is little overlap between all three products with only 9 malicious entities (out of 191, 4.7%) explicitly mentioned in rules from *all three systems* and 37 malicious entities (19.3%) mentioned in at least two systems. 153 (out of 191, 80.1%) malicious entities were only mentioned in a single product. However, we *strongly emphasize* that this result does not suggest that these products are vulnerable or incomplete. It is likely that all vendors have examined threat intelligence for all of the malicious entities. In cases where dedicated rules are not present, they may have determined that their more generic detection rules were sufficient, that the creation of dedicated rules for a given threat would increase false alarms, or simply did not mention the malicious entity in the rule description. In any of these scenarios, our grouping method would have missed the fact that a malicious entity has already been accounted for. Instead, the value of this analysis is in identifying 37 malicious entities that have associated rules in more than one product to analyze how they apply the MITRE ATT&CK framework. A subset of these malicious entities include **CVE-2021-4034**, **Trickbot**, **Ryuk**, **Nobelium**, **SolarWinds**, **ps1**, **Meterpreter**, **SUNBURST**, **FIN7** – that all three products unambiguously set out to detect.

6.2 Technique Labeling Consistency Analysis

We examine the technique tags assigned by each product to the 37 common malicious entities to examine how consistently the ATT&CK framework is applied. We observe that there is generally very little agreement between the different products as to which techniques to associate with a particular threat. We report the detailed results for each malicious entity as a table in our supplementary materials [84]. Out of the 37 entities, 19 (51%) having *no agreement* in MITRE ATT&CK techniques between any pair of products. Only 1 out of the 37 entities (2.7%) have a *perfect agreement* in the techniques between the products. The result confirms the major inconsistency when applying MITRE ATT&CK to the same threat.

Among the 37 entities, 9 entities are covered by all three products' rulesets. We use Figure 5 to further visualize the level of agreement between systems for these 9 entities. We use the venn diagram to show the overlap of the technique tags for the associated rules. For instance, for the **FIN7** advanced persistent threat (APT), there is no agreement between the three products. More specifically, there are a total of 14 techniques associated with the FIN7 APT rules (9 from Splunk, 3 from Elastic, and 2 from Carbon Black), but there is no agreement about even a single technique from any of the systems under investigation. Across the 9 threats appearing in all rulesets, the three products agree on just 4 labels (2.8%) out of 141 technique annotations. When considering the 37 threats appearing in at least two rulesets, products agree on 37 (12.5%) out of 296 technique annotations. We acknowledge that threat groups and even individual malware implementations may exhibit a wide range of behavior which could contribute to differences in technique. However, within the groups of rules associated with a threat, we observe instances of products detecting the same system-level behavior where we expect to see technique agreement. In the following, we provide more detailed case studies on these rules and their ATT&CK technique labels.

CVE-2021-4034 [54]. This software vulnerability was disclosed in 2021 and describes a bug in polkit's `pkexec` utility that can be exploited to grant privilege escalation. The ATT&CK techniques that the three products associate with this vulnerability and their descriptions are shown in Table 6. This example highlights a significant issue analysts face when trying to apply MITRE ATT&CK – ambiguity and overlap between techniques. In this case, one source of disagreement is that Carbon Black uses `T1548` (Abuse Elevation Control Mechanism) while Elastic and Splunk use `T1068` (Exploitation for Privilege Escalation). The high-level descriptions provided by MITRE for these two techniques describe behavior that is difficult to distinguish, and in fact both techniques in this case appear to be a valid description of CVE-2021-4034's privilege escalation vulnerability.

Meterpreter [48]. As another case study, we consider a rule from each ruleset associated with the Meterpreter payload [48]. These rules all detect named pipe impersonation with minor differences in implementation.

EDR	Technique	Description
Carbon Blk	`T1548`	Abuse Elevation Control Mechanism
Elastic	`T1574`	Hijack Execution Flow
Elastic	`T1068`	Exploitation for Privilege Escalation
Splunk	`T1068`	Exploitation for Privilege Escalation

Table 6: **Inconsistent MITRE ATT&CK Technique Labels for CVE-2021-4034:** Techniques assigned to CVE-2021-4034 rules by different endpoint detection products.

```
event.type == "start"
and process.pe.original_file_name in ("Cmd.Exe", "
   PowerShell.EXE")
and process.args : "echo"
and process.args : ">"
and process.args : "\\\\.\\pipe\\*"
```

This rule from Elastic [21] is annotated with `T1134` (Access Token Manipulation) and tactics *Defense Evasion* and *Privilege Escalation*.

```
Processes.process_name=cmd.exe
OR Processes.original_file_name=Cmd.Exe
OR Processes.process=*%comspec%*
(Processes.process=*echo* AND Processes.process=*pipe*)
```

This rule from Splunk [78] is annotated with techniques `T1059` (Command and Scripting Interpreter) and `1543` (Create or Modify System Process) and tactics *Execution*, *Persistence*, and *Privilege Escalation*. Note that we have removed some Splunk specific syntax and only included the portion relevant to the detection here.

Carbon Black also has an overlapping rule with the same ATT&CK tags as Elastic (`T1134`). We observe that the following event, provided by Splunk [78] in the corresponding rule's description, would cause all three rules to fire:

```
cmd.exe /c echo 4sgryt3436 > \\.\pipe\5erg53
```

The technique labels for these rules are sensible, as named pipe impersonation may be used to assume the access token of the client user connected to the pipe, and here it involves misuse of the command line interpreter. Again, this example highlights ambiguity within the techniques when considering procedure-level behavior (i.e., logged system activity).

Tactic Disagreement Example. We conduct a case study of two similar rules from Elastic and Splunk that fire when DNS utility `nslookup.exe` is executed with specific command line arguments. This behavior has been associated with several actors and threats, including FIN7 and SUNBURST.

```
event.category:process
and event.type:start
and process.name:nslookup.exe
and process.args:
(-querytype=* or -qt=*
or -q=* or -type=*)
```

This rule from Elastic [21] is annotated with technique `T1071` (Application Layer Protocol) and tactic *Command and Control*.

```
Process.process_name = "nslookup.exe"
Process.process = "*-querytype=*" OR
Process.process = "*-qt=*" OR
Process.process = "*-q=*" OR
Process.process = "-type=*" OR
Process.process = "*-retry=*"
```

This rule from Splunk [78] is annotated with technique `T1048` (Exfiltration Over Alternative Protocol) and tactic *Exfiltration*. Note that we have removed some Splunk specific syntax and only included the portion relevant to the detection here.

The only difference between the rules is an additional command line argument ("*-retry=*) in the Splunk implementation of the rule. Thus there is a large overlap in the sets of system logs that would cause these rules to fire alerts. However, we again observe that there is a disagreement between products about which ATT&CK technique these rules cover. Elastic is annotated with `T1071` (Application Layer Protocol) while Splunk is annotated with `T1048` (Exfiltration Over Alternative Protocol). Both systems make reasonable decisions for technique coverage based on the high-level description. These descriptions are sufficiently general that there is no well-defined mapping between system-level behavior and the techniques associated to it.

More concerningly, we note that these two techniques fall under different tactics. Elastic tagged tactic *Command and Control* while Splunk tagged tactic *Exfiltration*. *If we take the perspective of a security analyst investigating a breach or conducting attack reconstruction, they may attribute the same system log activity to two completely different motivations depending on which product they are using.* From Elastic, we would assume this activity was aimed at gaining control of the host system, while with Splunk we would assume the goal was to steal host data.

Inconsistent Technique Labels within the same product. We also observe instances where a given product may annotate similar rules within their own product with different technique labels. For example, we consider two rules from Carbon Black associated with the NotPetya malware. Both rules detect child processes of `lsass.exe`; however, one rule specifies 4 known bad child processes, while the other looks for any child process excluding a list of known false positives. In short, the events that would cause the first rule to fire is a subset of the second rule. The first rule is only annotated with `T1547` (Boot or Logon Autostart Execution) under tactics *Persistence and Privilege Escalation*, and the second rule is annotated with `T1547` and a new `T1003` (OS Credential Dumping) under tactic *Credential Access*.

Another example for similar rules with different labels is Splunk's rules related to CVE 2021-34527 with spawned `rundll32` processes. One rule specifies that the parent process should be `spoolsv.exe`, annotated with `T1547` (Boot or Logon Autostart Execution) while the other rule is broader and does not specify a parent, annotated with `T1218` (System Binary Proxy Execution). This points to potential hierarchical relationships between different techniques within the ATT&CK Framework.

7 Disclosures

Following completion of this study, we reached out to the product vendors in an attempt to disclose our results. We successfully connected with one of the surveyed vendors' technical and marketing teams, who were "excited" to hear about this work. Contrary to our intuition that vendors may be concerned about our findings – indeed, some still might – this vendor felt that a deeper discussion of the ATT&CK framework's role in security products was a good thing. In particular, marketing staff saw our findings as an opportunity to counter-balance the emphasis on ATT&CK coverage in product reports such as Gartner's Magic Quadrant [27]. Our conversation indicated that technical and marketing staff were already aware of the potential for tension between ATT&CK coverage metrics and effective security monitoring.

We also reached out to MITRE's ATT&CK team and their Center for Threat-Informed Defense, and had an opportunity to share our results with multiple relevant MITRE staff. Although their guidelines advise against using ATT&CK techniques as a checklist to complete – warning users not to shout "Bingo" when they've covered a technique [81] – the staff we spoke to were aware of some community misconceptions surrounding the framework. The largest misconception they observed was that MITRE ATT&CK is a complete summarization of all attack techniques and behaviors–since it only includes information that has been repeatedly verified, it may not have coverage of new APT behaviors. Another guideline [81] warns against the assumption that identifying one method of performing a technique is sufficient, as attackers can have a variety of system behaviors associated with a single technique. Regarding evaluation of EDR systems, they confirmed the importance of investigating the details of low-level detection behaviors (e.g., in the Engenuity Evaluations [52]) rather than relying on coverage metrics. For this reason, one staff member argued that it may not be a problem that products inconsistently apply ATT&CK technique labels, that instead this diversity could be a positive thing.

Finally, we also discussed our results with a leading cyber risk assessment company, who provides evaluations of their customers' security posture based on hundreds of metrics. Practitioners from this company indicated that they saw the value in ATT&CK as an explanation tool for incidents rather than a predictive factor of future events. Further, they mentioned that the security community is not aligned about what "TTPs" (i.e., tactics, techniques, and procedures) are and how they happen at an endpoint. This is reflected in our findings on inconsistent ATT&CK labels across products. More concerningly, they noted a misalignment between practitioners and the industry at large—they observed that their own customers often relied on advertisements of ATT&CK coverage

to decide which security product to purchase and interpreted that coverage as a definite notion of security (i.e., 90% coverage of MITRE ATT&CK equals "90% secure"). Additionally, one staff member noted that incorporating signature-based rules with anomaly detection and confirming correct configurations and deployments was more important for security than addressing all ATT&CK techniques. This indicates that while many security practitioners are aware of how to properly use ATT&CK, others can still be influenced by its misuse in marketing materials and other communications.

8 Discussion

8.1 MITRE ATT&CK as a Security Metric

The MITRE ATT&CK framework is increasingly used as the basis for evaluating threat readiness. Owing to its systematization of threats and periodic evaluation challenges, using ATT&CK in marketing materials has become an industry-wide practice for security vendors (e.g., [15,31,70,87]). Based on this messaging, organizations regularly use ATT&CK technique coverage as a measure of the efficacy of their deployed security tools (e.g., [9,65]). The ATT&CK framework is beginning to be used for assessing cyber risk and liability, and may even be factored into calculations for some cyber insurance premiums [5]. Put another way, the MITRE ATT&CK framework is yet another (potentially problematic) security metric [23,63].

The present study highlights the many pitfalls of blindly using MITRE ATT&CK technique coverage as a security metric. We analyze three major endpoint detection products that choose not to pursue 100% coverage of ATT&CK, but instead hover at 48%-55% coverage. Even at this coverage level, many techniques are only implemented as low priority rules that vendors define as unreliable (e.g., [77]). We believe it is unlikely that vendors have been negligent in their usage of MITRE ATT&CK; instead, we interpret this as evidence that large portions of ATT&CK are not suitable to implement as endpoint detection rules. In addition, we find similar biases (with statistical significance) among vendors in their technique coverage, suggesting that vendors have similar preferences for which ATT&CK techniques to write rules.

Further undermining the notion of ATT&CK coverage as an infallible security metric is our discovery that different vendors apply the framework in different ways, through our investigation of specific threats mentioned in rules of multiple endpoint detection products. Even when all vendors were specifically attempting to detect the same malware behavior, we observed very little agreement between products as to the techniques that should be used to describe the threat. These inconsistencies at the technique level can even cause an analyst to reach the wrong conclusions about an attacker's tactical goal. While we agree with MITRE staff that, as an explanation framework, diversity (inconsistency) in ATT&CK labeling is unlikely to cause problems in the hands of experienced professionals, the problem arises when ATT&CK is instead misused as a coverage-based security metric. Given that vendors' apply the ATT&CK framework in different ways, it is unclear what "coverage" of a given technique can tell us about an organization's security posture. We identify in Section 7 that vendors have also begun to experience the negative effects of coverage as a security metric.

Our findings provide empirical evidence for anecdotal arguments against ATT&CK coverage metrics raised by practitioners. We highlight the potential implications of the lack of a strict hierarchy between techniques to tactics [69], and show how ambiguous and overlapping definitions may lead vendors to label the same behavior with conflicting technique tags. We also demonstrate that, in spite of financial incentives to inflate ATT&CK coverage as much as possible, vendors often leave large portions of the ATT&CK framework uncovered, or minimize the importance of certain techniques by assigning their rules a low priority. This apparent contradiction between marketing materials and the actual products supports the observation that many ATT&CK techniques are rarely used by adversaries or suffer from poor signal-to-noise ratios when implemented as rules [29]. In contrast with prior anecdotal narratives [69], we conduct a comprehensive qualitative analysis of the ATT&CK techniques. The findings of our systematic coding of ATT&CK techniques also support the argument that many techniques are difficult, if not impossible, to implement as detection rules [29]. Aside from attack behaviors that are not targeted at an endpoint (e.g., external infrastructure) and logically cannot be detected, endpoint detection products may suffer from false negatives related to chained attack events. Such attacks require provenance-based detection, while rules typically encode isolated behaviors. While industry blogs [29,69] discuss difficulties with usage of MITRE ATT&CK, we provide substantiated evidence to identify how they manifest in widely deployed endpoint detection products and their implications for security analysts and vendors. Aside from analyses at the tactic and technique level, we also conduct procedure-level comparisons in downstream usage of ATT&CK across products. This leads to more nuanced insight into the impact of hierarchies and ambiguities within ATT&CK. We observe that ambiguities in how ATT&CK is interpreted can lead to divergent conclusions during attack reconstruction depending on the utilized product.

Complementary to ATT&CK, MITRE has also recently introduced the D3FEND Framework to describe cybersecurity countermeasures [80], similar in objective to the NIST Cybersecurity Framework (CSF) [56]. Both D3FEND and CSF catalogue defensive cybersecurity capabilities, rather than threats. D3FEND is a newer framework, but is far more fine-grained than CSF in its description of defensive capabilities; in turn, the CSF is more process-driven and outlines how organizations can set out and achieve a target security posture. Both D3FEND and CSF are better positioned than ATT&CK

to evaluate an organization's cybersecurity preparedness. This is because they focus on defensive capabilities and procedures rather than the nature of threats. That said, neither defensive framework sets out to evaluate or prescribe specific countermeasures, so they are not an immediate remedy to how ATT&CK is used to market products. Further, there may be situations where two products offering the same capability provide different levels of security, which cannot be expressed in D3FEND or CSF.

8.2 Recommendations

In light of the above, we strongly advise vendors, practitioners, insurers, and even researchers to avoid overreliance on coverage-based evaluations of MITRE ATT&CK. The technique level of ATT&CK offers a seductive middle-ground for security evaluations — it is complex enough for coverage to seem meaningful, but ultimately still simple enough for non-experts to understand. Of course, real adversaries do not exist at the technique level of ATT&CK, but at the procedure level; techniques exist to provide generalizable descriptions of specific attack procedures observed in verified real-world incidents. Detection rules also operate at the procedure level, describing specific interactions between system entities. This fundamental disconnect between the *procedures used for detection* and the *techniques used for evaluation* may lead to misinterpretations of MITRE ATT&CK coverage analysis. We observe such misinterpretations in the advertisements discussed in Section 2. For example, Cynet's blog [18] on the 2022 MITRE ATT&CK Evaluation implies that their high coverage percentages are a good measure of system effectiveness. As a result, even if the issues of ambiguity were addressed, ATT&CK coverage statistics still lead to a false sense of security because technique coverage implies security against one of a (possibly unlimited) number of different procedure-level threats. While procedure-level coverage analysis may seem like an obvious way to address this issue, MITRE adopts a conservative approach that admits only *verified* threat groups and procedures [69]. Thus, while procedure-based analysis would bring evaluations more in line with actual product behaviors, it is also flawed because ATT&CK is not intended to be a comprehensive repository of threat intelligence.

For practitioners and rule authors, we recommend taking steps to support rule evaluation via other methods. In general, the problem of evaluating a detection rule is difficult because its performance depends on the context and environment. That said, we call for the development of feedback mechanisms that allow practitioners to share feedback about rule performance alongside the exchange of other threat intelligence. For example, many of the sources of false alarms for a given detection rule will be common across different organizations. Exchanging this information would be helpful in identifying detection rules with poor signal-to-noise ratios. Yet, we are not aware of any security product that directly collects practitioner feedback on a systematic level on whether an alert is a false alarm. The security products in our study have forums to receive this information individually, either internally or via GitHub issues. However, this collection is an ad hoc process and requires manual investigation by analysts. Further, it is difficult to synthesize feedback across products for similar rules. Open source projects like Sigma are particularly well-positioned as a repository for community-wide rule feedback. A promising direction for future work would be designing mechanisms for evaluating and providing feedback on detection rules.

Our work shows that different practitioners may assess similar rules with different ATT&CK techniques. Another future direction is a recommendation system for ATT&CK labeling that can automatically determine the appropriate set of techniques for a particular rule implementation. Depending on the context in which a rule fires, the appropriate tactic or technique could differ. In this case, it may be useful to have some dynamic assessment where the technique is assigned at the time of the alert given the surrounding system behavior. This would provide a more tailored attack contextualization to the analyst and improve the endpoint product's usability.

Just as this work is not intended as a critique of the surveyed security products, we also feel it is unfair to disproportionately blame MITRE ATT&CK for these issues. MITRE actively advises against the kinds of coverage-based analysis that has overtaken the industry, specifically emphasizing that evaluations are only a starting point, that there are no winners in their evaluations, and even that not all techniques are created equal [52]. Instead, we argue that these problems are a result of the misapplication of ATT&CK that arise as an emergent property of the security ecosystem — vendors need sales pitches, consultants need to offer actionable advice, and practitioners need ways to evaluate these claims.

Our primary recommendation to MITRE is to take a more active role in shaping how the ecosystem is (mis)using the ATT&CK framework. The available guidance for ATT&CK has focused on the point of threat intelligence creation, such as annotating malware samples with techniques. It is necessary for MITRE to more broadly disseminate how ATT&CK should and *should not* be used, especially as coverage-based analysis begins to find its way into the cyber liability and insurance industries. This is especially important given the misalignment between practitioners and the remainder of the industry, as raised during our conversation with the cyber risk assessment company (Section 7). MITRE could also consider providing more extensive guidelines about how to interpret the ATT&CK framework. We also suggest formalizing latent relationships within ATT&CK, such as hierarchies between discrete techniques. While these patterns may be realized anecdotally by individual organizations through their attack traffic, MITRE may be positioned to perform a large-scale survey or data collection to systematize this information. MITRE ATT&CK remains a fantastic knowledge base of real-world

threat behaviors, and we are confident that issues of technique ambiguity will continue to be iteratively addressed.

8.3 Limitations and Future Work

An important consideration of our findings is whether the surveyed products and rulesets are representative of the entire security ecosystem. First and foremost, we selected the rulesets in this work based on availability. The majority of top products [24, 26] are proprietary and do not make their rulesets visible to customers; instead, the existence of a rule can only be inferred when an alert is fired. We are not aware of any other public or semi-public commercial rulesets, but hope to expand our results in future work as more become available. Whether or not they are representative of other products, Splunk, Elastic, and Carbon Black combine to account for a huge proportion of the ecosystem, having been deployed on millions of machines in thousands of organizations from various regions and industries [61,76,85]. Thus, it is not necessary for our findings to be universally applicable to have important implications for real-world security. Further, our analysis of the crowdsourced Sigma ruleset, which is comprised of rules submitted by hundreds of contributors and has downstream use by industry partners such as IBM [72], appear to confirm the general trends observed in our main analysis.

Our work is focused on endpoint detection; it is a critical component of enterprise security, but may not represent other systems such as network threat detection. While conducting this study, we attempted to collect and analyze detection rules from Network Detection & Response (NDR) rulesets. However, of the public rulesets we obtained, we found that ATT&CK technique annotations were far less common than for endpoint detection rules. It is not clear whether this observation is generally true of network detection rules or is simply an artifact of our limited visibility into this ecosystem. Future work is needed to extend our analysis to network detection.

Another threat to validity is the possibility that our qualitative analysis (§5) may have been biased by the coders' background and expertise, which is inherent to this type of analysis. We mitigate this concern by using three coders and by taking a conservative approach; specifically for the "ineffective detection method" coding, we only classify techniques as such when explicitly mentioned in MITRE's text, or if its detection would *obviously* result in high false positives.

Finally, our method of grouping rules by malicious entity (§6) is *necessarily* incomplete. It may be the case that some rules were incorrectly excluded from a group because their description did not explicitly mention the threat entity. It is certainly the case that many rules were excluded because they were designed to capture a more general class of malicious behavior. We made this trade-off to ensure the soundness of the analysis – by being conservative in our assignment of rules to a given threat entity, we ensured that the rule was unambiguously intended to detect that entity. This lead to the most favorable conditions for consistency as different rule authors are assigning MITRE ATT&CK annotations; yet, in spite of this, we still discovered widespread inconsistency amongst this subset of rules. Future work may explore a more generalizable approach to comparing rules at the procedure level to expand this analysis.

9 Related Work

MITRE ATT&CK. Researchers have proposed to map vulnerabilities to MITRE ATT&CK using machine learning techniques [40, 47, 68, 88], and use ATT&CK to characterize security risks and facilitate threat modeling [2, 67]. Prior work has also analyzed malware [60] and threat intelligence reports [64] to identify common ATT&CK techniques used in practice. A recent work [66] systematizes ATT&CK research and highlight its use cases, application domains, and related frameworks. Our analysis has important implications for work that performs ATT&CK-based threat modeling and risk assessment, especially those that assume the framework is an exhaustive and uniformly-likely enumeration of possible attack behaviors. Based on our findings and how the knowledge base is constructed, we urge authors to avoid conflating ATT&CK tactics, techniques, and procedures as "TTPs."

EDR Systems. MITRE ATT&CK has been prominently figured into research that integrates data provenance analysis with traditional EDR [10, 19, 32, 33, 41, 51]. Systems like HOLMES [51] and RapSheet [32] specifically assume that the underlying EDR will generate alerts associated with every ATT&CK tactic; however, our analysis indicates that this is highly unlikely to occur in practice. Qualitative studies [3, 39] have identified usability issues caused by false positives. However, as shown in our analysis, disabling rules with high false alarms (i.e., low-confidence rules) further reduces EDR's coverage of ATT&CK. Our work is orthogonal to research on *false negatives* in EDR products [38, 58]. For example, Karantzas et al. [38] evaluate eleven EDR products against four attack scenarios and find that all the EDRs fail to detect at least one attack. Complementary to our work, Shen et al. [71] investigate the implications of the MITRE Engenuity evaluations on real world EDR performance.

Threat Detection and Intelligence. Thematically similar to our study, Bailey et al. [8] compared Internet malware classifications behaviors of various signature-based antivirus products. Prior work has also compared various sources in the threat intelligence community [11, 30, 43], evaluating metrics like latency [43]. and originality [30]. Several papers [4, 6, 7, 28, 82, 83] have performed comparative analysis of rule-based network intrusion detection systems (NIDS), with a focus on their performance against popular attacks [4, 82], and the potential overlap [7, 83] and evolution [83] of NIDS rulesets. However, different from our analysis, these studies did not focus on the application of MITRE ATT&CK on the rulesets.

10 Conclusion

We present a comprehensive analysis of how the MITRE ATT&CK framework is used across four widely deployed endpoint detection products. We find that *ATT&CK coverage* is inflated by the presence of low-risk rules and different vendors classifying rules describing the same system-level behavior with inconsistent ATT&CK techniques and tactics. The results indicate that *ATT&CK coverage* may not be a suitable security metric for evaluating endpoint detection products. We conclude by providing recommendations for endpoint detection vendors and MITRE to improve the usage of ATT&CK.

TID	Technique (*Tactics*)
T1021	Remote Services (*Lateral Movement*)
T1047	Windows Management Instrumentation (*Execution*)
T1053	Scheduled Task/Job (*Execution*, *Persistence*, *Privilege Escalat.*)
T1059	Cmd. & Scripting Interpreter (*Execution*)
T1218	Signed Binary Proxy Execution (*Defense Evasion*)
T1543	Create or Modify Sys Process (*Persistence*, *Privilege Escalat.*)

Table 7: **Multiple Technique Annotations of a Single Rule:** One Splunk rule with six technique annotations.

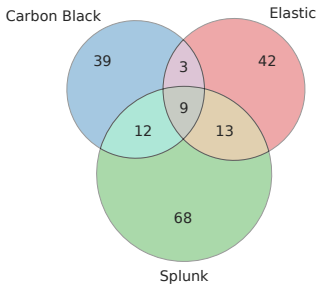

Figure 6: **Malicious Entity Coverage by Vendors:** Comparison of vendors including rules that *specifically* detect each of the malicious entities. Only 9 entities appear in all 3 rule sets. Note that limited overlap does not necessarily indicate insecurity, since EDRs may have other generic rules (that are not specifically designed for the given malicious entities) to detect these threats.

A Sigma

In this section, we replicate RQ1 and characterize how the Sigma threat detection ruleset [72] uses MITRE ATT&CK. As a crowdsourced ruleset, the quality control process for individual rules may be less uniform. This may introduce higher variation in how MITRE ATT&CK is used within the ruleset and thus we report the results separately.

First, we see from Table 1 that Sigma's coverage of ATT&CK techniques (79%) is over 20% greater than the coverage for any of the three commercial rulesets (48%-55%). Despite the higher coverage, we note that the Sigma ruleset follows similar trends in terms of technique coverage under each tactic, as shown in Figure 7. While it follows that there are fewer techniques with 0 implemented rules compared to the other EDRs, we observe in Figure 8 that Sigma also has a similar distribution of rules per technique. That is, the majority of techniques are covered by a handful of rules each.

Further, we find that the inclusion of Sigma does not change the top ATT&CK techniques across the four engines as seen in Figure 9. We replicate the Spearman coefficient calculations between the ranked list of techniques implemented by Sigma and the other three rulesets to identify if Sigma chooses to prioritize similar techniques. The Spearman coefficients are positive—0.701, 0.762, and 0.793 for Splunk, Elastic, and

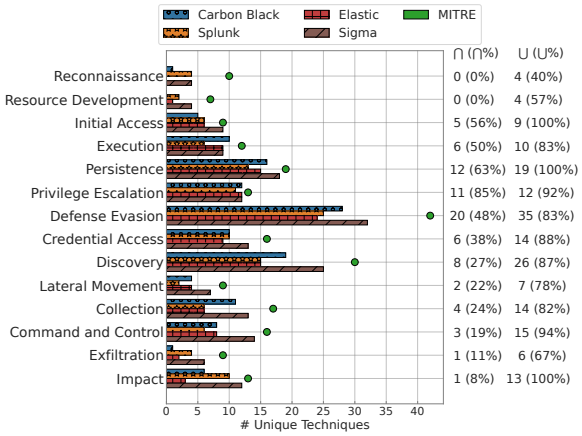

Figure 7: **Technique Coverage under Each Tactic:** The plot replicates Figure 1 with the inclusion of the Sigma ruleset.

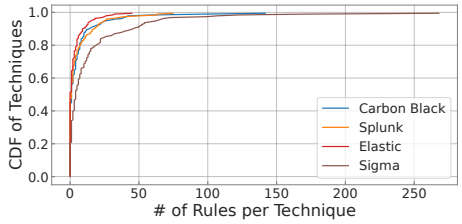

Figure 8: **Rules Per Technique:** Cumulative distribution of the number of rules per technique for each EDR system.

Carbon Black respectively—with a p-value < 0.001 for each corresponding t-test. This confirms that Sigma's similarity to all of the commercial rulesets is statistically significant in terms of which techniques each chooses to cover.

Each Sigma rule is annotated with a qualitative *level* indicating how critical the fired alert would be (i.e., how quickly a security analyst should respond), analogous to the risk and severity metrics provided by the commercial rulesets. There are five criticality levels (informational, low, medium, high, critical) and the majority of Sigma rules are assigned to either medium (34.7%) or high (48.8%) levels. We map the five levels to numeric values based on the CVSS scale [55] to investigate the level distribution for the top techniques (see Supplementary Materials [84] for figure) and find that it is fairly consistent across techniques. Similar to the commercial rulesets, we observe a drop in ATT&CK technique coverage when filtering out lower criticality level rules. If we consider only rules with at least a medium criticality level, the MITRE ATT&CK coverage slightly drops to 74%. If we consider only rules with at least a high criticality level, the MITRE ATT&CK coverage drops to 62%. Sigma also has a similar proportion of rules annotated with multiple ATT&CK techniques, as shown in Figure 10.

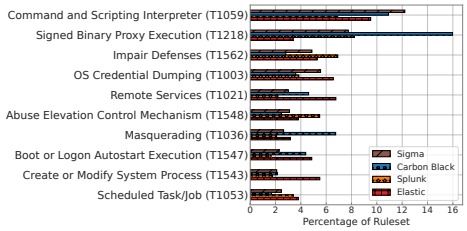

Figure 9: **Top ATT&CK Techniques:** Top 10 techniques ranked based on the sum of associated rules from the four engines. The x-axis shows the percentage of the rules for a given technique in each engine (e.g., 16% of the Carbon Black rules are tagged with `T1218`).

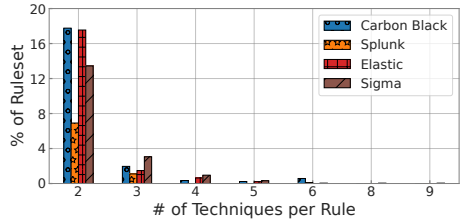

Figure 10: **Multiple Techniques Per Rule:** The distribution of the number of techniques per rule. Rules with a single technique label are omitted from the plot.

B Examples of Rules with High False Positives

```
process.name : "cmd.exe"
and event.type == "start"
and not cidrmatch(destination.ip,
"10.0.0.0/8", "127.0.0.0/8", ...)
```

This Elastic rule identifies `cmd.exe` making a network connection. The metadata stipulates that administrators may trigger this rule frequently for benign and regular tasks, causing false positives. The rule is annotated with techniques `T1059` (Command and Scripting Interpreter) linked to tactic `TA0002` (Execution), and `T1105` (Ingress Tool Transfer) linked to tactic `TA0011` (Command and Control). The severity assessment is 2.1 / 10 and the risk score is 21 / 100.

```
Processes.process_name=xclip
AND Processes.process IN ("*-o *", "*-sel *",
"*-selection *", "*clip *","*clipboard*")
```

This Splunk rule identifies the Linux tool xclip being used to copy data from the clipboard. This is commonly used by administrators and end users on Linux machines. This rule is annotated with technique `T1115` (Clipboard Data) linked to tactic `TA0009` (Collection). The confidence score is 40 / 100 and the risk score is 16 / 100.

```
Processes.process_name=curl
OR Processes.process_name=wget
```

This Splunk rule identifies usage of command-line tools curl and wget. The rule used in isolation will lead to false positives, as the behavior is likely to occur frequently in normal circumstances. This rule is annotated with technique `T1105` (Ingress Tool Transfer) linked to tactic `TA0011` (Command and Control). The confidence score is 10 / 100 and the risk score is 1 / 100.

Digital Discrimination of Users in Sanctioned States: The Case of the Cuba Embargo

Abstract

We present one of the first in-depth and systematic end-user centered investigations into the effects of sanctions on geoblocking, specifically in the case of Cuba. We conduct network measurements on the Tranco Top 10K domains and complement our findings with a small-scale user study with a questionnaire. We identify 546 domains subject to geoblocking across all layers of the network stack, ranging from DNS failures to HTTP(S) response pages with a variety of status codes. Through this work, we discover a lack of user-facing transparency; we find 88% of geoblocked domains do not serve informative notice of why they are blocked. Further, we highlight a lack of measurement-level transparency, even among HTTP(S) blockpage responses. Notably, we identify 32 instances of blockpage responses served with 200 OK status codes, despite not returning the requested content. Finally, we note the inefficacy of current improvement strategies and make recommendations to both service providers and policymakers to reduce Internet fragmentation.

1 Introduction

Internet fragmentation is of increasing concern across the world, with several countries proposing locale-based content-restricting legislation in recent years [17, 22, 32]. The resulting rise of digital inequity places democracy under threat by restricting the free flow of information; still, there remains a shortage of data-driven studies that explore this problem. Existing work focuses on inaccessibility due to nation-state censorship [28, 45, 47, 57] or infrastructure limitations [11], but there is increasing anecdotal evidence of the detrimental effects of server-side geodiscrimination, or *geoblocking*. Reasons for this geoblocking remain understudied [2, 35, 49], especially with regards to the role of economic sanctions in causing digital discrimination.

Digital discrimination resulting from sanctions has seen a notable uptick and garnered significant global attention in recent years, following U.S. sanctions against regions such as Iran, Syria, North Korea, and Cuba [41]. For example, service providers such as Amazon Web Services and Slack recently removed support immediately after the U.S. government announced a novel sanctions program in Russia [15], leading to the Office of Foreign Assets Control (OFAC) [40] receiving immediate backlash. The agency had to issue a subsequent clarification to the sanctions to emphasize the government's commitment to "support the flow of information." This incident highlights the critical lack of clarity between policymakers and service providers, and mirrors similar disjoint responses in other U.S. sanction deployments.

In this paper, we investigate web content inaccessibility as a result of U.S. sanctions. As sanctions are often applied to unstable or repressed regions, engaging in this type of work has inherent challenges, including the ethical risks associated with interacting with in-region contacts and difficulties with obtaining a vantage point (VP) that accurately captures a residential perspective. Furthermore, even with an appropriate VP, much care is needed to attribute connection errors accurately. Prior work on server-side blocking highlights these complexities, noting compounding factors, including DDOS prevention, IP reputation, and distinguishing geoblocking from censorship [2, 30, 35, 49].

We present one of the first in-depth and systematic investigations into geoblocking in the context of embargo sanctions, prioritizing clarity to end-users. Specifically, we explore the following questions: What popular domains and content categories are being geoblocked? How is geoblocking implemented at the network layer, and what are the effects on measurement-level transparency? Correspondingly, how is geoblocking experienced on the ground, and does it promote user-facing transparency? These questions are crucial to identify the gaps in understanding between policymakers and web service providers and to fully characterize the digital effects of embargo sanctions.

We chose to perform this study on Cuba, primarily because we could ensure both safety and ethics compliance of the highest order. Since Cuba has a relatively higher civil-liberty ranking than other sanctioned states [23] and no active con-

flicts, the potential risks to participants of this work are minimized. Additionally, imposed in the 1960s, the U.S. embargo on Cuba is the longest running in history [16, 46]. As such, the totality of the development of Cuba's Internet ecosystem has been in the shadow of these regulations; still, there is an absence of clear characterization of the digital effects of the embargo. Having identified Cuba as our location of study, we gather knowledge from users on the ground in Cuba using a small-scale user study to gain insight into their perspective of the day-to-day impact of U.S. sanctions. We then use these results to inform our comprehensive network measurements of popular domains to identify geoblocking.

We test 10,093 domains, drawn from the Tranco Top 10K [31] domains and augmented with those highlighted in our small-scale user study in Sec. 4. Our measurements are informed by the valuable perspectives shared by our respondents and guided by the desire to rigorously ascertain how domains are geoblocked. We take extensive measures to identify geoblocking across different layers of the network stack, conducting TCP and TLS traceroute measurements to localize failure points and manually examining relevant HTTP(S) response pages. This gives us insight into both measurement and user-facing transparency of different geoblocking implementations. Throughout this process, we uphold the highest ethical standards to minimize the risk to our respondents and the independent collaborator who provided us with a residential VP, with further details in Sec. 3.

We find 546 domains within categories such as Technology, Business, and Economy & Finance, are implementing geoblocking, including popular online services such as Spotify, MailChimp, and CourseHero. Spotify in particular hosts several podcasts discussing the U.S. embargo on Cuba [25], [1, 3, 25], yet is not accessible for Cuban netizens, pointing them to the page in Fig. 1. Furthermore, we identify 17 diverse geoblocking implementations, ranging from DNS failures to HTTP(S) response pages with a variety of status codes. Alarmingly, geoblocking implementation is also diverse among top domains such as `tiktok.com` and `mathway.com` that are hosted by popular Content Delivery Networks (CDNs) (*e.g.* Amazon, Cloudflare, Akamai); 7.7% of geoblocking CDN hosted domains serve blockpages with a 200 OK. This further highlights the lack of measurement-level transparency for geoblocking. In terms of user-facing transparency, we find that 88% of geoblocked domains do not serve informative notice of why they are blocked.

By highlighting the nonuniform nature of geoblocking implementations and lack of transparency at both the measurement and user-facing levels, as well as directly integrating the perspective of everyday Cuban Internet users, our study demonstrates a disconnect between policymakers and service providers regarding the scope and intention of the U.S. embargo on Cuba. We believe that there is a pressing need for policymakers to clarify existing sanctions and assist service providers in understanding their legal responsibilities. These actions, taken in tandem with service providers' commitment to standardizing and clarifying geoblocking implementations, represent a step towards reducing digital discrimination. We hope to provide the insights necessary to begin catalyzing these changes and inspire data-driven future work.

Figure 1: **Spotify Blockpage in Cuba.** While Cuban netizens see an informative blockpage when visiting Spotify, to reach this page we had to manually follow a redirect link from a 301 redirect response. This is an example of the dichotomy between measurement and user-facing transparency.

2 Background & Related Work

Civil society and technical organizations have noted how sanctions could limit access to information in states including Cuba [5, 12]. In 2021, Time magazine reported that technology-based companies severely and abruptly restricted their products from use in Cuba due to the volatile nature of U.S. sanctions, leaving Cubans who relied on these products for their livelihoods to scramble and find alternatives [9]. UC Santa Barbara's Media Fields Journal provided additional accounts that corroborated the capricious and nontransparent product restrictions that resulted from the confusion about embargo policies [29]. There have been few data-driven studies that focused on geoblocking in Cuba. One such work, McDonald *et al.* [35], found 66 of the top 10K Alexa domains unreachable from Cuba.

History of Internet Access in Cuba. Despite being one of the first countries in the Caribbean region to gain access to the Internet in the late 1990s, Cuba's connectivity and infrastructure development never got off the ground due to the communist government's passage of laws aimed at limiting the free flow of information [4]. The early 2000s brought a ban on ownership and use of computers and cellphones that stymied even more growth as the rest of the world progressed into the Internet age [21]; its repeal in 2008 and the subsequent building of a sub-sea cable connecting Cuba to Venezuela in 2013 led to citizens being able to use the Internet [11]. To further regulate Internet access, Cuba merged its existing telecommunications providers to make the only legal state ISP, Empresa de Telecomunicaciones de Cuba S.A. (ETECSA) [20].

The popularity of the Internet grew throughout the 2010s, leading to ETECSA offering 3G/4G access plans by late 2019 [23, 34]. Prior work investigating network conditions in Cuba found that most outgoing traffic is served via the aforementioned sub-sea cable instead of the slower satellite chain alternative [11]. However, Internet connections still remain slow to this day [20]. Today, Internet access has permeated throughout the insular nation; in 2021, it was estimated that 72% of the Cuban population actively uses the Internet [23]. The Cuban Internet experience has been significantly shaped by government censorship and embargo restrictions, especially those placed on it by the U.S.

2.1 Sanctions

Purpose and Implementation. Sanctions are used by governments to apply pressure to target nations [7]. Policymakers design sanctions to achieve broad goals, such as wholesale regime change, or limited goals, such as specific policy changes. They hope that experiencing economic pain will lead citizens to lobby their governments to change course, elites to put pressure on their peers to adjust, or leaders to anticipate unrest and bend to external pressure [24, 26, 38]. Successful sanctions require cooperation between private firms and national governments.

U.S. Sanction Compliance. Businesses looking to provide products or services in embargoed or sanctioned countries must either apply for and receive specific authorization from the U.S. Department of Treasury or be a member of a list of allowed products and service categories promulgated by the Bureau of Industry and Security (BIS) [41]. These two bodies work together with the Office of Foreign Assets Control (OFAC) to ensure compliance with these regulations; any businesses found in violation can be fined up to 1M USD depending on the scale and severity of the transgressions [41]. Under OFAC's mandate, offering digital services of any kind in comprehensively sanctioned states requires either a specific or general license [51].

While still requiring OFAC approval (via a general license) based on the technologies used [33], free services do not have to undergo financial approval. Still, some technologically advanced software, such as those with encryption above a certain complexity, remains completely interdicted [41]. Covering less complex software, the U.S. State Department recommended the first general license for digital services "to allow Iranians to download free, mass-market software" in 2009 [56] and released statements supporting the free flow of information to this sanctioned region [53].

Noncompliance Risks. Sanctions, then, present a significant regulatory risk for businesses. Faced with a choice, they could conduct business as usual and pay continued compliance costs to remain within legal boundaries. Alternatively, firms can de-risk from markets even if it is permissible to operate there [19]. Regarding the negative impacts of sanctions, the U.S. Treasury Department recognizes that "de-risking hampers the unencumbered flow of development funding, as well as humanitarian and disaster relief" [55]. Even if sanctions do not explicitly forbid an action, they create compliance costs for doing business in the sanctioned country.

The U.S. Embargo on Cuba and Exemptions. The Cuban embargo was initially proposed by President Kennedy in 1962 and expanded by Presidents Johnson and Reagan, finally formalized with the Helms-Burton Act of 1996 [16, 46]. The goal of the embargo was to pressure Cuba to return to a democratic form of government by cutting off imports from and exports to the country [42]. In recent times, these regulations have seen significant change [8, 16, 42].

While a blanket sanction on Cuba exists, the U.S. government has attempted to clarify how sanctions apply to digital services along with their potential exemptions. Internet-based services are covered by a general license in US 31 CFR §515, first issued in 2010 addressing "the exchange of communications over the Internet." General exemptions exist for software services and fee-based Internet services (*e.g.* e-mail, VOIP), providing Internet connectivity, or travel to set up digital services [54]. The general license makes an additional carve out allowing services "widely available to the public at no cost to the user" to be provided to normally prohibited officials of the Cuban Government or Cuban Communist party, although it does not include the same language for entities on the State Department's Cuba Restricted List. Additionally, OFAC and BIS published a fact sheet in 2021 [40], detailing the government's commitment to protecting the fundamental freedoms of citizens of Cuba and outlining relevant categories of services potentially subject to exemption by reemphasizing some of the aforementioned excerpts of the CFR, as well as "software design, business consulting, and IT management and support (including cloud storage)," and "certain Internet-based courses" [54].

2.2 Geoblocking

Before proceeding, we find it prudent to discuss and disambiguate a few related terms mentioned in this work. *Censorship* typically refers to nation-state actors denying access to particular Internet services or groups of websites, while *server-side blocking* refers to service operators denying access to users based on some attribute of the user's connection. *Geoblocking* is a type of server-side blocking conducted based on a user's location. A *blockpage* is a page served instead of regular content, ranging from a blank page or nondescript error message to an informative explanation regarding the inaccessibility. While geoblocking can present with a blockpage, this is not always the case as certain implementations can cause errors before the page is served [49].

Existing Geoblocking Studies. As the fragmentation of the

Internet has gained in prominence, geoblocking has emerged as a recent topic of study. Tschantz *et al.* [52] analyzed geoblocking by querying Cloudflare-hosted domains in the now deprecated Alexa Top 1M websites using virtual private servers (VPSes) in several countries, identifying geoblocked domains as those whose contain standardized indicators of geoblocking within CDNs. They found 524 out of 77K domains served such a blockpage.

McDonald *et al.* [35] conducted a wide-scale set of measurements on geoblocking, querying the Alexa Top 10K websites from thousands of VPSes in 177 countries. They focused on geoblocking implemented by Content Delivery Networks (CDNs), finding Cuba experienced geoblocking on 66 out of 10K and 165 out of the Alexa Top 1M websites, lagging behind Syria, Iran, and Sudan.

Afroz *et al.* [2] leveraged similar techniques and conducted measurements to study server-side blocking in Africa, Pakistan, and Ukraine. In an attempt to evaluate a more expansive range of geoblocking throughout the network stack, they used heuristics surrounding the distance traveled by an outgoing packet along the network path to localize the point of failure and determine its proximity to the server.

Kumar *et al.* [30] investigated geoblocking implemented via the Google Play Store, developing a semi-automated tool to download apps as seen by users in 26 countries. They found 3,672 out of 5,684 apps (64.6%) were geoblocked in at least one location by service providers, a departure from previous conclusions of sparse and category-specific geoblocking by McDonald *et al.* and Afroz *et al.*

Decoupling Geoblocking from Censorship. Previous work relied on the presence of blockpages or numerical heuristics to identify geoblocking [2, 35, 52]. In a bid to remedy these shortcomings, Ramesh and Sundara Raman *et al.* [49] studied both censorship and geoblocking during the Russian invasion of Ukraine with an eye towards an accurate, conservative decoupling mechanism. They developed and open-sourced a measurement tool [13] that checks the accessibility of a domain across different network layers. Additionally, they run traceroute measurements to differentiate between geoblocking and censorship, capitalizing on the disparate locations of connection failure in each case. We leverage and extend these methods, as discussed in Sec. 5.

Our Work in Perspective. We present an in-depth and systematic investigation into geoblocking through the lens of embargo sanctions, as well as conduct the first small-scale user study capturing the impact of these sanctions on everyday Internet users. We note the limited prior work on Cuba focuses on characterizing general service availability [11], and the only other geoblocking study including Cuba from McDonald *et al.* [35] limits its scope to CDN blockpages. In comparison, we consider geoblocking implementations across network layers, resulting in outcomes like failures in DNS resolution to blockpages served with 200 OK responses. From a technical network measurement perspective, we not only utilize state-of-the-art methodology [13, 49], but also necessarily extend it to deal with extremely poor network conditions in Cuba by adding a configurable sleep time between measurements. We have open-sourced these changes [13].

3 Ethics

We consulted with our Institutional Review Board (IRB) and received IRB exemptions for both our small-scale user study (Sec. 4) and network measurement study (Sec. 5). We further consider the design of our studies and their potential risks by reaching out to the general counsel, colleagues at our institutions, and collaborators with expertise in researching censorship. Furthermore, we aim to uphold the ethical principles in the Menlo Report [6], which is inline with prior work [27, 39, 44, 48, 59]. These principles impact the design and deployment of our studies.

The first principle is *respect for persons*. We carefully engage in secure, small-scale outreach through established contacts, with our resulting 10 respondents skewing more technically literate. This ensures that they can give informed consent and understand the potential risks involved. Before proceeding through the questionnaire, we provided a detailed disclosure form, noting participation was entirely optional.

The second principle is *beneficence*. We protected our respondents' anonymity by not collecting any personally identifiable information (PII), such as names or email addresses. For our network measurements, completely disjoint from the questionnaire, an Internet freedom community member with years of experience related to network traffic analysis of Cuba explicitly consented to provide the Cuban VP to facilitate the study. Due to an inability to identify another similarly experienced contact, we limited ourselves to the use of the single VP. Using this VP, we conducted measurements to determine the accessibility of domains within Cuba. A network observer could attribute regular requests to censored domains as being from the VP owner. We balance these risks with the understanding that our work could directly aid Cuban citizens in uncovering the extent of the digital effects of the embargo.

The third principle is *justice*. In Sec. 6, our findings highlight the inefficacy of current improvement strategies to reduce the negative impact of the embargo on the free flow of information in Cuba. As our work pushes for better standardization of geoblocking implementation to minimize consequences, this directly benefits all of our participants. The fourth principle is *respect for law and public interest*. To adhere to the embargo on Cuba, we conducted the small-scale user study with volunteers only (*i.e.* without financial compensation).

4 Small-Scale User Study

In this section, we explain how we conduct our small-scale user study to characterize the impact of the U.S. embargo sanctions on Cubans from a first-hand user perspective, as well as identify exact websites and services that are blocked for our respondents. Extracting these experiences and struggles helps inform our network measurements in Sec. 5 and our analysis of geoblocking in Sec. 6. The full questionnaire is provided in Appendix A.1.

4.1 Motivation and Methods

Despite ample news coverage surrounding the downstream effects of U.S. embargo sanctions on Cuban Internet, such as those detailing that Cubans cannot access major services such as MailChimp and OpenSea [9], there is a lack of data-driven studies that capture the embargo's technical impact from a user perspective. We seek to explore how the embargo affects users on the ground.

There are innate challenges associated with carrying out our questionnaire. First, we had to ensure through our contacts that our questionnaire platform, TypeForm, was accessible to Cuban respondents. Second, we had to solicit participation by conducting a small-scale ethical outreach through established contacts to mitigate respondent risks. As such, we leveraged personal and NGO contacts to distribute our questionnaire to 10 Cuban Internet users. We note that our selected respondents skew toward being technologically literate. Since our study centers around user perspectives of sanction-related geoblocking and its technical outcomes and impact, in addition to the ethical benefits detailed in Sec. 3, this skew is advantageous because technical respondents are more likely to provide relevant and accurate details. Additionally, we note that the limited and guarded mode of outreach ensures all users taking our questionnaire are fully aware of the risks associated with participation.

We begin the questionnaire with a statement detailing both respondent risk and the measures we take to ensure anonymity and privacy. Our first section collects anonymous general demographic and Internet usage information; we next ask about notable blocked web services and categories and their specific blocking indicators, such as blockpage screenshots. Finally, we ask respondents to rate how the inaccessibility of various categories of web services affects their daily lives to capture the human impact of geoblocking. Responses were collected in English (4) and Spanish (6), the latter translated to English with Google Translate and DeepL [58]. We cross-validate and perform manual lookups to verify correctness.

We briefly characterize user responses using the following approaches. For polar questions, as well as those answered with the Likert scale, we explored aggregated metrics. For long-form questions, in which nine out of 10 respondents provided answers, we apply a free-form coding approach and find responses largely fall under two broad themes: the impact of sanctions on respondents' daily lives and their perspectives on sanctions policy; we highlight excerpts to characterize the depth of our respondents' perspectives.

4.2 Findings

All respondents reside in Cuba and the majority are between the ages of 26–35. Their familiarity with Internet technologies varies from daily Internet users to software professionals; five respondents identified as software developers or network administrators, one as a government official, and the remaining noted various other occupations.

Geoblocking Characterization. Respondents identified 36 domains as subject to geoblocking and pointed us to a community-maintained repository with 95 domains purportedly geoblocking Cuban users. We augment our test list with these domains in Sec. 5, with results in Sec. 6. Regarding common user-facing instances of geoblocking, all 10 respondents report encountering 403 Forbidden pages, and nine identify location-based language such as "Not available for users in your region." R2 additionally highlights non-standard blockpages, adding in an optional response,

> "The page loads, but not all the content. Vital bits of it say it's not available from my location." (R2)

Only five respondents attribute ambiguous browser error feedback (*e.g.* `No Internet`) to server-side blocking. Among the categories of services subject to geoblocking, Communication Tools (8 respondents), File-sharing (6 respondents), and E-commerce (6 respondents) were the most common.

Notably, although we sought instances of geoblocking rather than censorship, respondents still attributed blocking in categories like Political Criticism and Human Rights Issues to geoblocking when they are more likely to be censored. In fact, one respondent identified `cibercuba.com` as geoblocked, but we confirm that it is censored in Sec. 6. This suggests a lack of clarity surrounding the disambiguation of geoblocking and local censorship from an end-user perspective and a generalized lack of user-facing transparency.

Impact on Daily Life. Fig. 2 displays aspects of our respondents' daily lives impacted by sanctions. While some respondents highlight services with financial transactions that more directly fall under the scope of sanctions, several also note propagating impacts on their careers. For instance, R7 and R8 discuss barriers to information and the isolated nature of a Cuban developer work:

> "I do not have access to many tools that are blocked in my country, affecting my profession, limiting my knowledge." (R7) "...it makes it impossible for us to create projects that can be used internationally." (R8)

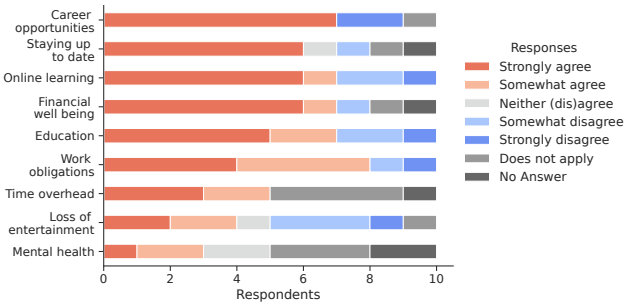

Figure 2: **Impact on Daily Life.** Respondents reveal how embargo sanctions impact their daily lives, with "Career opportunities," "Staying up to date," and "Online learning," noted as being the most negatively impacted.

Similarly, R9 complains at being excluded from the global community, *"The blocks to services that in the world are practically 'natural,' in my case they are impossible to use."*

Further, this isolation impacts respondents beyond their livelihoods. R4 notes *"The impact on my life is daily, whether it is to download and use apps, to pay, for work meetings and many more."* More broadly, R1, a tourist guide, notes, *"It is another form of segregation."*

In terms of the availability of substitutes for sanctioned services, seven out of 10 respondents were unaware of any local alternatives. For those aware of alternatives, the gap remained apparent.

> "There are some that we have had to create ourselves, although their capabilities are not as good as the originals." (R8)

Thus, it is unsurprising that nine of our respondents resort to circumvention tools to access sanctioned services. However, we emphasize the tech-savvy skew of our respondents and note that this is not generalizable to the greater Cuban populace. Notably, there are downsides to using these tools, such as safety concerns, as well as time and financial costs,

> "I expose myself to being discovered as it is considered illegal in my country." (R7) "[It] slows down my day to day, and makes my connection more expensive." (R2)

User Perspectives on Geoblocking. Five respondents offer perspectives on sanctions directly and indicate perceived unintended targets of their negative impacts. R7 fully disregards any harm to the government from sanctions, *"Blocked sites only affect the people who need the knowledge, not the government;"* while R10 takes a more moderate approach, criticizing the lack of precision of sanction effects,

> "I can understand the goal of restriction regarding to governments. But this should be better targeted to not affect people not directly related to the sanctioned government or state." (R10)

Similarly, R8 details their perspective on the embargo harming development,

> "In theory, these sanctions should only affect the government, but they affect all citizens directly, greatly limiting our chances of prospering and being able to develop like any other citizen in the world." (R8)

Takeaways. We observe consistent levels of frustration and claims about the negative impact of the U.S. embargo on Cubans. Our respondents are especially cognizant of how sanctions have affected their professional livelihoods, lamenting their loss of opportunities for international jobs and financial growth. Our small-scale user study informs our systematic measurement approach by augmenting our test list in Sec. 5. Notably, for Sec. 6, it underscores the importance of studying user-facing issues, like geoblocking transparency.

5 Measurements

Our goal is to identify and study instances of geoblocking in Cuba. However, due to the sensitive nature of U.S.-Cuban relations and poor network conditions inside Cuba, we apply nuanced and rigorous methods, mitigating potential data loss while adhering to ethical principles as outlined in Sec. 3.

Fig. 3 provides an overview of our approach to measuring and identifying geoblocking. Our test list comprises of the Tranco Top 10K domains [31], which we augment with 36 domains mentioned by respondents in our questionnaire in Sec. 4, as well as 95 domains from the aforementioned community-maintained repository [18]. For our control measurements in Sec. 5.1, we rent three VPSes in data centers, two in the U.S. and one in the U.K. For our Cuba measurements in Sec. 5.2, we rely on a collaborator in Cuba and obtain a VP located in the state-owned and only public ISP Empresa de Telecomunicaciones de Cuba (ETECSA). Notably, prior research has shown that measurements using data center VPSes are not representative of true user experiences in networks experiencing interference [57]. Thus, we run our measurements from a residential machine. Additionally, we retest domains in Cuba that fail all DNS requests or fail with a server error associated with timing out, as these could be due to poor network conditions, as further detailed below.

Measurement Runs and VP Instability. Our measurements were conducted over the period of May 11–22 of 2023, with corresponding control and Cuba measurements conducted within 24 hours of each other to ensure consistency. Throughout the data collection period, the instability of the VP's network remained a primary point of concern. Due to both a lack of access and the challenging nature of obtaining additional

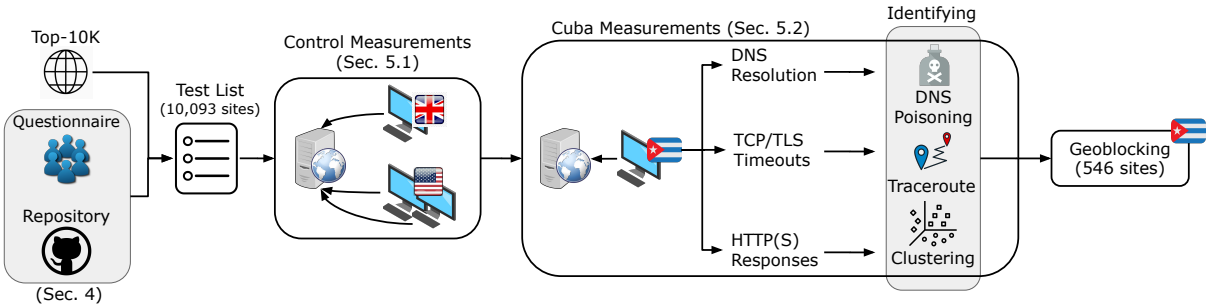

Figure 3: **Measurement and Geoblocking Identification Overview:** We first construct our test list with the Tranco Top 10K domains and augment it with domains from our small-scale user study and community-maintained repository. Then, we conduct control measurements from our three control VPSes. Next, we run Cuba measurements from our residential VP and identify instances of geoblocking across different layers of the network stack.

VPs, we operated under the necessary premise that loss of machine access could occur at any time.

Our initial measurements run 100 domains in parallel, with successive request batches spaced by one second. Due to the unreliability of the residential VP, in cases where test measurements fail all DNS resolution attempts or experience a server-level time out error, we retry each domain an additional time. We configure retest measurements with a lowered parallelization rate of 20 domains and increased batch spacing of 30 seconds. This allows us to distinguish slow network conditions from geoblocking. We update our open-source measurement software with this configurable wait time [13].

5.1 Control Measurements

Through our control measurements, we identify and remove inaccessible domains from our test list. This prepares the data as a benchmark for further analysis.

Our measurements begin in the DNS layer, where we perform three types of measurement for each domain. First, we query via our custom recursive DNS trace method, which enables us to function as the client by iteratively requesting each segment of the domain (*e.g.* for `a.example.com`, we query `.com`, then `example.com`, then `a.example.com`) until we reach the desired A-record. Next, we perform two rounds of public DNS resolution, via Cloudflare DNS (`1.1.1.1`) and Google DNS (`8.8.8.8`), the latter being the default DNS resolution server of the measurement machine. Cloudflare's nearest point of presence to Cuba is in the United States (Miami, Florida), and Cloudflare does not forward the Client IP information by default. Similarly, Google DNS connects to a server in the United States (Charleston, South Carolina).

We then attempt to establish a TCP connection with the web server using the IP address obtained during the DNS resolution. To clearly separate unavailability-related indicators from transient network failures, we retry failed TCP handshakes up to three times, within a given run of a domain. Once the TCP connection is established, we attempt to perform a TLS handshake, sending a TLS Client Hello with the Server Name Indication (SNI) field set to the domain, replicating browser behavior. After the TLS connection is established we send an HTTP GET request with the Hostname set to the test domain. We follow up to three redirects and store the response from the web server.

Removing Unreachable Domains. Only one domain's accessibility differed between the U.S. and U.K. machines, and we removed this domain from consideration. The majority of domains that fail to resolve consist of internal DNS domains used for name resolution within private networks, like `awsdns-37.org`, and internal CDN hosting domains not intended for direct access, like `cdnbuild.net` and `rackcdn.com`. In total, of our initial measurement test list of 10,093 domains, we found 8,537 passed control DNS runs and 6,396 passed control TCP. We use this sanitized list of 6,396 domains as a baseline for comparison in Sec. 5.2. We additionally provide a breakdown of our test list by category in Fig. 12 in the Appendix.

While we proceed with the Tranco list as it is a state-of-the-art domain ranking list robust against manipulation (*e.g.* fake traffic), we also takes steps to account for the domains lost in the sanitization process. To explain the 36% difference between the initial and final lists, we cite a known issue with the Tranco list. It is a composite of four existing top lists, and its constructors acknowledge that 10-50% of domains in these lists did not issue a 200 OK response code or were otherwise unreachable [31]. We further verify that the difference in our lists is not unexpected by performing a t-test for the difference in means between our sanitized test list and bootstrapped samples of the Tranco list, repeatedly sampling from a theoretical distribution parameterized by the four compositional components of the list. We find the difference is not statistically significant at a significance level of $\alpha = 0.05$, suggesting that our sanitized test list falls within the expected distribution of accessible and inaccessible domains.

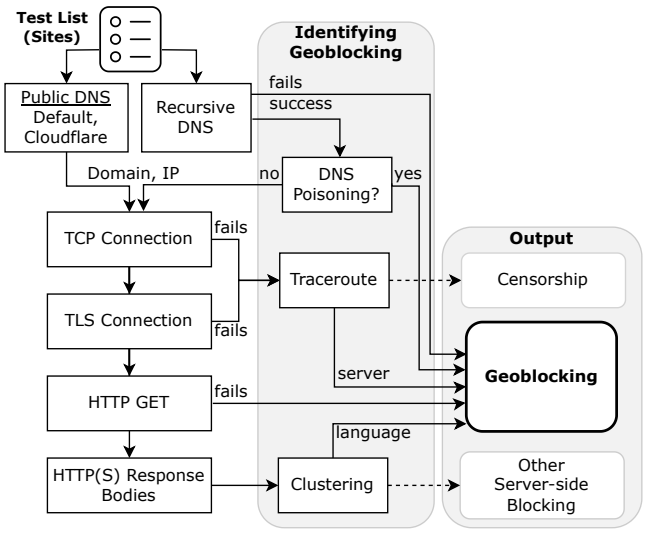

Figure 4: **Geoblocking Identification Pipeline:** We utilize various techniques to identify geoblocking and decouple it from censorship and other sever-side blocking at each layer of the network stack.

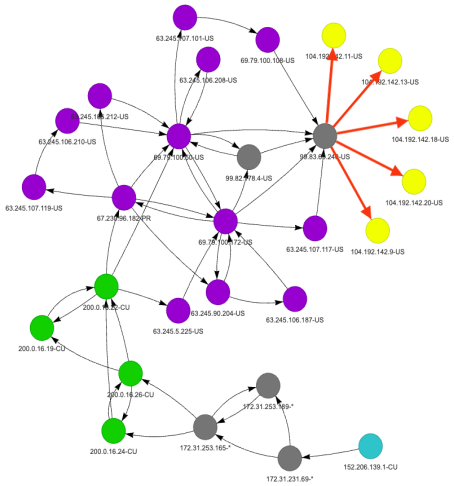

Figure 5: **TCP Traceroute Example.** Through our TCP traceroute measurements, we find Atlassian owned domains, `atlassian.com`, `atlassian.net`, `trello.com`, `atl-paas.net`, and `opsgenie.com`, failing upon reaching Amazon-AES (AS 14618). The red → indicates the hop where the SYN packet was dropped and nodes are colored by AS.

5.2 Identifying Geoblocking in Cuba

Fig. 4 illustrates our approach to measuring and identifying geoblocking in Cuba, broken down by layer-wise attribution. Throughout the following subsections, we detail how we decouple geoblocking from censorship.

Determining Layer of Failure. We conduct retests to compensate for poor network conditions in Cuba. Within the DNS and server-level (TCP, TLS, HTTP) failures, which never return an HTTP(S) response, we find nine cases where our retests have different outcomes from the initial measurement. We do the following to reconcile these differences: in the case of failures in different layers, we attribute the lower layer failure to transient error or path differences due to router load balancing and report the higher layer failure; in the case of failures in the same layer, we follow precedence orderings based on the informativeness of different errors.

5.2.1 DNS Geoblocking

We begin our DNS layer analysis by examining the output of our custom recursive DNS trace, as shown in Figure 4. Note, we group Google and Cloudflare together as public resolvers. Though we analyze all DNS results for DNS poisoning, we only consider outcomes from the recursive trace as potentially indicative of DNS geoblocking.

Analyzing for DNS Poisoning. To ensure the IP addresses we receive are correct and errors are localized to the precise location of the network stack, we examine them for DNS poisoning. We utilized MaxMind, GeoIP2 Tables, and Censys [14] to compare the autonomous system (AS) numbers and organizations between the 102 domains whose sets of returned IP addresses map to different ASes in the control and Cuba runs. In the public DNS resolution, we identify one suspicious case that returns a China Telecom IP address instead of an Amazon one via Google DNS resolvers from Cuba, suggesting blocking via the eDNS client subnet. The remaining successfully resolved IP addresses, along with their domains, move to the next step in our pipeline.

5.2.2 Web Server Geoblocking: Errors

Geoblocking can occur during the establishment of the TCP connection, TLS connection, or HTTP GET request. HTTP GET errors are easily identifiable as geoblocking; since we have already established the TLS session with the server, we can attribute errors such as HTTP truncated responses to our target web server for a given domain. In contrast, TCP and TLS errors necessitate a complex identification process. For TCP timeout outcomes, the TCP SYN packet could be dropped silently within Cuba, indicating IP-based censorship [49]; similarly, failures in the TLS layer could be caused by SNI-based censorship. Thus, we use traceroute measurements to localize the point of failure and decouple instances of censorship from geoblocking.

TCP Traceroutes. We conduct TCP traceroute measurements for 131 unique IP addresses corresponding to 95 domains that time out while establishing TCP connections, with an example shown in Fig. 5. In exactly one case, we find a termination very close to Cuba, indicating an instance of censorship: `eldiario.es` fails in AS 11960, the Internet exchange point

(IXP) through which all of Cuba's traffic propagates. Additionally, we successfully complete the TCP handshake with the server for seven of these 131 traceroutes. This can be caused by a variety of reasons, including servers handling the traceroute packets with short TTL values differently [37]; as well as routing differences due to the traceroute measurement necessarily being conducted with a different port number than the initial measurement, which has been shown to impact domain accessibility [10].

TLS Traceroutes. We also run traceroute measurements for 69 IP addresses corresponding to the 35 domains failing in the TLS layer. We find 35 traceroutes corresponding to 13 domains that terminate with either FIN or RST packet within Cuba's IXP (AS 11960), including `cibercuba.com` and `doubleclick.net`, which indicates censorship as opposed to server-side blocking.

Censorship Validation. In total, we find 14 censored domains. We corroborate our findings of censorship for seven of the domains discussed above with the OONI Explorer dashboard [43], which hosts in-country measurement data fine-tuned to capture Internet censorship. The remaining seven domains are not on the OONI test list.

Network Stages (5)	Measurement Outcomes (17)	# Domains
DNS Fails 37/546 **(6.8%)**	Failed iteration	33
	Failed AuthNS connect	2
	Manipulated IP	2
TCP Fails 97/546 **(17.7%)**	Timeout	95
	Network unreachable	1
	No route to host	1
TLS Fails 23/546 **(4.2%)**	Timeout	11
	Reset	9
	Fail	3
HTTP Fails 24/546 **(4.4%)**	Timeout*	6
	Reset*	3
	Truncated Response	6
	DNS fail in redirect*	10
HTTP Responses 395/546 **(72.3%)**	403 Forbidden	347
	451 Unavailable for Legal Reasons	9
	200 OK	32
	Others *e.g.* 404, 503	7
Geoblocked Domains		**546**

Table 1: **Geoblocked Domains.** We find explicit geoblocking signals for 546 domains. Percent failures are reported by stage on a per-domain basis. 30 domains block at multiple network stages; one domain has varying outcomes within the HTTP stage, which we denote with asterisks. We provide descriptions of HTTP response status codes in Table 3.

5.2.3 Web Server Geoblocking: Response Bodies

We now focus on HTTP(S) response bodies that we collected. Our goal is to identify geoblocking blockpages. However, there is much variety among these, especially between pages served by different CDNs [35] and domain owners. Blockpages served by CDNs are typically more uniform and standardized, whereas personalized blockpages served by individual domain owners vary widely in status codes and verbiage. Thus, we identify them through an iterative clustering process.

We leverage prior insight from Jones *et al.* [28] and McDonald *et al.* [35] and identify geoblocking patterns by comparing the length of Cuba measurement response bodies to their corresponding control response bodies. The intuition is that the geoblocking blockpages will have drastically different content. We first gather successful 200 OK responses from the control measurements and their corresponding responses in the Cuba measurements and use BeautifulSoup for text extraction. Then, we calculate a percentage change in response length for each extracted text pair. We identify potential blockpages as those whose lengths change by more than a certain threshold, which prior works empirically estimate at 30% [28, 49]. Next, since 403 and 451 response codes are known to be indicative of geoblocking [35, 49, 52], we also consider them as potential blockpages. In Sec. 6, we consider 403 and 451 response codes as *standardized* geoblocking implementations.

Using a threshold of 30% yields 932 domains with 1,062 unique HTTP(S) responses, in addition to 6 domains with 403 and 451 status codes below this threshold. We normalize the extracted text to remove interchangeable response qualities such as error ID numbers and url-strings and perform agglomerative clustering to group all responses with 90% unigram similarity. This results in 316 clusters, which we refer to as *fingerprints*. Examples of fingerprints are shown in Fig. 6. We classify fingerprints corresponding to responses with a 403 or 451 status code as geoblocking and examine the remaining fingerprints for explicit language-based indications of geoblocking. We detail the outcomes in Sec. 5.3.

Threshold Verification. To thoroughly identify responses containing indications of geoblocking, we test five linearly decreasing thresholds from 30% content difference down to 10% and carry out the above steps for each threshold. We find that using a threshold of 10% resulted in 97 additional false positive pages and only one more true positive. Thus, we choose to report results on our optimal value of 30% and include the singular additional true positive in our analysis for completeness; we further report the CDF of true and false positive HTTP(S) responses identified with respect to response length difference in Fig. 11 in the Appendix.

5.3 Data Characterization

Table 1 summarizes the diverse geoblocking implementations we identified in our Cuba measurements.

DNS Geoblocking. *We find 37 domains geoblocking in the DNS layer.* For two domains, we find their authoritative name servers engaging in DNS poisoning and returning `localhost`. Another two domains (*e.g.* `gitee.com` and `rt.ru`) reach their respective authoritative name servers but fail to connect.

For the remaining 33 of these domains, we fail to re-

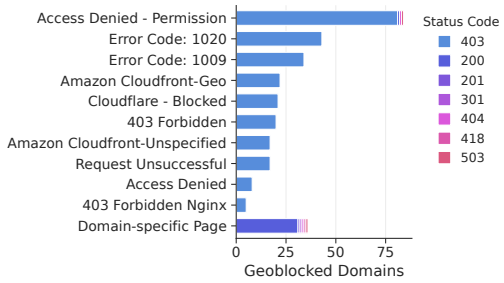

Figure 6: **Top 10 Fingerprints and Domain-specific Pages.** We show the top 10 fingerprints we find through our iterative clustering process and associated status codes served by domains. We bucket the personalized, domain-specific pages identified via language indicative of geoblocking.

trieve an IP address from the authoritative name server. To further investigate, we use our recursive DNS trace to locate the specific name server that failed to respond to our DNS query. Of these located name servers, we utilize MaxMind, GeoIP2 Tables, and Censys to confirm the ASes of 30 out of the 33 are directly associated with their corresponding domains. For instance, we find the name server `192.102.198.240` Intel-SC-AS (AS 4983) preventing access for three Intel-related domains (`01.org`, `intel.cn`, and `intel.com`). For the three domains where we were unable to definitely link the AS to the domain, we find two equivalent domains (`wdc.com` and `westerndigital.com`) and a government domain (`virginia.gov`). The equivalent domains both fail at the same server in Amazon-02 (AS 16509), and the government domain fails in a Verizon Business AS designated for customer usage and registered in Virginia.

Web Server Geoblocking Errors. *We find 97 domains implementing geoblocking via TCP handshake failures, and 23 domains via TLS connection failures. 24 domains were geoblocked at the HTTP GET stage.* During TCP connections, the most common failure we observe is connections timing out due to web servers not responding to TCP SYN packets. Analyzing traceroutes in the TCP layer, we find that 87 domains end within the same country as the destination IP address, 25 of which end inside the same autonomous system. Upon clustering on the AS of the last successful hop at the domain level, we find 10 domains reach Prolexic-DDOS-Network (AS 10794), 10 reach Level3 (AS 3356), eight reach Zayo-6461 (AS 6461), and seven reach Amazon-AES (AS 14618). Fig. 5 shows domains owned by Atlassian failing upon reaching Amazon-AES. In addition to blocking by organizational AS such as `bankofamerica.com`, which terminated in BankAmerica (AS 10794), we see the presence of transit networks such as Level3 (AS 3365), which blocks domains such as `adobe.com`, `barracuda.com`, and `citi.com`. We emphasize that the errors in these layers do not provide any transparency to the user about geoblocking.

Web Server Geoblocking Responses. *We identify 395 domains implementing geoblocking via blockpage HTTP(S) responses. Of these, 32 domains serve blockpages with 200 OK status codes.* Through our use of the iterative clustering and language-based methods to identify fingerprints, as described in Sec. 5.2.3, we find that while 356 domains serve status codes 403 and 451, the remaining 39 serve other various response codes including 200 OK, 404 Not Found, and 503 Service Unavailable. Fig. 6 depicts the 10 most common fingerprints associated with these domains, as well as an aggregation of domain-specific fingerprints.

We now focus our analysis on our geoblocking fingerprints. Recall we identified 316 unique fingerprints, of which we classified 100 as indicative of geoblocking. Of these, 71 fingerprints are classified as geoblocking because they contain responses served with 403 or 451 status codes. Notably, we find three domains matching these fingerprints, but returning non-403 or 451 response codes, which we also attribute as geoblocking. The other 29 fingerprints are classified as geoblocking because they contain indicative language (*e.g.* "Unavailable in your region"). We find these are all personalized to a given domain, except for domains `birmingham.ac.uk` and `sd.gov`, which serve the same fingerprint but with status codes of 503 and 200, respectively. We discuss geoblocking transparency afforded to users associated with these blockpages in Sec. 6 with examples in Table 2.

5.4 Manual Examination of Services

To better understand and characterize geoblocking, we manually examine geoblocked domains and their associated services to collect information that complements our findings.

Domain Exploration. It is common practice for companies to engage in embargo compliance disclosures on their websites. In order to identify these disclosing domains, two researchers independently visited all the 546 geoblocked domains from the U.S. on a university network and searched for privacy policies, terms and conditions, legal notices, and other compliance pages. Searches were conducted via a combination of browser and website-level keyword searches, as well as manual navigation. Relevant passages were extracted using keyword searches and manual readings. A list of keywords was maintained throughout, terms were iteratively added upon discovery, and domains were subsequently reexamined to ensure completeness. Some example phrases include the keywords "OFAC," "compliance," and "Cuba." All findings were cross-validated between researchers. We stress that this process was entirely manual, as prior work has shown the ineffectiveness of machine learning and automated approaches [36].

Free-tier Service Offerings. To characterize the blocking of types of services promoted for exemptions by the U.S. government (as noted in Sec. 2 and further discussed in Sec. 6), we map promoted types of services to relevant Cloudflare catego-

rizations. We identify the following categories: Technology, Information Technology, Business, Content Servers, Communication Tools, and Education. For the 388 geoblocked domains in these categories, we additionally collect information about free-tier service offerings during the manual domain exploration, as described above.

Country of Registration. We examine the country of registration for geoblocking services. We find 58 non-U.S. registered domains, all of which passed control measurements from the U.S. and U.K. While we cannot as clearly infer the reason for geoblocking for the non-U.S.-registered companies, six disclosed U.S. embargo compliance or Cuban inaccessibility, including `bmo.com` (Bank of Montreal) and `hootsuite.com` (Hootsuite), despite it being U.S. legislation. We discuss possible causes of non-sanctions geoblocking in Sec. 7.

Impact of Disclosures. Disclosures of sanctions compliance can further support our geoblocking identification methodology in Sec. 5.2, but have some restrictions. While a disclosure can help confirm geoblocking due to sanctions, the absence of one does not necessarily imply non-sanctions geoblocking. More critically, we want to acknowledge that disclosures do not help users in embargoed countries, as the websites themselves are inaccessible. This is particularly notable for domains like `webex.com`, which discusses the geo-availability of Webex services on its site, but provides no transparency to Cuban netizens, as it blocks via both the DNS and TCP layers. Further, even non-U.S. registered companies may comply with embargo sanctions, highlighting another component of the complexity of auditing geoblocking due to sanctions compliance. We further evaluate these effects in Sec. 6.

6 Results

In this section, we evaluate the 546 geoblocked domains to analyze the scope of blocking and compliance disclosures (Sec. 6.1), as well as user and measurement-facing transparency (Sec. 6.2), standardization (Sec. 6.3), and the inefficacy of current improvement strategies to minimize harm from U.S. sanctions (Sec. 6.4).

6.1 Geoblocking of Popular Domains

By Popularity. *We find that geoblocking is most prevalent across the Tranco Top 2K domains (27% of 546); we further observe that domains are geoblocked by diverse approaches across all ranks.* Fig. 7 shows a histogram of geoblocking of domains across the Tranco 10K+ domains. We observe responses served with 403 status codes like `att.com` (#337) and `ebay.com` (#97), and TCP timeouts, like `exacttarget.com` (#577) and `trello.com` (#299), are the most prevalent types of geoblocking approach throughout.

We verify that 56 of the 152 domains in the Tranco Top 2K (37.5%) provide some notice of embargo compliance on their website, compared to 111 of the 394 domains beyond the Top 2K (28.5%). Furthermore, we find that 38.6% of disclosing domains in the Top 2K mention Cuba specifically, compared to just 7.4% of domains beyond the Top 2K. This suggests that popular domains engage in more specific disclosures.

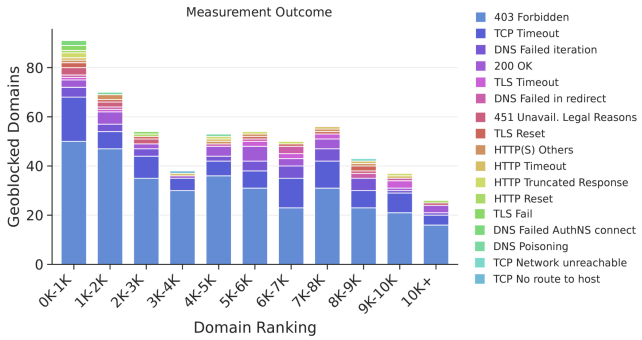

Figure 7: **Geoblocking vs. Popularity.** We show the number of domains geoblocked across our test list by Tranco rank and highlight outcomes from Table 1. Note, some test domains from our augmented test list fall outside the Tranco Top 10K.

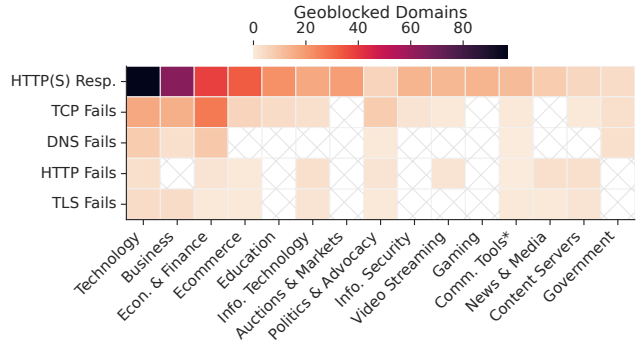

Figure 8: **Network Stages vs. Categories.** We show geoblocking by network stages for the Top 15 categories; and Communication Tools, an aggregation of Internet Phone & VOIP, Instant Messengers, Chat, and Forums, to compare with Sec. 4.

By Categories. *Technology, Business, and Economy & Finance are among the most geoblocked and often by 403 status codes, TCP timeouts, and DNS failures.* We use Cloudflare's Radar API to categorize each geoblocking domain; Fig. 8 details the presence of geoblocking across our Top 15 categories. We find that eight of these engage in various geoblocking methods over at least four network stages.

Technology domains, like `zoom.com`, implement geoblocking by returning a 403 status code more frequently than other methods, followed by Business and Economy & Finance related domains, such as `amplitude.com` and `geico.com`. In addition, these categories also engage in the highest amounts of geoblocking via TCP timeout.

Beyond the Top 15 categories (shown in Fig. 8), we find that

Transparency	Example Responses	Fingerprints	Domains	Disclosed
Informative	"This server denied by region", "Not available in your area", "IP address associated with a country or region currently subject to U.S. economic and trade sanctions"	48	79	59.5%
Vague	"Access Denied", "403 Forbidden", "Request blocked"	24	182*	30.2%
None	"There was a problem with the request", "Error"	28	135*	30.4%

Table 2: **Transparency of Geoblocking Fingerprints** We label each response as either "Informative," "Vague," or "None" to characterize user-facing transparency for blockpages. We further analyze these responses based on the number of fingerprints, geoblocked domains, and the proportion of disclosing domains. One domain served two different fingerprints (each in a different AS), classified as vague and none respectively, as indicated by the asterisks (*).

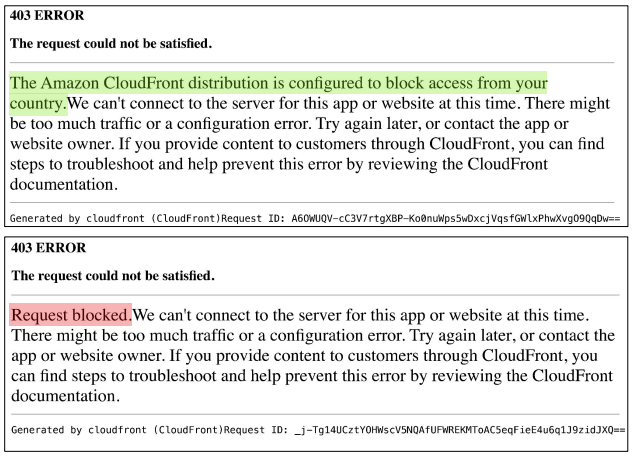

Figure 9: **Interchangeable Blockpages.** We find two fingerprints `Amazon Cloudfront-Geo` and `Amazon CloudFront-Unspecified` are identical other than the highlighted phrases.

while 32.4% of geoblocking domains in the Top 30 categories disclose embargo compliance on their website, we find higher rates within the subset of Technology domains (44.9%) compared to Economy & Finance (25.6%). We acknowledge the difference in sanctions compliance infrastructure surrounding services in these categories; for example, banking institutions have additional mechanisms to prevent unauthorized account registration and more complex and granular terms of service than corresponding Technology domains. Notably, we find categories with much lower levels of disclosures, such as Politics & Advocacy (5.8%).

6.2 Geoblocking Transparency

We observe 88% of geoblocked domains do not serve informative notice of why they are blocked. To further explore how geoblocking impacts users, we focus on the transparency of user-facing HTTP(S) responses, with examples in Table 2.

As discussed in Sec. 5.2.3, we identify 100 geoblocking fingerprints corresponding to HTTP(S) responses retrieved in our measurements. Here, we report the number of domains that correspond to these fingerprints. We find of the 395 domains that geoblock via a response page, 20% (79) of domains provide informative, explicit geoblocking disclosures to the user (*e.g.* "This Service is not availible [sic] in Cuba.") Another 46% (182*) of domains provide vague user-facing information, stating some form of blocking or denial-of-service (*e.g.* `AccessDenied`). The final 34% (135*) of domains either provide no information, a blank page, plain error code, or notice of unsuccessful requests. Interestingly, we find higher levels of disclosures in domains serving informative blockpages (59.5%) than in those serving vague (30.2%) or no information (30.4%).

Still, we emphasize that 88% (480) of geoblocked domains of 546 do not serve informative notice of why they are blocked. These websites demonstrate a clear lack of effort regarding end-user transparency; for example, `match.com`, which denies access via a TCP timeout, discloses in its terms of service, visible only to non-embargoed users, "[users] are not located in a country that is subject to a U.S. Government embargo." This is especially harmful to end users in Cuba; since they cannot see this disclosure and are met with an uninformative TCP error, they are unable to determine whether their failed request was subject to geoblocking or the result of poor network conditions.

Domain-Specific Blockpages. *We find 39 domains serving informative or vague non-standard blockpages with non 403 or 451 status codes.* Throughout our fingerprint identification and clustering process, we identified a specific set of blockpages with non-standard presentation. Recall in Sec. 5.2.3 we find these responses by filtering for content differences compared to the control and subsequently identify them as relevant blockpages via their use of language indicative of geoblocking. As an example, `etsy.com` returns a 200 OK response code in our measurements, suggesting a page was properly returned by the server. However, upon inspection, we see that the page is complete with all background artifacts including headers and links, but presents a sanctions policy page detailing their compliance policy. While this provides increased transparency to the end user, it presents a unique

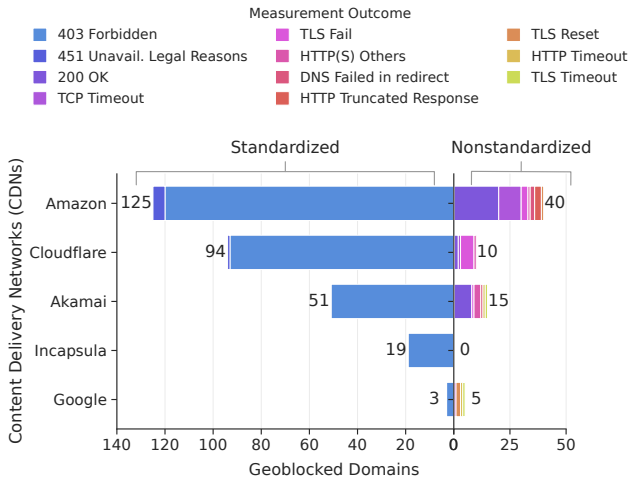

Figure 10: **CDN vs. Geoblocked Domains.** We show the number of geoblocked domains by CDNs and highlight relevant measurement outcomes. Note, 403 or 451 status code responses are on the left, indicating adherence to a standard protocol; all other implementations are on the right.

challenge in identifying geoblocking and a key auditability issue in the geoblocking ecosystem.

Small-scale User Study. Recall in Sec. 4 that we collected 36 domains from respondents and a further 95 from the repository we were pointed to. We find 37% (46) of these 123 domains experience geoblocking: one in the DNS stage, seven in the TCP stage, two in the HTTP stage, and 36 that serve HTTP(S) blockpages, of which six are informative and 10 are vague; the rest provide no additional information. We also explore our category-wise results in relation to our small-scale user study. Our findings corroborate our respondents' identification of the E-commerce and Communication Tools categories as containing high levels of geoblocking; we find 39 and 17 domains, respectively. Note that Communication Tools is an aggregated category, as denoted in Fig. 8.

6.3 CDN Geoblocking Standardization

We find domains hosted on five out of six prominent CDNs (e.g. Amazon, Cloudflare, Akamai) deploy a wide variety of geoblocking implementations, with 7.7% of CDN hosted domains serving blockpages with a 200 OK response. Although CDNs can streamline geoblocking for service providers by standardizing ways to serve blockpages, we still find that geoblocking implementations vary widely, even within individual ASes associated with CDNs, as shown in Fig. 10. Only Incapsula (AS 19551) serves uniform fingerprints with 403 responses; 17 domains serve the `Incapsula incident` fingerprint [35] and two use the `AccessDenied` fingerprint.

Across the other CDNs, the variance is greater. For instance, domains hosted in peering Amazon ASes, Amazon-02 (AS 16509) and Amazon-AES (AS 14618), engage in geoblocking through all layers of the network stack; for example, `megaphone.fm`, a podcast publishing service, blocks by sending a RST packet during the TLS connection, while `ecwid.com`, an e-commerce platform, blocks via poisoning the DNS resolution. In another case, domains hosted in peering Cloudflare ASes, CloudflareNet (AS 13335) and Cloudflare London (AS 209242), serve blockpages with not only 403 and 451 status codes but also with 302 and 200 OK. These blockpages have different transparency levels as well. Some are not informative, such as `error code: 1009` and `error code: 1020`, served by 63 domains, which are Cloudflare designated codes indicating denied access; others are more explicit and transparent, including phrases such as "...Sorry you have been blocked" served by 17 domains.

In an interesting observation, we find two fingerprints `Amazon CloudFront-Geo` and `Amazon CloudFront-Unspecified` are identical other than the switching of the phrases "The Amazon CloudFront distribution is configured to block access from your country" and "Request blocked." The serving of both pages in Amazon-02 (AS 16509) emphasizes not only the arbitrary amount of information provided to end users, but also suggests the ease of deploying informative blockpages as opposed to uninformative ones. This is detailed in Fig. 9.

6.4 Current Improvement Strategies

We find 44% of domains in Technology, Information Technology, Business, Content Servers, Communication Tools, and Education categories implement geoblocking, despite offering free-tier service options. The U.S. government has expressed support for a free Cuban Internet and promoted categories and types of services that are not restricted by embargo sanctions, as discussed in Sec. 2.1. Combining this with our manual exploration of free-tier service offerings in Sec. 5.4, we make a best-effort attempt to quantify the efficacy of these current improvement strategies.

We find domains in categories such as Technology (128), Information Technology (27), Business (87), Content Servers (10), Communication Tools (17), and Education (25) are geoblocked, see Fig. 8. In particular, we find geoblocking services such as `mailchimp.com` (Business), an email marketing platform, and `gitlab.com` (Information Technology), an open-source platform for software development, that additionally disclose their compliance with embargo sanctions regardless of the aforementioned provisions. This emphasizes the tendency of service providers to err on the side of caution with regard to compliance.

We find 44% of geoblocking domains in these lower risk categories provide free-tier service offerings. As all geoblocking we identify is enforced at the top-level domain, this indicates a blanket restriction of access to all services provided

by the domain. For example, `adobe.net`, a computer software company, blocks via a TCP timeout despite providing several free online services, such as PDF editors. Another domain, `databricks.com`, a data analytics platform, serves a 403 Forbidden page, but offers a free community version of its cloud-based services.

7 Discussion and Recommendations

Given the lack of standardized geoblocking implementation and transparency, along with the inefficacy of the U.S. current improvement strategies for a free Cuban Internet, in this section, we outline recommendations for improvement.

What can service providers do to help? We believe service providers should push for transparency and assist in reducing Internet fragmentation. While we understand that service providers may prefer a silent de-risking approach, we believe that they have a responsibility to communicate clearly and effectively. We encourage service providers to serve meaningful blockpages that contain explicit language indicative of geoblocking. This change would significantly help user-level transparency and come at little to no cost for providers. Regarding measurement-level transparency, we observe that domains implementing geoblocking unfortunately do not always return a 403 or 451 status code, despite these codes being most directly related to geoblocking. We urge providers to work towards standardization of geoblocking implementation. These proposed improvements would increase the ease of auditing the ecosystem by allowing for greater integration of automation and proportionally reducing time-consuming manual analysis.

Furthermore, we acknowledge blocking at the top-level domain with both free and paid offerings is simpler and lower risk for service providers. However, in the case that they have the means and a vested interest in promoting Internet freedom, strictly-free software could be consigned to a new domain and made accessible even to those under embargo. In support of this, we find that there are no existing cases where a digital service provider was punished by U.S. authorities for providing a free online service in Cuba.

What can policymakers do to help? Our findings highlight two necessary adjustments for policymakers. First, given the stated goal of increasing access to information in Cuba, policymakers must engage with service providers around the world to ensure sanctioned users are not overly geoblocked. Second, apparent attempts to distinguish between free and paid services in regulation have not resulted in equal consideration among service providers — many service providers still geoblock Cuban users from free versions of their services. We admit that there is currently a lack of motivation for service providers to act on our recommendations due to a minimal yield from incurred costs and efforts; we are keenly aware that policymakers are best positioned to motivate changes and must do so to back up their communicated intentions.

There is an irony to our findings. Over the past three fiscal years, the U.S. government has spent over $47M on the Office of Cuba Broadcasting to bring free information to the Cuban people. In 2016, the U.S. Coordinator for International Communications and Information Policy, Ambassador Daniel Sepulveda, pushed the Cuban government to adopt transparent Information and Communication Technology procurement policies, encourage competition, and liberalize the telecommunications sector [50]. Access to information is a clear goal of U.S. policy toward Cuba. However, the U.S. government must modify existing regulations if they intend for Cuban citizens to have access to free and widely available services. Existing attempts to push providers to allow free access as a lower-risk alternative have not resulted in meaningful changes.

Non-Sanctions Geoblocking. In Sec. 5.4, we discuss how we manually examine geoblocking domains to better characterize geoblocking attribution. We systematically evaluate domains for privacy policies, legal notices, and other compliance pages; we additionally document the country of registration, finding non-U.S. registered companies still disclose adherence to U.S. sanctions — underscoring the opaqueness of the compliance ecosystem. However, we acknowledge that aside from sanctions, there are other causes for geoblocking. For example copyright/licensing policies are often country-specific; differences in privacy legislation can impact service availability; and distributed denial-of-service (DDoS) prevention can discriminate against IPs from countries with a history of engaging in DDoS attacks. We note that Cuba has no increased privacy legislation like GDPR, or a history of launching of DDoS attacks like Russia.

Limitations. We acknowledge some limitations of our work. First, we are only able to test domain accessibility over HTTPS, so we cannot study domains available only over HTTP. However, as the majority of Internet traffic is over HTTPS, this is not a major hindrance. Second, due to the difficulties associated with mapping IP addresses to autonomous systems, we use a combination of GeoIP2 Tables and Censys to accurately link IPs to their associated AS [14].

8 Conclusion

In this work, we present the first in-depth and systematic investigation into the effects of sanctions on web content inaccessibility, specifically geoblocking in Cuba. We conduct network measurements on the Tranco Top 10K augmented with additional domains from our small-scale user study, which we further use to characterize the impact of digital sanctions for respondents in Cuba. We identify 546 geoblocking with 17 diverse implementations, ranging from DNS failures to HTTP(S) response pages with a variety of status codes. We highlight high levels of geoblocking in categories such as

Technology and Business, as well as identify the most common implementations like web servers dropping TCP SYN packets or serving blockpages with 403 status codes. Additionally, we discover a lack of user-facing transparency, finding that 88% of geoblocked domains do not serve informative notice of why they are blocked. We also highlight a lack of measurement-level transparency among HTTP(S) blockpages, identifying 32 instances of blockpages served with 200 OK status codes. Finally, we note the inefficacy of current improvement strategies and we provide recommendations to both policymakers and service providers to reduce Internet fragmentation. We hope our work inspires future interdisciplinary studies on the real-world impacts of embargo sanctions on geoblocking.

Acknowledgments

The authors thank the anonymous reviewers for their helpful feedback. We are also deeply grateful to Doug Madory, Afsah Anwar, Jedidiah Crandall, Kyle Astroth, and Yusei Uehara for all their help and support on this work. A Appendix

A.1 User Questionnaire

We provide the full questions that we ask our respondents from Sec. 4. We first present the respondent with the statement detailing the potential risk and the measures that we take to protect their anonymity and privacy, and then ask the following questions:

Disclosure of Risk. In this project, we are trying to understand how sanctions on different countries affect access to the Internet for users in that country. Anecdotal evidence and previous studies have shown that many online services tend to restrict access to users from certain regions. Please read the following information and consent document for all details regarding this study. Your participation and responses are completely anonymous. By proceeding with this survey, you express your consent and agree to be a part of this study. You may take this survey if you have faced restrictions by Internet services. Please keep in mind that this survey is intended to collect data about restrictions by content providers, and not by your ISP and Government. We will be collecting the answers you provide as a survey participant, but note that we do not collect your name, email address or any personal identifier along with the survey. Hence, we will not be able to attribute a survey response to any one respondent. The survey questions merely focus on our research concerns and do not ask for any personally identifiable information. We will only receive your survey response once you hit the submit button at the end of the survey. Please know you can always come back and update your answers. Most questions are not required, and we value any information you provide. Thank you very much for taking part in our user survey investigating the impact of Sanctions on Internet users.

Demographics. *Demographic information.*

Q1-3. Age, Country of Residence, Occupation

Understanding the websites that are inaccessible, and the impact of their unavailability. *In this section, we ask questions about the websites and services that are generally inaccessible in your country, and about the impact that this unavailability and inaccessibility has had on you as a user.*

Q4. Can you please list some other websites, desktop applications, and mobile applications that impose server-side blocking towards users in your country?

Q4.1. Can you please tell us what you see when you try to access the above services, apps, and websites? (Choose all) ☐ Access Restricted Page ☐ Browser or App Error ☐ Not available for users in your region ☐ Nothing (no change) ☐ Blank page ☐ Apps not found in stores ☐ No download button ☐ Other

Q4.2. If possible, could you please upload some example screenshots of the response you receive when you visit restricted sites?

Q5. What categories of services (website, applications, mobile apps) do they generally belong to? (Choose all)

☐ Alcohol & Drugs ☐ Anonymization and circumvention tools ☐ Communication tools ☐ Culture ☐ E-commerce ☐ Economics ☐ Environment ☐ File-sharing ☐ Gambling ☐ Gaming ☐ Government ☐ Hacking tools ☐ Hate speech ☐ Hosting and blogging platforms ☐ Human rights issues ☐ Intergovernmental Organizations ☐ LGBT ☐ Media sharing ☐ Miscellaneous content ☐ News media ☐ Online dating ☐ Political criticism ☐ Pornography ☐ Provocative attire ☐ Public health ☐ Religion ☐ Search engines ☐ Sex education ☐ Social networking ☐ Terrorism and militants ☐ Other

Q6. The inaccessibility of the above services affects the following aspects of my day-to-day life:

○ Online learning ○ Education ○ Career opportunities ○ Work obligations ○ Staying up to date ○ Financial well being ○ Mental health ○ Time overhead ○ Loss of entertainment

Q7. Please tell us why you chose the above options (or others), and elaborate the impact that the inaccessibility of the services had on your personal and professional life.

Understanding users' handling of the inaccessibility. *In this section, we ask questions regarding how you handle and manage the inaccessibility of necessary websites and services.*

Q8. If you use services to bypass restrictions, where do you find information about these services?

Q9. If you are comfortable disclosing, how do you bypass these restrictions to reach the website or service? (Choose as many as you like)

○ VPNs ○ Tor Browser ○ Proxy services ○ Other

Q10. Are there any services available in your country that act as an alternative to the unavailable services? How do they compare to the unavailable services?

Q10.1. How safe do you feel using the alternative services?

Q11. Is there anything related to website unavailability and inaccessibility that you wish to share with us?

A.2 Supplementary Figures & Tables

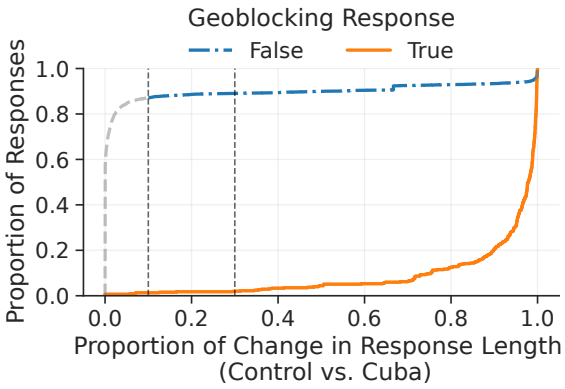

Figure 11: **Proportion of Change in Response Length.** We compare the response lengths between control and Cuba measurements. We annotate this with values (0.1 and 0.3) that denote our labeling thresholds as discussed in Sec. 5.2.3.

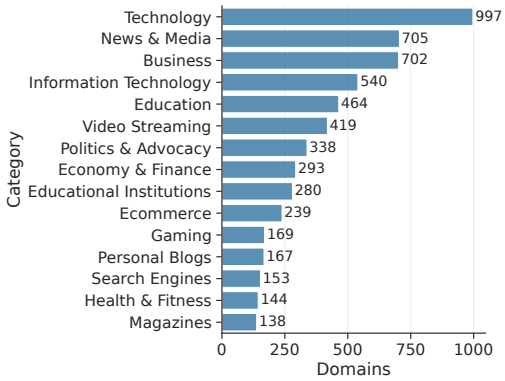

Figure 12: **(Passed Control) Top 15 Categories and Domains.** We analyze the category breakdown of all domains passing control measurements as detailed in Sec. 5.1.

Status Codes	Description
200 OK	Request succeeded
201 Created	Request succeeded, and new resource was created
301 Moved Permanently	Resource moved permanently, new URL given
403 Forbidden	Client is not authorized to view the resource
404 Not Found	Server cannot find the resource
451 Unavailable for Legal Reasons	Client requested a resource that the server cannot provide access to because of legal reasons
503 Service Unavailable	Server cannot handle the request due to maintenance or overload

Table 3: **HTTP Response Status Code.** Summary of HTTP status codes that we encountered. This complements our measurement findings in Table 1.

A Broad Comparative Evaluation of Software Debloating Tools

Abstract

Software debloating tools seek to improve program security and performance by removing unnecessary code, called bloat. While many techniques have been proposed, several barriers to their adoption have emerged. Namely, debloating tools are highly specialized, making it difficult for adopters to find the right type of tool for their needs. This is further hindered by a lack of established metrics and comparative evaluations between tools. To close this information gap, we surveyed 10 years of debloating literature and several tools currently under commercial development to taxonomize knowledge about the debloating ecosystem. We then conducted a broad comparative evaluation of 10 debloating tools to determine their relative strengths and weaknesses. Our evaluation, conducted on a diverse set of 20 benchmark programs, measures tools across 12 performance, security, and correctness metrics.

Our evaluation surfaces several concerning findings that contradict the prevailing narrative in the debloating literature. First, debloating tools lack the maturity required to be used on real-world software, evidenced by a slim 22% overall success rate for creating passable debloated versions of medium- and high-complexity benchmarks. Second, debloating tools struggle to produce sound and robust programs. Using our novel differential fuzzing tool, DIFFER, we discovered that only 13% of our debloating attempts produced a sound and robust debloated program. Finally, our results indicate that debloating tools typically do not improve the performance or security posture of debloated programs by a significant degree according to our evaluation metrics. We believe that our contributions in this paper will help potential adopters better understand the landscape of tools and will motivate future research and development of more capable debloating tools. To this end, we have made our benchmark set, data, and custom tools publicly available.

1 Introduction

Software debloating is an emerging research area focused on improving the security and performance of programs by removing unnecessary code (i.e., *bloat*) in the form of unnecessary features or extraneous library code. Bloat is pervasive in modern programs due to entrenched software engineering practices (e.g., design emphasis on reusable code modules) and tendencies (e.g., scope creep). To counter this, several debloating techniques targeting various stages of the software life cycle have been proposed. However, their practical adoption has not kept pace with research for several reasons.

First, debloating tools are highly specialized. Each tool targets a different kind of bloat, type of software (compiled, interpreted, kernels, etc.), stage of the life cycle (source, IR, binary, etc.) and has a unique analysis method. This makes it challenging for adopters to select the right category of tools for their specific problem. Second, the literature lacks established metrics resulting in unclear, incomplete, and potentially misleading claims regarding how different methods improve performance and security. This occurs because authors borrow or create their own metrics, which has been shown to be problematic [12, 51]. Ultimately, it is difficult for adopters to understand what benefits to expect as it is not immediately apparent which metrics are useful or relevant. This is exacerbated by superficial explorations of soundness risks in the literature, making it similarly difficult for adopters to understand debloating's trade-offs and consequences. Finally, the few comparative evaluations present in the literature are limited to a small number of tools, making it difficult for adopters to determine which tools are best in class.

While broad studies on bloat prevalence [14, 53, 54], debloating trade-offs [76], and security metrics [8, 12, 21] have been published, the largest comparative evaluation of software debloating tools to date [4] is limited to only four tools, each of a separate type. This permits comparing individual tools across categories and how well they compose, however the quantity and diversity of tools is not sufficient to compare tools within categories or draw conclusions about the relative merits of different types of debloaters. Also, the evaluation uses only four metrics and may fail to detect important negative impacts of debloating such as excessive runtime or memory consumption in debloated programs.

Motivation. To date, there has been no holistic review, classification, analysis, and evaluation of the tools, metrics, benchmarks, and use cases in the software debloating ecosystem. We close this knowledge gap by conducting a survey and comparative evaluation of software debloating tools that seeks to answer the following motivating research questions:

1. How can debloating tools be classified?
2. Which security, soundness, and performance metrics are useful? What new metrics are needed?
3. Which benchmarks and configurations provide a holistic evaluation of debloating tools?
4. How do tools within the same class compare?
5. How do debloating tools compare across classes?

Summary of Contributions. In this paper, we first present the findings from our survey of debloating literature in Section 2. We then describe our experimental methodology to evaluate debloating tools and their products in Section 3. We present the results of our evaluation in Section 4, and discuss the key findings of our study in Section 5.

2 Survey of Debloating Techniques

To conduct our survey, we first searched Google Scholar for articles on software debloating, customization, partitioning, and specialization. Next, we triaged each search result and it's references to identify duplicates and ensure relevance. We included refereed works from all venues in our study, provided they made a meaningful contributions to debloating discourse. The most common reason we excluded a search result for lack of relevance was for making only a passing and generic reference to software debloating, for example by referring to it as a related research area. Ultimately, we selected over 70 scholarly articles dating back to 2013 for our survey. Additionally, we included various commercial and work-in-progress techniques at various stages of development to fully cover the field's breadth. A number of these works have not been made publicly available; the authors of these works provided us with the information, technical artifacts, and support necessary for our survey (and subsequent evaluation).

As we used an intentionally broad definition of "software debloating", we included many works detailing debloating methods for technical artifacts not traditionally considered software such as containers [29, 56], operating systems and their APIs [23, 24, 27, 40], test cases [35, 58, 67], firmware [16, 79], and build dependencies [48], among others [30, 44, 46, 52, 80]. In the following sections, we establish a debloating taxonomy that defines and classifies types of bloat, debloating workflows, types of debloating techniques, metrics, and benchmarks we observed in our survey.

2.1 Types of Bloat

In general, debloating tools try to remove or neutralize two different types of unnecessary code, which we define as Type I and Type II bloat. Type I bloat is *universally unnecessary* and can be removed without impacting the program's behavior for all intended end uses. The most common manifestation of Type I bloat is library code that is dynamically loaded into a processes' address space at runtime but will never be called. Although less common, some debloating tools target Type I bloat in the form of operating system (OS) code (e.g., system calls) that a program does not call to prevent their malicious re-use. Dead and unreachable code is also Type I bloat, but is not heavily targeted by debloaters because compilers and interpreters are highly effective at removing it.

By contrast, Type II bloat is *end-use dependent*: code may or may not be Type II bloat depending on how its user(s) uses the program. Type II bloat typically takes the form of unnecessary program features, such as support for obscure or obsolete file formats in image processing software. Platform-dependent code that handles variations in OS and web browser interactions is another form of Type II bloat, however this kind of bloat is typically addressed by build-systems and scripting engines rather than debloating tools.

2.2 Debloating Workflow and Use Cases

Despite myriad technical differences, virtually all debloating tools share a common high-level, six-stage user workflow:

1. **Specification:** The user creates a tool-specific specification that outlines what program behaviors should be kept or eliminated.[1]
2. **Input:** The user provides the specification and program to the debloating tool.
3. **Analysis:** The tool uses information in the specification to analyze the program and label code (e.g., as unnecessary, as part of a feature).
4. **Transformation:** The tool modifies the program to separate bloat from useful code (e.g., cutting, reconstruction, attaching labels).
5. **Output:** The tool produces a modified program that either does not contain bloat or contains the necessary labels to remove bloat at runtime.
6. **Validation:** The user validates that the modified program is sound and behaves as expected via manual testing or automated tools (e.g., fuzzer) of their choice. If the output is invalid, the user may restart the workflow.

Despite a common high-level workflow, many tools define different use cases for potential end users. Tools targeting

[1] Tools targeting only Type I bloat may not require specifications.

Type I bloat prescribe a fairly straightforward use case: eliminate as much bloat as possible. Tools targeting Type II bloat employ three common use cases. **Aggressive** use cases remove all functionality except for a single desired feature or software configuration. For example, aggressively debloating a file compression tool might be defined as removing all code not necessary to compress a file and write the result to disk. **Moderate** use cases retain several core and peripheral features and debloat the rest. A moderate debloating use case for a file compression tool would keep code for compressing, decompressing, and testing a compressed file's integrity. Fianlly, **Conservative** debloating [11, 12] use cases are defined as those in which only a few peripheral features are removed.

2.3 Classifying Techniques

We sort the software debloating tools we surveyed into five distinct categories primarily differentiated by design choices made at various stages in the debloating workflow.

2.3.1 Source-to-Source (S2S) Debloaters

S2S debloaters remove bloat directly from a program's source code. They primarily target Type II bloat, although they can be readily adapted to remove Type I bloat in libraries. Debloating information-rich source code has several advantages over other representations (i.e., IR or binary). First, developers have many options for the analysis stage; S2S debloaters can use code coverage [31, 74–76], fuzzing [9], build system analysis [28, 72], and manual annotation [11] techniques to produce feature-to-code mappings. Second, source code is easier to transform without compromising the program's soundness because the compiler has yet to strip away high-level information and replace it with machine semantics. The compiler is also useful in this case for detecting errors and optimizing away inefficiencies after source transformation. Third, debloated source code is still relatively straightforward to maintain, as relevant bug fixes or security patches can be applied before compilation. Despite these advantages, transforming source code can be technically complex due to the flexibility in its expression (e.g., syntactic sugar) and lack of compiler support for direct transformation of source code.

S2S debloaters generally require the user to have working technical knowledge about both the tool itself and the program they want to debloat. Creating specifications for these tools typically involves specifying test cases that exercise program behaviors that the user wants to retain. In practice, this requires a large number of test cases even for moderately complex programs due to the need for test cases that exercise edge cases, security checks, error handling code, etc. As a result, creating specifications for S2S debloaters can take on the order of several hours for non-trivial programs.

2.3.2 Compiler-Based Specializers (CBS)

CBS are similar to S2S debloaters in that they take source code as input and primarily target Type II bloat. Rather than debloat source directly, CBS [2, 3, 41, 42, 45, 61, 64] use a compiler (e.g., LLVM) during the analysis and transformation stages to lower the source to IR, convert key input parameters or values to compile-time constants based on the user's debloating specification, and remove bloat via built-in compiler optimizations such as constant propagation, loop unrolling, and dead code elimination. This approach mitigates soundness concerns by using highly-reliable compiler passes instead of custom transformation routines. As a trade-off, CBS only support aggressive debloating use cases. While this means users generally do not need deep working knowledge of the program they are debloating, it makes them unsuitable for moderate or conservative use cases or scenarios where features are triggered by runtime inputs, such as network protocol commands.

Because CBS are limited to aggressive use cases, they generally only require the user to know how the program will be executed on their system (i.e., a single command line invocation). As a result, creating debloating specifications for CBS typically takes less than an hour. However, there are some notable exceptions that may increase the amount of experience or time needed to configure and use the tool. Since the tools are tightly coupled with the compiler, in some cases the user may need to have working knowledge of the tools build configuration (i.e., compiler flags). Additionally, some tools may require the user to perform manual steps, such as identifying the boundary between input parsing and program logic if it cannot be automatically identified [3].

2.3.3 Binary-to-Binary (B2B) Debloaters

B2B debloaters are conceptually similar to S2S debloaters, but differ in that they target program binaries (e.g., ELF, Java bytecode [13, 33, 34, 68]). Binary-only approaches are error-prone and fraught with challenges, however they have the key advantage of being able to debloat legacy or closed source binaries. B2B debloaters have limited options for the analysis stage; they must rely on inherently imprecise binary analysis techniques such as execution tracing of test cases [5, 15, 22, 26, 43, 51, 60, 70, 77] and binary lifting [5, 22, 26, 43, 60, 73, 77] as well as heuristics [43, 51] for generating feature-to-code mappings. The transformation phase is similarly difficult due to the unique nature of binary formats (e.g., co-mingling of program instructions and data, indirect branching, etc.). Because fully recovering a binary is undecidable in the general case, B2B debloaters must carefully manipulate the input binary without violating their original layout by blanking out code with no-ops or invalid instructions [15, 77] or adding a debloated version of the program as a new code section alongside the original code [5, 70]. Ultimately, the key disadvantages of B2B approaches are also

consequences of the limitations of binary analysis: they struggle to produce sound debloated binaries and require high quality binary recovery to be effective (e.g., Egalito [73] requires position-independent code to ensure recovery).

B2B debloaters generally require working technical knowledge of the target program only. Like test case-based S2S debloaters, creating a specification requires a large number of test cases in practice to minimize soundness issues. For more complex programs, this may take users one or more hours to enumerate. Once processed, debloated binaries are difficult to maintain or further modify due to the limits of the transformation techniques mentioned previously. However, given that B2B debloaters are primarily used for legacy programs, this may not be a significant detriment to their use.

2.3.4 Static Library (SL) Debloaters

SL debloaters focus on removing Type I bloat permanently from libraries consumed by a target program. They do not require a specification due to a straightforward analysis phase in which the tools statically compute the call graph for the target program and identify a precise set of required library functions. SL debloaters use a variety of transformation approaches including creating specialized libraries via rewriting to remove [7, 32, 36, 57, 65, 69, 78, 81] or blank unused functions with no-ops or invalid instructions [1, 62], fragmenting libraries [54], rewriting executables to statically link library functions [26], and replacing unnecessary library functions with stubs [71]. By limiting their scope to Type I bloat, SL debloaters avoid many of the challenges experienced by other classes of tools. First, SL debloaters do not risk creating unsound programs, although programming methods such as reflection and indirection may not be handled by some tools. Second, SL debloaters require little or no human effort to use beyond specifying the target program. However, the consequence of this design choice is that these tools are not suitable for scenarios where Type II debloating is required. SL debloaters may also nullify operating system-wide efficiencies that rely on mapping a single copy of a shared library into multiple processes' address space.

2.3.5 Runtime Debloaters

Runtime debloaters are similar to SL debloaters, the key difference being their transformation and output stages. To avoid permanent changes to libraries, runtime debloaters record required library functions as program metadata and interpose on the dynamic linking process during execution to debloat unnecessary library functions from the processes' memory. Approaches vary significantly, for example Piecewise Compilation and Loading (PCL) [55] embeds call graph information in binaries and uses a custom loader to rewrite unnecessary functions with invalid instructions at runtime; whereas BlankIt [50] and Decker [49] take the opposite approach of loading only necessary functions into the program's runtime memory based on the current execution point. Other approaches use information from the build system such as configuration options [37] and package dependencies [47] to remove bloat. In addition to the advantages of SL debloaters, runtime debloaters also have the advantage of not disturbing code at rest, providing high confidence in the soundness of the result. However, this comes at significant price: high runtime overheads required to manage process memory.

2.4 Analysis of Debloating Metrics

Software debloating literature does not have an established set of metrics for measuring success. Consequently there is significant variability in the metrics used across the works we surveyed. In most cases, metrics were adapted from similar program transformation techniques (e.g., code optimization), although in some notable cases new metrics have been introduced [12, 20, 54, 76]. In total, we noted 30 different metrics which we sorted into three categories and describe in the remainder of this section.

Performance metrics measure the resource consumption of both the debloating tools themselves and the debloated programs they produce. In the latter case, performance is compared to that of programs that were not debloated to determine if debloating improves or worsens performance. Commonly used performance measures include: CPU runtime, memory overhead, static binary size, number of external resources required, and manual effort required to use tools.

Correctness and Robustness metrics measure the stability and resistance to abuse of debloated programs. Typically, debloated programs are exercised by test suites or fuzzers to identify faulty outputs, crashes, and/or other undesirable outcomes. Interestingly, we observed that works using these metrics collected them for debloated programs only. Since correctness and robustness issues may be present in programs prior to debloating, such measures should be taken for both the original, non-debloated programs and their debloated variants to isolate issues introduced by a particular tool. Crystal and Casinghino's [20] comparative binary analysis tool uses an SMT-based weakest precondition approach to demonstrate equivalence of two program binaries or highlight differences in their behavior, providing a high-assurance metric for correctness that can be applied to debloating scenarios.

Security metrics measure improvements to the program's security posture achieved through debloating. In our survey, we noted two main categories of security metrics: vulnerability elimination and code-reuse prevention. Ostensibly, these metrics are used to claim desirable outcomes such as eliminating latent vulnerabilities, reducing the program's attack surface, and reducing the ease of code re-use attacks. However, the real-world utility of these metrics is subject to debate.

Vulnerability elimination is typically evidenced in literature by showing that known vulnerabilities (e.g., those reported in

MITRE's CVE database [17]) in benchmark programs are removed during debloating. While this metric demonstrates the *possible* benefits of debloating, it is ultimately flawed because a debloating tool's ability to eliminate vulnerabilities in evaluation is a poor indicator of whether or not it can measurably eliminate vulnerabilities in practice.

First, suppose our goal is to eliminate known (i.e., n-day) vulnerabilities in a program or a code library. Debloating is not a realistic strategy because applying a patch is generally less costly, complex, invasive and risky than debloating. In the uncommon case that there is no patch or mitigation available, debloating can only remove the vulnerability if it resides in code that the user does not need because debloating tools by design avoid altering required code. If the vulnerability is indeed resident in unneeded code, then removing may not be necessary unless it can be triggered by an attacker.

Now, consider the more realistic case where our goal is to eliminate unknown (i.e., 0-day) vulnerabilities via debloating. In this case, the benefits of debloating are highly circumstantial. Unknown vulnerabilities will only be removed if they happen to reside in code the debloater determines is unnecessary. Also, we have no way of knowing if we successfully removed a vulnerability or not. Thus it is a best effort strategy only. For both known and unknown vulnerabilities, a debloater's ability to remove vulnerabilities is primarily dependent upon what code the user needs and the location of the vulnerability, not the characteristics of the debloating tool itself.

Finally, the use of this metric can be misleading, inaccurate, or incomplete. For example, Qian et al. [51] showed that prior work claiming vulnerability elimination in Type II bloat [31] also *reintroduced* other historical vulnerabilities. Also, PCL [55] reports eliminating known vulnerabilities in Type I bloat as a benefit of their tool. However, these vulnerabilities are in library functions that are statically unreachable from the program. As such, they are exploitable only under extreme or contrived scenarios.

Attack surface reduction and code-reuse prevention metrics used in the literature largely focus on code-reuse gadgets as a unit of measure. Code reuse gadgets are small snippets of chain-able code present in the vulnerable program an attacker can use to implement an exploit in situations where code injection defenses prevent them from executing shell code directly. A common metric used to demonstrate security improvement is a reduction in the total number of gadgets available to the attacker. However, Brown and Pande [12] have shown this to be unsuitable due to the propensity of many debloaters to introduce new gadgets at a high rate despite reducing total gadget count and the likely possibility that large reductions in gadget counts fail to impose barriers on attackers creating exploit chains. In turn, Brown and Pande propose qualitative gadget set metrics for measuring costs imposed on attackers exploit (e.g., gadget set expressivity, composability, special capabilities, and locality) and a static analysis tool for computing them, GSA (Gadget Set Analyzer).

2.5 Benchmark Programs

The works we surveyed used a variety of different benchmarks to evaluate their tools. The majority of works employed benchmark sets that are commonly used in program analysis literature such as GNU Coreutils [25], SPEC CPU 2006/2017 [18, 19] and DaCapo [10]. Additionally, several works created and subsequently made available their own benchmark sets such as CHISELBench [6] and OCCAM benchmarks [66], however it is worth noting that these sets contain many benchmark programs from Coreutils and SPEC. Generally, the majority of benchmark programs used are of low complexity: they have command line user interfaces, make limited use of multi-threading, network interfaces, etc., and often run to termination with only a single set of inputs. This is unsurprising, as these types of benchmark programs are amenable to the complex tracing and transformation operations required for debloating. Many works also evaluated their tools on moderate-complexity benchmarks such as `bfptd`, `curl`, and `httpd`, although with less volume and frequency. Such benchmarks are characterized by use of complex inputs, multi-threading, network sockets, etc. Although rare, some works [51, 52] evaluated their tools on high-complexity software such as web browsers and document readers.

3 Evaluation Methodology

In the following subsections, we detail our methodology for selecting the tools, configurations, metrics, benchmarks that we used in our subsequent evaluation.

3.1 Tool Selection

Due to the size and diversity of the software debloating ecosystem, we first scoped our evaluation to tools that support userland C/C++ programs and libraries for x86/x86-64 machines. This benchmark profile is the most widely supported and had the largest pool of candidate tools. In total, we identified 31 candidate tools after filtering predecessor tools (e.g., including OCCAMv2 [45] versus OCCAMv1 [42]). We obtained source code via a public repository or request to the authors for 24 tools, and were able to successfully build and run 17 of them. We expended significant effort to resolve issues for the seven failing builds, however we were not successful due to irreconcilable technical issues [9, 47, 55, 75] or unresponsive authors [15, 64, 77]. Of the remaining 17 tools, we further excluded one because it requires a commercial license for IDA Pro [54] and six others because they were not readily adaptable to new targets. The underlying causes for exclusion included one tool that was hardcoded to its benchmarks [72], several tools that required time consuming and manual pre-

processing steps for new benchmarks [11, 49, 50, 76], and one tool with technical limitations [22].

Table 1 lists the ten tools that were suitable for our evaluation. For each tool, we prepared an isolated environment (i.e., virtual machine or docker container) configured with the tool's latest supported OS and all necessary resources required to use the tool and manipulate our benchmark programs. Of note, three tools are specialized versions of academic tools developed by commercial firms. To avoid confusion, we hyphenate the commercial firm's abbreviation to the tool title: CHISEL-GT (GrammaTech, Inc.), BinRec-ToB (Trail of Bits), and LMCAS-SIFT (Smart Information Flow Technologies). We disclose that development of these commercial tools and the evaluation presented in this paper was directed and funded by the Office of Naval Research (ONR). Further, the the authors of this paper are also the creators of BinRec-ToB and CHISEL-GT. The creators of LMCAS-SIFT also provided their tool and support for this evaluation.

3.2 Benchmark Selection

We selected 20 C/C++ benchmark programs (Table 2) that vary in size, complexity, and functionality. To represent low-complexity benchmarks, we use CHISELBench [6] as it is commonly used in debloating literature and provides a common point of comparison for prior work. We further add six medium-complexity and four high-complexity benchmarks sourced from other benchmark sets [59, 66]. To build reference 64-bit ELF binaries for these benchmarks, we used Clang/LLVM v10 on Ubuntu Linux v20 with two build options specified: position-independent code (`-fPIC`) and optimization level 3 (`-O3`). However, due to various tool- and benchmark-specific limitations, we used different methods to build some reference binaries. We built reference binaries for use with RAZOR and CHISEL on Debian Buster. Building `ImageMagick` required using GCC v9.4 (Ubuntu) and GCC v8.3 (Debian Buster) instead of Clang/LLVM. Finally, we built the reference binaries for BinRec-ToB as 32-bit ELF binaries as it does not support 64-bit programs.

3.3 Debloating Specifications

Due to varying support for debloating use cases across tools, we used three strategies for creating debloating specifications. First, specifications are not required for SL debloaters as they target Type I bloat only. Second, we adopted a moderate (Section 2.2) debloating use case for the S2S and B2B debloaters as this use case is most prevalent in the literature. Third, we adopted an aggressive use case for the CBS debloaters as this is the only use case they support.

For each benchmark, we created a general, tool-agnostic debloating specification consisting of several core and peripheral features to retain (i.e., the moderate use case). We defined each feature with a descriptive name and one or more sample commands (i.e., test cases) for the benchmark that exercises the feature. We further winnowed these specifications to a single command to create an aggressive version of the moderate use case. Using the general specifications as a guide, we then created tool-specific configuration files for each benchmark program. In total, we created 160 distinct debloating specifications for use in our evaluation [2].

3.4 Metric Selection

We selected 12 metrics (Table 3) for evaluating both the debloaters themselves and the debloated programs/libraries they produce. These metrics were drawn from those frequently used in the three categories outlined in Section 2.4. Generally, we selected metrics that are computed from analysis of program binaries, as this is the only common program representation to all debloating tools (e.g., debloated code output by S2S or CBS debloaters can be compiled and measured against B2B debloated binaries). Of note, we chose not to use CVE removal as a security metric in our evaluation due to its poor predictive power. We provide details for how each metric is computed and our evaluation results in Section 4.

4 Evaluation Results

We present the results of our evaluation organized by metric categories. First, we present performance results for the tools themselves, followed by performance, correctness, and security metrics calculated by analyzing the debloated artifacts they produce. Note that we discuss important findings and results for each metric in this section but leave a holistic and cross-category analysis for Section 5.

4.1 Tool Performance

Our evaluation of debloating tool performance is limited to its **CPU runtime** and **peak memory usage** during execution. We exclude various other aspects of tool use (e.g., preparing the tool, harnessing the target program, deploying the debloated program, etc.) from our performance evaluation as they are highly dependent upon the user's technical expertise and familiarity with tool, target program, and deployment environment. To conduct our performance evaluation, we placed each tool's isolated execution environment, their relevant debloating specifications, and our benchmark programs (source code and reference binaries) on our dedicated testing virtual machine (VM). We configured the VM as a server-class machine with access to 24 3.2 GHz processors and 128 GB of memory.

Some manual effort was required for three tools before we could execute our tool performance tests. First, we discovered

[2] General debloating specifications and tool-specific configurations are available in our data repository (Section 7).

Table 1: Debloaters Selected for Evaluation

Year	Cite	Name	Category	Bloat Type	Granularity	Spec. Type	Open Source
2018	[31]	CHISEL	S2S	Type II	Line	Test Cases	•
2023	[31]	CHISEL-GT	S2S	Type II	Line	Test Cases	
2019	[51]	RAZOR	B2B	Type II	Basic Block	Test Cases	•
2022	[5,70]	BinRec-ToB	B2B	Type II	Basic Block	Test Cases	•
2023	[26]	GTIRB Binary Reduce (Dynamic)	B2B	Type II	Basic Block	Test Cases	
2021	[2,61]	Trimmer (v2)	CBS	Type II	Instruction	Command	•
2022	[42,45]	OCCAM (v2)	CBS	Type II	Instruction	Command	•
2023	[3]	LMCAS-SIFT	CBS	Type I/II	Instruction	Command	
2023	[26]	GTIRB Binary Reduce (Static)	SL	Type I	Function	None	
2019	[62]	Libfilter	SL	Type I	Function	None	•

Table 2: Evaluation Benchmarks

Low Complexity (CHISELBench [6])				Medium Complexity		High Complexity	
Benchmark	**Size** (KLOC)	**Benchmark**	**Size**	**Benchmark**	**Size**	**Benchmark**	**Size**
`bzip2 v1.0.5`	12.2	`rm v8.4`	7.4	`bftpd v6.1`	4.7	`nmap v7.93`	233.4
`chown v8.2`	7.3	`sort v8.16`	14.7	`wget v1.20.3`	14.2	`nginx v1.23.3`	170.6
`date v8.21`	9.9	`tar v1.14`	31.3	`make v4.2`	24.6	`pdftohtml v0.60`	16.1
`grep v2.19`	23.8	`uniq v8.16`	7.4	`objdump v2.40`	59.7	`ImageMagick v7.0.1`	361.9
`gzip v1.2.4`	8.9			`memcached v1.6.18`	30.5		
`mkdir v5.2.1`	5.1			`lighttpd v1.4`	89.7		

NOTE: Due to incompatibilities with LMCAS-SIFT, we were forced to use different minor versions of some benchmarks when building this tool's reference binaries: `coreutilsv8.26 (chown, date, mkdir, rm, sort, uniq)` and `gzip v1.12`.

that CHISEL and CHISEL-GT were unable to run within a reasonable time frame of 48 hours for medium and high-complexity benchmarks as designed. CHISEL/CHISEL-GT requires many iterations to progressively identify unnecessary code in programs, each of which requires deleting some source code, compiling the resulting code, and executing the numerous test cases. As such, CHISEL and CHISEL-GT's debloating runtime is proportional to the runtime of the test cases that make up its specification. To evaluate these tools beyond the CHISELBench (i.e., low-complexity benchmarks), we worked with the authors of these tools to implement a parallelized test framework to improve its performance enough to meet our standard for reasonable run time (48 hours). In all, this engineering effort required 26 engineer hours to implement.

Second, LMCAS-SIFT introduces the concept of a program "neck", which is defined as the boundary between a program's configuration logic (i.e., command line and/or config file parsing code) and main logic (i.e., the rest of the program). LMCAS-SIFT requires that a suitable neck be identified prior to debloating, and provides an automated placement tool for this purpose called the neck miner. The neck miner does not always identify the neck properly, leading to debloating failures. If the neck miner fails, the user must manually identify it. In our evaluation, the neck miner failed to automatically place the neck for `gzip`, `mkdir`, `sort`, `tar`, and `uniq`, and required us to manually place them.

With our testing environment configured and manual harnessing complete, we then ran each tool ten times[3] on each compatible benchmark program recording the total CPU runtime and peak memory usage per run. We summarize the average run time in CPU minutes and peak memory use across all benchmarks at each level of complexity in Table 4. Note that we include debloating operations that fail in these calculations. We exclude only benchmarks that are not compatible with the tool for reasons such as the tool does not support C++ code, multi-threaded programs, etc. The first set of columns in Table 4 indicate the number of compatible benchmarks per tool at each level of complexity, out of the total 10 low, 6 medium, and 4 high complexity benchmarks.

Excluding a notable outlier (`objdump`), all debloaters except CHISEL and CHISEL-GT took 25 minutes or less on average to complete. CHISEL and CHISEL-GT took on the order of CPU hours and CPU days to run, respectively. This is due to their rather inefficient and indirect method of mapping features to source code by iterative deletion and compilation/testing. With respect to memory consumption, debloaters generally required memory comparable to the size of the target program. Across all tools, we observed a maximum average peak demand of 6.4GB of memory. Finally, we observed very little variability in tool CPU runtime and peak memory usage across all benchmarks and trials. In all cases, the standard deviation across each tool's ten performance tri-

[3]Due to prohibitively long run times on the order of several CPU hours/days (even with customization), we ran several tools on certain benchmarks only once: 1) all CHISEL and CHISEL-GT performance tests, 2) OCCAM and TRIMMER on `objdump`.

Table 3: Metrics Selected for Evaluation

Name	Category	Name	Category
Run time (tool)	Performance	Gadget Set Expressivity	Security
Peak Memory Use (tool)	Performance	Gadget Set Quality	Security
Run time	Performance	Gadget Set Locality	Security
Peak Memory Use	Performance	Special Purpose Gadget Types Available	Security
Static Binary Size	Performance	Executes Retained Functions	Correctness / Robustness
Number of Libraries Linked	Performance	Errors / Crashes during Differential Testing	Correctness / Robustness

als on a given benchmark was 1-2 orders of magnitude below the average value.

4.2 Program Performance

Software debloating tools seek to improve, or at the very least avoid negatively impacting a program's performance when removing its unnecessary code. The primary expectation is that the debloated program will occupy less space both on disk and in run time memory, however it is not unrealistic to expect that debloated programs may also execute faster if they are structured in such a way where unnecessary code is frequently executed. Conversely, it is also possible that the mechanics of debloating operations may degrade run time. We present in this section four performance metrics collected on the debloated binaries and libraries that capture the performance impacts of using these tools.

Static Binary Size. We recorded the size of each successfully debloated binary on disk and compare it to the size of the original program's binary. Our calculations are modified for LMCAS-SIFT and the SL debloaters due to differences in their implementation. Libfilter produces new, slimmed copies of the benchmark's linked libraries; thus we compare the aggregate sizes of the debloated libraries against the originals. The debloated programs created by LMCAS-SIFT and Binary Reduce (Static) are statically linked binaries. For these we compare the statically linked binary's size to the aggregate size of the original binary and its dynamically linked libraries.

We calculated size changes as a percentage, with values under 100% indicating size reductions. We then averaged the changes in binary size across the three complexity levels, shown in Table 5. The first set of columns indicates the number of successfully debloated benchmarks for each tool at each complexity level. BinRec-ToB was not able to successfully debloat any of the benchmarks, and as such we exclude it from this and all future tables in our evaluation.

Our evaluation reveals several interesting results. RAZOR and Libfilter produced debloated binaries that are larger on average across all complexity levels. This is not surprising, as RAZOR stitches the debloated version of the program into a new code section of the original binary and marks the original code section as non-executable rather than actually removing it. Similarly, Libfilter rewrites unreachable functions as `HLT` (halt) instructions rather than removing them. We note that reducing binary size is not a stated goal of either tool, and this metric was not evaluated by their authors. Further, the transformation methods used by these tools can be replaced with other methods that reduce binary size rather than increase it without fundamental changes to their approaches.

Generally, other tools achieved large size reductions for low complexity benchmarks but were noticeably less effective on high complexity benchmarks. This, combined with poor success rates on high-complexity benchmarks (only 3 of 10 tools successfully processed all four) suggests that these tools are likely over-fit to low- and medium-complexity benchmarks.

Number of Linked Libraries In addition to recording

Table 5: Average Change in Static Binary Size

	# Benchmarks			Static Binary Size		
Debloater	**Low**	**Medium**	**High**	**Low**	**Medium**	**High**
CHISEL	9	6	2	31.6%	98.4%	100%
CHISEL-GT	8	3	2	80.9%	79.7%	96.6%
RAZOR	10	3	3	117.2%	101.5%	107.3%
Binary Reduce (Dynamic)	10	5	4	54.4%	38.6%	76.4%
Trimmer (v2) [Agg.]	7	4	4	68.1%	60.6%	79.6%
OCCAM (v2) [Agg.]	10	6	4	80.5%	74.7%	93.9%
LMCAS-SIFT [Agg.][1]	7	2	1	6.4%	8.3%	33.0%
Binary Reduce (Static)[1]	10	5	1	22.2%	46.5%	49.0%
Libfilter	10	4	1	101.3%	101.1%	101.5%

[1] Size calculated over executable and libraries because output is a statically linked binary.

reduction in binary size, we also recorded the number of external libraries linked by our benchmarks before and after debloating to determine if removing Type II bloat in the main executable eliminated the need for one or more libraries. We exclude LMCAS-SIFT and the SL debloaters from this evaluation since they operate on libraries directly. Our results are intended to be anecdotal only because eliminating libraries via debloating is largely dependent upon the specification.

Binary Reduce (Dynamic), CHISEL and CHISEL-GT were generally successful in eliminating one or more libraries for medium- and high-complexity benchmarks. Such observations are expected based on their design, however we observed something unexpected: TRIMMER and OCCAM *introduced* new libraries into debloated programs. The introduced libraries are typically `libc++`, `libgcc`, and `libm`, and are likely the result of changes the tool makes to the program with its custom LLVM compiler transformation passes. These libraries are quite large and computationally complex. Depending on the user's goals for debloating (e.g., minimizing code size or re-usability), introducing new dependencies like this may prove counterproductive.

Program Run Time and Peak Memory Use. To determine how debloating processes impact the performance of debloated programs, we created test suites for each benchmark that exercise retained functionality according to our specifications (moderate and aggressive). These test suites are designed to be strenuous and long-running where possible. We ran each benchmark's reference binaries and each successfully debloated binary against these test suites ten times, averaging the total run time in CPU seconds and peak memory consumption in MB across the trials. In many cases, the debloated programs could not successfully complete the performance test due to crashes, infinite execution, or run-time errors. We excluded these failures from our calculations.

We calculated changes in run time and peak memory as a percentage, with values under 100% indicating reductions. We then averaged the changes across the three complexity levels, shown in Table 6. The first set of columns indicates the number of debloated benchmarks that successfully completed the performance tests for each tool at each complexity level. Note that we exclude 3 medium and 2 high complexity benchmarks for CHISEL from these counts and our calculations because CHISEL "successfully" processed these benchmarks by making no modifications to the source code.

Our performance evaluation surfaces an important finding: we observed a high failure rate for medium and high-complexity benchmarks across all debloaters. Collectively, only 22% of our attempts to debloat these benchmarks were successful, calling into question the utility of software debloating tools for complex programs. Further, the success rate on low-complexity benchmarks was also lower than expected. Despite CHISELBench being used extensively in the literature, only two tools, OCCAM and RAZOR successfully debloated all low-complexity benchmarks. Conversely, BinRecToB and Binary Reduce (Dynamic) failed to debloat any low complexity benchmarks.

With respect to our performance metrics, we observed only a few instances where debloated programs performed noticeably worse than their unmodified counterparts. Excluding an outlier for CHISEL, only TRIMMER and OCCAM demonstrated consistent and significant (>4%) negative impacts to run time or memory consumption across multiple complexity levels. The most significant of which are large (28% to 76%) increases in run time. This is somewhat unsurprising as these debloaters significantly alter the build chain and overall phase ordering of compiler optimizations to facilitate debloating. Phase ordering has significant effects on binary performance and is an open area of research [38, 39].

4.3 Program Security Posture

Aside from performance improvements, debloating literature often cites improving a program's security posture (i.e., reducing its attack surface) as a chief motivating goal. However, concrete definitions of attack surface reduction vary widely and there is a lack of sensible and effective metrics for measuring it. Given the shortcomings of other commonly used measures (i.e., elimination of known vulnerabilities), we adopt

Table 6: Average Change in Benchmark Run Time and Peak Memory Performance

	# Benchmarks			Run Time			Peak Memory		
Debloater	**Low**	**Medium**	**High**	**Low**	**Medium**	**High**	**Low**	**Medium**	**High**
CHISEL	7	2 [2]	0 [2]	207% [1]	97.9%	N/A	96.7%	99.6%	N/A
CHISEL-GT	7	2	1	97.6%	100.7%	101.8%	99.6%	99.7%	100.4%
RAZOR	10	3	2	95.8%	106.3%	100.9%	99.8%	% 99.4	100.6%

[2] Excludes 3 medium and 2 high complexity benchmarks that were "successfully" processed, but left unmodified by CHISEL.

four metrics that focus on code re-usability for our evaluation. We use GSA [12] to analyze our debloated binaries and their unmodified counterparts and compute these metrics, which capture how readily an attacker can re-use the code present in the program and its linked libraries to manufacture an exploit in the presence of common security controls such as W⊕X and ASLR. Without a priori knowledge of the actual vulnerabilities present in a program, these metrics provide a qualitative assessment of the hygienic security benefits of debloating.

Gadget Set Expressivity and Quality. The first two code re-usability metrics we evaluated are concerned with the aggregate properties of the functional code reuse gadgets available in a program binary. Attackers chain together functional code reuse gadgets like instructions in a programming language to write and launch an exploit without injecting code. Gadget set expressivity measures the collective expressive power of functional gadgets in a binary to determine if they are sufficient to launch practical exploits. GSA defines 11 different classes of functionality that must be met by gadgets in the set to meet this bar and reports expressivity as the number of satisfied classes. Gadget set quality measures the average chain-ability of gadgets in the set to determine how easily they can be composed. Gadgets useful to an attacker often contain machine instructions that are irrelevant for their purposes but may impose side constraints on creating a gadget chain (i.e., altering the stack pointer). GSA measures the quality of each gadget by using a starting score of 0.0 and adding to this score for each side constraint detected. Overall set quality is computed as the average score across all gadgets.

For both metrics, GSA compares set expressivity and quality in the debloated binary versus the original and reports the change in value. For LMCAS-SIFT and the SL debloaters, we include libraries in the comparisons as we did in Section 4.2 to make meaningful comparisons. Negative values for expressivity indicate negative outcomes: the gadget set in the debloated binary satisfies more expressivity classes than the original. The reverse is true for gadget set quality: positive values indicate that the average number of side constraints per gadget went down after debloating. However, it is worth noting that values less than 0.5 in either direction are not significant as GSA's quality scoring system values minor side constraints at 0.5 and major ones at 3.0. We averaged GSA's reported metrics across the three complexity levels, shown in Table 7. The first set of columns indicates the number of successfully debloated benchmarks for each tool at each complexity level.

Overall, the debloaters we evaluated did not have a significant impact on security posture according to these two metrics. In many cases, our data indicates expressivity and ease of chaining *increased* for some tools and complexity levels. However, we consider only one average increase to be significant, which we define as a change of 2 or more expressivity classes or a change of 0.5 or more for the quality score. This case is TRIMMER's performance on the four high complexity benchmarks, where is increased expressivity by 3.5 classes on average.

Special Purpose Gadget Availability. The third code re-usability metric we evaluated is concerned with the availability of special purpose code reuse gadgets in a program binary. Attackers use special purpose gadgets as scaffolding to organize functional gadgets or to accomplish specific tasks such as execute system calls (i.e., syscall gadget). The special purpose gadget availability metric captures how many different types of special purpose gadget types are available to an attacker, defined as the presence of at least one gadget per type. GSA defines 10 different types of special purpose gadgets, the most important of these types being syscall gadgets. Syscall gadgets are used to invoke operating system functions such as `exec` or `mprotect` on the attacker's behalf. These gadgets are rare outside of `libc`, as they only appear unintentionally in typical userland programs.

GSA compares the special purpose gadget types available in the debloated binary versus the original and reports the change in value. Negative values indicate negative outcomes: the gadget set in the debloated binary contains more types of

Table 7: Average Changes in Gadget Set Expressivity and Quality

	# Benchmarks			Gadget Set Expressivity			Gadget Set Quality		
Debloater	**Low**	**Medium**	**High**	**Low**	**Medium**	**High**	**Low**	**Medium**	**High**
CHISEL	9	6	2	1.3	0	0	-0.1	0	0
CHISEL-GT	8	3	2	0.3	0.7	0.5	0.1	0.2	0.1
RAZOR	10	3	2	-0.3	-0.3	-0.5	0.2	0	0.1
Binary Reduce (Dynamic)	10	4	4	1.3	1	1.25	0.2	0.2	0.2
Trimmer (v2) [Agg.]	7	4	4	0	-0.3	-3.5	0.4	0.2	-0.3
OCCAM (v2) [Agg.]	10	6	4	1.3	0.5	0.5	0.2	0	0.1
LMCAS-SIFT [Agg.]	7	2	1	0.1	0	-1	0.2	0.2	0
Binary Reduce (Static)	10	6	1	0.3	-0.5	-1	0.3	0.1	0
Libfilter	10	5	1	1	1	1	0	0	0

special purpose gadgets than the original. Due to the relative importance of syscall gadgets, GSA also records the number of syscall gadgets present in the binary. We averaged GSA's reported metrics across the three complexity levels, shown in Table 8. The first set of columns indicates the number of successfully debloated benchmarks for each tool at each complexity level. Additionally, the last set of columns displays the number of benchmarks where debloating introduced syscall gadgets where there were previously none (undesirable) or eliminated all available syscall gadgets (desirable).

Overall, debloating did not have a significant impact on the types of special purpose gadgets available. On average, the total number of types was increased or decreased by less than one type for almost all tools and complexity levels. CHISEL-GT and TRIMMER both introduced more than one type of special purpose gadget on average for medium+high and high complexity benchmarks, respectively. LMCAS-SIFT and Binary Reduce (Static) both reduce the availability of special purpose gadget types significantly at several levels of benchmark complexity, although it is important to note that this is due to the elimination of large amounts of code in libraries via static linking. Focusing specifically on syscall gadgets, the results were similarly mixed. Most tools either eliminated syscall gadgets for some benchmarks, introduced them in others, or more commonly, both.

Gadget Locality. The final code re-usability metric we evaluated is concerned with the portability of exploits written against the original program to debloated programs. Code re-use exploit payloads for methods such as return-oriented programming (ROP) and its variants reference gadgets selected by the attacker using their address in the binary. This exploit payload is fragile: it will only work on different versions of the same vulnerable program the attacker's gadgets can all be located at the prescribed addresses. While some highly complex exploitation techniques such as JIT-ROP [63] can overcome the need for static gadget addresses, in practice intentionally randomizing the code layout in binaries provides for moving target defense and breaks portability of exploits. This forces the attacker to create an exploit payload for each different version of the vulnerable program they wish to exploit. GSA scans the original and debloated binaries to identify which gadgets retain their *locality* after debloating, meaning the gadget remains at the same address in the binary and its instructions are not changed. GSA calculates locality as a percentage, where 0% indicates there are no local gadgets in the debloated binary and 100% indicates they are all local.

Of the 136 successfully produced debloated variants, the majority of them (109) exhibited 0% locality indicating they are immune to ported exploit payloads. These includes all of the debloated variants produced by LMCAS-SIFT, RAZOR, TRIMMER, and both SL debloaters. A further 18 debloated variants measured locality at less than 0.5%, indicating strong protection from ported attacks. All debloated variants produced by OCCAM and CHISEL-GT are included in these two levels. The remaining 9 variants were produced by Binary Reduce (Dynamic) and CHISEL with gadget locality values in the range of 4% to 82%, indicating weak protection from ported exploits.

4.4 Program Correctness / Robustness

Debloating transformations are complex and ensuring they do not compromise the soundness of the program is challenging whether they are implemented pre- (i.e., S2S), during (i.e., CBS), or post-production (i.e., B2B, SL). Flawed or incomplete transformations have the potential to negatively impact programs in many ways that can manifest as logic bugs, run-time errors, crashes, and in some cases, introducing new vulnerabilities. We discovered ample evidence of this during our benchmark performance tests (Section 4.2), where 36.6% of the debloated binaries produced in our evaluation failed to execute their retained functionality.

This highlights the importance of post-debloating validation, a stage of the debloating workflow that is often neglected or left entirely to the user for tools targeting Type II bloat. This is partly due to a lack of effective testing tools; existing approaches like regression and fuzz testing do not naturally support testing debloated programs against their original versions. To address this shortcoming in our evaluation, we have created a differential testing tool for transformed programs

Table 8: Average Changes in Special Purpose Gadget Availability and Overall Syscall Gadget Impacts

	# Benchmarks			S.P. Gadget Types Available			Syscall Gadget Impact	
Debloater	**Low**	**Medium**	**High**	**Low**	**Medium**	**High**	**Eliminate**	**Introduce**
CHISEL	9	6	2	0.6	-0.3	0	3	1
CHISEL-GT	8	3	2	-0.6	-2.3	-1.5	1	3
RAZOR	10	3	2	-0.9	0	0.5	1	2
Binary Reduce (Dynamic)	10	4	4	-0.8	-0.5	0.3	0	0
Trimmer (v2) [Agg.]	7	4	4	0.7	0.8	-2.8	0	2
OCCAM (v2) [Agg.]	10	6	4	0.4	-0.5	-0.3	1	0
LMCAS-SIFT [Agg.]	7	2	1	4	3.5	2	0	0
Binary Reduce (Static)	10	6	1	2.9	2	1	0	0
Libfilter	10	5	1	0	0	0	0	0

called DIFFER that combines elements from differential, regression, and fuzz testing approaches.

DIFFER allows users to specify seed inputs that correspond to both retained and debloated features. It runs the original program and one or more of its debloated variants with these inputs and compares their outputs. DIFFER expects that inputs for retained features will result in outputs that are the same for the original and debloated programs. Conversely, it expects inputs for debloated features to cause the original and debloated programs to produce differing outputs. If DIFFER detects unexpected matches, differences or crashes it reports them to the user to inspect. DIFFER's reports can help the user identify mistakes in the debloater's configuration or instances where the debloated program is unsound. As is the case with all dynamic analysis tools, it is possible that DIFFER reports may be false positives. To reduce false positive rates to a minimum, DIFFER allows users to define custom output comparators that can account for expected differences in outputs (e.g., a program timestamps its console output). Additionally, DIFFER supports template-based mutational fuzzing of seed inputs to ensure maximum coverage of the input space (i.e., avoid false negatives) for both debloated and retained features.

It is important to note that DIFFER does not and cannot provide formal guarantees of soundness in debloaters or the debloated programs they produce. Like other dynamic analysis testing approaches, DIFFER cannot exhaustively test the input space for complex programs in the general case. Still, DIFFER is quite useful for post-debloating validation as it is user-friendly and only requires a moderate about of user expertise to configure.

Using the general debloating specifications we created in Section 3.3 as a starting point, we configured DIFFER to test both retained and debloated functions for each benchmark program. We ran DIFFER on each of the debloated benchmark programs that successfully completed their performance test (a total of 90 variants) for a maximum of 12 hours to identify crashes, inconsistencies, or errors introduced during debloating as well as failures to remove functionality marked for debloating. Our results are concerning: after filtering for false positives, DIFFER discovered errors or crashes in 27.8% (25 of 90) of debloated benchmarks. Additionally, debloating tools failed to remove features marked for debloating in 60% (39 of 65) of the remaining debloated benchmarks. Of the final 26 debloated benchmarks that passed testing by DIFFER, thirteen were produced by Binary Reduce (static), seven were produced by libfilter, four were produced by LMCAS-SIFT, and OCCAM and CHISEL each produced one. Across our evaluation, 50% (20 of 40) of attempts to remove Type I bloat were ultimately successful, and *only 3.3%* of attempts to remove Type II bloat were successful (6 of 180)[4]. Our results indicate that the general lack of attention paid to post-debloating validation has resulted in over-reporting of successful debloating in the literature. This demonstrates the need for closer attention to post-debloating validation in future research to ensure accurate reporting of debloating success.

5 Discussion and Key Findings

In this section we discuss our key findings and provide actionable recommendations for future debloating research.

5.1 Low Tool Maturity

Our most important finding is that debloating tools currently lack the maturity required to be used on real-world software. This is evidenced by a slim success rate of 42.5% across all tools and complexity levels at producing debloated programs or libraries that can pass a performance test. The success rate across medium- and high-complexity benchmarks is only 22%, indicating that the current generation of debloaters are suitable for use on lower complexity programs only. To advance the state of the art in debloating, new approaches should focus on supporting more complex software packages and programming language features / paradigms.

[4]Five successes were on low-complexity benchmarks, one was on a medium complexity benchmark.

5.2 Soundness Issues

When tested for correctness and robustness with DIFFER, only two of the ten tools we evaluated, Binary Reduce static and dynamic, did not produce unsound debloated binaries (i.e., DIFFER did not detect any crashes, failures, or errors in kept functionality). In the case of Binary Reduce (dynamic), this tool produced only one debloated benchmark, and DIFFER did detect that it still contained features marked for debloating. As such, it is possible this binary is only sound because the tool did not successfully debloat any features, which is supported by the fact that this binary increased in size after debloating.

Each of the remaining tools produced far more faulty programs than successful ones (except for BinRec-ToB, which did not produce any debloated binaries). While the majority of soundness issues detected by our performance tests and DIFFER were problems with retained features, our results also reveal serious program soundness issues with respect to debloated functionality. New approaches must evolve to cauterize the void left by excised code. In our survey, we observed only one tool with the capability to do so: CARVE [11]. CARVE introduces the concept of *debloating with replacement* in which atomic (i.e., contiguous group of source code lines) debloating operations can be accompanied by replacement code that maintains the soundness and robustness of the program after debloating by inserting code to perform error handling, control-flow redirection, data-flow sanitization, etc. While promising, this feature requires manual inputs from developers and maintenance over time. A future research opportunity exists to explore automated and scalable methods for implementing debloating with replacement, potentially by re-purposing automated program repair techniques.

5.3 Marginal Performance/Security Benefits

Finally, the tools we evaluated demonstrated consistent and significant improvements in two metrics only: binary size and gadget locality. We observed marginal benefits at best for all other performance and security metrics. It is important to note that our security evaluation is limited to code re-usability metrics due to the difficulty of quantifying security improvements. These tools may have had positive impacts such as removing previously-unknown reachable vulnerabilities that are generally not possible to evaluate because they are undecidable.

Considering these marginal benefits in concert with the aforementioned maturity and soundness issues, users are likely to find the benefits of software debloating are currently outweighed by the costs and potential risks in real-world scenarios. Further research is needed to improve the benefits of debloating tools relative to the risks we identified above.

6 Conclusion

In this work, we presented our survey of the software debloating ecosystem. From this survey, we created a taxonomy of debloating tools, a collection of 12 metrics to measure their effectiveness, and a set of 20 benchmark programs of varying complexity useful for comparing tools against each other. Next, we evaluated and compared ten software debloating tools across the four most prominent types of debloating tools. Our evaluation measured the performance of the tools themselves, as well as the performance, soundness, and security improvements of the debloated programs they produce. Our evaluation indicates that the current generation of software debloating tools have several shortcomings that will prevent adoption of these techniques in real-world scenarios. Specifically, the software debloating tools we evaluated have limited support for medium- and high-complexity programs, struggle to maintain soundness and robustness during debloating, and have limited success in improving the performance or security posture of debloated programs. To drive adoption of software debloating tools, future debloating research should focus on improving support for complex programs, soundness, and metrics for quantifying positive security impacts. We have made our benchmark set, data, and custom tools publicly available to help drive debloater adoption and inform their future development.

7 Availability

We have made the full set of artifacts generated in this work including our benchmark set, metric tools, DIFFER, evaluation scripts, and the evaluated tools publicly available at:

LaserAdv: Laser Adversarial Attacks on Speech Recognition Systems

Guoming Zhang[1], Xiaohui Ma[1], Huiting Zhang[1], Zhijie Xiang[1], Xiaoyu Ji[2], Yanni Yang[1], Xiuzhen Cheng[1], and Pengfei Hu[1*]
[1]*Shandong University* [2]*Zhejiang University*

Abstract

Audio adversarial perturbations are imperceptible to humans but can mislead machine learning models, posing a security threat to automatic speech recognition (ASR) systems. Existing methods aim to minimize perturbation values, use acoustic masking, or mimic environmental sounds to render them undetectable. However, these perturbations, being audible frequency range sounds, are still audibly detectable. The slow propagation and rapid attenuation of sound limit their temporal sensitivity and attack range. In this study, we propose LaserAdv, a method that employs lasers to launch adversarial attacks, thereby overcoming the aforementioned challenges due to the superior properties of lasers. In the presence of victim speech, laser adversarial perturbations are superimposed on the speech rather than simply drowning it out, so LaserAdv has higher attack efficiency and longer attack range than LightCommands. LaserAdv introduces a selective amplitude enhancement method based on time-frequency interconversion (SAE-TFI) to deal with distortion. Meanwhile, to simultaneously achieve inaudible, targeted, universal, synchronization-free (over 0.5 s), long-range, and black-box attacks in the physical world, we introduced a series of strategies into the objective function. Our experimental results show that a single perturbation can cause DeepSpeech, Whisper and iFlytek, to misinterpret any of the 12,260 voice commands as the target command with accuracy of up to 100%, 92% and 88%, respectively. The attack distance can be up to 120 m.

1 Introduction

With rapid advances in artificial intelligence, ASR systems have become an integral part of our daily life. These systems are the driving force behind popular technologies such as digital assistants (e.g., Alexa and Open AI Whisper), transcription services and voice-controlled applications, improving the user experience by providing convenient and hands-free control. However, as these systems become more pervasive, they also become attractive targets for adversaries [1, 2]. Adversaries are often motivated by the ability to bypass security mechanisms, gain unauthorized access to systems, or disrupt services. Such attacks facilitate unauthorized access to sensitive information and control over physical security mechanisms, such as unlocking doors, which pose a direct threat to personal safety. Moreover, adversaries can remotely set devices to airplane mode, precipitating denial-of-service attacks, etc.

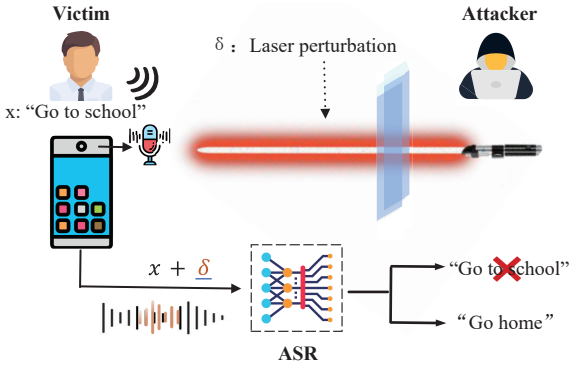

Figure 1: Attack Scenarios.

Previous researchers have increasingly focused on attacking ASR systems using audio adversarial attacks. Traditional methods for generating adversarial perturbations have primarily revolved around constraining the perturbation to a certain limit [3]. In parallel, some studies have gone a step further, which combined human perceptual models and music or ambient noise as a means of constraining the adversarial perturbation while ensuring quality masking [4–9, 11].

Unfortunately, existing research efforts have primarily concentrated on creating adversarial perturbations within the audible frequency range, which poses a significant challenge to achieving complete imperceptibility. In addition, the inherently slow speed of sound propagation results in longer transmission times, preventing effective synchronisation with the victim's voice command. Combined with the rapid attenuation of sound over distance, this can result in significant

* Corresponding Author.

perturbation distortion. Taken together, these factors reduce the effectiveness of the attack and may even cause it to fail over long distances. In contrast, the speed of lasers far exceeds that of sound, and they experience slower attenuation over the air. As a result, the laser is time-insensitive and may attack from greater distances. Thus, this is a significant leap from the limited attack distance and imperceptibility of traditional methods, allowing for more practical and extensive adversarial attack scenarios.

In this work, we are trying to answer the following questions: *Is it possible to launch an adversarial attack on ASR with laser beams? And is the attack efficacy of laser adversarial perturbation superior to that of laser commands [10] in the presence of victim speech?*

Inspired by LightCommands [10], we propose `LaserAdv`, a method that leverages laser beams to inject adversarial perturbations into VCSs (Voice Control Systems), as shown in Fig. 1. Compared to LightCommands, `LaserAdv` effectively reduces the signal-to-noise ratio (SNR) required for successful attacks. This reduction in SNR has several notable benefits: 1) **Broader range of vulnerable devices:** Although microphones can detect laser signals due to the photoacoustic effect, not all devices have high sensitivity to these signals, resulting in lower SNRs. The reduction in SNR means that `LaserAdv` is applicable to a wider range of device types; 2) **Improved power efficiency and attack stealth:** Requiring a lower SNR not only reduces power consumption but also increases the stealthiness of the attack signals when the perturbation has been received; 3) **Longer attack range.**

Even though ASR can successfully recognize voice commands injected via lasers, the utilization of lasers to inject adversarial perturbation still faces serious challenges. ASR systems typically undergo pre-processing, such as noise reduction, which can inadvertently mitigate the effects of such perturbations. It is well known that audio adversarial perturbations are often carefully crafted and superimposed on normal voice commands, after being fed into the ASR, the perturbation will be treated as noise and filtered out.

Therefore, `LaserAdv` faces the following main challenges: First, unlike the noise and distortion introduced when converting sound, microphones, as transducers designed specifically for sound, exhibit complex and unknown system characteristics when converting lasers, leading to the introduction of various unknown signal distortions. Second, it is challenging to simultaneously achieve inaudible, targeted, universal (one perturbation works on more than 10,000 speech), synchronisation-free (up to 0.5 s), long-range (over 120 m), and black-box attacks (successfully tested on black-box models)in the physical world. We refer to adversarial perturbations with the above attack capabilities as an integrated adversarial perturbation (IAP).

To address these challenges, we first investigated the bandwidth requirements of ASR for adversarial examples. Following this, we utilized laser pulse signals and multi-frequency signals to excite the laser channel of the microphone, investigating the system response characteristics and possible introduced distortions. We found that the frequency response of the laser channel drops off sharply with increasing frequency. To meet the bandwidth requirements and mitigate the distortion induced by frequency selective fading (FSF), we proposed a method called selective amplitude enhancement based on time-frequency interconversion (SAE-TFI). This method allows selective control of the fading components.

In addition to the distortion caused by FSF, microphones are also relatively insensitive to lasers, resulting in a low amplitude in the captured signal. To solve this problem, we imposed device-dependent constraints on the adversarial perturbation during its generation, while ensuring low computational complexity. As the adversarial perturbation works together with victim speech rather than drowning it out, the need for high sensitivity to the laser is reduced, making it suitable for a wider range of devices. The effectiveness and range of the attack are also significantly improved.

Third, to implement IAP, we introduced strategies for asynchrony, and content independence in the objective function. In particular, to ensure attack effectiveness in black-box scenarios simultaneously, we proposed a method for extracting target command attributes and model attributes based on audio data with a similar distribution. We have effectively tackled all challenges and validated `LaserAdv` in realistic scenarios. In summary, our contributions can be summarized as follows:

- We present *LaserAdv*, an approach that injects adversarial perturbations into state-of-the-art ASR systems via laser beams.
- We conducted a comprehensive analysis of the system characteristics of the laser channel to identify various sources of signal distortion. Based on these findings, we propose an innovative selective amplitude enhancement method to address the distortion. Additionally, by introducing different strategies, we effectively generate IAPs.
- We evaluate `LaserAdv` on three ASR systems (DeepSpeech, Whisper, iFlytek) across 6 devices. Our results show that more than 10,000 voice commands can be compromised into the same targeted sentence with the addition of a single laser IAP in black-box settings. Furthermore, in the presence of victim speech, the maximum range of attack can be up to 120 m without using a telephoto lens.

2 Background

2.1 Traditional Audio Adversarial Perturbations

Previous researchers have made considerable efforts to ensure that adversarial perturbations are imperceptible to humans,

and these efforts can be categorized as follows: 1) Minimizing the value of adversarial perturbations δ [3]; 2) Acoustic masking: Using the psychoacoustic model [8] or human perception model [11] to constrain the amplitude of adversarial perturbations. 3) Environmental sound mimicking: Making the adversarial perturbations sound like environmental sound [5].

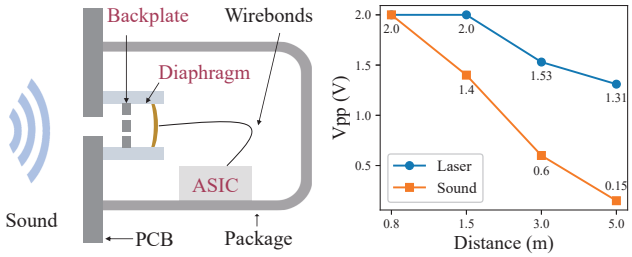
Minimizing the Value of δ. The basic idea of this type of method is to limit the perturbation to a relatively small range, so the optimization problem for creating an audio adversarial perturbation can be formulated as follows:

$$arg\min_{\delta} \mathcal{L}(f(x+\delta), y') + \varepsilon\|\delta\|_2 \tag{1}$$

where the target ASR system can be modeled as $f(\cdot)$, $\mathcal{L}(\cdot)$ is the loss function, x represents the original audio, δ is the generated adversarial perturbation, y' is the target transcription, and ε is the constraint hyperparameter used to limit the amplitude of the adversarial perturbation to increase concealment.

Acoustic Masking. In addition to simply using the L_p distance to limit the strength of the adversarial perturbation, some studies use the psychoacoustic principle of auditory masking to selectively introduce these perturbations into regions of the audio that are inconspicuous to the human ear [6]. The loss function can thus be formulated as follows:

$$\mathcal{L}(f(x+\delta), y') + \varepsilon \cdot L_\theta(x, \delta) \tag{2}$$



where L_θ constrains the normalized power spectral density (PSD) estimation of the perturbation to be under the frequency masking threshold of the original audio [8]. While the absolute amplitude of δ can be fine-tuned in alignment with the masking threshold, allowing larger δ values, the maximum value is still confined to a limited range.

Environmental Sound Mimicking. In order to make audio adversarial perturbations imperceptible to humans, another research effort has incorporated environmental sounds such as birds singing, car horns, and HVAC noise into the perturbations [5, 12]. This method ensures that the perturbations are sufficiently loud to maintain robustness in physical attack while remaining difficult for humans to detect. Given a chosen environmental sound template $\hat{\delta}$, the attack objective can be expressed as:

$$arg\min_{\delta} \mathcal{L}(f(x+\delta), y') + \theta \cdot dist(\delta, \hat{\delta}) \tag{3}$$

where $dist(\delta, \hat{\delta})$ denotes the distance between adversarial perturbation and the sound template according to a chosen distance metric, e.g., $L2$ distance [5], time-frequency pattern difference [12].

Although current adversarial perturbation attacks effectively minimize perceptibility by controlling or manipulating the magnitude of perturbation δ through various methods, the acoustic perturbations δ may still be audibly detectable under specific conditions, meanwhile, the attack distance is limited. Therefore, it is essential to investigate adversarial perturbations that are entirely inaudible and capable of facilitating long-range attacks.

(a) MEMS microphone (b) Attenuation characteristics

Figure 2: Structure of MEMS microphone and attenuation characteristics of sound and laser beam.

2.2 MEMS Microphone and Vulnerability

Due to their small size, robustness, high performance and low cost, MEMS microphones have become increasingly common in modern electronic devices, especially those with voice-based interaction capabilities such as smartphones, smart home devices and laptops. The structure of the MEMS microphone is shown in Fig. 2 (a). Nevertheless, the Light-Commands [10] attack confirmed the optical coupling phenomenon of the MEMS microphone, where changes in light intensity can generate an output voltage in the MEMS microphone. This makes it possible to inject signals from a distance, which presents both intriguing possibilities and worrying vulnerabilities. However, adversarial perturbation is more sensitive to distortion than voice commands, which introduces uncertainty when using the laser beam to carry the perturbation.

2.3 Attenuation Characteristics of Sound and Laser

Sound waves and laser beams exhibit unique attenuation characteristics as they propagate over a distance. In order to quantitatively analyze and compare the attenuation rate of sound and laser, we have carried out the following experiments. We initially set the distance between the signal sources (i.e. laser diode and loudspeaker) and the microphone at 0.5 m, carefully adjusting the drive power of both the laser and the loudspeaker to ensure that the signal strength received by the microphone remained constant at this distance. We then gradually increased the distance between the signal sources and the microphone at 1.2 m intervals, systematically recording

Table 1: Comparison of different bandwidths.

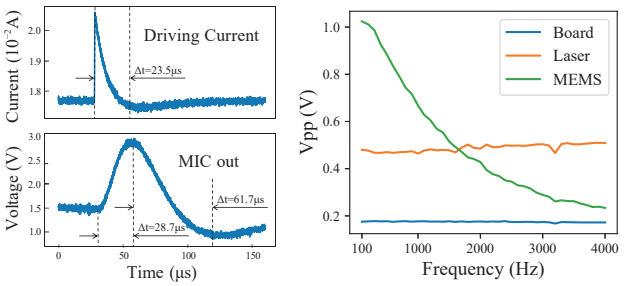
Frequencies	Numbers	Loss	Success Rate
0.1 - 0.6 kHz	21	8.65	-
0.1 - 0.8 kHz	323	0.70	96.90%
0.1 - 1 kHz	337	1.15	84.57%
0.1 - 2 kHz	377	0.35	99.73%
0.1 - 3 kHz	383	0.49	99.74%
0.1 - 4 kHz	382	0.11	99.74%

the received signal strength at each step. The maximum distance was set at 5 m.

The results are shown in Fig. 2 (b), we can observe that the attenuation of sound decreases rapidly as distance increases, while the attenuation of lasers is comparatively gradual. When the distance is expanded from 0.5 m to 5 m, the sound's intensity is reduced to 7% of its original value, whereas the laser's intensity is only reduced to 66.6% of its initial level. This difference, which is approximately an order of magnitude, clearly demonstrates the significant advantage of the laser for long-range attacks.

3 Feasibility Analysis

In this section, We provide a comprehensive analysis by considering both the bandwidth requirements of adversarial perturbations for effective ASR attacks and the two key characteristics of MEMS microphones: 1) the system response to the laser, and 2) the distortion of the signal within the laser channel. These factors provide insight into the practical challenges and potential opportunities for using lasers in audio adversarial attacks.



3.1 Bandwidth Requirements

Careful selection and tuning of the bandwidth are essential to the effectiveness of the attack, allowing the perturbations to exploit weaknesses in the ASR system's processing of audio signals. We generated adversarial perturbations by configuring different bandwidths and tested the attack performance on different ASRs.

As shown in Tab. 1, with the broadening of the frequency band, the number of generated perturbations increases and the loss decreases, and the success rate also increases gradually. Therefore, in order to successfully capture the wideband signal that is essential for carrying out black-box attacks in physical scenarios, it is better to have a high and flat frequency response in both the low (100 Hz) and high (4 kHz) frequency ranges.

3.2 Responses Characteristic of MIC to Laser

To investigate the feasibility of laser adversarial perturbations, we conducted a series of experiments to comprehensively

(a) Impulse response (b) Frequency response

Figure 3: The system response of MEMS microphone to laser beams.

analyze the system responses of microphones to laser beams, focusing specifically on both impulse response and frequency response aspects.

Impulse Response. The impulse response describes the time domain characteristics, a microphone with a good impulse response can accurately and faithfully transmit and convert complex signals and sudden changes, resulting in high-fidelity signal reproduction. Since it is impossible to produce a perfect impulse signal with physical equipment, we have developed a driving current of laser diodes that resembles an impulse by changing the frequency and using different types of waveforms, as shown in Fig. 3 (a) (Top). This waveform takes about 23.5 us to return to its initial state compared to an ideal pulse. The impulse response of the microphone, shown in Fig. 3 (a) (Bottom), although the input signal is instantaneous, the microphone takes approximately 28.7 us to respond and approximately 61.7 us to return to its initial state. For common applications such as general recording and speech recognition, an impulse response time within a few milliseconds is usually acceptable. The impulse response to the laser is therefore good.

Frequency Response. To analyze the frequency response to laser, we systematically generated single-tone sinusoidal signals (denoted s) within a frequency range of 100 Hz to 4 kHz, with a 200 Hz interval between successive frequencies. This signal is simultaneously input into two identical laser driving devices, designated as Device 1 and Device 2, for modulation. We record the output l_{out} from laser driving Device 1 using a data acquisition card, while Device 2 directly drives a laser diode. The emitted laser is then injected into a MEMS microphone positioned 50 cm away, with the recorded sound denoted as m_{out}. In addition to using the MEMS microphone to receive the laser signal, we also employ a photodetector (THORLABS APD430A2) to detect the laser's intensity, represented as p_{out}.

The frequency response curves of these three devices are shown in Fig. 3 (b). The curves corresponding to the laser drivers and photodiodes are relatively smooth, whereas the

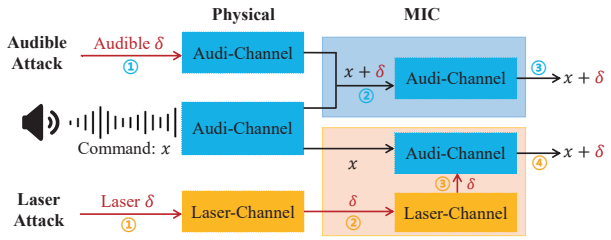


Figure 4: The transformation process of an adversarial perturbation δ in audible and laser channels. The audible and laser channels involve both the physical space and the microphone circuit.

frequency response of the microphone shows a pronounced drop with increasing frequency, from 1.02 V at 100 Hz to 0.2 V at 4 kHz. This result indicates that it's a FSF channel for laser signals, resulting in significant signal distortion. Such a characteristic limits the effectiveness of laser perturbation, especially given the stringent bandwidth requirements. Therefore, we have developed a specific method to effectively combat the FSF channel in the design section.

3.3 Distortion within Laser Channels

Theoretical Analysis. To gain a deeper understanding and facilitate a comparison of signal transformation and distortion in both the audible and laser channels, we first conduct a theoretical analysis combining the above results. As depicted in Fig. 4, given an audible adversarial perturbation $\delta(t)$ and voice command $x(t)$, the recorded signal $x'(t)$ can be expressed as $x(t)+\delta(t)$, ignoring the electrical and ambient noise present in the physical and electrical system. Nonetheless, in real-world scenarios, various noises are introduced, ultimately resulting in the received signal being represented as:

$$x'(t) = H_a(x(t)+\delta(t)) + n_a(t) \tag{4}$$

Here $n_a(t)$ represents the noise in the audible channel, e.g., ambient and electrical noise. $H_a(\cdot)$ is the transfer function of the audible channel.

At the same time, the transformation of the laser perturbation is shown in Fig. 4. Unlike audible perturbation, laser perturbation is transmitted through the laser channel within the physical and electrical systems. Given an laser adversarial perturbation δ and a voice command $x(t)$, the received signal can be expressed as:

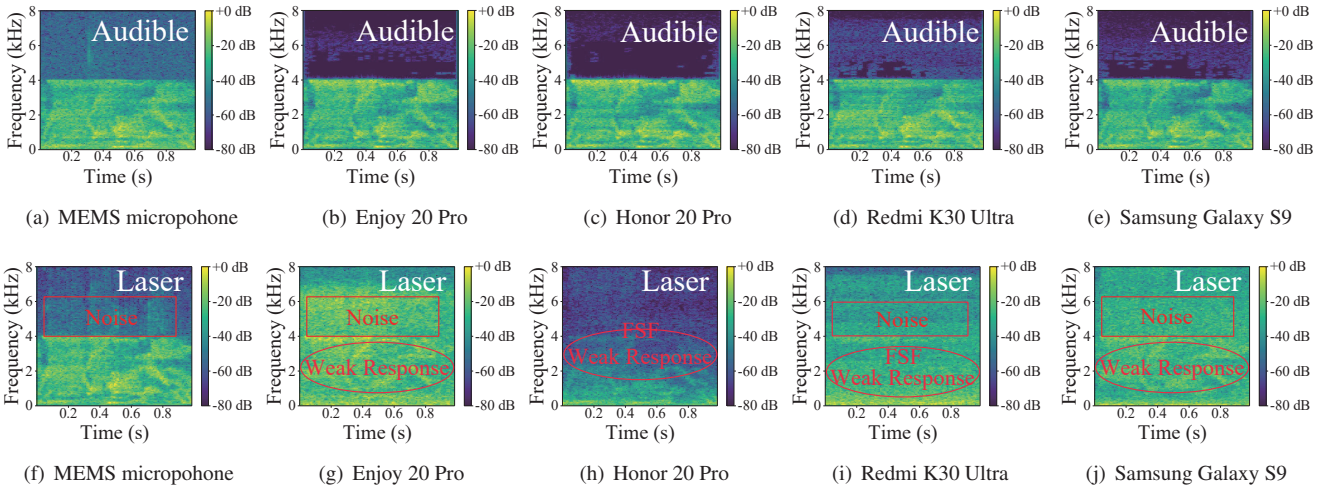
$$x'(t) = H_a(x(t)) + H_u(\delta(t)) + n_a(t) + n_u(t) \tag{5}$$

where $n_u(t)$ denotes the noise within the laser channel. $H_u(\cdot)$ is the transfer function of the laser channel, which leads to other types of signal distortion caused by factors such as FSF and weak response. Consequently, the overall signal distortion is aggravated compared to audible perturbations, owing to the inherent characteristics of the laser channel.

Evaluation. To investigate the distortion characteristics of both audible and laser channels, and analyze the feasibility of `LaserAdv`, we first generate an audio adversarial perturbation with a bandwidth ranging from 100 Hz to 4 kHz. We then play and record perturbation using a loudspeaker and five devices, including a MEMS microphone and four smartphones, designated as Enjoy 20 Pro, Honor 20 Pro, Redmi K30 Ultra, and Samsung Galaxy S9.

To obtain the laser perturbations, we fed the perturbation into the laser driver for modulation, subsequently using it to drive the laser diode. The emitted laser was then injected into the five devices. Fig. 5 illustrates the recorded perturbation of the five devices. The top five images from (a) to (e) display the recorded acoustic perturbations with very subtle distortions, while the bottom five images from (f) to (j) reveal the recorded laser perturbations. Each of these images exhibits two to three types of distortions: 1) the introduction of additional noise; 2) weak response, resulting in a low SNR; and 3) distortion caused by FSF. In subsequent designs, we will propose corresponding methods to address the distinct distortion.

These findings provide a nuanced insight into how to carefully design the adversarial perturbations to address the specific types of distortion encountered.



3.4 Threat Model

Attack Goal. The adversary's objective is to manipulate the output of the target's black-box ASR system from a distance of ten metres. This is achieved by introducing an laser adversarial perturbation that is unrelated to the content or timing of the victim's speech. Unlike the approach used in DolphinAttack [42] and LightCommands [10], `LaserAdv` assumes that the victim is speaking any voice commands at the time of the attack. In summary, the adversary must simultaneously fulfil the following conditions:

- *Synchronization-free*. In `LaserAdv`, synchronisation-free describes scenarios where adversarial perturbations, although delayed by up to 0.5 seconds, can still affect the first 0.5 seconds of voice commands. This indicates that the perturbations do not require precise synchronisation with the voice commands to be effective.

- *Transferability*. This refers to the adversarial perturbations generated for the white-box ASR system DeepSpeech, which can be utilized to attack black-box systems such as iFlytek and Whisper.

- *Universal*. It refers to the ability of a perturbation to effectively interfere with over 10,000 user's voice commands. Note that we do not use the term *Generalizability* to illustrate the `LaserAdv` attack.

Figure 5: Recorded acoustic adversarial examples (top) and laser-based adversarial examples (bottom) with 5 different devices.

- *Inaudible and targeted.*

Assumption on Attacker's Knowledge. We have designed our threat model to reflect a realistic scenario where an attacker with limited resources, only has detailed knowledge of one ASR system - DeepSpeech. The other two systems are state-of-the-art commercial and black-box ASR systems (Whisper and iFlytek) about which we have no detailed internal knowledge. Our study aims to demonstrate the potential transferability of the attack across different systems. Therefore, specific knowledge of these systems is not required to validate the effectiveness of our approach. The adversary has no knowledge of the content and timing of the victim's voice commands.

Adversary's Capability. `LaserAdv` assumes that laser perturbations are emitted when the victim is actively speaking. Since the adversarial perturbations are transmitted via laser rather than conventional audio, it is assumed that the adversary is equipped with the necessary equipment that can modulate and transmit laser beams. The total price for the laser driver, the laser diode and the battery are less than $20. Similar to other long-range attacks, the lack of visual or auditory feedback from the target device prevents the attacker from promptly determining the success of the attack. Typically, multiple attempts will be made to ensure the attack achieves its intended results. When LaserAdv achieves universal, the perturbations do not require synchronization with the spoken words. This capability allows the system to effectively manipulate voice commands regardless of their timing or content.

Assumption on the Victim's device. Since certain commands can only be executed on an unlocked device, in this case, we assume that the smart device is unlocked. For other commands, the device may be either locked or unlocked. As the smart device is already awakened during the interaction with the victim, we do not need to assume whether the device is specifically trained to recognize the speaker's voice.

4 `LaserAdv` Design

4.1 Basic Problem Formulation

In prior research, the basic optimization problem formulation should consider the perturbation to be imperceptible to humans. Consequently, strict constraints on the perturbation were necessary. The constraints limit the feasible space of solutions, making it more challenging for optimization algorithms to find the optimal solution. This may result in slower convergence, increased complexity, greater computational resource demands, etc.

In our study, we aim to find an adversarial perturbation δ that meets the condition $f(x+\delta) = y'$. Unlike previous methods, the adversarial perturbation δ is not subject to strict constraints for imperceptibility. Thus, the basic optimization problem can be expressed as follows:

$$\arg\min_{\delta} \ \mathcal{L}(f(x+\delta), y') \tag{6}$$

where $\mathcal{L}(\cdot)$ refers to the loss function of a white-box system, which in our work is DeepSpeech. Due to the lack of constraints on δ, solving the above optimization problem becomes much simpler and faster.

4.2 Transferability in Black-box ASRs

Transferability, while advantageous for an attacker, poses several challenges in crafting successful adversarial perturbation. Transferability arises from the observation that different ASR models, despite their unique structures and parameters, often capture similar high-level features for targeted voice commands. This consistency not only leads to identical results for similar speech inputs but also creates uniform vulnerabilities across models. Based on this, we considered a wide range

of other voice commands when generating perturbations for target commands. The dataset contains various elements of speech, including different volumes, accents, speech rates, background noise and more. As a result, the generated perturbations, when combined with any other voice command, have high-dimensional features similar to those of the target command. This makes them potentially effective for attacking models with different architectural parameters. During the perturbation generation process, we sampled audio inputs from this assembled dataset. Thus, the optimization problem can be expressed as follows:

$$\arg\min_{\delta} \mathop{\mathbb{E}}_{x\sim\mathcal{S}} \mathcal{L}(f(x+\delta), y') \tag{7}$$

where $\mathcal{S}$ represents the similar distribution of the audio inputs, and x is randomly sampled from $\mathcal{S}$.

4.3 Time and Content Independent

In realistic scenarios, the laser adversarial perturbation $\delta \in \mathbb{Q}^{1\times M}$ should be insensitive to both the relative position within the victim speech and the actual content of the victim speech $x \in \mathbb{Q}^{1\times N}$, where M, N are the length of δ and x.

In the process of perturbation generation, we randomly choose a time delay τ uniformly within the range from 0 to $N-M$ to compute the gradient at each iteration, thus the objective function Eq. 8 can be expressed as follows:

$$\arg\min_{\delta} \mathop{\mathbb{E}}_{x\sim\mathcal{S},\tau\sim\mathcal{T}} \mathcal{L}(f(x+\delta(t-\tau)), y') \tag{8}$$

Let $\mathcal{T} = \{kd \mid k \in \mathbb{N}, 0 \le k \le \frac{M}{d}\}$, where d is the number of sample points.

In `LaserAdv`, the value of d can be set to greater than 20, thereby reducing the number of iterations compared with previous work [5], where d is set to 1 sample point. That is because the laser perturbation is more position-insensitive and robust due to no strictly constrained amplitude. To validate this, we use Eq. 1 and Eq. 6 to generate two different adversarial perturbations, denoted δ_1 and δ_2. It takes approximately 1000 iterations to generate an effective δ_1, whereas only 200 iterations are needed for δ_2. The results show that the final successful attack delay ranges for δ_1 and δ_2 are $0-10$ and $0-50$ respectively. The number of iterations required to reach convergence directly correlates with the algorithm's complexity. Therefore, when using different objective functions to generate two distinct δ, the iteration count provides insight into which algorithm is more efficient. This is critical for practical applications where computational resources and time are constrained. In `LaserAdv`, the value of d can be set to 20 or even higher. This approach leads to quicker convergence of the objective function with fewer iterations while maintaining effectiveness.

To make the adversarial perturbation universal, the optimization problem should consider the generalization of the perturbation across a wide range of audio inputs. To achieve this goal, we propose the following optimization problem based on Eq. 8:

$$\arg\min_{\delta} \mathop{\mathbb{E}}_{\tau\sim\mathcal{T},\, x\sim\{\mathcal{S},\mathcal{D}\}} \mathcal{L}(f(x\cdot i+\delta(t-\tau)), y') \tag{9}$$

where $\mathcal{D}$ represents the distribution of the audio inputs x, Parameter i, which is adjusted between 0.1 and 1, is specifically designed to normalize and adjust the volume of audio inputs within the dataset. This adjustment not only enhances the efficiency of our perturbation generation but also helps prevent non-convergence issues during the optimization process.

4.4 Physical Adversarial Perturbation

According to the preliminary analysis, there are two kinds of distortion that should be carefully considered and addressed in `LaserAdv`.

Dealing with Low Sensitivity. Reviewing the aforementioned results of the feasibility analysis, we can see that some devices with MEMS microphones are insensitive to lasers and receive only a low intensity of laser-induced adversarial perturbations. However, the intensity of the adversarial perturbation is a critical factor in the success of the attack. As the intensity of the perturbation decreases, so does the success rate of the attack. Therefore, to address the issue of reduced intensity due to the limited gain of microphones, we impose certain constraints on the amplitude of the perturbation within our optimization problem. The parameter b is determined by the device's frequency response. When the frequency response is low, b is set to a smaller value, ensuring that even minimal perturbations remain effective. Consequently, successful attacks can be achieved even when the device receives only small amplitude perturbations. Furthermore, by setting a lower bound a on the perturbation, we avoid overly stringent constraints that could hinder the generation process. In `LaserAdv`, The values for a and b are based on experience and the frequency response of the equipment.

Dealing with FSF Channel. FSF causes wide-bandwidth perturbation to be attenuated unevenly across the spectrum after passing through the laser channel. Specifically, the high-frequency components experience much greater attenuation than the low-frequency components. This distinctive distortion phenomenon stands apart from distortions caused by ambient noise or low sensitivity, making it impervious to remedies such as the introduction of random noise or similar measures.

In `LaserAdv`, we propose a Selective Amplitude Enhancement method based on Time-Frequency Interconversion (SAE-TFI) aimed at compensating for the attenuation of

high-frequency components. To begin, we apply Short Time Fourier Transform (STFT) to the generated perturbation δ to convert it from the time domain to the frequency domain, which can be expressed as:

$$S(\delta) = STFT\{\delta(t)\}(\tau,\omega) = \int_{-\infty}^{\infty} \delta(t)h(t-\tau)e^{-j\omega t}dt \quad (10)$$

where $h(\cdot)$ is the Hann window function, and $\delta(t)$ is the converted perturbation signal. $S(\delta)$ is the complex spectrum of δ after applying STFT. $S(\delta)$ corresponds to a complex value at each time t and each frequency f. Next, we use Eq. 11 to obtain the amplitude spectrum and phase spectrum of the perturbation δ:

$$\begin{aligned} Amp &= abs(S(\delta)) \\ Phase &= angle(S(\delta)) \end{aligned} \quad (11)$$

where $abs(\cdot)$ means taking the absolute value of a complex number, $angle(a+bj) = arctan(\frac{b}{a})$. In order to recover the missing high-frequency components as much as possible, we perform linear enhancement on the amplitude spectrum using Eq. 12:

$$\hat{Amp} = \begin{cases} coef \cdot Amp, & if\ f > cut\_off, \\ Amp, & otherwise \end{cases} \quad (12)$$

where $coef$ is the coefficient representing the enhancement ratio, and cut_off represents the cut-off frequency. Although the linear method cannot completely reverse the unique distortion, it can effectively alleviate the high-frequency loss caused by FSF to a certain extent.

Finally, the inverse short-time Fourier transform (iSTFT) process is applied to obtain the enhanced time domain perturbation signal, and the formula is as follows:

$$\hat{\delta} = iSTFT\{\hat{Amp} \cdot e^{j \cdot Phase}\} \quad (13)$$

where $\hat{\delta}$ is the enhanced perturbation signal, and the function of iSTFT is to transform the specified complex spectrum into a time domain signal.

After thoroughly considering the other various distortion factors (i.e., ambient noise, etc.), we formulate our optimization problem as follows:

$$\arg\min_{\delta} \mathop{\mathbb{E}}_{\tau\sim\mathcal{T},\ x\sim\{\mathcal{S},\mathcal{D}\},\ h\sim\{H_1,H_2\}} \mathcal{L}(f(x\cdot i+\delta'), y') \quad (14)$$

$$\text{subject to} \quad a \le \delta' \le b$$

where, $\delta' = h \otimes F(\delta(t-\tau)) + n$, a and b are parameters restricting the amplitude of the perturbation δ', h is the room impulse response (RIR) sampled from the collected distribution H_1 and H_2 in the audible channel and laser channel respectively. n denotes the Gaussian white noise, and $F(\cdot)$ represents the band-pass filter. The RIR of H_1 is chosen from the Database [13]. To obtain the impulse responses of the laser channel, we play and record the impulse using a laser diode and microphone. These noise components effectively simulate the complexity of the laser channel state, also indicating the necessity of considering these complexities in the design and implementation of `LaserAdv`.

After solving Eq. 14, we obtain an adversarial perturbation within the bandwidth of 100 Hz to 4 kHz. By applying the SAE-TFI method, we are able to create adversarial perturbations taking into account all the factors involved.

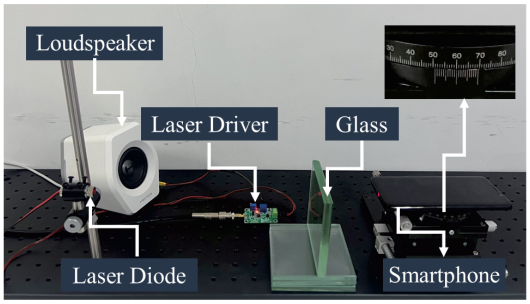

Figure 6: Illustration of the experimental setup.

5 Evaluation

5.1 Experiment Settings

Prototype. We implement `LaserAdv` using the TensorFlow framework on a server running Ubuntu 16.04 with an NVIDIA Tesla V100-16GB GPU. The default configuration is set as follows: $d = 20$, the maximum number of iterations is 2,000, and the frequency range of the band-pass filter $F(\cdot)$ is set to 100 Hz - 4 kHz. The maximum time delay τ between x and δ is set to 1.2 seconds. The target ASR models for our experiments are DeepSpeech, iFlytek, and Whisper. To modulate and emit the laser adversarial perturbations, We utilize a 5mW red laser diode with a wavelength of 650 nanometers, directing the beam vertically towards the smartphone's microphone. Simultaneously, we position a loudspeaker adjacent to the microphone to play voice commands during the attack, as shown in Fig. 6. Notably, we employ a telescope to obtain long-distance line of sight, precisely aiming the laser at the microphone's aperture for launching long-distance attacks.

Evaluation Metrics. We use the following metric to quantify the performance of `LaserAdv`.

Attack success rate. The success rate measures the proportion of adversarial perturbations that successfully cause the target ASR system to misclassify the perturbed audio signal. A higher success rate indicates a more effective adversarial

attack. Note that a successful attack is only achieved if the output of the ASR matches the target sentence perfectly. In other words, partial recognition of the command is insufficient for success.

Dataset. *Impulse Response.* We use 10 audible impulse responses randomly selected from database [13] and 30 laser impulse responses recorded by ourself.

Voice commands. In our experiments, by leveraging Google's text-to-speech service [15], we generate a diverse and high-quality dataset of voice commands covering various phrases, which we consider to be the original voice commands denoted as x.

5.2 Overall Performance

In this section, we present a detailed evaluation of the performance of laser adversarial perturbations, and the results are shown in Tab. 2. We first applied the perturbation to a subset of 12,260 voice commands from our dataset to evaluate the effectiveness in a digital scenario. The evaluation was performed under two different conditions: one with no delay and the other with a delay of 0.5 seconds imposed on the perturbation. Interestingly, our results showed that the success rate of the attack remained consistently high under both delay conditions for all three different ASR models tested (namely DeepSpeech, iFlytek and Whisper). Specifically, we observed an attack success rate of over 98% for all models, reaching a full 100% for DeepSpeech without delay.

In the physical scenario, we randomly selected a subset of 20 audio samples previously identified as vulnerable in the digital scenario. These experiments were conducted using a smartphone to record the adversarial perturbations. For each original voice command, we performed 50 attack attempts. We can see that DeepSpeech was the most vulnerable to the `LaserAdv` attack. A 100% success rate was consistently achieved across multiple voice commands. In contrast, the iFlytek model was the most resistant; in particular, when the delay was set to 0.5 seconds, the attack success rate dropped to 75%. Nevertheless, our adversarial perturbation scheme demonstrates a robust, synchronisation-free black-box attack capability in a physical environment.

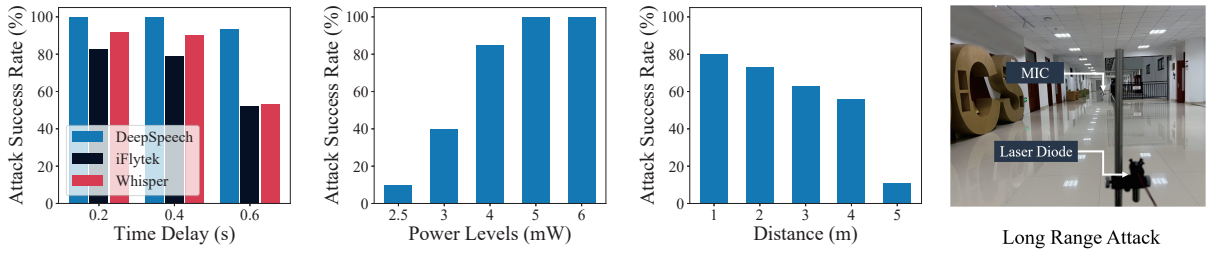

Table 3: Attack success rate under different perturbation durations (60 experiments per length).

Lengths	30%	40%	50%	60%	70%	80%	90%
Success rate	82%	100%	100%	100%	100%	100%	100%

5.3 Impact of Perturbation Duration

In order to evaluate the effect of perturbation duration on the attack success rate of `LaserAdv`, we conducted an experimental analysis where the length of the adversarial perturbation was varied over a wide range, specifically 30%, 40%, 50%, 60%, 70%, 80% and 90% of the voice command duration. For each predetermined duration, a series of 60 different attack attempts were made against the ASR system.

The results of these trials are systematically presented in Tab. 3. The results show that when the duration of the adversarial perturbation exceeds 40% of the total length of the voice command, `LaserAdv` is able to achieve an impeccable attack success rate of 100%. Notably, even when the perturbation is limited to only 30% of the voice command, `LaserAdv` still achieves a substantial success rate of 82%. These results show that `LaserAdv` demonstrates robust performance even when the perturbation is relatively short. Therefore, the perturbation can be successful even when it lags behind the normal voice command, thereby reducing the time sensitivity.

(a) The impact of time delay. (b) The impact of varying laser power levels. (c) The impact of distance between laser diode and smartphone. (d) The diagram of long-range attack scenario.

Figure 7: Illustration of the performance of LaserAdv and a long-range attack.

Table 4: Comparison of long-range attack performance.

Attack range	LaserAdv	LightCommands
20 m	100%	50%
40 m	100%	25%
60 m	95%	15%
80 m	80%	5%
100 m	65%	-
120 m	15%	-

5.4 Impact of Time Delay

Tab. 2 shows the attack performance of LaserAdv when there is no delay and the delay is 0.5 seconds. In this section, to further explore the impact of time delay of the perturbation, we lagged the perturbation relative to the user's speech by 0.2 seconds, 0.4 seconds, and 0.6 seconds respectively, and observe the results.

As shown in Fig. 7 (a), as the delay increases, the success rate of the attack on all three ASRs decreases. Notably, DeepSpeech exhibits the lowest level of robustness. Even with a delay of 0.6 seconds, its attack success rate remains above 90%. Meanwhile, iFlytek and Whisper experience significant drops but still achieve success rates of over 50%. This result highlights the impressive capability of LaserAdv attack to attain asynchrony of the adversarial perturbation.

5.5 Impact of Varying Laser Power Levels

In this section, we aim to explore the power requirements essential for effectively conducting the LaserAdv attack. we employ a laser power meter [44] to measure the maximum power at 6 mW. During the experiments, we adjusted the voltage of the laser driver board to incrementally increase the laser power from zero to the maximum, and then evaluate the performance of the attack.

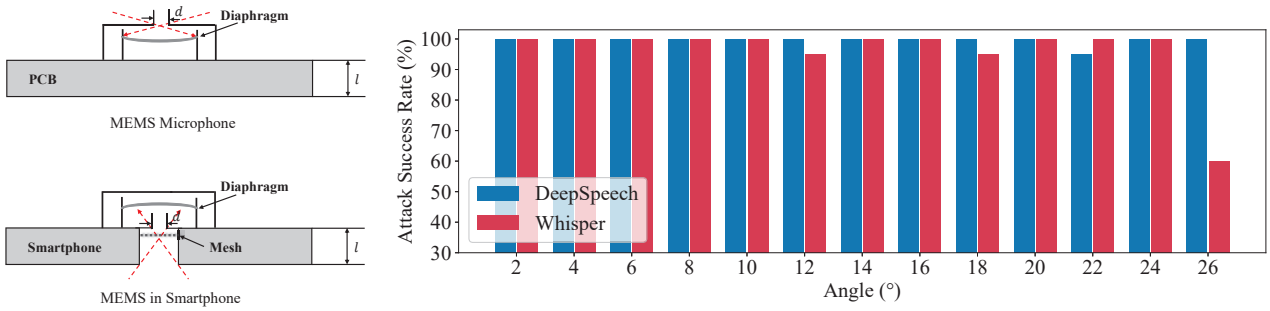

Fig. 7 (b) illustrates the success rate of the attack across varying driving laser power levels. When the power is 2.5 mW, the attack becomes effective and the success rate is only 10%. As the power gradually increases, so does the success rate. Notably, upon reaching the rated power of the laser diode at 5mW, a 100% success rate can be achieved. Consequently, in our experimental setups, we typically maintain the laser diode power within the range of 5 mW to 6 mW to ensure optimal performance for LaserAdv attack.

5.6 Impact of Distance

In this section, we aim to explore the attack performance of LaserAdv as the attack distance increases. We evaluated the performance of close-range attacks using Honor 20 Pro smartphone as a receiver. We then used a MEMS microphone to test the maximum attack distance. This two-step approach allows us to evaluate the performance of the attack under different conditions. As the sound inlet of MEMS chip is larger than that of the microphone in the smartphone, and there is no grille, the attack distance is greater for the MEMS microphone.

Fig. 7 (c) shows the performance of LaserAdv on the mobile phone as the distance varies. At a distance of 1 m, the attack achieves a success rate of 80%. As the distance increases, the success rate decreases. At a distance of 5 m, the success rate drops to only 11%. This phenomenon is attributed to the expansion of the laser diode's light spot as the distance increases. As a result, the laser light diverges, making it difficult to accurately target the small microphone hole with the higher-intensity laser.

We conducted a long-range attack in a wide corridor where the laser diode was significantly far from the MEMS microphone, as illustrated in Fig. 7 (d). The total length of the corridor is 120 m. The audible voice commands were continuously played at a volume of 55 - 65 dB. We conduct experiments at intervals of every 20 m, from 20 m to 120 m, and control the intensity of perturbations and voice commands equally, to compare the attack performance of LaserAdv and LightCommands. We performed 20 attack attempts at each distance and calculated the average attack success rate. Tab. 4 reveals a clear trend: as the distance increases, the attack success rate decreases. LightCommands achieve a 50% success rate at 20 m, dropping to just 5% at 80 m, and becoming ineffective beyond that range. In contrast, LaserAdv boasts a remarkable

(a) Area susceptible to laser illumination.

(b) The impact of angles.

Figure 8: Acoustic port of microphone in smartphone and MEMS microphone, and the impact of angles.

Table 5: Attack success rate under different environmental illumination conditions.

Illumination Conditions	Luminance	Success Rate
Curtains closed	38 lx	100%
Lights off	240 lx	100%
Lights on	460 lx	100%
Sunlight	2100 lx	100%

performance with a success rate exceeding 95% within 60 m, 80% at 80 m, and the ability to extend up to 120 m. Notably, LightCommands demonstrates an attack range of up to 110 m. However, it is dependent on a telephoto lens, and rather than modifying the victim's speech into a target command, it utilizes a laser to directly inject voice commands.

5.7 Impact of Environmental Illumination Conditions

To investigate the influence of environmental illumination conditions on `LaserAdv` attack, we designed four experimental conditions, i.e., curtains closed, lights off, lights on and sunlight. Using a luminous flux meter, we measured the light flux to be 38 lx, 240 lx, 460 lx, and 2,100 lx respectively. Then we conducted attacks under each condition to evaluate the performance of the attack.

The results are presented in Tab. 5, demonstrating that the `LaserAdv` attack attains a 100% success rate under various lighting conditions. This is attributed to the compact size of the smartphones' microphone hole, preventing ambient light from penetrating it and consequently, not impacting the efficacy of the `LaserAdv` attack.

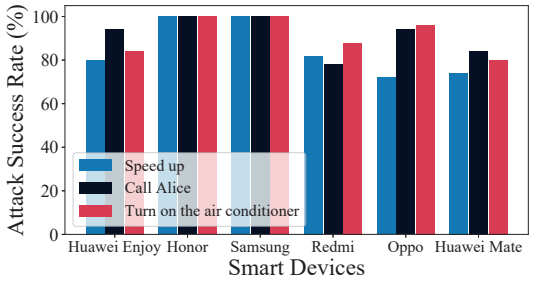
5.8 Impact of Angles

In this section, we will explore the effect of angles on the success rate of `LaserAdv` attack in real-world scenarios. In practical situations, it may not always be possible for laser to hit the microphone diaphragm directly. Therefore, understanding the performance of the attack from different angles is crucial to fully assess its effectiveness. There are significant differences between the microphone on a smartphone and a standalone microphone chip when exposed to laser at different angles. The smartphone microphone is embedded in the phone, so the laser has to pass through the pre-set sound holes of the device before reaching the microphone port, as shown in Fig. 8 (a). In addition, a protective grill or mesh is usually placed in front of the microphone to protect it from dust. In contrast, with a stand-alone microphone chip, the laser only has to pass through its own port. As a result, its response to laser at different angles can be very different.

In our experiments, we chose the MEMS microphone to evaluate the influence of angles. We maintained a fixed position for the laser diode, and controlled the angle of the laser to deviate from the microphone hole by adjusting the knob on the turntable. From the observations in Fig. 8 (b), we noticed that the angle was adjusted up to a maximum of 26 degrees. Surprisingly, the success rate of the attack did not decrease significantly as the angle increased on DeepSpeech. However, the success rate dropped to 60% on Whisper, that is because as the angle increases, the signal strength received diminishes, leading to a reduction in the signal-to-noise ratio (SNR). This drop in SNR is likely responsible for the decreased accuracy of attacks on Whisper. For DeepSpeech, the perturbation was specifically tailored for this system, which explains why the attack accuracy remains comparatively high despite the angle changes. Overall, these results demonstrate the remarkable effectiveness of the `LaserAdv` attack in realistic attack scenarios where the alignment between the laser beam and the microphone hole may not be perfect.

5.9 Impact of Different Smart Devices

To validate the efficacy of the `LaserAdv` attack on different smart devices, we employed 6 smartphones for experiments, including Huawei Enjoy 20 Pro and Mate 60 Pro, Honor 20 Pro, Samsung Galaxy S9, Redmi K30 Ultra and Oppo Reno 9. The attacks employ a universal perturbation with the target



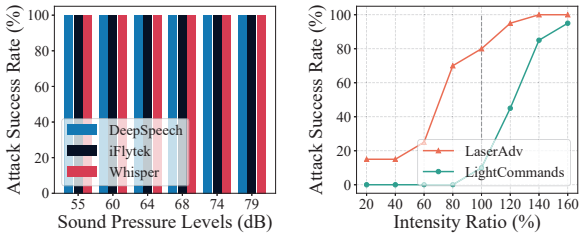


Figure 9: The impact of different smart devices.

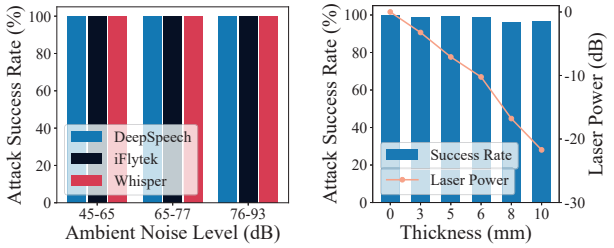
(a) The impact of SPLs of the voice commands.

(b) The impact of different loudness of perturbation or Malicious Commands.

Figure 10: The impact of different SPLs of the voice commands and loudness of perturbation.



phrase being "Hi", and three voice commands are randomly chosen for each device: "Speed up", "Call Alice" and "Turn on the air conditioner". Subsequently, we performed 50 attack attempts for each voice command to comprehensively assess its success rate.

Fig. 9 illustrates the attack performance on different smart devices. It is evident that the attack on Honor 20 Pro and Samsung Galaxy S9 yields the most favourable results, with a remarkable 100% attack success rate. On the other hand, the attack performance on other 4 smartphones is comparatively lower, though still significant, with a success rate exceeding 72%. The observed variations in attack performance can be attributed to the use of different microphones in each device, naturally leading to distinct results. Nevertheless, these results collectively validate the effectiveness of the `LaserAdv` attack.

5.10 Impact of SPLs of the Voice Commands

The variation in sound pressure levels (SPLs) of voice commands is an important factor in the effectiveness of laser perturbations. To investigate the effect of sound intensity on the performance of `LaserAdv` attack, we conducted an experiment in a typical meeting room with ambient noise of about 40 dB. We played voice commands at a range of 55 dB to 79 dB during the attack on the MEMS microphone.

As shown in Fig. 10 (a), it is interesting to note that despite the escalating SPLs, the success rate of the `LaserAdv` attack remains consistently 100% on all three ASR models tested.

(a) The impact of different ambient noise.

(b) The impact of different thicknesses.

Figure 11: The impact of different scenarios including office, restaurant and street, and thickness.

This result underlines the high effectiveness and robustness of the `LaserAdv` attack in the face of fluctuating acoustic intensities. Remarkably, even in scenarios where the target is speaking at a high volume, the attack continues to demonstrate a high success rate. This effectively undermines the ASR system's defences and leads to significant misinterpretations.

5.11 Impact of Loudness of Perturbations or Malicious Commands

We further investigate the attack performance changes due to different loudness of the perturbations in `LaserAdv` or malicious voice commands in LightCommands. We positioned a loudspeaker 50 cm away from the MEMS microphone to deliver the user speech, measuring the sound intensity within the range of 70 - 80 dB using a sound meter. Subsequently, we adjust the laser emission intensity to correspond with its intensity, varying from 20% to 160%, to observe the attack results.

As shown in Fig. 10 (b), at an intensity ratio of 20%, `LaserAdv` can attack successfully, despite with a relatively low success rate. As the intensity increases, the attack success rate gradually improves. When the laser intensity matches the user's speech intensity, `LaserAdv` achieves a success rate of 80%, while LightCommands is just successful under this condition. With increasing intensity, the success rate can be up to 100%. Our experiments confirm that `LaserAdv` requires substantially lower perturbation intensity compared to LightCommands. Consequently, it can achieve a broader attack range, and devices with lower laser response can also be attacked.

5.12 Impact of Different Ambient Noise

To assess the effect of varying ambient noise levels on the effectiveness of the `LaserAdv` attack, we set up an experiment in our office where pre-recorded ambient noise was played at various SPLs. In all of these experiments, the loudspeaker producing the ambient noise was located 50 cm from the

target device. A sound meter placed near the target device was used to measure the SPLs of the ambient noise.

The results are shown in Fig. 11 (a). As the noise level increases, the success rate of the attack remains at 100%. This indicates that the LaserAdv attack is unaffected when the noise level is below 90 dB, ensuring the effectiveness of the attack even in high noise conditions.

5.13 Attack through Transparent Glass

Real-world attack scenarios may involve long-range attacks where the attacker and the victim's smart device are not in the same room. These attacks can be carried out over obstacles such as windows and transparent glass on doors. We therefore positioned glass of different thicknesses between the laser emitter and the targeted mobile phone to conduct experiments. This setup allows us to thoroughly investigate LaserAdv's ability to penetrate the glass barrier.

Fig. 11 (b) shows the success rate of the LaserAdv attack through the glass of different thicknesses, demonstrating the remarkable ability of the laser to penetrate. First, the intensity of the laser beam decreases slightly after passing through the glass. The success rate of the attack is 100% when there is no glass, and as the thickness of the glass increases, the success rate remains above 98%. Thus, the thickness of the glass has no significant effect on the success rate of the attack. These results have significant implications for LaserAdv attacks in physical scenarios.

6 Defense and Discussion

In this section, we discuss potential defense strategies against LaserAdv and some of its limitations.

6.1 Defense

In previous studies, adversarial perturbations have been shown to be vulnerable to certain audio processing methods, such as local smoothing [16, 17], audio squeezing [4, 16, 18], compression [5, 19], and audio down-sampling [4, 17]. However, laser adversarial perturbations are not strictly amplitude-limited and exhibit robustness against distortion. Consequently, these methods might not be as effective against laser adversarial perturbations.

Another approach [17, 20–23] is to employ adversarial training, where the ASR model is trained with adversarial examples to enhance its robustness against adversarial attacks. However, it may still exhibit certain limitations when countering specific adversarial attacks or adaptive adversaries that continuously alter their attack strategies.

Inspired by EarArray [27], compared to acoustic perturbation, only one microphone can capture the laser beam. This property can be exploited to detect laser adversarial perturbations using two or more microphones. By analyzing the differences in the received signals across multiple microphones, it is possible to distinguish between genuine audible signals and laser adversarial perturbations. This approach could provide a practical defense mechanism against laser adversarial attacks, thereby enhancing the security and robustness of ASR systems against such threats.

We respectively captured the user's voice commands and injected either one or two beams of laser perturbations into the smartphone's microphone to create datasets. We first extract the audio features from normal voice commands and then train a simple machine learning model, i.e., support vector machine (SVM). Subsequently, the model is utilized to discern whether the audio received by the microphone corresponds to normal speech or adversarial perturbations.

Our final experiments revealed that the model can detect perturbations injected into a single microphone with an accuracy of 100%. However, when perturbations are injected into two microphones simultaneously, the model's detection accuracy decreases to 65.02%. The significant drop indicates the efficacy of LaserAdv in countering signal detection-based defense mechanisms.

6.2 Limitation

There are a few limitations to keep in mind. Firstly, LaserAdv requires the attacker to have access to the architecture and parameters of one ASR system to generate audio adversarial perturbations, a condition that may not be consistent with real-world scenarios. However, many white-box ASR models can be used to generate audio adversarial perturbations and transfer the attack to black-box ASR systems. As part of future research, we aim to investigate the applicability of LaserAdv under more realistic attack settings and explore the feasibility of targeting multiple systems directly.

Secondly, when the attack command is excessively lengthy or the feedback from the ASR system deviates from the command issued by the victim, it has the potential to draw his attention. Furthermore, owing to the considerable distance, the attacker can not perceive the feedback from the ASR system, and thus cannot immediately judge whether the attack can be successful. This challenge persists in long-distance attacks and remains unresolved.

Thirdly, although we can utilize the photoacoustic phenomena for LaserAdv attack, sometimes it is weak and may limit the effectiveness of the attack. Given these limitations, we plan to explore alternative channels (e.g. ultrasonic channel) and methodologies to develop a more robust and effective adversarial attack. We aim to investigate the properties of these new channels and potentially merge them with current techniques to improve the overall performance of perturbations. Such improvement may make them more resilient to varying environmental conditions and channel degradation.

Finally, LaserAdv requires an adversary to possess laser equipment. However, it is worth noting that this additional complexity does not pose a significant financial barrier. Encouragingly, the price of the equipment remains relatively low, under $20, making it affordable and accessible to potential threat actors.

7 Related Work

In this section, we review the existing studies of adversarial perturbations and sensor attacks, which can be illustrated as follows.

7.1 Adversarial Perturbation Attacks

One common approach for generating adversarial examples is to minimize the perturbation while making it challenging for humans to detect any changes. Previous works such as [16,17] focused on generating perturbations by incorporating perturbation volume into the loss function. Others like [28] utilized genetic algorithms to generate imperceptible perturbations. Another strategy to enhance imperceptibility involves shortening the perturbation and targeting weaker parts to decrease the chances of detection. For instance, Miao et al. [30] divided audio into frames and selected optimal locations for adding perturbations. Liu et al. [31] generated sparser perturbations that were less detectable while maintaining accuracy. O'Reilly et al. [32] employed weighted sampling to select perturbation points, leading to faster generation and greater robustness.

Furthermore, some studies focused on improving the imperceptibility of perturbations through psychoacoustic hiding methods [6, 8, 33–35]. These methods rely on the frequency masking effect in signal processing, where louder signals render nearby frequencies imperceptible. Additionally, some existing studies aim to make the perturbations resemble sounds commonly found in the environment, such as whistles, bird sounds, or alarm clocks. For instance, AdvPulse [5] successfully implements universal, synchronisation-free and targeted audio adversarial attacks using sub-second perturbations. However, to ensure the success of physical attacks, these perturbations must be embedded in loud, common environmental sounds that may inadvertently alert the victim due to the sudden onset of noise. In addition, the targeted ASR system is a convolutional neural network for small-footprint keyword spotting, and its feasibility has not been validated on commercial ASR models. Similarly, Shi et al. [12] developed an environmental sound simulation mehtod. Commandersong [4] quietly injected perturbations into a song to perform a physical adversarial attack.

The similarity to environmental noise can lead to easy detection when the perturbation sound abruptly appears. Furthermore, these methods require the perturbation to be approximated to a specific environmental sound, ensuring that the deviation remains below a certain threshold. This added complexity in training arises from the need to approximate the noise accurately and the necessity for more training data.

7.2 Signal Injection Attacks On Sensors

Sensors enable devices to perceive their surroundings, gather data, and respond accordingly, playing a pivotal role in shaping the modern technological landscape. However, despite their importance, recent studies have exposed vulnerabilities in many sensor systems, posing significant security challenges. S. Nashimoto et al. [36] proposed a method of injecting false information into sensors, leading to misleading or erroneous data interpretation. Many researchers have investigated attacks on radar systems [37], anti-lock braking systems (ABSs) using magnetic speed sensors [38], and even global positioning systems (GPS) [39]. Yan et al. [40] have delved deeper into the sensors used for driving guidance, such as millimeter-wave radars, ultrasonic sensors, and forward-looking cameras. Their work revealed vulnerabilities in these systems, leading to the development of contactless attacks capable of inducing blindness in autonomous vehicles. Similarly, Jang et al. [41] proposed an innovative anti-drone technique employing electromagnetic interference signal injection, effectively disrupting the communication channel between an Inertial Measurement Unit (IMU) and its control unit.

Researchers also have unveiled a range of signal injection attacks on microphones, exploiting various physical phenomena. Sugawara et al. [10] introduced a novel attack that converts light to sound to inject malicious audio signals into microphones. Zhang et al. [42] demonstrated successful modulations of low-frequency audio commands that attack VCSs by exploiting the nonlinearity of microphone circuits.

By scrutinizing various microphone studies, it becomes evident that these crucial audio sensors can be compromised through diverse attack vectors, including inaudible voice [42], light [10], and electromagnetic (EM) -based attacks [43]. Building upon this understanding, our research seeks to explore the potential vulnerabilities of microphones and ASR systems using lasers.

8 Conclusion

This paper introduces LaserAdv, a new method for launching adversarial attacks on ASR systems via laser adversarial perturbations. In our study, we identified critical factors that affect the effectiveness of the LaserAdv method, including the response characteristics of the microphone laser channel and the effects of frequency-selective fading and low sensitivity. To address these issues, we proposed a SAE-TFI method and further optimized the IAP generation objective function to facilitate more practical attack scenarios. Our results demonstrate the potential of LaserAdv in successfully attacking three ASR systems using IAP, including DeepSpeech,

Whisper, and iFlytek. In the presence of victim speech, the maximum distance can be up to 120 m at a cost of only $20.

Abstract

The integration of microphones into sensors and systems, serving as input interfaces to intelligent applications and industrial manufacture, has raised public concerns regarding their input perception. Studies have uncovered the potential dangers posed by out-of-band injection attacks on microphones, encompassing ultrasound, laser, and electromagnetic attacks, injecting commands or interferences for malicious purposes. Despite existing efforts on defense against ultrasound injections, there is a critical gap in addressing the risks posed by other out-of-band injections. To bridge this gap, this paper proposes MicGuard, a comprehensive passive detection system against out-of-band attacks. Without relying on prior information from attacking and victim devices, MicGuard leverages carrier traces and spectral chaos observed by injection phenomena across different levels of devices. The carrier traces are used in a prejudgment to fast reject partial injected signals, and the following memory-based detection model to distinguish anomaly based on the quantified chaotic entropy extracted from publicly available audio datasets. MicGuard is evaluated on a wide range of microphone-based devices including sensors, recorders, smartphones, and tablets, achieving an average AUC of 98% with high robustness and universality.

1 Introduction

Microphones capture sound, one of the most important information mediums, to record auditory aspects of the physical world and open a door for intelligent machines to 'comprehend' human sayings. Not to mention telephoning and music recording, the integration of compact MEMS microphones into wireless and commercial devices have gained significant prominence in smart home, industrial applications, and live broadcasting. Microphones serve as vital input interfaces in various contexts, exemplified by their use in voice assistants-enabled smartphones for human-machine interaction [5], anomalous sound detection for fault diagnosis of

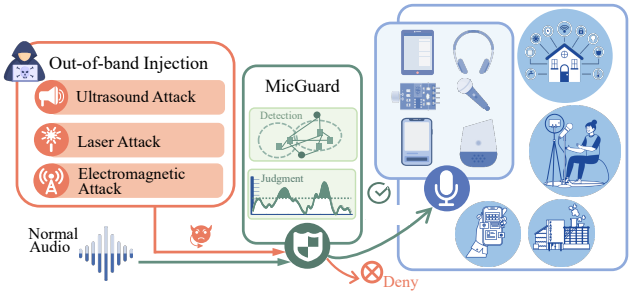

Figure 1: The designed MicGuard detects out-of-band injected signals and protects the microphone-based devices, promising the security of linked systems and applications

industrial processes [22], and television broadcasting for communication and recreation [12].

On the other side of the coin, the inherent open nature of microphones also unlocks a door for attackers to inject malicious *out-of-band* signals [13, 28, 30] for deception and sabotage. Surveying most injection attacks on microphones, out-of-band signals refer to signals that are outside the normal frequency range or transmission path of an audible pattern, such as ultrasound, laser, and electromagnetic (EM) signals. Given that these signals own high concealment and intrusiveness, particularly, attackers can perform ultrasound-based or laser-based attacks (i.e., dolphinattack [53], lightcommand [39]) to inject voice commands into voice-controlled devices. Additionally, they can also emit EM interference [23] to manipulate microphone recordings for further compromising linked broadcasting systems or sensor-fusion networks [38, 40].

However, prior works against injection attacks on microphones are limited to mitigating in-band injection (i.e., audible attacks [26, 47]) or further including ultrasound attacks [36], overlooking risks associated with the out-of-band injection. To fill this gap, we aim to design a comprehensive countermeasure against all mainstream out-of-band injection attacks. Compared with existing detection schemes, the desired detection facing out-of-band signals needs to meet the following requirements: 1) No extra hardware: the required sensors or hardware modification (e.g., speakers, IMU, mic arrays) in

some detection methods [18, 41, 52] bring about additional burdens for users and are unavailable for low-level mic-based devices [27]. 2) Independent of adversarial samples: most deep learning-based detecting mechanisms [15, 26] heavily rely on the quantity of training attacking samples. This is unfeasible to collect attacking samples that fully cover all possible attacking outcomes determined by victim conditions and attacking modes. 3) Low dataset cost: for ease of deployment, large amounts of positive data from the target microphone should not be required. 4) High accuracy and robustness: it should achieve high accuracy regardless of environment changes and microphone types.

To satisfy the requirements of usability and efficiency, we propose MicGuard shown in Figure 1, the first passive detection system against mainstream out-of-band injection attacks involving ultrasound, lasers, and electromagnetism. The key insight of MicGuard is to capture common traits caused by these out-of-band injection attacks without relying on prior knowledge from attackers or target microphones. By investigating the remaining attacking phenomena across ultrasound, laser, and EM modalities, we uncover two inherent characteristics: carrier traces and spectral chaos. It is found that carrier traces in recorded audio are possibly triggered by carrier waves serving as modulation and transmission of injection attacks, depending on victims' low-pass filters and attacking power. Based on it, we design a prejudgment stage for MicGuard to pre-reject some high-energy injection signals by identifying the carrier trace, minimizing computing cost and operation time. The spectral chaos refers to the disorder of acoustic spectra caused by out-of-band frequency response and non-speech radiation (e.g., thermal, electromagnetism). This is because the forced out-of-band injection definitely causes extra energy emissions in the transformation of non-speech analog-to-audio digital, given the internal circuits and parameters of microphones designed for in-band audio. To quantify these distortions, we propose the spectra-chaotic entropy, enabling MicGuard to memorize the normal entropy characteristic and then distinguish the abnormal. We design the memory-based detection network to store chaotic maps from normal audio in the feature memory bank. Notably, our designed detection model solely absorbs normal samples stemming from open-sourced audio datasets and distinguishes abnormal ones based on the distribution differences queried from the memory bank, all without requiring any information from target devices.

The MicGuard effectively bridges the gap between restricted defense and full-scale attacks to a considerable extent. It should be noted that the out-of-band attacks examined in this paper primarily focus on ultrasonic, laser, and EM attacks. These are chosen as they are among the most prevalent injection types and offer a representative cross-section of the injection attack landscape. In summary, our contributions are as follows:

- To the best of our knowledge, MicGuard stands as the most comprehensive detection system designed to combat out-of-band injection attacks against microphones.
- We explore the shared attacking patterns across three out-of-band injection attacks and uncover two key properties that can serve as benchmarks for detection. Building upon these findings, we develop MicGuard, a novel system capable of detecting anomaly-injected signals without requiring preliminary data from either attacks or targets.
- We evaluate MicGuard on 16 different levels of microphone-based devices, including smartphones, tablets, recording microphones, and sensors. Extensive experiments show that MicGuard can achieve exceptional detection ability with 98% AUC, and is resilient in ambient noise and attacking parameters.

2 Out-of-band Injection Attack Model

In this study, we introduce the out-of-band attacks on microphones, involving their vulnerabilities of microphones to ultrasound, laser, and EM modality, as shown in Figure 2, and consider the threat model that is also implicitly adopted in previous work.

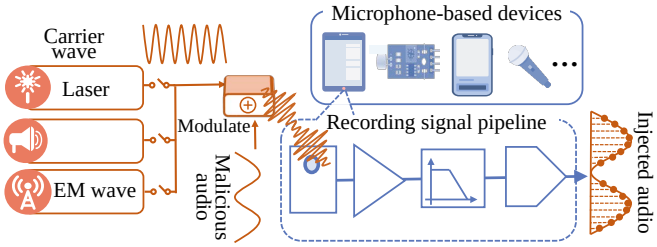

Figure 2: The attacking diagram of those three out-of-band injection attacks includes ultrasound, laser, and EM attacks, where the attacker modulates the malicious audio on the out-of-band carrier waves and transmits it into the microphones.

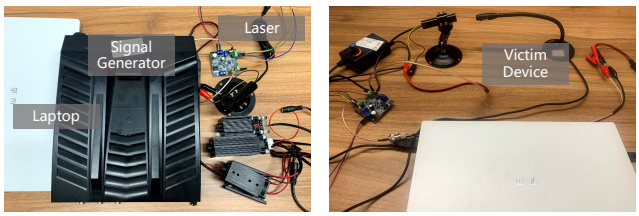
Attackers' Goal. The ultimate goal of attackers is to introduce malicious signals into microphones, compromising the associated systems, such as voice-controlled systems, television/radio broadcasting, and industrial automation.

Attackers' Capability. The victim microphones and microphones-based devices are commonly seen in daily life, multimedia, and industrial manufacturing, e.g., smartphones, recording microphones, and sound sensors. The attacker cannot gain physical or malware-based access to the target device. Aiming at successful injection, attackers can employ sophisticated hardware and energy resources to execute one of the following attacks:

- **Ultrasound attack** also called dolphinattack [53], is one of the mainstream out-of-band attacks on microphone sensors. Attackers modulate malicious audio on the amplitude of ultrasound carriers (e.g., $>$ 24kHz) and then transmit the ultrasound to interfere with microphones through

ultrasonic speaker arrays. Despite ultrasounds operating at high frequencies beyond the range of human hearing, the inherent non-linearity of amplifiers inside microphones inevitably generates multi-order multiplication of signals upon receiving the modulated ultrasound [35]. The second-order multiplication consequences render the microphone to record original audio modulated on carriers inadvertently. Detailedly, the well-designed ultrasound $S_{ultra}(t)$ is formulated as follows [18]:

$$S_{ultra}(t) = (m(t)+1)cos(2\pi ft) \quad (1)$$



where $cos(2\pi ft)$ denotes an ultrasound carrier with the frequency of f and $m(t)$ is the modulated audio, e.g., a human voice command signal saying "Alexa, mute yourself." The corresponding non-linearity production is $m(t)+\frac{1}{2}m(t)^2$, where the second-order production $m(t)^2$ is so weak that it can be ignored. Figure 3(a) depicts the ultrasound attack setup, which consists of three frequency bands (25kHz, 32kHz, 40kHz), high-power ultrasonic speaker arrays, and two amplifiers. This configuration ensures that the modulated ultrasonic signal is properly fed into the target microphones and remains intact. If necessary, the attack can be amplified by a high-performance amplifier, and it is effective within line-of-sight range.

(a) The setup of ultrasound attack. (b) Victim devices.

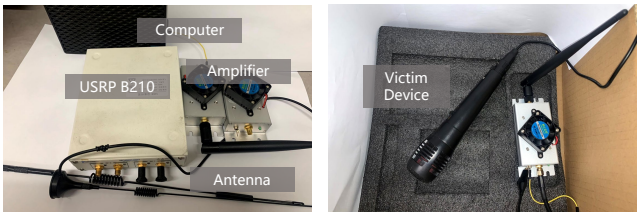


Figure 3: The experimental setup of ultrasound attacks is used and the targeted devices including smartphones, tablets, recording microphones, and sensors are tested in this paper.

- **Laser attack** also known as lightcommands [39], are a sophisticated means of compromising microphones using varying laser beams. By precisely modulating the intensity of lasers to encode audio, attackers can remotely manipulate the linked systems, e.g., voice-controlled systems and live broadcasting. The laser beam is supposed to be focused on the sound hole as hard as possible, whereby the laser directly shoots at the diaphragm to cause its vibration due to photoacoustic effects. The light-induced vibration is converted to the recorded audio of targeted microphones. The attacking setup of laser attacks is shown in Figure 4 and can be configured with 450nm laser transmitters at varying power levels of 100mW, 500mW, and 2500mW, respectively. The modulation driver of laser attacks are transistor-transistor-logic (TTL) modulation and amplitude modulation (AM), respectively.The attacker has remote line-of-sight access to the target microphone and emits lasers into its sound hole.
- **EM attack** targeting microphones in this paper are categorized as low-power intentional EM interference [23, 56], which manipulates the voltage changes of transducers by using specifically crafted EM signals. The stealthy injection of modulated signals on EM carriers into microphones can be attributed to the following reasons [41, 44]: 1) electronic components such as amplifiers and analog-to-digital converters (ADCs) in PCB circuits can couple with electromagnetic signals to absorb energy, which is also known as electromagnetic coupling; 2) the connecting wires between components act as antennas that can receive the invasive electromagnetic wave. To maximize the coupling effect, attackers must first determine the resonance frequency of target microphones using sweep frequency techniques. The manufactured signals that attackers intend to inject into microphones are AM-based modulated electromagnetic waves with a certain resonance frequency. Figure 5 shows the attacking setup for EM attacks, which includes an amplifier and a USRP. To ensure a high success rate for the EM attack, position the transmitting antenna as close as possible to the target or its USB cord, potentially removing the insulation from the charging wire. The attacking device's antenna is positioned close to the victim, potentially making direct contact with the wires to the charger of the target, and can also be connected to an amplifier to increase the intensity of the electromagnetic radiation.

3 Preliminary Analysis

Before we design a defense mechanism against out-of-band injections, it is necessary to analyze the consequence arising from these injection attacks and uncover their common characteristics. The characteristic is the key to detecting all injected traces across various microphones.

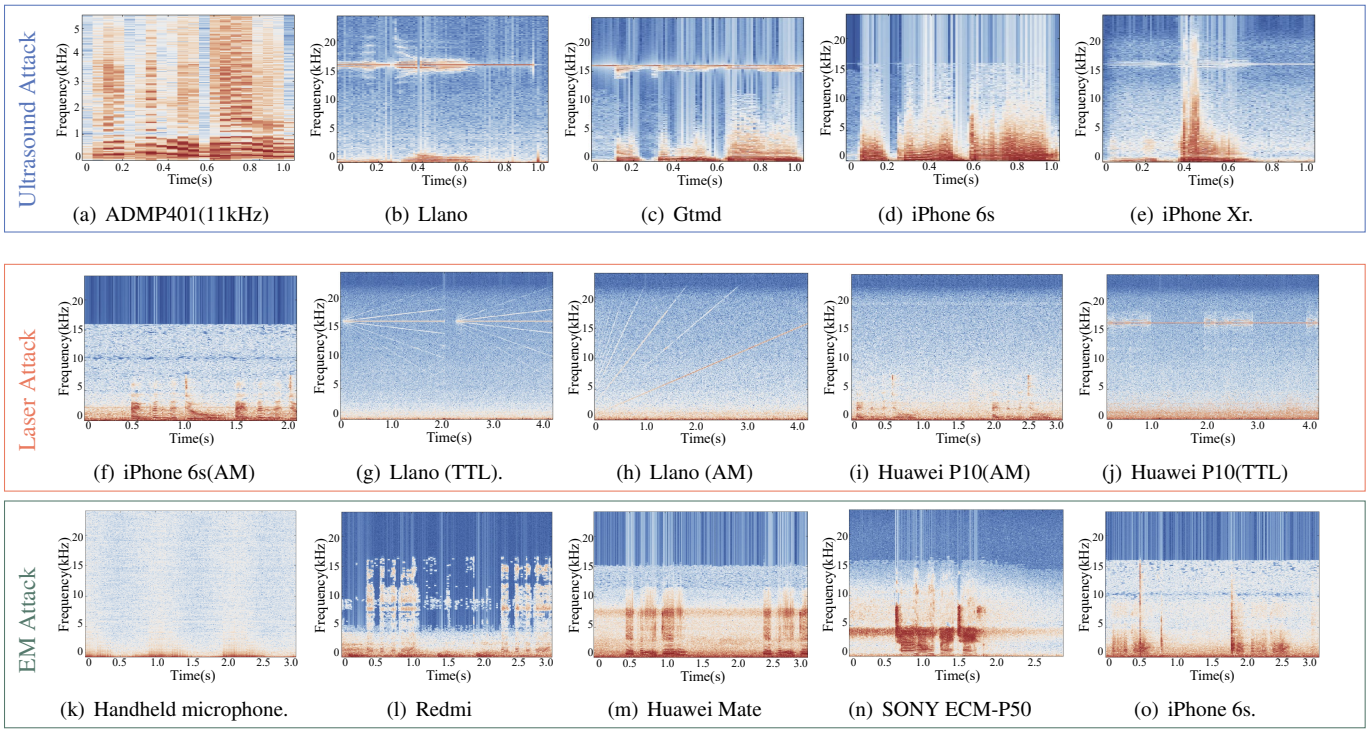

Figure 6: The measured spectrum of sampled sound from the microphone under ultrasound, laser, and EM attacks. The victim devices includes smartphone, recording microphones, and sensors, under ultrasound. TTL: laser attacks under TTL modulation. AM: laser attacks under amplitude modulation.

3.1 Trait 1 : Carrier trace

We execute the three out-of-band injection attacks on commonly-used microphones: microphone sensors, recording microphones, and smartphones. The attacking setups employed for these attacks are described in Section 2, and the victim microphones are shown in Figure 3(b). The injected results recorded by microphones are illustrated in Figure 6. The laser attacks are executed by TTL modulation and AM, respectively. The attacking results of TTL laser or AM laser are labeled by TTL or AM in the figure caption. The carrier frequency of ultrasound attacks and laser attacks under TTL is 32kHz and 16kHz, respectively. The 16kHz/32kHz in laser attacks is the frequency of emitted pulse of TTL laser, which stands as the carrier frequency of modulated audios.

Looking deeply at each spectrum of injected audio, we find that some frequency traces like straight lines span the entire timeline, as seen in Figure 6(b)(c)(e)(g)(j). Such frequency traces only happen in specific frequency points, whatever the types of victim microphones. Detailedly, a line of 16kHz frequency trace occurs in ultrasound-injected results of iPhone Xr and recoding microphones (i.e., Llano, Gtmd). Regarding the cause of this phenomenon, the observed frequency traces are the result of frequency shifting a single-frequency signal during the ADC sampling. Based on the following sampling formula:

$$|f_a| = |f - m f_s|, \quad |f_a| \leq \frac{f_s}{2}, \; m \in Z, \tag{2}$$

where a sinusoid of frequency f Hz is sampled at f_s samples/sec, and the sampled sinusoid of frequency f_a is folded in the band 0 to $f_s/2$. By substituting the 48kHz sampling rate f_s and 16kHz frequency traces f_a in Eq. 2, we can derive that the frequency value f of the signal being shifted is 32kHz. In a similar vein, look backing at the TTL laser injection results, it can be obtained that the frequency traces on the spectrum of laser injection results from a 32kHz or 16kHz.

Remarkably, *the frequency value is exactly equal to carrier frequency. 1)* Laser-injected trace attributed to the carrier: In laser attacks, the laser frequency range comprises the carrier wave (i.e., 16kHz) and modulated audio band, which does not extend beyond 16kHz significantly. Moreover, only TTL laser attacks can cause a straight trace in a spectrum. Whereby TTL-modulated lasers require a carrier while AM-modulated lasers do not, the trace effect is attributed to the carrier wave. *2)* Ultrasound-injected trace attributed to the carrier: However, it is generally seen that the carrier wave should be filtered out after the microphone low-pass filtering ($f >$ the cut-off frequency of the low-pass filter) and cannot be downsampled through ADC sampling. Practically, the gain-magnitude frequency response will gradually decay beyond the cut-off frequency of the low-pass filter (e.g., the cut-off frequency at 24kHz), rather than abruptly dropping to zero. Thus, the carrier with high power can bypass the low-pass filter. Particularly for professional recording microphones, the cut-off frequency of the low-pass filter is looser, which loosely allows carriers to pass through.

However, *why does the phenomenon of carrier traces not exist in the injection results of EM attacks?* To answer it, we should first understand the role of carrier signals among these

three injection attacks and analyze whether it can cause carrier traces in recordings of victim microphones. 1) Ultrasound attacks rely on ultrasonic carrier signals to modulate audio signals that adversaries want to inject and transmit into targets. The ultrasonic probe will inevitably emit ultrasonic waves that will be downsampled by the ADC, given that the internal low-pass filter does not entirely attenuate them. 2) Laser attacks choose a laser beam driven by TTL modulation wherein the carrier signal is a PWM optical signal. The carrier signal will vibrate the microphone's diaphragm consistent with its frequency so that the victim can record the carrier. Note that if the laser driver is amplitude modulation (at a much higher cost than TTL) and no carrier signal is required, then there will be no carrier trace in the laser injection results. 3) While EM attacks also need carrier signals for injection, the electromagnetic carrier is used to the electrostatic couple and is neither the actual sound nor sound source inside microphones. Thus, EM attacks cannot bring about carrier traces.

Insight 1: Considering the potential occurrence of carrier traces in the results of ultrasound-induced and laser-induced attacks, we can leverage the characteristic of carrier traces to quickly pre-determine whether an out-of-band attack exists.

3.2 Trait ② : Spectral chaos

While we have uncovered a trait to identify the attacking trace, its limited applicability drives us to explore additional detection trait that fulfills the following conditions: 1) Discriminability: this trait relies heavily on the distinctive characteristics of out-of-band injection attacks rather than normal sound; 2) Stability: This trait consistently exhibits strong reliability across all microphones.

Before we traverse all invented statistical or acoustic features, we first analyze the analog-to-digital process of microphones when facing out-of-band signals or sound, respectively. A MEMS microphone is an acoustic-electrical transducer that translates air pressure into an electrical quantity. The output voltage V_O of MEMS microphone can be modeled as a variable capacitor formed by a flexible membrane subject to incident pressure P_S [42]:

$$V_O = -\frac{\kappa C_0 V_B P_S}{\varepsilon_0 A}, \tag{3}$$

where A is the area of capacitor plate, ε_0 is the vacuum dielectric permittivity, V_B is the biased voltage, C_0 is the initial capacitance in the absence of sound and κ is the deformation sensitivity. For a linear microphone, the corresponding Fourier transformation is $V_O(\omega) = H_{mic}(\omega)P_S(\omega)$ and $H(\omega)$ is the frequency response function. When high-frequency signals, e.g., ultrasound and electromagnetic signals, flow through analog circuits of microphones, they will induce parasitic capacitance C or inductance L and thereby enhance the nonlinearity, simply formalized as: $\tilde{H}_{mic}(\omega) = H_{mic}(w)\frac{1}{j\omega C}$ or $\tilde{H}_{mic}(\omega) = H_{mic}(\omega)\, j\omega L$. Obviously, the out-of-band signals can cause deviations from the intended frequency response, resulting in distorted acoustic recordings. Moreover, since the hardware component of microphones is designed for in-band signals, the components cannot fully handle unwanted out-of-band signals, thus creating by-products, i.e., multiple harmonics and, in severe cases, crosstalk. According to the distortion measurement of the acknowledged formula [20]:

$$THD = \frac{\sum_{n=2}^{\infty} Power(\omega_n)}{Power(\omega_1)}, \tag{4}$$

the level of distortion is defined by the ratio of harmonic power to fundamental power. The harmonics originating from out-of-band sources substantially introduce distortions and chaos in sampled voltage.

Building upon the above analysis, we consider the distortion of recorded audio as an additional trait to identify the out-of-band injection occurrence. We leverage the concept of entropy, a well-established measure in information theory, to quantify the level of spectral chaos in audio and assess its resilience. Following the entropy principle introduced by Richman et al. [33], we utilize sample entropy to quantitatively assess the chaos of audio samples recorded from diverse victim devices exposed to various out-of-band injection scenarios. It is noted that audio samples contain distinct semantic content like 'open the door,' and each sample has a duration of 0.8-3 seconds with a 48kHz sampling rate. In Figure 8, the entropy evaluation demonstrates *1) high distinctiveness*: the original audio (avg: 0.0798) exhibits lower entropy compared to adversarial audio (avg: 0.3617, 0.6111, 0.3736), indicating that the injected audio has intense chaos; and *2) stability*: the high entropy of adversarial audios is consistent across different attacks, injected content and devices settings. These findings encourage us to design a detection method that leverages entropy information from the chaotic nature of microphone-recorded audios for out-of-band attack detection.

Insight 2: Out-of-band signal injection brings about distinct chaos across various types of victim devices, which can be employed as a key trait to detect attacking audio.

4 System Design

4.1 Prejudgment

As discussed in Section 4.1, the presence of carrier traces in recorded audio can serve as a prejudgment criterion to proactively reject signals arising from partial out-of-band attacks. This prejudgment module aims at fast detection with minimal computational overhead and operational time.

Notably, carrier traces in spectrums exhibit a horizontal line across the whole time domain. Based on it, we only need to detect the existence of horizontal lines in audio spectrum received by microphones to determine the abnormal out-of-band signals. In terms of straight-line detection, especially in image processing, there are several classical algorithms, such as Hough line detection [2] and line segment detector

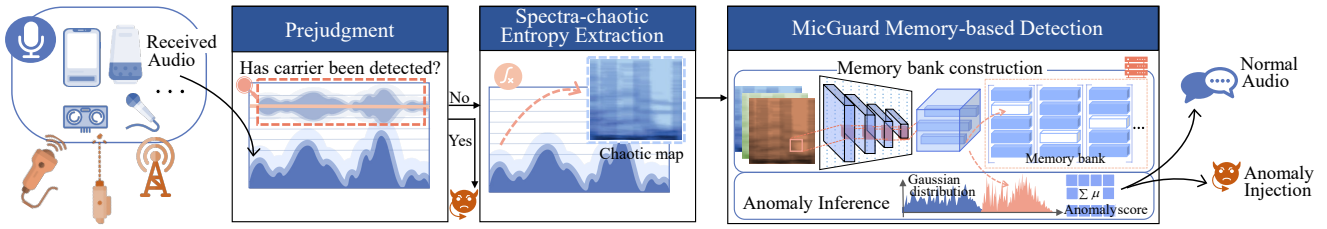

Figure 7: The system overview of MicGuard that firstly rejects partial injected out-of-band signals and identifies the remaining anomaly based on entropy extraction and detection model.

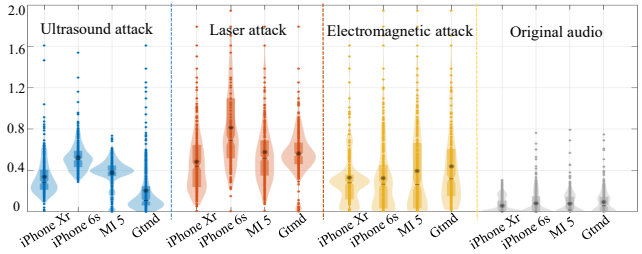

Figure 8: The calculated entropy results of received audio across different devices under different out-of-band attacks

(LSD) [14]. However, these methods require complex iterative computations and parameter adjustment, and they are more adept at handling high-quality images rather than chaotic images, making them unsuitable for the system prejudgment. In MicGuard, we design fast carrier trace detection, as detailed in Algorithm 1.

Algorithm 1 Fast Carrier Trace Detection

Require: A sample of recorded audio A
Ensure: The detected carrier trace C

$[S, f, t] = STFT(A)$;
$S = Normalize(S)$;
$CarrierTemplate = ones(1, length(t))$;
/*Calculate the correlation between each frequency line and carrier template*/
for each frequency point f_i in S **do**
  $Coeff(i) = corr(CarrierTemplate, S(f_i, :))$;
end for
$[Corr_{Max}, f_{MaxIndex}] = max(Coeff)$;
Calculate the slope L_S of $S(f_{MaxIndex}, :)$;
if $L_S \to 0$ and $Corr_{Max} > Threshold$ **then**
  Find the carrier trace $C = S(f_{MaxIndex}, :)$;
else
  No carrier trace in A;
end if

Once the microphone receives an audio sample A, the prejudgment module first performs short-time Fourier transform (STFT) on A to obtain the STFT matrix S where time frames span the columns and frequency frames span the rows. Considering that the carrier trace in the time-frequency diagram is the same as a straight line in shape, we construct a horizontal line template to match all frequency lines and locate the carrier trace by searching for the maximal correlation coefficient between each frequency line and template, as line (3)~(8) indicate. Higher correlation coefficients indicate that the energy distribution at the specific frequency point is closer to the horizontal line. After finding the frequency line with the maximal correlation coefficient, we calculate the slope of the selected frequency line to further judge whether the energy distribution is uniform. If the slope is approximately zero and its corresponding frequency line is highly relevant to templates, the system detects the carrier trace from out-of-band injection and rejects the audio sample at a fast response. Figure 9 shows the detection result of our algorithm and provides a comparison with other line detection algorithms (i.e., Hough line detection and LSD). While computer vision methods struggle to detect the horizontal carrier trace except for multiple thin broken line segments in a disordered spectrum, our approach can accurately locate the adversarial carrier required for certain out-of-band attacks. Considering the extreme recording scenario where users record single-tone signals, it is feasible for users to optionally store these pre-rejected signals after detection or turn off the prejudgment just this once.

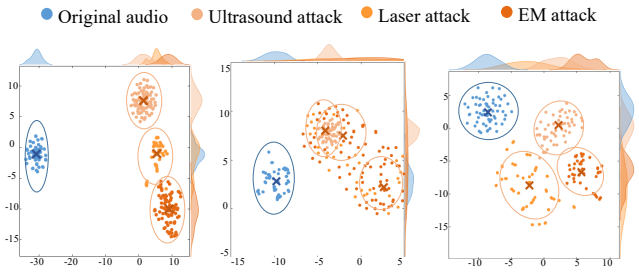
(a) Hough. (b) LSD. (c) Our.

Figure 9: The comparison of our proposed algorithm with Hough line detection and LSD.

4.2 Spectra-chaotic entropy extraction

Although we have built up a prejudgment stage to protect against some of the high-energy malicious signals speedily, there is an urgent need to set up a subsequent detection mechanism to re-detect signals that pass through the prejudgment. The goal of this section is to extract the chaotic feature of captured sound that is discussed in Section 4.2, as the criterion of the following detection model.

The mismatch between out-of-band signals and microphone hardware settings will give rise to chaos in the final digitized audio. It is necessary for MicGuard to investigate how to extract intricate chaos comprehensively. The entropy measurement always functions on an entire time sequence,



equivalent to downsampling the one-dimensional acoustic signal to a single value. Such high compression measurement overlooks multi-leveled disorders in injected audio and is unsuitable for out-of-band anomaly detection. To cope with it, MicGuard designs spectra-chaotic entropy extraction to avoid compression of informative entropy. Firstly, we use STFT on the audio sample to acquire a two-dimensional spectral matrix S where the frequency energy distribution changes over time. The STFT utilizes a Blackman window with a size of 512 points and an overlapping of 375 points. We adopt the local aggression on S by dividing S and composing each patch-level entropy representation without losing the time-frequency resolution and usability of the chaos feature. Mathematically, the patch window N with the patch size of p slides in spectrum S and locally aggregates information at position (x,y):

$$N_p(x,y) = \{S(i,j) | i \in [x-\frac{p}{2},...,x+\frac{p}{2}], j \in [y-\frac{p}{2},...,y+\frac{p}{2}]\}. \quad (5)$$

Then, we apply the entropy function on $N_p(x,y)$ to yield the spectra-chaotic map E_p as follows:

$$E_p(x,y) = f_{entropy}(N_p(x,y)). \quad (6)$$

Several optional entropy measurements, including power spectrum entropy [51], sample entropy, and local entropy [4], can substitute for the entropy function $f_{entropy}$. To determine the entropy function, we utilize t-distributed stochastic neighbor embedding (t-SNE) to assess the distinctiveness of the spectra-chaotic map across original audio and out-of-band injected audio. The visualization results of dimension-reduced entropy maps are shown in Figure 10. It is noted that the experimental data for analysis is sourced from Section 3.2. The corresponding inter-class distances are 65.50, 30.50, and 40.56, wherein the power spectrum entropy owns the largest distance between in-band and out-of-band classes. To sum up, the power spectrum entropy is chosen as $f_{entropy}$.

4.3 MicGuard Memory-based Detection

Following the extraction of spectra-chaotic maps, this section aims to identify anomalous instances resulting from out-of-band attacks, which exhibit notable deviations from the normal audio samples. In realistic detection applications, the characteristics of anomalies can not be observed during the model training phase due to the unexpectedness of ultrasound, laser, and EM signals. Additionally, for practical ease of use, it is advisable to minimize the acquisition of normal data from the microphone to be protected. To address these issues, this paper designs the MicGuard memory-based detection model, as shown in Figure 11, which memorizes the distribution of the normal-only from open-source audio datasets and detects the outlying features across different attacking modalities.

4.3.1 Memory bank construction

Feature encoding. The first stage is the encoding of spectra-chaotic entropy maps that will be stored to construct a memory bank [9,34]. The memory bank is a substantial feature dataset that models the normal distributions at various hierarchies of chaotic maps. Upon receiving an input feature map, MicGuard memory bank will be queried to retrieve the most relevant items to identify whether it is similar to the memory storage.

After producing an input chaotic map x_i from a training dataset $\mathcal{X} = \{x_1, x_2, ..., x_n\}$ consisting only of n normal samples from open-source audio online, the system utilizes the convolutional neural network (CNN) to extract the hierarchical embedded representations. Inspired by unsupervised classification tasks in ImageNet [10], the pre-trained CNN not only has sufficient downsampling and distinguishing in feature space but also incurs less training cost. We employ the frozen WideResNet50 [50] fully pretrained on ImageNet database as the feature encoder, composed of three bottlenecks $\{\mathcal{F}^1_{res}, \mathcal{F}^2_{res}, \mathcal{F}^3_{res}\}$ and the last average pooling layer $\mathcal{F}_{avg}$. Unlike classic residual neural networks (ResNets), the bottleneck of WideResNet50 has the core idea of widening the network by increasing the number of filters. Each bottleneck block has three convolution layers with twice the number of channels as ResNet and uses dropout for regularization. Augmenting the quantity of feature channels allows the network to refine a broader range of patterns, making it more adept at understanding intricate features and variations. Empirically, we make use of the intermediate feature maps from these four layers (i.e., three bottlenecks and an average pooling layers). These four feature maps are uniformly upsampled and then concatenated along the channel axis to form the multi-scale feature maps $z_i = \{\mathcal{F}^1_{res}(x_i), \mathcal{F}^2_{res}(x_i), \mathcal{F}^3_{res}(x_i), \mathcal{F}_{avg}(x_i)\}$. Notably, these feature maps are no longer original chaotic maps but rather their high-level compressed representation that contributes to the data distribution in the network memory.

Feature adaption. The following step is to fine-tune these feature maps on normal audio-oriented feature space rather than universally oriented domains, facilitating anomaly detection. This is because pre-trained encoder is not specifically designed for chaotic feature extraction. We propose using the deep support vector data description (DSVDD) [37] to learn a hypersphere that extracts common characteristics across normal data while eliminating non-informative interferences. The hypersphere encloses the input maps and clusters them densely within a feature space oriented toward normal audio. With the input features datasets $\mathcal{Z} = \{z_1, z_2, ..., z_n\}$, we

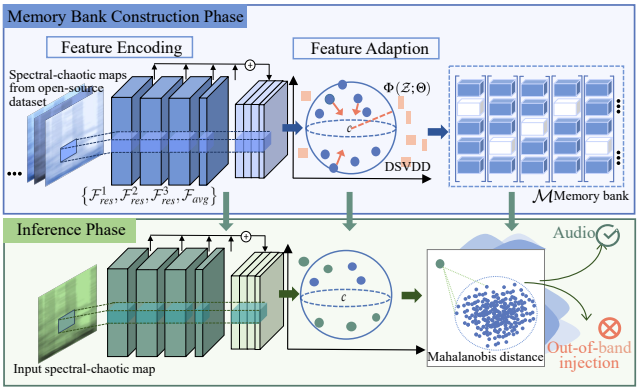

Figure 11: Illustration of MicGuard. Phase 1: The MicGuard encodes the spectral-chaotic maps extracted from open-source audio datasets to construct a memory-based feature bank. Phase 2: Once the input spectral-chaotic map is processed by encoding and adaption, MicGuard searches the memory bank to calculate the Mahalanobis distance between the input and stored normal characteristic distribution to reject the anomaly.

initialize the mapped results as $\Phi(\mathcal{Z};\Theta)$, where Φ is the mapping function with adaptable parameters Θ. The DSVDD employs deep neural networks as Φ to obtain high-dimensional representation and process massive data. The objective optimization is to learn the network parameters with minimizing the volume of a data-enclosing hypersphere, formulated as follows:

$$\min_{\Theta} \frac{1}{n}\sum_{i=1}^{n} \|\Phi(\mathcal{Z};\Theta)-c\|^2 + \frac{\lambda}{2}\|\Theta\|_F^2 . \quad (7)$$

The first item of optimizing objective Eq.7 is the quadratic loss of the distance between the every mapped representation $\Phi(z_i;\Theta)$ and the center of the hypersphere c. The second item is a network weight decay regularizer with hyperparameter λ to prevent over-fitting. The $\|\cdot\|_F$ denotes the Frobenius norm. The DSVDD contracts the hypersphere by progressively aggregating the normal inputs closer to the center of the sphere. As a result, we obtain the adapted feature bank $\mathcal{M} = \Phi(\mathcal{Z};\Theta)$ that can be used for subsequent anomaly inference.

4.3.2 Anomaly Inference

For each test input t_i from the above processing (i.e., encoding and adaption), the inference phase measures its similarity to the registered feature bank $\mathcal{M} = \{m_i = \Phi(z_i;\Theta), i \in [1,n]\}$ to identify whether it is out of the normal distribution. However, owing to environmental fluctuations and unstable acquisition equipment, noisy data is inevitably in the audio datasets or the received test input. Most unsupervised detection algorithms are susceptible to noise factors because they treat all information equally. To alleviate this noise impact, with the assumption that the amount and intensity of noise are less than the norm, we set multivariate Gaussian to model the joint probability density of multiple characteristic dimensions. The key advantage of using a multivariate Gaussian distribution is that it only fits the ordered principal feature distributions while disregarding out-of-order fluctuations such as noise. The multivariate Gaussian distribution model on memory bank $\mathcal{M}$ is defined as:

$$p(\mathcal{M}|\mu,\Sigma) = \frac{1}{\sqrt{(2\pi)^n|\Sigma|}}\exp\left\{-\frac{1}{2}(\mathcal{M}-\mu)^T\Sigma^{-1}(\mathcal{M}-\mu)\right\}, \quad (8)$$

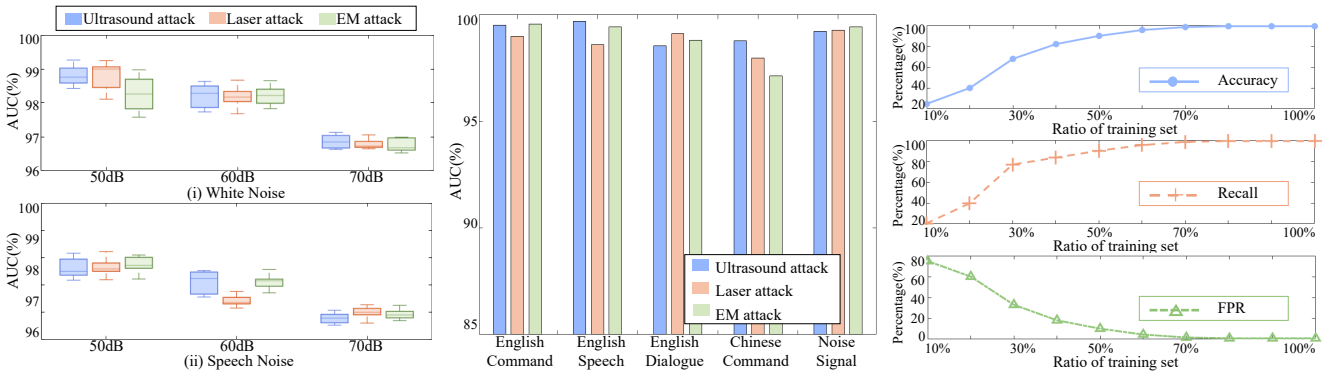
where μ is the mean of $\mathcal{M}$ and Σ is the variance-covariance matrix by using maximum likelihood estimation. Under the Guassian distribution with mean μ and convariance Σ, a Mahalanobis distance $\mathcal{D}$ between a test input point t_i and the modeled distribution is measured as:

$$\mathcal{D} = \sqrt{(t_i-\mu)^T\Sigma^{-1}(t_i-\mu)}. \quad (9)$$

The Mahalanobis distance $\mathcal{D}$ is interpreted as the anomaly score, with a higher Mahalanobis distance indicating a greater outlier score. The t_i with an anomaly score beyond the threshold boundary is judged as the out-of-band injection.

5 Evaluation

To evaluate our designed system, we pre-train MicGuard only based on audio datasets available online and collect out-of-band spoofing data. We employ diverse microphones and microphone-equipped devices to record the injected sound for evaluation in different conditions.



5.1 Evaluation Setup

Hardware Setup. The out-of-injected attacking setups have been described in Section 2. For victim devices, we employ smartphones, tablets, recording microphones, and microphone sensors. All subsequent experiments, including overall performance (Section 5.2) and robust analysis (Section 5.3), employ the identical attacking setup as delineated in our threat model (Section 2).

Dataset. Since MicGuard does not rely on any prior knowledge from the device to be protected, we only need to collect spoofing audio from diverse microphones and genuine audio for testing. *(1) Spoofing dataset:* In this phase, we utilize those three types of spoofing devices to inject audio samples into 16 devices, whose content includes voice commands, speeches, and artificial noises. After removing incorrectly recognized samples, we get 333,655 spoofing samples with 16kHz sampling rate. *(2) Genuine dataset:* In this phase, we recruit 20 participants to speak voice commands, which will be recorded by the same 16 microphone devices as in the spoofing audio collection. The experiments are under the approval of the IRB of our institutions. During the experiments, all participants are informed and approved of the purpose of our experiments. After splitting the audio and removing invalid samples, we collect 31,844 samples with 16kHz sampling rate. *(3) Training dataset:* In the training phase, we choose open-sourced LibriSpeech [31], a corpus of English speech, to fully pre-train the MicGuard memory-based detection model. We divide

Table 1: Experiment devices, category, and AUC results. We evaluate the detection ability of MicGuard among diverse devices and differnt powers of injection attacks in an office environment with a background noise with 30dB SPL.

(a) Noise. (b) Injected Content. (c) Training Size.

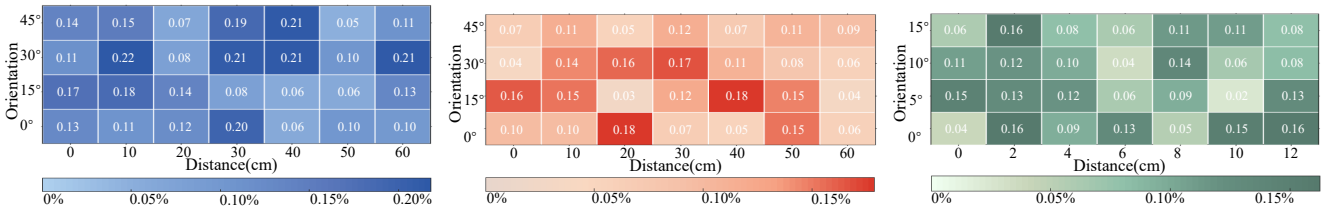

Figure 12: The Robustness analysis: the performance of MicGuard under ambient noise, injected content, and training size impact.

2,438 pieces of samples with a 16kHz sampling rate from LibriSpeech as our training dataset to construct a feature bank.

Metrics. We adopt the following metrics to evaluate the performance of MicGuard: False positive rate (FPR): it is the probability that the system fallaciously accepts the spoofer. False rejection rate (FRR): it is the probability where the system refuses access to the genuine. True positive rate (TPR): it is the probability that the system correctly accepts the normal audio, which is also called Recall. The receiver operating characteristic area under the curve (AUC): it is defined as the area under the ROC curve. When the number of positive and negative instance is imbalanced, AUC can provide a more robust evaluation of the model's performance Accuracy: it is the measurement of overall correctness in classification. Note that the unit of these metrics is percentage(%)

5.2 Overall Performance

We use the attacking setup as shown in Section 2 to perform those three out-of-band attacks and evaluate the overall performance of MicGuard in four categories of microphone-equipped products listed in Figure 3(b), including smartphones, tablets, recorders, and sensors. These products serve as voice interaction, social communication, industrial perception, and more. For each microphone device in evaluation, we set the attacking setup close to the target at a distance of 15cm. The default experimental environment is an office with background noise with a 30dB sound pressure level (SPL). We repeat the three out-of-band injection attacks on each device and also collect genuine audio from each device to measure the anomaly inference of MicGuard. In order to comprehensively assess the attacker's injection capability, we variably adjust the transmitted power of injection setups. The overall

(a) The FPR(%) under ultrasound attack. (b) The FPR(%) under laser attack. (c) The FPR(%) under EM attack.

Figure 13: The Robustness analysis: the detection distribution (FPR%) of MicGuard facing out-of-band injection attacks across various positions.

experimental results of MicGuard are shown in Table 1. MicGuard demonstrates remarkable effectiveness in countering out-of-band injected audio while accurately processing authentic samples across a wide range of devices. Specifically, MicGuard achieves an average AUC of 98.8%. We observe that there is a slight decrease in the AUC of the ADMP401 sensor. Presumably, unlike commercial microphones, such sensors have relatively poor audio sensing capabilities and occasionally produce loud noises or even garbled audio. Despite increasing the power of injection attacks, MicGuard maintains a high AUC above 97%. This is attributed to the fact that no matter how much power is injected, they invariably induce disruptions in the recorded audio.

5.3 Robustness Analysis

Noise. To investigate the impact of noise, we collect spoofing audio from three injection attacks and genuine audio under different types and strength levels of noise, respectively. Two commercial loudspeaker boxes play white noise and speech noise at the SPL of 50dB, 60dB, and 70dB. After collecting these audio, we feed them into the pre-trained model to calculate the AUC. Figure 12(a) shows the AUC of detection results, from which we can find that the averaging AUCs of all injection attacks are 98.61%, 98.20%, 96.79% under white noises and 97.66%, 96.88%, 95.90% under speech noises. The AUC decreases by up to 3%, and the higher the ambient noise, and the extent of the reduction is positively associated with the increase in ambient noise level, especially high-level noise. This is because the benign audio is falsely rejected since the added noise, similar to chaos, potentially disturbs the judgment of the model. The AUCs under speech noise are lower than those under white noise. It is speculated that the added speech noise may mask the original injected malicious signals, potentially causing a slight increase in the FPR.

Injected Content. Though we have obtained overall detection results on spoofing audio signals containing voice commands and speeches, it is unclear to what extent the semantic content modulated on out-of-band signals affects MicGuard detection outcomes. In this case, we divide and select the previously collected dataset into the commands, speeching, and dialogue datasets. Moreover, considering the limited language (i.e., English), we add two new spoofing datasets where the modulated content is Chinese commands and noise signals like pulse, Gaussian, and thermoelectric. The added noise data can furthermore confirm the anti-interference property of MicGuard. Figure 12(b) demonstrates the averaging AUC of 98.94%, indicating the robustness to the injected content. When the injected language is Chinese, there appears to be a slight decrease in AUC. This can be attributed to the fact that the pre-training dataset exclusively comprises English data, thereby leading to a more robust feature representation in the model for English inputs. Additionally, we attempt to inject noise to assess whether these artificial noises can bypass the decision boundary of models by accident. The high AUC surpassing 99% under noise injections demonstrates the robust performance of our system.

Training Size. It is well-known that the amount of training data is crucial in deep learning methods in terms of feature learning and generalizing. In this case, we split the training datasets into different proportions, namely, from 10% to 100%. Figure 12(c) shows the accuracy, recall, and FPR of our system with different training set sizes. As expected, the evaluation results substantiate that increased data for training achieves higher accuracy and recall. When the training proportion exceeds 70%, we observe a mere modest increase in system accuracy. This underscores the notion that merely augmenting the volume of training data may not enhance the generalization capacities of models.

Position. It is flexible for adversaries to launch out-of-band signals at varying distances and orientations from the victim devices. In this case, we investigate the attacking position on the effectiveness of MicGuard. Those three types of out-of-band injection signal launchers are positioned at distances ranging from 0cm to 60cm and off-axis angles spanning 0 to 45 degrees. In EM attacks, the attacking distance is restricted by the significant attenuation of electromagnetic radiation over distance. In realistic experiments, the EM attacking distance is 0cm to 12cm. For all attacking testing, we only collect efficient injected signals of victims. To ensure the success of injection attacks, we increase transmission power or the number of speaker arrays in ultrasound attacks. In laser attacks, the laser is aimed at microphones from different orientations. Note that 0cm means the transmitting probe is tightly attached to the target device. The visualized FPR of three injection attacks at different positions is illustrated in Figure 13. Overall,

our system can fully resist malicious signals from various angles and distances, achieving an impressively low FPR of just 0.113%. In fact, with the distance increasing, the energy of injected signals dissipates, even missing partial high-frequency spectrums, unlike typical audio. As a result, despite the reduction in causal-produced chaos, the excessively attenuated spectrum also exposes its out-of-band characteristics. Furthermore, there is no apparent correlation between orientation and FPR. It demonstrates that orientation variations have a minimal impact on the performance of MicGuard.

5.4 Ablation Study

Impact of Prejudgment. To assess the influence of the prejudgment module, we devise two models: one without the prejudgment module (i.e., W/O Pre) and the other retaining it intact. Both of them have the same testing data from three injection attacks and training data. Regarding overhead time, the comparison experiments run on an Nvidia GeForce RTX 2080Ti with a batch size of 24 and are repeated for 800 trials to measure the average overhead time. As shown in Table 2, W/ Pre has a small 0.4% improvement in accuracy over the spoofing injection datasets. Please note, that a reduction from an average time of 91.2ms (W/O Pre) to 55.0ms for W/ Pre means 1.7 times in running time efficiency. In personal use and industrial inspection, this is a relevant and significant runtime reduction. Compared to the W/O Pre method, the designed prejudgment fleetly detects the carrier if injected signals are AM modulated on ultrasound and TTL modulation on laser with no need for arbitrary follow-ups, which will largely reduce the time complexity. Furthermore, we test the latency of MicGuard on smartphones. We transfer the pre-trained MicGuard model into the mobile model for Android and use the standard Android Studio and Pytorch [32] to deploy it on the HUAWEI P40 smartphone. The average overhead on the smartphone is 231.4ms.

Table 2: Ablation studies of the prejudgment. W/O Pre means the MicGuard system is stripped of prejudgment. W/ Pre means the MicGuard system with the prejudgment

Method	Accuracy		Overhead Time	
	Ultra+Laser	Ultra+EM	Ultra+Laser	Ultra+EM
W/O Pre	98.87%	98.76%	93.22ms	89.26ms
W/ Pre	99.32%	99.11%	49.28ms	60.70ms

Impact of Spectral Chaotic Maps. To investigate the effectiveness of the proposed spectral chaotic maps, we conduct several ablation experiments where the input is changed into phase spectrum, magnitude spectrum, and raw signal without processing. Furthermore, we measure the combination benefits of spectral chaotic maps and each component of our method. The detailed experimental settings are as follows:

- Phase+W/ Adaption, where the input to the memory-based detection model is phase spectrums of received audio of microphones and the detection model still maintains the feature adaption module (W/ Adaption).
- Magnitude+W/ Adaption, where the input is magnitude spectrums.
- Raw+W/ Adaption, where the input is raw time-domain signals.
- Chaotic+W/O Adaption, where the input is spectral chaotic spectrums to the detection model that does not include feature adaption.
- Chaotic+Resnet50, where the input is chaotic maps but the feature encoding network is ResNet50 instead of WideResNet50 in detection designs.
- Chaotic+EfficientNet, where the input is chaotic maps and the feature encoding network is EfficientNet network.
- Ours, where the input is chaotic maps and the original system design retains integrity.

These above models are fully pretrained on the LibriSpeech database and equally evaluated on the same dataset. Table 3 presents the distinct results of model settings on out-of-band injection detection. Firstly, take a look at the case of changing the input feature to the detection model. Only the chaotic map has high performance, while conversely, all of the other remaining features exhibit unsatisfactory. This is because those conventional features cannot capture the inherent commonalities belonging to the consequences of out-of-band injection. At this time, when feature adaption is not used, the system experiences a reduction in accuracy and FRR, in comparison to the Chaotic+ResNet50 and Ours. By inducing normal features to be clustered more discriminatively, the memory feature library stores characteristic distributions that closely resemble acoustic disorders, which considerably enhances the ability to distinguish abnormalities. Lastly, there remains a question as to whether WideResNet50, when used as a feature encoding network, excels in transfer learning compared to other networks. According to the results of ResNet50, EfficientNet, and ours, it can be seen that the network with low model complexities performs worse in transfer learning of injection detection. The WideResNet50 has more convolution filters to produce wider feature maps that broaden feature spaces, allowing fine-tuning of the model on a new dataset with different characteristics.

Table 3: Ablation studies of the spectral chaotic maps, feature adaption and feature encoding.

Method	Accuracy(%)	FPR(%)	FRR(%)
Phase+W/ Adaption	74.71	24.70	31.47
Magnitude+W/ Adaption	76.22	23.03	31.60
Raw+W/ Adaption	73.58	25.89	31.92
Chaotic+W/O Adaption	92.91	7.11	6.87
Chaotic+Resnet50	93.98	5.89	7.43
Chaotic+EfficientNet	92.41	7.53	8.19
Ours	99.37	0.60	0.90

6 Discussion

6.1 Defense Scope

MicGuard focuses on the out-of-band injection attacks targeting microphones, expanding the existing defenses against more attacks and ensuring broader application coverage. Nonetheless, taking into account the various attack methodologies and target devices, certain limitations and potential improvements require further discussion.

Attacking methodology. There also exist some attacks aimed at microphones: *1) In-band attack:* The easy-to-operate replay attack and mimicry attack have the possibility to bypass speaker recognition. Whereas the defense scope of MicGuard excludes in-band audio, replaying audio and mimicking pronunciation can be effective in evading detection. In order to extend the defense scope, an alternative approach is to concatenate an existing in-band detection model [26] subsequent to MicGuard. Those existing detections primarily identify whether the sound source is from a human being or not. However, in some cases, the sound source is more than just the human voice, such as industrial production lines and live outdoor broadcasts. Thus, researchers are encouraged to design a more comprehensive detection mechanism for various application scenarios. *2) Adversarial attack:* We envision that the adversary has full knowledge of MicGuard system designs. Grounded on data-driven approaches, the adversary utilizes adversarial training to craft adversarial samples that will be modulated on ultrasound, laser, and EM waves. However, launching such an adversarial attack would still fail in practice due to the out-of-band effects that inevitably leave disorganized patterns in the injected audio.

Targeted devices. Inspired by other passive sensors similar to microphones, the design ideas of MicGuard can be transferred into temperature sensors, humidity sensors, and infrared sensors that also encounter out-of-band threats. The application scenario of MicGuard is not limited to anomaly detection on microphones and has the potential to be expanded into equipment failure prediction and production process monitoring.

6.2 Comparative Analysis of Existing Defenses

Compared with out-of-band defenses. In comparison to existing defenses, as listed in Table 4, MicGuard stands out as a remarkable solution in the field of out-of-band injection mitigation from the following perspectives. 1) Hardware independent: MicGuard operates independently of extra hardware components and microphone conditions, unlike hardware-based defenses and microphone-array methods. This versatility makes it suitable for various levels of microphone-equipped devices, ranging from low-end sensors and live recorders to smart home devices. 2) No prior attack data required: Our system needs no prior attacking data, in contrast to some detection methods that rely on pre-collected attacking data to train learning models. Due to the labor-intensive process of gathering malicious data and its unpredictability, our system is more adaptable to real-world scenarios. 3) No target data required: Our system also does not require prior acquisition data of target devices. Instead, it relies on a pre-trained feature dataset sourced from an open-access audio database. This approach not only reduces deployment costs but also enhances user-friendliness. 4) Defense scope: Taking into account that the majority of prior defense research is restrictively focused on a single injection attack type, MicGuard exhibits a significantly more comprehensive defense capacity, encompassing a wide array of out-of-band injection attacks.

Compared with liveness detection. Liveness detection is another well-known defense against in-band injection attacks on microphones and ultrasound attacks [54]. This technique resiliently counters voice replay attacks [8] and speech adversarial attempts [1] by leveraging the inherent vitality distinction between human voices and the audio speaker required to play spoofing voices. The key difference between liveness detection and MicGuard is application scope. 1) Limited to in-band ranges: Due to its reliance on "living traits," liveness

detection is tailored for human voice recording scenarios such as voice interaction [43, 55]. Though MicGuard is adept at safeguarding both human and non-human audio recording, it is not designed to defend against in-band spoofing signals. Moreover, most liveness detections overlook out-of-band injections like laser and EM waves or, at most, take into account ultrasonic injections. 2) Requirement of hardware setup: some liveness detection methods rely on the extra hardware setup, such as microphone arrays [29], radars [24], IMU [17], and magnetometer [7], rendering them unsuitable for low-level microphone-based devices due to either impracticality or high costs. MicGuard offers a versatile solution applicable across sensors to high-level tablet computers without requiring additional specialized hardware. 3) Need for prior data: MicGuard operates without the necessity of collecting preceding original and attacking data from victim devices. In contrast, traditional liveness detection methodologies [3, 6, 48] still require gathering such prior data to delve into biometric features through deep learning-based training and effectively distinguish anomalies. Delving into the strengths and weaknesses of both MicGuard and liveness detection, there is an anticipation of their combined application to mitigate both in-band and out-of-band attacks. The straightforward way is to add the liveness detection after MicGuard, but this incurs additional costs in terms of overhead, data, and hardware setup. A more comprehensive fusion of the two systems requires identifying the correlation features that underlie in-band and out-of-band detection, and we will leave it to future work.

7 Related work

Given the increasing risk of out-of-band signals compromising microphones, ongoing research is dedicated to uncovering the vulnerabilities of microphones susceptible to out-of-band injection attacks and introducing mitigation strategies to ensure the resilience of microphones.

Out-of-band injection attacks on microphones. Regarding the medium of injected signals, out-of-band injection attacks on microphones can be categorized as *1) Ultrasound attacks, 2) Laser attacks, and 3) EM attacks*. 1) Ultrasound attacks first arose from the nonlinearity of microphones [35, 53], whereby microphones can interpret voice commands modulated in the high-frequency band of ultrasound. By optimizing the arrangement of ultrasonic speakers to transmit disparate frequency-band spectra of signals, Roy et al. can achieve a remote attacking distance of up to 25ft [36]. 2) Laser attacks can directly cause microphones' diaphragms to vibrate in response to the amplitude change of the injected laser, first proposed by Sugawara et al [39]. Some attackers replicate the laser attack through windows to target in-vehicle VCSs [46] by virtue of the long-range propagation and penetration of laser nature, like 110m. 3) EM attacks can induce electrical currents or voltages inside circuits of microphones due to coupling effects, leading to unwanted sampled data in the pipeline of the analog-to-digital converter [21, 23]. Previous EM attacks need to be in close proximity to microphones owing to their rapid attenuation. One straightforward way to extend attacking ranges is to employ power amplifiers [45]. Rather than resorting to direct injection techniques on microphones, attackers exploit EM interference to infiltrate televisions [49] or power chargers to inject commands [11] into VCSs without physical access.

Mitigating out-of-band injection attacks on microphones is crucial for maintaining the integrity and security of sensing systems. One line of defense strategies relies on microphone arrays [26, 52] to differentiate the forged ultrasonic signals by analyzing the variations in multichannel acoustic signals. Spectrum features are also regarded as a vital criterion for distinguishing between sound and abnormal ultrasonic signals [25]. Another avenue for mitigating ultrasonic interference is sensor fusion techniques [15, 16]. By assembling different information from multiple diverse sensors, the intelligent integrated system rectifies conflicts to avoid erroneous judgment. Moreover, He et al. turn to utilize ultrasonic speakers to actively nullify the pernicious effects of invading aggressive ultrasounds [18]. In the domain of defense against EM interferences, researchers tend to modify the original hardware [19, 41, 56] to detect aberrant analog signals caused by out-of-band EM interference. Most systems are only concerned with mitigating one type of injection attack, i.e., either ultrasonic or electromagnetic attack. Regrettably, the defense against laser attacks has been largely overlooked despite their potential risks and emerging prevalence. It highlights a critical gap in security measures and prompts the need for heightened attention and proactive countermeasures to deal with all possible out-of-band injection attacks. This paper designs MicGuard as an attempt to fill the gap, first detecting the aberration on microphones induced by all out-of-band injection attacks.

8 Conclusion

This study tries its best to fill the blank of defense against out-of-band injection attacks, including ultrasound, laser, and EM interferences. We unveil the common characteristics underlying these out-of-band injection phenomena and design a prejudgment and detection system to distinguish the anomaly. Without the dependency on prior data from targets and attacks, the carrier trace is set as the first criterion, and the quantified chaos derived from open-source datasets is incorporated into the memory-based model for ultimate detection. MicGuard is comprehensively evaluated on low-level to high-level microphone-based devices such as sensors, recording microphones, tablets, and smartphones. It demonstrates exceptional detection capabilities, achieving over 98% accuracy against out-of-band attacks even under aggressive conditions.

Abstract

Wireless charging is becoming an increasingly popular charging solution in portable electronic products for a more convenient and safer charging experience than conventional wired charging. However, our research identified new vulnerabilities in wireless charging systems, making them susceptible to intentional electromagnetic interference. These vulnerabilities facilitate a set of novel attack vectors, enabling adversaries to manipulate the charger and perform a series of attacks.

In this paper, we propose *VoltSchemer*, a set of innovative attacks that grant attackers control over commercial-off-the-shelf wireless chargers merely by modulating the voltage from the power supply. These attacks represent the first of its kind, exploiting voltage noises from the power supply to manipulate wireless chargers without necessitating any malicious modifications to the chargers themselves. The significant threats imposed by *VoltSchemer* are substantiated by three practical attacks, where a charger can be manipulated to: control voice assistants via inaudible voice commands, damage devices being charged through overcharging or overheating, and bypass Qi-standard specified foreign-object-detection mechanism to damage valuable items exposed to intense magnetic fields.

We demonstrate the effectiveness and practicality of the *VoltSchemer* attacks with successful attacks on 9 top-selling COTS wireless chargers. Furthermore, we discuss the security implications of our findings and suggest possible countermeasures to mitigate potential threats.

1 Introduction

Given the widespread use of mobile devices that require daily charging, ensuring their charging security has become critical. Numerous attacks have been explored to target the charging process through cables, allowing attackers to control devices, install malware, induce touch events, inject voice commands, and compromise user privacy [11, 13, 17, 20, 25]. Most attacks affect primarily wired charging systems because they exploit the vulnerability of data wires in USB charging cables to conduct unauthorized data transmission with malicious power sources. Wireless charging, however, not only offers more convenient charging experiences but also inherently resists many attacks commonly existing in wired charging systems.

Wireless charging uses near-field magnetic coupling for power transfer, eliminating the need for direct electrical connections to the charged device. This feature prevents malicious attackers from accessing the direct data pathway to the charged device, even if the power supply is compromised. Moreover, wireless power transfer processes are secured by enforcing adherence to the Qi standards developed by the Wireless Power Consortium (WPC) [24]. Qi standards incorporate robust safety mechanisms to protect both the charged device and other objects from potential damages imposed by the intense magnetic fields. The benefits of wireless charging, including enhanced security, simplified charging, extended device longevity, and reduced clutter, have led to its widespread adoption and ease of deployment. Consequently, in recent years, the wireless charging market has rapidly expanded at a compound annual growth rate (CAGR) of 25.8% [9]. Wireless chargers are now widely deployed in various public places such as airports, restaurants, hotels, and coffee shops.

However, despite their numerous benefits, our research identifies new, critical vulnerabilities that can be exploited to invalidate the security characteristics of wireless charging systems and launch powerful attacks. Specifically, the schemed voltage noises from the power adapter can propagate through the power cable and modulate the power signals on the charger's transmitter coil due to the effects of electromagnetic interference (EMI) on the charger. This process directly modifies the power signal used for power transfer, opening the door for potential breaches. Qi wireless charging relies on in-band communication, in which the charger and the device exchange essential Qi messages through the direct modulation of the power signal. Therefore, an attacker can potentially control this communication channel by injecting finely-tuned voltage noises, thereby gaining the ability to instruct the charger to execute various malicious tasks.

In this paper, we introduce *VoltSchemer* attacks that exploit the newly identified vulnerabilities. These attacks enable an attacker to **gain complete control over wireless chargers using intentional electromagnetic interference (IEMI) via the voltage supplied by a connected power source**. *VoltSchemer* can modulate the strong magnetic field generated by the charger based on power electronics and EMI principles. This manipulation enables attackers to control smartphones' voice assistants by inducing unintended voice commands in their microphone circuits through near-field magnetic coupling. In addition, *VoltSchemer* can deceive a connected wireless charger with fabricated Qi messages, instructing it to initiate hazardous power transfers. These harmful power transfers can potentially damage the charged device or other valuable items susceptible to intense magnetic fields. To further validate the effectiveness of the *VoltSchemer* attacks, we conducted an evaluation on 9 top-selling Commercial-Off-The-Shelf (COTS) wireless chargers. The results show that all the tested chargers are vulnerable to our *VoltSchemer* attacks, highlighting their broad risks and potential impacts.

To summarize, the main contributions of this paper are:

- Through a comprehensive examination of the Qi wireless charging design, we discovered new vulnerabilities in its design and protocol. These vulnerabilities allow an attacker to gain full control over the charger by merely manipulating the power supply.
- We developed *VoltSchemer*, a suite of novel attacks that capitalize on these newly identified vulnerabilities, utilizing an interposed voltage manipulator to interfere with the power adapter's output voltage. This allows potential attackers to commandeer the connected wireless chargers and engage in various harmful activities.
- We illustrated the potential threats of *VoltSchemer* via three attacks: voice assistant manipulation, wireless power toasting, and foreign object destruction.[1]
- We conducted extensive experiments for *VoltSchemer* attacks on popular COTS wireless chargers. Our findings showcase the real-world applicability and the significant threats that our attacks pose.
- We discussed the security implications of our findings and proposed countermeasures to mitigate these threats.

2 Background

2.1 Qi Wireless Charging

A Qi wireless charging system comprises three primary devices depicted in Figure 1: a power adapter, a wireless charger, and a charged device. The power adapter's main function is to supply DC voltage to the wireless charger via a power cable, such as a USB cable. The wireless charger, also known as the power transmitter (TX device), utilizes an inverter to convert the DC voltage from the power adapter into AC voltage on the TX coil. The microcontroller unit (MCU) in the charger controls the amplitude and frequency of this AC voltage, generating a strong alternating magnetic field known as the power signal in wireless charging systems. The charged device, or power receiver (RX device), captures this magnetic field through the RX coil, inducing an AC voltage. The RX device's rectifier then converts this AC voltage back into DC voltage and provides power to load.

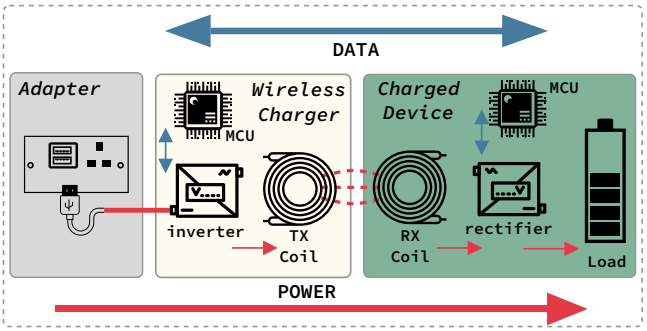

Figure 1: Overview of Wireless Charging System

One of the most significant distinctions between wireless and wired charging is the absence of physical electrical connections to the RX device during charging. A common vulnerability in wired charging is that electrical connections to a charged device can inadvertently allow malicious actors to gain unauthorized access to the charged device through the data wires in the charging cable [13, 20, 25]. Wireless charging effectively eliminates this direct data path introduced by physical connections. Therefore, an important **Security Characteristic (SC)** provided by wireless charging is:

SC 1: It eliminates physical connections to a charged device, thereby reducing its attack surfaces.

Qi wireless charging also features robust in-band communication, where RX and TX devices exchange data by modulating and demodulating power signals using different schemes. RX devices modulate power signals with Amplitude-Shift Keying (ASK) from the load side, while TX devices apply Frequency-Shift Keying (FSK) to modulate signals from the charger side. Numerous techniques are specified to ensure communication robustness. For instance, Qi wireless charging uses Biphase Mark Coding (BMC) for bit encoding, which is known for its resilience to interference. Additionally, error detection bits and checksum bytes are incorporated to ensure data integrity. The robust Qi communication is crucial for the Qi standards' key safety features, such as feedback charging control and foreign object detection, ensuring a safe charging process.

Feedback Charging Control During charging, a power re-

[1] Readers can view our practical attack scenarios and associated video clips by visiting https://sites.google.com/view/voltschemer/

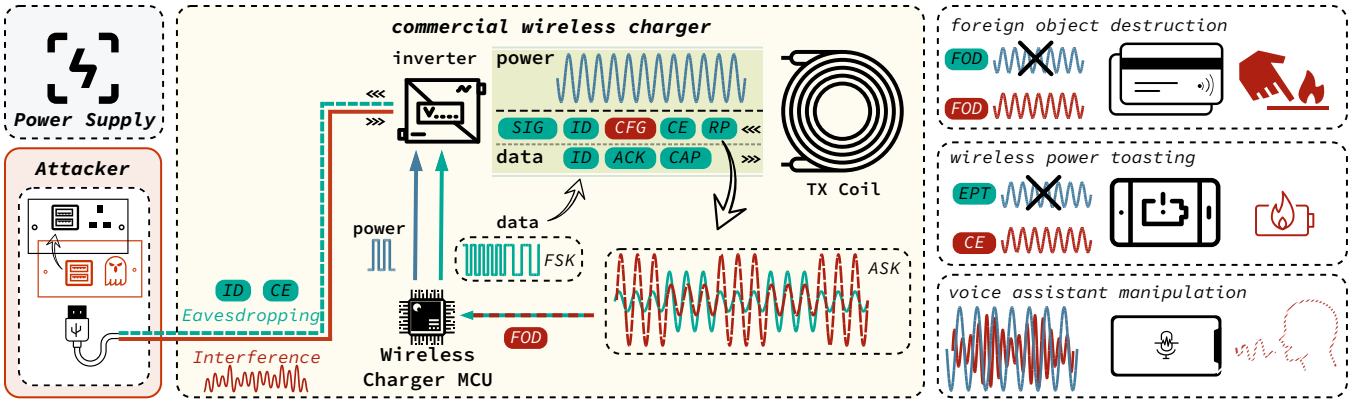

Figure 2: Attack overview: A victim uses Commercial-Off-The-Shelf Qi-compatible wireless chargers and power receivers. An intermediary-connected attacking device on the power adapter manipulates the output voltage and current to: 1) manipulate the magnetic field to interfere with the charged device. 2) interactively communicate with the charger and control the charging process. This setup enables foreign object destruction, wireless power toasting, and voice assistant manipulation attacks.

ceiver regularly sends Control Error (CE) packets to command the transmitter to adjust the charging power. In response, the transmitter feeds the CE value to a PID controller to update the controlling signal on the inverter. This feedback control is essential to guarantee the charging power is dynamically adjusted to meet the power receiver's needs. Furthermore, when the power receiver detects abnormal charging status or is fully charged, it sends the End Power Transfer (EPT) packet to command the transmitter to terminate the charging. Therefore, the second security characteristic provided by wireless charging is:

SC 2: It incorporates Qi communication-based feedback control to establish a safe charging process, thereby improving the longevity of charged devices.

Foreign Object Detection Qi standards define Foreign Object Detection (FOD) to avoid heating and damaging magnetic-field sensitive foreign objects exposed in the magnetic field, enhancing the charging safety. The FOD can be performed before and during the power transfer. Pre-power transfer is mandatory when the power receiver requests a high charging power using the extended power protocol. During this process, the power receiver sends a FOD packet containing the reference value of resonance properties to the transmitter. The transmitter compares this reference value with the value measured by itself to determine whether a foreign object is present. In-power transfer FOD is employed in both baseline and extended power protocols. During charging, the power receiver must update the transmitter with the Received Power (RP) packets. The power transmitter compares the transmitted power measured by itself with the reported power received by the power receiver to calculate the amount of unintended power transfer to foreign objects. If the difference exceeds a predefined threshold, the charger identifies it as unsafe and terminates the power transfer. Therefore, another security characteristic of wireless charging is:

SC 3: It specifies the FOD mechanism to restrict power transfer to foreign objects, thereby enhancing the safety and usability of wireless charging.

3 Threat Model and Attack Overviews

Our threat model and attack scenarios are depicted in Figure 2. We assume a commonly adopted threat model for charging attacks, where an adversary compromises the power adapter that supplies DC voltages to the wireless charging system. To achieve this, an attacker connects a disguised voltage manipulation device between the power adapter and wireless charger, inducing voltage fluctuations to manipulate the power signal via the EMI effect, enabling a series of attacks. We do not presuppose the necessity for attackers to interfere with data transmission lines in USB cables. The attacks are initiated when a victim unsuspectingly leaves a smartphone or metallic personal items near the charging area either for charging or non-charging purposes. The attacks listed below can invalidate all three security characteristics introduced in Section 2.

Attack Overviews

Attack 1: An attacker can modulate the high-power magnetic field to inject voice commands into charged smartphones and manipulate the voice assistants.

Attack 2: An attacker can intercept the communication between RX and TX devices to induce a hazardous charging process that impairs the charged device.

Attack 3: An attacker can initiate unsafe power transfer to metallic foreign objects in close proximity to cause irreversible damage.

4 Wireless Charging System Security Analysis

To understand why and how attacks can be carried out through the power cable of a wireless charging system, two critical questions must be answered: ❶ **How can interference impact a wireless charging system through its power cable, and in what ways?** ❷ **What detailed information regarding the status of a wireless charging system can be collected from the power cable?**

To answer these questions, we conducted a comprehensive analysis of the wireless charging system depicted in Figure 3. In Section 4.1, we examine how the schemed voltage interference at the power adapter's output propagates in the systems and impacts the transmitted power signal of the system. In Section 4.2, we explore how the workload behavior-induced signals propagate back to the power adapter's output and impact the output voltage.

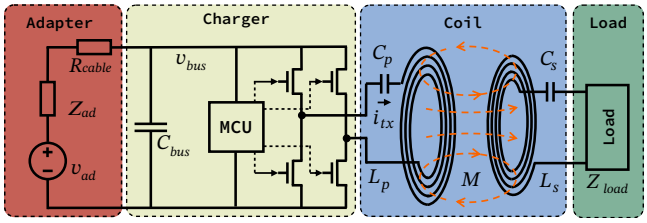

Figure 3: The schematic of a wireless charging system

4.1 Adapter-to-Load Propagation

A regular wireless charging system follows electromagnetic compatibility and power electronics principles: ensuring that the noise from a power supply, a power adapter in this case, does not disrupt the system's normal power conversion. However, the in-band communications employed in Qi wireless charging systems may encounter a different story. This section analyzes how an interference signal at the output of a power adapter affects the in-band communication, which is realized by modulating power signal transferred to the charging receiver via the couplings between the coils. We consider a scenario where the output voltage v_{ad}, as defined in Equation 1, of an interfered power adapter is composed of the nominal DC output voltage V_{ad} superimposed by a noise with an interference depth m_i and frequency f_i,

$$v_{ad}(t) = V_{ad}(1 + m_i sin(2\pi f_i t)), \tag{1}$$

Because of large number of electronic components, including multiple non-linear components such as time-variant loads, analyzing the impact of noise on wireless charging power in such a complex wireless charging system is challenging. To perform a precise yet manageable analysis, we introduce rational simplifications based on electrical principles and the significance of components' impacts. For this analysis, the workload is assumed to remain in a steady state, effectively modeled as a constant resistor R_{eq}. The system is segmented into three parts for sequential analysis of interference's impacts. Part 1 (Figure 4) examines the impact of the changes of v_{ad} at the power adapter's output on v_{bus}, the DC input of the inverter. Part 2 (Figure 5) explores how v_{bus} impacts the AC voltage v_{tx} across the resonant capacitor C_p and TX coil at the output of the inverter. Part 3 (Figure 6) models the influence of the inverter's output AC voltage v_{tx} on the current i_{tx} in the TX coil, which directly reflects the power signal's property.

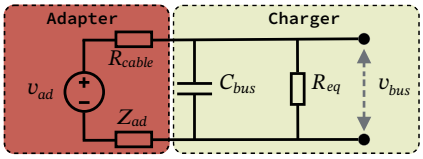

Figure 4: Circuit model to analyze the impact of power adapter's output voltage v_{ad} on bus voltage v_{bus}

Part 1: Transfer function from the adapter to the charger The influence of power adapter output voltage v_{ad} on bus voltage v_{bus} can be analyzed based on the model in Figure 4. The bus voltage v_{bus} that drives the inverter is a function of the power adapter's Thevenin equivalent output voltage source v_{ad}, Thevenin equivalent impedance Z_{ad}, cable resistance R_{cable}, bus decoupling capacitor C_{bus}, and the equivalent load resistance R_{eq}. Given the interfered power adapter's output voltage v_{ad} in Equation 1, the disrupted voltage v_{bus} can be derived from Figure 4 as in Equation 2 [2]. In Equation 2, v_{bus} is composed of a periodic noise with frequency f_i and amplitude Km_iV_{bus} superimposing on a DC component V_{bus}. K is a voltage scaling factor dependent on the impedance of the model in Figure 4.

$$\begin{aligned} v_{bus}(t) &= V_{bus}(1 + Km_i \sin(2\pi f_i t)) \\ V_{bus} &= \frac{R_{eq}}{R_{eq} + R_{cable} + Z_{ad}} V_{ad} \\ K &= \frac{R_{eq} + R_{cable}}{|R_{eq} + R_{cable} + Z_{ad} + j2\pi f_i R_{eq}(R_{cable} + Z_{ad})C_{bus}|} \end{aligned} \tag{2}$$

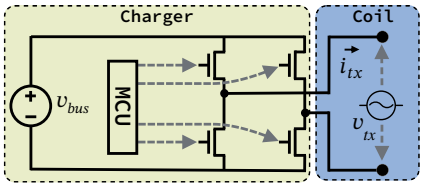

Figure 5: DC-AC inverter schematic

Part 2: Transfer function from the charger to the resonant tank The circuit of the inverter is shown in Figure 5. The

[2] In the equations presented in this paper, we use "$|x|$" to represent the magnitude of a complex number x.

inverter's primary role is to convert v_{bus} into AC voltage v_{tx} across the resonant capacitor C_p and TX coil, thereby creating the alternating magnetic field from the TX coil for power transmission. The inverter's operation is controlled by the MCU through two parameters: the pulse width modulation (PWM) signal with duty cycle D, and the power signal frequency, f_p. The output of the inverter is a staircase waveform as shown in the Appendix B. It is fed into the resonance tank, C_p and the TX coil. The harmonics of the staircase waveform outside of the bandwidth of the resonant tank are filtered out, leaving a sinusoidal signal with a frequency equal or close to the resonant frequency of the tank. As such, the output voltage of the inverter, v_{tx}, is derived in Equation 3, with the derivation process detailed in Appendix B. With steady-state workload, the primary factor influencing v_{tx} is v_{bus}, which determines the amplitude of v_{tx}.

$$v_{tx}(t) = \frac{4}{\pi}\sin\left(\frac{\pi}{2}D\right)v_{bus}\sin(2\pi f_p t) \tag{3}$$

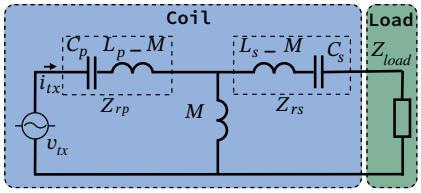

Figure 6: Circuit model for wireless power transfer analysis

Part 3: Wireless Power Transfer The wireless power transfer section in Figure 3 can be modeled in Figure 6. The v_{tx} drives the TX coil, generating an alternating magnetic field and transferring power to the receiver. Based on the model, the current i_{tx} in the TX coil can be calculated in Equation4 [3]. The equivalent impedance Z_{total} is a function of the load, coupling conditions, and power signal frequency. Given that the load, coupling conditions, and power signal frequency remain constant during this analysis, v_{tx} is the primary influential factor of the TX coil current.

$$\begin{aligned} i_{tx} = \frac{v_{tx}}{Z_{total}},\ Z_{total} &= (Z_{load} + Z_{rs}) \parallel (j2\pi f_p)M + Z_{rp} \\ \text{where} \quad Z_{rp} &= \frac{1}{j2\pi f_p C_p} + j2\pi f_p \cdot (L_p - M) \\ Z_{rs} &= \frac{1}{j2\pi f_p C_s} + j2\pi f_p \cdot (L_s - M) \end{aligned} \tag{4}$$

Analysis Results From Equations 2,3, and 4, the TX coil current, i_{tx}, can be derived in Equation 5. From Equation 5, the schemed voltage noise on v_{ad} in Equation 1 impacts i_{tx} in the TX coil by modulating its amplitude. Because the Z_{total} is a complex number, a phase difference ϕ_{total} exists between i_{tx} and v_{tx}. The carrier signal amplitude I_{tx} is determined by duty cycle D. The modulation depth m is proportional to the interference depth m_i and the voltage scaling factor K.

$$\begin{aligned} i_{tx}(t) &= I_{tx}(1 + m\sin(2\pi f_i t))\sin(2\pi f_p t + \phi_{total}) \\ \text{where } I_{tx} &= \frac{4V_{bus}\sin\left(\frac{\pi}{2}D\right)}{\pi|Z_{total}|}, m = Km_i \end{aligned} \tag{5}$$

In Equation 2, K can be approximately estimated using typical values of $R_{eq}(5\Omega)$, $R_{cable}(0.1\Omega)$, $C_{bus}(50\mu F)$. For the interference frequencies at 1 kHz, 10 kHz, and 100 kHz, the estimated voltage scaling factor K are 0.99, 0.95, and 0.30.

Conclusion Existing wireless charging systems effectively attenuate high-frequency interference but are less effective against low-frequency interference. Therefore, low-frequency interference from the power adapter can easily propagate to the TX coil and modulate the power signal's amplitude with a modulation depth close to the interference depth.

4.2 Load-to-Adapter Propagation

An ideal power adapter is supposed to provide a constant DC voltage with minimal fluctuation, regardless of the workload behaviors. However, a real-world power adapter's output is inevitably affected by workload behaviors mainly due to the limitations of switching regulator's close-loop bandwidth and phase margin. This section analyzes specific workload behaviors that lead to measurable information leaks in the power adapter's output based on the circuit model shown in Figure 7.

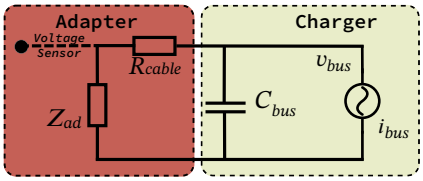

Figure 7: Circuit model used to analyze the impact of workload on the adapter's output voltage noise

The impact of workload behavior on the power adapter's output voltage noise can be analyzed by modeling the workload as an equivalent load current source i_{bus} in parallel with an equivalent impedance based on the Norton's Theorem. Since this impedance is much bigger than that of C_{bus}, it is ignored in Figure 7. Based on the analysis in Section 4.1, i_{bus} can be derived using v_{bus}, v_{tx}, and i_{tx} per Equation 6. It is composed of a DC component $I_{bus,dc}$ and an AC current $I_{bus,ac}$, which has a frequency of $2f_p$ with an amplitude proportional to $I_{bus,dc}$.

$$\begin{aligned} i_{bus}(t) &= \frac{v_{tx}i_{tx}}{V_{bus}} = I_{bus,dc} + I_{bus,ac}cos(4\pi f_p t + \phi_{total}) \\ I_{bus,dc} &= \frac{2I_{tx}sin(\frac{\pi}{2}D)cos\phi_{total}}{\pi}, I_{bus,ac} = \frac{I_{bus,dc}}{cos\phi_{total}} \end{aligned} \tag{6}$$

[3] In this paper, the "||" symbol denotes the equivalent impedance of two parallel-connected components.

In Equation 6, $I_{bus,dc}$ is a function of time. It is almost constant within one switching period of the inverter but varies as the load current i_{tx} changes, which has much lower frequencies than that of the inverter. In a wireless charging system, we identify two workload behaviors that cause measurable signals on the output of the adapter. The first one is the AC current caused by the inverter's switching behaviors at the frequency of $2f_p$. The other is the abrupt load-change behavior. These behaviors are analyzed individually to understand their specific impacts on the power adapter's output voltage.

Inverter-switching Induced Signal According to Equation 6, an AC component of frequency $2f_p$ is present in the bus current, where f_p is the power signal frequency controlled by the charger's MCU, typically around 140 kHz. The voltage changes at the output of the power adapter, denoted as ΔV_{ad}, can be expressed as Equation 7. With typical values of $I_{bus,dc}$(1A), f_p(140 kHz), Z_{ad}(10 mΩ), C_{bus}(50 μF), R_{cable} (0.1 Ω), and ϕ_{total} (70°), the amplitude of ΔV_{ad} can be estimated as $\sim$ 10 mV.

$$\Delta V_{ad}(t) = \frac{Z_{ad} I_{bus,dc} \cos(4\pi f_p t + \phi_{total})}{cos\phi_{total}(1 + j4\pi f_p C_{bus}(R_{cable} + Z_{ad}))} \quad (7)$$

Load-change Induced Signal Based on Equation 6, a load change, in other words, a change in i_{tx}, also leads to the change of the load current $I_{bus,dc}$ in Figure 7. From Equation 7, the load change will lead to the voltage change ΔV_{ad} at the output of the power adapter. Because of this, the load changes are detectable from ΔV_{ad}. But as the power adapter tends to minimize Z_{ad} with its high feedback control loop gain at low frequencies, the low-frequency spectrum of the ΔV_{ad} is attenuated. Only the high-frequency spectrum of the ΔV_{ad} due to the change of i_{bus} remain. As a result, for an abrupt load change, which is characterized with high high-frequency spectrum, the transient voltage deviated from the nominal voltage will be observed in the output voltage, and it will rapidly settle down to its steady state value due to the adapter's close-loop feedback control. This results in a series of pulse signals including the load information. This effect can be approximated as the effect of a convolution filter $\delta'(t)$. For a typical design, these pulses usually have small amplitudes, so they do not interfere with the normal operation of the power adapter.

Conclusion Voltage at the output of a power adapter contains the following workload behavior information signals: the timing of load change and the frequency at which the wireless power is transferred. Since ΔV_{ad} has a small amplitude it does not affect the functionality of a power adapter. The signals in ΔV_{ad} are also partially masked by other voltage noise, making them not immediately distinguishable in the raw data. However, understanding the generation and characteristics of these signals enables us to develop specialized signal processing techniques. These techniques can exploit the signals' unique features to successfully extract the embedded information.

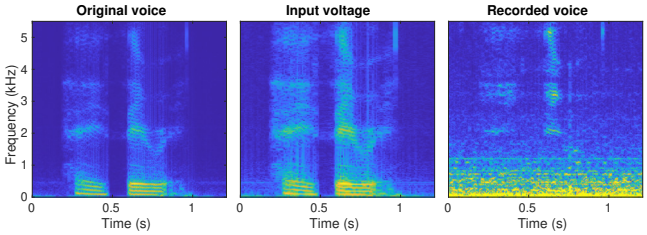
5 Preliminary Attack Vectors

Through comprehensive analysis, the two questions raised in Section 4 have been answered, yielding two essential insights concerning a wireless charging system:

Insights

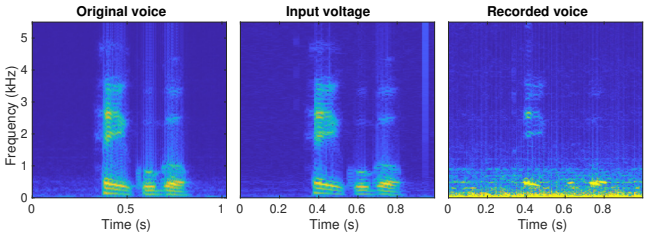
Insight 1: The manipulated low-frequency signals at the output of the power adapter can propagate to the TX coil and modulate the power signal with limited attenuation and distortions.

Insight 2: Information such as frequency, timing and amplitude of both the inverter switching and charging load change is reflected by the voltage noise at the output of the power adapter.



This section showcases three practical attacks derived from our insights. We cover exploiting voice signal induction in charging smartphones (Section 5.1), injecting malicious Qi messages to alter charging control (Section 5.2), and recovering communication messages through voltage noise analysis (Section 5.3).

5.1 Attack Vector 1: Voice Injection



This section introduces our first practical attack vector, which is injecting voice signals into the charged smartphones. The most significant information in typical voice signals is in the frequency band below 10 kHz [15]. Therefore, according to **Insight 1**, when a voice signal is added to the power adapter's output voltage, it can modulate the power signal at the TX coil with limited attenuation and distortions. A recent study [6] has demonstrated that an AM-modulated magnetic field can cause magnetic-induced sound (MIS) in the microphone circuits of modern smartphones through magnetic couplings. Thus, by adding voice signals to the power adapter's output, we will be able to inject voice signals into the charged smartphones exposed to this intense magnetic field. To validate this sound-inducing mechanism, we conducted tests on an iPhone SE and a Pixel 3 XL with a Renesas P9242-R-EVK wireless charger. In these tests, we recorded the activation commands of these two smartphone assistants spoken by their owners. When the iPhone SE is under charging, the waveform of "Hey Siri" is added to the supply voltage, and a recording application on the smartphone is activated to capture any potential audio signals. Similarly, for the Pixel 3 XL, the test involves adding the waveform of "Hey Google" to the supply voltage and recording any resulting audio signals. The recording process takes place in a normal office environment with a reasonable level of background noise.

Figure 8 compares the spectrograms of the original voice signal, the adapter's interfered output voltage signal, and the

signal captured by the microphone during charging. It is evident from the spectrograms that some features of the original sound signal are recognizable in the MIS. However, the signal-to-noise ratio (SNR) of the MIS is affected by a couple of key factors. First, when the intensity of the resulting sound is weak, some patterns are overwhelmed by background noise. To counter this, we can increase the interference depth m_i to enhance the SNR. Secondly, although the analysis in Section 4 demonstrates limited attenuation for low-frequency signals, different frequency components of the original voice signals are still subject to different attenuation. This unequal attenuation across the frequency band can distort the signal waveform and result in the loss of audio features.

(a) Spectrograms of "Hey Siri"

(b) Spectrograms of "Hey Google"

Figure 8: Spectrograms of signals collected during injecting MIS to smartphones

A security implication of this attack vector is that an attacker may exploit this mechanism to inject voice commands and control the voice assistants in the charged smartphones. The voice assistants will likely recognize a considerable amount of features preserved in the MIS and execute the commands.

5.2 Attack Vector 2: Qi Message Injection

In this section, we explore the attack vector of injecting ASK-modulated Qi messages into the communication channels between RX and TX devices. During charging, the RX device modulates the power signal at a frequency of approximately 2 kHz. As per **Insight 1**, an interference signal around this frequency at the output of the power adapter can modulate the power signal with small attenuation. Therefore, it is feasible to inject synthesized ASK modulation signals, which strictly adhere to Qi communication protocols, into the output of the power adapter to deceive the TX device.

To demonstrate this capability, we used a Renesas P9242-R-EVK wireless charger to charge an iPhone SE. We injected fake `CE` packets into the power adapter's output voltage to decive the charger. The charger adjusted its charging power as directed by the fake commands. The results are displayed in Figure 9, where the voltage trace shows three different `CE` messages, `CE`(-128), `CE`(0), and `CE`(+112), inserted at timestamps t_0, t_1, and t_2, respectively. The power trace correlates the output power changes with the respective `CE` values, confirming that the charging power was manipulated as expected.

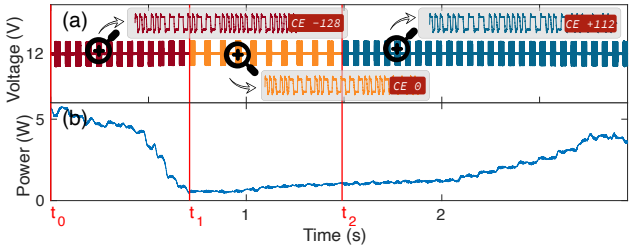


Figure 9: Inject `CE` packets to manipulate the charging power. (a) Input voltage with injected `CE` packets. (b) Charging power affected by the injected packets

A security implication of this attack vector is that it provides the attacker with a communication channel to send malicious messages to chargers. Injecting interference at the ASK modulation frequency into the power adapter's output can disrupt the genuine packets sent from RX devices and hijack the in-band communication. When the Qi communication is compromised, many charging safety mechanisms that heavily rely on this communication can be invalidated as well. An attacker can exploit this attack vector to induce hazardous charging processes that could severely damage the charged devices.

5.3 Attack Vector 3: Qi Message Eavesdropping

This section investigates the attack vector that enables an attacker to recover Qi messages using the voltage trace measured at the power adapter's output. As introduced in Section 2, the RX and TX devices modulate the power signal using ASK and FSK modulations, which impact the power signal by shifting the load and altering the power signal frequency, respectively. According to **Insight 2**, the load power modulation will lead to measurable signals at the power adapter's output. However, such information may not be directly visible in the measured raw traces due to the low intensity of these signals. Specialized signal processing techniques that target these signal features are necessary to extract this information. In the remaining part of this section, we present our methodologies for processing the signal to recover messages using ASK and FSK modulations. A voltage trace captured

at the beginning of the charging initiation process between a Renesas P9242-R-EVK wireless charger and an iPhone SE will be used to demonstrate these methodologies.

ASK Modulation Eavesdropping Analysis in Section 4.2 indicates that the effect of a load transition on the charged device on the power adapter's output voltage can be represented by being filtered with a convolution filter $\delta'(t)$. Therefore, to recover the waveform of the ASK modulation signal, we introduce the convolution kernel $h_1(t)$ in Equation 8. $h_1(t)$ is a triangle pulse smoothing filter designed to counteract the effects of the equivalent filter $\delta'(t)$. The combined result forms a matched filter that detects transitions between `LOW` and `HIGH` at the frequency of f_{ASK}. Given that BMC encoding schemes are used for bit encoding, a significant feature for distinguishing the transmission of `ZERO` and `ONE` is the phase shift pattern of the signal at frequency f_{ASK}. Based on this characteristic, we further employ the filter $h_2(t)$ in Equation 8 to enhance such phase shift patterns for the signals with frequency f_{ASK}.

$$
\begin{aligned}
h_1(t) &= 1 - f_{ASK}|t|, \; -\frac{1}{f_{ASK}} \le t \le \frac{1}{f_{ASK}} \\
h_2(t) &= \delta(t - \frac{1}{2f_{ASK}}) - \delta(t + \frac{1}{2f_{ASK}})
\end{aligned}
\tag{8}
$$

The effectiveness of these filters is demonstrated in Figure 10. While some pulses are visible in the raw trace, the modulating pattern is unclear. After filtering, we can effectively recover the signals with clear ASK modulation patterns, which can be further decoded into the binary `HIGH-LOW` sequence. For this specific example, we recover a `SIG` packet with the value 0x84 after decoding. Using the same technique, we can also recover other data packets sent by the power receiver, such as `ID`, `CFG`, `FOD`, `GRQ`, `SRQ`, `RP`, `CE`, etc.

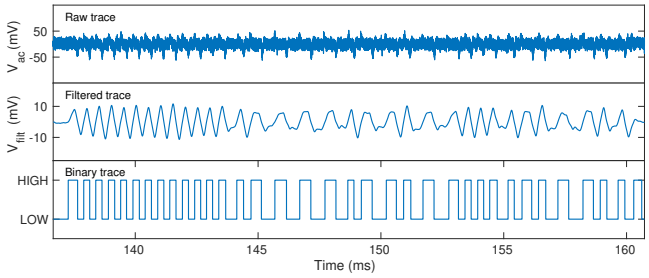

Figure 10: ASK modulation recovery

FSK Modulation Eavesdropping Analysis in Section 4.2 indicates that a weak signal at the frequency of $2f_p$ can be measured at the power adapter's output. With the TX device using FSK modulation to transmit data by altering the power signal frequency f_p, an attacker can track the frequency changes to recover modulation signals. To extract these frequency-domain features, we perform a discrete Fourier transform (DFT) on the measured raw voltage trace and analyze the spectrogram. As the results in Figure 11 show, while no features are visible in the time domain trace, distinctive patterns exist in the frequency domain. When f_p is around 140 kHz, frequency-switching patterns near 280 kHz are clear. In this case, we can decode the derived binary sequence to recover an `ID` packet, which discloses the charger's identification.

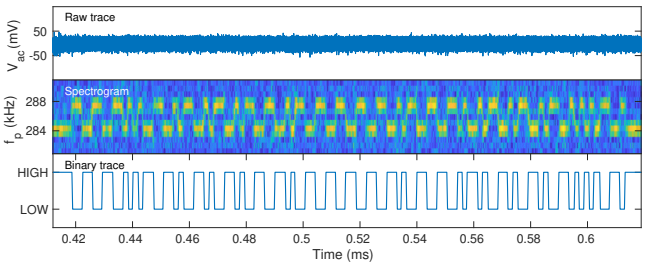

Figure 11: FSK modulation recovery

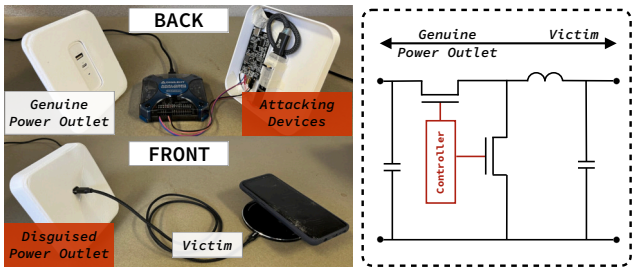
This attack vector reveals several security concerns. Initially, it exposes that normal charging processes unintentionally leak charger and device models, allowing attackers to profile and target specific devices. Furthermore, combining eavesdropping on and injecting Qi messages grants attackers the ability to simulate a legitimate receiving device's behavior. This deception could lead the charger to initiate power transfer under hazardous conditions, all achievable with mere access to the power adapter, indicating a significant threat to wireless charging security.

6 Practical Attacks Implementation



This section outlines conducting three practical attacks detailed in Section 5. It includes a setup for these attacks (Section 6.1), a method to manipulate voice assistants via injected commands (Section 6.2), a wireless power toasting attack causing charger-induced device damage (Section 6.3), and a foreign object destruction attack misleading the charger to damage non-targeted objects (Section 6.4).

6.1 Experimental Setup

In Figure 12a, we show a practical attacking setup that can be easily found in real-life scenarios. The attacker employs a disguised power port, which appears to be a regular USB-C port from the front but conceals a USB-C plug at the back. Behind this facade lies an attacker-controlled voltage manipulator connected between the power pins of the two USB-C connectors. As illustrated in Figure 12b, this manipulator alters the switching patterns of two MOSFETs to superimpose the manipulated AC voltage fluctuations onto the DC voltage.

In our experiment, we used the Analog Discovery 2 (AD2) as a controller to process the measured output and generate signals to control the injected noise waveform and intensity. For

mass production, this prototype can be significantly miniaturized by substituting AD2 with a compact controller chip, akin to the size depicted in Appendix A. Installation of this device only requires simply plugging it into a COTS power adapter's power port and replacing its functionality. Given the uniform function of power adapters to supply DC voltage, this method is universally applicable to all COTS power adapters. We tested Apple, Google, and Amazon power adapters to verify our ability to inject configurable voltage noise with specific m_i and f_i values. We show wireless chargers connected to this disguised power port are vulnerable to various attacks. The efficacy and practicality of *VoltSchemer* are validated through evaluations on 9 popular wireless chargers listed in Table 1, featuring a range of manufacturers and power ratings.

6.2 Voice Assistant Manipulation

As discussed in Section 5.1, by interfering with the supply voltage of the wireless charger, voice signals can be induced in the microphone of a charged smartphone. This section shows how this method can be used to manipulate voice assistants, which are widely used in modern smartphones. To assess the practical impact of this voice assistant manipulation attack, we focus on two key aspects. First, we measure the maximum distance between the charger and the smartphone at which the attack remains effective. Additionally, to confirm the attack's versatility in controlling voice assistants, we test it with a range of commonly used voice commands.

6.2.1 Attack Evaluations

We evaluated nine COTS wireless chargers, as listed in Table 1, using two smartphones: the iPhone SE and the Pixel 3 XL. The iPhone SE, manufactured by Apple, utilizes the iOS system and employs Siri as its voice assistant. The Pixel 3 XL, manufactured by Google, operates on the Android system and employs Google Assistant. Leveraging **Attack Vector 3**, the manufacturer information of the targeted smartphone can be procured from the eavesdropped `ID` packet sent by it.

Evaluations of Attacking Distance Because Qi Wireless charging requires precise alignment between TX and RX coils for stable power transfer, the maximum measurable attacking distance is limited to $\sim$ 3 cm. Beyond this distance, the charging process is terminated. To facilitate evaluations of longer attack distances, we placed a Renesas P9221-R power receiver on the charging pad to keep the wireless charger running even when the smartphone is moved out of the charging range, ensuring consistent power transfer during the evaluation. We introduced interference using the voice assistant activation commands "Hey Siri" and "Hey Google" to target the voice assistants of the iPhone SE and Pixel 3 XL, respectively. The interference depth is fixed at 0.3, which is the minimal level sufficient to activate all voice assistants without disrupting power transfer. We measured the maximum distances at which voice assistants can be successfully activated by placing the smartphone at different distances from the charging pads.

The evaluation results in Figure 13 indicate that although successful attacks have different maximum attacking distances from 3 cm to 10 cm between the chargers and the smartphones for different wireless chargers, the maximum distance is not smaller than the 3 cm wireless charging range limited by the misalignment constraint in Qi standard, therefore, the voice assistant manipulation attacks can always be successfully conducted to the charged smartphones.

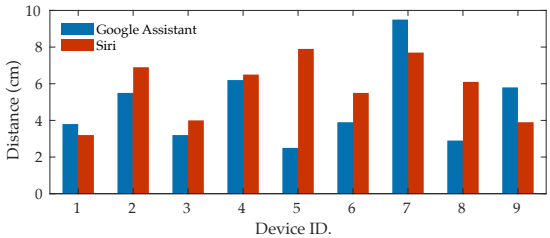

Figure 13: Maximum attacking distance

Evaluations of Voice Commands We evaluated six frequently used voice commands on the iPhone SE and Pixel 3 XL to assess the effectiveness of injecting different voice commands across various wireless chargers and smartphones. These commands are designed to prompt specific actions with the voice assistant, including activating the assistant, initiating a phone call, browsing a website, launching an app, using the

speaker, and controlling the camera. The system's resilience to a voice assistant manipulation attack depends on many factors, including the electrical characteristics of the system, the features of the voice signals, and the algorithms of the voice assistants. To launch a successful attack on a more resilient system, a higher interference depth m_i is required to induce a stronger voice signal. Meanwhile, an excessively high interference depth m_i may intermittently disrupt the charging process and compromise the stealthiness of the attack. For instance, we observed that intermittent charging interruptions start occurring when m_i exceeds 0.35 and become more frequent when m_i surpasses 0.5. Therefore, our evaluations aim to identify the minimum interference depth m_i required for successful command injection. Lower m_i means more efficient and stealthier attacks. We increased the interference depth by a 0.005 step from 0 to measure this threshold precisely.

ID.	Google Assistant						Siri					
1	0.14	0.08	0.06	0.06	0.06	0.06	0.18	0.08	0.29	0.16	0.14	0.35

: Hey Siri/Google, : Call Alice, : Go to google.com, : Open Amazon, : Play music, : Take a selfie

Figure 14: Required interference depth of successful command injection to Siri (iPhone) and Google Assistant (Pixel)

The results in Figure 14 demonstrate how effective this attack is on various devices and voice commands. 105 of 108 voice commands can be successfully injected at interference levels lower than 0.35. Only 3 of 108 injections require an interference depth between 0.35 and 5. This shows the efficacy and feasibility of our voice assistant manipulation attacks.

6.3 Wireless Power Toasting

As demonstrated in Section 5.2, injecting interference with ASK modulation patterns into the supply voltage enables an attacker to manipulate the charging control. This section illustrates how this capability can be used to launch a wireless power toasting attack, potentially damaging the charged smartphones through overcharging and overheating. Vendor documentation indicates that modern smartphones typically incorporate multiple techniques to mitigate risks associated with overcharging and overheating [7, 8]. Therefore, a strategic approach is necessary to circumvent these protection measures. Smartphones typically adopt three protection measures: *P1* - terminating charging, *P2* - shutting down all apps and disabling user interaction, and *P3* - initiating an emergency shutdown. While *P2* and *P3* focus on reducing heat generation within the smartphone itself, *P1* poses a direct challenge to the attack. This protection involves two actions: commanding the charger to stop power transmission by sending an `EPT` message and deactivating the smartphone's power receiving module. The charger may cease power transmission either immediately upon receiving an `EPT` message or, alternatively, due to a loss of communication if it fails to receive regular `CE` and `RP` packets from the smartphone.

Thus, besides increasing charging power with `CE` packets, we developed a strategy fulfilling two additional critical requirements to execute the wireless power toasting attack: ❶ Inject interference to disrupt legitimate Qi messages from the smartphone to prevent charging termination triggered by `EPT` packets. ❷ Continuously inject `CE` and `RP` packets regularly to sustain the Qi communication with a charger, even after the smartphone's power receiving module is deactivated.

6.3.1 Attack Evaluations

To evaluate whether the wireless power-toasting attack can succeed even with the protection measures employed in smartphones, we conducted experiments using a Samsung Galaxy S8 smartphone [4]. Upon injecting `CE` packets to increase power, the temperature rapidly rose. Shortly after, the phone tried to halt power transfer (*P1*) by transmitting `EPT` packets due to overheating, but the voltage interference introduced by our voltage manipulator corrupted these, making the charger unresponsive. Misled by false `CE` and `RP` packets, the charger kept transferring power, further raising the temperature. The phone further activated more protective measures: closing apps and limiting user interaction (*P2*) at 126 F° and initiating emergency shutdown (*P3*) at 170 F°. Still, power transfer continued, maintaining a dangerously high temperature, stabilizing at 178 F° as per Figure 15. The actual core temperature inside the phone often surpasses the surface temperature.

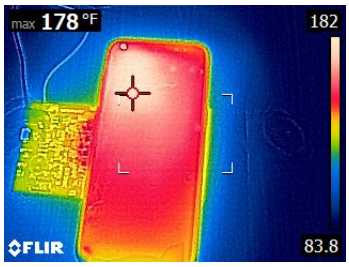

Figure 15: Thermal image of the overheated phone

In experiments conducted on all evaluated chargers, we recorded the maximum charging power and highest tempera-

[4] A different smartphone was used for potentially destructive experiments.

ture each charger could induce on a smartphone, and checked the activation of three thermal protection measures, *P1*, *P2*, and *P3*. Using a thermal camera and battery health monitor app, we monitored the surface and core battery temperatures on the phone. The measured core temperature using the app stopped at 131 F° due to the activation of *P2*, although the actual temperature continuously increased far beyond that. The recorded surface temperature with the thermal camera reaches as high as 179 F°. As detailed in the results from Table 2, our results reveal concerning findings. All compromised chargers pushed the phone's temperature beyond its specified working temperature (95F°). High-power chargers caused even more thermal stress. All tested chargers, when compromised, can trigger the power receiving termination protection measure. High power chargers (~10W) can force the phone into the second thermal protection mode, restricting user interactions. In the worst scenarios, ~15W chargers can force smartphones to shutdown due to excessive heat. Such persistent overheating attack presents a much higher risk than typical phone-generated overheating, potentially causing battery failure or explosion.

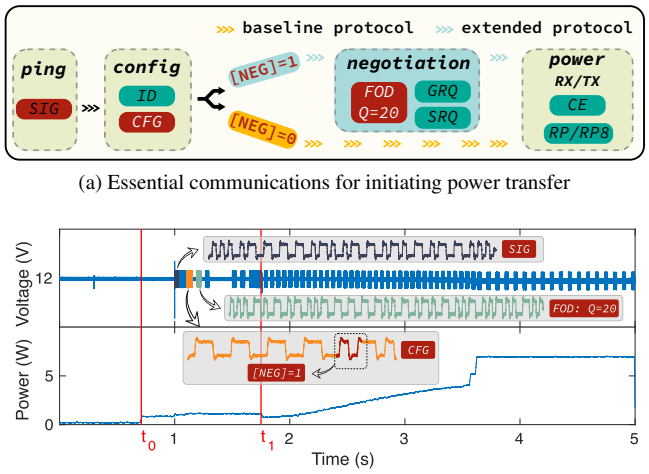

Table 2: Charging Power Manipulation Range

ID.	*P1*	*P2*	*P3*	Core Temp (°F)	Surf Temp (°F)	PWR (W)

5	✓	✓	✗	131+	126	7.6
6	✓	✓	✗	131+	126	9.2
7	✓	✓	✓	131+	179	18
8	✓	✓	✓	131+	173	17
9	✓	✓	✗	131+	149	13.2

6.4 Foreign Object Destruction

Leveraging **Attack Vector 2** and **Attack Vector 3**, an attacker can inject and receive Qi communication packets, thus enabling interactive communication with the wireless charger and mimicking a legitimate RX device. This capability allows an attacker to manipulate the charger into transferring power even without actual RX devices present. This section demonstrates the foreign object destruction attack, where the charger is controlled to damage foreign objects by transferring power to them and causing excessively high temperatures.

Through an in-depth analysis of the Qi wireless charging protocol, we identified critical steps to initiate power transfer to foreign objects. The procedure is detailed in Figure 16a, and its practical implementation is demonstrated in Figure 16b, which shows the interfered voltage and output power traces during the manipulation of a charger to transmit power to a metal foil. The process involves three key stages: **`ping`**, **`configuration`**, and **`negotiation`**. In the **`ping`** stage, starting at t_0, the charger applies a power signal and awaits a response. We must respond with a `SIG` packet within the required timeframe to proceed to the **`configuration`** stage. Here, a fabricated device ID is sent to the charger, and the power protocol is selected by setting the `NEG` bit in the `CFG` packet. To ensure higher charging power, the extended protocol is selected by setting `NEG` to 1 and proceeding to the **`negotiation`** stage. Otherwise, the charger defaults to the baseline protocol with a maximum charging power of 5W. During **`negotiation`**, a key step is injecting a `FOD` packet with a low reference Q-factor. This strategy exploits the charger's FOD check mechanism, which compares the measured Q-factor against the reference value provided by the RX device. By setting a low threshold, the charger is misled into passing the FOD check and issuing an `ACK` response. Subsequently, we request further details from the charger, such as its ID and charging capabilities, by injecting general request (`GRQ`) and specific request (`SRQ`) packets. After **`negotiation`**, the charger is successfully directed to the power transfer stage with the extended protocol at t_1. At this point, the power transfer rate is adjusted and kept high through the injection of tailored `CE` and `RP` packets, heating up and potentially damaging foreign objects.

(a) Essential communications for initiating power transfer

(b) Interfered voltage trace and measured output power

Figure 16: Process of initiating power transfer

6.4.1 Attack Evaluations

We carried out the attacks on six common personal items, initiating power transfer and maintaining the maximum charging power until visible damage occurs or the maximum temperature is sustained for two hours. Our evaluations, as shown in Figure 17, reveal some concerning outcomes:

Key Fob: Upon initiating power transfer to a car key fob placed on the charging pad, the battery inside reached a critical temperature. As a result, the key fob didn't merely overheat. Instead, it detonated and caused the disintegration of the

device in an explosive display.

Paper Clips: The temperature exceeded 536°F when heated, which can potentially damage or destroy important documents affixed by these clips.

USB Drive: The high temperature caused significant damage to the USB drive and the memory chip, making the contained data unrecoverable.

Solid-State Drive (SSD): SSD is commonly found on laptops and can be accidentally placed on the charging pad. We find that our attack can overheat the controller and flash of SSD into unrecoverable states thus rendering it to suffer data loss.[5]

Passport and NFC Cards: Personal identification documents often contain RFID tags as identification chips. Similarly, NFC cards are often used as security tokens for verification. However, when these items are accidentally left on the charging pad, the strong magnetic field generated by the charger can immediately destroy these identification tokens.

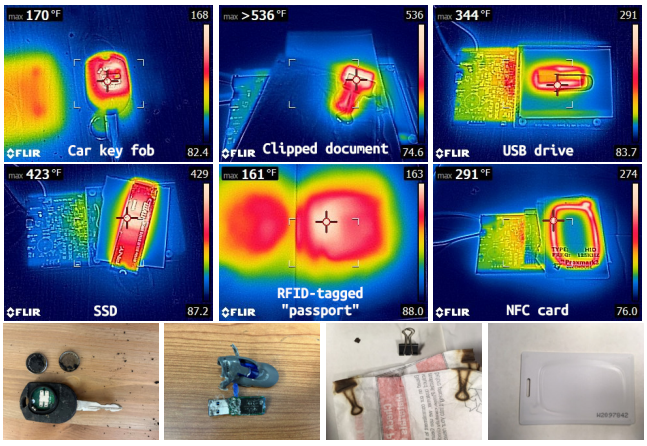

Figure 17: Thermal images and visible damages on different targets

We tested each charger for its destructive potential on the objects and measured the maximum charging power achievable when transferring power to a paper clip. The results listed in Table 3 show that all chargers can readily destroy RFID tags and NFC cards. The damage potential increases with the increased charging power. Even if some chargers do not directly damage certain objects, they can generate temperatures exceeding the safe limits for components like SSDs and USB drives, thereby causing permanent data loss.

7 Discussion

In this section, we discuss the practicality and stealthiness of our attacks, compare our work with state-of-the-art research, and provide insights for diverse charging protocols. We also propose countermeasures to mitigate the risks of our attacks.

[5]The SSD is expected to be more susceptible to high temperature when actively operating in a laptop because the maximum operating temperature specified for SSD is 149 °F.

7.1 Comparison With Prior Works

To clarify the uniqueness of *VoltSchemer*, we conducted a detailed comparison with state-of-the-art wireless charger manipulation attacks [6, 27]. This comparative analysis, outlined in Table 4, focuses on the practical implementation aspects and the specific attack capabilities of these methods. In-depth discussions of these two aspects are provided in the remaining part of this section.

Table 4: Comparison with state-of-the-art works

Work	Practicality				Attacks		
	🔧	⇄	👁	🛒	🎙	🔋	✂
Qi Hijacking [27]	✓	✓	✗	✗	✗	✓	✗
Wormheart [6]	✗	✗	✓	✗	✓	✗	✗
Parasite [6]	✓	✓	✗	✗	✓	✗	✗
VoltSchemer	✓	✓	✓	✓	✓	✓	✓

🔧: Feasible installation, ⇄: Versatility, 👁: Stealthy modification, 🛒: COTS evaluations, 🎙: Voice assistant manipulation, 🔋: Charging manipulation, ✂: Foreign object destruction

Comparison of Implementation Practicality Figure 18 shows three different methods of wireless charger manipulation attacks: ❶ adversarial coil plate insertion, ❷ charging pad alternation, and ❸ power supply interposing.

The "Wormheart" attack [6] involves installing customized firmware in the charger, usually by modifying or replacing its MCU. However, as detailed in Appendix A, the MCU's small size and dense integration on the charger board make malware installation infeasible. Moreover, this method's versatility is limited as each distinct charging system necessitates a uniquely customized malware. The work by Wu *et al.* [27] and the "Parasite" voice assistant manipulation attack [6] both require inserting adversarial coils over the genuine wireless charger. Because users must place devices on the adversarial coil for each charging session, such frequent interaction increases the chance of discerning the anomalies, thereby undermining the attack's stealthiness. Our *VoltSchemer* attacks employ IEMI on the power supply to control the charger, requiring only an intermediary device connection to the power adapter. While both *VoltSchemer* and adversarial coil methods involve adding a device, ours is more covert. Primarily,

our method capitalizes on the infrequent inspection of power adapters and charging cables, in line with wireless charging's core principle of minimal wire interaction. Furthermore, replicating a standard power port is more viable, owing to the common, simple design of regular outlets. In addition to these advantages, our approach's versatility is demonstrated by testing on 9 different wireless chargers, including COTS devices, a significant expansion from previous works [6, 27] that only assesses a single evaluation board charger.

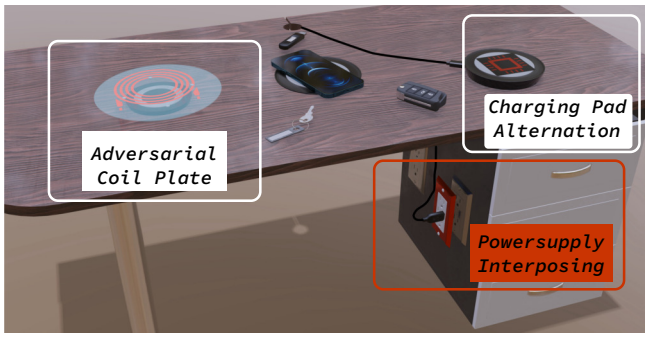

Figure 18: Three wireless charger manipulation methods

Comparison of Attack Capability Our research outweighs state-of-the-art works in both the breadth and depth of evaluations concerning three attack capabilities. The voice assistant manipulation attack in [6] is narrowly focused on a single custom-built wireless charger, only testing the activation of voice assistants. Our *VoltSchemer* approach broadens this scope significantly by evaluating 9 varied COTS wireless chargers with 6 different common voice commands. This not only proves the versatility of *VoltSchemer* across various hardware configurations but also uncovers deeper insights into the security risks associated with voice assistant manipulation attacks, highlighting the importance of comprehensive security measures in wireless charging technologies. Wu et al.'s work [27] demonstrates the impact of injected `CE` packets on charging power, but didn't progress to practical attacks. Our *VoltSchemer* evaluations reveal that altering `CE` packets alone is ineffective against modern smartphones' overcharging protections. Leveraging an in-depth understanding of Qi wireless charging protocols, we develop a practical power toasting attack with more skillfully controlled implementations. Our tests confirm that *VoltSchemer* can circumvent three protective measures, causing dangerously high temperatures in smartphones, thereby demonstrating a deeper insight into the attack's causes and impacts. Moreover, we introduce an unprecedented attack scenario in existing research. Our extensive evaluations show that *VoltSchemer* can manipulate wireless chargers to breach the protections of Qi standard, causing damage to metallic foreign objects, showcasing the potential for significant property loss and safety hazards.

7.2 Insights for Diverse Charging Protocols

The core issue facilitating our attacks is the insufficient noise suppression in certain frequency bands, leaving systems vulnerable to interference even if they meet existing EMC/EMI standards. This gap makes all wireless charging technologies potentially vulnerable to interference-based attacks, particularly high-power systems like electric vehicle (EV) wireless charging. Despite the nascent stage of EV wireless charging standards and efforts to incorporate safety measures, our research demonstrates the significant risks of system compromise, including property damage and threats to human safety. Our findings reveal the urgent need for improved protective measures against such IEMI interference, pointing to the critical importance of safeguarding wireless charging infrastructure from these sophisticated threats.

7.3 Countermeasures

A practical countermeasure to our attacks involves integrating noise suppression components, such as additional DC/DC converters, to remove noise in the input voltage. To validate this approach, we connect a DC/DC converter to the input power port of a Renesas P9242 wireless charger and assess the attenuation of injected noise. By injecting voltage noises across frequencies ranging from 500 Hz to 10kHz and measuring the voltages both before and after the DC/DC converter, we quantify the attenuation level. As Figure 19 illustrates, the converter achieves a minimum noise reduction of 15 dB, with more substantial attenuation at lower frequencies. This additional converter effectively mitigates all three attacks. However, this solution comes with trade-offs. For instance, it increases the charger's cost, size, weight, and failure rate. Moreover, the additional components also increase the power consumption and pose more thermal stress challenges.

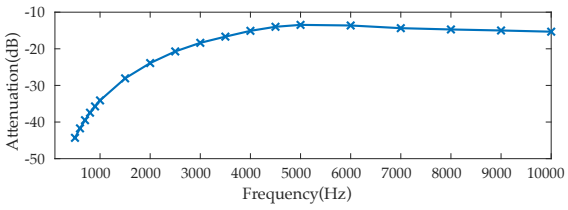

Figure 19: A DC/DC converter's noise attenuation for input voltage as a function of frequency

An alternative countermeasure involves real-time monitoring the voltage waveform DC bus. If the charger detects abnormal noises, which may indicate IEMI injection, it can respond by triggering alarms or shutting down to avoid further damage. However, the cost implications of implementing this mitigation may also pose a challenge for low-cost devices.

8 Related Work

8.1 Attacks during Charging

Smart devices often exchange information with chargers during the charging processes via USB cables, which also help to transfer files or install applications. The charging process can be exploited for eavesdropping, as changes in power consumption can be detected through the charging channel.

With ***Wired Charging***, studies have shown that malicious charging cables can be used to control mobile devices and install malicious applications [13, 17, 22]. Certain techniques can bypass the port lock mechanism, inject voice commands [25], or inject touch events onto touchscreens [11]. There are also techniques to procure sensitive information from the charged devices, like screenlock passwords [4, 20], browsing activities [28], and installed applications [3]. ***Wireless charging***, while popular due to its cordless design, presents new challenges. It has been demonstrated that wireless charging can also be vulnerable to side channel attacks [12, 16]. Vulnerabilities in the Qi wireless charging protocol have been exposed, which can be exploited to inject malicious charging commands and eavesdrop using an externally placed coil [26, 27]. Further improvements in eavesdropping attacks have been made by measuring the power consumption of the wireless charger [14]. There are also techniques that use a customized wireless charging coil to induce magnetic interference and inject voice commands [5, 6].

8.2 Inaudible Voice Injection Attacks

There are many well-known attacks on microphones to manipulate the sensed voice on smart devices and inject malicious voice commands. Among these voice injection attacks, two main categories of attacks are often discussed.

Indistinguishable Voice Injection generates malicious audio that can be interpreted by speech recognition systems but not by humans. This attack is demonstrated by Vaidya *et al*. [23] and Carlini *et al*. [2], further improved by Yuan *et al*. [29] by embedding voice commands into songs. Sch"onherr *et al*. [19] and Abdullah *et al*. [1] further refined the attack for broader use and practicality. Although researchers use several means to generate better malicious audio, this type of attack still relies on the fact that an audible voice carrier is needed, which is a hard requirement.

Inaudible Voice Injection produces voice signals only detectable by microphones. Wang *et al*. [30], Sugawara [21], and Roy *et al*. [18] proposed using ultrasonic frequency carrier signals, laser signals, and ultrasound speaker arrays for such attacks. Ji *et al*. [10] used an implanted capacitor for this purpose. Dai *et al*. [5, 6] and Wang *et al*. [25] demonstrated this attack can be executed via a wireless charger or a charging cable.

9 Ethical Considerations

Responsible Disclosure We have contacted vendors to report the identified vulnerabilities, including NXP, Renesas, Infineon, ST, Wireless Power Consortium, etc. Countermeasures that can be employed by hardware vendors are under discussion and will be further disclosed in the future.

IRB Approval The University of Florida Institutional Review Boards have approved this research. The IRB approval number is ET00020284.

Impact on Power Grid Integrity Following reviewers' recommendations, we evaluated our experiment's potential impact on the power grid's integrity. We can ascertain that the impact is negligible. This is largely due to the power adapter's noise-isolation design and the low-power interference signals used. However, future research involving IEMI should proactively and thoroughly assess the potential impact on the integrity of power grid, particularly in scenarios where interference is injected closer to the grid or with higher intensity.

Safety Measures In our study, certain experiments posed risks of battery fires and explosions. To address these concerns, we set up a controlled environment to ensure safety. The experiments took place in a clean, non-flammable area, equipped with adequate ventilation to prevent the accumulation of hazardous gases. Protective barriers were installed around the Device Under Test (DUT) to contain any fragments from potential explosions. Moreover, we ensured the availability and accessibility of specialized fire extinguishers, specifically designed for handling electrical and chemical fires, as a crucial safety measure.

10 Conclusion

In this paper, we identified vulnerabilities of wireless chargers that enable the implementation of *VoltSchemer*, a set of powerful and practical active attacks against COTS wireless chargers. Exploiting voltage interference on the power adapters' output voltage, *VoltSchemer* can manipulate the chargers to perform malicious activities like injecting inaudible voice commands to control voice assistants, overheating the charged devices, and destroying metallic foreign objects. Comprehensive evaluations of top-selling wireless chargers confirm the effectiveness and practicality of *VoltSchemer* attacks.

A Attacking Practicality Discussion

Figure 20 shows a microcontroller chip in a wireless charger. Due to its compact size and high level of integration on the board, malicious charging pad modifications requiring chip replacement are difficult to perform. This feature limits the practicality of the "Wormheart" attack.

Despite their small size, such chips are capable of performing complex computations, including processing voltage traces, decoding Qi messages, and generating control signals for power signal modulation. Thus, if mass production is needed, the size of our prototype *VoltSchemer* can be significantly reduced by substituting the AD2 with a chip at this scale.

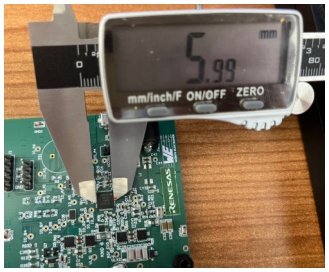

Figure 20: Microcontroller chip on the wireless charger

B Inverter Output Voltage

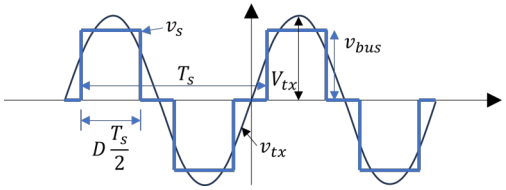

Figure 21: Waveform of inverter output voltage

When an inverter operates at a switching frequency f_p with a duty cycle D, the waveform $v_s(t)$ of the inverter output voltage is illustrated in Figure 21. $v_s(t)$ is mathematically described by Equation 9 over the interval $\left[-\frac{T_s}{2}, \frac{T_s}{2}\right]$, where T_s, the period of the switching pattern, is defined as $\frac{1}{f_p}$.

$$v_s(t) = \begin{cases} v_{\text{bus}} & \frac{T_s}{4}(1-D) < t < \frac{T_s}{4}(1+D) \\ -v_{\text{bus}} & -\frac{T_s}{4}(1+D) < t < -\frac{T_s}{4}(1-D) \\ 0 & \text{otherwise} \end{cases} \quad (9)$$

If the voltage v_{tx} corresponds to the fundamental harmonic of $v_s(t)$ at frequency f_p and the amplitude of the fundamental of $v_s(t)$ at f_p is V_{tx}, when filtered through a resonance tank that only retains the fundamental component, the voltage v_{tx} can be expressed as:

$$\begin{aligned} v_{tx}(t) &= V_{tx} sin(2\pi f_p t) \\ &= \frac{4}{\pi} \sin(\frac{\pi}{2} D) v_{bus} \sin(2\pi f_p t) \end{aligned} \quad (10)$$

VibSpeech: Exploring Practical Wideband Eavesdropping via Bandlimited Signal of Vibration-based Side Channel

Abstract

Vibration-based side channel is an ever-present threat to speech privacy. However, due to the target's frequency response with a rapid decay or limited sampling rate of malicious sensors, the acquired vibration signals are often distorted and narrowband, which fails an intelligible speech recovery. This paper tries to answer that when the side-channel data has only a very limited bandwidth (<500Hz), is it feasible to achieve a wideband eavesdropping based on a practical assumption? Our answer is YES based on the assumption that a short utterance (2s-4s) of the victim is exposed to the attacker. What is most surprising is that the attack can recover speech with a bandwidth of up to 8kHz. This covers almost all phonemes (voiced and unvoiced) in human speech and causes practical threat. The core idea of the attack is using vocal-tract features extracted from the victim's utterance to compensate for the side-channel data. To demonstrate the threat, we proposed a vocal-guided attack scheme called VibSpeech and built a prototype based on a mmWave sensor to penetrate soundproof walls for vibration sensing. We solved challenges of vibration artifact suppression and a generalized scheme free of any target's training data. We evaluated VibSpeech with extensive experiments and validated it on the IMU-based method. The results indicated that VibSpeech can recover intelligible speech with an average MCD/SNR of 3.9/5.4dB.

1 Introduction

Sound-induced vibration is a common phenomenon and prevalent when a sound source (e.g., a loudspeaker) produces acoustic waves. Researchers have revealed great threats posed by these sound-related vibrations via different sensing methods, e.g., optical sensors [14, 34, 38–40, 45], motion sensors [5, 8, 18, 21, 37], wireless devices [9, 19, 20, 36, 50–52], and vibration-sensitive components [28, 44]. For a protected zone like a soundproof room, millimeter-wave (mmWave) sensors can be exploited for through-wall eavesdropping due to the advantages of penetrability and high precision.

However, current mmWave-based works [19, 56] either require an ideal reflector with a wideband frequency response or require abundant training data from the target to achieve satisfactory performance. These methods suffer narrowband frequency responses and the strong assumption of targets' training data. With a laser vibrometer (Figure 1), we found that narrowband frequency response is often the case due to the forced damped vibration [15] induced by excitation audio.

In this paper, we reveal a new speech threat that adversaries can recover wideband (up to 8kHz) intelligible speech from acquired narrowband (<500Hz) vibration signals on loudspeakers. An attacker can use a mmWave sensor to capture the sound-related vibrations in a soundproof zone and leverage the proposed wideband-speech-recovery scheme called *VibSpeech* to recover intelligible speech. The core idea of our work is using vocal-tract features extracted from a pre-obtained utterance of the victim to compensate for acquired narrowband signals during the attack and recover wideband speech. Compared with prior works, our proposed attack is

(1) *Free of a tough requirement of wideband frequency response of the target.* Frequency response plays an important role in vibration-based speech recovery. However, an ideal target with wideband frequency response is not always available. Our study (Section 5) indicates that due to the characteristic of the forced vibration, the vibration amplitude on loudspeakers can suffer over 20dB degradation when the excitation frequency is above 500Hz. A consequence is that high-frequency vibration is overwhelmed by noise and practically unavailable. VibSpeech focuses on the prevailing narrowband status quo while holding the goal of wideband speech recovery.

(2) *Free of training data from the target.* Although using a neural network to learn the mapping between narrowband vibration signals and wideband audio may merge the gap between the two signals, such a method requires a large training dataset of the target to achieve satisfactory performance, which is impractical to conduct in real cases. One of our goals is to free the narrowband-wideband speech transition from the abundant training data of the target. Only with a short utterance (2s-4s) of the victim, our work can recover wideband

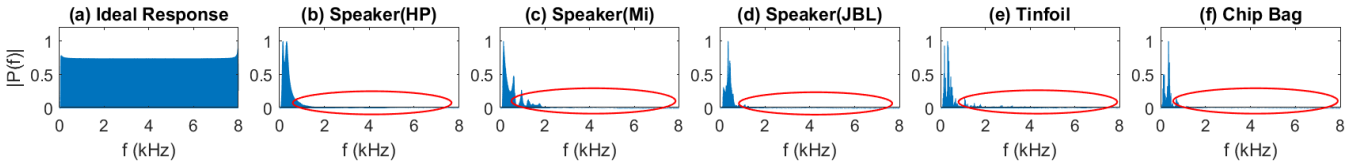

Figure 1: Frequency response of sound-forced vibrating objects measured by a laser vibrometer (Figure 4(a)). Compared with (a) the ideal frequency response, pervasive uneven response on objects (b)-(f) challenges a wideband and intelligible speech recovery from the distorted and narrowband vibration signals. Please refer to Section 5 for a detailed investigation.

intelligible speech during the attack.

(3) *A through-wall and non-invasive attack.* Although existing works revealed that the vibration signals can be acquired using lasers, cameras, optical sensors, and motion sensors, these methods either cannot penetrate opaque obstacles or work in an invasive manner of deriving data from the target via malware. Our mmWave-based attack can break through soundproof protections in a non-invasive manner, and achieve a better resolution than the ones based on other radio-frequencies techniques such as WiFi and ultra-wide-band radio.

(4) *An intelligible speech recovery with a bandwidth of up to 8kHz.* Although many works revealed that attackers can use narrowband vibration signals to infer speech contents (i.e., word recognition), such a method is restricted to specific vocabulary and cannot recover arbitrary speech that is not contained in the vocabulary. By contrast, VibSpeech can recover hearable speech with high intelligibility and quality.

To achieve the attack, we aim to solve the following challenges. **First**, how to eliminate the distortion and artifacts in acquired narrowband vibration signals? In a real case, the collected vibration signal often suffers distortions and artifacts due to the target's uneven frequency response and noise (Section 5). To solve this problem, we proposed adaptive multi-bandpass filtering to suppress distortion and inter-harmonic noise in the narrowband signal (Section 6.2). **Second**, how to merge the bandwidth gap between the vibration signal and intelligible speech? Formants of consonants can be up to 4k-8kHz (Figure 2). Narrowband audio with incomplete formants can be blurred and unintelligible. To solve this challenge, we designed a vocal-guided scheme by fusing narrowband speech and the target's vocal-tract features. The vocal-tract features are extracted via a *SpkEnc* network that only requires a short utterance (2s-4s) from the victim (Section 6.1). Further, the wideband speech is reconstructed via a bandwidth-extension network (Section 6.3) and a generalized vocoder (Section 6.4). **Third**, how to free the narrowband-wideband speech transition from the labor-intensive and impractical assumption of training data collected from the target? To achieve this goal, we proposed to manipulate the bandwidth of public audio datasets to generate narrowband audio as training data. This training strategy makes the attack free of the requirement of abundant data from the target to achieve satisfactory performance and becomes a general scheme that can also applied to other vibration side channels, e.g., IMUs (Section 8).

Our contributions are summarized as follows:

- We revealed a new speech threat that when the vibration side-channel data has a limited bandwidth as low as 500Hz, it is feasible to recover wideband (8kHz) intelligible speech. The attack is based on the assumption that a short (2s-4s) utterance of the victim is exposed to the attacker.
- We first investigated the narrowband characteristic of the vibration-based side channel. We proposed a vocal-guided attack scheme (VibSpeech) and used a mmWave sensor to penetrate soundproof protections to demonstrate the threat.
- We performed extensive experiments to evaluate the proposed attack. The results indicate that VibSpeech can recover wideband and intelligible speech with an overall MCD/SNR score of 3.9/5.4dB. The evaluation under different conditions shows the robustness of the attack. We also validated the generalization of the attack on the IMU-based method. Audio samples are available at https://demo-online.github.io/VibSpeech/.

2 Related Work

Sound-induced vibrations on objects can be measured by sensors or vibration-sensitive devices for speech recovery, e.g., lasers [38, 45], inertial measurement units (IMU) [5, 8, 18, 21, 37], wireless signals [19, 20, 36, 49, 51–53], optical sensors [14,34,40], vibration motors [44], and hard drives [28]. These works revealed great threats to speech privacy. Table 1 shows the comparison with typical and state-of-the-art work. Different features are involved to discuss their pros and cons, such as the dependency on the target's prior data, invasiveness, through-wall capability, sensing distance, and the bandwidth of recovered speech. Considering that metrics used in these works are different, common metrics (e.g., SNR) are reported for quantitative comparison. Furthermore, we conducted an experiment under the same experimental setting (Section 7.13) for a fair comparison with related methods [20, 56].

Optical-based: Laser microphone has been studied since the 1980s [38]. Adversaries can use laser transceivers to measure sound-induced vibrations on objects to recover sound. Sami *et al.* [45] revealed that the Lidar sensor on a robot

[1] The result was acquired under the same experimental setting with VibSpeech. More details are introduced in Section 7.13.

cleaner can sense the speech-related vibration on objects for eavesdropping if the attacker hacks the robot cleaner and accesses the sensor data. Besides the laser, visible light can also be used for vibration measurement. The Visual Microphone [14] decoded audio from videos via a high-speech camera. Lamphone [40] and Glowworm [39] used electro-optical sensors and telescopes to capture the light bulb's vibration and the light changes of power indicators to recover speech of around 7.4dB SNR. With a professional lens, the sensing distance can be enlarged over 10m but can only work without opaque walls. Recently, Long *et al.* [34] revealed that pixel changes in smartphone images can also be used for speech decoding. It achieves 81% accuracy for digit recognition. Optical-based methods can sense delicate vibrations and often have a longer sensing distance than other methods with professional lenses for enhancement. But this kind of method cannot penetrate opaque blockage for sensing. Although VibSpeech has a lower SNR of 5.4dB than the state-of-the-art (7.4dB) due to the penetrating attenuation, it still indicates satisfactory performance for speech recovery.

IMU-based: Motion-sensor-based attacks have been widely studied these years [5, 8, 18, 21, 37]. Gyrophone [37] exploited smartphone gyroscopes to capture the external loudspeaker's vibration for digit inference. AccelEve [8] achieved word reconstruction and gender inference via the built-in accelerometer to collect the vibration of the smartphone's loudspeaker. Recently AccelEar [21] exploited generative adversarial networks to recover audible speech from accelerometer data. For the IMU-based attacks, an intelligible speech recovery is challenging due to the low sampling rate of IMUs. Although recent work [21] revealed the possibility of using a more powerful network to learn the mapping between the distorted vibration signal and the corresponding utterance, they still required abundant vibration data and ground-truth audio from the specific target to achieve satisfactory performance. Compared with current IMU-based work, we do not rely on the strong assumption of abundant training data from the specific target while holding the attack goal of recovering intelligible speech. For the motion-sensor-based attacks, another drawback is their intrusive manner, i.e., requiring malicious applications on the target to collect vibration data. IMU-based methods can cause threats to smartphones besides external loudspeakers. This kind of attack can be achieved with low-cost motion sensors but often requires physical contact with sound sources for vibration measurement. Compared with non-invasive methods like optical-based and mmWave-based ones, the IMU-based methods also require to hack the target for data collection. VibSpeech works in a non-invasive manner and achieves a lower MCD of 3.9 (better performance) than the state-of-the-art (4.8) of IMU-based methods [21].

Wireless-based: Wireless signals have been exploited by researchers for speech inference [9, 19, 20, 30–33, 48–50, 52, 53]. An advantage of wireless signals is that it can penetrate soundproof obstructions. Benefiting from a shorter wavelength, mmWave sensors can acquire more dedicated vibrations for speech recovery. Work [19] proposed a phase-calibration method to recover vibration signals. However, an ideal object is not always available and current work still cannot essentially solve the narrowband dilemma that is pervasive in vibration-based side channels. Our work does not rely on the ideal reverberator but leverages the prevalently-narrowband vibrating signals. mmSpy [9] and mmEve [50] are good works to reveal the vibration-based side channel on smartphones that can cause threats to speech played by the earpieces. They found that the built-in earpieces can induce vibration on the smartphone backshell, which can be used to infer words or recover narrowband sound. However, these works still suffer the narrowband condition of vibration-based side channels and can only recover bandlimited sound with damaged speech intelligibility. For comparison, VibSpeech seeks to solve the pervasively narrowband feature of vibration-based side channels and can recover 8kHz-wideband sound that shows practical threats. Besides, VibSpeech is a generalized framework for different vibration-sensing methodologies, e.g.,mmWave sensors, laser vibrometers, and IMUs. Compared with laser-based and IMU-based methods, the mmWave-based methods often have a moderate sensing distance of several meters(<10m) but can penetrate opaque walls for non-contact vibration sensing. It is also a non-invasive manner without hacking the target. However, current works still suffer the narrowband limitation of vibration-based side channels and rely on heavy training data from the target to achieve

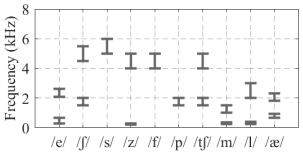

Figure 2: Frequency range of phoneme formants (F1, F2).

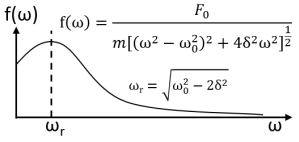

Figure 3: Freq. response of forced damped vibration [4].

satisfactory performance. Recent work [20, 56] used neural networks to learn the mapping between the acquired vibration signals and corresponding audio. However, they required both abundant vibration data and ground-truth audio collected from the victim to achieve satisfactory performance. This constrains prior work to a target-dependent attack with the strong assumption of requiring a large training set from the victim. Without sufficient training data from the target, the performance can get worse with SNR/MCD scores of 0.2dB/10.7. By contrast, VibSpeech uses vocal-tract features to compensate for narrowband audio instead of learning the mapping. It achieves better performance (5.4dB/3.9) with less prior data (2-4s audio) from the target. This frees the attack from a tough requirement of training data from the victim.

3 Background

Speech Production. Human speech is produced by the cooperation among vocal organs (e.g., lungs, vocal cords, and articulators). The lungs pump the air through the vocal cords to cause an acoustic resonance and produce low-frequency components (e.g., pitch and its low-order harmonics) of the speech. The resonating air further passes through the vocal tract composed of the articulators (e.g., the tongue, mouth, and lips), and is fine-tuned to generate higher frequency components (e.g., formants) to make a hearable speech. The **phoneme** is the basic unit of pronunciation. In the case of English, there are seven categories of phonemes, i.e., vowels (e.g., "/e/" in b<u>e</u>t), fricatives (e.g., "/s/" in thi<u>s</u>), stops (e.g., "/p/" in <u>p</u>ap), affricates (e.g., "/tʃ/" in <u>ch</u>ange), nasals (e.g., "/m/" in <u>m</u>ake), glides (e.g., "/l/" in <u>l</u>ip), and diphthongs (e.g., "/æ/" in <u>a</u>t). Each phoneme is produced by different configurations of human vocal organs and has different formant frequency bands [10, 35] as shown in Figure 2 (F1 and F2 mean the first and second formants). The combination of phonemes with transitions (e.g., bigrams) helps people distinguish the words. *A damaged frequency band of phonemes (e.g., losing high frequencies) will make the speech blurred and unintelligible for human hearing.*

mmWave-based Vibration Sensing. Millimeter-wave sensors operating in frequency-modulated continuous-wave (FMCW) mode are widely used in automatic driving and industrial monitoring. Benefiting from the millimeter-level wavelength, the mmWave sensor can measure delicate vibrations from the phase of demodulated intermediate-frequency (IF) signals. The reflected signal can be taken as a delayed replica of the transmitted signal. Given a transmitted signal with a frequency slope of S, the IF signal demodulated by the sensor can be represented by $A\sin(2\pi f_0 t + \phi_0)$. The frequency f_0 of the IF signal indicates the distance d of the target from the sensor $d = \frac{f_0 c}{2S}$ where c is the speed of light in a vacuum. To acquire the target's vibration signals, we can apply fast Fourier transform on the IF signal (called *range-FFT*) and acquire the rang-bin (i.e., f_0) corresponding to the target. Then the vibration signal Δd can be derived from the phase change $\Delta\phi$ of the range-bin $\Delta d = \frac{\lambda\Delta\phi}{4\pi}$ where λ is the wavelength of the transmitted signal. To acquire the range-bin corresponding to the target, we can apply a high-pass filter (f_c=80Hz) on all derived phase sequences and calculate the power density. Then we choose the one with the highest score as the derived vibration signal. The sampling rate f_s of the vibration signal is determined by the chirp rate f_{chirp}, i.e., $f_s = f_{chirp}$.

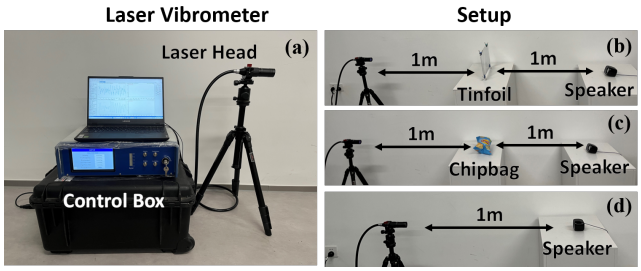

Figure 4: The laser vibrometer and experimental setup to measure the frequency response of vibrating objects.

4 Threat Model

Attack Scenario and Goal. We consider an attack scenario where an individual is having an online conversation in a soundproof room. The individual uses a loudspeaker to play the speech. The speech may contain private information and secrets. An attacker who is interested in the speech launches eavesdropping from the outside of the isolated zone. The attacker can use a portable mmWave sensor to penetrate the sound insulator and capture the sound source vibration for speech recovery. To cause a practical threat, the attacker aims to overcome the limitations of the distorted narrowband vibration signals, and recover wideband intelligible speech.

Assumption. Considering the practicality of the attack, we do not assume the attacker has plenty of vibration data and audio data collected from the victim to train a target-dependent model. By contrast, we assume that the attacker can acquire a short (2s-4s) utterance of the victim before launching the attack. The utterance can be collected by a hidden microphone or acquired in cyberspace, e.g., by making phishing calls to record seconds of audio of the victim.

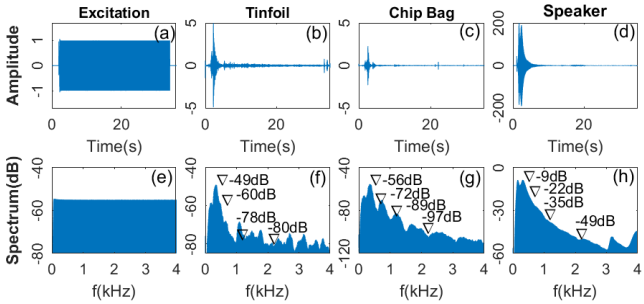

Figure 5: Frequency response measured by the laser vibrometer. (a)(e) show the waveform and spectrum of played chirp audio. (b)(c)(d) show measured vibration on objects. (f)(g)(h) show corresponding spectrums. The marked points in (f)(g)(h) indicate the maximum magnitude, and the magnitudes when the excitation frequency equals 500Hz, 1kHz, and 2kHz.

5 Characteristic of Vibration-based Side Channel: the Narrowband Nature

In this section, we first introduce the theoretical model of sound-related vibration and reveal the significant nature of the vibration-based side channel, i.e., *the sound-related vibration can attenuate with the increasing frequency of audio signals, resulting in uneven frequency response and ubiquitously-narrowband vibration signals*. Then we introduce our investigation and observations about the narrowband phenomenon via a professional laser vibrometer and a mmWave sensor.

Frequency Response of Vibration-based Side Channel. Frequency response characterizes the relationship between the object's vibration and the excitation signal in the frequency domain. Sound-induced vibration (e.g., on passive diaphragms) or coil-driven vibration (e.g., on a loudspeaker) can be taken as forced damped vibration [15]. Given an excitation signal with acoustic-wave function $P(t) = P_0\cos(\omega t+\phi)$, the radiation force on the object can be represented by $F = F_0\cos(\omega t+\phi)$ where $F_0 = AP_0$ and A is the object's equivalent surface area. Then the forced vibration on the object m can be characterized by the typical spring-oscillator model [4] and the forced displacement is formulated by

$$x(t) = \frac{F_0}{m[(\omega^2-\omega_0^2)^2+4\delta^2\omega^2]^{\frac{1}{2}}}\cos(\omega t+\phi), \qquad (1)$$

where δ and ω_0 are constants and known as the damping coefficient and the natural angular frequency of the object, respectively. Eq.1 indicates that when $\omega > [\omega_0^2-2\delta^2]^{\frac{1}{2}}$, the displacement amplitude $\frac{F_0}{m[(\omega^2-\omega_0^2)^2+4\delta^2\omega^2]^{\frac{1}{2}}}$ of the vibrating object degrades greatly with the increasing frequency $f=\frac{\omega}{2\pi}$ of the excitation signal, as shown in Figure 3. When the vibrating frequency increases to the point where the induced displacement is overwhelmed by noise, the captured vibration loses high-band components and causes a narrowband result.

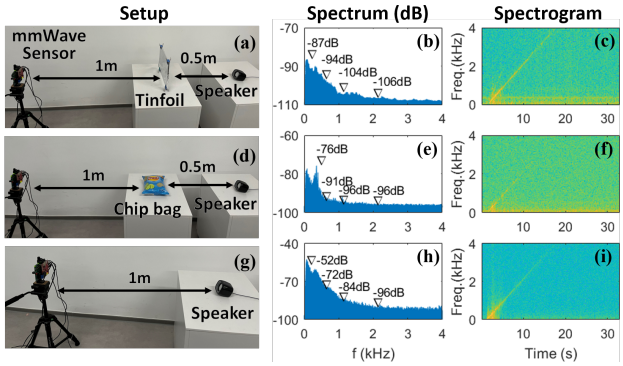

Figure 6: Frequency response measured by a mmWave sensor.

Laser Vibrometry. To quantitatively investigate the characteristic of the vibration-based side channel, we used a laser vibrometer (LV-FS01 [3]) with a displacement resolution smaller than 1nm, to measure sound-related vibration as shown in Figure 4. Tested objects included tinfoil, a chip bag, and an HP loudspeaker. The object vibrated due to the excitation of chirp audio (80-8kHz, 68dB) played by the loudspeaker. The frequency response of tested objects is shown in Figure 5. Compared with the flat spectrum of the excitation signal shown in Figure 5(e), we can observe that the spectrums of vibrating objects have an attenuating magnitude with increasing frequency as shown in Figure 5(f)(g)(h). Compared with the strongest response at the frequency band below 1kHz, the attenuation of the frequency response achieves 11dB-16dB when f=500Hz, 26dB-33dB when f=1kHz, and 31dB-41dB when f=2kHz. *The result validated that, with the increasing frequency of excitation audio, the amplitude of induced vibration on objects will decrease. On one hand, the uneven frequency response causes distortions in captured signals (i.e., distorted speech) compared with the ground-truth audio. On the other hand, the attenuated high-frequency components are prone to be overwhelmed by background noise resulting in narrowband signals. The narrowband dilemma of the vibration-based side channel causes loss of abundant speech information in the high-frequency band, and challenges intelligible speech recovery.*

mmWave Sensing. As shown in Figure 6, we used a mmWave sensor (AWR1843Boost) to capture the vibration of the same objects mentioned above. The same chirp audio was played as the excitation signal to acquire the frequency response. The vibration signals are derived from the mmWave signals as introduced in Section 3. The spectrogram and spectrum of acquired vibration signals are shown in Figure 6. From Figure 6(c)(f)(i), we can observe that the power density of the vibration signal decreases with increasing frequency and is overwhelmed by background noise when the frequency reaches a specific high-frequency band. Compared with the strongest response shown in Figure 6(h), we can find that the frequency response of the loudspeaker suffers attenuation of

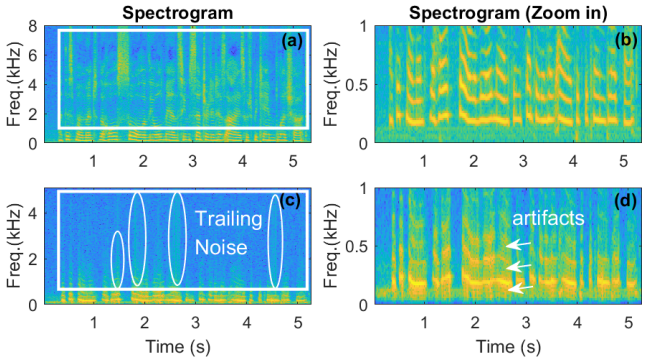

Figure 7: Through-wall results. (a) and (b) show the spectrograms of played audio. (b) shows the 0-1kHz band of (a). (c)(d) show spectrograms of mmWave-recovered audio. (d) shows the 0-1kHz band of (c).

20dB/32dB/44dB at the frequency of 500Hz/1kHz/2kHz.

mmWave Sensing (Thru-wall). To further investigate the impact of wall blockage on captured vibration signals, we set the mmWave sensor outside a room to penetrate the soundproof glasses and sense the loudspeaker's vibration from a distance of 3m (Figure 10(a)). The loudspeaker played speech audio that contained frequency components of up to 8kHz, i.e., "at this moment, the whole soul of the old man seemed centred in his eyes which became bloodshot". Spectrograms of the excitation audio and raw mmWave-recovered audio (i.e., derived vibration signals) are shown in Figure 7. Compared with the original audio as shown in Figure 7(a), we can find that the recovered audio shown in Figure 7(c) suffers a significant loss of high-frequency response, especially the frequencies above 500Hz. The result is consistent with our observation and analysis mentioned above, i.e., the vibration-derived audio has a limited bandwidth due to the uneven frequency response with rapid decay of the vibration-based side channel. The high-band speech components are prone to be buried in the noise resulting in unintelligible speech. We can also find that there is trailing noise in the mmWave-recovered audio as shown in Figure 7(c). Besides, for the 0-1kHz band of the mmWave-recovered audio as shown in Figure 7(d), there are artifacts between the pitch and harmonics due to the sensor noise. These artifacts degrade the signal-to-noise ratio of the speech and make speech blurred, which should be suppressed.

Short Summary. Based on the above investigation, we can find that *(1) the amplitude of sound-related vibration actually does not follow linearity with the excitation audio, but degrades with the increasing frequency of the excitation audio. This also explains the narrowband results in prior work on vibration-based side channels [14, 20, 40, 56]. Such characteristic of the vibration-based side channel causes distortion in the vibration-derived audio and restricts the recovered speech to the dilemma of a narrow band. (2) Although mmWave sensing is feasible for through-wall vibration sensing, the mmWave-recovered audio still suffers the loss of high-band response (especially for f >500Hz) and artifacts in the available low-frequency band (f <500Hz), which challenge intelligible and wideband speech recovery.*

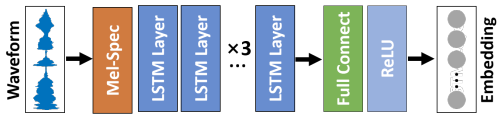

Figure 8: The structure of *SpkEnc*.

6 VibSpeech: A Wideband Speech Recovery Scheme for Vibration-based Side Channel

System Overview. In this section, we introduce how to overcome the aforementioned challenges. We propose to use the vocal-tract features of the speaker to compensate for the compromised and narrowband speech. We first introduce *SpkEnc* to extract speaker embeddings that characterize the speaker's vocal-tract features (Section 6.1). The feature extraction only requires a short utterance of around 2s-4s from the victim. Before feeding the narrowband vibration data for wideband speech recovery, we preprocess the vibration signal to suppress the distortion and artifacts in the low-frequency band (Section 6.2). Then a vocal-guided bandwidth extension network is proposed to compensate for the narrowband signal using extracted vocal-tract features (Section 6.3), and produce an enhanced spectrogram. Finally, a vocoder transforms the enhanced spectrogram into audible waveforms (Section 6.4).

6.1 Vocal-tract Feature Extraction

Deep-learning-based vocal-tract feature extraction has shown a powerful ability to characterize the features of human vocal-tracts [7, 11, 23, 47]. An ideal way of vocal-tract feature extraction is to collect all the phonemes/bigrams from the speaker for the feature extraction. However, in a real case, speech contents of acquired utterances from the victim can be arbitrary and cannot be promised on expected phonemes. Thus, a key challenge of the vocal-tract feature extraction is how to make the extraction independent of the pronounced phonemes (i.e., utterance-independent features) of the speaker and achieve an accurate extraction based on a short utterance with acceptable duration. To achieve this goal, we designed a speaker-encoder network *SpkEnc*. We trained *SpkEnc* with the GE2E loss [47] which computes the loss on each embedding and aims to push the embedding result to the centroid of the same speaker on the feature space and away from ones of other speakers. For a satisfactory generalization performance, we randomly chose fragments from utterances of different individuals. The training process randomly takes utterances from different speakers without the requirement of utterance alignment to achieve an

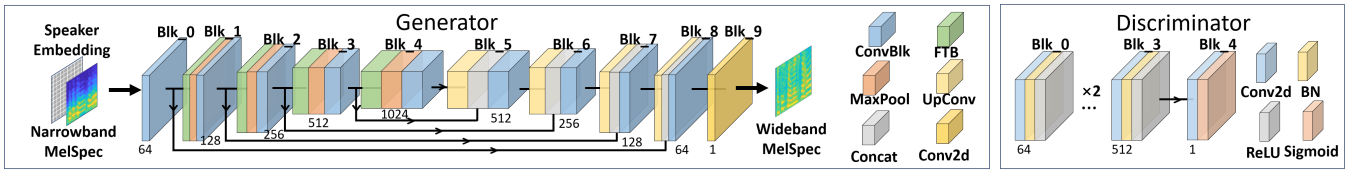

Figure 9: Vocal-guided bandwidth extension. The network parameters are detailed in Appendix C.

utterance-independent embedding extraction. The GE2E loss is detailed in Appendix A. The network consists of six layers of Long-Short-Term-Memory (LSTM) blocks followed by a full-connected layer as the projection layer. The feature size of each LSTM layer and the projection layer is 256 which is consistent with the embedding size. A Rectified Linear Unit (ReLU) outputs the final embedding from projected features.

Training: We used a public dataset (Voxceleb2 [13]) to train *SpkEnc* with 5.9 million steps for convergence. During training, we applied voice-activity-detection (VAD) [25] to remove internal silence parts and segmented the utterance into fragments of 1.6 seconds with an overlap of 0.8 seconds. The 40-band mel spectrogram of each fragment is fed into *SpkEnc* to generate the embedding of each fragment. The final speaker embedding is derived by calculating the L2-normalization of these embedding vectors. Note that the network for vocal-tract feature extraction is trained offline in advance and free of target's training data. Based on the trained *SpkEnc*, the attacker can collect a short utterance from the victim and feed the utterance into *SpkEnc* to derive the victim's speaker embeddings. During the attack phase, the attacker uses the extracted embeddings for wideband speech reconstruction(Section 6.3).

6.2 Preprocess

As investigated in Section 5, besides the limited bandwidth, the vibration signal also suffers distortion and artifacts due to the uneven frequency response of objects and the sensor noise in the raw vibration signal. Thus, before feeding the narrowband signals for wideband speech reconstruction, we need to correct the distortion and remove the artifacts first. The derivation of vibration signals from mmWave data is introduced in Section 3. From Figure 7(d), we can find that the artifacts exist between the pitch and its harmonics. For such inter-band noise, an intuitive solution is to apply a finite impulse response (FIR) filter with multiple passbands to remove the noise. However, finding proper filter parameters (e.g., center frequency) is hard and impractical to achieve considering that the frequency of pitch and harmonics can change according to different pronunciations. To address this problem, we propose an adaptive bandpass-filtering algorithm based on the feature of human speech. The core idea is based on the fact that for a short fragment, the pitch often shows a high power density in the low-frequency band (80-255Hz) while the harmonics are multiples of the pitch. Thus, we can first acquire fragments of the speech (*OverlapSegment*) and estimate the fundamental frequency f_0 for each fragment s_n (*PitchEstimation*). Then we apply multiple bandpass-filtering $BPF(s_n, f_c)$ on the harmonics by setting the center frequency f_c of the filter into multiples of f_0, i.e., $f_c = M \cdot f_0$. To suppress the low-band distortion, a correction coefficient is applied on m-th harmonic based on its power density $|S_m|$. The final result is acquired by adding the segments with overlap (*OverlapAdd*). The algorithm is shown in Algorithm 1 (Appendix B). After the preprocessing, the artifacts and distortion in the raw vibration signals are suppressed. The result is fed into the vocal-guided bandwidth extension to derive a wideband spectrogram.

6.3 Vocal-guided Bandwidth Extension

The core idea of VibSpeech is to use the extracted vocal-tract features of the victim to compensate for acquired narrowband vibration signals. The key is how to fuse the narrowband spectrogram and extracted vocal-tract features (i.e., speaker embeddings mentioned in Section 6.1) to acquire a wideband spectrogram. To achieve this goal, we designed an attention-based neural network as shown in Figure 9 to fuse the speaker embedding and narrowband signal. Specifically, we used adversarial training to improve the generality of the model. The generator takes an encoder-decoder structure that shows superior performance in pixel-to-pixel transformation, as the backbone. The shortcut connection between every two blocks helps to maintain details in the upper level [43]. To capture non-local correlations among harmonics in the time-frequency (T-F) domain, we adopted a frequency-transformation-block (FTB) for each block. The core of FTB is to learn a transformation matrix applied on the frequency axis and has a full-frequency receptive field [55]. Its inner convolution layers predict an attention map in the T-F domain and help to capture the essential correlation among speech harmonics using the channels with speaker embeddings. The discriminator aims to justify the consistency of two inputs and output the predicted label, i.e., real or fake. It consists of four convolution blocks to extract pixel-wise features of inputs, and a Sigmoid layer to predict the result. The network parameters are introduced in Appendix C.

Training: During the training of the generator, we adopt the mel loss and adversarial loss to improve the distortion of reconstructed spectrograms. We use the BCE loss to update the discriminator. Details of the loss functions are in-

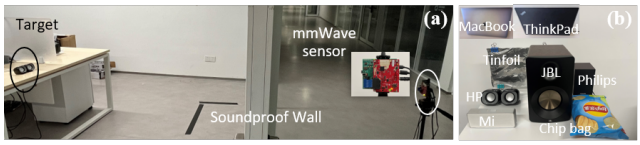

Figure 10: (a) A room with the soundproof wall (two layers of 1cm-thick glass). (b)Tested vibrating objects in the evaluation.

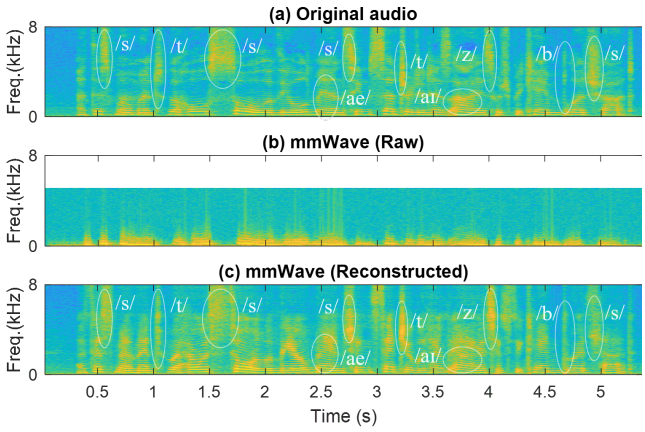

Figure 11: The spectrograms of (a) original audio, (b) raw-recovered audio via mmWave, and (c) reconstructed audio by VibSpeech. (Speech: *at this moment the whole soul of the old man seemed centred in his eyes which became bloodshot*)

troduced in Appendix C. The generator takes narrowband spectrogram and speaker embedding as inputs to reconstruct lost formants in the high-frequency band. The narrowband spectrograms used for training are derived from public audio datasets (train-clean-100/train-clean-360/train-other-500 of LibriSpeech [41]) by applying low-pass filtering (with a cut-off frequency f_c of 500Hz) to each audio trace. The generator and the discriminator are updated alternatively. The network was trained with 61k steps for convergence. During the attack, the attacker feeds the preprocessed narrowband signal (Section 6.2) and pre-extracted speaker embedding (Section 6.1) into the trained generator to acquire a wideband spectrogram.

6.4 Vocoder

To recover hearable voice, we need to transform the enhanced spectrogram (Section 6.3) into waveforms in the time domain. The transformation can be achieved by a vocoder. In recent years, generated adversarial network (GAN)-based vocoders such as WaveRNN [24], MelGAN [27], HiFiGAN [26], and BigVGAN [29], have shown great improvement in the naturalness and fidelity of reconstructed speech compared with traditional methods (e.g., Griffin-Lim vocoder [16]). Thus, we adopt the state-of-the-art structure, i.e., BigVGAN [29], which achieves superior performance and generality for audio synthesis. The vocoder is composed of six blocks of transposed 1-D convolution followed by an anti-aliased multi-periodicity composition (AMP) module. To model complex waveforms, the AMP module contains multiple signal components with learnable periodicities and adopts a low-pass filter to reduce the high-frequency artifacts. **Training:** The vocoder takes the mel spectrogram as the input and produces hearable audio waveforms. We used public datasets (train-clean-100/train-clean-360/train-other-500 of LibriSpeech [41]) to train the vocoder. The mel-spectrograms are produced by applying a 128-mel-transform on the result of a short-time Fourier transform. The model was trained with 110k steps for convergence.

7 Evaluation

7.1 Setup and Metrics

We used samples from a widely-used speech corpus LibriSpeech (dev-clean) [41] for evaluation. The dataset contains 2,073 audio traces sampled at 16kHz from 40 individuals (i.e., 20 males and 20 females). We played the audio (68dB) via an HP loudspeaker and collected corresponding vibration data via a mmWave sensor (AWR1843Boost) as shown in Figure 10(a). The derived vibration signal is at a sampling rate of 10.2kHz and resampled at 16kHz for further processing. Note that in a real case, the speech contents for vocal-tract feature extraction may be different from the spoken ones during the attack phase. Thus, for each tested individual, we randomly chose one trace for the vocal-tract feature extraction, and used the left samples to evaluate the performance of the speech reconstruction. The models were trained offline with four NVIDIA RTX A6000 GPUs and deployed on a laptop (ThinkPad) for speech recovery. For robustness experiments (Section 7.4-7.9), the used corpus includes 663 samples of the first five males and five females in the 40-individual dataset.

Mel-Ceptral Distortion (MCD): The MCD is a widely used metric to quantify the speech distortion between the recovered audio and the original audio. Considering the target waveform x_{targ} and the reference waveform x_{ref}, the MCD can be calculated by

$$MCD = \frac{10}{T \ln 10} \sum_{t=0}^{T-1} \sqrt{2 \sum_{d=1}^{D} [c_d^{targ}(t) - c_d^{ref}(t)]^2}, \quad (2)$$

where $c_d^{targ}(t)$ and $c_d^{ref}(t)$ denote the MFCC [17] of x_{targ} and x_{ref} respectively. T and D mean the total frames and MFCC dimensions. Typically, the recovered audio with an MCD value smaller than 8 indicates satisfactory performance [54]. A lower MCD score indicates better speech intelligibility.

Frequency-weighted Signal-to-Noise Ratio (SNR): To quantify the gain and quality of the reconstructed speech, we used the frequency-weighted SNR [22] calculated by the average gain across multiple frequency bands of the signal:

$$SNR = \frac{10}{N} \sum_{n=1}^{N} \frac{\sum_{k=1}^{K} W(k,n) \log_{10} \frac{|S(k,n)|^2}{(|S(k,n)|-|\hat{S}(k,n)|)^2}}{\sum_{k=1}^{K} W(k,n)}, \quad (3)$$

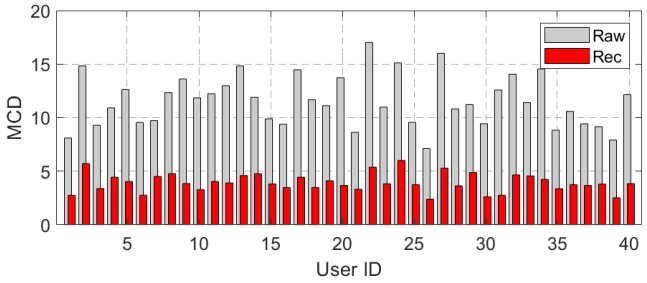

Figure 12: Raw: the score of raw-recovered audio. Rec: the score of reconstructed audio by VibSpeech.

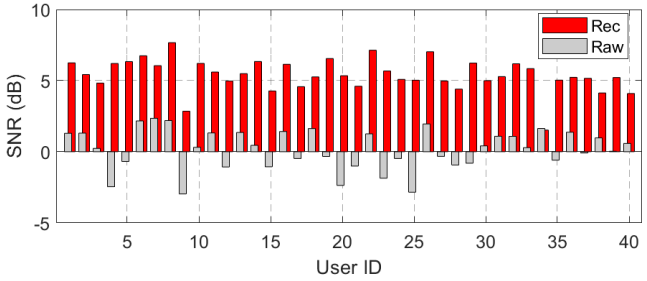

Figure 13: Raw: the score of raw-recovered audio. Rec: the score of reconstructed audio by VibSpeech.

where $S(k,n)$ and $\hat{S}(k,n)$ are weighted spectrums in the k-th frequency band at the n-th frame of original and reconstructed speech. $W(k,n)$ is the weight placed on the k-th frequency band where $W(k,n) = |S(k,n)|^{0.2}$. N is the total number of frames. A higher SNR indicates a better speech quality.

7.2 Overall Performance

To intuitively observe the performance of the wideband speech recovery, we compared the spectrograms of original audio, raw-recovered audio, and reconstructed audio by VibSpeech, as shown in Figure 11. Compared Figure 11(a) with Figure 11(b), we can observe that the frequency components above 500Hz in the raw-recovered audio are absent due to the narrowband frequency response of the vibration-based side channel. From Figure 11(c), we can observe that the high-frequency components are recovered with a bandwidth of up to 8kHz (e.g., consonants /s/ and /z/) after the reconstruction. The reconstructed spectrogram shows a high similarity with the original one in (a). The overall MCD and SNR scores are shown in Figure 12 and Figure 13, respectively. Overall, VibSpeech-reconstructed audio achieves an average MCD/SNR score of 3.9/5.4dB while the raw-recovered audio only achieves an average MCD/SNR score of 11.5/0.2dB. This indicates that VibSpeech can effectively correct the distortion and suppress artifacts in raw-derived vibration signals, and improve the speech intelligibility and quality significantly.

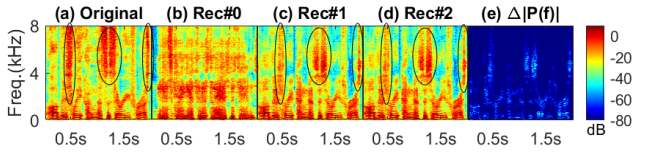

Figure 14: (a) Original audio of speaker A. (b) Reconstructed audio without speaker embedding (speaker A). (c)(d) show results with speaker embeddings extracted from two different utterances of speaker A. (e) Difference between (c) and (d).

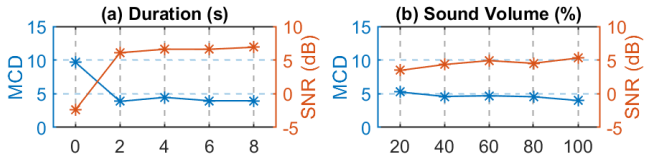

Figure 15: Impact of (a)speaker embedding and (b)volume.

7.3 Impact of Speaker Embedding

To investigate the impact of the speaker embedding, we used different durations of the audio trace for speaker embedding extraction, including 0s (random noise), 2s, 4s, 6s, and 8s. The tested dataset is the one we constructed in Section 7.1. For each tested individual, we randomly chose a trace and selected one of the fragments for the embedding extraction. The collected vibration data corresponding to the left samples are used for the speech reconstruction. The calculated MCD and SNR scores are shown in Figure 15(a). (1) Overall, the MCD score decreases and the SNR score increases with the increasing duration of the embedding audio. (2) We can observe that without the speaker embedding from the victim (i.e., 0s), the recovered audio achieves a limited performance with an MCD score of 9.7 and SNR of -2.4dB. (3) With a short utterance ($\geqslant$2s) for speaker embedding extraction, the reconstructed audio achieves an MCD score lower than 4.5 and an SNR higher than 6.1dB, which indicates satisfactory speech intelligibility and quality. The results indicate that VibSpeech can effectively extract speaker embeddings from the short utterance of the victim to recover wideband speech.

To intuitively observe the impact of the speaker embedding, we used random noise and two different utterances from the same speaker for speaker embedding extraction and compared the spectrograms of reconstructed audio. The results are shown in Figure 14. (1) Compared the original spectrogram (Figure 14(a)) with the reconstructed spectrogram without speaker embedding (Figure 14(b)), we can find although the latter maintains low-band speech components, the reconstructed high frequencies are random-like instead of consistent with formants as shown in the original spectrogram. (2) Figure 14(c) and Figure 14(d) show the reconstructed spectrograms with speaker embeddings extracted from two different utterances of the same speaker. Compared with the original

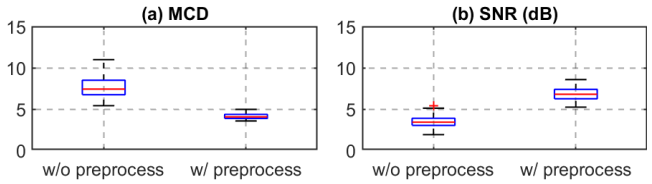

Figure 16: Impact of preprocessing.

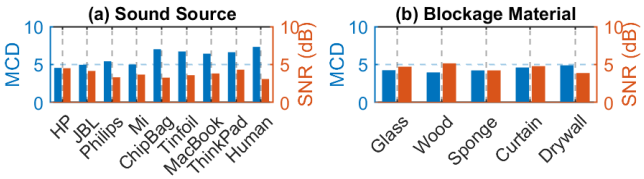

Figure 17: Impact of (a) oscillators and (b) blockages.

audio shown in Figure 14(a), we can observe that the two reconstructed audio in Figure 14(c)(d) contain most of the high-band components of up to 8kHz and the two spectrograms both show high similarity with the original spectrogram. This indicates that VibSpeech can accurately reconstruct lost formants in high band and recover wideband speech. Figure 14(e) shows the difference between the spectrograms shown in Figure 14(c)(d). We can observe that the difference is subtle, which indicates robust speaker-embedding extraction.

7.4 Impact of Sound Volume

We played audio by setting the volume into different values including 20% (63dB), 40% (68dB), 60% (72dB), 80% (78dB), and 100% (84dB). We conducted the experiment in the same scenario as shown in Figure 10(a) with a sensing distance/angle of 3m/0°. The calculated MCD and SNR scores are shown in Figure 15(b). We can observe that the performance is satisfactory in a normal sound volume (e.g., 20%-40%). We also noticed that the performance does not show great promotion but a steady improvement as the sound volume increases. The possible reason is that even though the sound volume increases, this does not change the narrowband frequency response of the vibrating target. Thus, the improvement is not as significant as we expected but shows a smooth ascent. Overall, the reconstructed audio by VibSpeech has an average MCD score of below 5.3 and an average SNR score of above 3.5dB, which indicates satisfactory performance with intelligible speech recovery.

7.5 Impact of Preprocessing

A key training strategy for vocal-guided wideband extension (Section 6.3) is generating narrowband speech from public audio datasets by applying low-pass filtering. However, as investigated in Section 5, the difference between the narrowband audio and narrowband vibration signal is that the raw vibration signals suffer distortions and artifacts in the low band. Thus, we proposed *Preprocess* in Section 6.2 to merge the gap between normal narrowband audio and distorted vibration signal. To study the impact of *Preprocess*, we compared the results of speech reconstruction with and without *Preprocess* and kept other settings the same. The tested dataset is the one we constructed in Section 7.1. As shown in Figure 16(a), we can find that the MCD score degrades from 7.7 to 4.1 when the speech is reconstructed with *Preprocess*. As shown in Figure 16(b), the SNR increases from 3.4dB to 6.7dB with over 3.3dB improvement. This indicates the *Preprocess* in Section 6.2 can effectively suppress the distortions and artifacts in the low band of vibration signals and thus contributes to speech recovery with better intelligibility and quality.

7.6 Different Oscillators

We chose different targets for speech recovery, including loudspeakers (HP, JBL, Philips, and Mi), passive films (chip bag and tinfoil, 40cm from the HP loudspeaker), built-in loudspeakers of laptops (MacBook and ThinkPad), and human speaker (male, 40cm away from the tinfoil). We placed the mmWave sensor outside the soundproof room (Figure 10(a)) with a sensing distance/angle of 3m/0° and captured the vibration of the in-room target. The loudspeakers and laptops played audio with an SPL of 68dB. The human speaker read the same corpus with around 72dB SPL and induced vibrations on the tinfoil. A microphone recorded the audio at the same time. From Figure 17(a), we can observe that the MCD ranges from 3.5 to 7.3 and the SNR score ranges from 3.1dB to 4.5dB. The results on loudspeakers are better than the ones on passive films and human speaker (MCD/SNR: 7.3/3.1dB). The reason is that the vibration amplitude on loudspeakers is larger than the sound-induced vibration amplitude on passive films by loudspeakers or a human speaker, which results in a higher SNR on the reflected mmWave signals. This also reveals that compared with passive films, loudspeakers can be more prone to be a compromised target. We can also find that the results on external loudspeakers are better than the ones on built-in loudspeakers of laptops (6.4/3.8dB, 6.6/4.3dB). The reason is that the solid-propagated vibration on the laptop shell can suffer more attenuation compared with the former. Overall, VibSpeech can both cause threats to passive films and loudspeakers. When passive films are not available in the attack scenario, VibSpeech can still cause threats to the commonly used loudspeakers and recover intelligible speech.

7.7 Blockage Materials

We performed experiments by penetrating different materials for vibration sensing. Tested materials include soundproof glass, wood (0.5cm-thick), sponge (1.5cm-thick), curtain, and drywall (2cm-thick). We placed the mmWave sensor 3m away

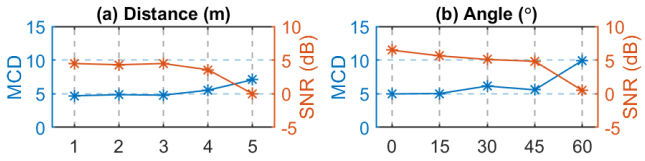

Figure 18: Impact of sensing (a) distance and (b) angle.

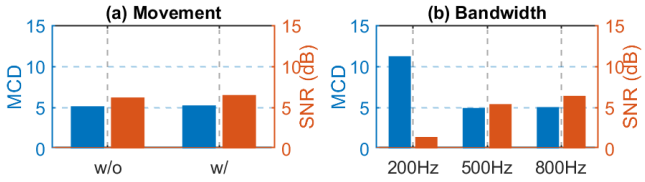

Figure 19: Impact of (a) movement and (b) raw bandwidth.

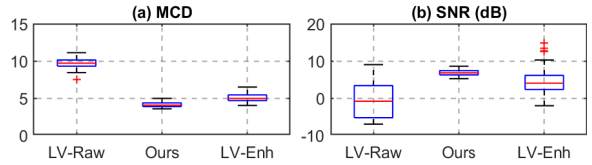

Figure 20: Comparison with laser vibrometry.

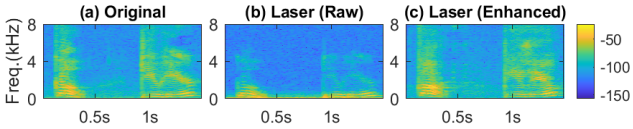

Figure 21: Spectrograms of (a) original, (b) laser-recovered, and (c) VibSpeech-enhanced audio (*"go, do you hear"*).

from the HP loudspeaker with an angle of 0°, and penetrated these materials for speech recovery. The loudspeaker played audio with an SPL of 68dB. The result is shown in Figure 17(b). We can observe that although the performance varies across different materials, the overall MCD and SNR scores are below 5.0 and above 3.9dB, respectively. This indicates that VibSpeech is resistant to common-used soundproof materials and can recover intelligible speech.

7.8 Sensing Distance and Angle

The SNR of reflected mmWave signals can change with the sensing distance and angle, and may affect the performance of speech recovery. Thus, we performed a quantitative experiment penetrating the soundproof wall (Figure 10(a)) to investigate the impact of sensing distance and angle. The distance refers to the distance between the mmWave sensor and the target (i.e., an HP loudspeaker). The angle refers to the angle between the orientation of the loudspeaker and the transmitted-beam direction of the sensor. The loudspeaker played audio with an SPL of 68dB. The results are shown in Figure 18(a)(b). We can find that when the distance increases up to 5m and the angle reaches 60°, the performance shows a noticeable degradation. The reason is that the attenuating reflection due to the increasing distance and angle causes a lower SNR on the received signals and the delicate vibrations are prone to be overwhelmed by the noise floor. But overall, with a sensing distance of around 4m and an angle within 45°, the calculated MCD and SNR scores are lower than 6.2 and above 4.8dB, which indicates a satisfactory performance.

7.9 Impact of Movement

VibSpeech extracts the range-bin of the target after the range-FFT and removes irrelevant range-bins to eliminate interferences, e.g., background movements. Considering that there can be moving subjects around the target during the attack, we conducted a comparison experiment to investigate the impact of surrounding movements. We asked a volunteer to sit on a chair and type randomly at a distance of 1m from the targeted loudspeaker (HP) in the room (Figure 10(a)). Another volunteer is asked to pace back and forth at a distance of 1.5-2.5m from the target. The loudspeaker played audio with an SPL of 68dB. The result is shown in Figure 19(a). We can find that when there are movements around the target (i.e., w/), the MCD score achieves 5.2 which is close to the score of 5.1 when without (i.e., w/o) the movements. The calculated SNR scores under the two conditions are also very close (i.e. 6.2dB for w/o and 6.5dB for w/). The result indicates that VibSpeech is resistant to surrounding movements in the attack scenario.

7.10 Bandwidth of Raw Narrowband Signal

To investigate the impact of the bandwidth of raw-acquired vibration signals, we performed low-pass filtering with different cut-off frequencies f_c on the raw vibration data to acquire narrowband signals with different bandwidths. We used the constructed dataset in Section 7.1. For each experiment, we retrained the bandwidth-extension model (Section 6.3) by setting f_c of the low-pass filter to 200Hz/500Hz/800Hz while keeping other processing (e.g., SpkEnc, Preprocess, and the vocoder) in Section 6 unchanged. We calculated scores of reconstructed audio under different f_c. As shown in Figure 19(b), we can observe that the performance is improved when f_c increases from 200Hz to 800Hz. Because a higher bandwidth of raw-vibration signal contains more speech components and contributes more to the bandwidth extension.

We also notice that the performance is limited when the raw vibration signal has a bandwidth of 200Hz with MCD>11.2 and SNR<1.4dB. The possible reason is that the limited bandwidth compromised the pitch considering the pitch ranges from 80Hz to 255Hz. Besides, we can notice that there is a significant improvement when the bandwidth of vibration signals increases from 200Hz to 500Hz. This indicates that a

Table 2: Performance on the Common Voice corpus.

Performance	Overall	A-C	B-C	C-C
MCD	3.7	9.1	10.2	3.3
SNR	6.1dB	0.1dB	0.2dB	5.9dB

wider bandwidth of the narrowband vibration signal can bring great improvement in the speech recovery and the performance is satisfactory when only with a bandwidth of 500Hz. To investigate the root cause of this result, we used a motion sensor to measure a male speaker's throat vibration when he spoke. We found that frequency components of human vocal-cords vibration can be around 500-600Hz rather than just the pitch (as shown in Figure 26 in Appendix E). Note that these basic frequencies induced by human vocal cords pass through the vocal tract to produce intelligible speech. Thus, when the narrowband (<200Hz) signal loses these frequency components, the produced high-frequency components after the vocal tract can be compromised. This is possibly another reason for the limited performance of VibSpeech when the raw signal has a bandwidth below 200Hz. Note that such narrow bandwidth (<200Hz) is rare for common sound sources as we have investigated in Section 5 and Section 7.6. Overall, VibSpeech can recover intelligible speech even though the raw vibration signal has a narrow bandwidth as low as 500Hz.

7.11 Different Vocal Tracts

To further investigate the performance of VibSpeech across different vocal tracts, we tested VibSpeech on another public dataset (i.e., Common Voice [6]). There were 400 utterances from twenty individuals (10 males and 10 females) involved. We made sure that none of the samples was used to train the model of VibSpeech. We used the trained model in Section 7.1 and kept the setup the same for speech recovery. The calculated MCD/SNR scores of recovered speech are shown in Table 2. We can find that the overall performance is satisfactory with average MCD/SNR scores of 3.7/6.1dB. The result validates the generalization ability of VibSpeech across different vocal tracts. To better understand the impact of vocal-tract features (i.e., speaker embeddings), we chose samples of three individuals and used the embedding from individual A (male), individual B (female), and individual C (male) to compensate for the narrowband speech of individual C. The results of reconstructed speech with embeddings of A, B, and C are denoted as A-C, B-C, and C-C, respectively. We can find that VibSpeech performs well with embedding C (3.3/5.9dB). But the performance degrades when with embeddings from another person (e.g., A or B). Considering that VibSpeech used target's vocal-tract features (i.e., speaker embedding) to compensate for the narrowband speech, the degradation possibly results from the differences in vocal tracts between C and A/B. The result indicates that currently vocal-tract features of the target are still required to achieve satisfactory performance.

7.12 End-to-End Attack

We performed an end-to-end attack to demonstrate the attack process of VibSpeech by penetrating the soundproof wall shown in Figure 10(a) with a sensing distance/angle of 3m/0°. We asked a volunteer to sit in the room and play the speech audio (68dB SPL) of five males and five females chosen from the 40 individuals via an HP loudspeaker. For each individual, we randomly selected one audio trace to extract his/her speaker embedding and used the remaining samples for testing. The used models for speech recovery are the ones pre-trained in Section 6. During the attack, we used the mmWave sensor to transmit and receive mmWave signals from the room outside, and derived captured vibrations of the loudspeaker on a laptop. (1) The derived vibration signals were first fed into the *Preprocess* (Section 6.2) to suppress the low-band distortion and artifacts. (2) Then the preprocessed signal and corresponding speaker embedding were fed into the vocal-guided bandwidth extension module (Section 6.3) to recover the high-frequency band. (3) Finally, the enhanced spectrogram was fed into the vocoder (Section 6.4) to generate an audible waveform.

To fully understand the performance of the end-to-end attack, we compared the performance of VibSpeech with the laser vibrometry. For the laser vibrometry, we performed the experiment in a line-of-sight condition (1m) without blockage as the same configuration shown in Figure 4(d) and used the same speech corpus as the one for VibSpeech. We calculated the scores of raw laser-recovered audio (*LV-Raw*), VibSpeech-recovered audio (*Ours*), and the laser-recovered audio but enhanced by our method (*LV-Enh*, i.e., we precessed the audio of *LV-Raw* with VibSpeech as mentioned above to acquire the audio of *LV-Enh*). The results are shown in Figure 20.

We can find that the average MCD/SNR of the laser vibrometry (*LV-Raw*) achieves 9.7/ -0.1dB which indicates the worst performance. By contrast, VibSpeech (*Ours*) performed better with an average MCD/SNR score of 4.1/6.8dB. The reason is that although the laser vibrometry has a higher resolution than the mmWave sensor for vibration sensing, the recovered audio is still distorted and has large attenuation in the high-frequency band due to the uneven frequency response of the vibration-based side channel (Section 5). The attenuated high-frequency components can cause mel distortions in the laser-recovered audio and result in poor performance. Enhanced by our proposed scheme, the performance of the laser vibrometry (*LV-Enh*) is improved with an average MCD/SNR score of 4.3/5.6dB. Figure 21 shows the result of *LV-Raw* and *LV-Enh*. Compared with the original audio shown in Figure 21(a), we can find that high-frequency components (>500Hz) of the raw laser-recovered audio attenuate significantly as shown in Figure 21(b) while the enhanced audio shown in Figure 21(c) has a wider bandwidth which contributes to higher speech intelligibility. This result also validates that VibSpeech can be applied to laser vibrometry for speech enhancement.

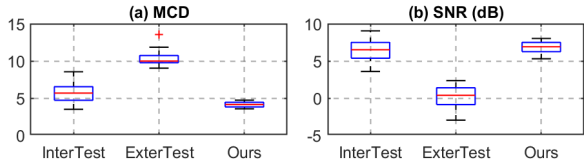

Figure 22: Compared with target-dependent speech recovery.

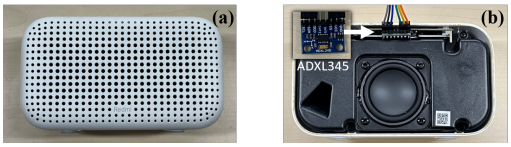

Figure 23: (a) We played audio via a smart speaker (Redmi). (b) The accelerometer captured the vibration of the speaker.

7.13 Comparison with Target-dependent Speech Recovery

To achieve intelligible speech recovery, an intuitive method is to learn the mapping between narrowband vibration signals and wideband audio of the victim using an end-to-end neural network [20, 56]. In such a case, the attacker is required to collect both vibration (narrowband) data and ground-truth (wideband) audio from the target at the same time to train the model, i.e., a target-dependent attack. Besides, such trained models represent the mapping between limited combinations of phonemes in the training set. But for the same combination of phonemes, the interval and duration of each phoneme can be different for two individuals. Next, we compared our method quantitatively with the one mentioned above.

Quantitative Experiment. For a fair quantitative comparison with related methods [20, 56], we used the same dataset constructed under the same experimental setting in Section 7.1. For the end-to-end learning, we used the widely-used Unet structure [20, 56] to learn the mapping between the spectrograms of vibration signals and corresponding ground-truth audio, and used the vocoder in Section 6.4 to generate audio waveforms. We separated the 40-individual dataset into three parts, 80% data from the first 20 individuals as the training set, the remaining 20% data from the first 20 individuals as a testing set (*InterTest*), and the data of the remaining 20 individuals as another testing set (*ExterTest*). For VibSpeech, we used the models in Section 6 and used the same dataset as *ExterTest* to show the performance on untrained targets.

Result Analysis. To compare the performance of above methods, we calculated the MCD and SNR scores of recovered audio and the results are shown in Figure 22. For the end-to-end learning, we can observe that when the testing data is from individuals included in the training set (*InerTest*), the performance is satisfactory with an MCD/SNR of 5.7/6.5dB. However, for unseen targets that are not included in the training set (*ExterTest*), the performance is poor with the MCD

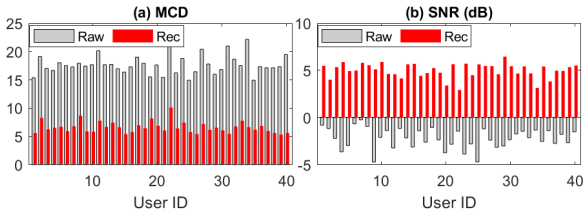

Figure 24: Overall performance of the IMU-based method.

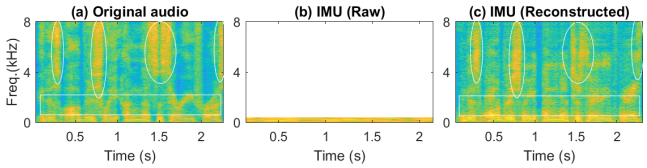

Figure 25: (a)Original, (b)IMU-recovered, and (c)VibSpeech-enhanced audio (*"it is obviously unnecessary for us"*).

score increasing to over 10.3 and the SNR degrading to below 0.2dB. The result illustrates the limitation of the end-to-end learning on the cross-target attack. For unseen targets, our method outperforms the former with an MCD score lower than 4.7 and an SNR higher than 5.3dB, which indicates an intelligible and high-quality speech recovery. The results indicate that our method has a better generality for unseen targets which is more practical in a real attack case.

8 Extension to IMU-measured Vibration

In this section, we applied the proposed scheme (Section 6) to IMU-measured vibration signals for speech recovery. Modern commercial acoustic devices [1] are equipped with accelerometers to enable tap gesture controls to pause/resume music or detect position changes of the device. Adversaries e.g., malicious service suppliers or man-in-the-middle attackers, may use the acquired vibration data from the motion sensor for eavesdropping. Due to the inaccessibility of the motion-sensor data on commercial loudspeakers, we attached an accelerometer (ADXL345) to a smart speaker's motherboard as shown in Figure 23 to reveal the threat.

End-to-End Wideband Speech Recovery. We played audio of the same corpus in Section 7.1 via the smart speaker (68dB SPL) and acquired corresponding accelerometer data over the SPI interface of a Raspberry Pi 4B at a sampling rate of 1kHz. For each individual, we randomly chose a sample and used 3s of audio for his/her speaker embedding extraction (Section 6.1). The remaining samples of the individual are used for testing. The detailed process for each audio reconstruction is as follows. (1) We upsampled the vibration signal to 16kHz and preprocessed (Section 6.2) the data to remove artifacts and correct low-band distortions. (2) We performed the vocal-guided bandwidth extension (Section 6.3) with the

preprocessed vibration data and the extracted speaker embedding, and acquired the enhanced spectrogram. (3) We fed the enhanced spectrogram into the vocoder (Section 6.4) and acquired the reconstructed audio. Note that all the models are the ones introduced in Section 6 without re-training.

Result Analysis. For comparison, we calculated scores of recovered audio from raw vibration data (*Raw*) and reconstructed audio by VibSpeech (*Rec*). The results are shown in Figure 24. From Figure 24(a), we can observe that the audio recovered from the raw IMU-captured vibration data suffers significant distortions with an average MCD score of 17.7 and SNR of -2.2dB. The reason is that the sensor can only recover frequency components lower than 500Hz due to the limited sampling rate of 1kHz according to the Nyquist theorem [42]. The absence of higher frequency components causes severe distortions and a poor SNR of the recovered audio. However, after the enhancement by VibSpeech, the IMU-recovered audio has a wider bandwidth of up to 8kHz, and thus achieves a better MCD score of 6.5 and SNR of 5.1dB. Figure 25(a)(b)(c) show the spectrograms of original audio (ground-truth), raw-IMU-captured vibration signal, and VibSpeech-reconstructed audio based on the raw IMU data, respectively. Comparing (b) with (a) in Figure 25, we can find that the raw vibration signal captured by the IMU loses high-frequency components above 500Hz. After reconstruction (Figure 25(c)), the lost speech formants are recovered which contributes to better speech intelligibility and quality.

9 Limitation and Discussion

Vibration Signal with a Narrower Bandwidth. VibSpeech achieves wideband speech recovery with up-to-8kHz bandwidth for narrowband vibration signals below 500Hz. However, we find that the performance is not satisfactory when the raw narrowband signal has an extremely limited bandwidth under 200Hz. As analyzed in Section 7.10, the vocal-cord-induced components (denoted as *source components*) can be around 500Hz, which pass through the human vocal tract to generate higher frequencies and finally produce intelligible speech. Thus, a narrowband signal with incomplete source components may cause a limited performance on wideband speech recovery by VibSpeech. The frequency aliasing should also be considered when with a low sampling rate. To make VibSpeech work under a narrower bandwidth (e.g., smartphone IMUs), a potential improvement is to investigate the inner relationship between the pitch and low-order harmonics.

A General Model for Wideband Speech Recovery. Recovering wideband audio from band-limited signals has always been a challenging problem, especially for the vibration-based side channels. Besides addressing the uneven frequency response, another key challenge lies in how to reconstruct the high-band components accurately without information loss or bias. From an attacker's point of view, an ideal solution is to design a general model that can recover high-band speech components of an arbitrary victim without any prior knowledge about the victim. However, there is a fact that the high-band components are determined mostly by human vocal-tract features (i.e., the classic source-filter model [46]) that are diverse among people. This introduces a contradiction between the goal of a **general** model and the **uniqueness** of human pronunciation. VibSpeech reveals the threat that vocal-tract features can be used to extend the bandwidth of narrowband audio once the attacker acquires a short (2s-4s) utterance from the victim. This reminds the public that people should be aware of their casual speech leakage to avoid exposure of their vocal-tract features, e.g., be careful with unknown calls or posting voice samples on the Internet.

10 Countermeasures

RF-based methods. To defend against the malicious mmWave sensor, (1) an intuitive method is to deploy electromagnetic shielding to block the transmitted mmWave signals, such as a Faraday cage. However, it is costly to deploy the shielding materials for a conference room with hundreds of square meters. By contrast, (2) passive smart surfaces [12] can be a potentially cost-effective solution to defend against malicious mmWave signals. The user can deploy the tag near the loudspeaker to manipulate reflected mmWave signals and disturb the acquired vibration in the reflected signal. To actively defend against the attack, (3) the user can use a wireless jammer to interfere with the malicious receiver. However, such defense requires parameters of the malicious device [50], such as operating frequency band and chirp duration.

Acoustic-based methods. The mmWave-based attack in this paper works in a scenario where the user plays audio via a loudspeaker. To avoid speech leakage via the outside vibration-based side channel, the user can choose a headset for confidential communication. However, note that VibSpeech not only works in the mmWave sensing methodology but also works for other vibration-based side channels, such as IMU-based speech recovery. Nowadays, IMUs are widely used in headsets and earphones [2] for touch control and position estimation, which may still be able to acquire the inner vibrations and become potential attack surfaces.

11 Conclusion

In this paper, we revealed a new speech threat that adversaries can recover wideband (up to 8kHz) intelligible speech from narrowband (<500Hz) signals of vibration-based side channels, when a short utterance (2s-4s) of the victim is exposed to the attacker. We proposed a vocal-guided general scheme (VibSpeech) and a mmWave-based prototype to demonstrate the threat. We evaluated VibSpeech with extensive experiments and validated its generality on the IMU-based method.

A Loss Function of SpkEnc in Section 6.1

The Generalized End-to-End (GE2E) loss [47] characterizes the similarity of embeddings from different speakers by building a similarity matrix. Considering the embeddings $e_{ij}(1 \leqslant i \leqslant N, 1 \leqslant j \leqslant M)$ of M utterances from N speakers, the similarity matrix $S_{ij,k}$ is calculated from a two-by-two comparison of all embeddings e_{ij} against the embedding centroid $c_k(1 \leqslant k \leqslant N)$ for every speaker:

$$S_{ji,k} = \begin{cases} \omega \cdot \cos(e_{ji}, c_j^{(-i)}) + b & \text{if } k = j; \\ \omega \cdot \cos(e_{ji}, c_k) + b & otherwise, \end{cases} \tag{4}$$

where $c_k = \frac{1}{M}\sum_{m=1}^{M} e_{km}$, $c_j^{(-i)} = \frac{1}{M}\sum_{m=1}^{m\neq i} e_{jm}$. ω and b are learnable parameters of the network. Then the loss on each

embedding e_{ji} and GE2E loss L_G can be calculated by

$$L(e_{ji}) = S_{ji,j} - \log \sum_{k=1}^{N} \exp(S_{ji,k}), L_G = \sum_{j,i} L(e_{ji}). \quad (5)$$

Abstract

The heap is a critical and widely used component of many applications. Due to its dynamic nature, combined with the complexity of heap management algorithms, it is also a frequent target for security exploits. To enhance the heap's security, various heap protection techniques have been introduced, but they either introduce significant runtime overhead or have limited protection. We present CAMP, a new sanitizer for detecting and capturing heap memory corruption. CAMP leverages a compiler and a customized memory allocator. The compiler adds boundary-checking and escape-tracking instructions to the target program, while the memory allocator tracks memory ranges, coordinates with the instrumentation, and neutralizes dangling pointers. With the novel error detection scheme, CAMP enables various compiler optimization strategies and thus eliminates redundant and unnecessary check instrumentation. This design minimizes runtime overhead without sacrificing security guarantees. Our evaluation and comparison of CAMP with existing tools, using both real-world applications and SPEC CPU benchmarks, show that it provides even better heap corruption detection capability with lower runtime overhead.

1 Introduction

The heap is a region of memory that is dynamically allocated during runtime. It is widely used for dynamic memory allocation and for storing data structures with variable sizes. Due to its frequent use and complex nature, the heap is vulnerable to spatial and temporal memory errors. The prominence of heap errors as a source of vulnerabilities has been consistently high over the years. According to Microsoft, heap errors were responsible for 53% of Remote Code Execution (RCE) CVEs in their products [40]. Google Project Zero discovered that heap errors accounted for 69% of zero-day vulnerabilities observed in the wild [59] in 2022. Until now, 65% vulnerabilities are confirmed as heap-based zero-day in Linux, 2023 [7].

Over the years, various heap protection techniques have been introduced to enhance the security of the heap, including improved heap management algorithms [49] and the implementation of layout randomization techniques [34, 44]. These advancements have made the heap more secure. However, the continuous discovery and development of new vulnerabilities and exploitation techniques [16, 24, 33, 54, 58] suggest that heap exploitation remains an ongoing challenge.

To address heap exploitation effectively, we believe that detecting and capturing heap memory corruption is a key solution. Previously, various research efforts have been made towards this goal, such as Memcheck [27] and Address Sanitizer (ASAN) [47] for comprehensive protection or works that mitigate use-after-free errors [11,12,23,31,42,49,53] or detect out-of-bound access [19,41,56] for partial protection. However, these techniques either introduce significant runtime overhead or offer weak security guarantees. To be specific, MemCheck [27], though capable of delivering full heap detection, suffers from a substantial 26x overhead. ASAN and its variant ASAN–, as we will discuss in Section 6, face challenges with false negatives in both temporal and spatial heap error detection [32]. Other tools like FFmalloc [11], Delta Pointer [30], and Oscar [18] only offer partial heap protection, limiting their effectiveness.

In this work, we introduce CAMP (**C**ompiler and **A**llocator-based Heap **M**emory **P**rotection), a novel heap sanitizer, for detecting and capturing spatial and temporal heap errors. Unlike previous works [19,22,28,32,46,55,56,61] that require hardware support, CAMP is a software-only tool, consisting of a compiler and a seglist allocator. The compiler instruments the target program to validate the pointer boundary and build point-to relation at runtime. The customized memory allocator tracks memory ranges for each allocation, supports the instrumented instructions, and neutralizes dangling pointers when a memory object is freed.

In comparison with previous works [60, 62], the key novelty of CAMP is mainly manifested in its design that leverages the run-time guarantee to optimize static instrumentation and thus reduces overhead. For example, to capture dangling pointer dereference, previous methods need to check each pointer dereference. In our design, CAMP introduces a runtime scheme that could guarantee that no dangling pointer exists and thus allow CAMP's compiler to eliminate corresponding pointer dereference checks. Furthermore, as we will detail in Section 4, CAMP implements its run-time scheme based on the extension of an existing allocator. This allocator has an $O(1)$ computation complexity in pointer validation. As a result, CAMP can perform pointer validation more efficiently.

In summary, this paper makes the following contributions.

- We present a novel approach CAMP that employs a customized allocator and a compiler to safeguard against heap

memory corruption. Additionally, we propose optimization strategies to reduce the performance overhead introduced by the instrumentation.

- We implement CAMP by customizing a segregated list allocator – tcmalloc and building our instrumentation optimization mechanism on top of LLVM 12.0 compiler framework. We open-sourced our prototype of CAMP at [8].
- We conduct a thorough evaluation of CAMP using the real-world application Nginx, as well as the SPEC CPU 2006 and 2017 benchmarks, from both security and runtime overhead perspectives. The evaluation compares CAMP' performance with other defense solutions offering similar heap protection levels.

The rest of the paper is organized as follows. Section 2 introduces the background of memory corruption on the heap as well as heap allocators. Section 3 discusses the assumptions of our research and the threat model. Section 4 describes the details of the proposed techniques. Section 5 presents our implementation details. Section 6 evaluates the security and runtime overhead of our proposed techniques. Section 7 provides the discussion of some related issues, followed by the related work in Section 8. Finally, we conclude the work in Section 9.

2 Background

2.1 Heap Memory Corruption & Protection

In general, there are two main types of heap memory corruption, overflow and use-after-free. In the following, we describe those two types of memory corruption in detail and discuss their protection.

Heap Overflow. Generally, each heap object has its own memory space. When the access to a heap object exceeds its memory space, a heap overflow happens. One common way to detect heap overflow is to reserve some memory as heap cookies or red zones. Once the magic value in the reserved area is tempered, the heap overflow could be detected [37]. However, this design naturally has the drawback of being bypassed. For example, the attacker could fail the detection by leaking the heap cookie [5] or overflowing the memory with the red zone intact [45]. An alternative approach is to validate pointers making sure no out-of-bound access happens [19, 38, 56]. This approach is effective in general but often introduces non-negligible overhead [41].

Heap Use-After-Free. When the memory space of a heap object is freed, the references to the object left become dangling pointers. The program should never deference the dangling pointer. Otherwise, a use-after-free would occur. Researchers have proposed many techniques to detect use-after-free. ASAN [47] uses shadow memory to record the memory status and instruments every memory access. Accessing a freed object could be detected immediately by checking the shadow memory. Although ASAN's approach only introduces reasonable overhead, its security guarantee is weak where the attacker could overwrite the shadow status by reallocating the freed object. A more effective approach proposed is to never reuse freed memory [11] or delay the free of memory [57], so that the attacker would not be able to corrupt freed objects. Other than that, once an object is freed, one could nullify all its existing references [17,31,53], which also prevents use-after-free fundamentally.

2.2 Heap Memory Allocator

Heap memory allocators manage dynamic "global" memory and aim for quick allocation/deallocation with minimal memory waste. This summary presents three prevalent types.

Firstly, sequential-fit allocators use a freelist connecting all freed memory objects. When an allocation request is made, the allocator searches the freelist until an adequately sized object is found. It splits larger memory objects, reallocating the excess back into the freelist, and merges neighboring freed objects to minimize fragmentation. Secondly, Segregated List allocators (seglist) manage an array of freelists, each holding freed objects of identical size. Allocation and deallocation require identifying the corresponding freelist for the requested size, avoiding the need for splitting and merging but introducing additional steps. Lastly, the buddy system allocator, similar to seglist, also maintains freelists for varying sizes. When the freelist for a requested size is empty, the allocator splits a larger object to fulfill the request. On deallocation, it reconsolidates the remaining portion back into a larger object.

3 Assumptions & Threat Model

CAMP focuses on detecting heap errors, including spatial and temporal heap errors. We assume the target program (written in low-level language) is compiled by CAMP and contains at least one heap-based memory vulnerability. As our work focuses on protecting userspace applications, the security of lower-level kernel is out of the scope. In our threat model, the attacker, who is aware of the deployment of CAMP, has access to the heap vulnerability and is seeking to exploit it for privilege escalation.

4 CAMP

4.1 A vulnerable toy program

List 1 illustrates a toy program that contains two heap memory corruption vulnerabilities. Specifically, the program allocates 16 bytes of memory (line 2), then accesses the memory object at index 32 which exceeds the boundary of the

```
1 void main() {
2     char *buf = malloc(16);
3     buf[32] = 'x';
4     free(buf);
5     buf[1] = 'y';
6 }
```

Listing 1: A toy vulnerable example.

```
1 void main() {
2     char *buf = malloc(16);
3     __escape(&buf, buf);
4     __check_range(buf, &buf[32], sizeof(char));
5     buf[32] = 'x';
6     // free buf, which neutralizes the dangling
  ↪   pointer stored in &buf
7     free(buf);
8     __check_range(buf, &buf[1], sizeof(char));
9     buf[1] = 'y';
10 }
```

Listing 2: The toy program with CAMP's protection.

memory range (line 3), causing a heap memory overflow. It is noted that this heap overflow could not be detected by ASAN because the overflow skips the red zone. In line 4, the memory object is freed, which makes the pointer `buf` a dangling pointer. After this, the dangling pointer is dereferenced (line 5), resulting in a use-after-free memory corruption.

4.2 CAMP's Protection

Briefly speaking, CAMP instruments the program to detect memory corruption and prevent exploitation. List 2 illustrates the toy program protected by CAMP. In the following, we describe how CAMP protects the vulnerable toy program.

Pointer Validation. CAMP detects heap overflow by validating result pointers from pointer arithmetic, making sure no out-of-bound pointer is generated. This is achieved by adding a check instruction at the site of the pointer arithmetic to query the runtime and verify that the result pointer is within the range of the base pointer. As demonstrated in List 2, pointers `&buf[32]` and `&buf[1]` are generated based on the buffer `buf` in lines 5 and 9, respectively. CAMP automatically instruments check instructions in lines 4 and 8 to validate these pointers. If the runtime detection determines that `&buf[32]` is an out-of-bound pointer, CAMP will abort the execution to prevent exploitation. Note that the query requires CAMP to maintain awareness of each memory allocation and its associated memory range, which is recorded during runtime for each heap allocation (line 2).

Neutralizing Dangling Pointers. CAMP prevents use-after-free by neutralizing dangling pointers. At runtime, CAMP constructs the point-to relation by instrumenting the program. When a memory object is freed, CAMP could look up the built point-to relation and identify the dangling pointers to the freed memory. By neutralizing those dangling pointers, use-after-free access is no longer possible. Copying pointers (i.e., *pointer escapes* [51]) is tracked to build the point-to relation.

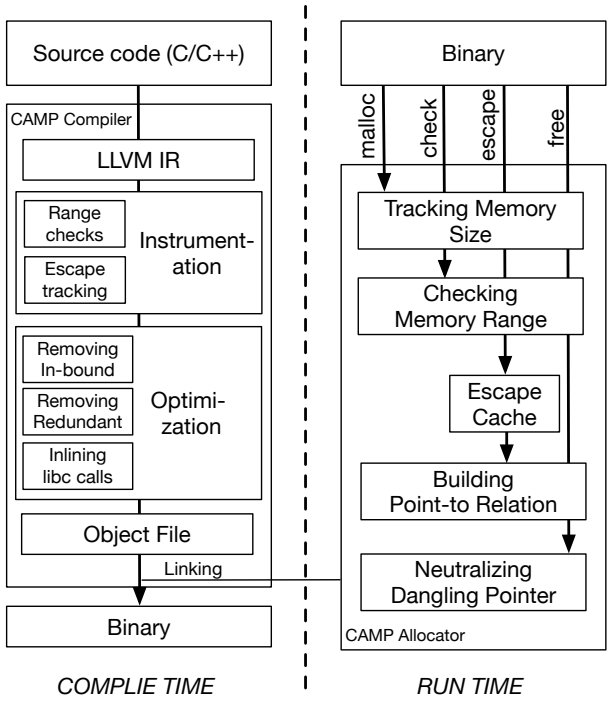

Figure 1: The design overview of CAMP.

For example, the program copies the heap pointer to the variable `buf` (line 2 of List 2), which is a pointer escape and CAMP instruments an escape tracking instruction after that (line 3). The escape tracking instruction takes as input the address of the variable and the pointer, annotating which address contains a reference to the memory allocation. After this, the program frees the memory (line 7). Inside the free, CAMP will identify the existing dangling pointers to the freed memory and neutralize them as non-congenial. As a result, the variable `buf` no longer references the freed memory and the program crashes when it is dereferenced (line 9).

4.3 Design Overview

Figure 1 shows the core components of CAMP, which consists of a compiler and a memory allocator. The CAMP compiler, which is built on top of LLVM, takes the source code as inputs and outputs binaries linked with CAMP allocator. During the compile time, the compiler first translates the source code into LLVM IR and then instruments the range checking and escape tracking instruction to defend against heap memory corruption. After this, the compiler applies several novel compiler optimizations to reduce the overhead of protection, without sacrificing security guarantees. At run-time, CAMP's allocator handles the heap memory allocation/deallocation request. In addition, it provides support for instrumented instructions. Specifically, the allocator tracks the memory range for each allocation, so that the allocator could validate the bound information of pointers for each range checking

query. The allocator also handles the escape tracking instruction to build the point-to relation. With this, whenever a memory object is freed, it is capable of neutralizing the corresponding dangling pointers, preventing the UAF access from dangling pointers.

4.4 Compiler Instrumentation

Instrumenting Range Checking. As our program model does not allow casting integers to pointers, initial pointers are all from either explicit memory allocation (i.e., malloc), or taking the address from global or stack variables. [41] Those pointers then are used through *pointer arithmetic* to create new pointers, then to access memory. The range checking in CAMP is to ensure that all pointers after arithmetic are still inbound, therefore, preventing heap overflow. As is shown in List 1, the range checking takes three arguments, which are the base pointer *src*, the result pointer *dst* of the arithmetic, and *dst*'s type size *size*, respectively. The run-time will assert that the memory ranging from *dst* to $dst + size$ is within the memory range of *src*.

It is noted CAMP only protects heap memory, so validating non-heap memory pointer is redundant. To save unnecessary validation, CAMP performs dataflow and alias analysis on the LLVM IR to determine the point-to relation of pointers. If a pointer could be determined at compile time that it does not point to the heap, CAMP will not instrument range checking for it.

Instrumenting Escape Tracking. The inserted escape tracking allows CAMP to build the point-to relation of memory objects at run-time. We follow a similar approach introduced in CARAT [51, 52] and DangNull [31] to insert the tracking after *pointer escapes* (i.e., copying pointers). As is described in Section 4.2, the tracking takes the copied pointer and its stored address as arguments. Different from CARAT and DangNull, which instrument all the potential pointer escapes, CAMP skips pointer escapes if the pointer of which is determined not to reference the heap at compile time. As the goal of CAMP is protecting heap memory error, skipping those non-heap point-to relations does not jeopardize the security but helps CAMP obtain better performance.

4.5 Runtime Support

The runtime of CAMP provides underlying support of CAMP's instrumentation. The performance of executing inserted instruction is critical to the overall performance of CAMP. Assuming that a program has m pieces of memory allocated, and CAMP maintain the record of the allocated memory in a linked list. In the worst case, performing a single range checking will cause $O(m)$ time complexity, which apparently would introduce unattainable runtime overhead. Likewise, a dummy design that records n pointer escapes in a linked list would introduce $O(n)$ time complexity when freeing an object. In the following, we describe how our design cooperates with the allocator to provide fast runtime support.

Seglist Allocator. As we mentioned in Section 2, a Seglist Allocator uses different free lists for different sizes of memory objects. For example, tcmalloc [25], a Segregated List Allocator developed by Google, uses *span* as the basic memory management unit. Each span manages a size class of memory objects on several continuous memory pages. The spans are stored in a page table where the page is used as the key. Whenever allocating/deallocating a memory object, tcmalloc could find its span, and then retrieves the freelist with constant time complexity.

CAMP's allocator leverages the design of the Segregated List Allocator to provide fast runtime support. For each span, CAMP records the size of memory objects as one of the metadata. Since the seglist allocator splits the memory page equally into objects, given a heap pointer denoted as *ptr*, we could first calculate the index of the object with:

$$idx = (ptr - page\_base)/size$$

where *idx* is the object index to the span, *page_base* represents the start address of the page in the span, and *size* refers to the size of the object. With this information, the lower bound of the memory range can be identified as $page\_base + idx * size$ and the upper bound as $page\_base + (idx+1) * size$. This straightforward approach results in constant time complexity for pointer validation.

Maintaining Point-to Relation. CAMP differs from DangNull [31] and CARAT [51, 52] in its approach to encoding the point-to relation. While DangNull and CARAT use a red-black tree structure, which optimizes the time complexity of finding a relation to $O(logN)$, CAMP integrates the point-to information into the seglist allocator, optimizing cost to constant time complexity. Specifically, CAMP's seglist allocator maintains an escape table for each span, which is a map of object indices to their escape lists. The escape lists are linked-list structures that chain corresponding escapes to their dedicated objects. When an escape tracking call is made, CAMP calculates the memory object's index in the span, retrieves its escape list from the table, and inserts a record into the list. Upon a memory object is freed, CAMP's allocator checks its escape list and neutralizes all the existing dangling pointers to the memory object.

To further boost the overall performance of CAMP, we design a cache mechanism for maintaining the point-to relation. New point-to relations are temporarily stored in the cache until it becomes full, at which point the records are transferred to the allocator in a batch, while skipping any duplicates. This cache design boosts runtime speed and reduces memory overhead, particularly in scenarios where the program operates repeatedly in the same block and creates similar point-to relations.

```
1  struct obj {
2      int a;
3      int b;
4  };
5  struct obj* bar() {
6      // type-casting from void* to obj*
7      struct obj *o = malloc(sizeof(struct obj));
8      __check_range(o, o, sizeof(struct obj));
9      ...
10 }
11 int foo(struct obj *ptr) {
12     __check_range(ptr, &ptr->a, sizeof(ptr->a));
13     ptr->a = 1;
14     __check_range(ptr, &ptr->b, sizeof(ptr->b));
15     ptr->b = 2;
16 }
```

Listing 3: An example of optimizing structure field access checks.

4.6 Compilation Optimization

One of the CAMP's characteristics is that it leaves a large room for potential optimization during the compilation time. This characteristic could boost performance significantly and, at the same time, preserve security. In the following, we describe three optimization algorithms we design for CAMP.

Optimizing range checks with type information. A naive design against out-of-bound access is to have range checks on every pointer arithmetic to ensure that pointers do not exceed memory bounds. As an example, consider the function `foo` in List 3. The variable `ptr` in lines 13 and 15 involves two pointer arithmetics, and CAMP must insert range checks for the result pointers (lines 12 and 14) for security purposes. An optimization strategy is that if the compiler knows the pointer is in-bound, the validation of which could be removed to improve the performance. However, the compiler typically lacks information about the memory range of a pointer, making it challenging to determine which pointers are within bounds.

To apply the optimization, we use type information to determine the memory range of a pointer during the compilation process. This involves not only validating pointer arithmetic, but also validating type-casting operations to ensure the memory space referenced by a typed pointer is adequate for its corresponding type. For example, in the code shown in List 3, the function `bar` allocates a new object `obj` (line 7). The return type of `malloc` is `void*`, not `struct obj*`, so the compiler inserts a type-casting instruction, after which CAMP inserts a range check to ensure the memory space is sufficient to hold the structure `obj` (line 8). With this type-casting validation, the compiler can safely infer that the memory space of a typed pointer is at least its type size. As a result, the compiler can conclude that pointers referring to the structure field are in-bound. Therefore, CAMP can remove the range checks in lines 12 and 14. Further, The compiler can also guarantee that the memory of pointer `o` (line 6) is at least the size of its type, so the range check in line 7 can also be optimized and eliminated.

Algorithm 1: Removing Redundant Validation

```
1  Input: A function F ;
2  Output: A set of pointer to be validated S ;
3  Initialize: NewPointerSet = getNewPointerSet{F} ;
4  In = Out = changeSet = dict() ;
5  foreach ptr ∈ NewPointerSet do
6      if pointerMapbase[base(ptr)] == NULL then
7          pointerMapbase[base(ptr)] = set() ;
8      pointerMap[base(ptr)].add(ptr) ;
9  In = pointerMap ;
10 changeSet = In − Out ;
11 while changeSet ≠ ∅ do
12     foreach key, val ∈ In do
13         if ∃ p, p' ∈ val and RedundantPair(p, p') then
14             val.remove(p') ;
15             val.p.offset = MAX(p.offset, p'.offset) ;
16             Out[key] = val ;
17             break;
18         else
19             Out[key] = val ;
20     changeSet = In − Out ;
21     In = Out ;
22 foreach key, val ∈ Out do
23     S.add(val) ;
```

The optimization is made possible by the unique design of security checks in CAMP, which eliminates the risk of accessing to a dangling pointer, such as `ptr` in function `foo`. This allows for aggressive optimization of range checks for field pointers without the concern of casing a false-negative for use-after-free vulnerability. As we will show in Section 6, the proposed optimization approach above dramatically improves CAMP's runtime performance, especially for programs that contain pointers associated with types. It should be noted that for pointers that have no type information (e.g., `void*`, `char *`) or their type sizes could not be determined at compilation time (e.g., elastic objects [16]), we do not apply the optimization above. As ASAN's security design cannot guarantee those conditions, applying this optimization to it may result in use-after-free and out-of-bound access.

Removing Redundant Instructions. A redundant instruction in this work refers to a range checking that validates pointers that have been validated or an escape tracking that builds point-to relation that has been recorded. The optimization opportunity for this is to remove the redundant ones to obtain better performance.

Intuition suggests that if two range checks validate the same result pointers from pointer arithmetic, one of them could be removed. For example, in List 4, the pointer `& ↪ ptr->mem[1]` in line 9 and 11 aliases. We could simply

```
1  struct obj {
2      char *mem;
3  };
4  void foo(struct obj *ptr, bool flag) {
5      __check_range(ptr->mem, &ptr->mem[0x100], 1);
6      ptr->mem[0x100] = 'x';
7      if (flag) {
8          ptr->mem[0x30] = 'y';
9          ptr->mem[0x1] = 'y';
10     }
11     ptr->mem[0x1] = 'z';
12     ptr->mem++;
13 }
```

Listing 4: Example codes of applying eliminating redundant optimization.

remove the validation for `&ptr->mem[1]` in line 9. Further, CAMP's security design allows merging several pointer validations into one validation. Initially, CAMP needs to validate the result pointers `&ptr->mem[0x100]` (line 6), `&ptr->mem[0x30]` (line 8), and `&ptr->mem[0x1]` (line 11), respectively. However, if pointer `&ptr->mem[0x100]` is in-bound, the other two pointers must be in-bound as well. Therefore, we could remove their validations and move the validation of `&ptr->mem[0x100]` to line 5, as is illustrated in List 4. Formally, given two result pointers $ptr1$ and $ptr2$ from the same base pointer ptr, their validation can be merged if the following function returns True.

function REDUNDANTPAIR($ptr1, ptr2$)
  if *ptr1.offset >= ptr2.offset* **then**
    if *dominate(ptr1, ptr2)* ***or***
      post-dominate(ptr1, ptr2) **then**
        return True
  return False
end function

The $offset$ in the first condition represents the maximum access offset from the base pointer. As such, the condition requires $ptr2$ to be in the range of $[ptr, ptr1]$. The second condition ensures the redundancy of validation, where the two validations will be executed together. We follow Algorithm 1 to remove redundant pointer validation. The algorithm takes as input a function F, and outputs a set of pointers to be validated S. We first collect all the result pointers (line 3) and categorize them into a map according to their base pointers (line 5 to 8), where the key is the base pointer, value is the set of result pointers. Then we follow the fixpoint algorithm [13] to apply the optimization. In each iteration, we go through the element in the map (line 12). if we find two pointers that satisfy the condition of the redundancy (line 13), we remove the latter one (line 14) and adjust the remaining one's offset with their maximum value (line 15). After this, we update the output of iteration (line 16) and exit the loop to start the next iteration. Noted that if no redundancy pair is found, the output will be just the input of the iteration (line 19). When there is no redundancy pair left, meaning that the fixed point is reached. Then we collect the remaining pointers from the *out* to S (line 22 to 23). List 4 showed CAMP's instrumentation after applying this optimization, where only the validation in line 5 is preserved, but the security guarantee remains. Note that applying this optimization to redzone-based protection (e.g., ASAN) may remove out-of-bound access checks. Assuming that `ptr->mem` ↪ is a 0x20 bytes memory chunk with 0x10 bytes red zone, normally the overflow will be detected through the check for `ptr->mem[0x30]` in line 8. However, applying the proposed optimization will remove this valid check but keep the one for `ptr->mem[0x100]`, which skips the red zone and miss the overflow detection, thereby leading to false negatives.

In line 12 of List 4, the pointer `ptr->mem` is self-updated. If we break this statement down, there are three operations involved. First, the program retrieves the pointer stored in address `&ptr->mem`. Then, it creates a new pointer based on the retrieved pointer, where a range checking will be inserted. This check guarantees the newly created pointer references to the same memory object as the old one does. Then, the new pointer is copied into address `&ptr->mem`, after which CAMP will insert an escape tracking to the pointer copying. One key observation is that the address `&ptr->mem` should have been initialized somewhere before, which means such a point-to relation must have been recorded. Because the memory object of the new pointer is not changed, recording the same point-to relation is redundant. Therefore, we could optimize this escape tracking for performance without sacrificing precision. Our optimization strategy is to identify those escape pairs that are doing self-updating.

Merging Runtime Calls. Ideally, for the same memory pointer (including alias), the validation can be optimized with the aforementioned approach into a single range check. However, if the pointer arithmetic is dynamic, where the result of pointer arithmetic cannot be determined at the compilation time, CAMP has to instrument different range checks for them. List 5 illustrates such example codes. Line 5 and 7 access the same array `ptr` that does not have type information. Besides, the access is dynamically based on the runtime value `i` and `j`, making the optimization of removing redundancy not applicable. To this end, CAMP needs to instrument both Line 5 and 7 respectively. Each time executing a range check, CAMP has to switch its context into the library, query the memory range, and then validate the pointer. This process is time-consuming. One strategy to optimize this is that we could merge the range checks since they share the same base pointer. This can reduce the cost of constantly switching contexts and save the time of querying the memory range.

To do this, we first follow the same approach in Algorithm 1 of constructing a *pointer map* where the pointer arithmetic with the same base pointer is categorized into the same group. Then, for each group, we go through the CFG of the function and find their nearest ***dominator*** instruction, where a range query is inserted to initialize the memory chunk's

```
1 void foo(char *ptr, int i, int j) {
2     unsigned int start, end;
3     __get_range(ptr, &start, &end);
4     assert(&ptr[i]>=start && &ptr[i]+1<end);
5     ptr[i] = 'x';
6     assert(&ptr[j]>=start && &ptr[j]+1<end);
7     ptr[j] = 'y';
8 }
```

Listing 5: Example codes of applying merging runtime calls optimization.

range variables. After this, the original range check then is replaced with assertion to ensure the boundary. List 5 also shows the result after applying this strategy. Line 3 queries the memory range of `ptr` and initializes the memory ranges into variables `start` and `end`. After this, validation for `&ptr[i ↪ ]` and `&ptr[j]` is done through two assertions in line 4 and line 6.

5 Implementation

In this section, we describe our implementation of CAMP's compiler and the allocator.

CAMP Compiler. CAMP's compiler is built on top of LLVM 12 compiler framework. We implement the instrumentation and the optimization in an LLVM pass, loadable by clang.

To defend against heap overflow, it instruments all pointer arithmetic and type-casting instructions. In the context of pointer arithmetic, the compiler collects the `getelementptr ↪` instruction from the LLVM IR, which represents the sole pointer arithmetic instruction as CAMP prohibits casting integers to pointers. CAMP adds a range checking instruction after every `getelementptr` instruction, with three inputs: the base pointer, the result pointer, and the type size of the result pointer. The `getelementptr` instruction's pointer operand, result value, and type size serve as these inputs respectively. To determine if the `source` operand refers to the heap, CAMP backtracks it following LLVM's SSA to identify its origin. If the source is a stack or global variable, the system presumes it doesn't refer to the heap, skipping the `getelementptr` instruction's instrumentation. The compiler also instruments the `bitcast` instruction, which symbolizes type-casting in LLVM. For each type-casting instruction, CAMP adds a checking instruction with two inputs - the result pointer and its type size - to ensure adequate memory for the object.

Following CARAT's approach [51,52] to tracking escapes, CAMP instruments store instructions if their value operand type is a pointer. If the escape is on heap memory, the compiler inserts an escape tracking CALL instruction before the store instruction.

Memory Allocator. The allocator is built on tcmalloc [25]. Tcmalloc maintains a page table mapping page addresses to a `span`. Notably, a span can handle multiple continuous memory pages for larger objects. To ensure any heap pointer can find its `span`, we register every memory page used by tcmalloc in the page map. Each span is supplemented with two metadata to facilitate CAMP's runtime checks: the object size and a reference to the escape pointer array containing linked escapes to the objects it manages. For each page, we compress its span's start address and size class into an 8-byte unit and map it into the *size class map*. With this design, CAMP can retrieve the necessary data and validate pointers in constant time. For unrecorded spans, CAMP resorts to the original routine of retrieving the `span`.

To accommodate coding styles that use out-of-bound pointers as memory boundaries, we reserve one-byte memory at the end of each allocation, ensuring such pointers remain in-bound. Each pointer escape prompts CAMP to create a record containing the pointer's location, stored in the span of the referenced object. Linked escape records for the same object are created, and all related records are freed when a memory object is freed. During this process, CAMP neutralizes any pointers still referencing the object. CAMP features a temporal escape array cache mechanism. Every time a new escape track is invoked, CAMP checks the array for an identical record before appending. Once full, all records are committed to the span and the array cleared, ensuring all dangling pointers are neutralized.

CWE (number)	Good Test (Selected/Total/Passed)	Bad Test (Selected/Total/Passed)
Buffer Overflow(122)	3870/3870/3870	2308/3870/2308

Invalid Free(761)	288/288/288	288/288/288

Table 1: Security evaluation of CAMP on Juliet Test Suite.

6 Evaluation

In this section, we first evaluate CAMP's effectiveness in detecting heap overflow and use-after-free memory corruption on a standard vulnerability benchmark and a set of real-world vulnerabilities. Then, we show CAMP's protection in detail with two case studies on real-world vulnerabilities. After this, we discuss CAMP's security capability with a comparison to related works. Finally, we show CAMP's performance/memory overhead using SPEC CPU benchmarks and real-world applications, and demonstrate its advantage against tools from the most recent research. All the experiments were conducted on a bare-metal machine configured with Ubuntu 22.04 system, 12th Gen Intel i7-12700 CPU at 4.9 GHz, 32GB RAM, and 1T SSD storage.

Table 2: The security evaluation results of CAMP and related tools on real-world vulnerabilities. ✔ represents that the corresponding tool successfully detected the memory corruption in the vulnerability. ✖ indicates the tool failed to detect the memory corruption that happened. "/" represents the tool does not support protecting the corresponding type of vulnerability. "Run Well" means the application runs well without causing any memory corruption with the PoC input. "Run Fail" represents that the tool failed to run due to compatibility issues. "Build Fail" means the tool failed to compile the targeted application to enforce protection.

6.1 Security Evaluation

Juliet Test Suite. To evaluate the effectiveness of CAMP's protection, we conducted experiments using the Juliet Test Suite, following recent works [23, 32]. The Juliet Test Suite includes test programs for various vulnerability types, each with both bad and good tests. The proof-of-concept (PoC) in the bad tests triggers the corresponding vulnerability, while the PoC in the good tests does not.

As CAMP focuses on preventing heap memory corruption, we only included heap-related vulnerability types from the Juliet Test Suite. It is important to note that CAMP's overflow prevention mechanism is based on the size of the memory object. Therefore, heap overflows that do not exceed the memory boundary are treated as benign because they do not corrupt other memory objects. Following this logic, we used a customized ASAN[1] to exclude the bad tests in which the overflow is contained within the memory object.

Regarding CAMP's use-after-free protection, it neutralizes dangling pointers, so instead of reporting an error, dereferencing a dangling pointer will cause the program to abort without a report. To evaluate the test cases in the use-after-free category, we used a gdb script to confirm that the abortion of the program was due to the dereference of neutralized dangling pointers.

The results of the selected tests are presented in Table 1, which shows the selected vulnerability type, the number of

[1] A customized ASAN that rounds up each allocation and includes a large red zone to prevent overflows from affecting adjacent objects and escaping detection. When evaluating tests for overflow, if ASAN does not report any issues, it indicates that the overflow occurs within an object. In such cases, the test can be safely removed from the test suite.

selected tests, the total number of tests, and the number of tests passed. Some of the tests originally categorized as Heap-Based Buffer Overflow do not contain heap overflow, such as cases `Heap_Based_Buffer_Overflow__c_src_char_cat_*`. These tests trigger a buffer overflow when copying data from the heap to the stack, causing a stack overflow rather than a heap overflow. These cases were excluded from the selected test cases using the customized ASAN. In all selected tests, CAMP passed without producing any false-positives or false-negatives.

Real-world Applications. In addition to the Juliet Test Suite, we also evaluated the security of CAMP by using a set of real-world vulnerabilities. We included all the real-world vulnerabilities used in [11]. Additionally, we collected other types of vulnerabilities from the CVE database [2, 3, 10]. Table 2 lists the selected vulnerabilities. Our dataset includes 14 use-after-free and 18 heap overflow vulnerabilities across 19 applications, including language interpreters, commonly used libraries, browsers, web servers, and commonly used UNIX tools. Our goal was to evaluate CAMP's effectiveness in preventing different heap memory corruption vulnerabilities and its scalability over various real-world applications. As a comparison, we also evaluate related tools, including ASAN/ASAN-- [62], Memcheck [27], DangNull [31], MarkUs [12], and Delta Pointer [30] for their effectiveness in detecting and preventing heap errors.

Table 2 presents the security evaluation results on real-world applications. CAMP successfully detected and prevented all use-after-free vulnerabilities. In the case of heap overflow vulnerabilities, CAMP was able to detect 16 out of 18 and report them. The other two ran well and did not cause any reports or crashes. But upon manual investigation using a debugger, we found that the overflow had occurred, but the memory bounds were not exceeded due to the rounded-up memory allocation of CAMP's seglist allocator. As a result, the overflow is mitigated and no memory corruption happened. We argue that these two cases do not count as false negatives of CAMP as the exploitation is prevented.

For tools providing a comparable level of heap protection, Memcheck was able to detect all the heap errors in the dataset. ASAN-- reported all the heap errors except CVE-2021-26259 [1]. The reason behind this is that ASAN uses red zone to detect heap overflow vulnerabilities. However, CVE-2021-26259 is a non-linear heap overflow that skips the red zone, thus ASAN--'s detection is defeated. Unlike ASAN--, CAMP was able to detect this case successfully as it detects heap overflow based on the memory boundary, making it impossible for non-linear heap overflows to bypass its protection. We argue that CAMP's protection is stronger and more robust than those two tools. As discussed in prior work [32], ASAN and Memcheck's use-after-free protection could be defeated if the attacker reclaims the freed memory that the dangling pointer refers to, thus enabling a possible exploitation against use-after-free vulnerabilities. As a comparison, CAMP mitigates the heap error fundamentally by naturalizing all dangling pointers.

For tools offering partial heap protection, DangNull and Delta Pointer showed limited compatibility support. 4 out of 14 use-after-free cases were not able to build with DangNull. Among 10 use-after-free cases that could be successfully compiled, only 4 of them were detected. Others just crashed with the PoC input as if there is no protection. Note that DangNull has a similar use-after-free protection scheme as CAMP, but it fails to detect 6 cases that CAMP could detect. This is because DangNull only tracks the point-to relation from heap to structured object on the heap, which will miss the detection if the dangling pointer is on stack/global memory, or the use-after-free object has no type information. MarksUs showed better compatibility support but failed to detect 6 out of 14 use-after-free vulnerabilities. Delta Pointer showed even worse compatibility support, which can only compile 5 out of 17 cases, but all the out-of-bound in compatible cases were detected. However, due to its design weakness, it is not capable of detecting buffer underflow.

We argue that CAMP provides a much more comprehensive heap error detection capability when compared to similar tools. Our evaluation demonstrates that CAMP outperforms the combination of partial heap protection tools (such as Delta Pointer + DangNull/MarkUS) as well as ASAN--. It is worth mentioning that CAMP does not miss any bugs that ASAN-- can detect. In addition, CAMP outperforms ASAN-- from the following aspects. First, ASAN--'s detection for use-after-free is fragile, which could be bypassed by reclaiming free memory with new heap allocation. As such, some use-after-free vulnerabilities in allocation-intensive applications could not be detected. We observed such a case when evaluating ASAN-- in 600.perlbench of SPEC CPU2017, where ASAN-- missed the bug but CAMP did not. Besides, some use-after-free POCs that accidentally re-occupy the freed memory will not be reported by ASAN--. We tweaked the original POC for CVE-2015-2787 and CVE-2015-6838 and found that the use-after-free was missed by ASAN-- as the freed memory is reclaimed. Second, ASAN-- utilizes a red zone mechanism to flag out-of-bound access. In the case of non-linear overflow, the overflow may jump over the red zone and thus fail overflow detection. Although it is unknown how frequently non-linear overflow may happen in the real world, we argue that the missed detection of such bugs will cause serious security issues. For example, CVE-2021-26259 is a non-linear overflow that would lead to code execution.

6.2 Performance Evaluation

In the following, we evaluate CAMP's performance on the two SPEC CPU benchmarks with the comparison with related tools. Then, we evaluate the effectiveness of each design component of CAMP, including the compiler optimiza-

Benchmark	Time and Memory Overhead				
	CAMP	ASAN--	ASAN	ESAN	Memcheck
600.perlbench_s	237.95% / 2241.12%	76.95% / 366.92%	143.59% / 358.20%	644.00% / 4.15%	3496.46% / 138.97%

tion, and the customized allocator. Finally, we evaluate `CAMP` on the real-world applications.

SPEC CPU Benchmark. We compared the performance of `CAMP` with related tools including ASAN [47], ASAN -- [62], ESAN [20], Softbound+CETS [41], and Memcheck [27]. All programs in the benchmark suite were compiled using default configurations and used reference input. Besides, all tools were configured to ignore detected errors to avoid termination. Note that, to ensure a fair comparison, we only enabled ASAN -- and ASAN's heap error detector. Unfortunately, ASAN and Memcheck were unable to compile and run the `omnetpp` and `dealII` programs, and therefore, they were excluded from the evaluation. Softbound+CETS showed limited support, failing to compile all programs in SPEC CPU2017 and only supporting 7 programs in SPEC CPU2006, so we only compare with it in SPEC CPU2006. Our evaluation of the tools did not take PACMem [32] into account, as it requires specialized hardware (ARM PA) for the detection of heap memory errors. For baseline evaluation, we used tcmalloc as the default allocator for better comparison as `CAMP`'s allocator is based on tcmalloc. For each tool, we ran the benchmark 10 times and reported the average result to minimize the randomness.

The evaluation results in terms of time overhead and memory overhead are presented in Table 3 for the SPEC CPU2017 benchmark suite. Each row in the table represents a specific application benchmark, with the benchmark name listed in the first column and the subsequent columns display the relative time and memory measured compared to a baseline. Following the most recent works [23, 32], we utilized geometric mean value to represent the average overhead of each tool. `CAMP` exhibits the best runtime speed compared to other tools, with an average overhead of 21.27%, while ASAN --, ASAN, and ESAN have overhead rates of 38.27%, 44.78%, and 65.31%, respectively. Memcheck has the worst runtime performance, which introduces 2546.88% overhead compared to the baseline. In terms of memory overhead, `CAMP` has a higher rate of 127.47% compared to roughly 104% for ASAN and ASAN --. ESAN has the best memory overhead performance, with -1.94% which is mainly cased by the difference of allocators. As we discussed in Section 4, `CAMP` tracks different forms of object point-to relation, which is more comprehensive and could obtain better security guarantee as we showed in Section 6.1. The cost of this design is that the performance overhead will be higher on allocation-intensive programs, such as `600.perlbench_s` and

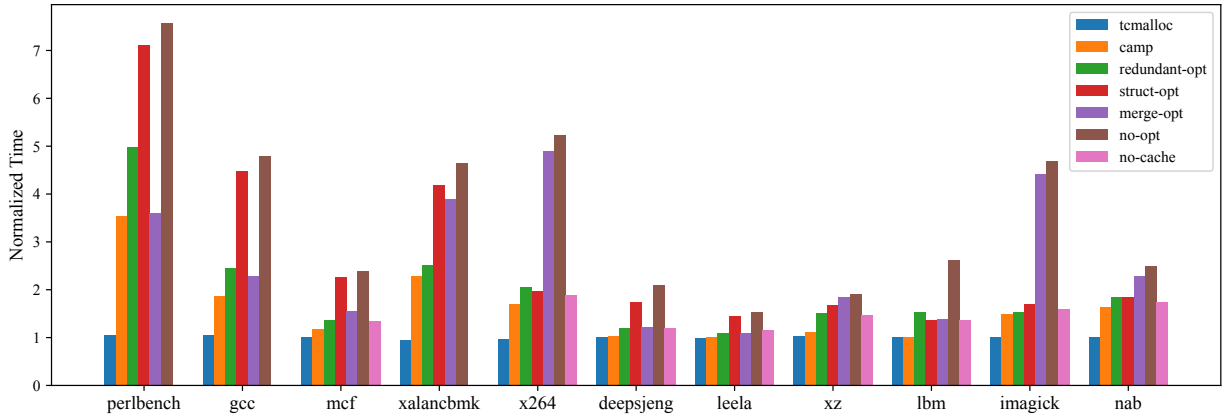

Figure 2: Evaluation result of CAMP breakdown on SPEC CPU2017. From left to right, the bars show the normalized time of tcmalloc replacement, CAMP, CAMP with each optimization disabled, and CAMP without optimization.

`623.xalancbmk_s`. We found that CAMP recorded a number of escape tracks, resulting in notable time and memory overhead. The average time and memory overhead of CAMP without those two cases will be reduced to 13.21% and 44.24%, respectively. For case `638.imagick_s` and `644.nab_s`, where CAMP's time overhead is higher than ASAN--, we observed the proposed optimizations are less effective in those two cases. Specifically, the type-based range checks removing and redundant checks removing are less effective on them. For the remaining cases in the benchmark, CAMP's time overhead is minimal with an even lower geomean value of 8.86%.

As for SPEC CPU2006, the evaluation results could be found in Table 8 and Table 9, we put them in Appendix due to the limited space. CAMP still outperforms all other tools in terms of runtime speed. Specifically, it introduces an overhead of 54.92%, while ASAN --, ASAN, ESAN, SoftBound+CETS, and Memcheck have the overhead of 56.77%, 67.02%, 123.08%, 319.75%, and 1990.02%, respectively. As we discussed before, CAMP performs worse in allocation-intensive programs. As such, for cases like `400.perlbench`, `482.sphinx3`, `453.povray`, `453.povray`, `473.astar`, `483.xalancbmk` ↪ , CAMP traces a large number of runtime point-to relations and costs more memory on maintaining them, which eventually slows down the overall speed. The time and memory overhead without those cases will be reduced to 34.52%, and 39.3%, respectively. Since the SPEC CPU2006 contains more allocation-intensive cases than SPEC CPU2017, CAMP reports higher overhead on SPEC CPU2006.

We further compare CAMP with other tools that offer partial memory protection, following the same setup of the previous evaluation on the SPEC CPU Benchmarks, we present the results in Table 4. LowFat, which only provides out-of-bounds (OOB) protection, exhibits slower performance than CAMP, with time overheads of 160.62% and 96.96% on the two SPEC benchmarks, respectively. Delta Pointer, which could only run SPEC CPU2006, incurs 37.39% time overhead. In terms of use-after-free (UAF) protections, FreeGuard, MarkUs, and FFMalloc introduce approximately 10% overhead on the benchmarks. DangNull exhibits 28.61% overhead on SPEC CPU 2017, which is slightly high than CAMP. It is noted that DangNull only includes a similar but weaker use-after-free protection scheme, highlighting the fast runtime speed provided by the CAMP allocator while offering a stronger security guarantee. We argue that CAMP is the optimal solution for achieving comprehensive heap protection in comparison to the other tools currently available. Firstly, as opposed to tools that only offer partial heap protection, CAMP presents a more holistic solution, with the ability to detect both spatial and temporal heap errors. Moreover, even when considering the combination of the faster Out-of-Bounds protection tool (e.g., Delta Pointer) and Use-After-Free protection tool (e.g., FFMalloc), the overhead incurred by CAMP is remarkably similar to their collective overhead (54.92% vs. 46.89%). Despite this, CAMP outperforms this combination in several ways. On the one hand, due to design limitations, Delta Pointer is only capable of detecting overflow errors, leaving underflow errors undetected, a challenge that CAMP effectively addresses. On the other hand, Delta Pointer's support is restricted to a 32-bit address space, allowing for a maximum of only 4GB of memory. In parallel, FFMalloc may demand a considerable amount of physical memory if the program continues to persist [23]. Hence, their combined use could rapidly exhaust the available 4GB of memory, resulting in incompatibility issues.

Component Evaluation. The configuration of CAMP contains various components, including compiler optimization and the integration of a seglist allocator. To determine the impact of each component on performance, we conducted evaluations using different setups of CAMP.

To analyze the impact of CAMP's customized allocator, we

Benchmark	Time (s)		Overhead
	Native	CAMP	
cfrac	2.91	3.82	31.27%
espresso	3.62	3.62	0.00%
barnes	1.35	1.34	-0.74%
redis	2.66	2.68	0.75%
leanN	25.35	26.18	3.27%
alloc-test1	2.99	3.06	2.34%
alloc-testN	2.91	3.42	17.53%
sh6benchN	2.41	2.39	-0.83%
sh8benchN	5.79	8.3	43.35%
xmalloc-testN	2.664	2.306	-13.44%
cache-scratchN	0.43	0.44	2.33%
Geomean	-	-	9.79%

Table 5: Time Overhead on mimalloc-bench. Native represents using the default allocator – ptmalloc, CAMP means using its customized seglist allocator based on tcmalloc.

conducted an evaluation using mimalloc-bench to compare the allocator differences. The evaluation results are presented in Table 5. The "Native" column represents the performance of the system's native allocator (ptmalloc), while the "CAMP " column indicates the results obtained with CAMP's customized allocator. The two allocators exhibited distinct behavior across different test cases. For instance, in the case of cfrac, the Native allocator was 31.27% faster than CAMP, whereas in the xmalloc-testN case, it was 13.44% slower. Overall, CAMP's allocator demonstrated a 9.79% slowdown compared to the native allocator.

To evaluate the effectiveness of compiler optimization, we disabled each optimization one by one in different configurations of CAMP, represented as struct-opt, redundant-opt, merge-opt and no-opt in Figure 2. To gain insight into the role of the allocator cache design, we measured the performance of CAMP allocator cache disabled. Finally, to assess the impact of the seglist allocator, we compared the results to a baseline using tcmalloc. These setups and their results on SPEC CPU2017 are presented in Figure 2.

Our evaluation results confirm that the seglist allocator offers minimal benefit. The tcmalloc baseline, compared to default ptmalloc, only improves average speed by 2.26%. We then took a further look at the contribution of allocator cache design, we found three programs (perlbench, gcc , xalancbmk) experienced memory exhaustion and were unable to complete the test, so they were excluded from Figure 2. The remaining programs resulted in an average overhead of 40.34%, nearly double the overhead with cache enabled (20.94%). Our investigation revealed that these three programs made many repeated point-to relationships, leading to a high consumption of memory for metadata maintenance. Specifically, all these programs contain a language interpreter that builds ASTs during input parsing, which creates connections that require CAMP to maintain point-to records. In gcc, as the compiler optimization progressed, more nodes are connected, leading to more point-to records being constructed, and eventually, the program exhausted all the memory available. In perl, after parsing the AST, the execution of the AST utilized the heap as a stack, leading to repeated references that further constructed more pointer escapes. These cases demonstrate the effectiveness of the cache design. With it, repeated point-to relations could be saved, thus reducing both memory and time overhead.

System	Output (req/s)	Latency (μs)				
		Average	50%	75%	90%	99%
Native	150,368	643.23	625	635	649	910
CAMP	108,322	880	850	870	910	1070
ASAN--	103,688	930	880	900	960	1860
ASAN	97,095	970	900	930	1040	1910

Table 6: CAMP, ASAN, and ASAN--'s output and latency evaluation results on Nginx. In the Latency column, the "Average" represents the average latency of the requested connection, the others show the latency distribution.

In addition, we found that the proposed compiler optimization significantly reduced the performance overhead. The CAMP without compiler optimization imposed an overhead of 204.09%, while the default CAMP had an overhead of 20.94%. Among the tested programs, imagick saw the best optimization results, with its overhead reduced from 368.18% to 48.47%. Upon analyzing the breakdown of each optimization, we found that the greatest impact came from the structure optimization. If this optimization is disabled, the overhead increases from 20.94% to 113.39%. While disabling redundant optimization, and merging runtime call optimization introduced 64.20%, and 95.73%, respectively.

Nginx. To evaluate the performance of CAMP on a large-scale, real-world application, we conducted experiments on Nginx v1.22.1 using the wrk v4.2.0 benchmarking tool. For these experiments, we configured the tool with 8 threads, 100 connections, and a test duration of 60 seconds. To ensure consistency, we repeated the test 30 times and recorded the average results. The findings are presented in Table 6. On average, CAMP introduces a 27.96% overhead on Nginx's request output, In terms of latency, CAMP adds 36.81% more time. The results reflect CAMP's efficiency on real-world applications with mild overhead. As a comparison, ASAN and ASAN-- incur a 35.43% and 31.04% overhead on request output and have a latency overhead of 50.80% and 44.58%, respectively.

Chromium. In addition to Nginx, we also evaluated the performance of CAMP on Chromium. We used three popular browser benchmarks: Kraken, SunSpider, and Lite Brite.

Benchmark	Time (*ms*)		Overhead
	Native	CAMP	
kraken	1069	1722	61.09%
sunspider	521	813	56.05%
Lite Brite	2930	5520	88.40%
Geomean	-	-	67.14%
google.com	1101	1427	29.61%
facebook.com	831	1199	44.28%
amazon.com	2298	3120	35.77%
openai.com	1444	1791	24.03%
twitter.com	1479	1708	15.48%
gmail.com	1691	2032	20.17%
youtube.com	2143	2628	22.63%
wikipedia.org	984	1535	56.00%
Geomean	-	-	28.59%

Table 7: CAMP's performance evaluation results on the Chromium browser. In the Benchmark column, kraken, sunspider and Lite Brite are three browser benchmarks, whereas the following are websites used to measure the loading time of the browser.

Furthermore, we measured the loading time for websites, as this metric is highly relevant to end users' browsing experience. To measure loading time, we utilized a browser extension and recorded the average loading time for the 8 most popular websites according to the Top Websites Ranking [9]. Each benchmark experiment was repeated 30 times, and the mean value was calculated to mitigate any random variations. The evaluation results are presented in Table 7, with the average overhead of CAMP represented by the geometric mean.

We observed that CAMP introduced a 67.14% overhead on the three browser benchmarks. However, the loading time for web pages increased by only 28.59% on average. It is important to note that these benchmarks focus on specific components of the browser, which may not fully reflect the overall performance. In contrast, loading web pages involves JavaScript engine execution, DOM processing, and other factors, thus it is more representative of real-world browsing. In this regard, we argue that the overhead introduced by CAMP to Chromium is minimal.

7 Discussion

False Positive and False Negative. As a pointer-based protection approach, CAMP shares similar weaknesses with prior works [19, 41, 56]. First, C/C++ allows the use of out-of-bound pointers as the memory boundary, which may cause CAMP to generate false positives. To mitigate this, we reserve additional memory space allocated for each allocation so that those boundary pointers will be still in bound, as is discussed in Section 5. This approach of changing the memory layout effectively mitigated this issue, thus we did not find any false positives in our evaluation. We consider this to be more of a compatibility issue that should be resolved at the source code level. This not only eliminates the potential for false positives, but also strengthens the security of the code.

Second, in C/C++, integers may be used for pointer arithmetic instead of actual pointers. This poses a challenge for CAMP as it may result in out-of-bounds pointer accesses that go undetected. To address this issue, we enforce a policy within the compiler that prohibits the casting of integers to pointers. Thus, the generation of out-of-bounds pointers from integers can be prevented. In cases where developers have to perform such casts, they could explicitly indicate their intention using compiler attributes to disable the policy locally.

Preventing In-bound Overflow. The design of CAMP's overflow detection is based on memory boundaries, meaning that it only identifies overflows that cross the boundaries as violations. Therefore, CAMP's design shares a similar weakness with prior works [36, 41, 56], as it cannot be used to prevent in-bound heap overflows. However, we found that, by leveraging a proper implementation, CAMP could mitigate some in-bound overflow. Specifically, if pointer arithmetic is performed on an array of a structure, we can use the array size to validate the pointer and ensure that the result pointer stays within the array of the structure, as such it mitigates the in-bound overflow with the type information. However, we do not claim this as CAMP's capability of preventing in-bound overflow. Because the type information is not always available, besides, the array may be dynamic thus CAMP has no clue how to validate it to make sure no overflow is inside the structure. Therefore, we consider the prevention of in-bound overflows to be a future research direction.

Protecting Shared Library. As CAMP uses the compiler for instrumentation, it naturally supports the protection of any programs that the compiler can build, including shared libraries. To achieve this protection, users must re-compile the shared library using the CAMP compiler. By doing so, the library will be instrumented with function calls to the CAMP runtime, ensuring that protection is enforced.

Supporting Multi-threaded Programs. CAMP is compatible with multi-threaded programs. Data race could be avoided by employing locks for the metadata in each span. In addition, we evaluated several multi-threaded programs (e.g., PHP, mruby, Lua, FFmpeg, Chrome, Nginx) in Section 6 and did not observe any incompatibility – CAMP successfully detected the bug in those programs without reporting any false positive.

8 Related Work

Safe allocator. To combating heap memory corruption attacks [16, 24, 33, 54, 58], various safe heap allocators [11, 18, 23, 29, 35, 39] are proposed. Specifically, FFmalloc [11] proposes a one-time memory allocation. DieHarder [44] randomizes heap address space to unstabilize heap exploitation. Oscar [18] prevents temporal memory error with shadow memory allocated for each heap object, thus detecting dangling pointer access. Markus [12] employs a strategy that quarantines freed memory to eliminate any lingering dangling pointers. DangZero [23] interacts with the kernel page table to implement an alias-based UAF detection mechanism, ensuring the virtual memory is never reused. FreeGuard [49] improves performance with freelist and optimizes shadow memory scheme. CAMP differs from those works as it does not exclusively rely on allocators to enable protection.

Pointer invalidation. Several works [15, 21, 30, 31, 36, 41, 42] detect memory errors through pointer invalidation. For instance, CETS [42] employs a lock-and-key identifier-based approach to track separate metadata for each pointer to detect dangling pointers. Undangle [15] uses dynamic taint tracking to identify and eliminate unsafe dangling pointers. DangNull [31] nullifies pointers when their associated objects are freed. In regards to spatial safety, Redfat [21] combines redzone and low-fat pointers to detect buffer overflow. Delta Pointer [30] introduces a pointer tag to invalidate overflow pointers, thereby preventing errors. Softbound [41] utilizes shadow memory to track memory bounds and employs runtime checks for efficient overflow detection. CAMP achieves full heap protection with pointer validation, however, unlike the aforementioned works, CAMP cooperates with the compiler and the allocator to optimize pointer invalidation.

Memory Sanitizer. Memory sanitizers typically offer full heap error detection. ASan [47] employs shadow memory and redzones for detecting temporal and spatial errors. To reduce its overhead, ASan-- [62] and SANRAZOR [60] propose several compiler optimizations to reduce instrumented checks on memory access, without security compromise. FuZZan [26] presents new metadata structures to decrease memory management overhead. CUP [14] proposes a hybrid metadata scheme that supports all program data including globals, heap, and stack. EffectiveSan [20] presents a dynamic type system to detect memory errors, but it has some limitations on detecting temporal errors. Memcheck [27], part of Valgrind [43], detects full memory errors. CAMP differentiates itself from those approaches by its protection scheme, thereby offering superior speed.

Hardware-assisted protection. There are also a bunch of works [19, 22, 28, 32, 46, 55, 56, 61] that leverage hardware to enforce memory safety. Specifically, Low-Fat [19] extends the pointer representation with base and bounds information so that the runtime or hardware can prevent spatial safety violations. In-Fat [56] enhances the hardware-assisted tagged-pointer scheme, employing three complementary object metadata schemes to decrease the number of pointer tag bits required. Several works, including PtAuth [22], AOS [28], and PACMem [32], utilize the Pointer Authentication Code (PAC) feature of ARM to identify memory errors. HeapCheck [46] leverages pointer bits in 64-bit systems for a bounds table, aiding in memory error detection with an 8 KB on-chip SRAM cache. BOGO [61] employs Intel MPX for memory safety, while CHEx86 [48] innovatively targets memory errors via microcode-level code instrumentation. In contrast, CAMP doesn't need extra hardware support.

9 Conclusion

Mitigating memory corruption on the heap is a complex task. Existing techniques to address heap memory corruption either provide limited protection or introduce significant runtime overhead, making their adoption in real-world products challenging. By leveraging a carefully designed code instrumentation and a customized allocator, CAMP provides comprehensive protection against heap memory corruption. The instrumentation imposes some runtime overhead, but we demonstrate that this overhead can be significantly reduced through a series of optimization strategies that eliminate and consolidate unnecessary instrumentations. Our evaluation of CAMP using a large-scale real-world application and SPEC CPU Benchmarks shows that the performance impact is significantly reduced. The low overhead, combined with CAMP's ability to effectively detect and prevent heap memory corruption, makes it a promising solution for safeguarding programs against heap memory corruption.

Abstract

As modern applications increasingly rely on GPUs to accelerate the computation, it has become very critical to study and understand the security implications of GPUs. In this work, we conduct a thorough examination of buffer overflows on modern GPUs. Specifically, we demonstrate that, due to GPU's unique memory system, GPU programs suffer from different and more complex buffer overflow vulnerabilities compared to CPU programs, contradicting the conclusions of prior studies. In addition, despite the critical role GPUs play in modern computing, GPU systems are missing essential memory protection mechanisms. Consequently, when buffer overflow vulnerabilities are exploited by an attacker, they can lead to both code injection attacks and code reuse attacks, including return-oriented programming (ROP). Our results show that these attacks pose a significant security risk to modern GPU applications.

1 Introduction

Graphic Processing Units (GPUs) were originally designed and used for high-quality graphics rendering. However, over the past decade, they have evolved into general-purpose computing platforms. Due to their high-throughput capabilities, GPUs are now used in various fields, including weather prediction [37], crypto-currency mining [28], and bioinformatics analysis [34]. In addition, today GPUs have become the *de facto* standard choice for running deep learning applications [9, 17, 24, 29, 30, 47, 52, 55, 56]. Given the growing significance of GPUs, NVIDIA recently announced the Grace Hopper Superchip [42] which is designed for giant-scale artificial intelligence (AI) and high-performance computing (HPC) applications. This superchip combines the NVIDIA Grace CPUs and Hopper GPUs using the high-speed interconnect, NVLink [43]. This wide employment of GPUs inevitably urges a thorough study on their security implications.

Memory safety violations (memory errors) have long been a significant security concern for computing systems. These violations are the most common root cause of modern exploits (attacks). For example, buffer overflows can allow attackers to overwrite return addresses and thus hijack the control flow of a program, potentially leading to the execution of malicious code. In fact, reports from Google and Microsoft show that memory errors account for around 70% of all security issues addressed in their products [23, 39]. Memory safety violations, together with the associated exploitation techniques, have been widely studied for CPU programs. Modern CPUs have even implemented certain built-in defense mechanisms against these vulnerabilities (e.g., [31, 32, 59]). However, the vulnerabilities in GPU programs have not received the same attention.

CUDA [41], developed by NVIDIA, is one of the most popular general-purpose GPU programming languages in use today. Since CUDA is extended from C and C++–languages known for their memory-unsafe characteristics–there is a concern that CUDA programs could have similar memory safety vulnerabilities. In this paper, we delve into this concern, aiming to answer the following questions:

Can memory errors occur in CUDA programs running on NVIDIA GPUs? If so, what types of attacks can arise from these errors?

Several prior studies have explored the memory safety vulnerabilities in CUDA programs [19, 38, 48]. They show that memory safety violations, especially buffer overflows, can occur in CUDA programs as well. However, they also argue that conventional CPU memory exploitation techniques, such as code injection and code reuse, are *inapplicable* for attacking CUDA programs. We found that their investigations have significant limitations.

First, the investigations in these studies are preliminary and lack a comprehensive analysis of the memory safety vulnerabilities inherent to GPU programs. For example, unlike C and C++, CUDA features multiple, distinct memory spaces, aligning with the GPU's specialized memory hierarchy. Data

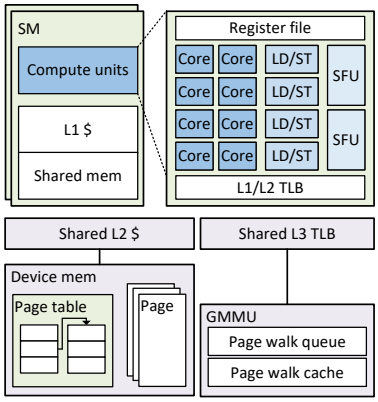

Figure 1: GPU architecture overview.

in different memory spaces have different scopes and are accessed in different manners. Prior studies have only shown that buffer overflows can occur within individual memory spaces. They have not explored whether a buffer overflow in one memory space can directly affect data in another memory space. Second, these studies were conducted on earlier NVIDIA GPUs, with older architectures (Pascal and earlier) and CUDA compute capabilities (sm_60 and earlier). Notably, NVIDIA has made significant changes to the GPU system starting with the Volta architecture (sm_70), which was released in 2017. Thus, the conclusions made in prior studies may not apply to modern GPU architectures.

In this work, we conduct a thorough examination of the buffer overflow problem on modern NVIDIA GPUs. First, we reverse engineer the mechanisms used to access various memory spaces. Specifically, we show how GPU hardware identifies memory references to each memory space and how it conducts address translation for these memory spaces. Based on the reverse engineering results, we demonstrate that an out-of-bounds (OOB) operation on data in one memory space can influence data in another, despite the fact that different memory spaces utilize different instructions for access. Furthermore, we reveal that OOB operations can be exploited to access data beyond their legitimate scopes. For example, one thread can access the local memory belonging to another thread.

Then, we study potential GPU attack methodologies leveraging these buffer overflow vulnerabilities. We found that modern NVIDIA GPUs are missing fundamental memory protection mechanisms. As a result, traditional memory exploitation techniques (which have been mitigated on CPUs) remain feasible on GPUs. For example, GPUs do not distinguish between code and data pages: data pages are executable, and code pages are writable.

In addition, we analyze the mechanics of function calls and returns on modern GPUs. Our investigation reveals that code reuse attacks, such as return-oriented programming (ROP) [50], can be employed against CUDA programs. We further discover that the CUDA driver API library is linked for each CUDA program; certain functions from this library are loaded into GPU memory upon the execution of any CUDA program. Importantly, this library code contains multiple ROP gadgets, including several memory read/write gadgets, which can enable powerful ROP-based attacks.

Finally, we show that the above memory exploitation techniques can be used to attack modern GPU applications such as deep neural network (DNN) inference. For example, by modifying the DNN weights, the attacker can significantly degrade the DNN inference accuracy, reducing it to the same level of random guessing in the most severe cases.

Responsible disclosure. We disclosed our findings to NVIDIA in October 2023, who acknowledged our work and requested to be notified when the results become publicly available.

2 Background

In this section, we provide an overview of the GPU architecture, programming models, and memory spaces. Note that while the concepts we describe are general to GPU computing platforms, we use NVIDIA's terminology for our descriptions.

2.1 GPU Basics

GPU architecture. Figure 1 shows an architecture overview of a typical GPU. The basic processing units in a GPU are called streaming multiprocessors (SMs). Each SM has a set of simple cores. With these cores, an SM can execute a group of parallel threads (known as a warp) in a Single-Instruction Multiple-Thread (SIMT) fashion. Modern GPUs usually have tens to hundreds of SMs. With a typical warp size of 32, a GPU can run thousands of threads simultaneously.

Each SM in a GPU contains its own register file, consisting of general-purpose registers and special registers. The general-purpose registers are partitioned among the threads that run on the SM. For example, in NVIDIA Ampere GPUs, every thread in an SM has its own 256 general-purpose registers, labeled from `R0` through `R255` [12, 46]. These registers temporarily store data that threads need immediate access to, such as variables or intermediate computation results. On the other hand, special registers have different roles and are used for specialized tasks. For example, `CLOCK` provides the current clock cycle count. Unlike general-purpose registers, some of the special registers are shared among all threads in the SM.

To serve the memory bandwidth demands of a large amount of threads, a GPU has its dedicated memory system, as shown in Figure 1. Each SM has its own private L1 cache and shared memory. SMs are connected to the shared L2 cache through a hierarchical on-chip network; The L2 cache is further connected to memory controllers which interface with the off-chip device memory. Similar to host memory on the CPU side, device memory is also based on DRAM. Currently, GDDR6 and HBM2 are the two most widely used DRAM types in

client and server GPUs, respectively. Note that the memory systems of the CPU and GPU are independent of each other. Before a program starts running on the GPU, the GPU driver loads the corresponding code into the device memory. Similarly, the data required by the GPU program must also be transferred to the device memory (before the data can be accessed). This is typically done through explicit operations in the program, although there are instances where the driver manages this data transfer implicitly [1].

```
1  /** device function **/
2  __device__ void add(char* d_global){
3      d_global[0] += 1;
4  }
5
6  /** CUDA kernel **/
7  __global__ void mem_type(char* d_global){
8      char d_local[10];
9      d_local[0] = d_global[0];
10     __shared__ d_shared[10];
11     d_shared[0] = d_global[0];
12     add(d_global);
13 }
14
15 /** CPU function, calling the cuda kernel **/
16 void kernel_launch (char* d_cpu){
17     char* d_global;
18     /** Allocate a GPU buffer **/
19     cudaMalloc(&d_global, 1024);
20     cudaMemCpy(d_cpu, d_global, 1024,
21                cudaMemcpyHostToDevice);
22     mem_type <<<8,32>>> (d_global);
23 }
```

Listing 1: An example CUDA program that uses multiple GPU memory spaces.

GPU virtual memory management. Modern GPU memory is virtualized, operating on a paging system. When SMs generate virtual addresses, the memory management unit (MMU) on the GPU performs virtual-to-physical address translation using the GPU page tables. Each running GPU program (i.e., a GPU context) has one page table. These page tables (from different active GPU contexts) are stored in the GPU memory and are regulated by the GPU driver [58][1]. Similar to CPU page tables, a GPU page table also has multiple levels: given a virtual memory address, the GPU MMU walks through these levels to find the page table entry (PTE) that contains the desired translation information. Prior work [58] has shown that recent NVIDIA GPUs use 5-level page tables. During a page table walk, a 49-bit virtual address is segmented, and its parts are used to select the walking path through the hierarchy.

2.2 GPU Programming and Execution

GPU programming model. GPUs were originally designed to accelerate graphics and multimedia processing; they could only be programmed using certain APIs such as OpenGL [53] and DirectX [36] to support 2D/3D graphics rendering. As the demand for utilizing GPUs in non-graphics computing tasks increases, various general-purpose GPU programming models have emerged. Of these, CUDA stands out as arguably the most successful and broadly used [41]. Listing 1 presents a simple CUDA program. Within the context of a CUDA program, there are several specific terms:

- **GPU kernel.** A kernel (line 7) is a function that is executed on the GPU and can be invoked from the host CPU. A CUDA program may consist of one or more kernels. To invoke a kernel, the GPU driver sends a corresponding kernel launch command to the GPU. It will first create a grid of thread blocks, with each block containing a certain number of threads. These thread blocks are then scheduled onto the available SMs on the GPU. When launching a kernel, the host code needs to specify the desired number of thread blocks and threads. For example, Listing 1 launches a kernel with 8 thread blocks and 32 threads in each block (line 22).
- **Device function.** A device function is a function that can only be called from kernels or other device functions. It can only be executed on the GPU (line 2).

NVIDIA PTX and SASS. PTX is an intermediate-level instruction set for NVIDIA GPUs that remains stable across different GPU generations. CUDA code is first compiled into PTX, and PTX is further compiled down to SASS, the low-level assembly language for NVIDIA GPUs. SASS instructions directly execute on NVIDIA GPU hardware. These instructions are tailored to the specific architecture of the GPU; different GPU generations may use different SASS instructions.

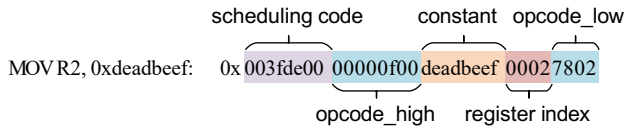

Figure 2: The encoding of the `MOV` instruction on Volta GPUs.

SASS instruction encoding. NVIDIA GPUs use a fixed-length instruction encoding format. Originally, the instruction length was 8 bytes. Starting with the Volta generation (released in 2017), the instruction length has been extended to 16 bytes. Unlike CPUs that typically use hardware-based instruction scheduling, NVIDIA GPUs delegate this scheduling task to the compiler. On Volta and later GPUs (with 16-byte instructions), the scheduling codes are embedded into the higher bits of each individual instruction, which specify the minimum wait time between consecutive instructions to meet dependency constraints. Figure 2 shows the encoding of the `MOV` instruction on Volta GPUs.

2.3 GPU Memory Spaces

Most GPU programming models allow memory allocation in different memory spaces, each of which has its unique behavior. Listing 1 shows a CUDA program that uses global,

[1]The GPU driver also maintains a copy of the page tables in host memory.

local, and shared memory, which are the most frequently used memory spaces in CUDA programs. The specific features of these memory spaces are shown in Table 1. We omit the discussion of other memory spaces, such as texture memory, as they are not related to our study.

- **Global memory** is managed by the GPU driver. Buffers in global memory can only be allocated by CPU code (before kernel launches) through driver API calls (line 19 in Listing 1). Global memory resides in the GPU's off-chip device memory; it can be cached in both the L1 and L2 caches. A buffer in global memory is accessible to all the threads in all the kernels of the program, until the buffer is freed. The load and store operations for global memory are usually performed using the instructions `LDG` and `STG`, respectively. In Listing 1, `d_global` is a buffer in global memory.
- **Local memory** is private to each thread. It is used to store the stack of a thread and is thus also called stack memory. Similar to global memory, local memory also resides in the device memory (and the caches). However, unlike global memory, data in local memory do not persist across kernels (since they are thread-private). The instructions `LDL` and `STL` are particularly used for local memory. `d_local` in Listing 1 is a buffer stored in local memory.
- **Shared memory** is a scratchpad memory region. It is shared among all the threads within the same thread block. As shown in Figure 1, shared memory is on-chip. Developers can place the data that is accessed frequently by threads in the same block into shared memory, in order to avoid the slow global memory access. Data in shared memory are not backed up in the off-chip device memory. `LDS` and `STS` are used for shared memory operations. `d_shared` in Listing 1 resides in shared memory.

In addition to the instructions mentioned above that are used for each particular memory space, there are also generic load and store instructions `LD` and `ST`, which can be used for accessing all the memory spaces.

3 GPU Memory Safety

3.1 Prior Art

Since CUDA is an extension of C/C++, CUDA programs can also have memory vulnerabilities similar to those in C/C++ programs. Several prior studies [19, 38, 48] have revealed that some of the memory errors found in CPU programs, such as buffer overflows, can also occur in CUDA programs. However, these studies have some limitations, which we explain below.

First, the investigations presented in these studies are fundamental and do not delve deeply into the problems particular to GPUs. For example, as explained in Section 2.3, CUDA features multiple, distinct memory spaces (unlike C and C++). Prior studies have only identified that buffer overflow errors can occur within a specific memory space. For instance, an OOB operation on a local memory buffer can compromise other data stored in that same local memory. However, they have not explored whether such an OOB operation can affect data in a different memory space.

Table 1: The specification of the pointers in Listing 1.

Pointer	Memory type	Storage	Cached	Load/store instructions	Scope
d_global	Global memory	Device memory (off chip)	Yes	`LDG/STG`	Process
d_local	Local memory	Device memory (off chip)	Yes	`LDL/STL`	Thread
d_shared	Shared memory	Shared memory (on chip)	No	`LDS/STS`	Thread block

Second, given that these studies were carried out several years ago, they only examined older GPUs (before Volta). However, NVIDIA has made significant changes to their GPUs since the Volta architecture [25]. For example, a new ISA has been introduced, where the instruction length was changed from 8 bytes to 16 bytes. Therefore, conclusions from these studies may not apply to newer GPU architectures. For example, these prior studies have two common conclusions. 1) Exploiting buffer overflow to hijack control flow in CUDA is very difficult because the return address is stored in an undisclosed memory location, not on the stack. 2) Traditional code injection attacks cannot be applied against CUDA programs because code and data are separated in memory. However, through our analysis (in Section 4), we found that **their conclusions do not hold.**

3.2 Our Goal

As GPUs have become a major computing component these days, it is important to understand the security problems that exist in modern GPUs. Our objective is to present an in-depth analysis of buffer overflow vulnerabilities on these computing devices, shedding light on the hidden threats that have been overlooked for years.

4 Demystifying GPU Memory

In this section, we provide a detailed analysis of GPU buffer overflows, addressing the limitations mentioned in Section 3. To gain a thorough understanding of the GPU memory model, we develop a tool using Direct Memory Access (DMA) to dump the content of device memory. We further manage to recover the page tables stored in device memory. NVIDIA has made their driver source code public. Therefore, from the driver code section concerning GPU page management [2] (and other NVIDIA documents [45]), we can obtain the overall format of the page table on NVIDIA GPUs. This allows us to identify and reconstruct the page table from the extracted device memory. Note that unless specified otherwise, all the experiments in this section are conducted on a system

with an NVIDIA GeForce RTX 3080 GPU, NVIDIA driver 470.63.01, CUDA 11.4, and the Ubuntu 20.04 OS. To simplify the analysis, we turn off CUDA ASLR.

4.1 Buffer Overflows across Memory Spaces

Here we study the buffer overflow issues in CUDA programs. As explained in Section 3, prior studies (e.g., [38]) have already shown that buffer overflows can cause memory corruption within a single memory space. Thus, we focus more on investigating the impact of buffer overflows across different memory spaces. Specifically, we first explore this problem between local and global memory, and then extend the study to cover the problem between these two and shared memory.

4.1.1 Accesses to Global and Local Memory

Global memory accesses are relatively straightforward. Global memory is indexed using a 49-bit virtual address (which is stored as a 64-bit value). There are two primary ways to access global memory: using the specialized `LDG/STG` instructions or the generic `LD/ST` instructions (cf. Section 2.3). These two pairs of instructions operate in a similar manner: as demonstrated in Listing 2, the target virtual memory address of the instruction is stored in a 64-bit register, which is formed by combining two 32-bit registers. We are not aware of any fundamental differences between accessing global memory using these two pairs of instructions. The choice of which pair to use appears to be based on the compiler's preference. Empirically, we observe that when the debugging option is enabled, the NVCC compiler always chooses `LD/ST`, otherwise it prefers `LDG/STG`.

```
/** R6: 0xcda00000 **/
/** R7: 0x7fff **/
/** R6.64 means R7||R6 **/
LDG R8, [R6.64]
STG [R6.64], R8

LD R8, [R6.64]
ST [R6.64], R8
```

Listing 2: Code for accessing global memory.

```
/** R6: 0xfffd80 **/
LDL R8, [R6]
STL [R6], R8

/** R6: 0xf2fffd80 **/
/** R7: 0x7fff **/
LD R8, [R6.64]
ST [R6.64], R8
```

Listing 3: Code for accessing local memory.

As local memory is private to individual threads, local memory accesses are more complicated than global memory accesses, as detailed below.

Instructions. Much like global memory, there are also two sets of instructions for accessing local memory, `LDL/STL` and `LD/ST`. However, they work very differently. As shown in Listing 3, `LDL/STL` uses a 24-bit address[2] stored in a 32-bit register. In contrast, as explained earlier, `LD/ST` requires a 49-bit virtual address (from a 64-bit register). In fact, we found that when `LD/ST` are used to access local memory, the 49-bit address appears to be the 24-bit address prefixed with a 25-bit value (which is `0x7ffff2` on our system). Note that virtual addresses belonging to other memory spaces *never* begin with this prefix value on our machine. Unlike global memory, the compiler always prefers to access local memory with `LDL/STL`, even when the debug flag is on.

```
1  __global__ void local_arr(){
2      uint32_t arr[10];
3      for(int i = 0; i < 10; i++)
4          arr[i] = 0xdead0000+threadIdx.x;
5      uint32_t* ptr = arr;
6      printf("thread %u addr %p data %u\n",
7              threadIdx.x, ptr, ptr[0]);
8  }
9  int main(){
10     cuda_kernel<<<1,32>>>();
11     return 0;
12 }
```

Listing 4: A simple CUDA program that allocates buffers in local memory.

Memory layout. We use the program in Listing 4 to explain the local memory layout: the CUDA kernel (`local_arr`) is launched with 32 threads per thread block and just one thread block overall. In this kernel, every thread allocates a local array (`arr`), resulting in 32 individual arrays in total. According to NVIDIA, each thread is only able to access its own array, but not the arrays that belong to other threads.

To understand how local memory is stored in the device memory, we execute the program in Listing 4 and pause it at line 6. Then, we dump the device memory content and identify the location of `arr` within it (by the data pattern). Figure 3 (b) shows a segment of the dumped device memory where `arr` resides. From this figure, we can observe that the local memory of different threads appears interleaved in the device memory. Specifically, the device memory sequentially stores `arr[0]` from all threads, then `arr[1]` from all threads, and so forth. We then conduct further experiments, adjusting the total thread count and the array's data type. These experiments reveal that every 32 bits of local memory from threads in a warp (comprising 32 threads) are always stored contiguously within the device memory. For variables larger than 32 bits, they are split into 32-bit segments and stored separately. Note that this layout information can help an attacker deliberately tamper with the local memory data, which we will show later.

Addressing. Given that each thread has its own private `arr`, one might naturally expect that each `arr` would have a distinct virtual address, which is similar to the scenario on CPUs. However, when we print the address of `arr[0]` (or `ptr[0]`) as done in line 6 of Listing 4, we have two interesting observations, as shown in Figure 4. First, `arr[0]` of different threads actually have the *same virtual address*. This virtual address is `0x7ffff2fffd80` on our machine (prefix+local memory address, cf. Listing 3). Second, when performing a data access using this address, each thread retrieves different data. More specifically, for a given thread, the retrieved data corresponds

[2] We found that the local memory for each thread is indexed with a 24-bit address using CUDA-GDB. This observation aligns with the findings from prior research [57].

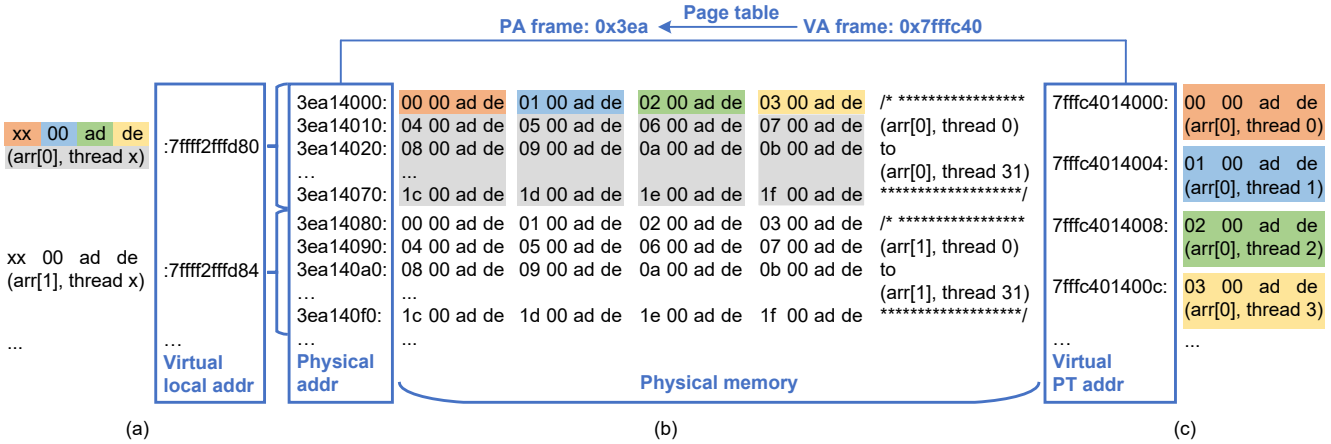

Figure 3: The mapping details of local memory: (a) the translation between virtual local addresses and physical addresses; (b) the layout of local memory (in device memory); (c) the translation between virtual PT addresses and physical addresses.

to `arr[0]` of that thread. With these results, we believe the mapping between the virtual and physical addresses of local memory aligns with the one depicted in Figure 3 (a) and (b): the physical address that a virtual address points to may vary, depending on the ID of the thread accessing this virtual address.

A natural question here is how the same virtual address is translated to different physical addresses (for different threads). While the specifics of local memory address translation on NVIDIA GPUs remain undisclosed, we give a conjecture here: there is likely a unique address translation mechanism for local memory, which is based on both the address and the thread ID. Moreover, the GPU hardware is able to recognize that a given memory operation is targeting the local memory (instead of other memory spaces) based on the given virtual address or the instruction. Specifically, it is considered a local memory operation if 1) the instruction is `LDL/STL` or 2) the instruction is `LD/ST` and the address begins with a certain pattern (e.g., `0x7ffff2`).

```
thread 0   addr 0x7ffff2fffd80   data 0xdead0000
thread 1   addr 0x7ffff2fffd80   data 0xdead0001
thread 2   addr 0x7ffff2fffd80   data 0xdead0002
...
```

Figure 4: The output of line 6 in Listing 4.

Upon examining the page table of the program in Listing 4, we have a very interesting observation. The aforementioned virtual addresses for local memory data (e.g., `0x7ffff2fffd80` for `arr[0]`) *are not mapped to* any valid physical addresses, according to the page table.[3] Instead, for each data block in the local memory, a disparate virtual address (e.g., `0x7fffc4014000` for thread 0's `arr[0]`)–seemingly unrelated to the unmapped virtual address above–is mapped to the physical address of this data block, as shown in Figure 3 (c). Importantly, when using this virtual address to access local memory, every thread gets the same data when accessing the same virtual address. For example, any thread accessing the address `0x7fffc4014000` will retrieve the value of thread 0's `arr[0]` (`0xdead0000`), regardless of its thread ID. Similarly, using the address `0x7fffc4014004`, every thread gets the value of thread 1's `arr[0]` (`0xdead0001`).

From the above results, we have two conclusions. First, for each physical address in local memory, there are two virtual addresses that can be used to access this physical address. Only one of them has a valid mapping in the page table; we refer to this virtual address as *the virtual PT address* (e.g., `0x7fffc4014000` in Figure 3 (c)), and refer to the other virtual address as *the virtual local address* (e.g., `0x7ffff2fffd80` in Figure 3 (a)). Second, as explained above, when accessing a virtual local address, the GPU hardware can recognize that this address is targeting the local memory and triggers a special address translation routine for it. This special routine takes the thread ID into account, and thus ensures that each thread can only access its own local memory. However, when accessing a virtual PT address, the GPU hardware does not recognize it as a local memory access, and therefore does not employ this special translation routine. Once knowing this address, one thread can access/modify the local memory of another thread in the program.

To further validate that both the virtual local address and the virtual PT address point to the same physical address, we conduct a read-after-write experiment. First, we write to `arr[0]` of thread 0 using the virtual PT address. Then, we read `arr[0]` of thread 0 using the virtual local address. We found that we can only read out the previously written value if we access another buffer whose size is at least 128B between our write and read operations. Given that the L1 Dcache on our GPU is 128B and L1 is indexed using virtual addresses and tagged using physical addresses, we believe that these

[3] This also confirms that there is a special address translation path for local memory addresses.

Table 2: Summary of the buffer overflow problem in CUDA; ✓ means the OOB operation can affect this memory space, while ✗ means it cannot.

OOB		Global mem				Local mem				Shared mem			
		Same thread	Same thread block	Same kernel	Same program	Same thread	Same thread block	Same kernel	Same program	Same thread	Same thread block	Same kernel	Same program
Global mem	LDG/STG	✓	✓	✓	✓	✓	✓	✓	✗	✗	✗	✗	✗
	LD/ST	✓	✓	✓	✓	✓	✓	✓	✗	✓	✓	✗	✗
Local mem	LDL/STL	✗	✗	✗	✗	✓	✗	✗	✗	✗	✗	✗	✗
	LD/ST	✓	✓	✓	✓	✓	✓	✓	✗	✓	✓	✗	✗
Shared mem	LDS/STS	✗	✗	✗	✗	✗	✗	✗	✗	✓	✓	✗	✗
	LD/ST	✓	✓	✓	✓	✓	✓	✓	✗	✓	✓	✗	✗

two virtual addresses are linked to the same physical address.

> Takeaway 1: On NVIDIA GPUs, each data block in local memory is linked to two virtual addresses; one of these addresses allows a CUDA thread to access/-modify the local memory of other threads.

4.1.2 Overflows across Global and Local Memory

OOB global memory references. Recall that global memory operations always use a 64-bit address, regardless of the instruction used. Therefore, attackers could exploit a buffer overflow vulnerability in global memory to influence any location in the device memory, including the local memory. Specifically, when accessing a global memory buffer with an OOB index, the attacker can manipulate the index to direct the target address (base address + index) towards either 1) the virtual PT address or 2) the virtual local address of the data in the local memory. Here we discuss the feasibility of these two approaches:

- **Accessing a virtual PT address**. As mentioned earlier, there are two sets of instructions for global memory references, `LD/ST` and `LDG/STG`. From our experiments, providing any of these instructions with a virtual PT address causes them to execute as expected, accessing the data in the local memory (of any thread) with the given address.
- **Accessing a virtual local address**. When providing a virtual local address to `LDG/STG`, it prompts a runtime error citing an illegal memory access. In contrast, when providing such an address to `LD/ST`, the instruction executes without any error. However, as explained before, using a virtual local address prevents us from modifying or accessing data belonging to other threads. We discuss this approach only for completeness. In real-world scenarios, the attacker would likely choose the former approach.

In short, a buffer overflow error in global memory may allow an attacker to target a virtual PT address, granting the attacker potential access to, or the ability to modify, the local memory data of any active thread in the program.

OOB local memory references. We found that there is a substantial gap between the virtual local addresses (of the local memory) and the virtual addresses of the global memory. On the tested system, the minimum difference between such addresses is `0x10000000`. With this discrepancy, whether an OOB operation on local memory can affect global memory actually depends on the specific instruction handling the operation: when using `LDL/STL`, which operates with a 24-bit address (the lower 24 bits of the virtual local address), OOB operations on local memory cannot affect global memory. In contrast, if `LD/ST` which takes the full 64-bit virtual local address is used, an OOB operation on local memory has the potential to fetch/modify data in global memory.

4.1.3 Overflows across Shared Memory and Local/-Global Memory

Data in shared memory is accessed in a similar manner to data in local memory. Specifically, shared memory can be accessed with either 1) the specialized instructions `LDS/STS`, using a 24-bit address, or 2) the generic instructions `LD/ST` using a 49-bit address. Again, the 49-bit address is formed by adding a prefix to the 24-bit address, which is `0x7ffff4` on the tested system. Consequently, when using the `LD/ST` instructions, an OOB operation on data in shared memory may affect the data in global or local memory. In addition, an OOB operation on data in global or local memory (with `LD/ST`) can affect the data in shared memory. Note that, unlike local memory, shared memory does not have a virtual PT address, since it is not part of the device memory. This means, accesses to shared memory remain confined to their legitimate scope (within the thread block). We cannot utilize virtual PT addresses to perform out-of-scope shared memory accesses (as done for local memory).

4.1.4 Summary

We provide a comprehensive summary of the overflow problem in CUDA in Table 2. First, with respect to the memory space, when using the generic memory instructions `LD/ST`, the problem can occur within a single memory space or across different spaces. In contrast, when using the specialized instructions (e.g., `LDL/STL`), the problem is restricted to a single memory space. An exception is that, OOB global memory references with `LDG/STG` can influence local memory.

Second, in terms of memory scope (i.e., visibility), when targeting local memory, an overflow error can result in ac-

cesses beyond the intended scope. This is due to the use of virtual PT addresses. In other scenarios, memory accesses are always confined to the legitimate scope.

Notice that the conclusions presented in this section, particularly those related to how GPU memory accesses are managed, are based on extensive reverse engineering efforts. While they are supported by thorough experimentation, we cannot claim with absolute certainty that our findings are entirely accurate. However, it is crucial to note that the primary objective of our reverse engineering analysis is not to perfectly reconstruct the GPU memory access functionality, but rather to investigate the potential for buffer overflow vulnerabilities in CUDA programs. Despite any potential inaccuracies in our reverse engineering results, we have conclusively demonstrated that buffer overflows on GPUs can be exploited to access/modify data across different memory spaces and beyond legitimate scopes (Table 2).

4.2 Return Address Corruption

Return address corruption is a severe security threat as it allows an attacker to hijack a program's control flow, potentially leading to arbitrary code execution. On CPUs, an attacker can exploit a stack buffer overflow vulnerability to overwrite the return address on the stack. However, prior studies [38, 48] suggest that such exploitation is not feasible on GPUs: they claim that on GPUs the return address is stored in an undisclosed location in the device memory, rather than on the stack (local memory). We reexamine this claim in this section.

4.2.1 Stack Management

To understand the management of the return address on GPUs, we launch a simple CUDA kernel whose only task is to call a device function. The device function allocates a 64B local array and fills it with `0xdeadbeef`. Figure 5 shows assembly code snippets of this device function, illustrating the stack management at the beginning and end of the function. When the function starts, certain registers that the function intends to modify are pushed to the stack to be later restored upon the function's completion. Conversely, after the function finishes, these registers are popped from the stack and restored. These code snippets provide two key insights into CUDA's stack management:

- **The role of `R1`.** In CUDA, `R1` is a general-purpose register, not a special register [44]. However, the above code implies that `R1` can be used as the stack pointer. In fact, by further examining common CUDA libraries such as `libcudnn`, we found that `R1` is the only register that has been used as the stack pointer. Notably, NVIDIA's list of special registers does not contain any register for stack pointer [44].
- **Stack commands.** Similar to the RISC-V architecture, NVIDIA GPUs do not have dedicated `push/pop` instructions. Instead, a push operation is achieved through a local memory write together with a decrement of the stack pointer. Conversely, a pop operation is achieved by a local memory read and an increment of the stack pointer.

Return address. In Figure 5, the return instruction (`RET`) uses `R20` as an operand. This register is pushed to the stack upon entering the function, and retrieved right before the `RET` instruction. Intuitively, the value in `R20` should be related to the return address. To validate this, we run the program in CUDA-GDB and we found that the value of `R20.64` (i.e., `R21||R20`)[4] is the same as the expected return address (which in our specific case is `0x7fffd6fad8e0`). To better understand this, we extract the device memory (before `RET` is executed) and show the local memory section in Figure 6. We can see that the value of `R20.64` is located in the local memory, near the local array (filled with `0xdeadbeef`). This observation confirms that the return address, represented by `R20.64`, is stored together with the local variables on the stack, in contradiction to the conclusions of previous studies.

Figure 6: Part of the local memory in the dumped device memory; the local array and `R20.64` (i.e., `R21||R20`) are highlighted; "*" means the data is the same with above.

[4] While not explicitly specified in the instruction, `RET` appears to always retrieve the return address from `R20.64` rather than just `R20`.

We further perform an OOB operation on the local array to overwrite the return address, pointing it into another function in the program. As anticipated, when the function returns, it proceeds with the overwritten address, executing the code located there, rather than returning to the original caller address. Similar behavior occurs when we perform an OOB operation on global memory (or shared memory) to overwrite the return address (cf. Table 2).

> Takeaway 2: In CUDA, exploiting a buffer overflow vulnerability allows an attacker to modify the return address stored in the local memory (stack), and therefore redirect the control flow of the program.

4.2.2 Return Address on the Stack

In Section 4.2.1, we focus on the scenarios where the return address register (e.g., `R20` in Figure 5) is pushed to the stack during the execution of the function. However, the NVCC compiler does not always opt for this approach. Rather than pushing the return address register to the stack, the compiler often avoids using that register throughout the function. It only chooses to push this register if it is challenging (or infeasible) to ensure that this register remains untouched in the function. Below are some scenarios where the return address register is pushed to the stack.

1. The device function is recursive.
2. The device function has a substantial number of local variables, resulting in insufficient registers (i.e., register spill-out).

4.3 Code Injection

Executing data pages. With the capability to overwrite the return address, the attacker can redirect the execution to a data page which they have filled with shellcode. Then, when the function returns, the execution is diverted to this malicious code, resulting in a code injection attack. Such attacks have already been mitigated on CPUs: for example, most CPU systems have the `W^X` policy implemented, which mandates that every memory page can be either writable or executable, but not simultaneously both. This prevents the shellcode from being directly executed. However, we found that this policy is not implemented on modern GPUs.

Our results show that by manipulating the return address, we can redirect the control flow to a global memory address and execute the data there (as code). We can also change the control flow to point to a local memory address and execute the data on the stack.[5] These findings suggest that GPUs do not make the writable data pages non-executable. We also found that according to the page table format [2, 45] released by NVIDIA, there is not an "executable bit" (nor a "dirty bit") in the PTE. This implies that GPUs do not check whether an address is a legitimate code address before executing its content. Note that prior studies claim that executing a data buffer is infeasible on GPUs; they believe that this is either because the code and data addresses are separated, or because the data pages are not executable [38, 48]. We found that neither of these hypotheses is accurate.

Modifying code pages. Given that data pages are executable, a natural question that arises is whether code pages are modifiable. In fact, prior work has already shown that it is possible to modify code pages on older GPUs. We further verify this on modern GPUs by examining the device memory before and after writing to a code page. Additionally, when inspecting the GPU page table format, we notice a "read-only bit" in the PTE. However, after analyzing the page table (extracted from the device memory), we found that this bit consistently remains unset, even for code pages.

> Takeaway 3: NVIDIA GPUs do not differentiate between code and data pages.

4.4 CUDA ROP

Return address corruption can also lead to code reuse attacks, of which ROP is a primary example. ROP has proven to be highly effective on CPUs, with numerous ROP gadgets found in commonly used library code, such as `libc`. Here we study the feasibility of ROP on modern GPUs.

CUDA library code. Upon inspecting the content of the device memory during the execution of a CUDA program, we found that, besides the application-specific code, there is additional code loaded into the device memory. This additional code is the same for every CUDA program. We compare this code with the machine code of common CUDA libraries and found that this code is part of `libcuda`. NVIDIA describes `libcuda` as the CUDA driver API library, which handles tasks related to direct interaction with the GPU, such as memory management, error handling, and stream management. Functions within this library include (but are not limited to) `printf`, `cuMemcpy`, and `cuMemFree`. In addition, our experiments show that after redirecting the control flow of a CUDA program to an address within this driver API code, we can execute this code without triggering any errors.

CUDA ROP gadgets. We examine this driver API code and found 190 return instructions (`RET`). Out of these `RET` instructions, only 52 are accompanied by an instruction that pops the return address. This means, there are only 52 possible ROP gadgets in this drive API code, consisting of 7 memory corruption gadgets and 45 others. Listing 7 shows two example gadgets: the first one writes data from a register to a mem-

[5] The control flow cannot be redirected to a shared memory address, meaning we cannot execute the data stored in shared memory as if it were code.

Figure 7: CUDA ROP gadgets.

ory address, while the second one reads data from a memory address and then writes it to another address. Unfortunately, our analysis suggests that this CUDA gadget set is not Turing complete. However, later in Section 5 we show that even with these limited gadgets, the attacker can significantly reduce the performance of DNN-based applications on GPUs. In addition, using the memory corruption gadgets, we might be able to modify the CUDA code (which is not write-protected) to create a Turing-complete collection of gadgets, thus achieving arbitrary computation.

Note that it is difficult to have unintended ROP gadgets, since all the GPU instructions must be 8B aligned. In addition, including other common CUDA libraries, such as `libcublas` and `libcudnn`, does not really bring more ROP gadgets: these libraries are so optimized that the return address is almost never pushed to the stack; it is typically stored in a register instead.

> Takeaway 4: ROP can be used to read or write the memory on NVIDIA GPUs.

Generality. In this section, we discuss and present the investigations using the platform specified at the beginning of this section. However, the conclusions drawn from these investigations, including the feasibility of memory corruption across memory spaces (cf. Table 2), and the potential for code injection and code reuse attacks, are applicable to other modern NVIDIA GPUs as well.[6] We have verified these vulnerabilities on multiple NVIDIA GPUs spanning several recent architectures, including Volta, Turing, Ampere, and Ada Lovelace; we conduct experiments on these GPUs with various NVIDIA drivers ranging from version 470.63 (released in July 2021) to version 550.67 (released in March 2024), and multiple CUDA toolkits ranging from version 11.2 to version 12.4. The results consistently demonstrate that these vulnerabilities exist across all tested GPUs, regardless of the driver/CUDA version used. The complete list of the tested GPUs is provided in Appendix A.

[6]The specific details, such as the number of ROP gadgets, may vary slightly depending on the CUDA version.

5 Case Study: Corruption Attacks on DNN

In this section, we demonstrate how the GPU memory corruption vulnerabilities discussed in Section 4 can pose significant security risks for DNN-based applications, which are one of the most common GPU applications.

5.1 Threat Model

Victim. The victim is a DNN-based application running on a server equipped with a modern NVIDIA GPU. This application receives requests from remote users, processes these requests using a DNN model, and sends the responses back. We assume that some of the CUDA kernels involved in the process of DNN inference have memory corruption vulnerabilities, (the vulnerability examples will be discussed later in Section 5.2). As a common practice, model parameters, such as weights, are loaded into the device memory during application initialization. To minimize response latency, these parameters persist in memory across user requests, rather than being reloaded for each new request or removed after processing a request.

Attacker. The attacker is a remote user who can send requests to the victim application. By crafting a malicious request (detailed in Section 5.2), the attacker is able to exploit a buffer overflow vulnerability in the GPU kernels used by the victim application. The primary goal of the attacker is to alter the model parameters, such as the weights, through this vulnerability. Consequently, the inferences for future requests from other users will be compromised. We assume that the attacker has knowledge of the layout of the victim's DNN

model weights.

5.2 Application Setups

Under the aforementioned threat model, we choose four widely used vision models as potential victims for our evaluation: ResNet-18 [26], ResNet-50 [26], VGGNet [54], and Vision Transformer (ViT) [35].[7] We implement these models with popular DNN frameworks in cloud environments, such as PyTorch [49].

We host the DNN inference application (i.e., the victim application) in a virtual machine on a cloud system equipped with a server-grade GPU, which is different from the system used for the experiments in Section 4. We utilize NVIDIA's virtual GPU (vGPU) technology to virtualize the GPU [13]. This is a common configuration for DNN inference in cloud environments [7, 8]. The detailed specifications of this system can be found in Appendix D. Note that **vGPU does not support CUDA ASLR**; with vGPU, addresses are not randomized even when ASLR is activated. We keep CUDA ASLR activated in our configuration as it is the default setting. However, it has no effect. We discuss CUDA ASLR in non-virtualized environments later in Section 6.2.

Previous work [18] has suggested that modern DNN frameworks may be vulnerable to GPU buffer overflow issues, but has not disclosed any specific instances. Similarly, we have not identified any overflow vulnerabilities in these frameworks. However, the goal of this paper is not to uncover such vulnerabilities; we leave that task for future research. Instead, for the purpose of our evaluation, we intentionally introduce buffer overflow vulnerabilities into the DNN frameworks.

Buffer overflow vulnerability. We include a CUDA device function for matrix-vector multiplication (with an overflow vulnerability) in the victim application, as shown in Listing 5. Matrix-vector multiplication is important and commonly used in DNN inference. This code uses multiple CUDA threads for each row in the matrix to calculate the partial sums, and each thread transfers the necessary portion of the vector from global memory to its local memory prior to the calculation. We deliberately introduce a vulnerability in this kernel: it lacks proper checks to ensure that the size of the vector portion handled by each thread does not exceed the capacity of the thread's local array. Consequently, a stack overflow can occur when the vector size, which is controlled by the user (explained below), is larger than expected.

Triggering the buffer overflow vulnerability. In order to trigger the vulnerability in Listing 5, we assume that the size of the vector (`n`) is controlled by the users. An example of this situation occurs during the data preprocessing stage. Specifically, the size of the input data provided by the user may not always match the required input size of the DNN model. For example, a user might provide an image of size 512×1024 pixels, while the DNN model is designed to process images of only 256×512 pixels. To handle such discrepancies, a convolution layer might be used to preprocess the user input before feeding it into the DNN model. This convolution layer often employs matrix-vector multiplication for performance optimization [16]. In this preprocessing convolution layer, the dimensions of the matrix and vector (`m` and `n`) are determined by the size of the user input. This potentially allows a user to trigger the vulnerability in Listing 5, if the input size is significantly larger than the size expected by the DNN model.

5.3 Attack Methods and Results

In this section, we examine the two strategies that an attacker can employ to modify the weights: code injection and ROP attacks. We discuss the specific steps an attacker must take to launch these attacks, as well as the resulting outcomes.

5.3.1 Code Injection Attack

We implement the code injection attack as a controlled weight attack: the attacker has control over the data written to memory and can modify the weights to any desired value. Specifically, the attacker prepares a data buffer with shellcode that writes specific values to given addresses, and uses a stack overflow vulnerability to redirect the control flow to this buffer (cf. Listing 5). Details of the shellcode can be found in Appendix C. There are three steps in the attack:

Step 1: The attacker prepares a data buffer whose size is large enough to trigger the buffer overflow error in the victim (cf. Listing 5) when this buffer is sent to the victim for DNN inference.

Step 2: The attacker manipulates the data in the buffer to achieve two critical objectives: 1) the local array of each thread (`arr_local` in Listing 5) is filled with expected shellcode after this buffer is copied to the local memory; 2) the return address of each thread is overwritten with the address of this local array (where the shellcode resides), after the data copy.

[7] We also test the memory corruption attacks on several large language models (LLMs) which we obtain from Hugging Face [10], the details can be found in Appendix E.

Table 3: The DNN inference accuracy with the weight modification attacks (only for weights in the first layer).

DNN model	Clean acc.	Weight modification (controlled)				Weight modification (uncontrolled)			
		10%	20%	50%	100%	10%	20%	50%	100%
ResNet-18 (CIFAR-10)	87.37%	10.00%	10.00%	10.00%	10.00%	87.14%	87.32%	81.65%	10.83%
VGG-19 (CIFAR-10)	83.56%	13.46%	13.46%	11.19%	9.66%	74.90%	62.77%	59.01%	10.00%
ResNet-50 (ImageNet-1K)	84.97%	58.21%	55.21%	54.75%	44.35%	84.93%	84.27%	80.64%	65.33%
ViT (ImageNet-1K)	93.64%	0.09%	0.08%	0.12%	0.09%	92.78%	90.56%	90.33%	88.54%

These preparations are crucial to ensure that when the buffer overflow is triggered, it leads to the expected code injection attack.

Step 3: The attacker initiates a DNN inference request using this data buffer as the input.

5.3.2 ROP Attack

We implement the ROP attack as an uncontrolled weight modification attack: the attacker repeatedly executes a single memory write gadget to modify the weights. The attacker controls the register providing the address used in the write operation, but does not control the register that supplies the data to be written. Details of the gadget are in Appendix B. Similar to the code injection attack introduced in Section 5.3.1, this ROP attack also has three steps, which are very similar to those in the code injection attack. However, the objectives in the second step, preparing the data buffer, are slightly different. Specifically, the attacker needs to manipulate the data in the input buffer to ensure that, after the data copy, 1) the return address on the stack is overwritten with the address of the ROP gadget, and 2) certain registers, which will be used by the ROP gadget, receive the expected values when popped from the stack.

5.3.3 Address of the Malicious Code

In the aforementioned two types of attacks, in order to modify the DNN weights, the attacker needs to know the address of the malicious code (either the ROP gadgets or the shellcode). As explained in Section 5.2, CUDA ASLR has no effect when using vGPU, making this address predictable and stable across executions. As a result, it is rather straightforward for the attacker to determine the address of the shellcode/ROP gadgets. For example, once the attacker profiles the memory of one NVIDIA GPU and identifies the addresses of the ROP gadgets, it can launch ROP attacks on all NVIDIA GPUs of the same generation and using the same CUDA toolkit, since these gadgets are loaded at fixed addresses. We discuss the scenarios in which ASLR takes effect (in native environments without virtual machines) in Section 6.2.

5.3.4 Results

We test the accuracy of the model after modifying the weights in the first layer of each model, using the attack methods in Section 5.3.1 and Section 5.3.2. Table 3 shows the accuracy results after modifying 10%, 20%, 50%, and 100% of the weights. In the code injection attack where the attacker can specify the desired weight value, we choose a large value for each weight. This is because most weight values in DNN models are very small; using a large value is expected to substantially impact the model performance. As shown in the table, this approach significantly reduces the accuracy across all tested models. ResNet-18 and ViT are especially affected, with the accuracy nearly mirroring random guesses. In contrast, in the ROP attack where the attacker does not have control over the modified weight value, the accuracy remains largely unaffected. This is because the ROP gadget used in the attack happens to change the weights to a small value, rather than a large value, which is close to the original values of the weights.

6 Discussion

6.1 `BSYNC` in CUDA ROP Gadgets

Usage of `BSYNC`. CUDA provides synchronization mechanisms at different levels. The `BSYNC` instruction is specifically used for intra-warp synchronization. Although threads in a warp are intended to execute the same instruction simultaneously, some scenarios, such as conditional branches, can lead to thread divergence. `BSYNC` and `BSSY` are used to manage such situations: `BSSY` signals the hardware to prepare for divergence and specifies the address for re-convergence [25]. `BSYNC` serves as the synchronization barrier: when a thread in the warp reaches `BSYNC`, it waits for other threads in the warp.

We found that `BSYNC` and `BSSY` always appear together (in a pair) in CUDA binaries. However, this pairing might not be maintained in ROP gadgets. For example, the gadgets in Figure 7 contain only `BSYNC` but not `BSSY`. This means, the re-convergence address is not specified when `BSYNC` executes, which may cause an error. Interestingly, our analysis reveals that if the threads in a warp do not diverge, `BSYNC` does not influence the execution. Thus, as long as threads remain in sync when executing a ROP gadget, the gadget will function as expected without being affected by `BSYNC`. This is a feasible condition, especially for DNN-based applications, where thread divergence rarely occurs.

6.2 CUDA ASLR

In non-virtualized environments, CUDA supports ASLR for both data and code. In addition, the activation of CUDA ASLR

depends on the ASLR settings in the OS. If ASLR is enabled in the OS, CUDA ASLR is also enabled (by the GPU driver), reflecting a similar level of randomization (e.g., no, conservative, or full randomization [11]) as the one in the OS. Note that, as mentioned in Section 5.2, CUDA ASLR does not function in virtualized environments with the vGPU technology [13].

CUDA ASLR, when functioning, makes it more difficult for the attacker to obtain the address of the shellcode and thus can help mitigate code injection attacks. However, the attacker may be able to bypass CUDA ASLR through GPU side channels (e.g., [58]). In addition, we found that the CUDA driver API library mentioned in Section 4.4 is always loaded at a fixed address, even when full randomization is applied. Therefore, we cannot rely on CUDA ASLR to completely stop the attacker from exploiting the ROP gadgets in this library.

6.3 CUDA JOP

Similar to ROP, jump-oriented programming (JOP) [15] is also an advanced code reuse attack technique. Instead of chaining gadgets that end in a return, JOP makes use of gadgets that end in an indirect jump. These jumps use registers to determine the destination address. To chain the JOP gadgets we need a "dispatcher" (also called "dispatcher gadget"). Its role is to load the address of the next gadget into the appropriate register and then jump to it.

On NVIDIA GPUs, the indirect jump instruction is `BRX` (e.g., "`BRX R3, 0xa0`"). With this instruction, it is possible to form JOP on GPUs. As mentioned in Section 4.4, we did not find any ROP gadgets in common CUDA libraries such as `libcudnn` and `libcublas`. However, we found that some of these libraries do use `BRX` and therefore contain JOP gadgets. Unfortunately, after analyzing these gadgets, we found that they can only perform limited functionality. For example, the `libcuda.so.470.63.01` library contains 156 JOP gadgets, but 151 of these are merely for shifting register values. Similar observations have been made with other common CUDA libraries, such as `libcudnn_cnn_infer.so.8.2.2`. However, we may combine the ROP and JOP gadgets to achieve more functionality. More details of this can be found in Appendix F.

6.4 Memory Errors in Real-World GPU Applications

Memory errors, especially buffer overflow errors, have been identified in existing GPU applications. First, a previous study [22] analyzed 175 commonly used GPU programs in 16 benchmark suites and found 13 buffer overflow errors in 7 of these programs; some of these errors are very similar to the one we assumed in the ML attacks. Second, buffer overflow errors have also been found in web browsers that utilize GPUs to accelerate rendering tasks. For example, in 2022, researchers discovered a buffer overflow error in Chrome that occurs during the data transfer between CPU and GPU memory [3]. This allows a remote attacker to escape the sandbox through a crafted HTML page. In addition, in 2023, it was demonstrated that buffer overflows can also occur within WebGL programs running on GPUs, causing the browser to crash [4].

Furthermore, previous studies on fuzzing ML frameworks (e.g., [18]) have identified significant bugs in their GPU kernels. These include computation bugs, which lead to inaccurate results, and crash bugs, which can cause the entire application to crash. However, these preliminary fuzzing studies have not yet revealed any exploitable memory errors in these frameworks, which we leave for future work. Note that given the similar programming model between CUDA and C/C++, we believe it is likely that exploitable memory bugs exist in these frameworks.

6.5 CUDA Heap Exploitation

CUDA supports dynamic memory allocation: buffers dynamically allocated in CUDA kernels (using the `malloc()` function) reside in the GPU's heap memory.[8] The heap memory is persistent during the lifetime of a GPU process and is shared among the kernels in this process. NVIDIA has not released the specific memory allocator used in CUDA. However, our experimental results suggest that this allocator follows policies similar to those in CPU memory allocators (e.g., ptmalloc [14]). Consequently, CUDA programs may also be vulnerable to spatial/temporal heap exploits, similar to those found in CPU programs. However, the use of dynamic memory allocation on GPUs is generally discouraged due to its significant performance overhead [33]. After analyzing common CUDA applications and benchmarks, we did not find any scenario where dynamic buffer allocation is used. Thus, we believe that this issue is much less significant compared to overflows in memory that is statically allocated (local/global/shared memory).

6.6 Countermeasures

OOB detection tools. There have been many tools to statically/dynamically detect buffer overflow errors in GPU programs. First, NVIDIA Compute Sanitizer [40], a tool for GPU memory safety checks, is based on dynamic binary instrumentation: it intercepts every program instruction at runtime before the execution. While effective, this approach introduces considerable performance overhead. Second, cuCatch [57] is a compile-time tool that can help detecting both spatial and temporal memory errors during the execution of a CUDA program. It stores the necessary metadata for memory safety

[8] Heap memory is different from global memory. Global memory buffers can only be allocated by the CPU code (prior to a kernel launch, cf. Section 2.3), while heap buffers can be allocated by the GPU code during the execution of a CUDA kernel.

checks in a table, with one entry for each allocation. Given a pointer, the correpsonding table entry index can be either embedded in the upper bits of the pointer (if possible), or stored in the shadow memory. cuCatch introduces much less performance overhead compared to NVIDIA Compute Sanitizer. However, it is important to note that neither of these tools can achieve a 100% detection rate.

Stack cookies. Stack canaries or stack cookies are secret values that are placed between a buffer and control data on the stack to monitor for stack overflows. Unfortunately, NVIDIA has not adopted this technique on their GPUs. In addition, it is important to note that previous studies have already shown that the attacker might be able to determine the value of the stack cookies, thus bypassing the detection mechanism (e.g., [51]).

In fact, several canary-based detection tools (for GPU buffer overflows) have been proposed by researchers, such as GMOD [21], GMODx [20], and clARMOR [22]. They insert a canary before and after every GPU buffer (not just stack buffers) and detect buffer overflows by periodically verifying the integrity of these canaries. These tools have minimal performance overhead. However, they cannot detect OOB read operations or non-adjacent OOB read/write operations.

ASLR and PIE. Both Position Independent Executable (PIE) and ASLR are supported on NVIDIA GPUs. However, we found that the CUDA driver API library that contains powerful ROP gadgets is not compiled as PIE and is loaded at a fixed address even with CUDA ASLR activated (cf. Section 6.2). As a result, ASLR cannot thwart ROP attacks on GPUs. It is not clear why NVIDIA has chosen this design approach. To effectively prevent ROP attacks, it is crucial for NVIDIA to compile this library as PIE and ensure that it is subject to ASLR. In addition, ASLR makes it more difficult for the attacker to launch code injection attacks. However, the attacker might be able to bypass ASLR through side-channel attacks (cf. Section 6.2).

W^X policy. Differentiating between code and data pages is critical for counteracting code injection attacks. As mentioned in Section 4, there is already a read-only bit in the PTE. To understand whether this bit takes effects, we modified the bit through IOMMU during the execution of a CUDA program, and found that setting this bit effectively prohibits any modifications to the page. Thus, the GPU driver can set this bit for code pages to prevent code modification. In addition, an executable bit needs to be included in order to prevent the execution of data pages.

6.7 Related Work

Research in memory vulnerabilities on GPUs has been very limited. First, in 2016, Miele conducted a preliminary exploration into buffer overflow vulnerabilities in CUDA [38]. This research shows that, on a GTX TITAN Black GPU (Kepler architecture with sm_30), it is possible to exploit a stack overflow to overwrite function pointers, therefore redirecting the execution flow. It further shows that the function call and return mechanism on these GPUs is based on a `PRET` instruction followed eventually by a `RET` instruction. The `PRET` instruction stores the return address in an *unknown location*, making the traditional ROP impractical on these GPUs. In addition, this research concludes that code and data address spaces are separated and thus executing data buffers is not possible. Note that this work also confirmed the feasibility of CUDA heap overflows, although heaps are rarely used in CUDA programs [33].

Second, in the same year, Di et al. conducted similar experiments on a GeForce GTX 750Ti GPU (Maxwell architecture with sm_50) [19], reaching conclusions that align with those from Miele. However, compared to Miele's study, this work provides a much more detailed analysis on GPU heap overflows.

Third, later in 2021, Park et al. performed a deeper analysis of GPU memory exploitation techniques. They presented the first attack on DNN frameworks based on GPU memory manipulation [48]. The experiments in this work were carried out on a GTX 950 GPU (Maxwell architecture with sm_50) and a GTX 1050 GPU (Pascal architecture with sm_60). This work reached several conclusions that are the same as prior work, such as the hidden return address. However, it also made a new discovery that the code pages are writable on NVIDIA GPUs.

7 Conclusion

In this paper, we present a comprehensive study of the buffer overflow issues in CUDA programs. First, we reverse engineered the mechanisms used to access various GPU memory spaces, demonstrating that buffer overflow errors can cause memory corruption across memory spaces and exceed data's legitimate scopes. Second, we explored the code and data management policies on GPUs, revealing that traditional code injection attacks remain functional on GPUs. We also analyzed the mechanics of function returns and proved the feasibility of CUDA ROP. Finally, we demonstrated that the vulnerabilities discovered in this paper pose significant security risks to DNN applications running on GPUs. The Proof-of-Concept for CUDA code injection and CUDA ROP is available at https://github.com/SecureArch/gpu_mem_attack.

A GPU List

Table 4 lists all the GPUs on which we have verified the conclusions presented in Section 4.

Table 4: The complete list of tested GPUs.

Architecture	GPU Model
Volta	Tesla V100
Turing	GeForce RTX 2070
Ampere	GeForce RTX 3080
Ampere	A100
Ada Lovelace	GeForce RTX 4090

B ROP Gadgets

An example of the ROP gadget in Section 5 is shown in Listing 6. Each execution of this gadget modifies a weight value, and we execute it repeatedly to modify multiple weights. Specifically, we prepare the stack so that each time the gadget executes, two conditions are met: 1) the address of the first instruction in the gadget is stored at `[R1+0x18]` and is thus loaded into `R20`; 2) the address of the next weight is stored at `[R1+0x38]` and is thus loaded into `R28`. Consequently, each execution of this gadget first modifies a weight value using the `ST` instruction, then updates `R28` to the address of the next weight, and finally returns to the start of the gadget to modify the subsequent weight. If there are a large number of weights to modify and the stack size is insufficient to support the repeated execution of this gadget, we use multiple malicious user requests—and thus multiple ROP attacks—to complete the task.

Listing 6: An example ROP gadget.

C Shellcode

An example of the shellcode used in the code injection attack is shown in Table 7. It writes the value `0xffffffff` to a range of memory addresses, from `0x7fffdeadbeef` to `0x7fffdeadbeef+0xaaaa`.

D System Specifications

The cloud system used for the experiments in Section 5 is specified in Table 5.

Table 5: Platform details.

CPU	Intel Xeon Silver 4114
Hypervisor	KVM on Ubuntu 20.04
Virtual machine	Ubuntu 20.04
GPU	NVIDIA A100
GPU architecture	Ampere
vGPU version	15.4
vGPU license	vWS
vGPU memory	40GB
CUDA version	12.4

E LLM Attacks

We test the memory corruption attacks, including the code injection attack and the ROP attack, on three LLMs, Flan-T5-Small, Flan-T5-Base, and Flan-T5-Large [5]. We assume a buffer overflow vulnerability in the data pre-processing stage (e.g., for noise removing [6]), similar to the one assumed in Section 5.

Table 6: The LLM inference accuracy (with MMLU [27]) after the weight modification attacks.

DNN Model	Clean acc.	Uncontrolled Weight modification			
		10%	20%	50%	100%
Flan-T5-Small	29.5%	29.2%	28.6%	28.3%	28.2%
Flan-T5-Base	34.2%	33.2%	32.6%	28.9%	29.5%
Flan-T5-Large	42.0%	41.3%	40.5%	39.1%	35.0%

Similar to the attacks on the vision models (cf. Section 5), the code injection attack (with controlled written values) can reduce the accuracy of the LLMs to the same level of random guessing. However, as shown in Table 6, the ROP attack, where the written value is not controlled by the attacker, has a limited effect on the accuracy of the LLMs.

F JOP+ROP Attack

An example of combining JOP and ROP gadgets is shown in Figure 8. Here we assume that `R4` contains the address of the helper gadget, which is used to chain the JOP gadgets (with the ROP gadgets). Every time after executing a JOP gadget, it jumps to the helper gadget, which then pops the address of the next gadget from the stack and returns to it.

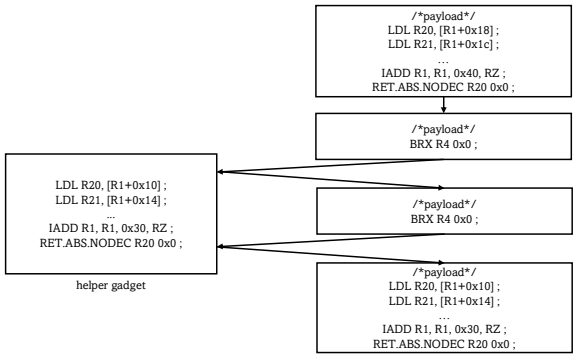

Figure 8: An example of combining JOP and ROP, assuming that `R4` contains the address of the helper gadget.

Table 7: An example shellcode.

Abstract

While the number of vulnerabilities in the Linux kernel has increased significantly in recent years, most have limited capabilities, such as corrupting a few bytes in restricted allocator caches. To elevate their capabilities, security researchers have proposed software cross-cache attacks, exploiting the memory reuse of the kernel allocator. However, such cross-cache attacks are impractical due to their low success rate of only 40 %, with failure scenarios often resulting in a system crash.

In this paper, we present SLUBStick, a novel kernel exploitation technique elevating a limited heap vulnerability to an arbitrary memory read-and-write primitive. SLUBStick operates in multiple stages: Initially, it exploits a timing side channel of the allocator to perform a cross-cache attack reliably. Concretely, exploiting the side-channel leakage pushes the success rate to above 99 % for frequently used generic caches. SLUBStick then exploits code patterns prevalent in the Linux kernel to convert a limited heap vulnerability into a page table manipulation, thereby granting the capability to read and write memory arbitrarily. We demonstrate the applicability of SLUBStick by systematically analyzing two Linux kernel versions, v5.19 and v6.2. Lastly, we evaluate SLUBStick with a synthetic vulnerability and 9 real-world CVEs, showcasing privilege escalation and container escape in the Linux kernel with state-of-the-art kernel defenses enabled.

1 Introduction

Operating system kernels, such as Linux, are susceptible to memory safety vulnerabilities due to their size and complexity. However, most of these vulnerabilities have limited capabilities, such as corrupting a few bytes in restricted allocator caches. These limitations make exploitation difficult in practice. To make these vulnerabilities even more difficult to exploit, researchers and kernel developers have included defenses such as SMAP, KASLR, and kCFI [37]. In addition, the kernel's allocator is designed to restrict exploits that propagate from heap vulnerabilities. One particular hardening strategy is to enforce coarse-grained heap separation. This separation places objects in distinct allocator caches that maintain blocks of adjacent pages, called slabs, and separate security-critical objects from frequently used objects. Hence, vulnerabilities in frequently used caches cannot be directly exploited to manipulate security-critical objects, such as credentials.

To circumvent coarse-grained heap separation, security researchers [50] presented software cross-cache attacks, which have been used by several kernel exploits [2, 13, 17, 19, 28–30, 47]. Software cross-cache attacks exploit the memory reuse of the kernel allocator as follows: Initially, an adversary triggers a heap vulnerability to obtain and hold on to a write capability for a victim object. They then free all memory slots on the slab page containing the victim object and allocate a different (sensitive) object type. This triggers the allocation of new slab pages, presumably reclaiming the previously freed and recycled slab page. The adversary then continues to overwrite the victim object, which now resides in the same memory location as the newly allocated sensitive object, corrupting it.

The Linux kernel has two types of allocator caches: dedicated and generic caches. While dedicated caches can be reliably exploited for cross-cache attacks [2, 17, 19, 28, 47], generic caches cannot [28, 50]. In particular, exploitation of generic caches has a success rate of only 40 % [50], with failure scenarios often leading to system crashes. To increase the reliability of generic cache exploitation, security experts [13, 29, 30, 47] have used stabilization objects, e.g., `msg_msg` or `pipe_buffer`. However, these objects cannot be used in newer kernel versions due to more refined heap separation, i.e., v5.14 introduced `kmalloc-cg-*`. Therefore, for newer kernel versions, cross-cache attacks on generic caches do not provide the reliability required in practice [28, 50].

In this paper, we present SLUBStick, a novel kernel exploitation technique that converts a limited kernel heap vulnerability into an arbitrary read-and-write primitive. At its core, SLUBStick exploits timing side-channel leakage of the kernel's allocator to reliably trigger the recycling and reclaiming process for a specific memory target. Exploiting this side-channel leakage significantly enhances the success rate of soft-

ware cross-cache attacks, exceeding 99 % for generic caches with a single slab page and 82 % for multiple slab pages. With this substantial increase, our approach overcomes the prior unreliability and makes cross-cache attacks practical for exploitation. Using our reliable side-channel supported approach, SLUBStick performs a cross-cache attack to recycle a slab page that contains a write capability. SLUBStick then reclaims the slab page as a page table, i.e., Page Upper Directory (PUD), used for userspace address translation. By triggering the write capability, SLUBStick overwrites page table entries, obtaining arbitrary read and write capabilities.

To perform SLUBStick, we overcome the following technical challenges: First, we present reliably exploitable primitives for our timing side channel that are accessible to unprivileged users. Second, hardly any kernel heap vulnerabilities provide the capability to modify kernel data directly. Therefore, we present techniques that exploit code patterns prevalent in the Linux kernel. These techniques convert heap vulnerabilities before the recycling phase to allow a write capability after reclamation as a page table. Third, manipulating page table entries to obtain an arbitrary memory read-and-write primitive is challenging because the physical memory layout is randomized due to KASLR, and we do not assume address information leakage. Hence, we introduce a reliable solution that obtains such a primitive from an overwrite.

We conduct a systematic analysis for two Linux kernel versions, v5.19 and v6.2, providing a comprehensive list of primitives to successfully execute SLUBStick for all generic caches from `kmalloc-8` to `kmalloc-4096`. We also evaluate SLUBStick with a synthetic vulnerability as well as with 9 real-world CVEs for both kernel versions on x86_64 as well as aarch64, demonstrating its architecture and kernel version independence. Based on these findings, we conclude that SLUBStick poses a significant threat to kernel security.

Contributions. The main contributions of SLUBStick are:

(1) Side-Channel Supported Recycling and Reclaiming: We present a novel approach to reliably trigger the recycling process of a specific memory target and reclaim it by using a software timing side channel. Our approach shows success rates exceeding 99 % for frequently used generic caches, making cross-cache attacks practical.

(2) Novel Exploitation Method: Leveraging our reliable side-channel supported recycling and reclaiming approach, we present a novel exploitation technique to convert kernel heap vulnerabilities with limited capabilities into an arbitrary memory read-and-write primitive with state-of-the-art kernel defenses enabled.

(3) Comprehensive Analysis and Attack Evaluation: We systematically analyze two Linux kernel versions, v5.19 and v6.2, showing that SLUBStick can be executed for generic cache from `kmalloc-8` to `kmalloc-4096`. We also evaluate SLUBStick using a synthetic vulnerability and 9 real-world CVEs to escalate privileges.

Outline. Section 2 describes the background and threat model. Section 3 presents SLUBStick. Section 4 introduces our reliable recycling and reclaiming process. Section 5 describes pivoting heap vulnerabilities. Section 6 details how to gain arbitrary read-and-write capabilities. Section 7 comprehensively evaluates our attack. Section 8 discusses valuable insights and kernel defenses. Section 9 concludes this work.

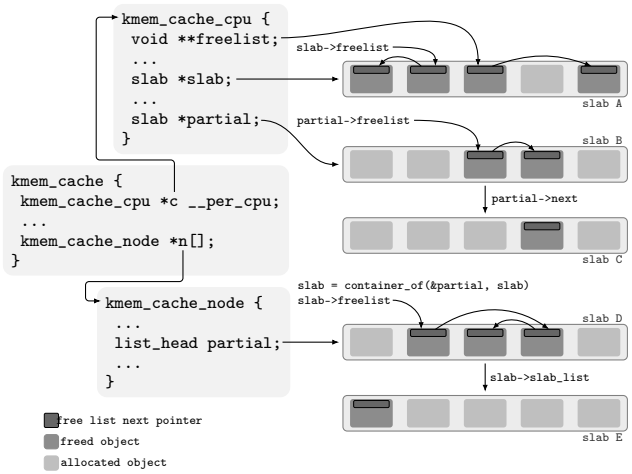

Figure 1: `kmem_cache` layout for the SLUB implementation.

2 Background and Threat Model

2.1 Buddy and SLUB Allocator

Linux's page allocator is based on the *Binary Buddy Allocator* [23], mainly referred to as buddy allocator. It allocates physical contiguous memory in chunks of page order size, i.e., $2^{\mathtt{n}} \cdot \mathtt{PAGE\_SIZE}$, where `n` is the page order. Moreover, it combines this page-order allocation with free chunk merging.

SLUB allocator. As the buddy allocator only provides page-order allocations, the slab allocator caches available objects with a predefined size in a multi-level free-list hierarchy, using pages obtained from the buddy allocator. There are three main implementations: SLUB is the default choice for several Linux distributions [22], while SLOB has become obsolete, and SLAB will be deprecated soon [8].

In the Linux kernel, the SLUB allocator provides two primary types of allocator caches: dedicated and generic caches. Dedicated caches are employed for frequently used fixed-size objects, such as `cred` or `task_struct`. Generic caches are utilized for generic object allocation and deallocation or for objects whose sizes are not known during compile-time, e.g., elastic objects [5]. Both types of caches utilize `kmem_cache`, with each dedicated cache having its own `kmem_cache`, while generic caches have multiple `kmem_caches` matched to different sizes. When allocating memory from a generic cache, the kernel matches the requested size to one of these caches and allocates an object from the corresponding `kmem_cache`.

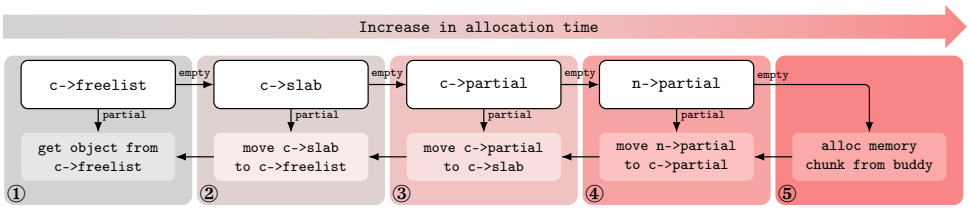

Figure 2: SLUB allocation of an object, where the terms `c` and `n` refer to the `kmem_cache_cpu` and `kmem_cache_node`, respectively. The free lists (i.e., `c->freelist` and `c->slab->freelist`) and slab lists (i.e., `c->partial` and `n->partial`) are checked to be either `empty` or `partial`.

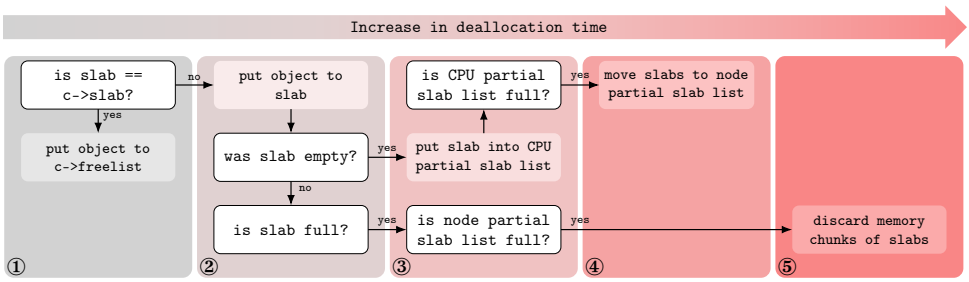

Figure 3: SLUB deallocation of an object, where the term `slab` refers to the slab that contains the object to be freed. The term `c` represents the `kmem_cache_cpu` associated with this slab. The `slab` is either active (i.e., slab stored as `c->slab`), or stored in the partial slab list (i.e., slab located within `c->partial`) or node partial slab list (i.e., slab located within `n->partial`).

The Linux kernel incorporates cache aliasing to optimize memory management. Cache aliasing merges freed objects stored in distinct `kmem_caches` with similar characteristics, e.g., object size and allocation properties. For security reasons, `kmem_caches` of dedicated or generic caches considered security-critical are marked as accounted to prevent aliasing. Essentially, these accounted `kmem_caches` separate accounted objects from the non-accounted ones. Security-critical caches include those that store sensitive information, such as `cred`, and objects commonly used for exploitation (allocated using `kmalloc-cg-*`), such as elastic objects [5].

Architecture. The architecture of a `kmem_cache` [22], shown in Figure 1, includes a `kmem_cache_cpu` for each logical CPU and an array of `kmem_cache_nodes`. The `kmem_cache_cpu` comprises various free lists: a CPU free list (`c->freelist`), a slab free list (`slab->freelist`), and additional free lists of partial slabs (`partial->freelist`, maintained as a single-linked list). Despite each slab having its free list, the separate CPU free list allows lockless allocation, improving performance. The `kmem_cache_node` has a double-linked list of slabs (`partial`) also containing freed objects. In the context of this work, we refer to a list (i.e., free list, and single- and double-linked list) as full when it reaches its capacity of containing objects. It is considered empty when no object is present in it. A list is classified as partial when it is neither full nor empty.

Allocation and deallocation. `kmem_cache` stores objects in a multi-level free-list hierarchy. As shown in Figure 2, the allocation process starts by searching for an available object in the lower free-list levels [22]. This process continues throughout the hierarchy until an available object is found. These levels include the CPU free list ①, slab free list ②, CPU partial slab list ③, and node partial slab list ④, with each level taking more allocation time. If no object is available in any of these free lists, the SLUB allocator falls back to the buddy allocator ⑤, which allocates a memory chunk.

When deallocating, the SLUB allocator attempts to place the object in the lower free-list levels, e.g., CPU free list ① [22], as shown in Figure 3. Upon deallocation, the kernel may check the number of free slabs, i.e., the number of slabs with full free list stored in the node partial slab list ③. If this number exceeds a particular capability (see Table 4), the SLUB allocator deallocates the slab's memory chunks ⑤, returning them to the buddy allocator. Memory chunks returned in such a recycling phase are reused for future allocations.

Timing attacks on allocation. Lee et al. [26] demonstrated with PSPRAY the feasibility of performing a timing side channel on the SLUB allocator. PSPRAY deduces when the allocator allocates a fresh memory chunk (see ⑤ in Figure 2). This insight increases the likelihood of successful kernel heap exploitation, which primarily relied on heap spraying, i.e., for Use-After-Free (UAF) and Double-Free (DF), or heap grooming, i.e., for Out-Of-Bounds (OOB) [4, 26, 53].

However, their method relies on a precise measurement primitive that is no longer available in recent kernel versions. Their primary proposed primitive uses `msg_msg`. Since it is allocated via the segregated `kmalloc-cg-*` for kernel versions v5.14 or higher, it is limited to scenarios where the vulnerable

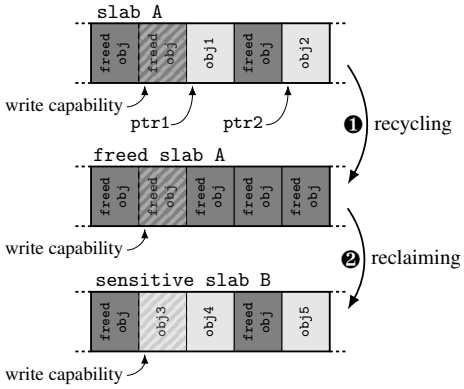

Figure 4: Software cross-cache attack with an initial state, where a write capability refers to a freed object. An attacker enforces a recycling ❶ of `slab A`'s memory chunk by freeing `obj1/2`. By allocating sensitive objects, the attacker presumably reclaims ❷ the chunk for a sensitive `slab B`, resulting in write capability referring `obj3`. Lastly, `obj3` is overwritten.

object is also allocated from the segregated generic cache. Other proposed primitives are limited because the computational overhead of non-allocation tasks primarily masks allocation timing (e.g., `read`). Furthermore, their approach fails to identify suitable measurement primitives, e.g., for `kmalloc-8/16`. For other identified primitives, we could not reproduce the allocation of a single data object (e.g., `fchown`), or the primitives are privileged and therefore unusable (e.g., `kexec_load`). We contacted the authors about the applicability of using their identified syscalls (apart from `msg_msg`) to determine the timing difference. They confirmed that the overhead of the syscalls they identified limits their applicability. In summary, while their work demonstrates feasibility, its applicability is limited to older kernel versions.

2.2 Software Cross-Cache Attacks

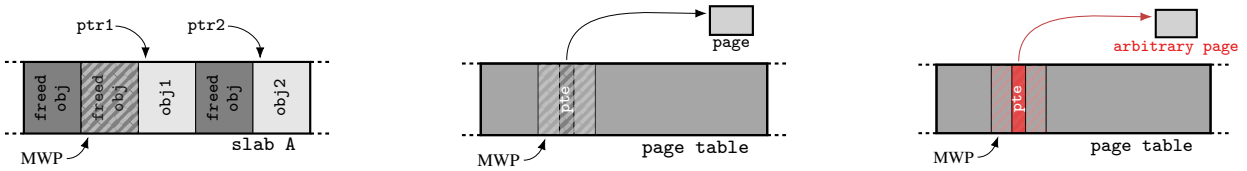
When the SLUB allocator frees memory chunks using the buddy allocator, as shown with ⑤ in Figure 3, these chunks are reused. Classic cross-cache attacks [2,17,19,28,29,47,50] exploit this reusing behavior. Initially, an adversary compels the SLUB allocator to recycle a memory chunk containing a write capability due to vulnerabilities. Subsequently, they allocate numerous sensitive objects from another allocator cache, hoping to reclaim the previously freed chunk. If successful, the memory that was previously occupied with the write capability will now be occupied by sensitive objects. Lastly, they trigger the write capability to this memory, corrupting a sensitive data object. The recycling ❶ and reclaiming ❷ phases are shown in a simplified setting in Figure 4.

Xu et al. [50] demonstrated the feasibility of cross-cache attacks, and subsequent research [28,29] has further explored their impact. However, executing such attacks is notably challenging, particularly for frequently used generic caches. One significant hurdle is the introduction of noise through uncontrolled allocations, complicating to achieve state ⑤ in Figure 3. For example, unknown allocations from a kernel thread can thwart the freeing of the slab's memory chunk, thereby preventing the reclamation [28]. Adding to the complexity, the unpredictable occurrence of both phases, recycling ❶ and reclaiming ❷, introduces instability to the exploit.

In summary, mounting cross-cache attacks is complex and fraught with challenges. Although these attacks are compelling, in practice, they have a limited success rate, as low as 40 % [50]. Importantly, this percentage only represents the success rate of the cross-cache attack, excluding additional stages of an end-to-end exploit, e.g., vulnerability triggering and memory manipulation, which further reduces the overall success rate. The process of repeatedly triggering vulnerabilities carries its risks. Traces left in the kernel often make it difficult to trigger the same vulnerability again. For instance, an OOB write may corrupt lists when triggered. Hence, repeated activation of the vulnerability can result in a crash, severely limiting the attack's practicality.

2.3 Threat Model

We assume that an unprivileged user has code execution. Additionally, we consider the presence of a heap vulnerability in the Linux kernel. We assume that the Linux kernel incorporates all defense mechanisms available in version 6.4, the most recent Linux kernel version when we started our work. These mechanisms include features such as `W^X`, KASLR, SMAP, and kCFI [37]. We do not assume any microarchitectural vulnerabilities, e.g., transient execution [24,31], fault injection [43], or hardware side channels [3,51].



In this work, we primarily focus on heap vulnerabilities (most common type of software vulnerability according to Microsoft [36]) that result in a Double-Free (DF), or a Use-After-Free (UAF) or an Out-Of-Bounds (OOB) allowing for a limited writing capability. For instance, CVE-2023-21400 enables the double free of an object within the `kmalloc-32` generic cache, while CVE-2023-3609 permits a write operation at offset 0x18 on an object allocated from `kmalloc-64`.

3 Technical Overview and Challenges

This section outlines SLUBStick's capability to overcome several technical challenges when exploiting a limited heap vulnerability to obtain an arbitrary read-and-write primitive.

3.1 Overview

Obtaining an arbitrary read-and-write primitive with SLUBStick involves *three stages*, as depicted in Figure 5. In the *first stage* (see Figure 5a), SLUBStick exploits a heap vulnerability to acquire a Memory Write Primitive (MWP). This

(a) *Stage 1* deallocates objects `obj1` and `obj2` to trigger the recycling process of `slab A`'s memory chunk, with a Memory Write Primitive (MWP) referring to it.

(b) *Stage 2* reclaims the recycled memory chunk for a page table used by the userspace address translation, containing one entry, `pte`, which refers to the user-accessible `page`.

(c) *Stage 3* triggers the MWP to manipulate the page table entry `pte`. This manipulated entry indexes then the `arbitrary page`, allowing it to be overwritten from the userspace.

Figure 5: High-level overview of SLUBStick subdivided into three stages exploiting an MWP.

MWP provides an adversary with a write capability at an adversary-determined time, with the primitive referring to the memory of a freed object. Subsequently, SLUBStick triggers the recycling process of its slab's memory chunk by deallocating all objects of the slab. This chunk is then returned to the buddy allocator for future allocations. Crucially, even after the recycling, the MWP still refers to the recycled chunk.

In the *second stage* (see Figure 5b), SLUBStick allocates page tables to reclaim the recycled memory chunk for a page-table page used to translate a userspace address. The entries in this table refer to user-accessible pages, storing crucial information, e.g., their page frame number and access permissions.

In the *third stage* (see Figure 5c), SLUBStick triggers the MWP to overwrite the referenced memory of the page table. This manipulation allows an adversary to change the page frame number and permission bits, granting access to any physical page and adjusting user access permissions. As a result, the virtual address now refers to the selected page with permission to modify it from userspace. For example, by referring to kernel code, this capability allows the adversary to alter the kernel's behavior. As another example, the adversary can reference data of privileged files such as `/etc/passwd`, thus modifying it to bypass authentication checks.

SLUBStick does not violate the kernel's control flow or any of the existing kernel defenses outlined in Section 2.3. Hence, these existing kernel defenses cannot mitigate SLUBStick, highlighting its severe threat to current systems. Furthermore, efforts to separate generic caches [9] are ineffective in mitigating SLUBStick. We discuss the limitations of existing kernel defenses in Section 8.

3.2 Technical Challenges

This section briefly describes how SLUBStick overcomes several technical challenges to escalate privileges, while the subsequent sections discuss our solutions in more detail.

Triggering recycling/reclaiming. SLUBStick performs a cross-cache attack on generic caches. As described in Section 2.2, cross-cache attacks have been challenging to execute because they are unstable and unpredictable [28, 50]. Uncontrolled allocations and deallocations introduce noise, making it difficult to determine when the recycling and reclaiming phase will occur. However, we present a side-channel supported approach to reliably trigger the recycling process of a targeted memory chunk, which is then reclaimed. This significantly increases the success rate, exceeding 99 % for slabs with single page-size chunks and 82 % for multi-page-size chunks, which were previously considered impractical. In Section 4, we explain our novel approach, which exploits the side-channel timing leakage of the SLUB allocator.

Pivoting heap vulnerabilities. Pivoting a kernel heap vulnerability to establish an MWP presents two sub-challenges: First, SLUBStick obtains a dangling pointer from the vulnerability. DF vulnerabilities provide us with this capability, while OOB and UAF write vulnerabilities do not. Hence, SLUBStick requires an appropriate pivoting approach to utilize them fully. Second, in most cases, a dangling pointer does not directly allow for controlled overwriting with controlled timing. Hence, SLUBStick must pivot the dangling pointer, performing an adversary-controlled write, i.e., MWP. In Section 5, we explain the process of adequately pivoting capabilities from kernel heap vulnerabilities to obtain the MWP.

Arbitrary read-and-write. By triggering the MWP, SLUBStick can overwrite a page table used for address translations of a userspace address. As the kernel memory layout is randomized (for physical addresses) by KASLR, and we do not assume any address information leakage, pivoting an MWP to an arbitrary memory read-and-write primitive is not straightforward. In Section 6, we explain how we achieve this pivot to an arbitrary read-and-write primitive.

4 Triggering Recycling and Reclaiming

In this section, we present a novel approach that reliably triggers the recycling process of a targeted memory chunk and reclaims it, making cross-cache attacks practical for exploitation. Our approach leverages a software timing side-channel attack on the SLUB allocator. Through this side channel, we gain valuable information about when a memory chunk is allocated and deallocated using the buddy allocator. These insights allow us to reliably trigger the recycling process of a targeted chunk (see Section 4.1). To ensure the return of this

chunk during the reclamation phase, we massage the buddy allocator's internal state (see Section 4.2). By combining these two strategies, our novel approach triggers the recycling and reclaiming process reliably. To demonstrate the effectiveness, we provide a proof-of-concept (including experiments), offering comprehensive details on deploying generic caches from `kmalloc-8` to `kmalloc-4096` (see Section 4.3).

4.1 Side-Channel Supported Recycling

To trigger the recycling of a targeted memory chunk, our approach first groups allocated objects according to their slab by using a software timing side channel on the allocation. It then deallocates these grouped objects, prompting the kernel to recycle the slabs' chunks, including our targeted chunk.

The principal approach to grouping allocated objects involves timing measurements during standalone object allocation from userspace. A fast to medium timing indicates that the object was allocated from one of the slab's lists (①, ②, ③, or ④ in Figure 2). Hence, we group it with the previously allocated object in the same slab. Conversely, if the allocation time is notably higher (⑤), this indicates that the object originates from a newly allocated memory chunk and thus a new slab, which prompts us to group it separately. As a result, we obtain a list of grouped objects organized by their slabs.

One challenge with this approach is the lack of primitives in the Linux kernel to accurately measure standalone allocation times with minimal non-allocation tasks from userspace. This is because a single object allocation involves notable non-allocation tasks, e.g., allocating an object by opening its device. Using primitives with notable non-allocation tasks, as proposed by PSPRAY [26] for non-separated generic caches, leads to inaccurate and unusable results. To address this challenge, we separate the timing measurement from the persistent object allocation. While an allocation primitive persistently allocates an object, the timing measurement primitive is used to group this allocated object based on its slab.

Measurement primitive. We measure the timing of primitives that involve both allocation and deallocation within a single syscall while only performing minimal non-allocation tasks. During the deallocation process within this primitive, the previously allocated object is consistently set to the active CPU free list (state ① in Figure 3), which only minimally affects the measured timing. The minimal non-allocation tasks executed during the syscall exhibit high consistency, which also minimally affects the results. Thus, the measured timing depends primarily on the allocation. This allows us to determine when a new memory chunk is allocated from userspace, indicated by a notable slow allocation timing. To illustrate the notable difference between fast and slow allocation timings, we provide detailed experiments in Appendix B.

An example of a measurement primitive is the `add_key` syscall, shown in Listing 1. To ensure minimal interference from non-allocation tasks, our approach invokes the `add_key` syscall with a `_desc`, which fails the validation check at Line 8. As a result, the syscall primarily involves two privilege switches, allocation and deallocation, with the execution time mainly depending on the allocation. By measuring the timing of this syscall, our approach determines whether Line 4 allocates a new memory chunk. Crucially, while the `add_key` syscall is one example, measurement primitives are common in the Linux kernel, as we later illustrate in Section 4.3.

```
1  ssize_t __do_sys_add_key(const char __user *_desc) {
2    ssize_t ret;
3    size_t len = strnlen_user(_desc) + 1;
4    char *desc = kmalloc(len, GFP_KERNEL);
5    size_t n = copy_from_user(desc, _desc, len);
6    if (n) goto ERR;
7    desc[len - 1] = 0;
8    if (IS_INVALID(desc)) goto ERR;
9    ... /* add_key code execution */
10 ERR:
11   kfree(desc);
12   return ret;
13 }
```

Listing 1: The `add_key` syscall serves as a measurement primitive to determine whether Line 4 allocates a new chunk.

```
1  size_t timed_alloc(int *time) {
2    /* allocate the 64 byte struct snd_ctl_file */
3    int fd = open("/dev/snd/controlC0", O_RDONLY);
4    /* timed allocation with invalid add_key */
5    char _desc[64] = INVALID_DESC;
6    size_t t0 = rdtsc_begin();
7    add_key(_desc);
8    size_t t1 = rdtsc_end();
9    *time = t1 - t0;
10   /* return allocated object */
11   return fd;
12 }
```

Listing 2: An example of a 64 byte allocation from userspace, where Line 3 allocates a `snd_ctl_file` object. Between Lines 6 and 8, we use the `add_key` measurement primitive to determine whether a new chunk was allocated.

Persistent allocation primitive. A persistent allocation refers to a situation where the allocated kernel object remains allocated until the corresponding deallocation counterpart is executed. Crucially, the deallocation of the object must occur within the deallocation syscall, not at a later time. Therefore, objects released inside a Read-Copy-Update (RCU) [35] callback function cannot be used for persistent allocation. Also, the de-/allocation syscalls must be unprivileged.

Triggering the recycling process. Using our method of accurately measuring allocation timing and persistently allocating objects, our approach to reliably triggering the recycling process consists of *two stages*.

In the *first stage*, we allocate and group kernel objects based on their slabs. We start emptying all free lists within the cache's multi-level hierarchy by allocating many objects. Next, we persistently allocate objects to fill the free memory slots of the slab while using our measurement primitive to

exploit the timing side channel for grouping the allocated objects. Listing 2 shows an example of combining a measurement primitive (e.g., `add_key`) with a persistent allocation primitive (e.g., `snd_ctl_file`). The `timed_alloc` function provides two outputs: the measured timing at Line 9 and the allocated object as an identifier at Line 11. Using the measured `*time`, we determine whether the object belongs to the same slab as the previously allocated object (i.e., indicated by a low value) or whether it originates from a new memory chunk and hence a new slab (i.e., indicated by a notably high value). This allows us to group objects identified with `fd` by their slabs.

In the *second stage*, we proceed to free the grouped objects, prompting the Linux kernel to deallocate their slabs via the buddy allocator, as denoted by the state ⑤ in Figure 3. The release of slabs occurs when the number of free slabs exceeds the capacity of the node's partial slab list ③, detailed in Table 4. Since we know the objects of the slabs and the capacity of the partial slab list, we retain control over when the memory chunks, including our target, are recycled. While uncontrolled deallocations may introduce noise, we show remarkable noise resilience in our experiments in Section 4.3.

4.2 Massaging the Buddy Allocator

This section determines the reclaiming phase of a targeted memory chunk based on the recycling phase, where our approach is tailored to the generic cache size. A memory chunk can consist of a single or multiple pages, as shown in Table 4. Our goal is to ensure the reliable reclaiming of either the recycled chunk or a page-size part of it. Notably, the reclamation chunk's size is required to be one page, as SLUBStick reclaims it as a page table, as we later show in Section 6.

For generic caches from `kmalloc-8` to `kmalloc-256`, the memory chunk consists of a single page. When releasing slabs' memory chunks, the buddy allocator follows a Last In First Out (LIFO) principle to return recycled memory chunks. Therefore, to obtain a targeted chunk, one can request a page-size chunk shortly after the recycling process in the opposite order of the deallocation process.

In contrast, for generic caches from `kmalloc-512` to `kmalloc-4096`, the memory chunk consists of multiple pages. To ensure the reclaiming of the recycled memory chunk as page size, we need to put the allocator in a state where it splits the targeted memory chunk into smaller ones. To accomplish this, we take the following strategy: First, we empty smaller memory chunks, reducing the number of available smaller chunks. Next, we perform the recycling process, preparing for subsequent chunk splitting and reclaiming. Finally, we allocate multiple page-size chunks. This compels the kernel to split the targeted memory chunk into smaller ones, making it available for allocation. Through these steps, we ensure that the buddy allocator splits the targeted memory into smaller chunks and returns them for page-size allocation.

4.3 Proof-of-Concept and Experiments

For our Proof-Of-Concept (POC), we first systematically analyze the Linux kernel to identify kernel objects suitable for a measurement and allocation primitive. We then combine our approaches discussed in Sections 4.1 and 4.2 to reliably trigger the recycling and reclamation phase. Our POC demonstrates the feasibility and effectiveness of our approach with a success rate of between 99.3 % to 99.9 % for single page-size chunks and 82.1 % to 93.5 % for multi-page-size chunks.

Systematic analysis. Our approach requires a *measurement* (e.g., `add_key` in Listing 1) and an *allocation* (e.g., `snd_ctl_file` in Listing 2) primitive. We scan the kernel code for suitable code patterns using the query language CodeQL [15], as we explain in detail in Appendices C.2 and C.3.

Many kernel execution paths in the kernel allow *measurement* primitives, as any snippet that copies user data to a dynamically allocated buffer and subsequently performs validation checks can be leveraged. This includes functions that delegate the allocation and copying process to commonly used routines like `strndup_user` and `memdup_user`. Hence, our analysis yields a measurement primitive for each generic cache from `kmalloc-8` to `kmalloc-4096` (see Table 8).

Similarly, the kernel has many execution paths that allow persistent *allocation* primitives, as any unprivileged syscall that persistently allocates an object and has a freeing counterpart that instantly releases the object can be leveraged. As a result, our analysis also yields an allocation primitive for each of these generic caches (see Tables 6 and 7).

We conduct this analysis for Linux kernel versions v5.19 and v6.2. Our results, presented in Table 8 for measurement primitives and Tables 6 and 7 for allocation primitives, underline the high applicability of our approach across versions.

Experiments. We demonstrate the feasibility and effectiveness of our approach by showcasing how to reliably trigger the recycling process of a targeted memory chunk and reclaim it during the reclaiming phase. To perform this experiment, we use a read device driver `rdd`, shown in Listing 6. The driver provides object allocation (`ALLOC`), deallocation (`FREE`), and reading of the object's contents (`READ`). Allocation and deallocation are used to allocate and release an object on a target memory chunk while reading determines if the reclamation was successful. In this experiment, we use a page table as the object that reclaimed the recycled memory chunk. To allocate a page table, we map a page without all page table levels mapped. We consider the experiment successful if we can read the page table entries from our `rdd` after the reclaiming phase since this means that the page table successfully reclaimed our target memory chunk. The experiment is considered unsuccessful if we can not trigger the recycling process for the chunk containing the target object or if the recycled page is not reclaimed as a page table.

We ran this experiment 100 times to determine the success rate, which we repeated 10 times to compute the mean

Table 1: Success rate of triggering the recycling and reclamation process for generic caches.

Generic Cache	#Pages	Success Rate		
		Idle	No CPU pinning	External noise
		%	%	%
kmalloc-8	1	99.9 ± 0.1	99.9 ± 0.1	99.6 ± 0.7
kmalloc-16	1	99.4 ± 0.6	98.9 ± 1.2	99.9 ± 0.4
kmalloc-32	1	99.4 ± 0.9	99.7 ± 0.5	99.9 ± 0.3
kmalloc-64	1	99.2 ± 1.3	99.2 ± 0.9	81.0 ± 6.4
kmalloc-96	1	99.9 ± 0.4	99.9 ± 0.1	99.8 ± 0.6
kmalloc-128	1	99.9 ± 0.4	99.8 ± 0.5	99.9 ± 0.3
kmalloc-192	1	99.9 ± 0.4	99.8 ± 0.4	99.3 ± 1.2
kmalloc-256	1	99.9 ± 0.3	99.9 ± 0.3	99.7 ± 0.7
kmalloc-512	2	90.2 ± 5.4	87.2 ± 3.1	65.2 ± 2.8
kmalloc-1024	4	88.1 ± 7.2	79.5 ± 3.3	70.3 ± 8.1
kmalloc-2048	8	83.1 ± 9.2	70.5 ± 16	57.8 ± 5.7
kmalloc-4096	8	82.1 ± 3.4	73.3 ± 19	53.8 ± 10

and standard deviation. We tested under an idle system with *CPU pinning* and two noise conditions: *no CPU pinning* and external *noise*, demonstrating our noise resilience. Our experimental setup was Ubuntu 22.04 LTS with the generic Linux kernel v6.2 for x86, where v5.19 gives similar results. We ran this on a machine with Intel i7-1260P and 48 GB RAM.

CPU pinning is the method used to fix a process to a CPU, preventing CPU migration. Since both the slab and buddy allocator maintain per-CPU lists, CPU migration may introduce noise. To examine this effect, we included both scenarios: with and without CPU pinning. To introduce external *noise*, we ran `stress-ng` concurrently with two workers for each CPU, IO, and VM, saturating approximately 100 % usage on all CPUs. This aligns with prior noise evaluation [26].

Results. Under idle, our experiments (see Table 1) show remarkable results, with a more than 99.2 % success rate for generic caches with page-size chunks, i.e., `kmalloc-8` to `kmalloc-256`. The failure scenarios are primarily due to the targeted chunk that can not be reclaimed as a page table. The results of generic caches with multiple page-sized chunks decrease with increasing size from 90.2 % to 82.1 %. This is primarily due to the failure in reclaiming the targeted page from the split chunk. The larger the original chunk, the more error-prone the reclaiming is, as seen by the lowest success rate of about 83 % for generic caches with 8 pages.

Our results demonstrate remarkable noise resilience for almost all generic caches with page-size chunks with more than 98 % for no CPU pinning and external noise. One exception is `kmalloc-64` for the noise evaluation since `stress-ng` performs frequent allocation directly following deallocation for `kmalloc-64`. Hence, it appends a memory chunk to the node partial list, which makes it confusing to reclaim the memory chunk before the actual target chunk as the target chunk. For multiple page-sized chunks, no CPU pinning decreases the success rate to 70.5 %, while external noise decreases it to 53.8 %. Crucially, despite the induced noise, our approach is still notably better than the prior success rate of 40 % with no noise [50].

5 Pivoting Kernel Heap Vulnerabilities

SLUBStick leverages a kernel heap vulnerability to gain a Memory Write Primitive (MWP). This primitive provides an adversary with a write capability to previously freed memory at a controlled time. To achieve this, SLUBStick initially obtains a dangling pointer (see Section 5.1), i.e., a pointer referencing an already freed object from a heap vulnerability. SLUBStick then establishes an MWP from this dangling pointer (see Section 5.2). Crucially, we must extend the time window between converting the dangling pointer to an MWP (i.e., before the recycling) and when it is triggered (i.e., after the reclaiming). These steps provide the adversary with an MWP that can be triggered at the desired time.

5.1 Obtaining a Dangling Pointer

In this section, we pivot DF, and UAF and OOB write vulnerabilities to obtain a dangling pointer.

Double-Free. By exploiting a DF vulnerability and freeing an object twice, we induce a situation where the pointer to an object becomes dangling. However, freeing the same object twice will cause it to reside twice in the CPU free list, corrupting this free list and causing a system crash. Hence, to leverage a DF vulnerability for obtaining a dangling pointer, SLUBStick allocates an object after its initial freeing and then utilizes the subsequent double free to create a dangling pointer pointing to this newly allocated object. Reallocating the object prevents the duplicate free list entry, avoiding free-list corruption and a subsequent system crash.

Out-Of-Bounds and Use-After-Free write. While UAFs that allow write control over dangling pointers might work, they often fall short in practice. For direct use in SLUBStick, a UAF vulnerability would need specific criteria: First, they must retain overwriting capability post-zeroing during recycling. Second, they must be triggerable after reclaiming as a page table. Third, they require the ability to overwrite specific values, i.e., malicious page-table entries. However, most UAFs [2, 19, 40, 52] provide limited write primitives and small race windows, thus failing these criteria.

Hence, SLUBStick leverages significantly weaker write capabilities offered by UAF (and OOB) vulnerabilities commonly found in practice to enforce a double free of an object. It does so by using this capability to manipulate either a *reference counter* or an *object pointer* within an object of the same cache. By corrupting these members, SLUBStick forces an object into a DF state (see **Double-Free** above).

In Linux, *reference counters* manage the lifetime of an object. At its core, the counter increases with each new reference and decreases with each release. When the counter reaches zero, all the object's resources are released. For exploitation, SLUBStick identifies a victim object within the same cache containing a reference counter located at the write capability. Using heap manipulation [6, 26, 50], it aligns this victim

```
1  int ipmi_open(void) {
2    ipmi_file_private *priv;
3    /* allocate object */
4    priv = kmalloc(sizeof(*priv));
5  }
6  long ipmi_ioctl(file *f, u64 data) {
7    ipmi_file_private *priv;
8    ipmi_timing_parms parms;
9    /* copy data from user */
10   copy_from_user(&parms, data);
11   priv->parms = parms;
12 }
```

Listing 3: Persistent code pattern 1.

```
1  u64 netlink_sendmsg(msghdr *msg, u64
       len) {
2    /* allocate object */
3    sk_buff *skb = kmalloc(len);
4    /* copy data from user */
5    copy_from_user(obj, msg, len);
6  }
```

Listing 4: Persistent code pattern 2.

```
1  u64 keyctl_pkey_verify(void *uaddr, void *
       uaddr2, u64 size, u64 size2) {
2    /* allocate and copy data from user */
3    void *in = kmalloc(size);
4    copy_from_user(in, uaddr, size);
5    /* second copy for extending time window */
6    void *in2 = kmalloc(size2);
7    copy_from_user(in2, uaddr2, size2);
8    /* free obj */
9    kfree(in2);
10   kfree(in);
11 }
```

Listing 5: Temporal code pattern.

Figure 6: Examples of code patterns allowing to be exploited as a Memory Write Primitive (MWP).

object in memory with the write capability. SLUBStick then utilizes the write capability to corrupt the counter, forcing the release of the object still in use and placing it in a DF state.

To demonstrate the applicability of this approach, we analyze the kernel for the available objects with a reference counter located at each potential 8 byte write capability. We found 873 objects with a reference counter. They cover 100 % of overwrite locations for generic caches up to `kmalloc-32` and more than 80 % for generic caches between `kmalloc-64` and `kmalloc-256`. For caches between `kmalloc-512` and `kmalloc-4096` the availability ranges from 73.4 % to 2.7 %.

Regarding *pointer* corruption, SLUBStick identifies a victim object within the same cache that contains a pointer to an object from a separate cache. SLUBStick then places the victim object to align the overwrite capability and triggers it to corrupt the pointer by zeroing out the two least significant bytes. This creates an additional reference to another object in the separate cache. When the kernel releases this object, SLUBStick obtains a dangling pointer to the other object stored in the separate cache without leaking KASLR.

The uncorrupted pointer must refer to an object in a different slab. Otherwise, the slab that now contains a double-referenced object cannot be recycled, as the object that was originally pointed to has lost its reference and cannot be freed. To ensure that the uncorrupted pointer refers to an object in a different slab, SLUBStick employs our side channel (see Section 4.1). This technique allows for detecting and preventing failure scenarios, enhancing the success rate of pivoting.

Primitive conversion. The success rate of converting a UAF (including DF) vulnerability to a dangling pointer relies on the time window between the free and use stages. Techniques like ExpRace [27] can enhance exploitability by widening the time window. Additionally, UAF and OOB write vulnerabilities require an object with a reference counter or pointer located at the write capability.

5.2 Establishing a Memory Write Primitive

In this section, we detail how SLUBStick establishes a Memory Write Primitive (MWP) from a dangling pointer, allowing an adversary to overwrite memory reclaimed for a page table (see Section 6). The main challenge is to extend the time window from converting the dangling pointer into an MWP before recycling, while triggering must be done after the reclaim as a page table. To address this challenge, we exploit three distinct code patterns prevalent in the Linux kernel, as demonstrated in our **systematic analysis**.

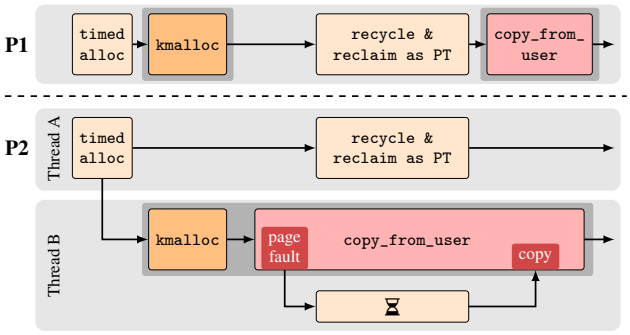


Figure 7: The execution timeline of persistent code patterns 1 (**P1**) and 2 (**P2**), where `timed alloc` performs persistent allocations combined with our timing side channel. `kmalloc` allocates the memory slot referenced by the dangling pointer. Since this slot resides on the page table after recycling and reclamation, `copy_from_user` overwrites page table entries.

Persistent code pattern 1. The pattern shown in Listing 3 grants SLUBStick an MWP with control over the timing. The process involves allocating the memory slot referred to by the dangling pointer, e.g., as an `ipmi_file_private` object at Line 4, before recycling. After reclamation, SLUBStick triggers the MWP with `ipmi_ioctl` to overwrite page table entries at Line 11. Figure 7 shows **P1** with its timeline.

While this pattern allows the MWP to be triggered arbitrarily, it has limitations as the allocated object, e.g., `ipmi_file_private`, is zeroed during recycling. If other code parts access the (unexpectedly) zeroed data, this could lead to a crash. Notably, this limitation does not affect `ipmi_file_private`, but others like `timerfd_ioctl`.

Persistent code pattern 2. The second pattern (see List-

ing 4) allows SLUBStick to trigger an MWP at a controlled time as follows: It allocates the memory slot referred to by the dangling pointer, e.g., as `sk_buff` at Line 3, before the recycling. Within the same syscall, the overwriting step at Line 5 follows after memory reclamation. To extend the time window between allocation and overwriting, SLUBStick can use techniques such as `userfaultfd`, Filesystem for USErspace (FUSE) [16], or slow page fault [20], controlling the duration of a user page fault, e.g., from of `msg` at Line 5.

While prior work [29, 40, 55] controlled the duration of copying from userspace with `userfaultfd`, recent systems restrict `userfaultfd` to privileged users for handling user page faults while in kernel mode [7]. Alternatively, researchers [16] showed that FUSE also allows control of the duration of copying from userspace. FUSE is a framework for userspace filesystems and can be utilized by an unprivileged user [16, 21]. We hence use FUSE to extend the time window between allocation and overwriting, allowing us to perform the recycling and reclaiming in between. Besides FUSE, SLUBStick can leverage the slow page fault approach [20].

We show **P2** with its execution timeline in Figure 7, where thread B's page fault starts before recycling and ends after reclaiming. The hourglass illustrates this time window extension, e.g., with FUSE. Hence, SLUBStick successfully overwrites entries in the reclaimed page table.

Temporal code pattern. Beyond persistent patterns, SLUBStick can also utilize temporal ones, as exemplified in Listing 5. This approach demands the management of two specific timing windows. The first ensures that object allocation at Line 3 and subsequent overwriting at Line 4 occur during the intended phases. The second window is crucial to avert premature object deallocation, leading to a potential failure scenario since the object is concurrently accessed as a page table. To extend these time windows, SLUBStick uses FUSE files as described for persistent pattern 2.

Systematic analysis. We use CodeQL [15] to identify suitable code patterns. We detail this approach in Appendix C.4. Our results for Linux kernel versions v5.19 and v6.2 are shown in Table 9. They indicate that persistent code pattern 1 is with 3 instances (and limited sizes) rare. For persistent code pattern 2, we identify 5 instances with sizes that cover generic caches from `kmalloc-8` to `kmalloc-4096`. A similar stands true for temporal code patterns with 7 identified. These findings underline the portability of the existing patterns.

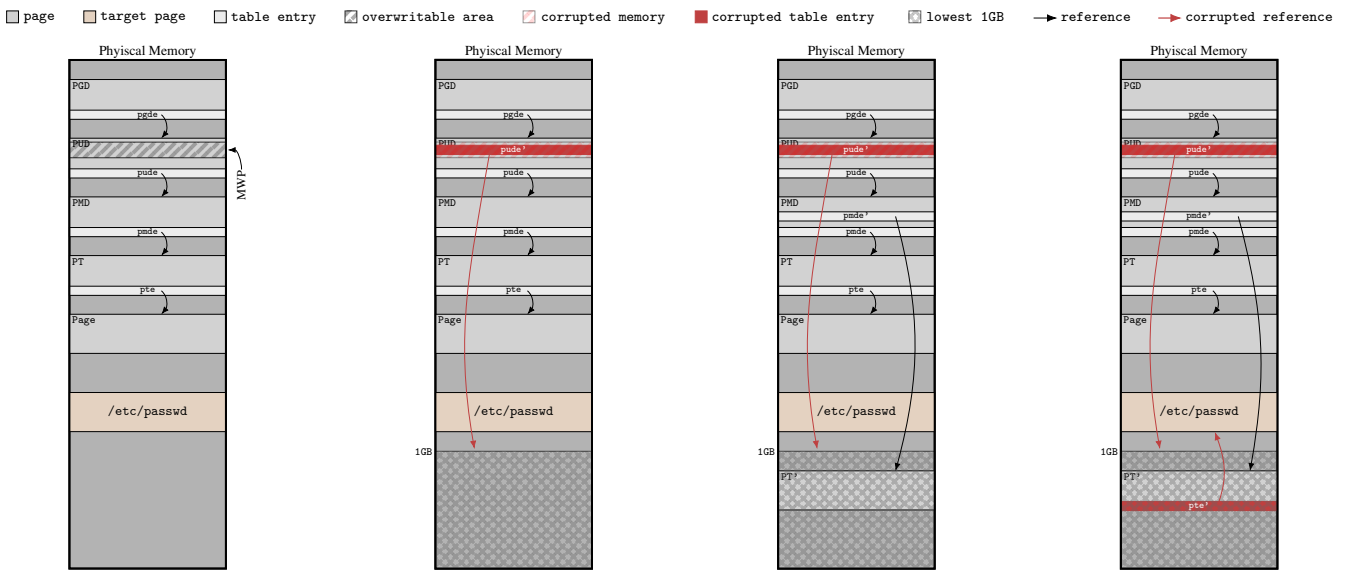
6 Arbitrary Memory Read-and-Write

This section describes the *three-stage* process to obtain an arbitrary memory read-and-write primitive by triggering an MWP once, with an example shown in Figure 8. The single triggering of the MWP is crucial since both the persistent pattern 2 and the temporal pattern only allow a single trigger.

Initially, SLUBStick starts with a mapped userspace page using a Page Upper Directory (`PUD`) for address translation, with an MWP associated with it. The goal is to corrupt the content of a targeted page. Figure 8a shows an example where the userspace page utilizes the `cr3->pgde->pude->pmde->pte->page` translation, and SLUBStick aims to corrupt the targeted page containing data of `/etc/passwd`. While `/etc/passwd` is the target in this example, any page can be targeted, including kernel code.

In the *first stage* (Figure 8b), SLUBStick utilizes the MWP to partially overwrite the `PUD` page with `pude'` entries, each comprising a page frame number of zero and set user-accessible and size bit. As a result, userspace addresses using these entries for the page-table walk (`cr3->pgde->pude'`) are granted read and write access over the first physical GB.

In the *second stage* (Figure 8c), SLUBStick maps userspace pages, prompting the kernel to map page tables. It continues this process until a page table (`PT'` in the case of Figure 8c) is mapped in the first GB of physical memory. Given SLUBStick's control over reading and writing the first GB, the content of this page table `PT'` can be modified.



In the *third stage* (Figure 8d), SLUBStick overwrites an entry in the page table `PT'` with `pte'`. This grants an arbitrary physical memory read and write, using the userspace page with the `cr3->pgde->pude->pmde'->pte'` address translation. Since `kpti` is enabled by default on Ubuntu, SLUBStick uses an invalid syscall to flush this translation from the TLBs and force a page-table walk. Other methods, such as using a TLB eviction set referring to zero pages, would also work. With this primitive, SLUBStick can locate the targeted page and tamper with its content to escalate privileges, e.g., adding a privileged user with no authentication required.

This example uses the MWP to overwrite a PUD page but can also be used to overwrite a Page Middle Directory (PMD) page. By tampering with a PMD page, SLUBStick has an access space to find `PT'` of 2 MB instead of 1 GB.

In fact, we can use our MWP to overwrite not just a single page table entry but the entire memory slot previously used by the object. For instance, the function `netlink_sendmsg` allows an adversary to overwrite `len` (see Line 5 of Listing 4) bytes of the page table page. Thus, to increase the access space after the first stage to find `PT'`, SLUBStick overwrites the page table with entries of increasing page frame number. This approach increases the access space to $\frac{\texttt{sizeof(cache)}}{8} \cdot 1\,\text{GB}$ and $\frac{\texttt{sizeof(cache)}}{8} \cdot 2\,\text{MB}$ for PUD and PMD, respectively.

Reliability of obtaining an MWP to a PMD/PUD page. In order to reliably obtain an MWP primitive to a PMD or PUD page, SLUBStick employs the following strategies.

For generic caches from `kmalloc-8` to `kmalloc-256`, SLUBStick maps a single PUD page, as explained in Section 4.2, with an MWP associating the PUD, as follows: Exploiting the LIFO approach inherent to the buddy allocator for returning recycled memory chunks, SLUBStick initiates the mapping of a user page with an unmapped PUD, PMD, and PT. This procedure guarantees the reliable reclamation of the recycled memory chunk for the PUD page.

(a) SLUBStick has an MWP to a PUD page used for a user address translation. It aims to tamper with the targeted page containing data of /etc/passwd.

(b) SLUBStick leverages the MWP to write pude' (i.e., pfn=0, size=1, and user=1) to the PUD page. As a result, user addresses using pude' now reference the first GB of the physical memory.

(c) SLUBStick maps alot of page tables, till a page table (i.e., PT') is mapped within the first GB of the physical memory.

(d) SLUBStick uses first GB mapping to tamper with the entry pte' of page table PT'. As a result, the user address using pte' now references an arbitrary page, e.g., /etc/passwd.

Figure 8: Converting an MWP to an arbitrary read-and-write primitive to find and tamper with the targeted page /etc/passwd.

Conversely, achieving an MWP to a PMD page involves another strategy. For generic caches from kmalloc-512 to kmalloc-4096, where the memory chunk size exceeds a single page, SLUBStick initially prompts the kernel to split the recycled memory chunk. To reliably reclaim the split part of the memory chunk containing the MWP, SLUBStick employs an extensive mapping strategy for PMD pages, accomplished by mapping 2 MB huge pages. This extensive mapping tactic compels the buddy allocator to predominantly allocate PMD pages, including the page associated with the MWP. There are two options for using huge pages: Transparent Huge Pages (THP) or hugetlbfs. Albeit hugetlbfs offers more stable exploitation results, these huge pages must be pre-allocated. However, due to the widely spread application of hugetlbfs [25], such as databases [38], virtualization, and even Java [18], SLUBStick utilizes hugetlbfs.

7 Attack Evaluation

In this section, we evaluate the effectiveness of SLUBStick. We initially exploit a synthetic DF vulnerability (see Section 7.1) to show its applicability across generic caches from kmalloc-8 to kmalloc-4096. We then exploit 9 CVEs (see Section 7.2), consisting of DF, UAF, and OOB vulnerabilities.

Evaluation setup. For our experimental setup, we run the exploits in a virtual machine via QEMU 6.2.0, equipped with 4 cores and 16 GB RAM. We ran Ubuntu 22.04 LTS, with Linux kernels v5.19 and v6.2 for x86, and v6.2 for aarch64, to demonstrate architecture and version independence. These kernels were the unmodified generic ones, which presents a considerable challenge for exploitation.

7.1 Synthetic Vulnerability

To evaluate SLUBStick for all generic caches, we create a synthetic DF vulnerability in the Linux kernel, integrated into a module, i.e., read device driver rdd. Its simplified code is seen in Listing 6. For the exploitation processes, we need this driver code's allocation (ALLOC) and release (FREE) functionalities. We compile and then include this driver code during the operating system's startup for our three kernels.

With the synthetic DF vulnerability in place, we execute SLUBStick on all generic caches from kmalloc-8 to kmalloc-4096. For the measurement primitive, we use add_key with the invalid argument _descr (see Section 4.1). As allocation primitive, we utilize objects retrieved via our systematic analysis (see Section 5.2). For the MWP, we accomplish the exploitation with all three types, persistent 1 and 2 as well as temporal, using do_signalfd4, replace_user_tlv, and key_ctl_key_verify, respectively. Table 2 shows all primitives used for this evaluation. Equipped with these primitives, we successfully execute SLUBStick, exploiting the DF for privilege escalation.

Table 2: Primitives used for our attack evaluation.

Generic Cache	MP	AP	MWP
kmalloc-8	add_key	signalfd_ctx	do_signalfd4
kmalloc-16	add_key	aa_revision	key_ctl_key_verfify
kmalloc-32	add_key	anon_vma_name	key_ctl_key_verfify
kmalloc-64	add_key	snd_ctl_file	key_ctl_key_verfify
kmalloc-96	add_key	vfio_container	key_ctl_key_verfify
kmalloc-128	add_key	dlm_user_proc	key_ctl_key_verfify
kmalloc-192	add_key	pp_struct	key_ctl_key_verfify
kmalloc-256	add_key	snd_compr_file	replace_user_tlv
kmalloc-512	add_key	tls_context	replace_user_tlv
kmalloc-1024	add_key	pipe_buffer	replace_user_tlv
kmalloc-2048	add_key	key.description	replace_user_tlv
kmalloc-4096	add_key	net_device	replace_user_tlv

MP: Measurement Primitive **AP**: Allocation Primitive **MWP**: Memory Write Primitive.

Table 3: Exploitability shown on real-world vulnerabilities.

CVE	Capability	Cache
CVE-2023-21400	DF	kmalloc-32
CVE-2023-3609	UAF	kmalloc-96
CVE-2022-32250	UAF	kmalloc-64
CVE-2022-29582	UAF	files_cachep
CVE-2022-27666	OOB	kmalloc-4096
CVE-2022-2588	DF	kmalloc-192
CVE-2022-0995	OOB	kmalloc-96
CVE-2021-4157	OOB	kmalloc-64
CVE-2021-3492	DF	kmalloc-4096

7.2 Real-World Vulnerabilities

In line with prior research [6,29,46,49,53], we evaluate SLUBStick with a selection of real-world vulnerabilities. We port these vulnerabilities to our kernels to demonstrate the version, architecture, and kernel binary independence of SLUBStick. Our evaluation includes 9 vulnerabilities that are systematically classified based on the capability they provide. If the root cause of a vulnerability is a race condition that allows an adversary to derive a kernel heap vulnerability, we classify it as a heap vulnerability. For instance, since both race conditions, CVE-2023-21400 and CVE-2022-29582, can be pivoted to a UAF and DF, respectively, we classify them as a UAF and DF. In total, our selection consists of 3 DF vulnerabilities that enable SLUBStick directly, as well as 3 OOB and 3 UAF that we pivot to achieve a DF state.

The feasibility of pivoting an OOB and UAF depends on the write capability provided. We demonstrate with our results that the capability to overwrite as low as two bytes is enough to pivot to a DF state. Examples include corrupting a reference counter (as seen in CVE-2022-29582 and CVE-2023-3609) or nullifying the two least significant bytes of a pointer (like in CVE-2022-27666). For pivoting, SLUBStick requires an exploitable object containing a data pointer or reference counter at the overwrite point. The purely manual identification of suitable objects is time-consuming due to the extensive nature of the Linux kernel. For this reason, we utilize CodeQL to assist in identifying suitable objects for OOB and UAF write vulnerabilities, described in Appendix C.1.

Exploitability results. Table 3 shows the exploitability of SLUBStick, showcasing its functionality across kernel heap vulnerabilities and cache sizes. Specifically, we can free objects twice for the CVE2023-21400, CVE-2022-2588, and CVE-2021-3492 vulnerabilities, allowing SLUBStick to exploit these vulnerabilities and directly escalate privileges.

Additionally, the CVE-2022-0995 vulnerability allows overwriting out-of-bounds originating from the `watch_queue` object. We exploit this write capability to corrupt the reference counter of an `anon_vma_name` object, both located within the same generic cache, i.e., `kmalloc-96`. With the corrupted reference, we create a DF state of an `anon_vma_name` object, which enables the execution of SLUBStick. For CVE-2022-27666, the OOB allows overwriting memory adjacent to the `page_frag` object (allocated from generic cache `kmalloc-4096`). We perform a cross-cache overflow to zero the `next` pointer's two least significant bytes of a `msg_msg` object positioned on the adjacent memory chunk. This allows us to free the `next` twice so we can execute SLUBStick. As a third OOB write vulnerability, CVE-2021-4157, we exploit the overwriting capability within `kmalloc-64` to tamper with the reference counter `kref` of an `eventfd_ctx` object. As a result, we can pivot this to a DF and perform SLUBStick.

Furthermore, the CVE-2022-29582 vulnerability allows a `file` UAF, specifically using the `file` object after it has been invalidly freed. By strategically pivoting this vulnerability using cross-cache, we can reclaim the memory chunk for the generic cache `kmalloc-256`. Subsequently, we reclaim the invalidly freed `file` object to corrupt its reference counter. This allows us to free the `file` a second time, creating a DF state to run SLUBStick. Similarly, CVE-2023-3609 allows to use a `tc_u_hnode` object after it has been freed. Reclaiming the memory within the same generic cache and overwriting the reference counter, we pivot this vulnerability to a DF state of `tc_u_hnode` to perform SLUBStick. Lastly, the CVE-2022-32250 vulnerability provides a write capability within the generic cache `kmalloc-64`, which we use to corrupt a data pointer within `fdtable` for a DF state.

8 Discussion

Impact on existing attacks. Our side-channel supported approach presented in Section 4 greatly enhances the reliability of cross-cache attacks from generic caches and makes them practical for exploitation. Thus, it amplifies the effectiveness of exploitation methods employing cross-cache attacks.

For instance, DirtyCred [29] relies on the cross-cache approach to exploit DF vulnerabilities. This exploitation entails pivoting DF vulnerabilities to trigger an invalid free on a credential object. With our enhancement of the cross-cache attack, DirtyCred's success rate in pivoting DF vulnerabilities from generic caches also significantly increases, making DirtyCred an even more significant threat to kernel security.

Moreover, SLUBStick is more versatile than DirtyCred

as it does not rely on an invalid free on a credential object. Instead, an invalid free operation on any object is sufficient.

Container escape. In addition to privilege escalation, our research demonstrates that SLUBStick can directly enable container escapes such as Docker. For containers permitting FUSE, SLUBStick uses FUSE to extend the time window in persistent code pattern 2 and the temporal pattern. For (hardened) containers prohibiting FUSE, SLUBStick uses persistent code pattern 1 or the slow page fault approach [20] instead of FUSE. It then modifies kernel code accessible from userspace via a syscall, i.e., `sys_setresuid`.

Noise. With SLUBStick, we present a reliable approach for privilege escalation, leveraging a software timing side channel on the SLUB's object allocation. To maximize the reliability of SLUBStick, we minimize noise as follows:

CPU migration, the process of moving a task to another CPU, can introduce instabilities as both the slab and buddy allocator maintain per-CPU lists. To mitigate migration and, hence, increase reliability, SLUBStick may pin all running processes used in exploitation to a single CPU. However, it is not essential as illustrated in Table 1.

Due to the preemptive nature of the Linux kernel, preemption may occur during the timing measurement of a measurement primitive, potentially corrupting the result. To limit this noise source, SLUBStick performs timing measurements and keeps track of the number of objects associated with the current slab. If SLUBStick observes slow timing, indicating the allocation of a new memory chunk, it validates this by checking the object number of the current slab. This validation prevents misinterpretation of slow allocations, ensuring that previous and current objects reside in the same slab.

Manual vs automated components. We use the CodeQL [15] static analyzer to generate a list of possible objects or primitives automatically. Through manual inspection, we then refine this list by selecting suitable candidates. To provide a representation of the effectiveness of our automated part, our evaluated kernel contains 66787 structures, where our automated tool outputs 8601 potential as allocation and memory write primitives. After manual inspection, we get 36 suitable structures for allocation primitives. For memory write primitives, the tool outputs 2046 copy locations, where manual inspection yields 15 memory write primitives. For measurement primitives, the tool outputs 195 primitives, with 14 after inspection. Tables 6 to 9 show our findings. Further details on this process are provided in Appendix C.

Cross version/architecture dependencies. Kernel exploitation often depends on the specific kernel version and system architecture, as various exploitation techniques are closely tied to these factors. For example, KASLR is bypassed either with a read primitive [5] or a hardware side channel [3]. Read primitives are closely tied to specific kernel versions and configurations, while hardware side channels depend on the system architecture. Additionally, numerous exploits rely on constructing ROP chains [48,54], which involves a detailed inspection of the kernel binary, a process connected with system architecture, Linux kernel version, and configuration. SLUBStick distinguishes itself by not relying on bypassing KASLR or constructing a ROP chain, nor does it use architecture-specific data. As a result, SLUBStick is resilient to variations in kernel versions and architecture dependencies.

Kernel defenses. The last decade has seen a surge of proposals to improve kernel security. We briefly discuss the defenses, particularly considering SLUBStick.

KASLR is designed to enhance kernel security by randomizing the memory layout, making it more challenging to exploit vulnerabilities to perform Code Reuse Attacks (CRA) and data-only attacks. To further complicate CRA, researchers have introduced Control-Flow Integrity (CFI) [1], which has been adapted to kernel software [10, 14, 32, 45]. CFI helps ensure the integrity of the kernel control flow by restricting it to an approximated control-flow graph. Moreover, the Linux kernel has incorporated various hardening strategies to make the allocator more resistant to memory corruption vulnerabilities. These include slab list randomization, protection of slab meta-data, and slab quarantine [39]. However, researchers have identified bypassing attacks [26, 39, 53] for these hardening strategies. Additionally, heap separation is a defense integrated into the Linux kernel to separate caches containing security-critical data, e.g., `cred`, or objects often used for exploitation [29, 40, 55], e.g., `msg_msg`. To further enhance the separation of kernel objects, researchers [9] have proposed to increase the separation granularity. This involves randomly assigning each allocation site to one of these separated caches, making heap spraying attacks more challenging. However, SLUBStick leverages common code patterns, allowing it to circumvent the separation attempt of generic caches. Going a step further, our timing side channel on the allocator can even be utilized to determine whether two allocation sites share the same cache. In summary, the described countermeasures, while valuable, appear ineffective in mitigating SLUBStick.

AUTOSLAB [28] is a defense provided by grsecurity via paid subscription. Since AUTOSLAB separates allocator caches based on their allocation types, it restricts that different allocation types share the same allocation cache. However, this granularity is still too coarse-grained, as, e.g., the type `char *` is used by multiple allocation, measurement, and memory write primitives. As a result, the allocation cache with type `char *` is still exploitable with SLUBStick.

SLAB_VIRTUAL [42], which is currently under development, is designed to mitigate cross-cache attacks by allocating kernel objects via virtual addresses rather than direct physical memory. However, Torvalds and Molnar noted that it has drawbacks like significant overhead and incompatibility with DMA [42]. If merged, DMA-allocated memory will most likely be excluded [42]. This leaves more than 350 allocation sites unprotected, exploitable to obtain all necessary code patterns (allocation, measurement, and memory write primitives, such as `sun8i_ce_aes_setkey`, `monwrite_new_hdr`,

and `sti_hqvdp_vtg_cb`). Hence, SLUBStick can exploit a vulnerability, e.g., CVE-2023-2194, of a DMA-allocated object. Since DMA-allocated memory is mainly used in drivers, known to be vulnerable [34], SLUBStick still poses a threat.

Lastly, prior academic works [11, 33, 41, 44] proposed defenses to protect page tables to mitigate data-only attacks.

While existing defenses such as AUTOSLAB and SLAB_VIRTUAL demonstrate promise in mitigating SLUBStick, none provide comprehensive protection. This underscores the threat SLUBStick poses to kernel security.

Public exploits. Recently, multiple non-academic exploits have been proposed [2, 12, 13, 17, 19, 30, 47, 52]. Some [2, 17, 19, 47] leverage cross-cache attacks using the dedicated `file` cache. In contrast, we focused on generic caches, which are considerably more challenging to exploit. This is primarily because generic caches have numerous allocation sites, resulting in significant allocation noise. Specifically, while the dedicated `file` cache has one allocation site (`dup_f`), generic caches have from 354 (`kmalloc-4096`) to 2250 (`kmalloc-64`) on systems like our evaluated Ubuntu. Hence, we proposed our side-channel supported approach to perform cross-cache attacks on generic caches reliably.

Two exploits, bad io_uring [30] and the exploit demonstrated by Wu et al. [47], highlight the exploitation of cross-cache attacks on older kernel versions (i.e., v5.10), targeting Android devices. Bad io_uring leverages a cross-cache attack to misuse `pipe_buffer` as an arbitrary read and write. Wu et al. (concurrently to our work) demonstrated page-table manipulation by misusing `signalfd_ctx`. Both exploits rely on stabilization objects in conjunction with multiple retriggers of cross-cache reuse. Specifically, bad io_uring utilized additional `pipe_buffer` objects for stabilization, while Wu et al. relied on `seq_operations`. However, kernel advances beyond v5.14 introduced heap separation (i.e., `kmalloc-cg-*`), rendering the reuse of these stabilization objects ineffective for exploitation. Consequently, these exploitation strategies are thwarted by newer kernel versions. In contrast, SLUBStick exploits more recent systems, including v5.19 and v6.2, for a wide variety of heap vulnerabilities.

9 Conclusion

This paper presented SLUBStick, a novel kernel exploit technique that enables arbitrary memory read-and-write primitives through a practical software cross-cache attack. For our cross-cache attack, we used a software timing side channel on the SLUB allocator, significantly enhancing the success rate for frequently used generic caches to over 99 %. Moreover, using page-table manipulation, SLUBStick effectively converts a limited kernel heap vulnerability into arbitrary read-and-write capabilities. We demonstrated privilege escalation in the Linux kernel using a synthetic vulnerability and 9 real-world CVEs, showcasing its serious threat.

Table 4: Detailed information of each generic cache, where ✶ denotes the number of slabs until the node partial slab list is full, prompting to discard the slabs' memory chunks.

Generic Cache	Memory Chunk	Number of Pages	Number of Objects	Node Partial Slab List Capacity✶
kmalloc-8	4096	1	512	6
kmalloc-16	4096	1	256	6
kmalloc-32	4096	1	128	6
kmalloc-64	4096	1	64	8
kmalloc-96	4096	1	42	12
kmalloc-128	4096	1	32	8
kmalloc-192	4096	1	21	12
kmalloc-256	4096	1	16	7
kmalloc-512	8192	2	16	6
kmalloc-1024	16384	4	16	6
kmalloc-2048	32768	8	16	6
kmalloc-4096	32768	8	8	6

A Generic Cache Information

To trigger the recycling process reliably, we provide insights (see Table 4) into how a generic cache manages memory chunks and stores available objects. Generic caches from `kmalloc-8` to `kmalloc-256` use one page per slab, with the slab storing 512 to 16 objects per memory chunk. Caches larger than `kmalloc-256` use multiple pages per slab, storing between 16 and 8 objects per chunk. The **Node Partial Slab List Capacity** column indicates when the SLUB allocator releases the chunks of the slabs, e.g., for `kmalloc-256`, if this cache reaches 6 free slabs, the SLUB allocator prompts the buddy allocator to discard and recycle the slab's chunks.

Table 5: Measured timing in timestamps for fast ① and slow ⑤ allocation (see Figure 2) using the measurement primitive `add_key` with an invalid `_descr` argument.

Generic Cache	Fast Allocation ①	Slow Allocation ⑤
kmalloc-8	1086 ± 53	> 4401
kmalloc-16	1114 ± 69	> 3224
kmalloc-32	1133 ± 58	> 2510
kmalloc-64	1130 ± 69	> 2468
kmalloc-96	1117 ± 44	> 2169
kmalloc-128	1250 ± 126	> 2470
kmalloc-192	1197 ± 86	> 2121
kmalloc-256	1359 ± 34	> 2439
kmalloc-512	1685 ± 84	> 3759
kmalloc-1024	1601 ± 30	> 3589
kmalloc-2048	1561 ± 23	> 3415
kmalloc-4096	1925 ± 33	> 3758

```c
typedef struct { size_t uaddr, size; } msg_t;
void *obj;
long rd_ioctl(struct file *_, unsigned num, size_t param) {
  msg_t msg;
  copy_from_user(&msg, param, sizeof(msg_t));
  switch (num) {
    case ALLOC:
      obj = kmalloc(msg->size);
      return 0;
    case FREE:
      kfree(obj);
      return 0;
    case READ:
      copy_to_user(msg->uaddr, obj, msg->size);
      return 0;
    default:
      return -1;
  }
}
```

Listing 6: Read device driver `rdd`, supporting an allocation (`ALLOC`), deallocation (`FREE`), and read (`READ`).

B Timings of Measurement Primitives

We perform experiments to verify that the slow allocation time ⑤ is higher than the fast allocation time ① (see Figure 2). We use `add_key` as the measurement primitive with an invalid `_descr` argument to fulfill the constraints described in Section 4.1, while others (e.g., `mount` with an invalid `dev_name` address) yield similar results. Our experimental environment is Ubuntu 22.04 LTS with a Linux kernel v6.2, running on a machine with Intel i7-1260P and 48 GB RAM. We allocate 16384 objects as a warm-up to ensure that the measured timing of the subsequent allocations is either from the CPU free list ① or from a new memory chunk using the buddy allocator ⑤. We then perform 4096 allocations and distinguish them between **Fast** and **Slow Allocation**. As shown in Table 5, the results demonstrate a notable timing difference between these allocation paths, with an average fast allocation from 1086 to 1925 timestamps and a minimum slow allocation from 4401 to 3758.

Table 6: Allocation primitives allocating a single fixed-size object during the syscall, with ✶ new objects identified.

Generic Cache	Object	Constraints

C Systematic Analysis Detailed

In this section, we present our systematic analysis in more detail. Our principal approach is first to identify a list of possible objects or primitives using the CodeQL [15] static analyzer. We then use these results to manually identify suitable results or discard those results that violate the constraints of the respective primitive. For each primitive, our systematic analysis results in a comprehensive list of suitable objects and functions, demonstrating the effectiveness of our approach.

CodeQL aims to find code patterns that cause vulnerabilities in software. At its core, it creates a database where essential meta-information about the examined software is stored. With this database, CodeQL uses queries as input to analyze the software and interpret the query results. We retrofit CodeQL to find allocation and measurement primitives (see Section 4.1). We also use CodeQL to find suitable victim objects for UAF and OOB write vulnerabilities (see Section 5.1) and suitable code patterns to exploit for an MWP

Table 8: Measurement primitives, where ✶ denotes allocation via the separated `kmalloc-cg-*` caches and ☆ denotes depending allocation size whether `msg_msg`/`msg_msgseg` is allocated.

C.1 Finding Suitable Objects to Pivot UAF and OOB Writes

To find suitable objects for pivoting UAF and OOB vulnerabilities with an overwriting capability, we need a victim object with a pointer to a dynamically allocated object or a reference counter at the location of the overwriting location. In the example of CVE-2022-32250, the UAF write vulnerability provides overwriting at offset 0x18 for objects allocated from the generic cache `kmalloc-64`. With these constraints, we use a CodeQL query to help find dynamically allocated objects with either a pointer or reference counter at an offset of 0x18. We find the `fdtable` object that satisfies these constraints with the pointer `open_fds` at an offset 0x18.

Our query takes the overwrite offset and object size as input and returns all matching objects available in the Linux kernel with default kernel configurations. From these possible objects, we manually identify a suitable object accessible from userspace as an unprivileged user, e.g., the `fdtable` for the CVE-2022-32250 vulnerability.

C.2 Finding Allocation Primitives

For allocation primitives, our CodeQL query identifies every persistent object allocation code location grouped by object size. From this list, we manually filter out those inaccessible from userspace as unprivileged users. The result is a list of fixed and variable-size objects, shown in Tables 6 and 7.

C.3 Finding Measurement Primitives

For measurement primitives, any code snippet that copies user data into a dynamically allocated buffer and then performs validation checks can be leveraged. This includes kernel functions that use `strndup_user`, `memdup_user` and `memdup_user_nul`. Therefore, we use a CodeQl query to obtain all the code locations where these functions are called. Next, we manually validate, e.g., by running test programs to execute the syscall that executes the function found, that these code locations are accessible from userspace as an unprivileged user. In the example of the `add_key` syscall, we execute this syscall with a `_desc` where the first byte is a `'.'`. All other conditions with additional information to execute the measuring primitives can be found in Table 8.

C.4 Finding Memory Write Primitives

For memory write primitives, our queries obtained all code locations that execute `copy_from_user`. With all these locations, we search for our three distinct code patterns, i.e., persistent code patterns 1 and 2, and temporal code patterns. We then filter out those that violate constraints, e.g., `timed_alloc` shown in Listing 2. As a result, we obtain functions that can be used as MWP, shown in Table 9.

Detecting Kernel Memory Bugs through Inconsistent Memory Management Intention Inferences

Abstract

Modern operating system kernels, typically written in low-level languages such as C and C++, are tasked with managing extensive memory resources. Memory-related errors, such as memory leak and memory corruption, are common occurrences and constantly introduced. Traditional detection methods often rely on taint analysis, which suffer from scalability issues (i.e., path explosion) when applied to complex OS kernels. Recent research has pivoted towards leveraging techniques like function pairing or similarity analysis to overcome this challenge. These approaches identify memory errors by referencing code that is either frequently used or semantically similar. However, these techniques have limitations when applied to customized code, which may lack a sufficient corpus of code snippets to facilitate effective function pairing or similarity analysis. This deficiency hinders their applicability in kernel analysis where unique or proprietary code is prevalent.

In this paper, we propose a novel methodology for detecting memory bugs based on inconsistent memory management intentions (`IMMI`). Our insight is that many memory bugs, despite their varied manifestations, stem from a common underlying issue: the ambiguity in ownership and lifecycle management of memory objects, especially when these objects are passed across various functions. Memory bugs emerge when the memory management strategies of the caller and callee functions misalign for a given memory object. `IMMI` aims to model and clarify these inconsistent intentions, thereby mitigating the prevalence of such bugs. Our methodology offers two primary advantages over existing techniques: (1) It utilizes a fine-grained memory management model that obviates the need for extensive data-flow tracking, and (2) it does not rely on similarity analysis or the identification of function pairs, making it highly effective in the context of customized code. To enhance the capabilities of `IMMI`, we have integrated a large language model (LLM) to assist in the interpretation of implicit kernel resource management mechanisms. We have implemented `IMMI` and evaluated it against the Linux kernel. `IMMI` effectively found 80 new memory bugs (including 23 memory corruptions and 57 memory leaks) with 35% false discovery rate. Most of them are missed by the state-of-the-art memory bug detection tools.

Shouling Ji and Qinming He are the co-corresponding authors.

1 Introduction

The operating system (OS) kernel constitutes a foundational component of modern computing systems, serving as the critical intermediary between hardware and user-level applications. Within the kernel, memory resources are ubiquitously employed to maintain data structures, manage I/O buffers, and facilitate inter-process communication, thereby highlighting their essentiality in kernel functionality. However, the complexity inherent in memory management introduces a multitude of memory-related bugs such as memory leaks, use-after-free (UAF), and double-free. These defects not only compromise system stability and performance by leading to resource exhaustion and unpredictable behavior, but also pose severe security threats. Exploitation of such vulnerabilities can result in unauthorized access, privilege escalation, and ultimately, system compromise [21, 35, 37, 39]. Given the universality of memory objects in the kernel space and the potential for widespread harm, it is imperative to address these memory bugs with rigorous and systematic approaches.

The most direct way to detect the aforementioned memory bugs is to statically track the data-flows of memory objects, which is commonly employed in the analysis of user-space applications [4, 7, 38, 42]. For instance, a memory leak is identified when a memory object remains unreleased upon program termination, whereas use-after-free (UAF) or double-free bugs arise when a memory object is accessed or deallocated subsequent to its initial release without any intervening reinitialization. However, the application of such a straightforward approach to OS kernels is impeded by significant scalability challenges. The vast codebase (e.g., the latest Linux kernel comprises approximately 28 million source code lines) introduces an overwhelming number of execution paths,

culminating in path and state explosion problems.

To mitigate this issue, practical kernel analysis tools instead utilize *function pairs* for memory bug detection [2, 16, 17, 34]. Specifically, OS kernels commonly use abundant memory management (MM) functions (e.g., `kmalloc` and `kfree`) to orchestrate the lifecycle of dynamically allocated memory objects. These MM functions are intended to operate in concert, reflecting the allocation and subsequent deallocation stages inherent to the lifecycle of memory objects. Tools like K-Meld [9] and Hector [26] identify memory leaks by scrutinizing the absence of the corresponding deallocation functions in these pairs. SinkFinder [3] and NLP_EYE [30] leverage MM functions to simplify the data-flow analysis in memory corruption detection. HERO [34] is specifically tailored to identify bugs that emerge from the improper sequencing of function pair usage. Some tools, on the other hand, employ similarity analysis to address the scalability challenges in kernel analysis. For example, IPPO [15] and NDI [46] detect memory bugs by identifying inconsistent memory operations across program paths that are semantically analogous.

These approaches have demonstrated their effectiveness in identifying memory bugs within OS kernels. However, they still suffer from several limitations. Firstly, there is an inherent assumption that the implementation of function pairs is intrinsically correct. This presumption does not always hold true within the complex landscape of OS kernels. In instances where a function pair harbors internal defects, such as a deallocation function failing to fully relinquish the memory resources allocated by its counterpart, the presence of a bug persists despite the ostensibly correct usage of the function pairs. Secondly, these approaches heavily rely on the availability of existing *correct* code snippets to facilitate effective MM function pairing or to perform similarity analysis. Tools such as HERO [34] and ErrDoc [29] identify function pairs within error handling paths by examining commonly paired functions. Similarly, IPPO [15], NDI [46], MLEE [31], and Hector [26] require at least one intra-procedural path that includes the anticipated memory release operation for accurate bug detection. Given the extensive amount of specialized code in OS kernels, many function pairs or code paths are unique, lacking appropriate or analogous references for comparison.

Existing research indicates that memory bugs frequently manifest within error handling paths [11, 12, 18, 29, 34, 44], where programs attempt to release previously allocated memory resources to revert to prior states. Ideally, there should be a consensus among all functions involved regarding the responsibility for deallocating a memory object upon a particular failure. Our key observation is that a multitude of memory bugs, despite their diverse symptoms, originate from a fundamental issue: the lack of clarity in ownership and lifecycle management of memory objects when premature release is necessitated. This is particularly problematic when memory objects are shared across multiple functions. For instance, if both caller and callee functions presume responsibility for managing a memory object during error handling, a double-free or UAF could happen, ultimately resulting in a memory corruption. Conversely, if neither assumes this responsibility, the memory remains occupied, leading to a memory leak. In essence, there exists *inconsistent intentions* regarding the management of memory objects.

Based on this insight, we introduce Inconsistent Memory Management Intentions (`IMMI`) as a heuristic for memory bug detection. We present an object-based method, augmented by Large Language Models (LLMs), to deduce MM intentions. The co-analysis leverages both the logical structure of the program and the natural language elements embedded within the code (e.g., code comments and implicit MM mechanisms). This enables precise inference of MM intentions within kernel-space at a fine granularity. Additionally, we propose several code slicing and summarization techniques to balance the precision and efficiency of `IMMI`. `IMMI` offers several distinct advantages over existing methods. Firstly, `IMMI`'s inference of MM intentions requires the analysis of only a limited set of code paths and call traces, thereby obviating the need for extensive data-flow analysis across the kernel. Secondly, `IMMI` operates independently of frequently used or semantically similar code snippets, thus maintaining efficacy in analyzing customized code. Additionally, `IMMI` does not rely on function pairs to identify bugs, avoiding the constraints associated with such methods.

We implement `IMMI` based on LLVM and apply it to the Linux kernel. Remarkably, `IMMI` completes its analysis of the entire kernel within 35 minutes, demonstrating its efficiency and scalability. As of the submission of this paper, `IMMI` has identified 80 new bugs, including 57 memory leak bugs, 6 UAF bugs, 16 double-free bugs and 1 null-pointer-dereference bug. Most of them have been confirmed or fixed by community maintainers with our patches. `IMMI` exhibits a false discovery rate of 35%. The incorporation of LLM effectively eliminates 43% false positives reported by `IMMI`, while only incurring an additional 4% in false negatives. We plan to open-source `IMMI` to facilitate bug detection in more projects. In summary, we make the following contributions.

- **A new approach for memory bug detection.** We introduce `IMMI`, a heuristic-based method that identifies memory bugs by analyzing inconsistencies in MM intentions. Compared to existing approaches, `IMMI` does not require long-term data-flow tracking, or frequently used or similar code snippets, thus is effective in analyzing customized code.

- **New techniques for MM intention inference.** We propose multiple techniques in implementing `IMMI`. Firstly, we propose an object-based analysis framework designed to infer MM intentions with fine granularity. Secondly, we introduce an object-based slicing methodology and a novel demand-driven function summarization technique, to enhance the efficacy of our analysis. Thirdly, we incorporate

```c
/* net/smc/smc_er.c */
int smc_wr_alloc_link_mem(struct smc_link *link)
{
    link->wr_tx_bufs = kcalloc(...);
    if (!link->wr_tx_bufs)
        goto no_mem;
    link->wr_rx_bufs = kcalloc(...);
    if (!link->wr_rx_bufs)
        goto no_mem_wr_tx_bufs;
    link->wr_tx_ibs = kcalloc(...);
    if (!link->wr_tx_ibs)
        goto no_mem_wr_rx_bufs;
    ...
    return 0;
    ...
no_mem_wr_rx_bufs:
    kfree(link->wr_rx_bufs);
no_mem_wr_tx_bufs:
    kfree(link->wr_tx_bufs);
no_mem:
    return -ENOMEM;
}
```

Figure 1: Example of callee-based management.

LLM into our framework to augment the capabilities of IMMI significantly.

- **New bugs in real-world OS kernel.** We have found 80 new memory bugs in the widely-used Linux kernel with the help of IMMI. We have reported these bugs, and most of them have been confirmed or fixed by working with the community maintainers. This results substantiate the efficacy of IMMI as a tool for enhancing OS kernel security.

2 Background and Study

2.1 MM Strategies of OS Kernels

OS kernels are responsible for managing substantial memory resources. In the event of an error, it is imperative for kernel functions to perform cleanup operations, reverting the system to its pre-error state (i.e., *error handling*). Through an extensive examination of the Linux kernel code, we have identified two primary categories of error-induced memory management strategies: callee-based management and caller-based management.

Callee-based management. Figure 1 shows a typical example of callee-based management in the Linux kernel. Specifically, `smc_wr_alloc_link_mem` is responsible for allocating multiple dynamic memory objects by calling `kzalloc`. In the event of an allocation failure, the function employs a structured jump to designated labels, ensuring the comprehensive deallocation of all previously allocated memory. Consequently, its caller can safely assume that, in the event of a failure in `smc_wr_alloc_link_mem`, no partial allocations remain. This eliminates the necessity for the caller to perform additional cleanup, allowing it to concentrate solely on the resources allocated prior to the call.

Caller-based management. Contrary to callee-based management, certain paradigms shift the onus of resource deallocation to the callers, as illustrated in Figure 2. In this example, `tm6000_alloc_urb_buffers` also allocates multiple memory resources using `kmalloc_array`. However, should an error transpire, it merely returns an error code without performing any cleanup. As a result, the onus falls upon the caller (`tm6000_prepare_isoc` in this example) to execute the appropriate release function (`tm6000_free_urb_buffers`) to free the allocated memory when `tm6000_alloc_urb_buffers` fails. While this approach may simplify the function's control flows by reducing the complexity of jump labels, it concurrently burdens the callers with augmented resource management duties.

```c
/* drivers/media/usb/tm6000/tm6000-video.c */
static int tm6000_alloc_urb_buffers(struct tm6000_core *dev)
{
    ...
    dev->urb_buffer = kmalloc_array(...);
    if (!dev->urb_buffer)
        return -ENOMEM;

    dev->urb_dma = kmalloc_array(...);
    if (!dev->urb_dma)
        return -ENOMEM;
    ...
    if (!dev->urb_buffer[i]) {
        tm6000_err("unable to allocate ... buffer %i\n",
                dev->urb_size, i);
        return -ENOMEM;
    }
    ...
    return 0;
}

static int tm6000_prepare_isoc(struct tm6000_core *dev)
{
    ...
    if (tm6000_alloc_urb_buffers(dev) < 0) {
        tm6000_err("cannot allocate memory for urb buffers\n");

        /* call free, as some buffers might have been allocated */
        tm6000_free_urb_buffers(dev);
        ...
        return -ENOMEM;
    }
    ...
}
```

Figure 2: Example of caller-based management.

2.2 Impact of Inconsisitent MM Intentions

Both MM strategies are extensively employed to facilitate comprehensive error handling. Nevertheless, when disparate functions exhibit inconsistent MM intentions for a particular memory object, the potential for memory bugs increases.

Memory corruption. When a callee function employs callee-based management while its caller adopts caller-based management, there exists a potential for a memory object to be accessed and subsequently deallocated following its initial release. Such scenarios frequently precipitate UAF or double-free vulnerabilities, which can lead to system crashes. Furthermore, these forms of memory corruption can be exploited to orchestrate sophisticated attacks, ultimately compromising the integrity of the system and allowing adversaries to seize control [6, 21].

Memory leak. Contrary to previous scenarios, another inconsistency arises when a callee function utilizes caller-based management while its caller adopts callee-based management. This inconsistency can result in a memory object being neglected, potentially culminating in a memory leak. Such leaks are deemed security critical within OS kernels, as they may precipitate denial-of-service (DoS) attacks, thereby rendering the entire system inoperative [9, 31].

2.3 Causes of Inconsisitent MM Intentions

In this section, we summarize three main causes of inconsistent MM intentions based on our empirical analysis of the Linux kernel and corresponding patches.

Complex logic in error handling. One of the predominant factors contributing to MM inconsistencies is the intricate error handling logic, which is known to be error-prone. A single kernel function may be responsible for managing multiple memory resources, each necessitating distinct MM strategies. Additionally, the complexity is exacerbated by the widespread sharing and transfer of memory resources among different modules and layers of abstraction. Such interactions necessitate collaboration among developers with disparate coding practices on managing the same memory objects, potentially resulting in discrepancies in the understanding and implementation of MM strategies.

Imperfect code updating. The OS kernel is a dynamic entity, subject to continuous evolution through frequent updates, with a multitude of patches being integrated regularly. These updates often originate from a diverse group of developers, including those who may not have been involved in the original development or maintenance of the codebase (e.g., security analysts who provide bug fixing patches). Contributors who lack a deep understanding of the existing code logic may inadvertently make assumptions about MM strategies that diverge from the intended design, thereby introducing potential vulnerabilities into the system.

Implicit OS MM mechanisms. Modern OS kernels have developed advanced MM mechanisms to simplify resource management for kernel developers. For instance, the Linux kernel employs reference counting, indirect calls, and compiler-assisted techniques to facilitate *automated memory resource management*, thereby obviating the need for explicit resource release operations. When memory resources governed by these mechanisms are intermingled with conventional resources, or when transitioning resources to these mechanisms, the potential for developer error escalates significantly.

2.4 Motivation of IMMI

Figure 3 illustrates a memory leak bug identified by IMMI in the Linux kernel. In this example, the memory object `qdev->lrg_buf` (line 5) allocated in `ql_alloc_buffer_queues` is not released, leading to a

```
1  /* drivers/net/ethernet/qlogic/qla3xxx.c */
2  static int ql_alloc_buffer_queues(struct ql3_adapter *qdev)
3  {
4      ...
5      qdev->lrg_buf = kmalloc_array(...);
6      if (qdev->lrg_buf == NULL)
7          return -ENOMEM;
8      ...
9      if (qdev->lrg_buf_q_alloc_virt_addr == NULL) {
10         netdev_err(qdev->ndev, "lBufQ failed\n");
11         return -ENOMEM;
12     }
13     ...
14     return 0;
15 }
16
17 static int ql_alloc_mem_resources(struct ql3_adapter *qdev)
18 {
19     ...
20     if (ql_alloc_net_req_rsp_queues(qdev) != 0) {
21         netdev_err(qdev->ndev, ...);
22         goto err_req_rsp;
23     }
24
25     if (ql_alloc_buffer_queues(qdev) != 0) {
26         netdev_err(qdev->ndev, ...);
27         goto err_buffer_queues;
28     }
29
30     if (ql_alloc_small_buffers(qdev) != 0) {
31         netdev_err(qdev->ndev, ...);
32         goto err_small_buffers;
33     }
34     ...
35     return 0;
36     ...
37 err_small_buffers:
38     ql_free_buffer_queues(qdev);
39 err_buffer_queues:
40     ql_free_net_req_rsp_queues(qdev);
41 err_req_rsp:
42     ...
43     return -ENOMEM;
44 }
```

Figure 3: A memory leak bug found by IMMI in the Linux kernel.

memory leak if an error occurs subsequent to resource allocation, as indicated by the error code returned at line 11. Existing approaches for detecting memory leaks typically involve tracking data-flows associated with a specific memory object [38, 41, 42] or referring to existing code snippets to deduce proper usage patterns [15–17, 43]. However, exhaustively tracing all potential paths to identify a definitive path that neglects to release memory across the entire kernel is impractical. In practice, many tools focus solely on intra-procedural contexts [9, 15, 23], presuming that callers will invariably manage errors and perform necessary cleanup correctly, which is frequently invalidated. Moreover, in the presented example, there is a lack of a reference for resource deallocation (e.g., a release operation in alternative error-handling paths of `ql_alloc_buffer_queues`), which would result in its omission by current memory bug detection methodologies.

When examining this bug through the lens of MM intentions, it becomes apparent that the absence of a release operation implies an expectation that the caller of `ql_alloc_buffer_queues` (line 17) is responsible for clean-

ing up `qdev->lrg_buf` upon failure. However, the caller function does not address this failure, instead deferring the cleanup of associated memory to a subsequent failure scenario (i.e., invoking `ql_free_buffer_queues` at line 38 to deallocate `qdev->lrg_buf` when `ql_alloc_small_buffers` fails). This indicates an inconsistency between the assumptions of the callee function and its caller regarding responsibility for memory management, leading to the observed memory leak. Our analysis suggests that a more holistic approach, one that considers the intentions inherent in MM practices, is necessary to effectively detect and prevent such memory-related bugs.

3 Overview

3.1 Challenges in MM Intention Inference

The design of `IMMI` is inspired by the insight that many kernel memory bugs come from the inconsistency of MM intentions. Though the idea is intuitive, there are several technical challenges.

How to infer MM intentions? MM intention inference necessitates a sophisticated comprehension of kernel memory operations and the ability to identify indicative patterns of memory utilization intentions. This task involves dissecting complex logic that dictates kernel behavior, which is non-trivial. Additionally, the implicit memory management mechanisms embedded within OS kernels are not only pervasive but also intricate, demanding a substantial depth of domain-specific knowledge for precise interpretation. As a result, these mechanisms frequently escape detection by conventional bug detection tools. Furthermore, MM intentions could be concealed within code comments, necessitating a level of natural language understanding that typically exceeds the capabilities of existing static program analysis techniques.

To address this challenge, we introduce a novel approach that synergizes behavior-based MM intention analysis with enhancements derived from large language models (LLMs). Our approach involves analyzing and extracting MM intentions from error handling logic, while concurrently leveraging LLMs to interpret pertinent code comments and implicit kernel MM mechanisms. `IMMI` aims to bridge the gap between the explicit code and the implicit intentions of memory management, thereby improving the accuracy and efficacy of kernel memory bug detection.

How to balance precision and efficiency? Achieving a high level of precision in MM analysis requires exhaustive and meticulous scrutiny, which could be both resource-intensive and protracted. For instance, identifying the memory leak in Figure 3 necessitates an inter-procedural, path-sensitive, and field-sensitive analysis approach, which is particularly burdensome when examining large-scale OS kernels. On the other hand, compromising on precision would result in a significant increase in both false positives and false negatives.

To address this challenge, we introduce several techniques aimed at bolstering the efficiency and scalability of our static analysis, while maintaining a high level of precision. Specifically, we propose an object-based program slicing method to confine the scope of our analysis. We also present a novel approach for summarizing memory operations that optimizes inter-procedural analysis. Diverging from conventional function-level summary generation, our method segments summaries into discrete units and reconstructs them on-demand. This technique promises to deliver accurate guidance on memory operations without the need for costly inter-procedural alias analysis.

3.2 The `IMMI` Framework

Figure 4 illustrates the workflow of `IMMI`, which consists of three phases. In the first phase, `IMMI` accepts LLVM Intermediate Representation (IR) files as input. `IMMI` constructs control-flow graphs (CFGs) for individual functions and a global call graph for the entire system. `IMMI` also implements a specialized alias analysis to determine aliasing relationships within functions.

In the second phase, `IMMI` first constructs memory operation summaries to facilitate following MM intention inference. Following this step, `IMMI` proceeds to extract memory objects in the target program and generates program slices centered based on these objects. By analyzing these slices in conjunction with the memory operation summaries, `IMMI` infers the MM intentions at the point of allocation within the respective functions. If `IMMI` detects divergent MM intentions for a single memory object within a function, it classifies this as a bug (i.e., *intro-inconsistency*), reports it immediately, and halts further analysis.

In the third phase, `IMMI` performs a backward inconsistency analysis for memory bug detection. This phase initiates with a verification step to ascertain whether a memory object has been propagated to the caller functions. If propagation is confirmed, `IMMI` meticulously analyzes the MM intentions for the caller functions in relation to the memory object. If an inconsistency arises between the MM intentions deduced in the callees and those in the callers, `IMMI` flags this as a potential memory bug (i.e., *inter-inconsistency*). `IMMI` persistently monitors the memory object across successive calling functions if the immediate caller does not deduce a definitive MM intention but rather delegates the MM responsibility to subsequent callers, thereby ensuring a comprehensive and thorough analysis.

4 System Design

4.1 Alias Analysis

To enhance the analysis of data-flows associated with memory objects, we employed *path-based alias analysis* [14], which is based on the *alias graph*. This data structure comprises nodes

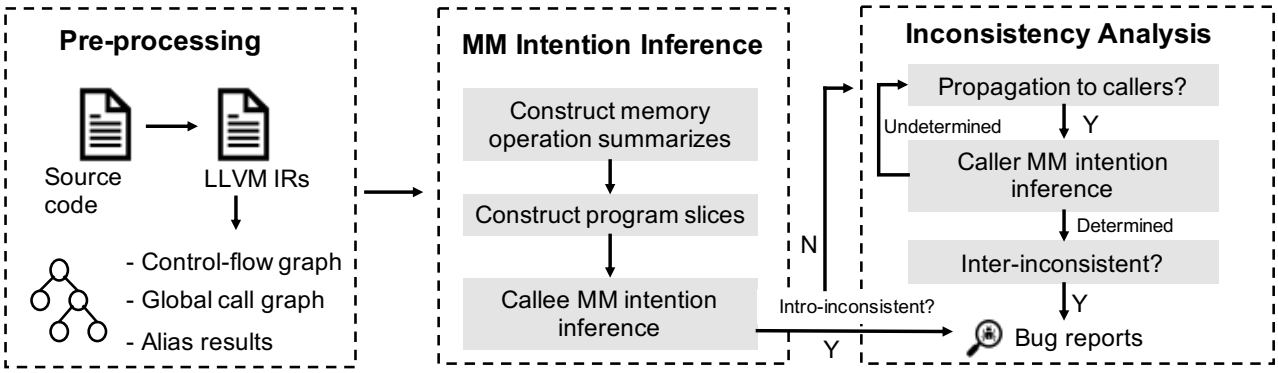

Figure 4: The overview of IMMI.

representing alias sets with edges that illustrate the relationships between pointers of discrete alias sets, such as pointer dereferencing and struct field accesses. A significant benefit of this approach is its capability to record pointer relationships comprehensively during the analysis. The approach is desiged to be inter-procedural, flow-sensitive, and field-sensitive.

To augment the efficiency and accuracy of our analysis, we reformed the alias updating algorithm to a flow-insensitive version, confining its use to intra-procedural contexts. The incorporation of inter-procedural information is achieved through a demand-driven summarization method, which will be expounded upon subsequently. Our approach limits alias analysis to the processes of summary computation and analysis of specific code slices, averting the demands of an extensive, full-program alias analysis.

Following the completion of alias analysis, the data-flow relationships among distinct pointers are succinctly recorded within the alias graph. It is pertinent to acknowledge that for array types, the indices associated with element access frequently vary and are non-static, presenting difficulties for static analysis. Therefore, our alias analysis conservatively assumes that elements within the same array act as aliases.

4.2 Memory Operation Summarization

Program summarization is an important technique in static analysis for streamlining inter-procedural analysis. In this paper, we focus on two primary types of memory operations within our summarization framework: resource release and resource resetting. Resource release is an essential element for inferring MM intentions. On the other hand, resource resetting significantly impacts the determination of potential bugs. For instance, reassigning a pointer that denotes a memory object typically signifies the end of that object's lifetime. Additionally, nullifying a pointer post-release, a practice known as *defensive programming*, ensures that subsequent deallocations of the same memory object are not misconstrued as double-free errors, given that deallocating a null pointer in the kernel is deemed safe.

Challenges. Current summarization techniques employed for OS kernel analysis are either excessively coarse-grained or prohibitively expensive. For instance, numerous memory bug detection tools operate under the assumption that memory allocations and deallocations have a one-to-one correspondence, an assumption frequently invalidated by one-to-many and many-to-many relationships. Goshawk [22] introduces a structure-aware and object-centric approach to memory summarization. Nonetheless, this strategy incurs significant overhead. Kernel developers typically implement memory management in a layered fashion, leading to extensive call chains. Consequently, memory summaries, especially for higher-level functions such as driver probe routines, tend to represent an excessive amount of memory resources. On the other hand, the generation of summaries that are not subsequently utilized in bug detection results in considerable waste of computational and storage resources.

Our solution: demand-driven summarization. To address the aforementioned challenges, we present a demand-driven memory operation summarization technique. Our approach involves decomposing memory operation summaries into discrete pairwise interactions, which are then cataloged within a global map. Each entry in this map meticulously records the intricate details of these interactions, which is structure-aware. When subsequent analysis necessitates a query of memory operations for a specific function, IMMI dynamically reconstructs the comprehensive summarization from these pairwise entries. This method allows for precise and targeted analysis without incurring the prohibitive costs associated with traditional summarization techniques

Definition 1. *In this work, a discrete memory operation summary is defined as a tuple:* $S = \{F, Arg, L_O\}$*, where* F *denotes the function encapsulating the summary,* Arg *represents the function's argument associated with the targeted memory objects, and* L_O *is a list that chronicles the memory operations executed within* F*. More precisely, each element in* L_O *is characterized by a tuple:* $\{O_{type}, O_{value}\}$*, with* O_{type} *specifies the operation type, which for the scope of this paper, is confined to either 'Release' or 'Resetting'. For 'Release' operations,*

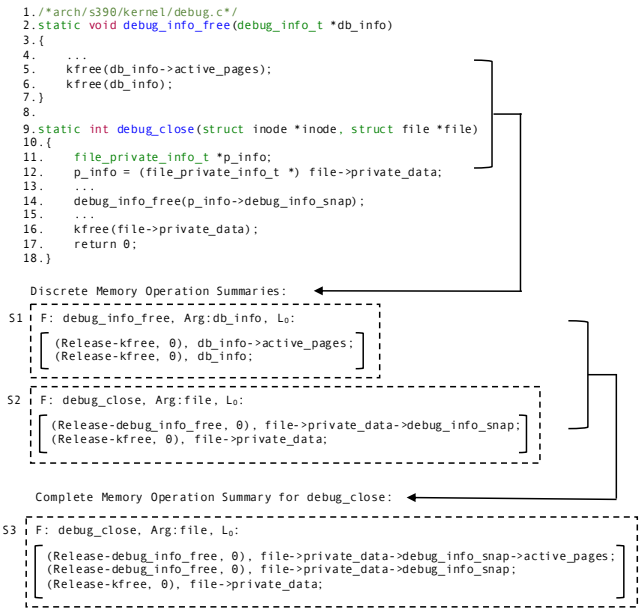

Figure 5: Example of demand-driven summarization.

Algorithm 1: Release summary generation

```
1  SummaryGen(List_Release, F);
   Input: List_Release: Release API list;
          F: Function to analyze;
2  CSet_analyzed ← R_S ← ∅ (Init once on the first call);
3  foreach Call_inst in F do
4      if Call_inst ∈ List_Release then
5          C_index ← GetReleaseIndex(Call_inst);
6          RecurAnalysis(F, Call_inst, C_index);
7      end
8  end
9  Function RecurAnalysis(F, Call_inst, C_index):
10     if Call_inst ∈ CSet_analyzed then
11         return;
12     end
13     CSet_analyzed ← {Call_inst} ∪ CSet_analyzed ;
14     M_O ← Call_inst.GET_OPERAND(C_index) ;
15     if M_O is derived from arguments of F then
16         F_argidx ← GetIndex(F, M_O) ;
17         V_arg ← F.GET_ARG_OPERAND(F_argidx) ;
18         S_R ← GetRelationString(V_arg, M_O) ;
19         Sum ← BuildSum(F, F_argidx, Call_inst, C_index, S_R) ;
20         R_S ← {Sum} ∪ R_S ;
21         foreach Caller_inst of F do
22             F_caller ← GetHostFunc(Caller_inst) ;
23             RecurAnalysis(F_caller, Caller_inst, F_argidx);
24         end
25     end
```

O_{type} further includes the release API name and the index corresponding to the resource parameter. The term O_{value} describes the memory object involved, represented as a string that articulates the structured relationship between the memory object and the function's arguments.

Figure 5 presents an example of memory operation summarization. In this example, `IMMI` produces two distinct summaries of memory release operations for the functions `debug_info_free` and `debug_close`, denoted as S1 and S2, respectively. Within `debug_info_free`, a pair of release invocations (`kfree`) are recorded in S1. Given that `kfree` accepts a singular parameter, the index number in L_O is consequently noted as 0. This function is subsequently invoked by `debug_close` at line 14, with its memory release operations encapsulated in S2. Both S1 and S2 accurately capture the structure-aware relationships between the released memories and the function arguments.

Summary generation. `IMMI` generates release summaries from a set of official kernel release APIs, as detailed in Table 6. The goal of `IMMI` in this process is to identify all function calls that directly or indirectly release memory objects (i.e., release wrappers). Algorithm 1 outlines the process for creating these summaries. Specifically, `IMMI` examines each function within the target system and employs `SummaryGen` to produce individual release summaries. This component accepts two inputs: a predefined list of general release APIs ($List_{Release}$) and the function under analysis (F). The resulting summaries are stored in R_S. The procedure begins by scanning the call instructions within F (line 3). Upon identifying a release call, `IMMI` performs a recursive analysis using `RecurAnalysis` (line 6). During this process, `IMMI` extracts the memory object being released from the release API (line 14) and determines if it originates from an argument of F. If so, `IMMI` extracts this argument (lines 16-17) and examines the derivation relationship between the argument and the memory object (i.e., O_{value}). This analysis is conducted via a backward graph traversal on the alias graph of F (line 18). With all pertinent information collected, `IMMI` constructs and records the summary entity for the current memory object (lines 19-20). At this stage, it is inferred that the released memory objects are propagated through the callers of F, prompting a recursive analysis of these callers to assemble comprehensive release summaries (line 21-24).

Memory resetting summaries are generated in a manner akin to release summaries. In this process, `IMMI` extracts memory objects from release APIs and conducts a further analysis of store instructions that reset these memory objects. To enhance efficiency, `IMMI` maintains a record of the analyzed instructions, thereby avoiding redundant analysis (line 10-13).

Reconstructing complete summary on-demand. The memory operation summaries previously generated are distinct but not exhaustive, failing to encapsulate all memory operations within a given function. For instance, summary S2 in Figure 5 merely indicates that the callee `debug_info_free` has released some memories, lacking comprehensive details. To derive an all-encompassing summary for `debug_close`, it is imperative to amalgamate S2 with S1, which delineates the

specific memory operations performed by `debug_info_free`. When querying the memory operation summaries of a function, `IMMI` first extracts the function's direct summary (e.g., S2 for `debug_close`). Subsequently, `IMMI` examines the memory operation list (L_O) to determine if any listed functions possess additional summaries. If affirmative, `IMMI` recursively aggregates these summaries to formulate a complete summary, concurrently updating the O_{value} throughout the process. For example, by combining the `db_info->ccactive_pages` in S1 and `file->private_data->debug_info_snap` in S2, `IMMI` could precisely reconstruct the actual release memory object is `file->private_data->debug_info_snap->active_pages`. The fully integrated release summary for `debug_close` is depicted as S3 in Figure 5.

4.3 Object-based Code Slicing

The goal of code slicing is to refine the analysis scope, thereby enhancing efficiency and scalability. To this end, `IMMI` initially identifies the error handling paths for each function, subsequently extracting the relevant memory objects contained therein. Ultimately, `IMMI` confines the analysis to those error handling paths that are reachable to the identified memory objects.

Identifying error handling paths. The MM intention analysis in this paper primarily concentrates on error handling mechanisms, necessitating the accurate identification of error handling paths. Current methodologies for this task can be broadly classified into two predominant approaches: the first employs backward data-flow analysis, commencing from return instructions that yield error codes [15, 20]; while the second approach engages in forward data-flow analysis, initiating from function calls that could potentially propagate errors [34]. Our assessment reveals that the former approach often overlooks numerous error handling paths, particularly those associated with function calls, whereas the latter may erroneously classify non-error handling paths as such. To address these shortcomings, `IMMI` synergizes these two strategies, integrating their strengths to enhance the precision and coverage of error path detection. Specifically, `IMMI` initially applies the backward analysis to enumerate error paths within each function and to annotate call instructions that affect branching conditions. It then uses forward analysis to follow these annotated call instructions, capturing the paths that address their failures and excluding irrelevant paths. This integrated approach ensures a more robust and accurate identification of error handling paths.

Extracting memory objects. OS kernels conventionally manage memory resources through established MM application programming interfaces (APIs) [1]. Within this framework, memory objects are typically denoted by pointers. Similar to prior methodologies, our approach extracts memory objects by capturing the pointers returned from the standard kernel memory allocation APIs, as detailed in Table 6 in the Appendix. Additionally, it is commonplace for kernel developers to employ these APIs as foundational elements for crafting bespoke MM allocation functions. To accommodate such practices, our analysis extends to tracking the propagation of memory objects allocated by standard MM APIs to subsequent callers. If these objects are passed forward as return values, we incorporate them into our analysis targets. This comprehensive tracking ensures the integrity and completeness of our memory object analysis scope, thereby enhancing the reliability of our subsequent analysis.

Code slicing. In the context of MM inconsistent analysis, which often spans across multiple functions, it is imperative that the memory objects of interest represent shared resources. Upon obtaining a memory object, `IMMI` tracks its subsequent usage to pinpoint the instruction that permits access to the object for other functions (e.g., a store instruction that commits it to a function's argument). `IMMI` then scrutinizes the collected error handling paths and eliminates those that are not reachable by this instruction (e.g., error paths preceding the memory allocation). This elimination is conducted through a Control Flow Graph (CFG) reachability analysis.

Additionally, `IMMI` filters out error paths that reset the memory object subsequent to its release, by examining the memory operation summaries collected in §4.2. This step is essential as it excludes instances of *safe inconsistent MM*. For example, setting a memory object to NULL post-deallocation renders subsequent deallocations by the callers inconsequential and bug-free, as freeing a NULL pointer is generally benign in kernel contexts. The code segments that remain after this filtration process constitute the slices that lay the groundwork for the subsequent inference of MM intentions.

4.4 LLM-assisted MM Intention Inference

Callee MM intention inference. `IMMI` conducts an object-oriented analysis to infer the memory management (MM) intentions. Utilizing the analysis scope (i.e., the code slices derived in §4.3), alongside summaries of memory operations, `IMMI` deduces the MM intentions for the object within the function responsible for its allocation (denoted as F_{obj} for brevity). These intentions are categorized into three distinct types:

- **Callee-based management.** In scenarios where all error paths within the code slices ensure the release of the memory object, the callers of F_{obj} are not required to manage the memory object upon failure of F_{obj}.
- **Caller-based management.** Conversely, if none of the error paths within the code slices release the memory object, it is expected that the callers of F_{obj} will handle the cleanup of the memory objects in the event of F_{obj}'s failure.
- **Undetermined management.** This category arises when some error paths within the code slices release the memory

```
1  /* drivers/dax/bus.c */
2  static int devm_register_dax_mapping(struct dev_dax *dev_dax, ...)
3  {
4      ...
5      mapping = kzalloc(sizeof(*mapping), GFP_KERNEL);
6      if (!mapping)
7          return -ENOMEM;
8      ...
9      mapping->id = ida_alloc(&dev_dax->ida, GFP_KERNEL);
10     if (mapping->id < 0) {
11         kfree(mapping);
12         return -ENOMEM;
13     }
14     ...
15     rc = device_add(dev);
16     if (rc) {
17         put_device(dev); //Reference counting
18         return rc;
19     }
20
21     rc = devm_add_action_or_reset(..., unregister_dax_mapping,
22             dev); //Indirect release call
23     if (rc)
24         return rc;
25     return 0;
26 }
```

Figure 6: Example of implicit memory management mechanisms in the Linux kernel.

```
1  /* net/netfilter/x_table */
2  static int xt_jumpstack_alloc(struct xt_table_info *i)
3  {
4      ...
5      if (size > PAGE_SIZE)
6          i->jumpstack = kvzalloc(size, GFP_KERNEL);
7      else
8          i->jumpstack = kzalloc(size, GFP_KERNEL);
9      if (i->jumpstack == NULL)
10         return -ENOMEM;
11     ...
12     i->jumpstack[cpu] = kvmalloc_node(size, GFP_KERNEL,
13             cpu_to_node(cpu));
14     if (i->jumpstack[cpu] == NULL)
15         /*
16         * Freeing will be done later on by the callers. The
17         * chain is: xt_replace_table -> __do_replace ->
18         * do_replace -> xt_free_table_info.
19         */
20         return -ENOMEM;
21
22     return 0;
23 }
```

Figure 7: Example of valuable code comments in the Linux kernel.

object, while others do not. Such inconsistency typically indicates a bug. If the caller attempts to release the memory again, a double-free error may occur. Conversely, inaction by the caller can lead to a memory leak along certain paths. Consequently, `IMMI` reports this scenario as exhibiting intra-inconsistent MM intentions and ceases further analysis.

LLM integration. The complexity of kernel memory management mechanisms poses additional challenges for accurately deducing MM operations. Figure 6 shows such an example in the Linux kernel. A heap memory allocation for the variable `mapping` occurs at line 5, with a corresponding deallocation on the error path at line 11. However, the error paths returning at lines 18 and 24 lack explicit deallocation for this resource. Specifically, the error path at line 18 employs reference counting to manage the resource, resulting in an automatic deallocation when `put_device` is invoked. Similarly, the function `devm_add_action_or_reset` at line 21 registers a callback function, `unregister_dax_mapping`, for release (an indirect call), which is triggered upon its failure. Traditional analysis techniques often fail to account for these implicit resource releases, leading to a substantial number of false positives. We also observed that code comments often encapsulate critical insights regarding memory management, as exemplified in Figure 7. Specifically, the annotations spanning lines 15-18 suggest that the responsibility for deallocating the memory allocated to `i->jumpstack` falls to the calling function in the event of a failure signaled at line 20. Discerning these memory release patterns poses a significant challenge for purely static analysis methodologies due to the necessity of tracing complex call hierarchies.

Recent advancements in large language models (LLMs) have demonstrated their proficiency in various security tasks [5, 13, 24, 25, 27]. To tackle the challenges previously mentioned, we utilize the capabilities of LLMs to scrutinize the implicit MM strategies and extract insightful code annotations within the target systems. For each memory object, should `IMMI` detect any sliced path from prior static analysis that fails to deallocate the object, it crafts a tailored LLM prompt to investigate the possibility of an implicit memory release pertaining to that object. To fully leverage the LLM's potential, we decompose the analysis into three distinct phases: targeting the memory object, discerning error handling paths, and examining the relevant code to determine whether the memory object is governed by the calling functions or is subject to automatic deallocation. `IMMI` incorporates the function's source code, where the memory object is instantiated, into the prompt input. The LLM is then instructed to encapsulate its findings in a separate line, from which `IMMI` extracts the LLM's conclusions to augment subsequent analyses. Should the LLM uncover such information, `IMMI` will update its analysis results for the object accordingly. We provide a prompt message example for the code in Figure 6 in Table 5 in the Appendix, where the LLM successfully identifies the implicit memory release mechanisms through reference counting and an indirect call.

4.5 Inconsistency-based Bug Detection

Caller MM intention inference. In the preceding phase, a shared memory object was classified according to its management strategy: either callee-based or caller-based. `IMMI` extends this analysis by examining the callers to deduce the MM intentions for this object. Specifically, `IMMI` begins by identifying the error-handling path associated with the caller instruction and ascertains whether this path deallocates the memory object. If deallocation occurs, the caller function

is designated as employing caller-based management for the object. Conversely, if no release is detected, IMMI proceeds to aggregate all error handling paths that follow the successful execution of the caller instruction. Should any of these paths involve the release of the memory object, the caller function is then categorized under callee-based management. In the absence of these conditions, IMMI conducts a deeper investigation to determine whether the memory object is propagated further along the call chain. When such transfer is detected, IMMI recursively applies the aforementioned analysis until the MM intentions for the memory object can be conclusively identified.

Memory bug detection. In the process of inferring the caller's MM intentions, should there be inconsistency between the caller's and callee's MM intentions for a given memory object, IMMI halts further analysis and flags it as a memory bug. Specifically, when the callee operates under caller-based management, while the caller adheres to a callee-based strategy, IMMI identifies this as a potential memory leak. This occurs because neither party assumes responsibility for deallocating memory upon a particular failure scenario. Conversely, when both the caller and callee attempt to manage the same memory object, IMMI recognizes this as a double-free bug.

We use the memory leak bug in Figure 3 as an example to illustrate the workflow of IMMI. During the callee MM intention inference phase, IMMI discerns that the memory object `qdev->lrg_buf` is allocated at line 5. However, IMMI observes that subsequent error handling paths fail to deallocate it. Consequently, IMMI designates the function `ql_alloc_buffer_queues` as adhering to caller-based management for this object. Upon inspecting the caller function `ql_alloc_mem_resources`, IMMI evaluates its MM intention by analyzing the error paths following the failure of `ql_alloc_buffer_queues` (lines 26-27 and 39-43), noting the absence of deallocation for the memory object. Further analysis of the error paths after `ql_alloc_buffer_queues` has successfully executed reveals a jump to `err_small_buffers`, where the memory is appropriately released at line 38. IMMI thus determines that `ql_alloc_mem_resources` employs callee-based management for the object. This finding is in direct conflict with the handling method of the callee `ql_alloc_buffer_queues`. As a result, IMMI reports a memory leak bug due to this inconsistency.

5 IMMI Implementation

We have implemented IMMI based on LLVM with 5.3K lines of C++ code. We choose ChatGPT-4 (accessed through ChatGPT-4-1106-preview) as our target LLM and implement the LLM query with 200 lines of python code. We record the LLM query results and bug reports in a local MySQL database to facilitate further bug verification.

Pre-processing. To mitigate the risk of path explosion, we unroll loops by transforming the control flow of loop constructs into conditional (`if`) statements. This technique is a common practice in static analysis, as evidenced by its application in various works [20, 32, 33, 43]. We employed multi-layer type analysis [19] for analyzing indirect calls. Nevertheless, our findings indicated that numerous indirect calls involving nested struct types were inaccurately resolved. To address this, we introduced an additional data-flow analysis specifically tailored for these indirect calls to extract more precise nested type information. This refinement led to a reduction of approximately 23% in superflous indirect call targets.

Code exploration settings. In the current implementation, we confine the inter-procedural MM intention analysis for each shared memory object to a maximum of four procedural transitions. This constraint is informed by empirical evidence suggesting that extending the call-chain analysis beyond this threshold yields a negligible increase in bug detection, while incurring a significant computational overhead. Moreover, we have instituted an early termination protocol: if a memory object is encapsulated within a structure, the analysis is promptly concluded upon the deallocation of the enclosing structure. In this case, IMMI deems the memory object as irretrievable and immediately flags it as a potential memory leak.

LLM settings. The outputs of LLMs exhibit a form of instability commonly referred to as *hallucination* [40, 45]. To mitigate this issue, we query each prompt four times, considering only those responses that maintain consistent conclusions in at least three instances as valid. To optimize analysis time and reduce costs, we deploy LLMs exclusively for analyzing the intentions of memory management in cases where IMMI has identified inconsistencies during the static analysis phase. We have also observed that constraining LLM outputs significantly affects its efficacy in our code analysis task. Consequently, we permit the LLM to initially present intermediate analysis results, subsequently synthesizing these into a definitive outcome.

Post-processing. IMMI sometimes produces multiple bug reports that, despite originating from the same root cause, exhibit distinct call chains. This situation often arises when a callee function responsible for managing a shared memory object is invoked by multiple callers. IMMI identifies and reports a bug for each unique caller that demonstrates inconsistent memory management intentions relative to the callee. In our analysis, we have observed that these instances are generally resolvable with a single patch and, therefore, should be considered as a single bug. Consequently, for clarity and accuracy in our statistical analysis, IMMI only retains a single report from such groups of related bug reports.

6 Evaluation

We conducted an evaluation of IMMI on a Linux server running Ubuntu 20.04.1, equipped with 126GB of RAM and an Intel

Table 1: Scalability of IMMI.

Bitcode Loading	ICall Analysis	Summarization	Bug Analysis	LLM I/O	Total
1m 11s	3m 58s	2m 15s	1m 59s	25m 49s	35m 12s

Table 2: Bug detection statistics of IMMI on the Linux kernel. The SA indicates the number of bugs reported by pure static analysis, while the SA+LLM specifies the number identified when static analysis is combined with the large language model (GPT-4).

Category	Reported Bugs		Real Bugs	Precision
	SA	SA+LLM		
Intro-inconsistency	63	52	35	67.3%
Inter-inconsistency	95	71	45	63.4%
Total	158	123	80	65.0%

Xeon Silver 4316 CPU at 2.30GHz. We evaluated the bug detection efficiency of IMMI against the Linux kernel 5.18. To ensure comprehensive module coverage, we compiled the kernel using the `allyesconfig`, resulting in a total of 21,438 LLVM bitcode files.

6.1 Analysis Performance

IMMI completed the analysis of the entire Linux kernel within 35 minutes, as shown in Table 1. Specifically, the static analysis component of IMMI required only approximately 9 minutes, with the remaining time predominantly consumed by I/O latency during queries to the LLM. These results underscore the efficiency and scalability of IMMI in bug detection. IMMI reported a total of 123 unique bugs.

6.2 Bug Findings

We manually analyzed all bug reports generated by IMMI and finally confirmed 80 new bugs, including 57 memory leak bugs, 16 double-free bugs, 6 UAF bugs, and 1 null-pointer-dereference bug. We have reported all the bugs to the Linux community. Until the submission of this paper, 72 bugs have been confirmed or fixed. The detailed bug list is available in the Appendix.

An intriguing observation from our bug analysis is that the majority of inconsistent memory management intentions can be deduced through a relatively constrained scope of analysis. Specifically, among all identified bugs, 35 (43.8%) were detected without necessitating inter-procedural analysis, as highlighted by the unresolved handling cases in §4.4. For the remaining bugs uncovered during inter-procedural analysis, 22 (48.9%) were identified when shared memory objects were propagated across a single procedural boundary. The memory leak bug exemplified in Figure 3 typifies such a scenario. Furthermore, 14 (31.1%) of the bugs were associated with two procedural boundaries, while 9 (20.0%) involved three or more. These findings underscore the efficacy of employing inconsistent MM intention analysis as a strategy for memory bug detection.

6.3 False Positives

The false discovery rate of IMMI stands at 35%, which is actually promising for a static bug analysis tool, outperforming several comparable tools in detecting kernel memory bugs [9, 15, 34]. Leveraging capabilities of LLM for code and comment interpretation, IMMI effectively mitigates false positives arising from complex kernel memory management mechanisms and developer tactics. Upon examining the false positives, we have identified the primary contributing factors as follows:

Infeasible paths. Kernel developers frequently impose constraints to govern the executability of certain program paths. For instance, developers may employ temporary variables to determine the executability of object release sequences. While memory resetting summaries can mitigate some instances of infeasibility, they are not universally effective. These unaddressed cases account for 44% of the false positives in our analysis. To resolve this challenge, IMMI needs to integrate with symbolic execution to discern and exclude infeasible paths. We defer the implementation of this enhancement to future work.

Imprecise error handling path analysis. Error handling mechanisms within operating system kernels are inherently intricate, frequently encompassing numerous layers of verification and a multitude of conditional statements. Despite the incorporation of both forward and backward analyses into our methodology, certain paths elude the scope of our model. This limitation leads to the occasional omission of error handling paths in our identification process, which contributes 26% of the false positives.

Imprecise alias analysis. Despite IMMI's implementation of a field-sensitive alias analysis, the approach falls short in accurately distinguishing between individual array elements when they are accessed via indeterminate indices within loops. Consequently, IMMI erroneously identifies distinct array elements as aliases, contributing to aliasing imprecision. This particular limitation is responsible for approximately 12% of the false positives reported by IMMI.

Other causes. Several less common factors also contribute to the false positives. These encompass limitations in the handling of specialized program logics that exceed the capabilities of our static analysis framework, even when augmented with large language models. Additionally, the complexity of kernel macros and deficiencies in the implementation of the static analysis component of IMMI are also responsible for false positives. Collectively, these issues account for 18% of the false positives observed.

6.4 False Negatives

Since there is no benchmark for false negative analysis, we have devised a test set by deliberately injecting MM intention inconsistencies into the Linux kernel. Specifically, we randomly selected 20 shared memory objects initially managed with caller-based management and altered them to adopt callee-based management. Conversely, we selected additional 20 memory objects that were originally callee-based and transformed their management to caller-based. This intentional perturbation resulted in the introduction of 20 double-free bugs and 20 memory leak bugs. IMMI successfully identified all 20 double-free bugs and 17 of the memory leaks. The three undetected memory leaks can be attributed to instances where the call chains surpassed our predefined threshold, thus evading our analysis.

It is important to note that the efficacy of IMMI's bug detection mechanism is contingent upon the manifestation of inconsistent MM intentions across different functions pertaining to the same memory object. In scenarios where bugs are confined to local resources within a single function, the detection capabilities of IMMI would diminish.

6.5 Performance of LLM

Overall performance. In the process of detecting bugs, IMMI constructed 158 unique query tasks aimed at inferring MM intentions through LLM. Each query was executed four times, consistent with the methodology outlined in §5. Out of these queries, IMMI garnered 128 (81.0%) valid responses. The average I/O latency for each LLM prompt was approximately 2 seconds. Throughout our analysis, the LLM demonstrated commendable stability in processing the tasks presented, considering the complexity of the analysis.

To evaluate the contribution of the LLM to the bug detection capabilities of IMMI, we deactivated the LLM component and reassessed the outcomes using only static analysis. Subsequently, the number of bug reports surged to 158. Upon manual inspection of these reports, we identified three additional true bugs and 32 extra false positives in comparison to the previous results. These findings suggest that the LLM is responsible for approximately 4% of false negatives in bug detection, yet it effectively reduces the false positives produced by IMMI by 43%. Without the LLM's assistance, the overall false discovery rate of IMMI escalates to 47.5%. The majority of these additional false positives stem from the Linux kernel's implicit memory management mechanisms, such as reference counting and release callback functions. Furthermore, LLM mitigates some false positives that arise from inaccurate error path identification. The results underscore the efficacy of IMMI in resolving intricate scenarios that pose challenges to traditional static analysis, demonstrating its value in enhancing system security.

False negatives. We checked the false negatives introduced by LLM, where we found all of them were caused by erroneous assumption in inferring code functionalities. Figure 8 illustrates a representative case, where a memory object qedf->global_queues is instantiated at line 4. All subsequent error handling paths in this function lead to the mem_alloc_failure label, triggering the invocation of qedf_free_global_queues for resource deallocation. Contrary to the LLM's assumption that this release function would adequately dispose of all allocated resources within qedf_alloc_global_queues, it fails to release the aforementioned object. Notably, such function naming conventions could also mislead human developers, potentially leading to a similar misjudgment with the LLM. This is a pitfall for many methods that rely on keyword-based function pairing as well. To address this issue, one approach could involve enriching the LLM queries with additional context, such as the release summaries produced by IMMI, and adopting a recursive query strategy. We identify this as an avenue for future work.

```
1  static int qedf_alloc_global_queues(struct qedf_ctx *qedf)
2  {
3      ...
4      qedf->global_queues = kzalloc(...);
5      if (!qedf->global_queues) {
6          QEDF_ERR(&(qedf->dbg_ctx), "Unable to allocate global "
7                "queues array ptr memory\n");
8          return -ENOMEM;
9      }
10     ...
11     status = qedf_alloc_bdq(qedf);
12     if (status) {
13         QEDF_ERR(&qedf->dbg_ctx, "Unable to allocate bdq.\n");
14         goto mem_alloc_failure;
15     }
16     ...
17     return 0;
18
19 mem_alloc_failure:
20     qedf_free_global_queues(qedf);
21     return status;
22 }
```

Figure 8: Example of false negative introduced by LLM.

Comparison with different LLMs. In this section, we provide a comparison of different LLMs for bug detection within IMMI framework, including GPT-4, GPT-3.5, and Llama-3-70B, as shown in Table 3. Smaller models, such as Llama-3-8B, exhibited difficulties in comprehending the analysis task and produced unpredictable outputs in our preliminary testing, and therefore are not included in the comparison. The prompts for all LLM evaluations are consistent with those used in our previous assessment of GPT-4.

Although GPT-3.5 and Llama-3 demonstrate an understanding of the analysis task, they do not consistently meet every detailed requirement. For instance, Llama-3 often overlooks the criterion that only error paths following the object allocation should be considered. GPT-3.5 struggles to maintain focus on a specific memory object when the error handling paths include memory releases for multiple objects. Moreover, their accuracy significantly diminishes in the context of ex-

Table 3: Comparison with different LLMs. The TP, FP, TN, and FN indicate true positive, false positive, true negative, and false negative, respectively.

LLM	Valid Reports	TP	FP	TN	FN
GPT-4	128 (81.0%)	67	26	32	3
GPT-3.5	140 (88.6%)	41	33	36	30
Llama-3	144 (91.1%)	58	47	19	20

tensive functions and indirect calls. As a result, their utility in aiding bug detection for this paper is suboptimal. Notably, GPT-3.5 and Llama-3 generate nearly as many false negatives as the false positives they reduced. The IMMI framework necessitates an LLM with a more robust reasoning capacity for the static analysis tasks. Models such as GPT-3.5 would necessitate further fine-tuning or prompt engineering to achieve the level of precision necessary for our analysis, a process that may exceed the scope of the current paper.

6.6 Comparison with Existing Tools

This section compares IMMI with four established tools: IPPO [15], HERO [34], MLEE [31], and Goshawk [22]. Each demonstrates proficiency in detecting kernel memory bugs and targets distinct facets of bug detection methodology. We have gathered data on analysis time and precision from the corresponding papers for each tool's evaluation of the Linux kernel and presented a high-level comparison in Table 4. Given that the kernel versions and experimental environments vary across these studies, the metrics provided should be considered indicative of their general capabilities. Overall, IMMI exhibits an effective balance between performance, precision, and the capacity to uncover bugs, with a minimal overlap in bug detection compared to the existing tools, indicating that IMMI could serve as a beneficial complement to them. Below, a detailed analysis of each comparison tool is presented.

Comparison with similarity analysis. IPPO [15] aims to identify bugs stemming from omitted security operations by examining discrepancies within semantically similar path pairs. Among the memory bugs detected by IMMI, IPPO could pinpoint 28 of them, and all of which were memory leak bugs arising during the intra-inconsistency analysis phase of IMMI. Owing to its design, IPPO is confined to the analysis of intra-procedural similar paths, which accounts for its failure to detect the majority of bugs uncovered by IMMI. Furthermore, IPPO is plagued by a low precision of 36.5%, a consequence of intricate code logic and its inability to analyze implicit kernel memory management mechanisms. In contrast, IMMI effectively mitigates these issues by leveraging LLM in understanding code semantics.

Comparison with function pairing. In this subsection, we compare IMMI with HERO [34], the state-of-the-art pairing-based bug detection tool. HERO excels in identifying function pairs through their co-usage patterns and could pinpoint bugs arising from redundant, missing, or disordered paired functions. It is capable of detecting both memory leaks and memory corruption issues. HERO was only able to identify 24 bugs uncovered by IMMI, including 23 memory leak bugs and one double-free bug. The majority of bugs uncovered by IMMI did not involve commonly used function pairs. In fact, aside from standard kernel memory management APIs such as kmalloc and kfree, the function pairs implicated in the bugs detected by IMMI are typically utilized only once or twice throughout the entire kernel. Consequently, the paucity of usage instances prevents HERO from inferring them as function pairs.

Comparison with memory leak detection tool. Given that a substantial proportion of the memory bugs identified by IMMI pertain to memory leaks, we compare IMMI against MLEE [31], which utilizes four weighted rules to detect kernel memory leaks bugs. The combined weight of these rules is 1, and each rule contributes either a score of 1 or 0 to the assessment. If the total weighted score reaches 0.5, MLEE classifies the case as a memory leak. Due to the lack of access to MLEE's source code and the undisclosed rule weights in its research publication, we initially chose to allocate equal weights, assigning 0.25 to each rule on the presumption that MLEE would report a leak upon the concurrent satisfaction of at least two rules. However, we determined that two particular rules are excessively broad[1]. Even bug-free kernel code often meets both criteria, leading to numerous false positives. Given that MLEE's false discovery rate is reported as only 18%, we fine-tuned the weight of these two generic rules to 0.24 and elevated the others to 0.26 to better reflect MLEE's actual performance. Furthermore, our evaluation conservatively presumes MLEE's flawless execution of inter-procedural analysis for memory deallocation and an errorless approach in its alias and liveness analyses.

In our evaluation, MLEE was able to identify 26 memory leak bugs found by IMMI, with 25 exhibiting intra-procedural inconsistencies. The empirical rules demonstrated limited effectiveness in detecting memory leaks that occur across function boundaries, highlighting a weakness in inter-procedural context analysis. Additionally, MLEE recognizes caller-based memory management as a bug pattern, which can lead to misclassification of legitimate memory management strategies as leaks.

Comparison with memory corruption detection tool. We also compare IMMI with a kernel memory corruption detection tool, where we choose Goshawk [22] as our comparison target. It employs a memory operation synopsis technique to streamline the tracking of data flows, thereby facilitating the detection of memory corruptions such as UAF. Upon deploy-

[1] One rule stipulates that if a memory object is allocated within a kernel function, it typically necessitates deallocation along the following error paths of that function. Another rule asserts that when multiple memory objects are allocated within a kernel function, all objects allocated prior to an allocation failure must be deallocated.

Table 4: Comparison with existing tools.

Tool	Methodology	Supported Bug Types	Analysis Time	Precision	Overlap with IMMI
IPPO	Similarity analysis	Memleak, memory corruption, ref-count leak, deadlock, missing check	2h	37%	28
HERO	Function pairing	Memleak, memory corruption, ref-count leak, deadlock	11h	52%	24
MLEE	Rules checking	Memleak	30 min	82%	26
Goshawk	Memory operation synopsis	Memory corruption	7h	63%	0
IMMI	MM intention analysis	Memleak, memory corruption	34 min	65%	80

ing Goshawk on the Linux kernel, we observed that there is no overlap between the bugs detected by Goshawk and those identified by IMMI. A meticulous manual examination of the double-free bugs reported by Goshawk revealed a high incidence of false positives, with all 34 cases being incorrectly flagged. Similar to IPPO, Goshawk's memory operation synopsis fails to account for implicit kernel memory management mechanisms like reference counting, which contributes to this high rate of false positives.

7 Related Work

Memory bug detection. As we evaluated in §6, various previous works try to detect memory bugs in different ways. IPPO [15] detects inconsistencies between similar path-pairs, positing that a memory bug is present if two similar paths exhibit divergent error-handling behaviors. MLEE [31] formulates four rules derived from empirical observations, specifically targeting memory leaks within early-exit paths. HERO [34] identifies function pairs and checks for disordered follower functions including redundant and inadequate ones. FREEWILL [10] detects UAF bugs by identifying inaccuracies in reference counting. These methodologies rely on predefined rules or the extraction of patterns (e.g., function pairs), which, while effective to a degree, may not encompass the full spectrum of memory bug manifestations. Our work aims to bridge this gap by analyzing the high-level memory management intentions.

LLM-assisted program analysis. The advent of Large Language Models (LLMs) has marked a significant milestone in the domain of program analysis, offering novel methodologies for understanding and manipulating code. GPTScan [28] harnesses the capabilities of GPT as a multifaceted code comprehension instrument, adept at identifying critical variables and deconstructing complex bug-finding rules into more tractable properties. ChatRepair [36] employs LLMs to iteratively generate patches based on test failure data, thereby advancing the frontier of automated program repair. FuzzGPT [8] integrates LLMs with a repository of historical bug-inducing programs and anomalous edge cases to cultivate the capacity for autonomously generating fuzzing inputs. LLMs have demonstrated proficiency in assimilating high-level semantic patterns and interfacing effectively with the inputs and outputs of conventional analysis tools. Despite these advancements, the independent deployment of LLMs for bug detection in complex programs remains an elusive goal. Our work explores the potential of LLMs to augment the intricate task of kernel bug detection, suggesting a promising avenue for leveraging these models to enhance the security of critical systems.

8 Conclusion

In this paper, we present IMMI, a novel system designed to identify memory bugs by analyzing the inconsistencies in memory management intentions. IMMI employs advanced techniques such as code slicing and demand-driven memory operation summaries to optimize both efficiency and effectiveness in bug detection. Furthermore, we integrate IMMI with a LLM to augment its code interpretation capabilities. When applied to the Linux kernel, IMMI successfully uncovered 80 new memory bugs, comprising 57 memory leaks and 23 memory corruptions, while maintaining a false discovery rate of only 35%. Our evaluation demonstrates that IMMI is both scalable and proficient at detecting Linux kernel memory bugs.

Table 5: LLM prompt example. The red-highlighted words within the prompt message are generated by the static analysis of `IMMI`.

Description	Prompt messgaes
Prompt message	You are now a program static analysis expert. Your following analysis is based on the following function: [code of devm_register_dax_mapping] We define "error path" in a function as follows: A sequence of basic blocks that finally returns a non-zero number or null pointer. Note that if a call returns error but the path finally does not return a negative number or null pointer, this path is not an error path. A heap memory "mapping" is allocated through "mapping = kzalloc(sizeof(*mapping), GFP_KERNEL);" Please identify all of the LATER error paths after the allocation. Then, please analyze whether all of these paths have freed the heap memory. Pay attention to the implicit kernel memory release operations. Your final conclusion should be a seperate line like: [Conclusion: Answer], "Answer" should only be "yes" or "no".
Reply from LLM	Analyzing the function "devm_register_dax_mapping", we can identify the error paths that occur after the allocation of heap memory for "mapping" with "kzalloc". We need to check if the allocated memory is properly freed on each error path. 1. The first error path is when "ida_alloc" fails (returns a negative number). In this case, the allocated memory for "mapping" is freed with "kfree(mapping)" before returning "-ENOMEM". 2. The second error path is when "device_add" fails (returns a non-zero number). In this case, "put_device(dev)" is called, which will eventually lead to the release of the device and the associated memory. Since "dev" points to "mapping->dev", and "mapping" is embedded within the "struct device", the memory for "mapping" will be freed when the device is put. 3. The third error path is when "devm_add_action_or_reset" fails (returns a non-zero number). In this case, the function returns "rc" directly. However, "devm_add_action_or_reset" is designed to automatically clean up resources by executing the provided action ("unregister_dax_mapping") if the device managed by "devm" is removed or if the driver is unloaded. This means that if "devm_add_action_or_reset" fails, it will not add the cleanup action, but since "device_add" has already succeeded at this point, the device's release function will be called when the device is removed, which should take care of freeing the "mapping" memory. Based on the above analysis, all error paths after the allocation of "mapping" have mechanisms to free the allocated heap memory, either explicitly with "kfree" or implicitly through the device management functions. [Conclusion: yes]

Near-Optimal Constrained Padding for Object Retrievals with Dependencies

Pranay Jain

Abstract

The sizes of objects retrieved over the network are powerful indicators of the objects retrieved and are ingredients in numerous types of traffic analysis, such as webpage fingerprinting. We present an algorithm by which a benevolent object store computes a memoryless padding scheme to pad objects before sending them, in a way that bounds the information gain that the padded sizes provide to the network observer about the objects being retrieved. Moreover, our algorithm innovates over previous works in two critical ways. First, the computed padding scheme satisfies constraints on the padding overhead: no object is padded to more than $c\times$ its original size, for a tunable factor $c > 1$. Second, the privacy guarantees of the padding scheme allow for object retrievals that are not independent, as could be caused by hyperlinking. We show in empirical tests that our padding schemes improve dramatically over previous schemes for padding dependent object retrievals, providing better privacy at substantially lower padding overhead, and over known techniques for padding independent object retrievals subject to padding overhead constraints.

1 Introduction

Extracting information about the contents of encrypted traffic from other features of the traffic, or so-called *traffic analysis*, is a topic with a long history and that remains relevant today in the context of, e.g., webpage fingerprinting (see Sec. 2). Among the most difficult network-visible features to obscure is the size of objects transmitted over the network, since thoroughly doing so incurs substantial cost. For this reason, even many systems designed to support private or anonymous communication do not attempt to address this side channel [16, 32, 45, 52] or assume it away by stipulating that messages be small and fixed-size (e.g., [1, 14]).

The premise of this paper is that the research community can facilitate the adoption of *pretty good* defenses against traffic analysis by benevolent—but perhaps not generous—service providers, by first constraining the costs that will be incurred by the service provider for providing privacy and then enabling the service provider to implement the best privacy protections possible subject to those cost constraints. To that end, in this paper we consider a specific but broadly relevant instance of this problem: an object store that serves objects in response to client requests. We seek to equip the object store with a scheme for padding objects before returning them to clients (encrypted) so as to best hide from a network observer which objects are returned to clients, while adhering to the constraint that the padding can increase each object to at most $c\times$ its original size for a specified constant $c > 1$. Since we allow the network observer to be a client of the object store, as well, we presume the observer knows all of the original object sizes, before padding.

Reed and Reiter [43] recently addressed exactly this problem in the case of *independent* object retrievals, as will be detailed in Sec. 2. However, there are few, if any, practical circumstances in which object retrievals are truly independent. Perhaps the most prominent reason is hyperlinking between objects, as between web objects, which can result in one object being retrieved after another (either automatically or by user action) in a causal fashion. Even when not causally related, retrievals in most applications will exhibit correlations, e.g., based on the topic to which the objects pertain. Unfortunately, achieving an optimal padding scheme (to achieve some well-defined notion of privacy) for *dependent* object retrievals is a challenging problem, as demonstrated by a limited literature rife with heuristic solutions only (again, see Sec. 2).

In this paper we take a significant step forward for the case of dependent object retrievals, by providing and evaluating an efficient algorithm to generate a *padding scheme* for an object store. This padding scheme prescribes how to pad objects before serving them, to hide the object identities from a network observer able to see their padded sizes. The measure of leakage that we use in this work is the Sibson mutual information of order infinity, denoted $\mathbb{I}_\infty(\mathsf{S};\mathsf{Y})$ and defined in Sec. 4, where S is a random variable representing the secret (i.e., the object(s) retrieved) and Y is a random variable

representing what the adversary observes (i.e., the padded object size(s)). Issa, et al. [26] advocate for this measure of leakage because it bounds the information gain $\mathbb{I}(\mathsf{S};\mathsf{Y})$ that Y provides to the adversary (i.e., $\mathbb{I}(\mathsf{S};\mathsf{Y}) \leq \mathbb{I}_\infty(\mathsf{S};\mathsf{Y})$) regardless of the distribution of S and because it has a natural operational interpretation [26]. We reiterate that our efforts to minimize $\mathbb{I}_\infty(\mathsf{S};\mathsf{Y})$ are provided subject to a constraint that no object be padded to more than $c\times$ its original size, for a tunable constant $c > 1$. As such, the object store's bandwidth use—per retrieval, per client, and overall—will grow by at most a factor of c. Moreover, the padding scheme produced by our algorithm is memoryless, and so the object store need not track a client's retrievals to know how to pad objects for it.

We demonstrate the practicality of our algorithm by applying it to three real-world datasets and comparing the padding scheme it produces to other padding schemes in the literature for protecting the identities of objects retrieved from being leaked by their padded sizes [5, 34, 35]. While these other schemes were designed to achieve different privacy measures, we nevertheless show that the scheme produced by our algorithm, measured using *their* measures of privacy, provides competitive results with far less padding overhead. We also show that for our measure of privacy, the schemes in previous works fare poorly compared to ours, even while incurring orders of magnitude greater padding overhead. The datasets on which we demonstrate these improvements were chosen to be representative of ones in which dependent object retrievals are commonplace, namely a dataset of autocomplete lists sent in response to increasingly long sequence of characters (which is typical in search engines), and two datasets of hyperlinked web objects.

To reiterate, our contributions are as follows:

- We devise an efficient algorithm to generate a padding scheme that prescribes how to pad objects before serving them in response to requests. The resulting padding scheme approximately minimizes (specifically, minimizes an upper bound on) $\mathbb{I}_\infty(\mathsf{S};\mathsf{Y})$, for object retrievals S padded to sizes Y, subject to constraints that it be memoryless and that no object be padded to more than $c\times$ its original size for a specified constant $c \geq 1$.

- We introduce three object datasets with dependencies among object retrievals: a Google Autocomplete dataset that models suggestions for search queries; a Wikipedia dataset that models a dense graph of interconnected pages; and a Linode documentation dataset that models a tree-like browsing pattern, where a user navigates to a particular page on a website by starting at the index. On these datasets, we show empirically that our algorithm produces padding schemes that substantially outperform previous work. Even in comparisons to previous algorithms on different privacy measures *they* were designed to optimize, our algorithm achieves comparable privacy with dramatically lower (and bounded) padding overhead. In comparisons that test an adversary's precision and recall in identifying sequences of object retrievals, our algorithm provides better security in most cases, with the same or lower padding overhead.

2 Related Work

The study of padding schemes that minimize information leakage about the objects being retrieved is a topic that has received considerable attention in the literature. There are two camps of closely related work, one focused on privacy for dependent object retrievals (as we consider here) but without constraints on padding overhead, and another that allows for constraints on padding overhead (as we do here) but assuming independent object retrievals. We introduce these areas of related work below, and then elaborate on several more distantly related areas of research.

2.1 Dependent object retrievals

Padding schemes that attempt to reduce leakage about the objects retrieved when retrievals are dependent have been studied for about the past decade, to our knowledge. Backes, et al. [5] proposed one design that assumes that object retrievals satisfy a Markov assumption, i.e., that the client's next object retrieval is only dependent on the object it most recently retrieved. The measure of leakage that they seek to minimize is $\mathbb{I}(\mathsf{S};\mathsf{Y})$, though they do so only heuristically. Liu, et al. proposed methods to render sequences of retrieved object sizes either k-anonymous [44, 48], meaning that at least k objects are padded to every possible padded size [35], or ℓ-diverse [37], meaning that no object accounts for more than $\frac{1}{\ell}$ of any padded size's probability [34]. None of these algorithms, however, accommodate the specification of padding overhead constraints. Indeed, the Liu, et al. algorithms [34,35] are generally not consistent with a padding constraint c if, e.g., there is an object for which the allowed padding range does not intersect the allowed padding ranges of $k-1$ other objects. We show in our experiments that the overhead they therefore impose is dramatic on the datasets we consider.

2.2 Padding overhead constraints

To our knowledge, object padding schemes subject to padding overhead constraints as we consider here have received attention primarily within the last several years (e.g., [12, 40, 43]). The latest work in this area [43] proposes algorithms to generate padding schemes that optimally hide objects from a network observer in several cases of interest: for an object store that pads its objects once but serves them repeatedly, a padding scheme that is deterministic and that minimizes information gain $\mathbb{I}(\mathsf{S};\mathsf{Y})$ among all deterministic schemes; for an object store that can re-pad objects each time it serves them, a padding scheme that is probabilistic and that minimizes

$\mathbb{I}(\mathsf{S};\mathsf{Y})$; and for an object store that cannot trust (or does not wish to track) the distribution of object retrievals, a padding scheme that minimizes $\mathbb{I}_\infty(\mathsf{S};\mathsf{Y})$. This last algorithm, called PwoD, provides a close comparison point for our work, since it targets the same leakage measure (i.e., $\mathbb{I}_\infty(\mathsf{S};\mathsf{Y})$) and adopts the same form of padding overhead constraint. However, the guarantees of these algorithms hinge on object retrievals being independent, which is exactly the assumption we intend to relax in this paper.

2.3 Webpage fingerprinting

More distantly related work includes research in webpage fingerprinting, by which a network adversary attempts to discern the webpage or website that a client is visiting, based on traffic features the attacker can observe. Some works have explored padding of web objects as a defense against such traffic analysis (e.g., [12, 47]) but, to our knowledge, no such work has shown how to maximize privacy (by a precise measure) subject to a bandwidth overhead constraint, as we do here. The vast majority of the research in webpage fingerprinting is specific to the networking context via which the web objects are transferred to the client, leveraging features—for attack or defense—of TCP and/or HTTP (e.g., [36, 47]), HTTPS (e.g., [2, 11, 15, 19, 39]); web proxies (e.g., [24, 47]); SSH proxies (e.g., [6, 33]); or Tor (e.g., [7, 12, 22, 23, 27, 41, 49, 50]). We stress that our research focuses specifically on object sizes, allowing this feature to be discernible to the network attacker, whatever the network context. Our study therefore addresses a central challenge in defending against webpage fingerprinting [17], though by no means the only one [51].

2.4 Untrusted object store

In our threat model (see Sec. 3), the object store is trusted. A substantial body of literature, in contrast, addresses a threat model wherein the object store is itself the adversary from which the secret should be hidden (e.g., [8, 21, 25, 30, 31]). For example, in *private information retrieval* [13], this secret is the object retrieved, whereas in *searchable encryption* [46], the secret is the search term resulting in the retrieval of a set of objects. This threat model is more permissive than ours and so typically requires tools to address it that are different in nature, and that are more expensive, than we consider here, including introducing fake queries (e.g., [20, 38, 42]); breaking retrievals into multiple fixed-size queries of total size larger than the original object and so that themselves are padded (e.g., [28, 29]); or using oblivious RAMs (e.g., [4, 9, 10, 18]). In contrast, our approach does not alter the communication pattern between the client and object store, aside from padding each object to within a factor of c of its original size.

3 Problem Statement

We consider a trusted object store that stores n fixed-size objects $\{\mathsf{obj}_s\}_{s\in S}$ where $\#S = n$ (and $\#S$ denotes the cardinality of S), and serves them to clients over encrypted channels. Each client request contains the identifier s of the object to return, which we presume to be of constant size. Objects themselves, however, can be of different sizes; in symbols, if $|\mathsf{obj}_s|$ denotes the size of object obj_s, then for $s \neq s'$, it can be the case that $|\mathsf{obj}_s| \neq |\mathsf{obj}_{s'}|$. Even though objects are returned on encrypted channels, the size of each object (as transmitted, after padding) will be revealed to our adversary, a network observer. This network observer seeks to identify which objects were retrieved by a client, given their sequence of padded sizes. Since we allow the network observer to also be a client of the object store and so to retrieve objects itself, the adversary knows the unpadded size $|\mathsf{obj}_s|$ of each obj_s.

3.1 Padding scheme

Our goal is to provide an algorithm to compute a *padding scheme* $\lceil\cdot\rceil$ for $\{\mathsf{obj}_s\}_{s\in S}$. Formally, $\lceil\cdot\rceil$ takes as input an object identifier s and an object size $|\mathsf{obj}_s|$ and produces a padded object size (a positive integer) with properties defined below. To emphasize that padding will be applied to this object before transmission, we denote this invocation of $\lceil\cdot\rceil$ by simply $\lceil\mathsf{obj}_s\rceil$, and when convenient, we will also use $\lceil\mathsf{obj}_s\rceil$ to denote the padded object or its size. The padding scheme $\lceil\cdot\rceil$ is itself randomized, and so repeated invocations of it with the same object (i.e., same object identifier and size) can return different results. Moreover, since s is an input to $\lceil\cdot\rceil$, $\lceil\mathsf{obj}_s\rceil$ can behave differently from $\lceil\mathsf{obj}_{s'}\rceil$ even if obj_s and $\mathsf{obj}_{s'}$ are of the same size.

The padding scheme $\lceil\cdot\rceil$ that our algorithm will solve for should be *memoryless* in the sense that the object store does not need to track each user's retrieval history in order to implement the padding scheme. We believe that this ensures that our technique is as broadly implementable as possible. First, there is the obvious cost saving for not having to store every user's retrieval history. Second, our technique is "privacy-friendly," i.e., it will work if an object store cannot store the retrieval history of its users, whether that is due to (i) government regulation, (ii) privacy-aware tools employed by the user, or (iii) as a feature of the object store itself.

Let S be a random variable denoting the identifier of the object a client retrieved from the object store, and let Y be a random variable denoting the size to which it was padded when retrieved; i.e., Y takes the value $\lceil\mathsf{obj}_s\rceil$ when $\mathsf{S} = s$. Our first requirement, discussed in Sec. 1, is that padding never grow an object by a factor of more than c, for a padding factor $c \geq 1$.

$$\mathbb{P}\big(\mathsf{Y} > c \times |\mathsf{obj}_s| \;\big|\; \mathsf{S} = s\big) = 0 \tag{1}$$

In addition, we assume that objects cannot be compressed

before their transmission over the network, and so

$$\mathbb{P}\big(\mathsf{Y} < |\mathsf{obj}_s| \;\big|\; \mathsf{S} = s\big) = 0 \tag{2}$$

While numerous networking technologies *do* compress data before transmitting it, we presume that the same network-stack layer that pads the object then encrypts it, rendering the object incompressible by network layers underneath it.

Before we present the privacy goals for the padding scheme $\lceil\cdot\rceil$ in Sec. 3.2, note that due to (1)–(2), it might not be possible for the padding scheme to protect the privacy of all object retrievals. That is, if one object obj_s is of a size such that $[|\mathsf{obj}_s|, c\times|\mathsf{obj}_s|] \cap [|\mathsf{obj}_{s'}|, c\times|\mathsf{obj}_{s'}|] = \emptyset$ for each other object $\mathsf{obj}_{s'}$, then (1)–(2) leave no option but for obj_s to be the only possible object being retrieved when a retrieval of size $\lceil\mathsf{obj}_s\rceil$ is observed on the network. This observation informs the privacy goal we adopt in Sec. 3.2.

In the remainder of this paper, we treat mathematical expressions in which c or $c-1$ is a factor to be integers. In particular, for notational simplicity, we omit the floor function when writing $c\times|\mathsf{obj}_s|$, $(c-1)\times|\mathsf{obj}_s|$, etc., and simply treat them as integers.

3.2 Privacy measure

We would like to produce a padding scheme so that sequential invocations of $\lceil\cdot\rceil$ leak as little about the identities of the requested objects as possible, subject to the constraints on the padding scheme discussed in Sec. 3.1. Issa, et al. [26] argue that the leakage about the value of a discrete random variable S with support S by observing the value of another random variable Y is best captured by

$$\mathbb{I}_\infty(\mathsf{S};\mathsf{Y}) = \log_2 \sum_y \max_{s\in S} \mathbb{P}\big(\mathsf{Y} = y \;\big|\; \mathsf{S} = s\big) \tag{3}$$

Both Issa, et al. [26] and Alvim, et al. [3] advocate for the use of $\mathbb{I}_\infty(\mathsf{S};\mathsf{Y})$ as a measure of leakage as it upper-bounds an adversary's multiplicative gain in correctly guessing any function of S after observing Y, over all distributions of S.

To highlight that we are concerned here with *sequences* of possibly dependent object retrievals, we extend (3) to sequences. Specifically, let $\vec{S} \subseteq S^*$ be a set of sequences of object retrievals, let $\vec{s} \in \vec{S}$ denote a sequence of object retrievals, and let $\vec{\mathsf{S}}$ be a random variable with support $\vec{S}$. (We assume $\mathbb{P}\Big(\vec{\mathsf{S}} = \vec{s}\Big) > 0$ for all $\vec{s} \in \vec{S}$.) We denote the i-th element of a sequence $\vec{s}$ by $\vec{s}_i$, and the length of $\vec{s}$ by $\mathrm{len}(\vec{s})$.

For each $s \in S$, let

$$Y_s \subseteq [|\mathsf{obj}_s|, c\times|\mathsf{obj}_s|] \tag{4}$$

be the padded object sizes that we allow for $\lceil\mathsf{obj}_s\rceil$. While Y_s might be all of $[|\mathsf{obj}_s|, c\times|\mathsf{obj}_s|]$, it need not be, and indeed we will leverage this flexibility in Sec. 4. We define

$$\vec{Y}_{\vec{s}} = Y_{\vec{s}_1} \times \cdots \times Y_{\vec{s}_{\mathrm{len}(\vec{s})}} \tag{5}$$

$$\vec{Y} = \bigcup_{\vec{s}\in\vec{S}} \vec{Y}_{\vec{s}} \tag{6}$$

In words, $\vec{Y}_{\vec{s}}$ is the set of all possible sequences to which $\vec{s}$ could be padded, and $\vec{Y}$ is the set of all possible padded sequences. Finally, let $\vec{\mathsf{Y}}$ be a random variable taking on a sequence of padded sizes. Given this notation, we interpret (3) in our context as

$$\mathbb{I}_\infty\Big(\vec{\mathsf{S}};\vec{\mathsf{Y}}\Big) = \log_2 \sum_{\vec{y}\in\vec{Y}} \max_{\vec{s}\in\vec{S}} \mathbb{P}\big(\vec{\mathsf{Y}} = \vec{y} \;\big|\; \vec{\mathsf{S}} = \vec{s}\big) \tag{7}$$

Our goal, then, is to produce a padding scheme $\lceil\cdot\rceil$ that minimizes (7).

4 Design

In this section we present a linear program that minimizes an upper-bound on $\mathbb{I}_\infty\Big(\vec{\mathsf{S}};\vec{\mathsf{Y}}\Big)$. We then describe a technique that allows us to reduce the number of variables in the linear program, thereby enabling it to run more efficiently on large datasets.

4.1 Linear program

Below, we denote the i-th element of a sequence $\vec{y}$ by $\vec{y}_i$, and the i-th element of a sequence taken on by random variables $\vec{\mathsf{S}}$ and $\vec{\mathsf{Y}}$ by $\vec{\mathsf{S}}_i$ and $\vec{\mathsf{Y}}_i$, respectively. For any $\vec{y}$ and $\vec{s}$ of the same length, and any $i' \in [\mathrm{len}(\vec{y})] = \{1,\ldots,\mathrm{len}(\vec{y})\}$,

$$\prod_{i=1}^{\mathrm{len}(\vec{y})} \mathbb{P}\big(\vec{\mathsf{Y}}_i = \vec{y}_i \;\big|\; \vec{\mathsf{S}}_i = \vec{s}_i\big) \le \mathbb{P}\big(\vec{\mathsf{Y}}_{i'} = \vec{y}_{i'} \;\big|\; \vec{\mathsf{S}}_{i'} = \vec{s}_{i'}\big) \tag{8}$$

since each probability is ≤ 1. By summing (8) over $i' \in [\mathrm{len}(\vec{y})]$, we can conclude

$$\mathrm{len}(\vec{y}) \prod_{i=1}^{\mathrm{len}(\vec{y})} \mathbb{P}\big(\vec{\mathsf{Y}}_i = \vec{y}_i \;\big|\; \vec{\mathsf{S}}_i = \vec{s}_i\big) \le \sum_{i'=1}^{\mathrm{len}(\vec{y})} \mathbb{P}\big(\vec{\mathsf{Y}}_{i'} = \vec{y}_{i'} \;\big|\; \vec{\mathsf{S}}_{i'} = \vec{s}_{i'}\big) \tag{9}$$

As a result, we can upper-bound (7) as

$$\mathbb{I}_\infty\Big(\vec{\mathsf{S}};\vec{\mathsf{Y}}\Big) = \log_2 \sum_{\vec{y}\in\vec{Y}} \max_{\vec{s}\in\vec{S}} \prod_{i=1}^{\mathrm{len}(\vec{y})} \mathbb{P}\big(\vec{\mathsf{Y}}_i = \vec{y}_i \;\big|\; \vec{\mathsf{S}}_i = \vec{s}_i\big) \tag{10}$$

$$\le \log_2 \sum_{\vec{y}\in\vec{Y}} \max_{\vec{s}\in\vec{S}} \frac{1}{\mathrm{len}(\vec{y})} \sum_{i'=1}^{\mathrm{len}(\vec{y})} \mathbb{P}\big(\vec{\mathsf{Y}}_{i'} = \vec{y}_{i'} \;\big|\; \vec{\mathsf{S}}_{i'} = \vec{s}_{i'}\big) \tag{11}$$

where (10) follows from (7) because our padding scheme is memoryless and (11) follows from (10) by substituting (9).

$$\text{minimize} \sum_{\vec{y}\in\vec{Y}} \Pi^{\vec{y}} \quad \text{subject to} \tag{12}$$

$$\sum_{y\in Y_s} \pi_s^y = 1 \qquad \forall s \in S \tag{13}$$

$$\pi_s^y \geq 0 \qquad \forall s \in S, y \in Y_s \tag{14}$$

$$\pi_s^y \leq 1 \qquad \forall s \in S, y \in Y_s \tag{15}$$

$$\Pi^{\vec{y}} \geq \frac{1}{\text{len}(\vec{y})} \sum_{i=1}^{\text{len}(\vec{y})} \pi_{\vec{s}_i}^{\vec{y}_i} \qquad \forall \vec{s} \in \vec{S}, \vec{y} \in \vec{Y}_{\vec{s}} \tag{16}$$

Figure 1: LP to minimize (11).

We formulate a linear program (LP) to minimize (11). It uses a variable π_s^y to represent $\mathbb{P}\big(\mathsf{Y} = y \;\big|\; \mathsf{S} = s\big)$, and a variable $\Pi^{\vec{y}}$ to represent $\max_{\vec{s}\in\vec{S}} \frac{1}{\text{len}(\vec{y})} \sum_{i'=1}^{\text{len}(\vec{y})} \mathbb{P}\big(\vec{\mathsf{Y}}_{i'} = \vec{y}_{i'} \;\big|\; \vec{\mathsf{S}}_{i'} = \vec{s}_{i'}\big)$. This LP is shown in Fig. 1. Constraints (13)–(15) ensure that π_s^y forms a probability distribution for each $s \in S$. Constraint (16), together with the minimization objective (12), ensure that a solution to the LP sets $\Pi^{\vec{y}}$ to its intended value. Once solved, the object store can instantiate a padding scheme $\lceil\cdot\rceil$ by padding obj_s to size y (i.e., $\lceil \mathsf{obj}_s \rceil = y$) with probability π_s^y; i.e., $\mathbb{P}\big(\mathsf{Y} = y \;\big|\; \mathsf{S} = s\big) \leftarrow \pi_s^y$.

Note that any two distinct sequences $\vec{s}, \vec{s}' \in \vec{S}$, even if of the same length ($\text{len}(\vec{s}) = \text{len}(\vec{s}')$) and consisting of the same objects ($\{\vec{s}_i\}_{i\in[\text{len}(\vec{s})]} = \{\vec{s}'_i\}_{i\in[\text{len}(\vec{s}')]}$), will result in a constraint of the form (16) for every $\vec{y} \in \vec{Y}_{\vec{s}} \cap \vec{Y}_{\vec{s}'}$. That is, our LP optimizes the probabilities of padded sequences based on both length and the order of object sequences that can pad to them.

4.2 Efficiency

The LP presented in Sec. 4.1 has $\#Y_s$ variables π_s^y for each $s \in S$. The LP also includes one variable $\Pi^{\vec{y}}$ for each $\vec{y} \in \vec{Y}$; recall that $\#\vec{Y}$ also depends on $\#Y_s$ for $s \in S$ (see (5)–(6)). As such, reducing $\#Y_s$ for each s is central to scaling this LP. At the same time, the values in Y_s must be chosen to maximize the intersection with other $Y_{s'}$ sets, subject to each of these sets being small (and subject to (1)–(2)), so that the LP has the opportunity to pad objects to the same size.

To accomplish these contradictory goals, we consider the *anchor sizes* of the object set, defined as follows. Let X represent the set of all unpadded sizes; i.e., $x \in X$ implies that there exists an object for which $|\mathsf{obj}_s| = x$. For any $X' \subseteq X$, define the *anchor sizes* $A(X')$ inductively as follows:

$$A\big(X'\big) = \{a\big(X'\big)\} \cup A\big(X' \setminus B\big(X'\big)\big) \quad \text{where} \tag{17}$$

$$a\big(X'\big) = \min X' \quad \text{and} \tag{18}$$

$$B\big(X'\big) = \{x' \in X' : x' \leq c \times a\big(X'\big)\} \tag{19}$$

In words, the anchor sizes of X' include the smallest unpadded object size of X' (see (18)) and the anchor sizes of the set remaining after removing all sizes at most c times this anchor size (see (17), (19)). Note that for any two $a, a' \in A(X)$, it will be the case that $[a, c\times a] \cap [a', c\times a'] = \emptyset$.

For a fixed parameter $k \geq 1$, we select up to k candidate padding sizes $\hat{Y}_a$ from $[a, c\times a]$ of approximately equal distance apart. Specifically, we select

$$\hat{Y}_a = \{a + zq + \min\{z, r\}\}_{z\in[k]} \tag{20}$$

where $(c-1)a = qk + r$ and $0 \leq r < k$. Then, we set

$$Y_s = [|\mathsf{obj}_s|, c\times|\mathsf{obj}_s|] \cap \bigcup_{a\in A} \hat{Y}_a \tag{21}$$

No Y_s is empty, since at least $c \times a \in Y_s$ for the largest anchor size $a \in A(X)$ such that $a \leq |\mathsf{obj}_s|$. Moreover, for any $s \in S$, there are at most two anchor sizes $a, a' \in A(X)$ such that $[|\mathsf{obj}_s|, c\times|\mathsf{obj}_s|] \subseteq [a, c\times a] \cup [a', c\times a']$. So, $\#Y_s \leq 2k$, ensuring that $\#Y_s$ is small. Finally, by limiting each Y_s to elements of $\bigcup_{a\in A} \hat{Y}_a$, we encourage common padding sizes for objects.

For the remainder of this paper we refer to our LP as Padding for Sequences (PFS).

5 Evaluation

In this section we begin by describing the datasets that we created for our assessments and then present three algorithms for padding objects to which we compare. We compare PFS to each of them according to their intended privacy metric and others. We conclude the section with an assessment of the padding overhead that results from each algorithm's padding scheme for each dataset.

5.1 Datasets

For our experiments, we constructed three datasets. We constructed these datasets to be representative of datasets used to evaluate previous padding schemes and to provide significant variations in object sizes and numbers of sequences.

Each dataset consists of (i) a selection of objects from a given object store, which we denote $\{\mathsf{obj}_s\}_{s\in S}$; (ii) the set of possible sequences of object retrievals $\vec{S}$; and (iii) distributions $\mathbb{P}(\mathsf{S} = s)$, $\mathbb{P}\Big(\vec{\mathsf{S}}_{1\ldots i} = \vec{s}_{1\ldots i}\Big)$, and $\mathbb{P}\Big(\vec{\mathsf{S}}_{i+1} = s' \;\Big|\; \vec{\mathsf{S}}_i = s\Big)$, since some algorithms to which we compare require these distributions. Below, we let E denote the set of directed edges in the sequences $\vec{S}$, i.e., $E = \Big\{(s, s') \;\Big|\; \exists \vec{s} \in \vec{S}, i \in [\text{len}(\vec{s}) - 1] : \vec{s}_i = s \wedge \vec{s}_{i+1} = s'\Big\}$.

For each dataset, in order to create $\vec{S}$, we first created a set of maximal length sequences which we denote as $\vec{S}^{\Omega}$. We then created $\vec{S}$ as

$$\vec{S} = \bigcup_{\vec{s}\in\vec{S}^{\Omega}} \bigcup_{i\in[\text{len}(\vec{s})]} \{\vec{s}_{1\ldots i}\} \tag{22}$$

where $\vec{s}_{1\ldots i}$ represents the subsequence of $\vec{s}$ up to, and including, the i-th object. In words, $\vec{S}$ is the prefix closure of $\vec{S}^{\Omega}$. Finally, for each $i \in [\max_{\vec{s}\in\vec{S}^{\Omega}} \text{len}(\vec{s})]$ we calculate $\mathbb{P}\left(\vec{\mathsf{S}}_{1\ldots i} = \vec{s}_{1\ldots i}\right)$ as

$$\mathbb{P}\left(\vec{\mathsf{S}}_{1\ldots i} = \vec{s}_{1\ldots i}\right) = \frac{\sum_{\vec{s}'\in\vec{S}^{\Omega}:\vec{s}'_{1\ldots i}=\vec{s}_{1\ldots i}} \mathsf{count}(\vec{s}')}{\sum_{\vec{s}''\in\vec{S}^{\Omega}:\text{len}(\vec{s}'')\geq i} \mathsf{count}(\vec{s}'')} \tag{23}$$

In (23), for each $\vec{s} \in \vec{S}^{\Omega}$ we use $\mathsf{count}(\vec{s})$ to represent a dataset-specific statistic from which we can calculate a distribution.

Google Autocomplete dataset This dataset was created in January 2023 and models the distribution of responses from Google search autocomplete suggestions. For a given search string, Google responds with a list of autocomplete suggestions for each prefix of the string. To obtain these autocomplete responses, we wrote a script that takes a list of words as input and queries the Google autocomplete API for each successive prefix of each word. The dictionary of words was obtained from xkcd Simple Writer[1], a dataset containing the 1,000 most common English words. In this dataset, each $s \in S$ is a prefix of a word, and obj_s is Google's autocomplete response for that prefix. Each $(s,s') \in E$, then, represents two consecutive queries of word prefixes in which s' extends s by one character and in which s' is a prefix of some word in the dataset. We define $\vec{S}^{\Omega}$ to contain each sequence $\vec{s}$ of prefixes of increasing length (i.e., $\vec{s}_i$ is a word prefix of i characters) such that $\vec{s}_{\text{len}(\vec{s})}$ is a word in the dataset. In total, after omitting plurals of words that are formed by simply adding the letter 's', for this dataset $\#\vec{S}^{\Omega} = 899$ words, $\#S = 3{,}870$ word prefixes, and $\#E = 3{,}846$ word prefix extensions. Moreover, $\#\vec{S} = \#S$ since each $s \in S$ is a prefix of a word and since $\vec{S}$ is the prefix closure of $\vec{S}^{\Omega}$.

In addition to S and E, the method of Backes, et al. [5] also requires the transition probabilities between word prefixes, i.e., an actual value for $\mathbb{P}\left(\vec{\mathsf{S}}_{i+1} = s' \mid \vec{\mathsf{S}}_i = s\right)$ for each $(s,s') \in E$. We model this using the technique they proposed, which uses the number of search results returned by Google for a given word $\vec{s}_{\text{len}(\vec{s})}$ as the value for $\mathsf{count}(\vec{s})$, and then $\mathbb{P}\left(\vec{\mathsf{S}}_{i+1} = s' \mid \vec{\mathsf{S}}_i = s\right)$ is estimated as

$$\mathbb{P}\left(\vec{\mathsf{S}}_{i+1} = s' \mid \vec{\mathsf{S}}_i = s\right) = \frac{\sum_{\vec{s}'\in\vec{S}^{\Omega}:\vec{s}'_{i+1}=s'\wedge\vec{s}'_i=s} \mathsf{count}(\vec{s}')}{\sum_{\vec{s}\in\vec{S}^{\Omega}:\vec{s}_i=s} \mathsf{count}(\vec{s})} \tag{24}$$

Wikipedia dataset This dataset was created in June 2023 and models pages retrieved during web surfing. It was created by selecting $s =$ `https://en.wikipedia.org/wiki/Cat` to obtain the HTML of the web page as obj_s. We then selected the first 50 hyperlinks (to articles) on this page and included those in S, retrieving the HTML of the web page for each. We repeated this step once more for these added pages, but increased the number of hyperlinks that we added from those pages to the first 100. We increased from 50 to 100 hyperlinks to help increase the reach of this dataset, as we observed that the articles had many common hyperlinks.

This initial step yielded a set of $\#S = 2{,}804$ articles. To then create the set of sequences $\vec{S}^{\Omega}$, for each $s \in S$, we generated two random walks of length six that both begin at s as the start vertex. This resulted in $\#\vec{S}^{\Omega} = 5{,}606$ unique sequences of webpages that a user might explore while browsing among the articles included in S with an associated $\#E = 10{,}182$ hyperlinks. Taking the prefix closure of these sequences then yielded $\#\vec{S} = 32{,}683$.

For this dataset, we used the Wikipedia Page Views API to instantiate $\mathsf{count}(\vec{s})$ for each $\vec{s} \in \vec{S}^{\Omega}$. To do so, we retrieved the total number of page views for each $s \in S$ for January 2016, which we denote as $\mathsf{pv}(s)$. For each $\vec{s} \in \vec{S}^{\Omega}$ we then set $\mathsf{count}(\vec{s})$ equal to its average page views, i.e.,

$$\mathsf{count}(\vec{s}) = \frac{\sum_{i=1}^{\text{len}(\vec{s})} \mathsf{pv}(\vec{s}_i)}{\text{len}(\vec{s})} \tag{25}$$

Finally, we instantiated $\mathbb{P}\left(\vec{\mathsf{S}}_{i+1} = s' \mid \vec{\mathsf{S}}_i = s\right)$ for each $(s,s') \in E$ as

$$\mathbb{P}\left(\vec{\mathsf{S}}_{i+1} = s' \mid \vec{\mathsf{S}}_i = s\right) = \frac{1}{\#\{\hat{s} : (s,\hat{s}) \in E\}} \tag{26}$$

We reiterate that this dataset only captures the size of each article's HTML file. We address this limitation with our next dataset, though we stress that our goal for all of our datasets is to enable a meaningful comparison of candidate padding algorithms (described below) based on the privacy they achieve and padding overhead they induce. Our goal is not to make specific claims about privacy in the context of Wikipedia retrievals, for example.

Linode dataset As with the Wikipedia dataset, this dataset models pages retrieved during web surfing where S represents webpages and E represents hyperlinks between webpages. It was created by crawling the Linode documentation website[2] in April 2020. A difference from the Wikipedia dataset, though, is that in the Linode dataset $|\text{obj}_s|$ represents the total sum of data for the given page's HTML file and all the hyperlinked objects that would be retrieved automatically (images, scripts, etc.).

Another difference between our Wikipedia and Linode datasets is the way in which we generated maximal length sequences. Let $s_{\text{home}} =$ `https://www.linode.com/docs`. Then, for each $s \in S \setminus \{s_{\text{home}}\}$ we include in $\vec{S}^{\Omega}$ all shortest paths from s_{home} to s. In other words, $\vec{s} \in \vec{S}^{\Omega}$ iff: (i) $\vec{s}_1 = s_{\text{home}}$, (ii) $\vec{s}_{\text{len}(\vec{s})} \neq s_{\text{home}}$, and (iii) $\vec{s}$ is a shortest path. This dataset therefore models a user that begins at the Linode documentation homepage and then navigates to a destination page

[1] `https://xkcd.com/simplewriter/words.js`

[2] The crawl included every webpage and linked-to file where the URL began with https://www.linode.com/docs.

Table 1: Dataset statistics.

Statistic	Autocomplete	Wikipedia	Linode
$\min_{s\in S}\lvert\mathsf{obj}_s\rvert$	11B	36,425B	438B
$\text{median}_{s\in S}\lvert\mathsf{obj}_s\rvert$	330B	203,310B	101,325B
$\max_{s\in S}\lvert\mathsf{obj}_s\rvert$	480B	1,745,780B	15,406,625B
$\#S$	3,870	2,804	1,569
$\#\vec{S}^{\Omega}$	899	5,606	2,095
$\#\vec{S}$	3,870	32,683	2,096
$\#E$	3,846	10,182	2,029

by clicking as few links as possible. The dataset contains $\#S = 1{,}569$ webpages, $\#\vec{S}^{\Omega} = 2{,}095$ unique sequences of webpages, and $\#E = 2{,}029$ links between webpages. Since the sequences in this dataset are all shortest paths, taking the prefix closure of $\vec{S}^{\Omega}$ only yields one additional sequence: the sequence of length one that consists of s_{home}.

As this dataset does not have an accompanying Page Views API, for each $\vec{s} \in \vec{S}^{\Omega}$ we set $\mathsf{count}(\vec{s}) = 1$ and we instantiated $\mathbb{P}\left(\vec{\mathsf{S}}_{i+1} = s' \;\middle|\; \vec{\mathsf{S}}_i = s\right)$ for each $(s,s') \in E$ as

$$\mathbb{P}\left(\vec{\mathsf{S}}_{i+1} = s' \;\middle|\; \vec{\mathsf{S}}_i = s\right) = \frac{1}{\#\{\hat{s} : (s,\hat{s}) \in E\}} \tag{27}$$

Dataset statistics In Table 1 we list various statistics for each of our datasets. The Linode dataset presents the widest variation of object sizes, ranging across five orders of magnitude, despite it having the fewest number of objects ($\#S$) of any of the datasets. The Wikipedia dataset stands out as having both the largest $\#\vec{S}^{\Omega}$ and $\#\vec{S}$ since our strategy for creating this dataset ensured that it consisted of a large number of maximal length sequences which do not share prefixes.

5.2 Comparison algorithms

Here we detail the three algorithms to which we compare. We selected these algorithms as they each target a different privacy metric, and so comparing to all three provides a robust assessment of PFS.

BDK Backes, et al. [5] propose an algorithm to create a deterministic (i.e., per-object) padding scheme $\lceil\cdot\rceil$ such that, for any padded sizes $y, y' \in Y$ and any $s, s' \in S$ such that $\lceil\mathsf{obj}_s\rceil = \lceil\mathsf{obj}_{s'}\rceil = y$,

$$\sum_{\substack{\hat{s}\in S:\\ \lceil\mathsf{obj}_{\hat{s}}\rceil = y'}} \mathbb{P}\left(\vec{\mathsf{S}}_{i+1} = \hat{s} \;\middle|\; \vec{\mathsf{S}}_i = s\right) = \sum_{\substack{\hat{s}\in S:\\ \lceil\mathsf{obj}_{\hat{s}}\rceil = y'}} \mathbb{P}\left(\vec{\mathsf{S}}_{i+1} = \hat{s} \;\middle|\; \vec{\mathsf{S}}_i = s'\right) \tag{28}$$

In other words, for any two objects obj_s and $\mathsf{obj}_{s'}$ that pad to size y, it must be equally likely for each that its retrieval will be followed by a retrieval padded to size y'. In the remainder of this paper, we refer to the Backes, et al. algorithm as "BDK".

BDK assumes that the generation of object retrieval sequences can be modeled as a Markov chain (i.e., that the distribution over the next object retrieved depends only on the previous). Subject to this assumption, it efficiently calculates entropy $\mathbb{H}\left(\vec{\mathsf{Y}}\right)$ for any arbitrary sequence length. It therefore works by randomly producing many candidate per-object padding schemes $\lceil\cdot\rceil$ and then selecting the scheme $\lceil\cdot\rceil$ that produces the lowest $\mathbb{H}\left(\vec{\mathsf{Y}}\right)$ for a target average padding overhead. $\mathbb{H}\left(\vec{\mathsf{Y}}\right)$, then, serves as an upper-bound for $\mathbb{I}\left(\vec{\mathsf{S}};\vec{\mathsf{Y}}\right)$, i.e., the mutual information between $\vec{\mathsf{S}}$ and $\vec{\mathsf{Y}}$.

MVMD and MVMD-D Whereas BDK seeks to control $\mathbb{H}\left(\vec{\mathsf{Y}}\right)$—and thereby $\mathbb{I}\left(\vec{\mathsf{S}};\vec{\mathsf{Y}}\right)$—Liu, et al. [34, 35] propose techniques that strive to ensure different metrics, namely k-anonymity and ℓ-diversity. In the summary of these algorithms below, recall that we use the subscript $1\ldots i$ to indicate the subsequence of a sequence from the first through the i-th element, inclusive; e.g., $\vec{s}_{1\ldots i}$ represents the subsequence of $\vec{s}$ up to, and including, the i-th object. Similarly, $\vec{S}_{1\ldots i}$ represents the set of all such subsequences, and $\vec{\mathsf{S}}_{1\ldots i}$ represents the random variable over this set. Note that this notation will also be applied to $\vec{y}$, $\vec{Y}$, and $\vec{\mathsf{Y}}$ with the same interpretation.

Now, for the k-anonymity setting, a per-object padding scheme $\lceil\cdot\rceil$ is said to provide k-anonymity for sequences if, $\forall\vec{y} \in \vec{Y}$ such that $\mathbb{P}\left(\vec{\mathsf{Y}} = \vec{y}\right) > 0$, and $\forall i \in [\text{len}(\vec{y})]$, it holds that $\#\{s \in S : \mathbb{P}\left(\vec{\mathsf{S}}_i = s \;\middle|\; \vec{\mathsf{Y}}_{1\ldots i} = \vec{y}_{1\ldots i}\right) > 0\} \geq k$. That is, if an adversary were to observe the first i padded object sizes, there must be $\geq k$ possible objects that could be $\vec{s}_i$. For the ℓ-diversity setting, a padding scheme $\lceil\cdot\rceil$ is said to provide ℓ-diversity for sequences if, $\forall\vec{y} \in \vec{Y}$ such that $\mathbb{P}\left(\vec{\mathsf{Y}} = \vec{y}\right) > 0$, $\forall i \in [\text{len}(\vec{y})]$, and $\forall s \in S$ such that $\mathbb{P}\left(\vec{\mathsf{S}}_i = s \;\middle|\; \vec{\mathsf{Y}}_{1\ldots i} = \vec{y}_{1\ldots i}\right) > 0$, it holds that $\mathbb{P}\left(\vec{\mathsf{S}}_i = s \;\middle|\; \vec{\mathsf{Y}}_{1\ldots i} = \vec{y}_{1\ldots i}\right) \leq \frac{1}{\ell}$. That is, if an adversary were to observe the first i padded objects sizes, the conditional probability of each object that could be $\vec{s}_i$ must be $\leq \frac{1}{\ell}$.

For both settings, Liu, et al. present greedy algorithms that attempt to create per-object padding schemes $\lceil\cdot\rceil$ that ensure either k-anonymity or ℓ-diversity, and that also attempt to minimize the sum of padding overhead applied to objects. We refer to these algorithms as MVMD and MVMD-D, respectively, and when parameterizing MVMD-D with a target ℓ, we refer to the algorithm as MVMD-ℓ. So, for example, when parameterized with a target $\ell = 3$, we refer to the algorithm as MVMD-3. Roughly, the MVMD and MVMD-D algorithms iterate through each $i \in [\max_{\vec{s}\in\vec{S}}\text{len}(\vec{s})]$ and—for each $\vec{S}' \subseteq \vec{S}$ where for every $\vec{s} \in \vec{S}'$ it is the case that $\vec{s}_{1\ldots i-1}$ is padded to the same $\vec{y}_{1\ldots i-1}$—construct $\lceil\cdot\rceil$ so that $\vec{S}'_i = \bigcup_{\vec{s}\in\vec{S}'}\{\vec{s}_i\}$ is split into two subsets that remain either k-anonymous or ℓ-diverse, and that do so with minimal total overhead. Since the algorithms are greedy, they are not guaranteed to create

Table 2: Inputs required per algorithm.

Algorithm	Sets			Distributions		
	S	$\vec{S}$	E	$\mathbb{P}(\mathsf{S}=s)$	$\mathbb{P}\left(\vec{\mathsf{S}}_{1\ldots i}=\vec{s}_{1\ldots i}\right)$	$\mathbb{P}\left(\vec{\mathsf{S}}_{i+1}=s' \middle\vert \vec{\mathsf{S}}_i=s\right)$
BDK [5]	✓		✓	✓		✓[3]
MVMD-D [34]	✓	✓			✓	
PwoD [43]	✓					
PFS	✓	✓				

the padding scheme $\lceil\cdot\rceil$ that minimizes the padding overhead for a given k or ℓ. Furthermore, there are instances where k-anonymity or ℓ-diversity cannot be achieved, either due to their algorithms making a greedy choice at i that prevents upholding k or ℓ at $i' > i$, or simply because the distribution $\vec{\mathsf{S}}_{1\ldots i}$ is not distributed in a way that supports the chosen metric. In such cases, these algorithms will construct $\lceil\cdot\rceil$ so that all $s \in \vec{S}'_i$ (which cannot be split further) will be padded to the same y.

Note that ℓ-diversity subsumes k-anonymity, in that an ℓ-diverse padding scheme is also ℓ-anonymous. In our security evaluations we compare only to the MVMD-D algorithm, as the more challenging (i.e., more secure) competitor.

Finally, for both MVMD and MVMD-D, $\lceil\cdot\rceil$ is a function of both $\mathsf{obj}_{\vec{s}_i}$ and $\{\mathsf{obj}_{s'}\}_{s'\in\vec{s}_{1\ldots i-1}}$; i.e., the resulting padding schemes are not memoryless, as are the other algorithms we consider (including our LP). Thus, an object store that uses either of these algorithms must be capable of (i) tracking a client's previous object retrievals and (ii) storing a value for $\lceil\mathsf{obj}_s\rceil$ for each $\vec{s}_{1\ldots i-1} \in \vec{S}_{1\ldots i-1}$ such that $\mathbb{P}\left(\vec{\mathsf{S}}_i = s \;\middle|\; \vec{\mathsf{S}}_{1\ldots i-1} = \vec{s}_{1\ldots i-1}\right) > 0$.

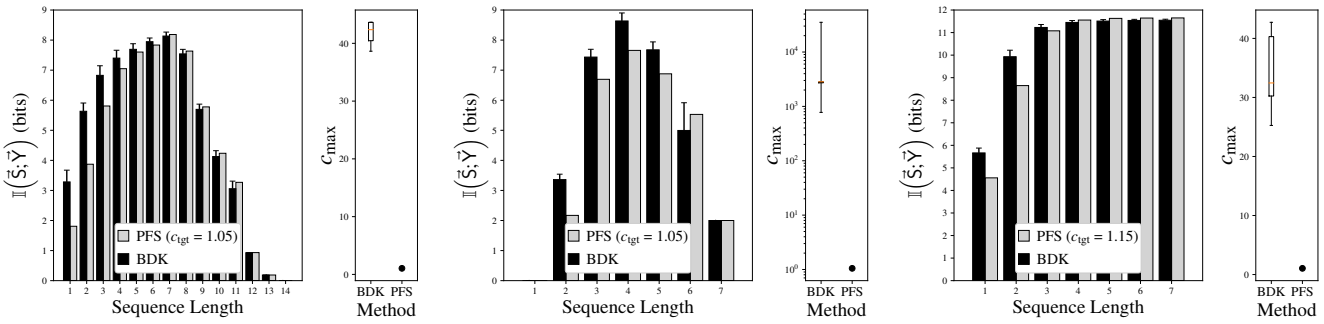
PwoD Reed and Reiter [43] present an algorithm, called Padding without a Distribution (PwoD), that produces a per-object padding scheme $\lceil\cdot\rceil$ minimizing $\mathbb{I}_\infty(\mathsf{S};\mathsf{Y})$ for the case of independent object retrievals. Also, unlike BDK and MVMD-D, PwoD enforces constraint (1). We therefore include PwoD as an algorithm to which we compare.

Summary of algorithm inputs To summarize, Table 2 shows the inputs taken by each of the algorithms to which we compare, and the inputs taken by our own. BDK and MVMD-D require more detailed information than PFS, in that they require probability distributions. Still, below we will show that PFS outperforms them, in terms of both privacy and padding overhead. PwoD requires less information be input than PFS, but as we will show, PFS puts its knowledge of the sequences $\vec{S}$ to good use.

[3] Backes, et al. assume $\mathbb{P}\left(\vec{\mathsf{S}}_{i+1} = s' \;\middle|\; \vec{\mathsf{S}}_i = s\right)$ is the same for all i.

5.3 BDK and MVMD-D comparisons

Since both BDK and MVMD-D were designed to address a different metric, in this section we compare PFS against these two algorithms in "head-to-head" tests using the competitor's metric.[4] For each test, we calculated the competitor's metric over increasing sequence lengths for each of our three datasets. Specifically, for each $i \in [\max_{\vec{s}\in\vec{S}^\Omega} \text{len}(\vec{s})]$, the metric was calculated over all $\vec{s} \in \vec{S}^\Omega$ such that $\text{len}(\vec{s}) \geq i$. Additionally, at each i, those sequences that are longer than i were truncated to i and then the metrics were calculated over these truncated sequences. This method is consistent with our calculation of $\mathbb{P}\left(\vec{\mathsf{S}}_{1\ldots i} = \vec{s}_{1\ldots i}\right)$ in (23).



We calculated the various metrics in this way in order to model the adversary's knowledge *as the adversary observed sequential object retrievals*. For example, if the adversary observed i retrievals, then the adversary knew that $\vec{s}$ could not be any sequence where $\text{len}(\vec{s}) < i$, and so those sequences were no longer included when calculating the given metric. However, it could be the case that $\vec{s}$ was longer than i, and so those sequences were included when calculating the metric.

As mentioned in Sec. 1, the premise of our work is to enable an object store to provide privacy for its clients while simultaneously constraining the amount of padding overhead applied to each object that it serves. Therefore, in addition to comparing PFS against each algorithm using the algorithm's intended privacy metric, we also calculated the maximum pad factor c resulting from the competitor's padding scheme $\lceil\cdot\rceil$. We will leverage $c_{\max}$ when referring to this *resultant* c produced by a padding scheme $\lceil\cdot\rceil$ and c_{tgt} when referring to the *target* c that is provided as an input parameter to PFS. We do this to enable a comparison between the cost (in terms of overhead) of PFS to that of each competitor when "competing" on each of their privacy metrics.

Finally, note that for all tests in Sec. 5, we set our efficiency parameter $k = 2$. We describe the effect of varying k in Sec. 6.

BDK For our comparison to BDK [5], we measured against $\mathbb{I}\left(\vec{\mathsf{S}};\vec{\mathsf{Y}}\right)$, as this is the metric it is designed to reduce. As mentioned in Sec. 5.2, BDK is designed to be run multiple times to produce candidate solutions for $\lceil\cdot\rceil$, from which an object store would then select the most suitable $\lceil\cdot\rceil$ in terms of privacy and padding overhead. To model this intended usage, for each dataset we ran BDK 1,000 times and, for each $i \in [\max_{\vec{s}\in\vec{S}^\Omega} \text{len}(\vec{s})]$, we plot the minimum and maximum values (the bar and whisker extending above the bar, respectively) for $\mathbb{I}\left(\vec{\mathsf{S}};\vec{\mathsf{Y}}\right)$ across all 1,000 candidate padding schemes $\lceil\cdot\rceil$. For each padding scheme we also computed its $c_{\max}$ and plot these values as a box plot, to the right of the $\mathbb{I}\left(\vec{\mathsf{S}};\vec{\mathsf{Y}}\right)$ plot.

[4] We save the comparison to PwoD for Sec. 5.4. We do this because our chosen metric $\mathbb{I}_\infty\left(\vec{\mathsf{S}};\vec{\mathsf{Y}}\right)$ is the extension of $\mathbb{I}_\infty(\mathsf{S};\mathsf{Y})$—the privacy metric that PwoD minimizes—to our setting.

(a) Autocomplete (b) Linode (c) Wikipedia

Figure 2: Comparing PFS to BDK using $\mathbb{I}\left(\vec{S};\vec{Y}\right)$ as the privacy metric.

As shown in Fig. 2, BDK was outperformed by PFS with $c_{\text{tgt}} = 1.05$ for both the Autocomplete and Linode dataset, and for $c_{\text{tgt}} = 1.15$ for Wikipedia. This is despite BDK yielding ranges for $c_{\max}$ much higher than PFS. We attribute BDK's under-performance to the fact that the algorithm will not allow two objects to be padded to the same size if doing so would violate the strict equality in (28).

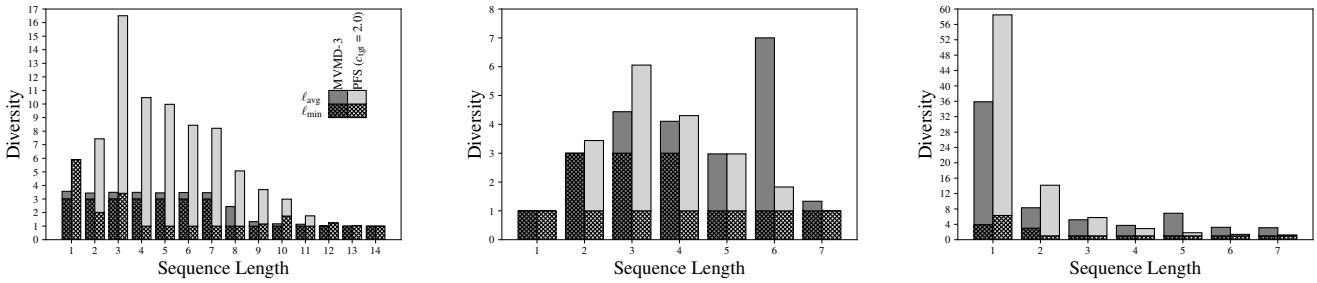
We draw attention to two trends in these plots. The first is that for both the Autocomplete and Linode datasets, the values for $\mathbb{I}\left(\vec{S};\vec{Y}\right)$ rise and then fall as the sequence length increases. This is attributable to the fact that the number of sequences of a given length begins to decrease at length 7 for Autocomplete and at length 4 for Linode. The second trend is that the results for $\mathbb{I}\left(\vec{S};\vec{Y}\right)$ for Wikipedia are non-decreasing. This is attributable to the fact that, since all sequences are of length 7, the information leaked about $\vec{S}$ cannot decrease as the sequence is extended.

MVMD-D For our comparison to MVMD-D [34], we assessed each algorithm's ability to ensure that ℓ-diversity is achieved. In this section, we use ℓ_{tgt} when referring to the *target* ℓ that was provided as an input parameter to MVMD-D. For these tests, we compared MVMD-D with $\ell_{\text{tgt}} = 3$ (i.e., MVMD-3) against PFS with $c_{\text{tgt}} = 2.0$. Additionally, in Fig. 3 we depict the results of our tests using (i) $\ell_{\min}$, which we define for a given i as

$$\min_{\vec{y}_{1\ldots i} \in \vec{Y}_{1\ldots i}} \frac{1}{\max_{s \in S} \mathbb{P}\left(\vec{S}_i = s \;\middle|\; \vec{Y}_{1\ldots i} = \vec{y}_{1\ldots i}\right)} \tag{29}$$

and which is equivalent to Liu, et al.'s [34] definition of ℓ (see Sec. 5.2), and (ii) ℓ_{avg}, which we define for a given i as

$$\frac{\sum_{\vec{y}_{1\ldots i} \in \vec{Y}_{1\ldots i}} \frac{1}{\max_{s \in S} \mathbb{P}\left(\vec{S}_i = s \;\middle|\; \vec{Y}_{1\ldots i} = \vec{y}_{1\ldots i}\right)}}{\#\vec{Y}_{1\ldots i}} \tag{30}$$



We define ℓ_{avg} in this way as it enables us to describe how privacy-preserving an algorithm's resultant padding scheme $\lceil\cdot\rceil$ was across all $\vec{y}_{1\ldots i} \in \vec{Y}_{1\ldots i}$, even if the algorithm failed to achieve ℓ-diversity in the strict sense. This is helpful even when assessing MVMD-D, as it is not guaranteed to yield a padding scheme that respects its ℓ_{tgt}.

In Fig. 3, we see that, for $c_{\text{tgt}} = 2$, PFS was generally unable to achieve $\ell_{\min} > 1$. When we broaden our analysis to gauge how well PFS achieved ℓ_{avg}, we see that PFS provided roughly the same, and in some cases much better, ℓ_{avg} than MVMD-3 for the objects in our datasets. Moreover, PFS offered this protection for $c_{\max}$ that was far less than MVMD-3's. Indeed, the $c_{\max}$ for each of MVMD-3's padding schemes $\lceil\cdot\rceil$ was similar to that of BDK across each of the three datasets. Finally, we see that even MVMD-3 yielded $\ell_{\min} = 1$ for each of the three datasets, starting at lengths 8, 5, and 3 for Autocomplete, Linode, and Wikipedia, respectively.

5.4 $\mathbb{I}_\infty\left(\vec{S};\vec{Y}\right)$ comparisons

In this section we compare each algorithm against our chosen metric $\mathbb{I}_\infty\left(\vec{S};\vec{Y}\right)$. Since both PwoD and PFS take c as input, for this test we ran both algorithms with $c_{\text{tgt}} \in \{1.05, 1.25, 1.5, 2.0\}$ for each of our three datasets. For BDK we compare to a single run of the algorithm, and for MVMD-D we compare to MVMD-3. The results are shown in Fig. 4.

In both Fig. 4a and Fig. 4b we observe that, as c_{tgt} increased, there was a trend that PFS performed increasingly better than PwoD until $c_{\text{tgt}} = 2.0$, at which point PFS and PwoD performed similarly. Indeed, for $c_{\text{tgt}} = 1.5$, in Fig. 4b, PFS yielded $\mathbb{I}_\infty\left(\vec{S};\vec{Y}\right)$ that is 7.4% lower than PwoD for length 4, and in Fig. 4a, PFS yielded $\mathbb{I}_\infty\left(\vec{S};\vec{Y}\right)$ that is 24.2% lower than PwoD for length 8. Also, we see that BDK was not competitive in either Fig. 4a or Fig. 4b, and that MVMD-3 was not competitive in Fig. 4a but was competitive in Fig. 4b for only the longest sequences. This is despite both BDK and MVMD-3 yielding values for $c_{\max}$ that were much larger than

(a) Autocomplete (MVMD-3 $c_{\max} = 31.73$) (b) Linode (MVMD-3 $c_{\max} = 5707.33$) (c) Wikipedia (MVMD-3 $c_{\max} = 43.07$)

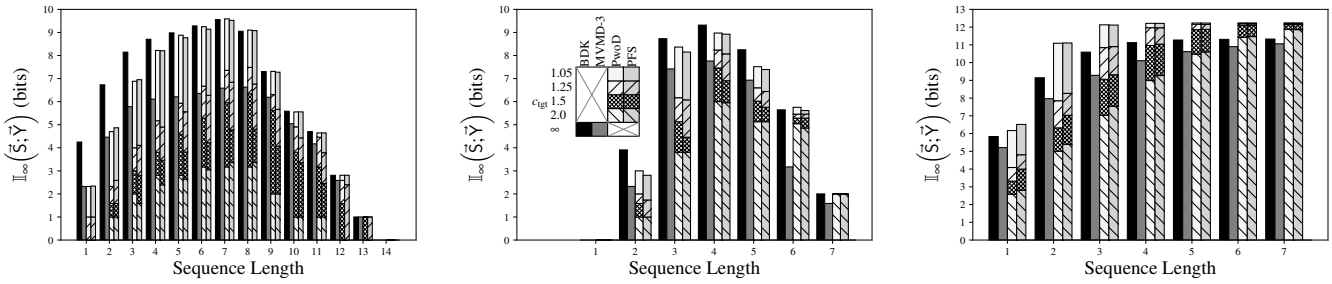
Figure 3: Comparing PFS to MVMD-3 using ℓ-diversity as the privacy metric.

PFS (see Fig. 2 and Fig. 3).

In Fig. 4c we observe that PwoD performed slightly better than PFS for short sequences. However, by length 5, the difference is only noticeable for $c_{\text{tgt}} = 2.0$, and by length 7, PFS yielded lower values for $\mathbb{I}_\infty\left(\vec{S};\vec{Y}\right)$ for $c_{\text{tgt}} = \{1.05, 1.25, 2.0\}$ (though in all cases PFS and PwoD differed by ≤ 0.01bits). We also see that both BDK and MVMD-3 were competitive for longer sequence lengths, though we reiterate that their solutions for $\lceil\cdot\rceil$ yielded large values for $c_{\max}$.

Although PwoD performed well on our three datasets—and indeed comparable to PFS on the Wikipedia dataset—it is possible for PwoD to perform arbitrarily worse than PFS as the length of sequences increase. To demonstrate this point, we created a synthetic dataset as follows. We first created 256 sequences, each of $\text{len}(\vec{s}) = 8$, i.e., each sequence represents eight successive object retrievals. For these first 256 sequences, the sizes of the objects were assigned one of $\{1\text{B}, 2\text{B}\}$ so that the resultant sequences yield all of the binary combinations from $[0, 255]$. In addition to these 256 sequences, we added a single sequence where each object in the sequence is 3B. We then created another 256 sequences as before, but whose objects were assigned one of $\{20\text{B}, 21\text{B}\}$. Finally, we added a single sequence where each object in the sequence is 10B. Thus, for our synthetic dataset $\#\vec{S}^{\Omega} = 514$.

Given this synthetic dataset, we set $c_{\text{tgt}} = 2.0$. In this case, $\mathbb{I}_\infty\left(\vec{S};\vec{Y}\right)$ is minimized when $\lceil\cdot\rceil$ pads all objects of size $\{1\text{B}, 2\text{B}\}$ to 2B and all objects of size $\{20\text{B}, 21\text{B}\}$ to 21B. This causes the smallest 256 sequences to be indistinguishable from each other, as well as the largest 256 sequences, leaving only the 3B-sequence and 10B-sequence isolated. Indeed, PFS yielded this solution for $\lceil\cdot\rceil$. The $\lceil\cdot\rceil$ given by PwoD, however, padded all objects of size $\{2\text{B}, 3\text{B}\}$ to 3B, thereby leaving the smallest 256 sequences identifiable. As shown in Fig. 5, this caused $\mathbb{I}_\infty\left(\vec{S};\vec{Y}\right)$ for PwoD to increase linearly as the sequence length increased, whereas the $\mathbb{I}_\infty\left(\vec{S};\vec{Y}\right)$ for PFS remained constant at 2 bits.



PwoD struggled against this dataset since, by default, it iterates through object sizes from largest-to-smallest, thereby assigning objects that are 20B to be padded to 21B, and objects that are 2B to be padded to 3B. However, simply running PwoD from smallest-to-largest would yield a similarly suboptimal $\lceil\cdot\rceil$, as then PwoD would pad all objects of size $\{10\text{B}, 20\text{B}\}$ to 20B, thus leaving the *largest* 256 sequences identifiable.

5.5 Attacker's recall and precision

One challenge of minimizing $\mathbb{I}_\infty\left(\vec{S};\vec{Y}\right)$ in our algorithm is that this measure might be less familiar and understandable than others. To put the benefits of our algorithm into a form that might be more understandable, in this section we report the results of a study that demonstrates the privacy that our algorithm and others' achieve, in terms of the *precision* and *recall* with which a network adversary can identify sequences of interest when retrieved.

For this study, we assumed that the adversary had a set of *target* sequences $\vec{S}^{\odot} \subset \vec{S}^{\Omega}$ that it aimed to identify by observing the padded (and encrypted) traffic. The adversary observed a sequence of padded objects up to a given length m—to include the m-length prefixes of those sequences in $\vec{S}$ that are longer than m—and afterwards determined whether this sequence corresponded to a sequence from its target set $\vec{S}^{\odot}$. More specifically, upon observing a sequence $\vec{s}$ of object retrievals padded to sizes $\vec{y}$, the attacker can calculate $\mathbb{P}\left(\vec{S} \in \vec{S}^{\odot} \;\middle|\; \vec{Y} = \vec{y}\right)$ for any $\vec{S}^{\odot}$ of interest. For any threshold τ, the adversary returned *true* iff $\mathbb{P}\left(\vec{S} \in \vec{S}^{\odot} \;\middle|\; \vec{Y} = \vec{y}\right) \geq \tau$. For a given τ, the adversary's *recall* is the fraction of sequences from $\vec{S}^{\odot}$ for which the adversary returned *true*, and the adversary's *precision* is the fraction of its *true* detections for which the sequence was in $\vec{S}^{\odot}$.

We conducted the precision-recall tests as follows. For a given dataset and sequence length m, an individual trial consisted of randomly selecting 5% of the elements of $\vec{S}^{\Omega}$ of length m to constitute $\vec{S}^{\odot}$. We ran 100 such trials and we present the precision-recall curves as the average over these 100 trials. In the context of this study, lower values of the adversary's precision and recall indicate a more secure padding algorithm.

(a) Autocomplete (b) Linode (c) Wikipedia

Figure 4: Comparing all algorithms using $\mathbb{I}_\infty(\vec{S};\vec{Y})$ as the privacy metric.

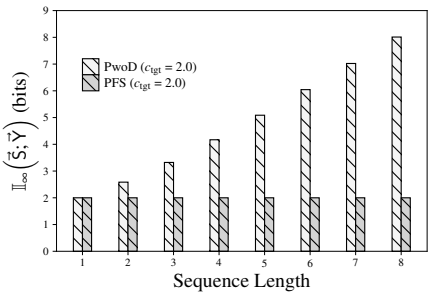


Figure 5: Comparing PFS to PwoD on the synthetic dataset.

Results for Autocomplete are depicted in Fig. 6. For this dataset, we tested at sequence lengths of 7, 8, and 9. For each of these lengths, the dataset consisted of a sufficiently large number of words to model an adversary's target set. As shown in Fig. 6, at all three lengths, PFS yielded the lowest precision and recall values. The only exception is with sequences of length 7, where MVMD-3 achieved better precision and recall values for two values of τ. Furthermore, it is evident from the plots that as the sequences grow longer, the performance of PFS increased relative to that of the other algorithms. Indeed, for sequences of length 8 and 9, PFS performed significantly better than the competitors. Moreover, an apparent trend in this dataset is that, whereas the adversary's performance against PFS was fairly consistent, the adversary improved against the other algorithms as the sequence length increased.

Fig. 7 shows the results of the precision-recall study on the Linode dataset. For this experiment, we chose sequences of length 3, as a majority of the sequences in the dataset were of length 3. In this experiment, we see that PFS achieved the lowest values of adversarial precision and recall, again beating out the competitors, though PwoD produced results that were competitive with PFS.

Fig. 8 shows the results of the precision-recall study on the Wikipedia dataset. This dataset was constructed such that all sequences have length 7. For this experiment, we found that higher values for c_{tgt} were needed to significantly reduce the adversary's performance, and so we set $c_{tgt} = 2.0$ for both PFS and PwoD. Still, despite this large value for c_{tgt}, we show in Sec. 5.6 that even this choice of c_{tgt} resulted in much lower padding overhead than BDK and MVMD-3. Overall, as shown in Fig. 8, PFS and PwoD yielded similar results, both offering better security than MVMD-3 and BDK.

5.6 Padding overhead

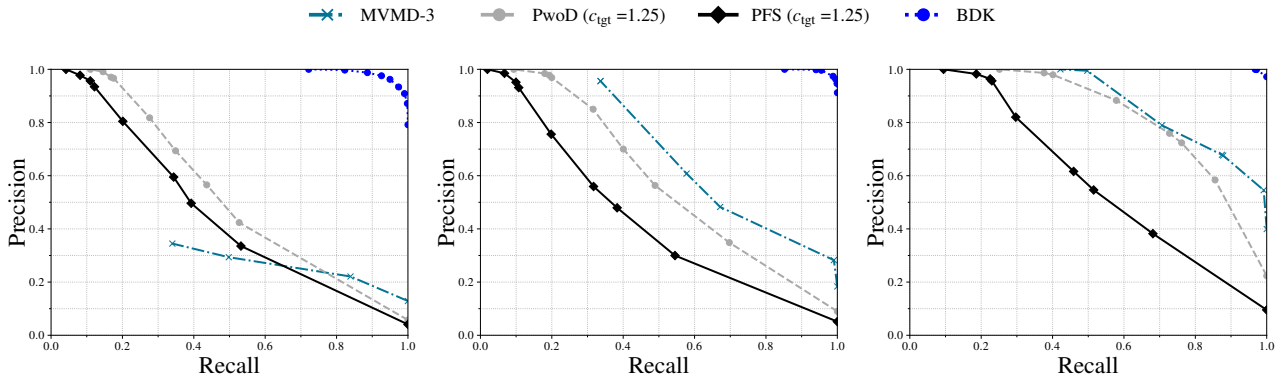

Fig. 9 depicts the padding factors produced by each algorithm, where the x-axis shows c_{max}, the maximum padding factor across all objects in the dataset, and the y-axis shows c_{avg}, the mean value of the padding factors across the dataset. We calculated c_{avg} as

$$\frac{\sum_{s\in S}\sum_{y\in Y}\mathbb{P}\left(\lceil \mathsf{obj}_s \rceil = y \;\middle|\; \mathsf{S}=s\right)\times \frac{y}{|\mathsf{obj}_s|}}{\#S} \tag{31}$$

Unsurprisingly, both BDK and MVMD-D produced significantly higher values for c_{max} across all three datasets, as neither place any constraints on the padding size. On the other hand, c_{max} for both PFS and PwoD are constrained by c_{tgt}, and thus were close to the chosen value of this parameter. Regarding c_{avg}, on the Autocomplete dataset, BDK and MVMD-D yielded comparable results to PFS and PwoD since the distribution of object sizes in this dataset varies less than the others; most of the objects are in the range of 200B to 480B. For the Linode and Wikipedia datasets, though, using either BDK or MVMD-D would cause the object store's objects to grow substantially in size, and would likely be impractical to implement.

6 Execution Cost

In this section, we evaluate the execution cost of PFS on the datasets described in Sec. 5. We begin with a description of our experiments and their results in Sec. 6.1 and then describe a much faster, and nearly as good, alternative in Sec. 6.2.

(a) Sequence length = 7 (b) Sequence length = 8 (c) Sequence length = 9

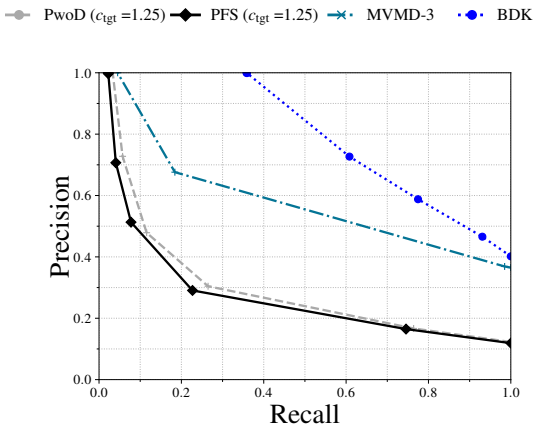

Figure 7: Adversary's recall and precision for detecting sequences of length 3 from the Linode dataset.

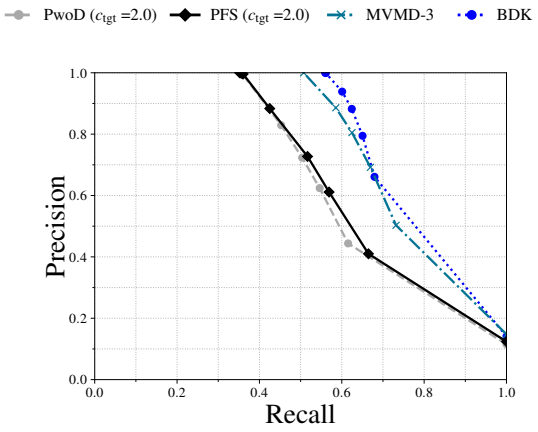

Figure 8: Adversary's recall and precision for detecting sequences of length 7 from the Wikipedia dataset.

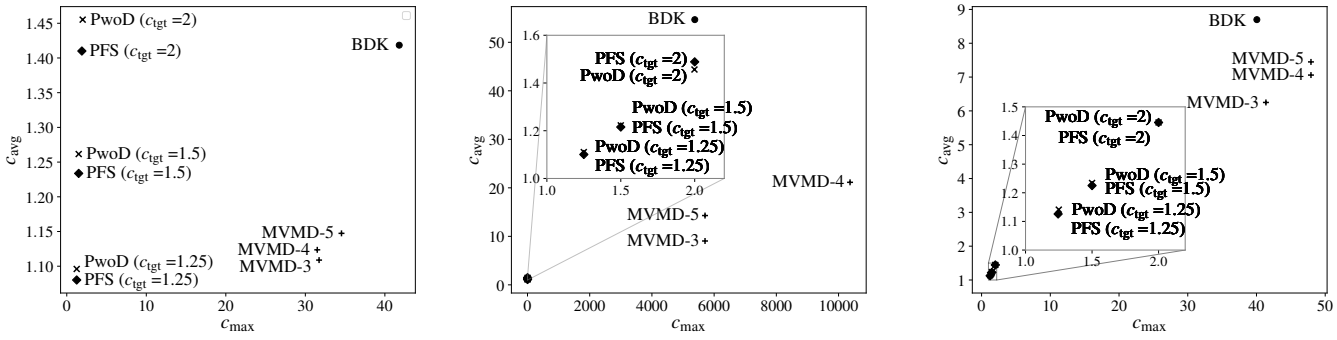
6.1 Runtime of PFS

We implemented PFS with the Gurobi Optimizer[5] and ran tests on a server with a 24-core CPU and 128GB of memory. For each dataset, for $c_{tgt} \in \{1.01, 1.05, 1.1, 1.25, 1.5, 2.0\}$, and for $k \in \{2, 3\}$, we ran PFS and measured the time it took for PFS to (i) create the model, (ii) run the optimization, and (iii) return $\lceil \cdot \rceil$. For $k = 2$ we ran each test 10 times and report the average runtimes; for $k = 3$ we ran each test a single time. Our results are shown in Fig. 10.

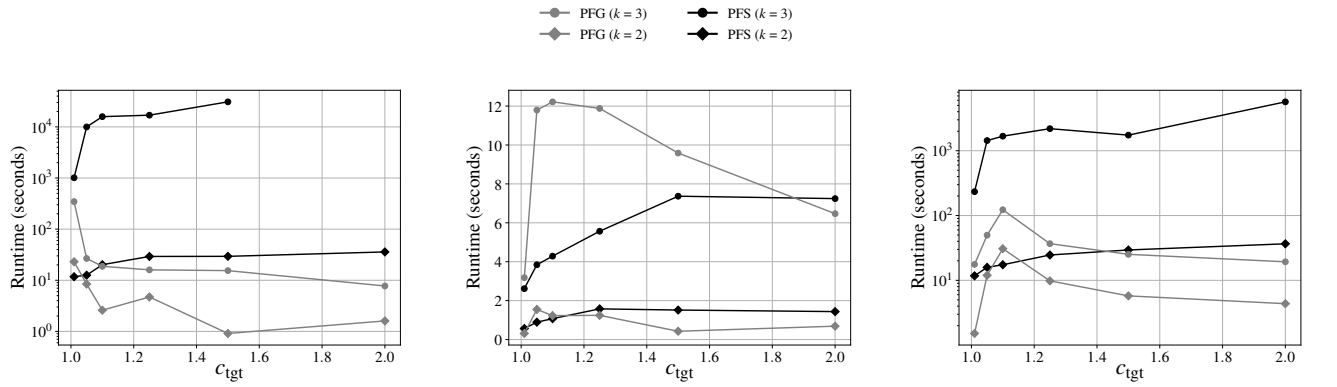
Our runtime results demonstrate that on some datasets PFS (with $k = 2$) was able to quickly produce $\lceil \cdot \rceil$, e.g., under 2 seconds for Linode (Fig. 10b), and so could be run as objects are added to the object store or their sizes are modified. On those datasets where PFS takes longer to produce $\lceil \cdot \rceil$, PFS could be run on a scheduled basis and applied as batch updates to the object store.



Our results also depict the challenge of increasing k. For instance, in Fig. 10a and Fig. 10c, $k = 3$ resulted in runtimes that were orders of magnitude longer than $k = 2$. Additionally, for Autocomplete (Fig. 10a), the results for PFS with $c_{tgt} = 2.0$ are not plotted as the memory requirements exceeded the capacity of our test setup.

6.2 Alternative Approach: PFG

As just described, PFS is costly for large datasets. Moreover, not all object stores may be able to produce $\vec{S}$, e.g., if it is not possible to enumerate all $\vec{s} \in \vec{S}$ or if $\#\vec{S}$ is too large to work with. For those object stores, so long as they can produce both S and E,[6] an alternative approach is to create the set $S \cup E$, i.e., treat each $s \in S$ as a sequence of length 1 and each $(s, s') \in E$ as a sequence of length 2, and then give this set in place of $\vec{S}$ to the LP from Fig. 1 without any further modifications. The rationale for this approach is that S and E together form a directed graph, from which $\vec{S}$ can be seen as a subset of the walks possible in this graph. Thus, this approach targets the



[5] https://www.gurobi.com

[6] An example of such an object store might be a web server that can easily enumerate S, the pages that it serves, and E, the hyperlinks between pages.

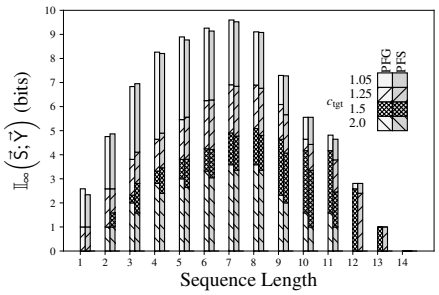
Figure 10: Model runtime for PFS and PFG as a function of c_{tgt}.

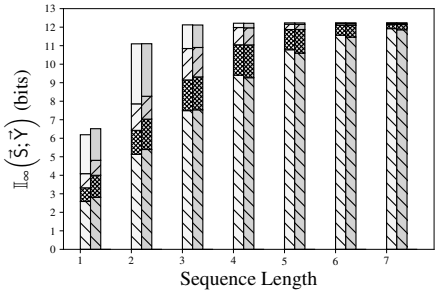
graph of objects and their dependencies in an effort to reduce $\mathbb{I}_\infty\left(\vec{S};\vec{Y}\right)$. We refer to this alternative method as Padding for Graphs (PFG).

We additionally executed PFG and show its performance results in Fig. 10, alongside those for PFS. Our results show that PFG is quite efficient overall. For all three datasets, PFG (with $k = 2$) yielded fast runtimes, with most tests finishing in under 10 seconds. Furthermore, our results show that, for the same k, PFG tended to beat PFS by a wide margin in our runtime evaluations, with the only exception being for Linode (Fig. 10b) with $k = 3$.



We also evaluated PFG to compare its privacy results to those of PFS, i.e., using the same tests as in Fig. 4. We present the results of this test in Fig. 11. (We do not present the results for the Linode dataset, as PFG yielded values for $\mathbb{I}_\infty\left(\vec{S};\vec{Y}\right)$ that were almost indistinguishable from PFS.)

In Fig. 11, we see that for both Autocomplete and Wikipedia, for $c_{tgt} \in \{1.25, 1.5\}$, PFG outperformed PFS for shorter sequences (up to length 5 for Autocomplete and length 4 for Wikipedia). This is particularly noteworthy for the Autocomplete dataset, given that PFS outperformed PwoD by quite a large margin for these same values of c_{tgt}. We attribute these results to the fact that PFG optimizes for short sequences (specifically, single-object and two-object sequences).



As sequence lengths increased, though, Fig. 11 shows that PFS began to outperform PFG. This is most apparent on the Autocomplete dataset for lengths ≥ 9. Still, these results demonstrate that if an object store is unable to use PFS (due to an inability to produce $\vec{S}$ or due to runtime concerns), it can still use PFG and leverage its knowledge of S and E to effectively reduce $\mathbb{I}_\infty\left(\vec{S};\vec{Y}\right)$.

7 Conclusion

In this paper, we provided an algorithm, PFS, that is able to efficiently produce a padding scheme $\lceil\cdot\rceil$ that an object store can use to conceal from a network observer the objects it serves to clients, despite the network observer leveraging object dependencies in its inferences. We compared PFS's security against prior algorithms, including on the security metrics that those algorithms themselves aim to optimize. We showed that PFS outperformed prior work while maintaining reason-

(a) Autocomplete

(b) Wikipedia

Figure 11: Comparing PFG to PFS with $k = 2$.

able constraints on the padding overhead. Compared to BDK, PFS achieved lower values for $\mathbb{I}\left(\vec{S};\vec{Y}\right)$ with little padding overhead; against PwoD, PFS achieved either comparable or lower values of $\mathbb{I}_\infty\left(\vec{S};\vec{Y}\right)$; and compared to MVMD-D, PFS achieved better diversity across all objects in each dataset, for less padding overhead. We also compared each algorithm by assessing an adversary's precision and recall as it predicted sequences of objects by observing their padded sizes. Our results showed that PFS was highly effective in such a setting, as it was consistently either among the top performers or beat the other algorithms by a wide margin. Most importantly, in all cases, PFS was constrained by the tunable padding factor c. By providing a configurable limit on the padding overhead, PFS is able to provide an object store with a means to pad sequences of objects that is both effective against a network observer and that is practical to implement. Finally, we provided a competitive alternative to PFS named PFG that is based on the same underlying LP, and which is suitable in settings where an object store is unable to generate $\vec{S}$ or doing so is too costly.

Abstract

While privacy-focused browsers have taken steps to block third-party cookies and mitigate browser fingerprinting, novel tracking techniques that can bypass existing countermeasures continue to emerge. Since trackers need to share information from the client-side to the server-side through link decoration regardless of the tracking technique they employ, a promising orthogonal approach is to detect and sanitize tracking information in decorated links. To this end, we present PURL (pronounced purel-l), a machine-learning approach that leverages a cross-layer graph representation of webpage execution to safely and effectively sanitize link decoration. Our evaluation shows that PURL significantly outperforms existing countermeasures in terms of accuracy and reducing website breakage while being robust to common evasion techniques. PURL's deployment on a sample of top-million websites shows that link decoration is abused for tracking on nearly three-quarters of the websites, often to share cookies, email addresses, and fingerprinting information.

1 Introduction

Web browsers and browser extensions are actively cracking down on new and emerging online tracking techniques. For example, almost all mainstream web browsers now already block or will soon block third-party cookies [1]–[3] and some privacy-focused browsers even deploy countermeasures against emerging tracking techniques, such as browser fingerprinting [4]–[6]. In response, online trackers continue to evolve and devise innovative tracking techniques that can bypass existing privacy-enhancing countermeasures [7]–[10]. The key limitation of existing privacy-enhancing tools is that they aim to mitigate specific types of tracking (e.g., third-party cookies, first-party cookies, email addresses, canvas fingerprinting, AudioContext fingerprinting, CNAME cloaking) [8], [11]–[13]. This approach works reasonably well to protect against known forms of tracking but fails against new or unknown forms of tracking, which routinely emerge from time to time [7], [10], [14], [15].

Our key insight is that trackers need to share information (e.g., user/device identifiers) from the client to the server side regardless of what type of tracking is employed. Therefore, we contend that a promising orthogonal approach to anti-tracking is to detect and block the sharing of tracking information in network requests. Trackers commonly include tracking information in "decorated" network request URLs (aka link decoration). Existing privacy-enhancing tools outright block network requests to endpoints using filter lists of known tracking services. However, a decorated link can include both tracking (e.g., user/device identifiers) and functional (e.g., CSRF tokens, identifying news/product subpages) information, which renders existing request blocking countermeasures ineffective – they risk breaking legitimate functionality as collateral damage if they block the request and risk allowing privacy-invasive tracking if they do not. This is fundamentally a granularity issue. To the best of our knowledge, there is an unmet need for a fine-grained approach that can precisely remove tracking information in decorated links.

To sanitize link decoration (i.e., precisely removing just the tracking information from a request URL), privacy-focused browsers and browser extensions such as Safari, Firefox, Brave, uBlock Origin, and AdGuard employ a manually-curated list of query parameters that are known to be abused for tracking [16]–[20], similar to the request-blocking filter lists such as EasyList and EasyPrivacy [21], [22]. While the manual approach might work for a small number of tracking query parameters, it cannot keep pace with the increasing adoption of query parameters by trackers [23], a problem that has also severely impacted filter lists [24]–[26]. Thus, it is not surprising that the filter lists to sanitize link decoration conservatively target only 10-100s of query parameters.

In this paper, we propose PURL (pronounced purel-l), a machine-learning approach to distinguish between tracking and functional link decorations. PURL makes use of a cross-layer graph representation to capture the complete execution of a webpage, which includes interactions between the HTML DOM structure, JavaScript execution behavior, information stored in browser storage, and network requests issued during

a webpage load. PURL then extracts distinguishing features from this rich graph representation and uses a supervised classifier to detect tracking link decorations.

Our evaluation on a sample of top-million websites shows that PURL can effectively (98.87% recall) and safely (98.62% precision) sanitize link decoration. Overall PURL achieves 98.74% accuracy, significantly outperforming existing countermeasures by at least 7.71% in terms of precision, 4.83% in terms of recall, and 6.43% overall accuracy while reducing website breakage by more than 8×. Our evaluation also shows that PURL is robust against common evasion attempts such as changing link decoration names and splitting/combining link decoration values.

We deploy PURL on a subset of top-million websites to measure the prevalence of link decorations for tracking. PURL detects that 73.02% of the sites abuse link decorations for tracking, with an average site using 10.75 tracking link decorations. We find that the most common abusers of link decoration include well-known advertising and tracking services, which use link decorations to share cookies, email addresses, and fingerprinting information.

Our key contributions are as follows:

1. We propose and evaluate **an automated machine learning approach**, called PURL, to detect tracking link decorations using features that capture interactions and flow of information across multiple layers of the web stack.

2. We **deploy PURL on top-million sites** to measure the prevalence, abusers, and type of tracking information shared via link decorations.

3. We **use PURL to generate a filter list**, which can and is already being used by privacy-focused browsers and browser extensions.

To promote reproducibility and facilitate further research, we are also open-sourcing PURL source code, including the OpenWPM patch, the machine learning pipeline, and the detected list of link decorations [27].

2 Background & Related Work

In this section, we discuss preliminaries, review related work, and survey existing countermeasures against the abuse of link decoration for tracking in industry and academia.

2.1 What is Link Decoration?

A URL is composed of the following key components: scheme, fully qualified domain name (FQDN), resource path, query parameters, and fragments. We use `https://a.site.example/YYY/ZZZ/pixel.jpg?ISBN=XXX&UID=ABC123#xyz`, as an example URL to define these segments below:

Base URL. `https://` is the scheme in this URL and `a.site.example` is the FQDN. These segments are combined to form the base URL.

Resource path. Immediately following the FQDN, `/YYY/ZZZ` is the resource path in the URL. It points to a directory, file, API endpoint, or other resource on the server. `pixel.jpg` is the name of the resource hosted on the server.

Query parameters. Immediately following the resource path after the ? delimiter, `ISBN=XXX&UID=abc123` are the query parameters in the URL. A query parameter consists of a key-value pair, where the key is separated from the value by the = delimiter. Multiple query parameters in a URL are separated from each other by the & delimiter.

Fragments. Immediately following the query parameters after the # delimiter, `xyz` is the fragment in the URL. Fragments can be a singular value or multiple key-value pairs that are separated by the & delimiter (similar to query parameters).[1]

While only query parameters are traditionally considered as link decoration [23], [28], we find that link decoration can be carried out using the resource path, query parameters, and fragments (discussed further in Section 3.1)[2]. Next, we describe the threat model we consider for tracking through link decoration.

2.2 Threat Model

Our threat model focuses on the sharing of identifying information through link decoration in third-party requests. We exclude first-party requests (i.e. requests sent from and to the first party) from our analysis, as we assume that first-parties would use identifying information to provide legitimate website functionality. However, our analysis includes first-party initiated requests sent to third-party domains, such as tracking via click identifiers used by social media and search engines. Our threat model considers the abuse of link decoration for both same-site and cross-site tracking because even same-site identifiers (e.g., first-party cookies [7], [8], [10]) can be combined with additional information for cross-site tracking. We consider two main entities in our threat model: the victim (users) and the adversary (third-party trackers). While third-party trackers require some cooperation from the website publisher (i.e., embedding a script on the page), we do not consider the publisher to be an active part of the threat model.

We assume that the victim/user:

• has third-party and first-party cookies enabled in the browser[3]

[1] In cases where fragments contain multiple key-value pairs, we treat these key-value pairs similarly as query parameters to facilitate easier comparison and analysis across different URL components.

[2] While fragments are not sent alongside a request to a server, the server can send a redirect to another page, which can access the fragments from the URL, e.g., through `window.location.hash`.

[3] We allow third-party cookies as they are supported in major browsers such as Chrome and Edge. However, PURL's approach is agnostic to using first- or third-party cookies for tracking.

• may provide personally identifiable information (PII) such as email address on the website (e.g., to log in)

We assume that the adversary/third-party tracker:

• may be present in a third-party context or a first-party context (i.e., a script embedded in the main frame) on the websites visited by the user

• aims to collect identifying information such as identifier cookies and email addresses for tracking

As described below, third-party trackers can use link decorations to share identifying information in several ways:

A user visits a website *website.example*, where tracker A is present in a first-party context (e.g., a script that sets a first-party identifier cookie) and tracker B is present in a third-party context (e.g., a pixel that sets a third-party identifier cookie). The user provides their email address on a form field that is accessible to only tracker A[4]. To send the email address to its server, tracker A has to append the email address as a link decoration in the request URL to its server. To send the first-party cookie to its server, tracker A again has to append the first-party cookie as a link decoration in the request URL to its server because first-party cookies would not be automatically sent to its third-party domain. Upon subsequent visits to the website by the same user, tracker A can associate its first-party cookie with the email address for same-site tracking, even though the user may not provide the email address in subsequent visits. Tracker A can also share the email address with tracker B by appending the email address as a link decoration in the request URL to tracker B's server. Tracker B can cross-site track the user with its third-party cookie, while also being able to associate it with the email address shared by tracker A.

2.3 Abuse of Link Decorations for Tracking

The abuse of link decoration for tracking is not a new phenomenon. To the best of our knowledge, the earliest evidence of link decoration abuse is from 1996, when Webtrends (an analytics service) used the `WT.mc_id` query parameter for click tracking in advertising campaigns [30], [31]. Since then, link decorations in general, and query parameters specifically, have been widely used for creating personalized links to track the success of advertising campaigns. For example, Urchin Tracking Module (UTM) parameters, such as `utm_source` identify the source of traffic on a website and attribute it to specific advertising campaigns [32]–[35].

Prior research has shown that trackers abuse link decoration to implement various tracking techniques [10], [36]–[42]. While prior work has proposed approaches to detect and block specific tracking techniques, which in turn rely on link decoration, these studies do not specifically study the abuse of link decorations for tracking. To the best of our knowledge, Randall *et al.* [23] is the first study to specifically study tracking query parameters. The authors found that 8.1% of the navigation URLs are decorated with identifiers as query parameters for tracking.

With new restrictions [1], [2], [43] on third-party cookies, trackers are moving towards alternative techniques of tracking, which include the use of first-party cookies [7], [8], [10], personally identifiable information (PII) [44], [45], and device/browser fingerprinting [46]–[48]. In contrast to third-party cookies that are automatically included as headers in outgoing HTTP requests, these alternative tracking techniques must rely on link decoration for sharing identifying information. As trackers shift their focus towards these alternative tracking techniques, it is reasonable to assume that the abuse of link decoration for tracking will also continue to increase.

2.4 Countermeasures Against the Abuse of Link Decorations for Tracking

Given the increased focus on alternative techniques to track users due to restrictions on third-party cookies, privacy-focused browsers, and browser extensions have started deploying countermeasures against the abuse of link decorations. These countermeasures can largely be divided into two different categories: filter list based countermeasures that rely on a static filter list of link decorations and heuristic-based countermeasures that rely on certain properties to identify tracking link decorations. Next, we describe existing countermeasures against tracking link decoration and highlight their limitations.

2.4.1 Filter List Based Countermeasures

Filter lists of link decorations contain both site-specific and site-agnostic rules which determine which link decorations should be allowed and which link decorations should be removed. These filter lists are manually curated and maintained, which has been shown by previous research to have issues such as slow updates and being error-prone [26], [49], [50]. As discussed below, filter list based countermeasures are used by both privacy-focused browsers and browser extensions.

Brave. Since July 2020 [51], Brave browser attempts to remove tracking query parameters from URLs by matching them against a list of known tracking query parameters. This filter list is curated by analyzing the documentation provided by the trackers themselves and from the reports submitted by Brave developers and users. At the time of writing, Brave's filter list of tracking query parameters contains 59 query parameters [18], [52].

Firefox. In January 2022, Firefox introduced the query parameter stripping feature [53] in Firefox Nightly 96.

Mozilla integrated this feature in Firefox 102.0 in June 2022 [54] although it was not enabled by default – Firefox users have to set *Strict* security level in Enhanced Tracking Prevention (ETP) to enable this feature. Firefox also allows users to remove tracking link decorations from copied URLs

[4] Prior research [10], [29] shows that email identifiers help trackers monitor user activity across websites

[55]. Similar to Brave, Firefox also relies on a curated filter list of tracking query parameters. At the time of writing, Firefox's filter list of tracking query parameters contains 23 query parameters [56].

Safari. Since June 2023, Safari 17 [57] removes known tracking query parameters in Safari's private browsing mode. Similar to Brave and Firefox, Safari also relies on a curated filter list of tracking query parameters. At the time of writing, Safari's filter list of tracking query parameters contains 24 query parameters [16].

AdGuard. AdGuard introduced a new filter type named `removeparam` to remove tracking query parameters from request URLs in 2021 [19]. At the time of writing, AdGuard's filter list includes more than one thousand query parameter rules [58]–[60].

uBlock Origin. uBlock Origin introduced new filter types `queryprune` in 2020 and then switched to `removeparam` [61]. Unlike AdGuard, uBlock Origin supports regular expression-based filters to remove tracking query parameters. At the time of writing, uBlock Origin includes 46 query parameter rules [62].

Requests-based filter lists. Filter lists such as EasyList [21] and EasyPrivacy [22], which are designed to block network requests to known trackers, would indirectly also block tracking link decorations. However, blocking the whole URL is not practical where tracking and non-tracking link decorations are mixed in the same URL. As we show later, using EasyList [21] and EasyPrivacy [22] results in non-trivial false positives and false negatives.

2.4.2 Heuristic Based Countermeasures

The aforementioned filter list based countermeasures are limited because they need to be manually created and updated. These limitations are apparent in their smaller size, with only one filter list including close to a thousand rules to detect tracking link decorations.

To address these issues, Randall *et al.* [23] proposed CrumbCruncher – a semi-automated heuristic-based approach to detect query parameters involved in the sharing of identifiers. CrumbCruncher conducts parallel and consecutive crawls to identify query parameters that are distinct across parallel crawls but persistent across consecutive crawls. However, their approach is prone to false positives and false negatives. Specifically, not all persistent parameters are predisposed to be tracking, e.g., parameters such as `share_button` or `en-US` remain consistent during multiple visits by the same user, however, they are not used for tracking. The manual review by the authors showed that CrumbCruncher suffers from a 36% false positive rate that needs to be addressed through a manual review. CrumbCruncher also suffers from false negatives because it incorrectly assumes that tracking query parameters are persistent across subsequent crawls. We find that almost 80% of potential identifiers (i.e., longer than 8 characters as defined by CrumbCruncher) that are shared to known tracking endpoints (defined using EasyList [21] and EasyPrivacy [22]) via query parameters change their value across consecutive crawls. For example, the `fbp` query parameter, which is used by Meta Pixel to share identifiers stored in the `_fbp` cookie, does not maintain its value in about 87% of the cases.[5] In summary, CrumbCruncher suffers from non-trivial false positives and false negatives due to its simplistic heuristic.

3 Motivating Measurements

In this section, we motivate the need for a tailored solution to curb the abuse of link decoration, such as PURL, by demonstrating that link decoration abuse is a prevalent phenomenon. Our key idea is to crawl a large set of websites and investigate the network requests, from known advertising and tracking services that appear on those websites, for link decoration. We exclusively focus on known advertising and tracking services because they are the main culprits who engage in such practices, and also because currently there are no current approaches to effectively detect link decoration abuse.

3.1 Methodology

Crawler configuration. We use OpenWPM (v0.17.0) [11] and Firefox (v102) [64] for crawling. Our crawls are stateless – i.e., we clear all cookies and other local browser states before crawling each website. By using stateless crawling, we ensure that each crawl is independent and not biased by the residual state from previous website crawls. We turn off all built-in tracking protections provided by Firefox (Enhanced Tracking Protection [ETP]) [65]. We conduct our crawls entirely from the vantage point of an academic institution in the US, hence, we do not interact with consent banners.

Websites crawled. We crawl a 20K sample of the Tranco top-million websites between March and April 2023 [66]. As previous research has highlighted the importance of making crawls representative of sites with varying popularity [67], we crawl all of the top-1K sites, uniformly sample another 9K sites from the sites ranked 1K–100K, and a further 10K from sites ranked 100K–1M. Additionally, to capture differing content on both the landing and internal pages [68], we perform an interactive crawl that covers both types of pages. Specifically, for each site, we crawl its landing page, randomly scroll and move the cursor (for bot mitigation), and then select up to 20 internal pages to visit at random. After each page load is complete (i.e., when the onLoad event is fired), we uniformly at random wait an additional 5–30 seconds for bot mitigation and other resources to finish loading. The success rate of our crawler is 98.79%. A tiny fraction of web pages do not load correctly because of server-side errors.

[5] Bekos *et al.* [63] showed that the value of the `_fbp` cookie (and consequently the `fbp` query parameter) is randomly chosen from a list of up to 50 different identifiers, resulting in a new identifier for the same user each time.

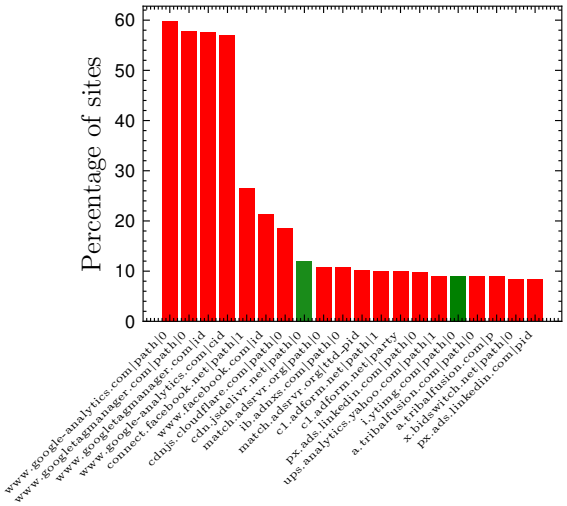

Figure 1: Percentage of sites where the same link decoration by top domain appears and their primary usage. The shades of red and green show link decoration's usage as ATS and Non-ATS, respectively.

Labeling tracking requests. To analyze the prevalence of link decoration in tracking requests, we use EasyList [21] and EasyPrivacy [22]. Specifically, we use them to label requests as Advertising and Tracking Service (ATS) or non-Advertising and Tracking Service (Non-ATS). We label a request as ATS if its URL matches the rules in either one of the lists. Otherwise, we label it as Non-ATS.

Naming link decorations. When link decorations are in the key-value format, the key can simply be combined with FQDN[6] to uniquely identify a link decoration. For example, if a link decoration with key *username* is sent to an FQDN *site.example.com*, *site.example.com+username* can be used to identify the link decoration. When link decorations are not in the key-value format (e.g., resource paths and fragments), we assign them keys based on the FQDN and their position in the URL. We identify link decorations for resource paths based on their distance (directory levels) from the root. For the example URL: `https://a.site.example/YYY/ZZZ/pixel.jpg?ISBN=ABC&UID=DEF123#xyz`, we identify the following link decorations as key-value pairs:

- `a.site.example` | $path_0$: `YYY`
- `a.site.example` | $path_1$: `ZZZ`
- `a.site.example` | *ISBN*: `ABC`
- `a.site.example` | *UID*: `DEF123`
- `a.site.example` | *fragment*: `xyz`[7]

This naming scheme allows us to compare link decoration values across different URLs.

[6] We combine FQDN with the link decoration key because different FQDNs can use the same key names.

[7] If fragments are in the key-value format like query parameters, we treat them similarly as query parameters.

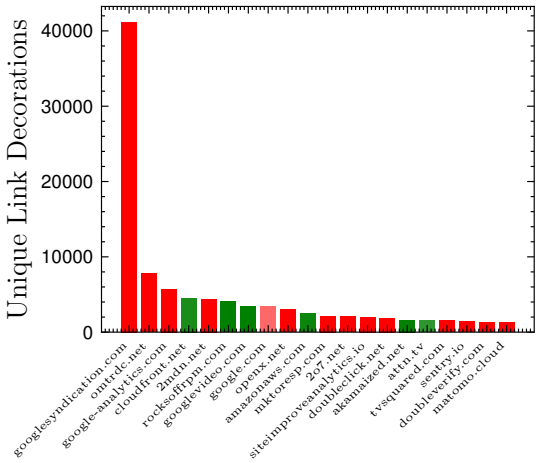

Figure 2: Total unique link decorations used by domains. The shades of red and green show link decoration's usage as ATS and Non-ATS, respectively.

3.2 Prevalence of Link Decoration

We investigate the prevalence of link decoration used on the 20K sample of the top-million websites. Of the 44,648,436 link decorations in our data, 41.22% are query parameters, 58.14% are resource paths, and 0.63% are fragments. Considering only unique link decorations, we observe a total of 584,174 decorations: 42.41% of which are query parameters, 53.85% are resource paths, and 3.73% are fragments.

Overall, 45.55% unique link decorations are in the URLs labeled as ATS, while the rest are sent to Non-ATS endpoints. We find that requests sent to ATS endpoints disproportionately contain more decorations on average (7.69) than the requests sent to Non-ATS endpoints (4.68), highlighting that link decorations are more frequently used by ATS than Non-ATS. A similar trend holds for third-party requests (4.80) vs. first-party endpoints (2.10).

We further find that the same link decorations are widely reused (use of the same link decoration key/name on more than one site) by advertising and tracking services. Figure 1 shows the top 20 link decorations and their prevalence in our dataset.[8] The color of the bar shows the usage of link decoration for either ATS or Non-ATS purpose (i.e., the red represents ATS and green represents Non-ATS). The plot shows that while both ATS and Non-ATS services show reuse of the same link decoration across multiple websites, it is ATS who predominately exhibit this behavior. For example, `www.googletagmanager.com|id` is used in around 55% of sites in our dataset and is primarily used in ATS requests. On the other hand, the most commonly used Non-ATS link decoration is `cdnjs.cloudflare.com|path|0`, which is found on slightly more than 10% of sites in our dataset.

[8] To simplify the illustration due to space constraints, we limit link decorations for each FQDN to only the top two.

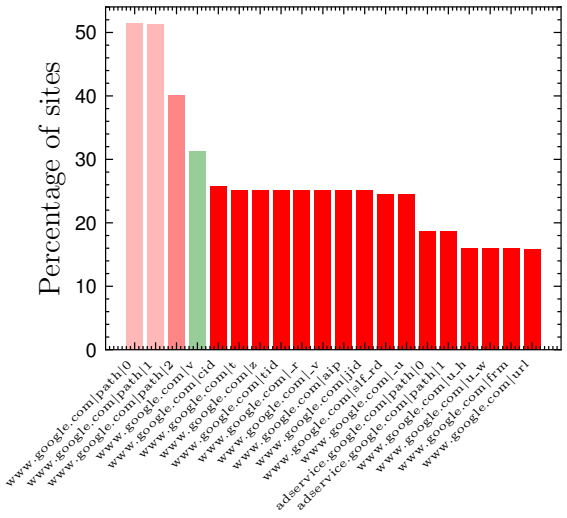

Figure 3: Average number of link decorations used by Google endpoints (minimum 1000 requests across 20K sites)

Next, we analyze the use of link decoration by ATS. Figure 2 plots top-20 tracking domains based on the number of unique link decorations they use. The intensity of the color (green for Non-ATS and red for ATS) in the figure for each domain shows its use of link decorations in ATS or Non-ATS requests. We note that *googlesyndication.com*, which is used by Google Ad Manager [69], uses the highest number of unique link decorations among the ATS domains. It is followed by *omtrdc.net*, which is used by Adobe Marketing Cloud [70], *google-analytics.com*, which aggregates and reports user stats for sites [71], and *cloudfront.net*, which is an Amazon-owned content delivery network [72]. Other well-known ATS such as Facebook, Baidu, and Microsoft are also among the domains that use the most link decorations in their requests. Our main finding is that link decorations are widely used by well-known advertising and tracking services. Crucially, Figure 2 also shows some mixed usage of link decorations. For example, link decorations used by *google.com* were part of 122,028 ATS requests and 56,026 Non-ATS requests (this is represented by a lighter shade of red in the figure as compared to other domains which are either darker shades or red or green). On the other hand, link decorations used by *amazonaws.com* were part of 863 ATS requests and 16,420 Non-ATS requests (represented by a darker shade of green in Figure 2).

To identify the reason behind significant mixed usage of link decorations by *google.com*, we take a closer look at different link decorations used by *google.com* and their prevalence in our dataset. Figure 3 plots the prevalence of the top 20 link decorations used by *google.com*. The color of each link decoration represents its use as ATS and Non-ATS, with higher shades of red representing predominant use in ATS requests and higher shades of green representing predominant use in Non-ATS requests. The top four link decorations have significant mixed usage between ATS and Non-ATS requests, with the top three: `www.google.com|path|0`, `www.google.com|path|1`, and `www.google.com|path|2` leaning towards more ATS while `www.google.com|v` slightly leaning towards Non-ATS.

Figure 4: Example URL with mixed link decorations. ■ indicates a Non-ATS link decoration while ■ indicates an ATS link decoration. Resource paths are highlighted as green and the query parameters with keys `source`, `ven`, `Tac`, `school`, and `Matchtype` are used for functional purposes, while `gclid` contains an identifier that is used to track ad clicks.

These results show that a single link decoration can be part of both ATS and Non-ATS requests. Next, we try to evaluate if a single request can also have both ATS and Non-ATS link decorations. To this end, we make use of query parameter filter lists used by Brave[18], Firefox[17], and Safari[16], as well as privacy-enhancing extensions uBlock Origin[20] and AdGuard[58], [59]. We label every link decoration not included in these filter lists as a Non-ATS link decoration. Overall, we observe 51,736 requests that contain one or more ATS link decoration, while only 248 of these requests contain no other Non-ATS link decoration. On average, an ATS link decoration is accompanied by 16.06 Non-ATS link decorations in the same request URL. An example of such mixed URLs is shown in Figure 4.

Takeaway. Our measurements show that a request URL can contain both ATS and Non-ATS link decorations. Moreover, the classification of a link decoration can change depending on which site it is used on and its destination domain. Thus, as we show later in Section 4.3, it is non-trivial to detect and block ATS link decorations using existing countermeasures.

4 PURL

In this section, we present PURL (pronounced purel-l), our machine learning approach to detect ATS link decorations. PURL's key idea is to use the execution traces of ATS link decorations as their signatures, which it learns and automatically detects with the help of a machine learning (ML) classifier. PURL captures detailed execution traces across the HTML, network, JavaScript, and storage layers of the web stack and models them in a graph representation. The graph representation captures the natural interaction between different layers of the web stack and provides a parse-able representation to extract various characteristics (i.e., features) of ATS link decoration execution, that are used to train a supervised ML classifier. Figure 5 provides an overview of PURL's design.

4.1 Design and Implementation

Browser instrumentation. PURL extends OpenWPM [11], an open-source web measurement tool, to record the execu-

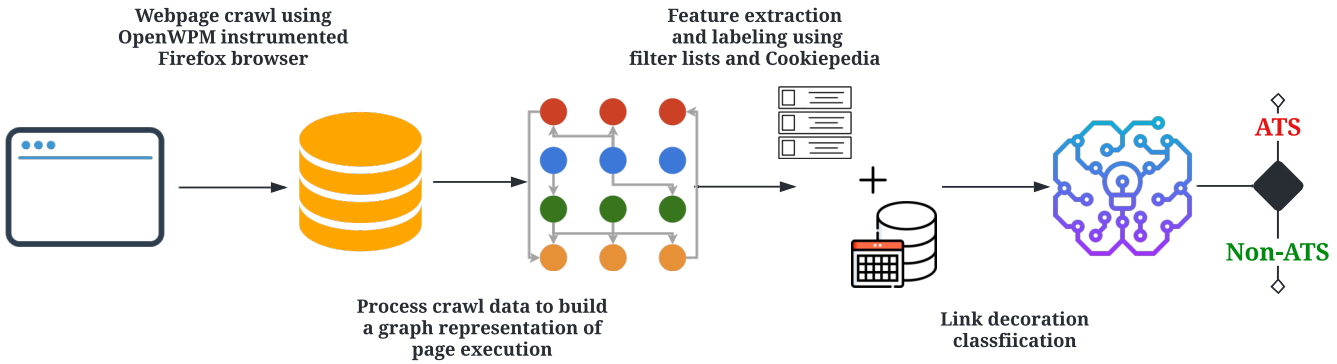

Figure 5: Overview of PURL pipeline: (1) Webpage crawl using an instrumented browser; (2) Construction of a graph representation to represent the instrumented webpage execution information; (3) Feature extraction for graph nodes that represent link decorations; and (4) Classifier training to separate out ATS and Non-ATS link decorations.

tion of a webpage across *HTML*, *network*, *JavaScript*, and *storage* layers during a webpage load. Similar to prior work on tracking detection (e.g., [10], [73], [74]), PURL captures the HTML elements created by scripts, network requests sent by scripts and HTML elements, responses received to these requests, sharing of identifiers stored in storage (local storage and cookies), and other read/write operations on storage mechanisms present in the browser.

PURL improves upon previous work by creating a more granular representation of the network layer of a webpage, which is essential for capturing characteristics of link decoration. Specifically, instead of coarsely capturing network requests and responses, PURL breaks them down and captures granular components of link decorations. For example, instead of identifying that a request contains a cookie value, PURL identifies the exact link decoration that was used to share that cookie value.

Graph Construction. There are five types of nodes in PURL's graph representation: *storage*, *HTML*, *script*, *network*, and *decoration*. *Storage* nodes refer to information stored in cookies and localStorage.*HTML* nodes are HTML Document Object Model (DOM) elements on a webpage. *Script* nodes map interactions of JavaScript execution on a webpage. *Network* nodes represent outgoing HTTP requests and incoming HTTP responses from network endpoints. *Decoration* nodes are created by splitting each *network* node into its link decorations.

We capture read and write operations performed on information in browser storage by different scripts, their sharing through network requests, and the setting of browser storage through network responses. We capture the interaction of different scripts with HTML elements and also map requests generated through HTML elements. In addition to these interactions, PURL captures actions and attributes that are specific to link decorations. Since link decorations may be used to share information stored in browser storage and the network responses received as a result of this sharing may be used to set browser storage elements using HTTP headers or JavaScript APIs, we monitor Base64-, MD5-, SHA-1-, and SHA-256-encoded[9] storage node values in decorations to associate relevant interactions between decoration, storage, network, and script nodes.

Figure 6 and 7 show how PURL constructs a graph representation for an example scenario where a script is reading/writing to browser storage and sending requests including link decorations to tracking sources. The nodes in the given example graph are storage, script, request, and decoration. The numbers on the edges represent a particular action, as represented in Figure 6. Dotted and dashed lines respectively show the flow of information from storage to decoration nodes (exfiltration) and the flow of information from request nodes to storage nodes (infiltration). PURL links the outward flow of information (exfiltration) to decoration nodes, and also maps the inward flow of information (infiltration) from a parent request/response node to the storage node. We use this graph structure to calculate features for decoration nodes that represent this flow of information.

Feature extraction. PURL leverages the graph representation to extract three different types of features that capture the execution traces of link decoration, referred to as *structural*, *flow*, and *content* features.

Structural features map the relationship of different nodes in the graph with each other, such as the connectivity of nodes and their ancestry information. For example, the connectivity of nodes captures how many different link decorations are in a request. As per Section 3, on average, ATSes use far more link decorations than Non-ATSes, resulting in stronger connectivity for ATS link decorations, which is also reflected in their structural feature values. Structural features help encode this information for our classifier using graph properties such as centrality, connectivity, and closeness[75], [76].

Flow features represent information flow across different layers of a webpage. Capturing this flow of information is important to track how user information is, extracted, stored,

[9] PURL can be extended to support other encodings.

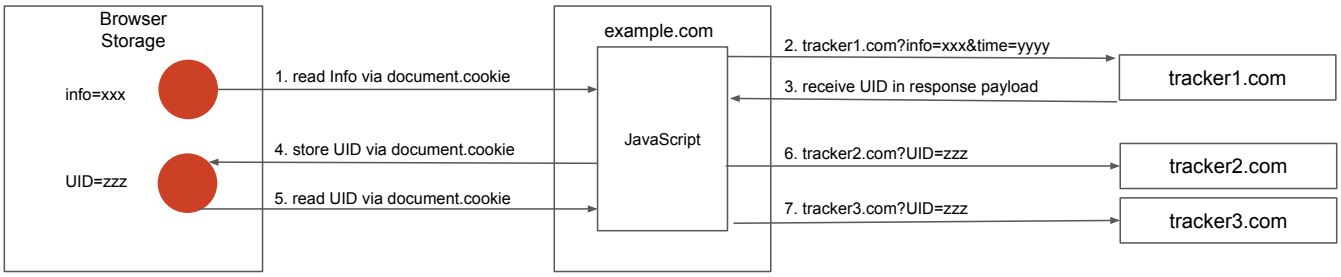

Figure 6: Example scenario to illustrate PURL's graph construction (shown in Figure 7). (1) A script on example.com reads info cookie from browser storage using `document.cookie`. (2) The script sends a network request to *tracker1.com* which includes the info cookie value and the current time in the decorated link. (3) *tracker1.com* sends a network response that contains UID in the response payload. (4) The script stores UID in the browser storage using `document.cookie`. (5) The script reads UID using `document.cookie` (6,7) The script sends the UID to *tracker2.com* and *tracker3.com* as decorated links.

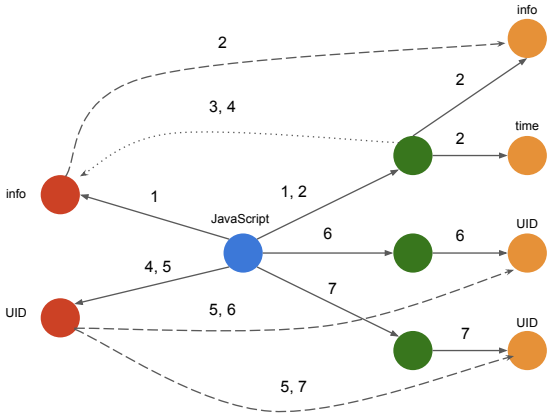

Figure 7: Graph representation of Figure 6 in PURL. ● network nodes, ● script nodes, ● storage nodes, and ● represent decoration nodes. The solid lines show the interactions of the script nodes with the storage and request nodes, while the dashed (_ _ _) and dotted (...) lines represent the flow edges captured by PURL from a storage node to a decoration node and from a network node to a storage node, respectively.

and sent out through tracking link decorations. First, PURL captures the direct sharing of storage values through the link decoration. As described in Figure 6, storage values can directly be sent out using link decorations. PURL represents this sharing as additional edges from storage nodes to decoration nodes. Second, PURL also keeps track of whether the parent request of a link decoration results in the setting of a storage node. This inward flow of information (infiltration) is usually used by ATS to set identifiers based on information sent out in requests (mainly through link decorations) [10]. PURL maps this infiltration through indirect edges connecting the parent request/response of decoration with the corresponding storage node. In addition, PURL monitors if the script sending the parent request of decoration is involved in sending storage information in non-parent requests or is part of redirects [37].

To determine the suitability of a decoration as a potential identifier, PURL also computes *content* features such as character-level Shannon entropy [77] and the relative position of the decoration in the URL. The complete list of the features used by PURL and their analysis is in the appendix.

Ground Truth Labeling. Once we capture the execution traces, we need to label them before they can be used to train a classifier. However, as discussed in Section 2, there are currently no readily available sources that can be reliably used to label link decoration abuse. Thus, we create our own set of labels by combining three different sources, which are: (i) filter lists of known advertising and tracking sources, (ii) a database of known tracking cookies, and (iii) short lists of manually curated tracking query parameters. Recall from Section 3.1 that each link decoration instance is a combination of the site where it appeared and the decoration key, and it is labeled as such. Next, we describe our ground truth labeling process that leverages the three aforementioned approaches.

1) Filter lists. Filter lists, such as EasyList and EasyPrivacy [21], [22], are the most reliable sources to identify tracking, which are used by almost all privacy-enhancing tools. However, their detection granularity is at the level of a URL and thus cannot be directly used to label individual parameters as ATS in a URL. This is because even a URL detected as ATS by filter lists might contain both tracking and non-tracking parameters [78], [79]. Despite this problem, filter lists can still be used to identify benign parameters, i.e., the parameters found in URLs from Non-ATS services, and we use them as such. Specifically, we rely on EasyList [21] and EasyPrivacy [22] filter lists to first identify Non-ATS URLs and then label all parameters in them as Non-ATS. As shown in Section 3.2, a single URL can contain both ATS and Non-ATS link decorations. In such cases, labeling all link decorations in URLs that are not blocked by filter lists as Non-ATS will result in incorrect labels for ATS link decorations. To account for this, we re-label all Non-ATS link decorations identified in this step as ATS if they are found to be involved in tracking in the next steps.

2) Cookiepedia. Link decoration can contain values stored in cookies, which are traditionally used to store and share user

identifiers [7], [10]. To identify such link decorations that can be used to exfiltrate tracking cookies, we make use of Cookiepedia [80], which is a database of cookies maintained by a well-known Consent Management Platform (CMP) called OneTrust [42], [81]. Primarily, Cookiepedia provides the purpose of each cookie in its database through its integration with OneTrust. Each cookie is provided one of the four labels: strictly necessary, functional, analytics, and advertising/tracking. We monitor the sharing of all cookies labeled as either analytics or advertising/tracking in Cookiepedia through a link decoration and label those link decorations as ATS.

3) Manually Curated Lists. Recall from Section 2 that several privacy-enhancing browsers and extensions maintain lists of known ATS link decorations parameters. Despite these lists being limited, they contain popular query parameters that are manually vetted to be used for tracking. Thus, we also make use of ATS link decoration lists, maintained by Brave [82], Firefox [17], AdGuard [83], and uBlock Origin [20].

Using a combination of these techniques, we were able to label 18.76% of our dataset, with 1.40% (60,573 instances) being labeled as ATS and 17.36% (749,553) as Non-ATS. Even though the ground truth is limited, especially for ATS samples, we argue that it is a significant improvement over the existing countermeasures. As described in Section 2.4, prior work has identified only a handful (maximum of around one thousand) ATS link decorations. Additionally, mislabelling link decorations can result in significant website breakage, necessitating a high-precision, albeit limited, ground truth.

Classifier. After curating the ground truth, we next train a supervised classifier to detect ATS link decoration. We use a random forest ensemble classifier because it is tolerant against noisy labeled data, is efficient to train, and is interpretable [84], [85]. We train the model using a balanced set of ATS and Non-ATS link decoration samples. We evaluate the accuracy of our classifier using stratified 10-fold cross-validation, to ensure that we do not train and test on the same samples. Overall, our classifier achieves 98.74% accuracy, 98.62% precision, and 98.87% recall, indicating that it is successful in detecting ATS link decorations.

The classifier accuracy is also comparable across different types of link decorations. For resource paths, it achieves an accuracy of 99.36%, 99.03% precision, and 99.69% recall. For query parameters, the accuracy is 96.40%, precision is 93.39%, and recall is 99.87%. Finally, for fragments the accuracy is 99.33%, precision is 98.75%, and recall is 100%.

4.2 Analysis of Disagreements between PURL and Ground Truth

We manually analyze PURL's false positives and false negatives to assess whether these are actual mistakes or limitations of our ground truth (recall that we curated a high-precision, albeit limited, ground truth).

First, we analyze the false positives of PURL. We manually verify the most common false positives in our dataset by first, analyzing information sent by false positive link decorations (user identifiers, values stored in cookies, etc.), and second, by analyzing available online documentation by senders/receivers of these link decorations. Our analysis of the most commonly misclassified ATS link decorations reveals that most of them are indeed used for tracking. In total, PURL classifies 8,058 Non-ATS instances (out of 749,553 total, 1.07%) as ATS, which correspond to 2,994 unique link decorations. The three most common false positive link decorations include `utk` query parameter sent to *hubspot.com*, `bsi` query parameter sent to *frog.wix.com*, and `iiqpciddate` query parameter sent to *api.intentiq.com*. We manually analyzed these three link decorations, which account for almost 10% of all false positives. Our analysis of the documentation for these three link decorations shows that these are not false positives, but rather these were falsely labeled as Non-ATS in our ground truth, and PURL actually correctly classified them as ATS. `utk` query parameter contains the HubSpot's `hubspotutk` cookie which is used to identify a user visiting a website [86]; `bsi` query parameter contains the identifier used by BSI's Customer Data Platform [87], while `iiqpciddate` accompanies `iiqpcid` query parameter which is used by IntentIQ to uniquely identify a user [88]. We conclude that PURL's false positives are, in actuality, false negatives in the ground truth, which was curated conservatively to be highly precise (rather than high recall).

Second, we analyze the false negatives of PURL. In total, PURL incorrectly classifies only 50 ATS instances as negatives (out of 60,573 total, 0.08%). In all of these instances, PURL was unable to link the sharing of stored information through these link decorations. In addition to this, values of structural features (e.g., number of edges) for these instances were also lower than true positive instances (e.g. 11,501.99 number of edges as compared to 14,762.86 for true positives). We conclude that false negatives happen when PURL is unable to trace certain tracking behaviors of ATS link decorations. We elaborate on PURL's implementation limitations in tracing storage sharing in Section 6.

Beyond these disagreements, PURL is more than the sum of its ground truth. Concretely, PURL detects 52,489 ATS link decorations that are not detected by Cookiepedia, EasyList [21], EasyPrivacy [22], or the manually curated filter lists for ATS link decorations.

4.3 Comparison with Existing Countermeasures

In this section, we compare PURL versus existing countermeasures against ATS link decorations to demonstrate that it significantly advances the state-of-the-art. We compare it against approaches that directly detect ATS link decoration and also approaches that were originally designed to detect ATS link decoration but can be repurposed to detect them.

We compare PURL against CrumbCruncher [23] and link decoration based filter lists, which are designed to detect ATS link decoration. For comparison with CrumbCruncher, we rely on the list of ATS query parameters published by Randall *et al.* [89]. For comparison with link decoration based filter lists, we rely on the lists offered by Brave [82], Firefox [17], Safari [16], uBlock Origin [20], and AdGuard [83]).

Additionally, we also compare PURL against Cookiepedia [80] and request-based filter lists (i.e., EasyList [21] and EasyPrivacy [22]), which we repurpose to detect ATS link decoration. We compare with Cookiepedia cookie labels by identifying link decorations that are used to exfiltrate values of cookies labeled as ATS by Cookiepedia. For comparison with request-based filter lists, we consider all link decorations in the requests labeled as ATS by filter lists to be ATS link decorations. We compare these approaches across two axes: (i) accuracy and (ii) breakage.

Accuracy. Table 1 shows the comparison of accuracy, precision, and recall of all four countermeasures against PURL. It can be seen from the table that PURL outperforms the runner-up countermeasure (i.e., request-based filter lists) by 6.43% in terms of accuracy and by 7.71% in terms of precision. Some of the most common ATS link decorations detected by PURL and missed by the runner-up countermeasure are `sync.intentiq.com|pcid`, `pr-bh.ybp.yahoo.com|path|2`, and `partner.mediawallahscript.com|uid`. As we discuss next, the higher precision results in a measurable reduction in website breakage when PURL is used as compared to runner-up countermeasures.

Classifier	Accuracy	Precision	Recall
PURL	98.74%	98.62%	98.87%
CrumbCruncher	50.16%	59.09%	10.67%
Cookiepedia	80.99%	99.01%	62.63%
Filter lists (Requests)	92.31%	90.91%	94.04%
Filter lists (Decorations)	50.50%	100.0%	10.15%

Table 1: Classification accuracy of PURL, CrumbCruncher, Request Filter lists, Decoration Filter lists, and Cookiepedia

Classifier	Navigation		SSO		Appearance		Miscellaneous	
	Minor	Major	Minor	Major	Minor	Major	Minor	Major
PURL	0%	0%	2%	0%	2%	1%	2%	0%
Filter lists	0%	2%	1%	2%	8%	6%	4%	1%

Table 2: Website breakage comparison of all three countermeasures.(▬) signifies no breakage, (▬) minor breakage, and (▬) major breakage. Each cell represents the percentage of sites on which breakage was observed.

Website Breakage. To determine what effect each countermeasure has on the usability of a site, we compare website breakage caused by PURL and the countermeasure with the second-highest accuracy and recall (request-based filter lists) on 100 sites. We use 20K sites from section 3, out of which 50 sites were sampled from those ranked 1-1000 and 50 from the rest to ensure the sample is representative. A list of sites used for breakage analysis is available at [90]. Our breakage analysis is divided into four different categories of how a website is used: navigation (moving from one page of the website to another), SSO (third-party login integrations), appearance (visual consistency and acuity), and miscellaneous (additional functionality such as shopping carts, chatbots, etc.). We also categorize each breakage into minor or major, the former implying that the underlying functionality is disrupted but still usable, and the latter implying that the functionality is completely unusable from the user's perspective. Two reviewers interact with the webpage while ATS link decorations detected by PURL or filter lists are removed. Any disagreements between the two reviewers are resolved after careful discussion.

Our evaluation shows that out of the 100 sites, PURL caused minor breakage on 5 sites and major breakage due to a failure to load CSS on *autodesk.com*[10]. On the other hand, requests-based filter lists caused minor breakage on 12 different sites and major breakage on 9 sites, including a complete breakdown of navigation on *directunlocks.com* and CSS issues on *engadget.com* and *mysuncoast.com*.

These results show that PURL not only significantly outperforms existing countermeasures in terms of accurately sanitizing more ATS link decorations, but it also does so without causing additional website breakage.

5 Deployment

In this section, we deploy PURL on a 20K sample of top-million sites to understand the prevalence and the nature of information shared in ATS link decorations.

5.1 Prevalence of ATS Link Decorations

We first analyze the breakdown of PURL's classification of link decorations. PURL classifies 4.56% (196,890) of link decorations in our dataset as ATS. 73.02% (14,604) of the tested sites contain at least one request with an ATS link decoration. Overall, an average site employs 10.75 ATS and 44.59 Non-ATS link decorations. Table 3 provides the breakdown of different types of ATS and Non-ATS link decorations. Out of the 196,890 link decorations labeled as ATS, 6.62% are resource paths, 93.36% are query parameters, and 0.02% are fragments. Our findings indicate that while query parameters account for the majority of ATS link decorations, trackers also abuse resource paths and fragments that are ignored in prior work [23](e.g., CMID cookie set by Casalemedia and shared through resource path in request to Yahoo: *https://pr-bh.ybp.yahoo.com/sync/casale/**ZBlPAJ28Qf7u...***).

Table 4 lists the top-50 most prevalent ATS link decorations. We note that a majority of the top ATS link decorations are used by various Google advertising and tracking endpoints

[10] PURL misclassified the second resource path in *https://static-dc.autodesk.net/etc.clientlibs/**v605.20230316.1511**/autodesk/clientlibs/clientlib-dhig.min.css*

	Resource Paths	Query Parameters	Fragments	Total
ATS	13,030 (6.62%)	183,813 (93.36%)	47 (0.02%)	196,890 (100.00%)
Non-ATS	1,295,246 (31.42%)	2,824,549 (68.52%)	2,233 (0.05%)	4,122,028 (100.00%)
Total	1,308,276 (30.29%)	3,008,362 (69.65%)	2,280 (0.05%)	4,318,918 (100.00%)

Table 3: Distribution of link decorations between ATS and Non-ATS across the 20K sample of top-million sites

www.facebook.com	ts	202	3.84

Table 4: Prevalence of Top-25 ATS link decorations and the number of cookies they share

on *doubleclick.net*, *google-analytics.com*, and *google.com*. For example, `cid` and `_gid` are used by all of the aforementioned Google domains, with `cid` and `_gid` on *www.google-analytics.com* shared on more than half of the sites. After Google, `fbp` on *www.facebook.com* used by Meta pixel [91] is present on nearly 20% of the sites. After Facebook, `vid` and `sid` on *bat.bing.com* used by Microsoft/Bing Ads Conversion tracking [92] are present on about 5% of the sites. All of the remaining top-50 ATS link decorations also belong to well-known advertising and tracking organizations such as BidSwitch [93], LiveRamp [94], Yahoo! [95], Magnite [96], Amazon [97], Criteo [98], OpenX [99], Oracle/BlueKai [100], The Trade Desk [101], Sovrn Holdings [102], Index Exchange [103], TripleLift [104], and LiveIntent [105]. The presence of these advertising and tracking organizations in top-50 ATS link decorations (and even beyond top-50, not shown here due to space constraints) highlights PURL's effectiveness in detecting both popular and relatively lesser known ATS link decorations.

Next, we investigate different types of information shared through these ATS link decorations.

5.2 Sharing of Browser Storage through ATS Link Decorations

Prior work has shown that browser storage, such as cookies and local storage, is widely used for tracking by ATS [7], [10], [74]. To investigate whether ATS link decorations are used to share browser storage, we look for the presence of browser storage in link decorations. Table 4 shows the number of distinct browser storage keys shared in the plaintext or encoded formats (Base64, SHA1, SHA-256, and MD5) by top-50 ATS link decorations. We find that most of the ATS link decorations detected by PURL are used to share a large number of browser storage keys (cookies and local storage). For example, `google_hm` on *cm.g.doubleclick.net* is used by Google's cookie matching service [106] to receive cookies of its advertising partners such as `CMID` (set by *casalemedia.com*), `suid` (set by *simpli.fi*), `__mguid_` (set by *mediago.io*), and `tuuid` (set by *adsrvr.com*). Other such well-known ATS link decorations that are similarly used to share browser storage keys set by various organizations include `partner_uid` (LiveRamp), `partner_device_uid` (Tapad), `uid` (Yahoo!), `put` (RubiconProject), and `ttd_puid` (The Trade Desk). We also note that some ATS link decorations are used to share only a few browser storage keys. For example, `fbp` (*www.facebook.com*) is mainly used to share ghosted [7], [10] `_fbp` cookie set by Meta pixel [91]. As another example, `vid` and `sid` (*bat.bing.com*) are mainly used to share ghosted `_uetvid` and `_uetsid` cookies set by Microsoft UET tracking tag [92]. A related interesting example is `cid` (*www.google-analytics.com*), which is mainly used to share ghosted `_ga` cookie set by Google Analytics [107], [108]. However, it is also used to share 250 other browser storage keys, potentially due to cookie name conflicts [109].

5.3 Sharing of Deterministic Information through ATS Link Decorations

Next, we look at the sharing of deterministic identifiers through ATS link decoration. Deterministic identifiers include email addresses and any commonly used user identifiers such as username, phone number, etc. provided by the user to log into a site. In contrast with identifiers stored in third-party cookies, these deterministic identifiers are not automatically sent with requests, necessitating their sharing through mechanisms such as link decorations. To study this sharing of deterministic identifiers, we crawl the 20K sample of top-million websites twice, both with and without providing deterministic identifiers such as email addresses in text input fields.[11] Similar to the aforementioned storage analysis, we analyze whether link decorations contain these deterministic identifiers in plaintext or encoded format using well-known hashing techniques (Base64, SHA1, SHA256, and MD5). We repeat these parallel crawls two additional times for a total of three

[11] To automatically fill in the text fields on web pages, we extended a crawler released by prior work [45].

FQDN	Key	Sites
p.adsymptotic.com	_expected_cookie	90

Table 5: Top-20 link decorations which were only present in at least 2 of the crawls where user email address was entered in text fields

crawls with and without entering deterministic identifiers. We find 538 link decorations that are present in multiple crawls where we enter deterministic identifiers, but are absent in crawls where we do not enter deterministic identifiers. PURL labels 62 of these 538 link decorations as ATS.

Table 5 shows the top-20 such link decorations. Most notable of these ATS link decorations are `ttd_id` used by Feathr (provides marketing campaign solutions to non-profits [110]), `pmUserId` used by Rich Audience (an advertising solution which works with major universal identifiers such as by ID5 [111] and The Trade Desk unified ID [112], [113]), and `ext__pubcid` used by LiveIntent (provides "cookieless email-based solutions" [114]).

5.4 Sharing of Probabilistic Information through ATS Link Decorations

Finally, we look at the exfiltration of probabilistic information through ATS link decorations. Probabilistic information includes features such as screen resolution, fonts, etc. that can be combined to extract a browser fingerprint [10], [46]. To determine if link decoration is potentially being used to send out probabilistic information, we use FP-Inspector an ML-based tool proposed by prior work [46] to detect whether the initiator scripts of link decorations are fingerprinters. We run FP-Inspector to detect 1,528 fingerprinting scripts on the tested websites. These fingerprinting scripts initiate requests containing 1,800 unique link decorations, out of which 200 are labeled as ATS by PURL. Table 6 shows the top 20 most common ATS link decorations sent by fingerprinting scripts. While it is challenging to reverse-engineer the scripts, names (e.g., `aduid`, `uuid`) of some of these link decorations make it fairly obvious that they contain some sort of identifiers.

6 Discussion

In this section, we further discuss the robustness of PURL to evasion, PURL's deployment in browsers and browser extensions, and coverage of PURL's dynamic analysis.

6.1 Robustness to Evasion

We evaluate the robustness of PURL against three different evasion techniques: manipulation of link decoration key names, splitting link decoration values, and combining of link decoration values.

First, we evaluate whether changing link decoration keys impacts PURL's accuracy. To this end, we randomly change the query parameter names as well as the position of resource paths and fragments. Our evaluation shows that there is no change in PURL's accuracy due to this randomization. This is because PURL does not directly use name features for query parameters and fragments, and thus there is no impact on the features. Moreover, changing the key names of resource paths by changing their position in the URL impacts just one feature (maximum depth of decoration) but does not end up changing the classification outcome for any link decoration.

Second, we evaluate whether splitting a link decoration into multiple link decorations impacts PURL's accuracy. If the individual character lengths of the new smaller link decorations are shorter than 8 characters, PURL's pre-processing would remove such link decorations from the classification pipeline – resulting in a successful evasion. To mitigate this issue, we can exclude this pre-processing step, but it might result in more false positives. We evaluate PURL (without this pre-processing step) against this evasion technique by splitting the link decorations longer than 8 characters into multiple smaller link decorations. Splitting link decorations results in only a 0.4% drop in accuracy, which corresponds to an increase of false positive rate by 0.17%.

Finally, we evaluate whether combining all link decorations into a single encrypted string impacts PURL's accuracy. This approach has been attempted by Facebook [115] to circumvent query parameter stripping. In Facebook's case, the obfuscated URL (e.g., *https://www.facebook.com/user/posts/pfbid0RjTS7KpBA...*) contains a single encrypted resource path that essentially combines multiple query parameters. A consequence of combining link decorations in an encrypted string is that PURL would be unable to attribute storage exfiltration features to this new link decoration. However, this change also results in higher entropy and, as discussed in Section A, increases the likelihood that the link decoration will be labeled as ATS. We evaluate PURL against this evasion technique by combining the link decorations in an SHA-256 encoded string for 156,348 requests containing both ATS and Non-ATS link decorations. Here, PURL only uses the features whose values are the same across all the combined link decorations (e.g., number of ancestors, descendants, presence of ad keyword in the ascendant). Our evaluation shows that PURL is still able to detect 83.4% of new link decorations as ATS.

We do not consider any attacks that adversarially modify the graph structure, as previous research [74] has found these attacks to be non-trivial and likely to cause collateral damage, deterring attackers from using such attacks.

6.2 PURL's implementation in privacy-focused browsers or browser extensions

While PURL's implementation is not suitable for runtime deployment (mainly due to the performance overheads of the browser instrumentation and subsequent dynamic analysis), it can be used in existing privacy-focused browsers and browser extensions as follows. Concretely, we run PURL on live webpages to detect ATS link decorations offline, and then add the detected link decorations to a filter list used in Brave, Firefox, Safari, uBlock Origin, or AdGuard for runtime URL sanitization [16], [17], [20], [82], [83]. We generated a filter list compatible with popular privacy-focused extensions such as uBlock Origin and AdBlock Plus by running PURL on our dataset [27]. Our filter list is incorporated in the `adfilt` filter list [116], which is used by AdGuard. Note that PURL's classifier can be periodically rerun to generate a new filter list in case a tracker frequently changes their link decoration keys/names. If a tracker randomly generates link decoration keys/names each time, PURL's filter list can applied based on their relative position in the URL. Note that it is challenging in practice for a tracker to change its link decorations at a fast pace because it requires changing both client-side and server-side logic across different servers and organizations.

6.3 Coverage

PURL builds a graph representation of the webpage execution. The number of interactions captured depends on the intensity and variety of user activity on a webpage (*e.g.*, scrolling activity, number of internal pages clicked). PURL may not detect certain ATS link decorations if its graph representation does not capture certain interactions between different elements in the webpage because it does not sufficiently emulate different user interactions. We attempt to mitigate this issue by randomly scrolling and clicking, but it might not be always sufficient. The coverage of PURL's dynamic analysis can be improved, if needed, using various techniques from prior research [117], [118].

7 Conclusion

In this paper, we investigated the abuse of link decoration for tracking. We found that link decoration is used by known trackers for both functional and tracking purposes, even within a single URL, necessitating a fine-grained approach to detect tracking link decorations. We proposed PURL— a machine learning approach to detect and sanitize tracking link decorations. PURL leverages a graph representation that captures interactions and the flow of information across multiple layers of the web stack.

Our evaluation showed that PURL significantly outperformed existing countermeasures in its ability to detect link decorations accurately and in minimizing website breakage. Our deployment of PURL on top-million sites showed that link decoration is abused for tracking on almost three-quarters of the websites by well-known advertising and tracking services to exfiltrate first-party cookies, email addresses, and fingerprints. We also showed that PURL is robust to common evasion attempts and is readily deployable in privacy-focused browsers and browser extensions as a filter list. While PURL is orthogonal to existing countermeasures that focus on detecting specific types of tracking, it can be deployed alongside them for a defense-in-depth strategy against new and emerging online tracking techniques. We also note that there are future research directions worth exploring for detecting tracking link decorations, namely the use of LLMs (large language models). Our exploration of existing LLMs shows that out-of-the-box solutions provide an accuracy between 79-81%; however, future work can explore better prompting, context, and fine-tuning to improve this performance.

A Feature Analysis

We rank the most important features for classifying ATS and Non-ATS link decorations by summing the feature contribu-

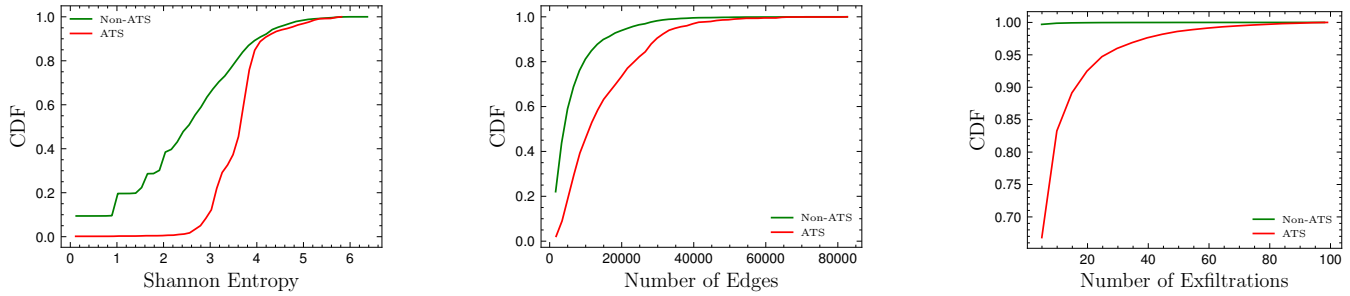

Figure 8: Distribution of the number of edges, Shannon entropy and number of exfiltrations for ATS and Non-ATS link decorations. ATS link decorations interact more with the neighboring nodes, have a higher Shannon entropy and are exfiltrated more as compared to Non-ATS link decorations.

tions during classification [119]. Table 7 reports the top-10 features ranked based on the percentage of instances where the feature was important for ATS classification. For ATS instances, Shannon Entropy, the number of nodes, edges, predecessors, and ancestors are the most important. Figure 8 plots the conditional distribution of two top-ranked features: Shannon entropy and the number of edges. The Shannon entropy for ATS decorations is higher than Non-ATS decorations – more than 70% of Non-ATS link decorations and only 8% of ATS link decorations have Shannon entropy lower than 3, respectively. The usage of higher entropy strings by ATS link decorations is expected, as they are more suitable for storing unique identifiers.

Figure 8 shows that ATS decorations are more connected as compared to Non-ATS decorations – less than 50% of ATS link decorations and more than 85% of Non-ATS link decorations have less than 10,000 edges, respectively. ATS link decorations tend to interact more with other elements of the webpage, which is expected as ATS link decorations are expected to be fetched and updated more frequently from storage and shared more frequently through network requests. Additionally, the flow of information from storage to link decoration nodes also affects the decision due to the importance of indirect features, which are calculated by exfiltration and infiltration to and from the storage nodes. ATS link decorations are more likely to exfiltrate storage values, with an ATS decoration averaging 7.4 exfiltrations (standard deviation of 20.56) while a Non-ATS decoration averaging only 0.06 (standard deviation of 1.41).

For Non-ATS instances, the lack of information flow was a strong indicator, with the top three features related to exfiltration and infiltration of storage values. The classifier also considered string entropy and advertisement-related keywords in ascendants as important features for classifying Non-ATS link decorations. Our analysis shows that information flow features, entropy, and the position of link decoration within the URL are the most critical for classifying link decorations into ATS and Non-ATS categories.

Feature	Percentage
Shannon Entropy	17.43%
Number of Nodes	16.38%
Closeness Centrality of Indirect Edges	13.22%
Ratio of Nodes over Edges	12.4%
Number of Edges	11.54%
Number of Script Predecessors	5.28%
Number of Ancestors	3.22%
Ratio of Edges over Nodes	3.06%
Number of Indirect Ancestors	2.83%
Closeness Centrality	2.03%

Table 7: Percentage of instances where a feature was the most important for ATS link decoration classification

Feature	Type
Graph size (# of nodes, # of edges, and nodes/edge ratio)	Structure
Degree (in, out, in+out, and average degree connectivity)	Structure
Centrality (closeness centrality, eccentricity)	Structure
Ascendant's attributes	Structure
Descendant of a script	Structure
Ascendant's script properties (Ad keyword, FP keyword, length of script)	Structure
Parent is an eval script	Structure
Depth of Link Decoration in URL	Content
Shannon Entropy	Content
Local storage access by parent (# of sets, # of gets)	Flow
Cookie accesses by parent (# of sets, # of gets)	Flow
Requests (sent, received) by parent	Flow
Redirects (sent, received, depth in chain) by parent	Flow
Common access to the same storage node	Flow
Cookie exfiltration	Flow
Cookie infiltrations by parent	Flow
Cookie Setter (# of exfiltration, # redirects) by parent	Flow
Graph size (# of nodes, # of edges, and nodes/edge ratio)	Flow
Degree (in, out, in+out, and average degree connectivity)	Flow
Centrality (closeness centrality, eccentricity)	Flow

Table 8: Features used by PURL. PURL calculates Graph size, Degree, and Centrality features using both normal and shared information edges. The former comes under structural features while the latter comes under flow features.

Fledging Will Continue Until Privacy Improves: Empirical Analysis of Google's Privacy-Preserving Targeted Advertising

Giuseppe Calderonio, Mir Masood Ali, and Jason Polakis
University of Illinois Chicago
{gcalde22, mali92, polakis}@uic.edu

Abstract

Google recently announced plans to phase out third-party cookies and is currently in the process of rolling out the Chrome Privacy Sandbox, a collection of APIs and web standards that offer privacy-preserving alternatives to existing technologies, particularly for the digital advertising ecosystem. This includes FLEDGE, also referred to as the Protected Audience, which provides the necessary mechanisms for effectively conducting real-time bidding and ad auctions directly within users' browsers. FLEDGE is designed to eliminate the invasive data collection and pervasive tracking practices used for remarketing and targeted advertising. In this paper, we provide a study of the FLEDGE ecosystem both before and after its official deployment in Chrome. We find that even though multiple prominent ad platforms have entered the space, Google ran 99.8% of the auctions we observed, highlighting its dominant role. Subsequently, we provide the first in-depth empirical analysis of FLEDGE, and uncover a series of severe design and implementation flaws. We leverage those for conducting 12 novel attacks, including tracking, cross-site leakage, service disruption, and pollution attacks. While FLEDGE aims to enhance user privacy, our research demonstrates that it is currently exposing users to significant risks, and we outline mitigations for addressing the issues that we have uncovered. We have also responsibly disclosed our findings to Google so as to kickstart remediation efforts. We believe that our research highlights the dire need for more in-depth investigations of the entire Privacy Sandbox, due to the massive impact it will have on user privacy.

1 Introduction

The digital advertisement industry has grown to massive proportions since the first incarnations of web advertisement banners in the early 1990s, and is expected to surpass the trillion dollar mark within the next five years [1]. Online ads not only constitute a major revenue stream for smaller or independent content publishers and developers (e.g., mobile app developers), but are also the main revenue stream of tech giants like Google and Facebook. Ad strategies have also evolved over time, as advertisers aim to improve conversion through behavioral advertising, where users are targeted based on their demographics, preferences and interests. As a result, the ad ecosystem is powered by widespread data collection (typically performed by third-party tracking scripts) for generating user *profiles* based on their browsing habits. Personal user data is amassed by a limited number of companies that have a digital presence on a large number of websites [2, 3], leading to major privacy concerns due to the nature of the data [4–7] as well as the inferences they enable [8, 9].

This has resulted in the commodification of personal data [3], advertisers employing privacy-invasive practices, and ads enabling harmful or problematic behaviors [10–12]. At the same time, users have become increasingly concerned about their online privacy, leading to anti-tracking and ad-blocking capabilities that aim to curtail privacy-invasive behaviors being deployed by privacy-oriented browsers and tools [13, 14]. This has resulted in an arms race, where advertisers and trackers employ new techniques for bypassing anti-tracking defenses deployed by browsers and extensions [15–18].

Recently, Google announced their plans to completely phase out third-party cookies (which enable cross-site tracking) and deploy a series of systems that provide privacy-preserving alternatives to existing advertising mechanisms so as to allow advertisers to maintain their revenue stream while respecting users' privacy. Given Google's role and positioning within the web ecosystem, the Google Chrome Privacy Sandbox initiative may prove to be the most impactful development of recent years in the ad ecosystem, and various privacy organizations and browser vendors have voiced concerns about this further strengthening Google's monopoly and undermining users' privacy [19–21].

In this paper, we present the first comprehensive exploration of the FLEDGE API,[1] which provides the mechanisms and infrastructure needed for running real-time ad auctions without compromising user privacy [22, 23]. The main idea behind

[1] While FLEDGE was recently renamed as the Protected Audience API, we will refer to it as FLEDGE for conciseness.

FLEDGE is to directly execute auctions in the browser, instead of running them on remote servers. By shifting computation to the client side, the need for sharing personal data with third parties can be eliminated. To accomplish that, Chrome has deployed a new type of browser storage called Interest Groups, which can be used to store the information about user preferences that is necessary for successfully running ad auctions. Initially, we provide a series of snapshots capturing the operational status of the FLEDGE API over a period of four months, capturing advertisers experimentation with the system prior to its release as well as after its official deployment in Chrome. Our study reveals a large number of services that have incorporated FLEDGE into their workflow, as well as Google's dominant role within the ecosystem. Subsequently, we conduct an in-depth investigation and empirical analysis of FLEDGE, culminating in twelve novel attacks. We present a series of techniques that target design or implementation flaws in FLEDGE's operation and enable four different classes of attacks: (i) tracking, (ii) cross-site information leakage, (iii) service disruption, and (iv) pollution attacks. In a nutshell, we demonstrate how websites can misuse FLEDGE to re-identify and track users across domains without any cost, partially infer a user's browsing history, prevent other sites from showing the user ads, crash the user's browser, and pollute a user's interest groups so as to manipulate the ads that they will ultimately be shown.

Due to the severe implications of our findings we have disclosed our research to Google. While they patched the issue that allowed us to crash a user's browser, our other attacks still affect Chrome's official deployment of FLEDGE. While some of our attacks may be mitigated by pending changes that Google has announced (e.g., deploying a private aggregation server), others will not be affected. Overall, we strongly believe that additional scrutiny of all Privacy Sandbox proposals is necessary for ensuring that users' privacy is not irreversibly undermined by Google's ongoing efforts.

In summary, our work presents the following contributions:

- We present a large-scale longitudinal measurement of the emerging FLEDGE ecosystem, shedding light on its inner workings and key market shareholders.
- We present the first, to our knowledge, comprehensive empirical analysis of Google's FLEDGE API, and demonstrate novel attacks with severe security and privacy implications.
- We have disclosed our findings to Google, and also propose a series of mitigations against our attacks. We have released our code and data to facilitate additional research [24].

2 Background

The advertising ecosystem plays a pivotal role in facilitating the interaction between publishers and advertisers, ensuring the efficient sale and purchase of ad space. This section provides an overview of the current advertising landscape, focusing on the underlying technologies and platforms involved in the process, and how they will be influenced by the introduction of the FLEDGE API. To understand the process of selecting relevant ads for users, it is essential to first briefly introduce the key parties involved.

Publishers are websites seeking to monetize their platform by offering ad space to advertisers, and **advertisers** are websites aiming to promote their products or services through ads.

Ad Networks. To streamline the complex process of managing delivering ads, various intermediaries that are collectively referred to as ad networks have emerged. These serve as distributed systems that connect publishers and advertisers, and are comprised of several components:

DSPs are services for advertisers to automate the purchasing of ad impressions across multiple publisher sites.

SSPs automate the selling of ad inventory for publishers, enabling them to offer their available ad space to various ad exchanges, DSPs, and networks.

Ad Exchanges function as platforms that automate the buying and selling of ad inventory from multiple ad networks. They act as intermediaries between SSPs and DSPs.

DMPs are data management platforms that store user information. Websites subscribe to DMP platforms to benefit from centralized data organization, while DMPs gather and sell user data, e.g., for real-time bidding.

Real-time bidding (RTB) is a process that aims to show users relevant ads that are tailored to their actual interests, which will be displayed on an publisher's page from a pool of available advertisers. In a nutshell, as outlined in Figure 1, this operates as follows: when a user's browser sends a GET request to a publisher's website, the returned page includes an ad slot. For simplicity, we assume a single ad slot, although multiple slots can exist in practice. The publisher embeds the URL of the SSP to retrieve the ad within the ad slot, and this URL contains crucial bidding-related data, such as the user ID and publisher URL. Upon receiving the request, the SSP processes it to comply with the ad exchange API standards and forwards it to the ad exchange server, which then routes the request to the most suitable DSP based on user preferences and ad type. The DSP will generate a bid request using the user ID and received data, subsequently returning the bid and associated ad URL to the ad exchange. The ad exchange will compute the winning bid and provide the SSP with the corresponding ad URL, and the SSP will deliver the ad URL back to the user's browser, which will fetch and display the ad. Even though this process involves multiple steps, it typically occurs within an short amount of time (e.g., average of 300ms for 24 bidders [25]). Additionally, DMPs and DSPs/SSPs exchange information about user preferences asynchronously with respect to the real-time bidding process. The specifics of this exchange may vary based on individual agreements, and are commonly implemented using APIs exposed by DMPs. DSPs and SSPs are responsible for storing relevant information regarding user preferences asynchronously, thereby enhancing the targeting capabilities of the advertising ecosystem.

Privacy concerns. The effective operation of the advertising process relies on the user IDs, which are typically obtained through third-party cookies, and stored within DMPs that employ various tracking techniques and JavaScript APIs to collect data and create comprehensive user profiles, each associated with a unique user identifier. However, the reliance on third-party cookies raises significant privacy concerns. Users often lack awareness and control over the sharing of their information, including the transmission of sensitive data exploited by DMPs to create detailed and accurate user profiles.

2.1 Privacy Sandbox Proposals

Google's Privacy Sandbox initiative constitutes a concerted effort to gradually phase-out third-party cookie support from the Chrome browser while offering privacy-preserving systems that will fill that void, thus allowing the advertising ecosystem to continue to operate in an effective manner.

FLEDGE (First Locally-Executed Decision over Groups Experiment) focuses on interest-based advertising. It introduces the novel `interestgroups` browser storage and provides a comprehensive set of browser API methods. These methods facilitate the creation and management of interest groups within the user's browser, allowing interest-based ad auctions to occur locally while preserving user privacy.

The core principle behind FLEDGE is to securely store user information within the browser itself, avoiding the transmission of data over the internet. This approach enables real-time bidding to take place within the browser, bypassing the need for ad exchanges. Importantly, FLEDGE's browser API can be leveraged by both publishers and advertisers, granting the flexibility to delegate ad management to SSPs and DSPs while maintaining privacy-enhancing measures.

It is essential to note that during the majority of the time in which this study was conducted, the FLEDGE API remained an experimental feature. This was a deliberate decision on our part, as our goal was to conduct a security and privacy analysis of FLEDGE in an effort to allow Google to address any flaws uncovered by our investigation prior to FLEDGE being officially released and potentially affecting billions of users. Informally, FLEDGE became available for testing purposes as of version 101.0.4951.26 in April 2022, and was officially released to the public and integrated into the stable Chrome browser as of version 117.0.5938.89 in mid September 2023. Despite being officially released, the current implementation still relies on mechanisms that Google has labeled as "temporary", with the plan of substituting them once third-party cookie deprecation is completed.

Interest Groups. The FLEDGE API introduces the concept of interest groups as a cross-context information storage mechanism (replacing third-party cookies) specifically intended for holding information for in-browser ad auctions. Essentially, interest groups contain advertisements and specific information about user interests based on their browsing activity. Each interest group is associated with a specific owner (the origin of the advertiser or DSP), and contains a set of fields, including the name of the group, the bidding logic (links to JavaScript code used to score the bid value), along with ads (renderUrl) and ad components. Unlike third-party cookies which are limited to 180 per-site in Chrome [26], interest groups are comprised of large JSON objects with a current limit of 2,000 interest groups (previously 1,000) associated with a single origin, and have a 10MB size limit. Interest groups are stored in the browser and are initially populated by the owner (advertiser or DSP) that created it. Thereafter, the browser refers to the `updateURL` field to make daily fetch requests to the advertiser's server for new versions. All interest group fields can be overwritten by an update, except for the name and owner.

Workflow. The functionality needed by FLEDGE is mainly implemented through four browser API calls.

`navigator.joinAdInterestGroup()`: This adds a new entry to the browser's storage in JSON format, with multiple fields and a specified lifetime (up to 30 days). It allows advertisers and DSPs to associate interest groups with the browser.

`navigator.leaveAdInterestGroup()`: By providing the relevant JSON format, this call removes an existing entry from the browser's storage. Advertisers and DSPs can utilize this call to remove interest groups when necessary.

`navigator.updateAdInterestGroups()`: This call updates the fields of all interest groups associated with the interest group owner in the user's browser. The updates are fetched from a trusted server, enabling advertisers and DSPs to keep the interest group information up-to-date.

`navigator.runAdAuction()`: This call initiates an auction process to determine the best ad, based on the auction input data provided as a JSON object. Publishers and SSPs use this call to run the auction and select the winning ad. Differently from the other API calls, this function returns the winning ad as an `opaqueURL`, a URL which hides the origin and path, while maintaining the website reference it points to.

FLEDGE's workflow can be summarized in two phases; first, when a user visits advertiser pages, either the page or a DSP on its behalf stores an interest group in the browser using `joinAdInterestGroup()`. The stored interest group contains information such as the owner (origin of the advertiser or DSP), the name of the group, its bidding logic (URL with code used by the advertiser/DSP to score the bid value), and a set of ads (URLs). Second, when the user visits a publisher's page where an ad needs to be displayed, the publisher or an SSP runs an auction using `runAdAuction()`. The auction specifies the seller (origin of the auction runner), the interest group buyers (an array of URLs representing the advertisers/owners), and the decision logic (URL with code used by the publisher/SSP to determine the winning bid and the ad to be displayed) in its most basic form. If an advertiser owns at least one interest group in the browser, it participates in the auction with its associated groups.

During the auction conducted by the publisher or SSP, `biddingLogicUrl` and `decisionLogicUrl` play a crucial

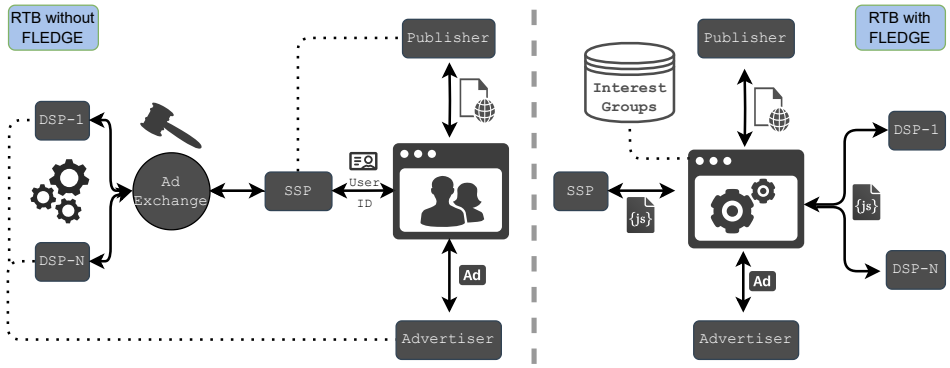

Figure 1: Overview of the traditional RTB workflow (left) and how that changes in the presence of FLEDGE (right).

role in determining the winning bid and the ad to be displayed. These URLs expose a JavaScript file containing the `generateBid()` and `scoreAd()` functions respectively. When the auction takes place, the two URLs are fetched and the functions declared inside are invoked in turn, for each interest group participating in the auction. `generateBid()` calculates the bid value based on the provided inputs and returns the bid value and the URL of the ad to render if the bid is successful. `scoreAd()` evaluates the bid value and additional metadata for each interest group. By considering this information, it generates a desirability score that helps determine the winning bid and the ad to display; in practice, the interest group with the highest desirability score wins the auction.

Within the `decisionLogicUrl` Javascript file, interest group buyers can optionally include the `reportWin` function. This serves the purpose of managing reporting activities for the winning interest group. It is important to note that the future implementation of this functionality will be integrated with the Private Aggregation API [27], according to Google's reports. However, as a temporary mechanism, a `sendReportTo` function allows sending a single GET request to the owner website and include reporting data as query parameters.

Additionally, other resources/URLs can be specified both by advertisers/DSPs and publishers/SSPs when joining interest groups or running an auction, which will be fetched at auction time. In particular, `trustedBiddingSignalsURL` for buyers and `trustedScoringSignalsURL` for sellers allow the designated party to fetch bidding-related data from a *Trusted Server*, intended to preserve user's privacy and avoid logging sensitive information.

After all interest groups have made their decision and the seller has evaluated them, the auction completes by returning the opaque URL associated with the winning ad to the JavaScript file. Upon completion, the seller should manually render the ad within a `fencedframe`, a modified version of an iframe which accepts an `opaqueUrl` and does not allow network access or visibility for the top page context. In future implementations of FLEDGE, the ad rendering mechanisms will be conducted with pre-rendering mechanisms such as web bundles. However, until third-party cookies are deprecated, ads will be fetched from the advertiser's website.

Finally, Chrome is planning to establish constraints regarding the ads that can be rendered, wherein at least 50 different browsers should have joined an interest group with the same ad, name and `biddingLogicUrl` for it to be displayed; essentially, this constraint will implement a form of `k-anonymity`.

Trusted Server. In addition to the information stored within interest groups, both buyers (via `trustedBiddingSignalsURL` in interest groups) and sellers (via `trustedScoringSignalsURL` in auction config) can fetch real-time signals from their own servers to be used in the bidding and scoring logic during auctions. Since this information is sensitive and could be used to track users, FLEDGE intends to enforce restrictions on the design of these servers. Specifically, the server must be a first-party server, must solely provide a key-value service, must not log incoming requests, and must handle the key-value service within a Trusted Execution Environment (TEE). However, the enforcement and trust-model for such servers has not yet been finalized or enforced, even after FLEDGE's official public release. Instead, a Bring Your Own Server (BYOS) "temporary" solution has been made available, allowing buyers and sellers to send themselves the URLs instead of relying on a trusted server, and fetching data directly from their non-isolated servers. As a result, the existing mechanism allows for the potential of tracking users and leaking sensitive information, and is not in line with the privacy-preserving goals of FLEDGE. Finally, we note that even TEEs have been shown to be vulnerable to attacks [28–32].

K-anonymity. To ensure that unique interest groups are not used to track individual users, Chrome is *planning* to establish constraints regarding the ads that can be rendered, wherein at least 50 different browser instances should have joined an interest group. If interest groups do not satisfy this constraint, they will not be made available during auctions. However, the k-anonymity constraint does not apply to the entire interest group and is instead enforced on specific fields, i.e., name, `biddingLogicUrl`, and ad (including `renderUrl`). Additionally, the 50-browser limit will be determined based

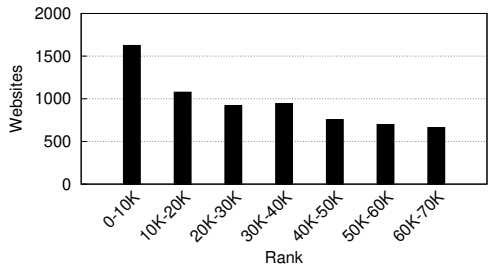

Figure 2: Publishers using FLEDGE, ranked by popularity.

on requests received from hidden browser IPs (routed through Oblivious HTTP [33]). We further discuss this in §5.

Privacy guarantees. FLEDGE aims to offer a privacy-preserving solution by shifting computation and bidding processes to the user's browser, eliminating the need for data sharing through third-party cookies. Users can gain better control over their data with interest groups managed directly in the browser. In their original framework explainer, the developers highlighted three key *privacy advancements* that the proposal is designed to achieve [34]:

- **PA1:** The browser, not the advertiser, holds the information about what the advertiser thinks a person is interested in.
- **PA2:** Advertisers can serve ads based on an interest, but cannot combine that interest with other information about the person — in particular, with who they are or what page they are visiting.
- **PA3:** The websites that the person visits, and the ad networks those sites use, cannot learn about their visitors' ad interests.

While FLEDGE aims to provide a privacy-conscious approach to targeted advertising, an in-depth investigation is necessary for assessing whether it meets those privacy advancements. As we show in §4, the current design and implementation of FLEDGE are vulnerable to numerous attacks that violate its fundamental privacy goals, exposing users to significant risk.

3 Measurements

In this section, we provide the first large-scale measurement of FLEDGE being deployed across the web ecosystem.

Methodology. To automate the process of identifying websites that use the FLEDGE API, we used Puppeteer to orchestrate Chrome. We visit each domain using a fresh browser instance to ensure that we correctly attribute our observations to individual publishers. Once each homepage is fully loaded, our crawler parses the DOM to gather a list of up-to twenty first-party links to visit, to increase coverage and the possibility of observing and capturing the use of relevant functionality. We detect the use of the FLEDGE API by developing function wrappers for calls made to `navigator.runAdAuction`, `navigator.joinAdInterestGroup`, and `navigator.leaveAdInterestGroup`. The Puppeteer script injects wrapper functions into the page and logs all corresponding accesses. After visiting all links under a domain, we close the browser and collect the SQLite Database where Chrome stores information about the Interest Groups of each browsing profile. Finally, we clear the state and all relevant files associated with the browsing session.

Table 1: Overview of sellers over time.

Month	Seller	#Publishers	#Auctions
June	securepubads.g.doubleclick.net	1,761	5,738
July	securepubads.g.doubleclick.net	1,038	2,960
	cdn.mediago.io	1	1
September	securepubads.g.doubleclick.net	565	3,243
	cdn.mediago.io	9	17

Dataset. Using our automated approach, we perform a crawl of the top 70K domains from the Tranco list [35]. We opted for this set based on the hypothesis that popular domains are more likely to expeditiously develop the infrastructure necessary for using new features introduced by the Privacy Sandbox. Our framework collected the API calls on these sites in June and July 2023, thereby capturing snapshots of FLEDGE usage while it was an experimental feature, and again in September 2023 when it was publicly released.

Publishers. We detected the use of FLEDGE APIs in 9.5% ($n = 6{,}682$) of the 70K sites that we visited during the measurement period. Figure 2 presents an overview of the sites ranked by popularity. Indeed, we observe a correlation between websites' popularity and the usage of FLEDGE, as it was most prevalent in domains from the top 10K. Interestingly, over the three measurement snapshots we observe a decline in the number of sites using FLEDGE. While 4,628 sites used FLEDGE in June, this number decreased to 3,903 sites in July, and further dropped to 3,585 sites in September. Since our measurements also covered a transitionary period for FLEDGE, wherein it evolved from a set of experimental features to a public release, the reduction in the number of sites using the system could indicate that sites are still experimenting with how to fully and effectively take advantage of FLEDGE features prior to its official release. We expect the number of sites to significantly increase as the system matures and grows more stable, with advertisers and sellers scaling support and updating their infrastructure. Importantly, while we captured FLEDGE calls within multiple top-level publisher domains, all the actions we observed were performed by third-party advertisers and sellers. Our observations indicate that Privacy Sandbox proposals may likely end up primarily being adopted by larger, ecosystem-wide entities instead of benefiting smaller, independent domains intending to remarket their products to their visitors and customers.

Sellers. We observed a total of 11,959 auctions for ad spaces during our measurement period, almost all of which ($n = 11{,}941$) were run by Google Ad Manager. Table 1 shows the number of auctions and the corresponding publishers

Table 2: Interest groups' `join` and `leave` actions.

Owner	#Publishers	Interest Groups #Joined	Interest Groups #Left
td.doubleclick.net	2,924	12,190	2,533
fledge.as.criteo.com	370	880	-

at-us-east.amazon-adsystem.com	1	1	-
adthrive.com	4	4	-

within which they were ran. Our findings about the dominance of Google Ad Manager are in-line with prior observations of the ad ecosystem [36]. Additionally, since the Privacy Sandbox initiatives are led by Google and are geared towards Chrome browsers, it is expected that their ad ecosystem will integrate the latest functionality into their operations. Finally, Google Ad Manager has been running FLEDGE operations on a small set of publishers, planned to scale to 10% of auctions by the end of 2023 [37, 38]. While most auctions that we observed were run by Google, these auctions also included a large number of *component auctions*, i.e., separate auctions from multiple sellers, the results of which were passed to the top-level auction. We report on these auctions later in this section. Nonetheless, other popular sellers including Xandr, Teads, RTBHouse, OpenX, PubMatic, and Criteo [39–42] have been working on integrating FLEDGE auctions into their workflows. We expect that future measurements of the ecosystem will include additional sellers once the ecosystem matures further.

Advertisers. We observed 7 advertisers (that map to 13 different domains) adding users to interest groups and participating in FLEDGE auctions. Table 2 provides an overview of the advertisers that we observed during our measurements. We observed three large advertising companies, Google (DoubleClick), Criteo, and RTB House (CreativeCDN), using the APIs from multiple domains. Since FLEDGE actions are restricted based on origin (i.e., protocol, domain, and port), using multiple origins enables advertisers to act as multiple individual participants in creating interest groups and placing bids. While this approach restricts interest group access to individual origins, advertisers can expand the size of their interest group set and bypass the current restriction of 2,000 groups per-origin [43]. Additionally, they can access multiple origin-based dedicated worklets to run bidding logic and also place multiple bids in a single auction [44].

Since FLEDGE allows advertisers to use personal data for ad personalization and access storage through interest groups, the EU User Consent Policy requires advertisers to gather user

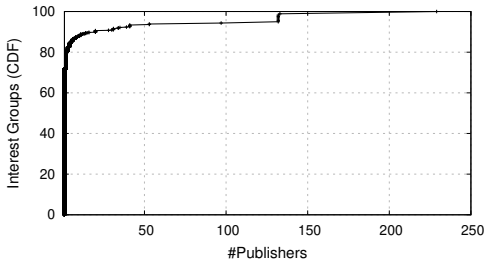

Figure 3: Publishers associated with each interest group.

consent before performing such actions [45]. Interestingly, we observed Criteo and RTB House creating region-based subdomains and adding browsers to multiple interest group sets under subdomains dedicated to EU, US, and Asia-based users. While all the measurements were performed through US-based IP addresses, we observed the browser joining interest groups from other regions as well. Advertisers may choose to create multiple interest group sets in an attempt to comply with varying consent and data handling regulations.

Interest Groups. We observed a total of 15,935 interest groups; Figure 3 shows the number of publishers within which the browser was added to each interest group. We found that 92% of the observed interest groups were only added upon a visit to a single top-level domain. Our observation is in-line with the intended use of interest groups, i.e., storing user interests based on their browsing activity. Additionally, due to the granular nature of this information it is crucial that the data held within these groups is protected, preventing leaks and misuse for privacy-invasive user tracking.

FLEDGE caps interest groups lifetime to 30 days, but it can be extended by repeating a call to `navigator.joinAdInterestGroup()` [44]. We observed 18.28% ($n = 2,913$) of the interest groups across all three dataset snapshots. Interestingly, while we observed 306,407 calls to join an interest group, 30.90% ($n = 94,673$) attempted to create an interest group with an expiration time greater than 30 days. While the browser enforces the 30-day expiration limit of interest groups, this indicates advertisers' attempts at making interest groups persist longer within browsers, which also explains the limited removal of interest groups shown in Table 2.

While joining and updating groups, advertisers can include arbitrary information within bidding signals that help inform bidding logic when the interest group is included in an auction. They can specify a list of keys in the `trustedBiddingSignalsKeys` field, for which values will be fetched in real-time from a key-value service that the advertiser hosts. We observed limited use of this approach with advertisers adding only 1 key to an interest group on average. Additionally, they may also include information through key-value pairs within the `userBiddingSignals` field. The values stored in this field will remain in the user's browser and be made available to the advertiser within on-device auctions. Given that advertisers

Table 3: Summary of our attacks, the mechanism they misuse, privacy advancements they violate, and planned mitigations.

do not need to set up a server-side service to `userBiddingSignals`, we found that they used the field in 92.59% ($n = 283{,}714$) to join interest groups and included 3 key-value pairs on average within an interest group ($SD = 0.59$).

Each interest group can store and bid on multiple ads. We observed that advertisers populated interest groups with 18 ads on average ($SD = 32$, $M = 7$). Additionally, ads can be further supplemented by ad components, intended to hold pieces (e.g., individual products) that can be associated with ad campaigns. While we found that only 1.4% ($n = 4{,}306$) of calls to join an interest group populated the `adComponents` field, they stored extensive information, populating it with 132 components on average ($SD = 96.5$, $M = 100$), Our observations highlight that interest groups are complex objects that contain data in ways that could not be previously captured within third-party cookies. With an extensive limit of 2,000 groups per-origin, coupled with a lax k-anonymity requirement on this information, our findings further motivate the importance of an in-depth analysis of FLEDGE's privacy implications.

Auctions. We observed a total of 11,959 auctions, wherein we observed 4 auctions on average ($SD = 6.4$,$M = 2$) for each publisher across 3 visits. FLEDGE includes support for component auctions, and their results are passed to the top-level auction. Out of 11,959 top-level auctions, we observed a total of 11,994 component auctions ($Avg. = 1$, $SD = 0.6$, $M = 1$). These included a limited number of participants, with 2.14 advertisers on average ($SD = 1.49$, $M = 2$). Moreover, sellers can include arbitrary information for assisting them in scoring bids. We found sellers making extensive use of this field, passing 20.88 signals on average ($SD = 3.95$, $M = 21$) for use in scoring bids gathered within component auctions. Additionally, FLEDGE allows sellers to pass arbitrary signals to individual buyers by using the `perBuyerSignals` field. We observed sellers passing extensive information to each buyer within individual component auctions, with seller passing 9.96 signals on average ($SD = 6.28$, $M = 6$) to each buyer. Since the values within these signals can be arbitrary, we observed that all signals were either passed as an array or an object. While the values contained were themselves obfuscated, the data structures were extensive, including additional arrays and objects, resulting in an average depth of 7.6 ($SD = 4.27$, $M = 6$).

Summary. Overall, we observed that FLEDGE interest groups and auctions include a large number of components that store granular user information and share arbitrary objects between multiple third-party entities. The inclusion of on-device logic execution, coupled with fetching real-time data from servers, and support for multiple sub-auctions creates a large ecosystem that needs to ensure proper handling of data, especially within fields that can hold arbitrary values. Our measurements highlight the adoption of the system across multiple publishers and its on-going use by prominent advertisers. Since Google has enabled the system by default for Chrome users, an empirical analysis of FLEDGE is necessary for understanding the inner workings of the ecosystem and to evaluate the system's effectiveness in preventing privacy-invasive misuse.

4 Empirical Analysis of FLEDGE

In this section, we present a series of novel attacks that misuse FLEDGE, and detail the functionality that we leverage to achieve them. Table 3 provides an overview of our attacks and highlights the privacy goals that each attack violates.

Threat model. Our attacks are performed by a web attacker that uses the FLEDGE API as an advertiser and/or seller. We assume that the user visits a website where the attacker has the ability to add the browser to interest groups, and to participate as a seller by running auctions. To that end, the attacker needs to own a domain with the server having been setup to handle FLEDGE requests, including support for key/value services and file responses for individual fields used by interest groups and auctions. Beyond the infrastructure setup, the threat model assumes a weak attacker with limited privileges since our attacks can be carried out by attackers embedded as third-party resources, and do not require the user to visit the attacker's domain. As FLEDGE APIs are enabled by default in Chrome, users do not need to enable any experimental flags.

Experimental setup and auditing process. The attacks we present in this section were designed and performed using

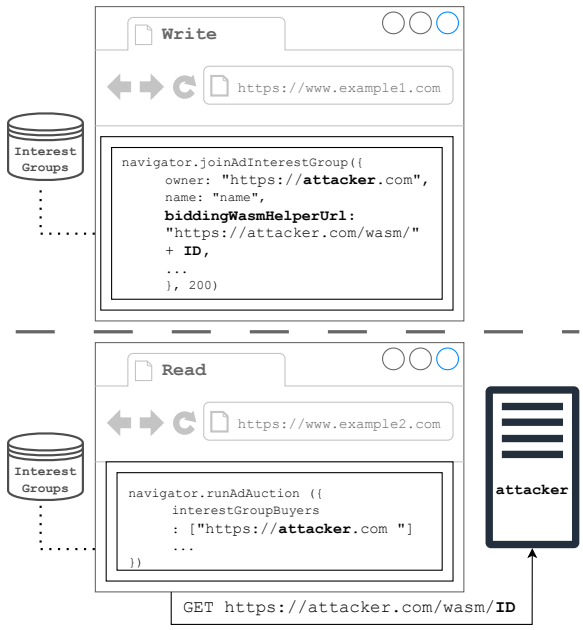

Figure 4: User tracking with bidding helpers.

our own infrastructure, and were guided by our detailed study of the FLEDGE documentation, code review, and empirical experimentation. This included creating test pages that use the FLEDGE APIs, understanding the purpose of each parameter, analyzing the flow of information across different entities, and identifying potential privacy violations and attack vectors. We then created custom exploits using controlled web pages to evaluate the attacks' practicality and feasibility. We did not perform any attacks on live users or websites. We used our own domains, hosted at an institutional IP address, and accessed these domains using Chromium browsers on our own machines. For the attacks described in §4.1 and §4.2, the scripts simulated both victim and attacker scenarios. Finally, for the attack describing pollution of Doubleclick interest groups, we made calls to Doubleclick from a website under our control and within browsing sessions on our own devices.

4.1 User Tracking

Bidding Helpers. FLEDGE allows advertisers to populate interest groups with multiple fields that describe the name and contents of the group but also determine how the group will participate in ad auctions. Advertisers can configure custom bidding logic using JavaScript through the `biddingLogicUrl`. In addition to the JavaScript code, advertisers can execute computationally-expensive subroutines by directing the browser to fetch WebAssembly code from a link provided under the `biddingWasmHelperUrl`. The API enforces restrictions on this field; first, the provided link should return a WebAsssembly binary with an `application/wasm` MIME type, and the browser will make the returned code available while generating bids. Second, the link must share its `origin` (i.e., protocol, domain, and port) with that of the owner of the interest group. However, the API does not enforce k-anonymity restrictions on this field. Therefore, each instance of the interest group can set a unique `biddingWasmHelperUrl` for identifying a specific browser. Figure 4 presents an overview of this attack.

Writing an identifier. An attacker can add the browser to a specific group by passing the interest group object as an argument to `navigator.joinAdInterestGroup()`. The attacker can embed a unique 32-bit identifier corresponding to a specific browser instance into the path of the `biddingWasmHelperUrl` field of the interest group object.

Reading an identifier. In subsequent browsing sessions, the attacker can participate in auctions as both a seller and a buyer. As a seller, the attacker can create a unique, single-buyer auction with its own origin as the only participant. Upon running the auction, the browser will trigger a fetch request to the `biddingWasmHelperUrl`, thereby passing the identifier to the attacker's server, enabling it to re-identify the browser instance.

Mitigation. This attack leverages two aspects of `biddingWasmHelperUrl`'s functionality. First, the API does not impose anonymity restrictions on the uniqueness of the link for each browser instance. Second, the logic is fetched through a network request at runtime. In order to restrict the field from being misused, the FLEDGE API should first extend its enforcement of k-anonymity restrictions to include `biddingWasmHelperUrl` so as to prevent unique identifiers from being set for each browser. Furthermore, the browser should trigger a single fetch for WebAssembly code upon joining an interest group, which should be cached and reused for all future auctions involving that specific interest group.

Real-time Rendering of Winning Bids. When an interest group wins an auction, the browser refers to the link specified in the interest group's `renderUrl` field, gathers the necessary components, and renders the ad within an embedded frame. As part of the privacy protections introduced by the Privacy Sandbox proposals, Google is implementing a new HTML Element called Fenced Frame. This element is similar in design to an iframe, but is restricted in its ability to interact with other frames in the page (including the top-level frame) and also has restrictions to network access. The FLEDGE API proposes rendering winning ads within fenced frames. This way, the winning bid is rendered in a restricted environment with limited ability to perform privacy-invasive actions while embedded in a third-party site. Moreover, given the restrictions on network requests within fenced frames, the browser will fetch ads from the `renderUrl` in an asynchronous manner, independent of the execution of specific auctions. However, the Fenced Frame proposal is experimental, and its use remains optional in the current public release of the FLEDGE API, which allows winning bids to trigger real-time network requests to the `renderUrl`. Figure 5 presents an overview of this attack.

Writing an identifier. An attacker can create and maintain 32 unique strings, each mapping to one bit of a 32-bit

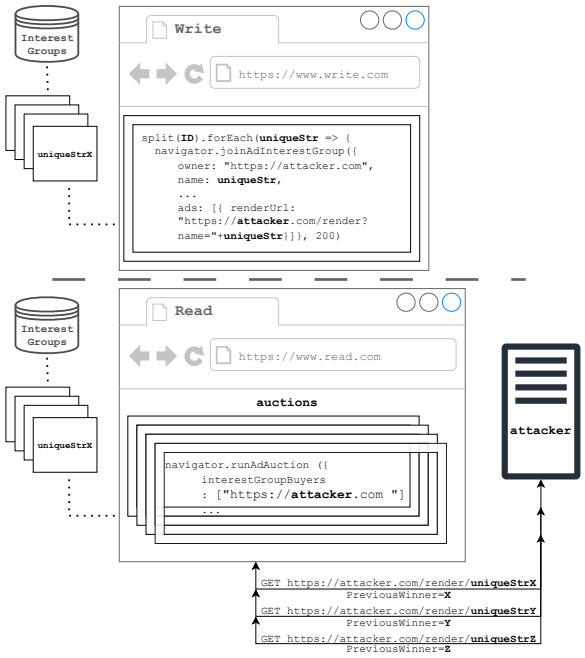

Figure 5: User tracking with rendering of winning bids.

identifier. For each new user the attacker gathers the list of strings that correspond to 1-valued bits and embeds them within the `name` and `renderUrl` fields of different interest groups. All interest groups share the same `owner` domain. The attacker makes the browser join all created interest groups by calling `navigator.joinAdInterestGroup()`. FLEDGE plans to impose a k-anonymity constraint on the `name`, `biddingLogicUrl`, and `renderUrl` fields. Thus, we avoid embedding the entire ID in a single interest group, and instead split it across 32-unique strings. Doing so reduces the number of unique interest groups that are required to satisfy the k-anonymity constraint. Additionally, in the presence of k-anonymity restrictions on other fields, the attacker ensures that all interest groups use the same `biddingLogicUrl`.

Reading an identifier. The attacker runs multiple single-buyer auctions, one for each stored interest group. With each auction, the browser calls the bidding logic and passes seller-defined `auctionSignals` as arguments. Since these can include arbitrary information, we add the list of the winners of completed auctions. The code within `biddingLogicUrl` can choose a random interest group to win each auction after filtering out the previous winners. This way, each group wins exactly once. Upon the completion of each auction, the browser triggers a network request to the `renderUrl`, and informs the attacker about the winner. The attacker can maintain a list of previous winners and use them for future auctions until all bits that correspond to a value of 1 have been gathered and a unique identifier has been reconstructed.

Mitigation: This attack is currently feasible due to the public release of the FLEDGE API before the development of privacy protections offered by Fenced Frames. Fetching the browser ads asynchronously will ensure that this attack cannot synchronously gather and maintain a list of winners and, thus, cannot regenerate an identifier across multiple auctions.

Bidding Logic. We also found a similar attack that makes use of the `biddingLogicUrl` instead of the `renderUrl`. The `biddingLogicUrl` contains JavaScript code that is invoked when the interest group is made part of an auction. As part of the FLEDGE API plans for the introduction of a k-anonymity server, advertisers will be required to ensure that the same `biddingLogicUrl` is present in at least 49 other browser instances. Even though the attack we present can be executed in spite of the anonymization requirement, the current public release of FLEDGE does not enforce any such restrictions.

Writing an identifier. The attacker again generates 32 unique strings, and gathers strings mapping to a bit value of 1. The attacker then creates interest group objects that share the same owner domain, and the corresponding string for each gathered bit is embedded in the `name` and `biddingLogicUrl` fields. The attacker will then make the browser join all created interest groups. When FLEDGE actually enforces k-anonymity in practice, the attacker would be required to ensure that interest groups corresponding to each unique string are available on at least 49 other browser instances (we discuss this and potential bypasses in §5). To do this, the attacker can design 32 unique interest groups, each corresponding to one bit of a 32-bit identifier. The attacker must ensure that interest groups containing a `biddingLogicUrl` corresponding to either value satisfies the anonymity requirement.

Reading an identifier. The attacker runs one single-buyer auction and the browser calls the `biddingLogicUrl`s corresponding to each interest group stored in the browser. The incoming requests let the attacker's server learn the value for each bit corresponding to a value of 1 that is stored in the browser. The attacker can fill in the values of 0 for the bits that are not stored in the browser and reconstruct the user's identifier. This attack is similar to the one presented in Figure 5, but the attacker reads the identifier during the execution of the auction, rather than when it wins the auction.

Mitigation. While introducing the k-anonymity constraint will impose restrictions on this attack, it does not eliminate the possibility of re-identifying the user. For this this attack to be effectively mitigated, the browser needs to fetch and cache the `biddingLogicUrl` in an asynchronous manner instead of gathering the code when running an auction. That way, the attacker receives requests for the `biddingLogicUrl` at arbitrary times and cannot map the request back to an individual instance or browsing session to reconstruct the identifier.

Trusted Bidding Signals. The FLEDGE API proposal aims to incorporate trusted servers into its auction infrastructure. These trusted servers can be used to add real-time bidding signals to bidding logic, which will execute within a Trusted Execution Environment (TEE). As this infrastructure is under development, Chrome allows advertisers and sellers to use cus-

tom implementations through their support for a *Bring Your Own Server* (BYOS) model. While this is a temporary solution to help with eventual migration to a TEE infrastructure, the BYOS model was made available by default in the public release of the FLEDGE API. To support the BYOS model, when running an auction the browser automatically passes the names of all stored interest groups that share the same key/value service defined by the `trustedBiddingSignalsUrl` field. An attacker can currently exploit this mechanism to embed and regenerate a unique identifier to track users across different sites.

Writing an identifier. The attacker generates the identifier and creates the unique interest group objects for each bit that corresponds to a value of 1. All groups share the same `owner` domain and the same `trustedBiddingSignalsUrl`, and the corresponding string for each bit is embedded in the `name` of the interest group fields. The attacker makes the browser join all created interest groups.

Reading an identifier. The attacker runs an auction with their own domain participating as the only buyer. The browser triggers a `GET` request to the `trustedBiddingSignalsUrl` and includes the names of all interest groups in the parameters. The attacker's server can then reconstruct the identifier by mapping the names of observed interest groups to a value of 1 and filling all other bits with a value of 0. This attack functions in a similar manner to the one presented in Figure 5, but reading an identifier only requires a single auction, and the identifier is read by the attacker's BYOS server.

Optimization. This attack can be optimized by storing the entire 32-bit identifier in a single interest group, by appending it in the `trustedBiddingSignalsUrl`. Thereafter, the identifier can be read when the browser initiates a `GET` request to the endpoint specified in the `trustedBiddingSignalsUrl` field, and does not need to be reconstructed from the names of multiple interest groups. This optimization is possible because of the trivial cost on the attacker to create new, untrusted key/value services on existing servers in the BYOS model.

Mitigation. Adding support for the BYOS model in its public release opens the API to misuse with new tracking vectors. The current infrastructure enables untrusted servers to log event-level data, i.e., the services can store and share details of individual requests with their servers to enable user tracking. When a requirement for the TEE-based key-value services is enforced, browsers will only send bidding signals to trusted servers. These servers will be required to not log event-level data or share details about individual requests they receive from browsers to any external servers.

Non-aggregated Win Reporting. The Privacy Sandbox includes functionality implemented by the Private Aggregation API, which ensures that events from bids and ad impressions are aggregated and anonymized before they are shared with advertisers. However, since the Private Aggregation API and its corresponding infrastructure are under development, the public release of the FLEDGE API adopts granular reporting. The triggers a network request that reports the winner of each auction back to the advertiser and includes the `name` of the winning interest group in these requests. An attacker can exploit this mechanism to track users by curating multiple auctions, with each one revealing one bit of information.

Writing an Identifier. The attacker can create a 32-bit identifier by generating 32 unique strings and creating interest group objects that share the same `owner` domain for strings that map to a value of 1. Additionally, within the bidding logic (made available at the link under `biddingLogicUrl`), the attacker exposes two functions: `generateBid()` which includes logic to create a bid, and `reportWin()` which can receive details about the bid upon winning an auction. Note that the `reportWin()` function is invoked by additionally calling `sendReportTo()` within the `generateBid()` function.

Reading an Identifier. The attacker runs multiple single-buyer auctions. With each auction, the browser reports the winner by calling the interest group's `reportWin()` function, which in turn triggers the `sendReportTo()` function and provides it with the name of the winning interest group. The attacker can ensure that each auction is won by a different interest group by keeping track of previous winners and passing their names in seller-provided auction signals. Once all stored interest groups have won at least one auction, the attacker's bidding logic returns a null value. Thereafter, all interest groups that won an auction can be considered to correspond to a bit value of 1 and the user's identifier can be recreated. This attack is designed in a similar manner to the one presented in Figure 5. However, each bit is read based on FLEDGE's current reporting mechanism instead of its ad rendering setup.

Mitigation. The attack relies on a measure that currently bypasses aggregation of ad impressions and allows advertisers to receive granular information about individual auctions. This can be limited by introducing the Private Aggregation API which will anonymize auction events before reporting them to the advertiser, thereby limiting their ability to synchronously gather and construct identifiers across multiple auctions.

Non-aggregated Event-level Reporting. FLEDGE also allows advertisers to gather events within rendered ads, including ad impressions and clicks. Fenced frames include functionality to support event-level reporting through the new `window.fence.reportEvent()` API call that is only triggered within the frame's context and handled by the browser. While events reported from fenced frames are intended to be anonymized with the Private Aggregation API, FLEDGE currently allows advertisers to gather information from individual ads.

Writing an identifier. The attacker can embed a unique, 32-bit identifier in the interest group's `userBiddingSingals` field. This field is made available to the advertiser's bidding logic when the interest group participates in an auction.

Reading an identifier. In subsequent sessions, the attacker runs an auction with itself as the only participating advertiser. The browser executes the advertiser's bidding logic, making the identifier from the previously defined `user-`

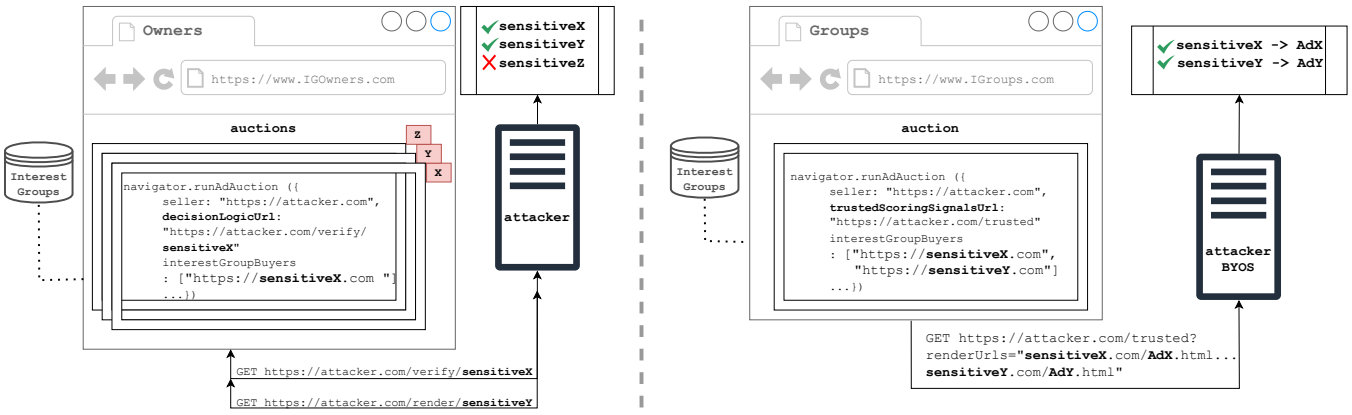

Figure 6: Cross-site leaks of owners (left) and interest group contents (right).

`BiddingSignals` available to the `generateBid()` function. The advertiser can place an infinitesimal positive bid value (FLEDGE limits bid precision values to an 8-bit mantissa and 8-bit exponent [44]) and specify an `adcost` of 0 to avoid costs. The identifier is returned to the seller as part of the `adMetadata`. Once the seller receives bids, the browser executes its `scoreAd()` function, within which it extracts the identifier from the `metadata` and designates it as a `desirability` score. The identifier embedded in the `desirability` score is available to the `reportResult()` function, from which the seller can pass it back to the server as a network request by using one of the following methods. First, it can create a custom event, say *track*, which is then reported as an event from within the fenced frame using `reportEvent()`, which generates a network request to the attacker's domain with the identifier embedded as a query. Alternatively, the attacker can use a temporary reporting mechanism, `sendReportTo()`, which passes similar reports to a URL specified by the seller without relying on the fenced frame's functionality. In addition to its design similarity to the win reporting attack described above, this attack additionally relies on code being shared between an advertiser and a seller, i.e., it assumes that the two parties either collude or a single entity participates as both. This assumption is reasonable, as we further discuss in §5.

Mitigation. This attack vector also relies on a measure that currently bypasses aggregation of ad impressions and allows advertisers to receive granular information about individual auctions, and can be prevented by ensuring that ad impressions are aggregated and anonymized with the Private Aggregation API before sending them out of the browser.

4.2 Cross-site Data Leaks

Gathering Interest Group Owners. First, we describe a technique that allows arbitrary sellers to learn the list of domains that have added that specific browser to an interest group. Our method exploits the default mechanisms with which the FLEDGE API handles auctions.

Existing exploitable data. When a user visits a website, say `example.com`, the website can add the user to an interest group that captures specific user interests corresponding to the user's actions on the site. Note that both top-level domains and third-party advertisers (embedded within frames or through script tags) can add a user to an interest group. In either case, the entity that created the interest group will be considered the owner.

Preparation. The attacker prepares a pre-defined list of domains that it intends to test against users. If this list includes "sensitive" domains, the presence of an interest group from specific domains can leak private or personal information about the user. In general, knowledge of whether the user has visited domains that are of interest to the attacker can be leveraged for a variety of privacy-invasive attacks depending on the nature of those domains (e.g., targeting users of competing businesses, targeting users with specific interests, extortion [46]).

Observing the presence of an interest group owner. When a user visits the attacker's website, it can execute auctions so as to infer the presence of an interest group owner. Specifically, for each domain in the pre-defined list of target domains, the website defines a new, single-buyer auction. The auction configuration includes a `decisionLogicUrl`, which is an attacker-controlled link that receives bid responses and decides the winner of the auction. However, if none of the buyers participating in an auction have an interest group stored in the browser, the network request to the `decisionLogicUrl` will not be triggered. This reveals the presence or absence of interest groups from each targeted owner to the attacker. Figure 6 (left) presents an overview of this attack.

Performance evaluation. The attack is scalable to a large list of pre-defined domains. For our evaluation we gathered a list of 500 domains and used Puppeteer to open a fresh browser instance and join interest groups from a subset of owners. Following the join operation, we navigated to a third-party attacker domain which executed the sniffing attack against the

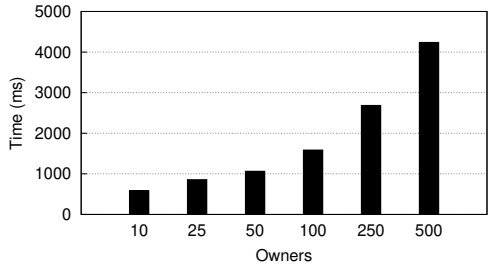

Figure 7: Performance of interest group owner-sniffing.

500 domains. For each subset size we repeated the experiment 10 times and gathered the average observed time. As can be seen in Figure 7, the attack duration depends on how many of the interest group owners are present in the user's browser. When all 500 owners were present, the attack took approximately 4.2 seconds to complete. It is important to note that the attack is transparent to the user since FLEDGE operations are performed within dedicated worklets outside of the main thread [44], and can be further scaled up based on the attacker's list of targeted owners. The attack was also fully accurate in all of the experimental runs (i.e., no false positives or negatives).

Multiplexing. We performed this attack with HTTP/2 connections. Since the browser only allows 6 HTTP/1.1 connections to be opened simultaneously, we multiplexed HTTP/2 connections to allow for a large number of concurrent streams over a single connection [47–49].

Mitigation. The attack is made possible by the synchronous approach and logic applied by the FLEDGE API before triggering requests to the `decisionLogicUrl`. This attack can be mitigated with a two-step approach; first, the browser would need to asynchronously gather and cache the decision logic code for a pre-approved list of sellers to prevent network requests from being triggered for each auction. Second, the decision logic needs to be restricted in its ability to trigger network requests outside of the current auction's context.

Interest Group Leaks. While the previous attack allows an attacker to learn the presence of interest group owners, it is unable to gather details about the contents of the interest groups stored by each owner. Here we present an additional attack that builds upon the previous attack for obtaining links to ads stored within individual interest groups within the `renderUrl` field. Gathering ads corresponding to the field helps an attacker learn details about user interests and browsing behavior towards which the specific ad is geared towards. This is done by running an additional auction with the list of previously identified owners as participants. When a browser observes this auction, it gathers bid responses from each of the interest group owners. Subsequently, along with the positive bids it will pass the `renderUrl` for each positive bid to the seller at the link defined in `trustedScoringSignalsUrl` for that auction. This functionality aims to assist the seller in deciding the winner of the auction.

Prerequisites. Within each interest group, the owner must have specified a valid `renderUrl`. When participating in an auction that is run by the attacker, we assume that the owner places a positive bid towards at least one interest group.

Trusted Scoring Signals. Similar to the previously described use of trusted bidding signals being passed to advertisers, the FLEDGE API includes an equivalent mechanism to help sellers gather information that can be factored in determining the outcome of an auction. These signals are intended to be made available through a secure key/value service and provided to the decision logic within a TEE-environment. However, in order to support BYOS models, the API provides the seller with the `renderUrl` along with individual bid responses for each advertiser that placed a positive bid within the auction, thereby enabling a cross-site leak of the contents of individual interest groups. Figure 6 (right) presents an overview of this attack.

Gathering Ad Links. Once the attacker has a list of domains for which it intends to gather interest group information, it creates an auction including the list of owners as participants. It ensures that the auction configuration defines a `trustedScoringSignalsUrl` that points to a service under the attacker's control. Upon running the auction, the browser collects the `renderUrl` from every interest group owner that placed a positive bid in the auction, and passes these links as parameters to a GET request sent to the attacker's trusted signal server. As such, the attacker can gather the `renderUrl` corresponding to one interest group per owner. Each `renderUrl` reveals the specific interest towards which the interest group is targeting the user. These links can leak specific information about a user including products that they have interacted with (e.g., specific hotel and flights that they are attempting to book) or even sensitive interests (e.g., products from sensitive sites that the advertiser is remarketing).

Mitigation. Adding support for the BYOS model in the public release of FLEDGE opens the API to misuse not only from advertisers but also from sellers attempting to infer details about a user's browsing activity. This can be mitigated through the use of an established TEE environment that would operate without the need for an individual `renderURL` to be passed to the seller, in an unsafe manner, for every bid.

4.3 Service Disruption

Browser Crash. Prior to its public release, we observed an out-of-bounds error that could be triggered in FLEDGE APIs, thereby causing the browser to abruptly terminate all on-going sessions. The vulnerability was the result of incomplete error handling in the event of a prioritized interest group exiting an auction before producing a valid bid.

Preparation. The attacker adds the browser to two interest groups with a specific composition of fields. The first group contains values for `name`, `biddingLogicUrl`, and `ads`. In addition to these fields, the second group also defines `trustedBiddingSignals` and is prioritized by setting the `enableBid-`

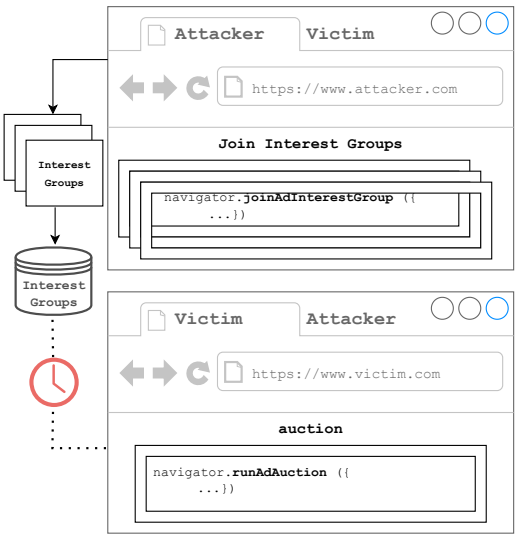

Figure 8: Blocking Ad Auctions.

dingSignalsPrioritization field to True. Finally, the biddingLogicUrl of the second group needs to return invalid bidding logic, like an empty or non-JavaScript response.

Triggering the crash. After making the browser join the two specially-crafted interest groups, the attacker can run an auction that only involves those two groups. The crash is triggered after an non-deterministic number of auction invocations and, therefore, is executed multiple times in a loop.

Bidding pipeline details. When running an auction, the FLEDGE API invokes and executes the bidding logic for both interest groups. However, note that the second invocation does not wait for the first invocation to complete, and only the order is determined by prioritization. Since the second interest group includes an invalid URL in the biddingLogicUrl field, the corresponding worklet crashes and is filtered out of the auction. However, upon doing so it fails to update an auction variable that tracks the expected number of bid responses. Thereafter, once the first interest group completes its bid, the browser attempts to read the result of an additional, non-existent bid, which results in an unhandled out-of-bounds exception that eventually crashes the browser.

Mitigation. we reported our findings to the Chromium team and they promptly fixed the bug prior to the public release of FLEDGE, by including a test case for the reported scenario to ensure that the error is promptly handled.

Blocking Ad Auctions. FLEDGE attempts to limit the impact that ad auction operations performed by one advertiser can have on operations performed by others. Figure 8 presents an overview of this attack.

Existing protections. The browser ensures that all FLEDGE operations performed by a domain are executed within a worklet dedicated to that domain. This restriction ensures that the operations of one domain do not impact the actions of other domains. Additionally, the browser ensures the timely completion of an auction by enforcing a 500ms timeout on the execution of the bidding logic for each buyer that is participating in an auction. However, regardless of the dedicated worklets, all FLEDGE-based operations interact with a global interest group database, access to which is not thread-safe, and on-going operations on the database can block access until the operations complete [50]. We note that while there is existing support for per-partition storage of interest groups [51], the official public release is vulnerable to the attack that we describe next.

Prerequisites. We assume that the user has visited two domains in different tabs within the same browsing window. The attacker is embedded as an advertiser on both domains. In the first tab, the attacker makes a large number of calls to navigator.joinAdInterestGroup(). In the second tab, an arbitrary seller runs an ad auction after the attacker has already issued a large number of calls to join new interest groups.

Blocking. When the attacker makes a large number of calls to navigator.joinAdInterestGroup(), each of these calls are queued to execute within the attacker's dedicated worklet. However, these operations also access and update the global interest group database associated with the browser's profile. When a seller starts an ad auction, the browser also queues a call for the bidding and decision logic to execute within other worklets, but their execution waits for access to the interest groups database, thus delaying the completion of their auction.

Attack details. In our experiments we found that by invoking 10,000 calls to navigator.joinAdInterestGroup() the attacker can prevent an ad from rendering for up to 25 seconds. The ad ecosystem benefits from displaying relevant ads to users in a timely manner that seamlessly integrates with their browsing session. Depending on the placement of the ad on the page, and the amount of time the user actually spends on that specific page, the attack may result in the user not even seeing any ads. Preventing the timely execution of ad auctions can prevent competitor advertisers, sellers, and publishers from gathering monetary gains from ad impressions or conversions. Performing this attack at a larger scale across multiple users and devices can significantly impact the revenue streams of participating entities.

Mitigation. The attack exploits the browser's lack of checks for locks placed on global resource pools. Implementing a per-origin limit on access to the interest group database and a use of caches for FLEDGE operations per-tab, can limit the delay introduced by one domain's operations on others.

4.4 Pollution Attacks

Polluting DoubleClick Interest Groups. Throughout 2023, Google Ad Manager introduced FLEDGE-based auctions to a small set of publishers, with the intention of scaling these auctions to 10% of all ads that they serve [37, 38]. As a result, during our measurement period, we observed the creation and use of a large number of interest groups owned by doubleclick.net.

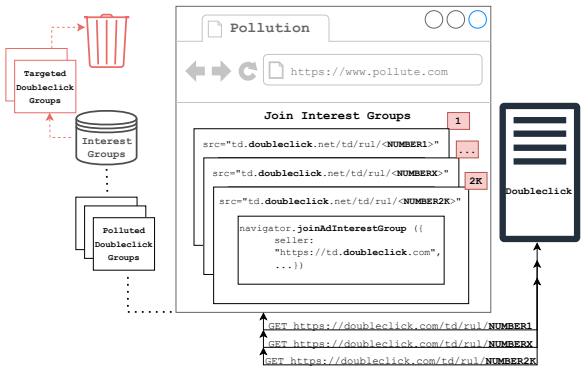

Figure 9: Polluting Doubleclick Interest Groups.

Specific URL Patterns. We noted that Google Ad Manager added interest groups from pages with embedded JavaScript code that, when loaded, automatically added the browser to interest groups. The frames were loaded from a URL with a common pattern, i.e., `td.doubleclick.net/td/rul/<NUMBER>`, where the `<NUMBER>` indicated a unique, 10-digit number corresponding to a specific interest group. Upon visiting these links, we observed that Google did not apply checks and authentication, and responded to all incoming requests without verifying their origin. The value of the `<NUMBER>` corresponds to the name of the Google-owned interest group that the browser will be added to. Using this approach, the names and purpose of the interest group is obfuscated, making it difficult to infer the specific user interest to which the group corresponds.

Per-origin Interest Group Limits. In order to limit the storage and compute resources taken by each advertiser, the Privacy Sandbox team initially placed a limit on the number of interest groups into which each interest group owner can place a browser to a total of 1K at the time of our experimentation (to accommodate negative interest groups, this was raised to 2K [43]). Once an interest group owner reaches this limit, joining a new interest group will result in the removal of the oldest interest group for that owner present within the browser.

Pollution. When a user visits a site containing code from the attacker's domain, it can create 1K frames (currently, 2K) that load from Google Ad Manager, each with the `src` attribute set to `td.doubleclick.net/td/rul/<NUMBER>`, where `<NUMBER>` corresponds to a different interest group. We compiled a list URLs captured during our measurement period. Making calls to each of these links results in the browser joining 1K new interest groups and removing pre-existing interest groups owned by Google Ad Manager. Figure 9 presents an overview of this attack.

Caveats. Some interest groups may be deprecated or invalidated over time; in practice, the attack may need to embed more than 1K frames.

Implication. While our attack prototype is specific to Google Ad Manager, it offers insight into potential pitfalls in the general adoption of FLEDGE. Specifically, the onus of enforcing access control to FLEDGE-related operations and preventing accidental, unauthenticated triggers of such code currently lies on the advertisers. In the absence of such protections, malicious attackers can deploy such attacks to influence bids placed by the advertiser, directing them to incorrectly target users and, as a result, observe a decline in their ad revenues. While in the case of Google Ad Manager the URL patterns corresponded to seemingly arbitrary or obfuscated interest groups, as the `<NUMBER>` does not directly reveal specific user interests, the attack can be fully targeted in cases where that information can be inferred – this could be achieved by employing a system like AdFisher [4] and mapping specific user interests to specific interest groups. The attacker can then pollute an advertiser's interest group set by adding the browser to interest groups corresponding to incorrect user interests or large campaigns, thereby having the advertiser serve irrelevant ads to users (including incorrect political ads and misinformation campaigns) at a large scale.

Mitigation. The backend server managed by Google Ad Manager (or any advertiser that stores interest groups in the user's browser) should implement authentication and verification mechanisms for validating incoming requests triggered from untrusted origins. Additionally, the browser can add checks to ensure that loaded HTML does not automatically execute code that adds users to a large number of interest groups.

5 Discussion and Limitations

Ethics and disclosure. Our analysis was conducted using test devices, accounts and websites. We did not include any users in our experiments. Moreover, due to the severe implications of the flaws uncovered by our research, we responsibly disclosed our findings to Google upon their discovery. In total, we have submitted 12 reports to Google, detailing our techniques and providing the necessary information to replicate and verify our attacks. At the time of this writing, Google has patched the issue that enabled the DoS attack that crashes the browser. They have also awarded us through their vulnerability report program for the pollution attack, which is being investigated. Additionally, they are currently investigating one cross-site leak and one tracking attack. We have not received feedback about the remaining attacks.

Attack practicality. The current public-release versions of Google Chrome are vulnerable to the attacks we present in §4 (apart from the "browser crash" attack that was patched after our disclosure). The user tracking attacks require the attacker to create single-buyer auctions and to participate as both an advertiser and a seller. Based on our observations (see §3), such dual participation in auctions is reasonable and found in the wild (e.g., Doubleclick). Importantly, FLEDGE does not restrict entities from participating in both roles, and also does not restrict single-buyer auctions. We tested cross-site leak attacks against public domains that we own, and in Figure 7, showed that 500 domains can be sniffed in 4.2 seconds. We also confirmed the service disruption attacks with the Chromium team.

Severity. The attacks we present in §4 assume a weak attacker, that can even be embedded as a third-party entity on a website that a user visits. In §3, we show that popular ad networks (e.g., Criteo, Teads, Amazon), i.e., third-party entities, use the FLEDGE API instead of the top-level domains themselves. As shown in Table 3, our attacks violate *all* the key privacy advancements detailed in the FLEDGE proposal. Additionally, our service disruption attacks present additional risks to both users and the ecosystem at large.

Evolution and planned mitigations. FLEDGE was officially released to the public in Chrome v117 in September 2023, even though its current implementation does not include all of the components detailed in Google's original designs. As a result, certain features or capabilities previously reported are not yet available in the stable release. Surprisingly, Google opted to officially deploy FLEDGE *without* having implemented components that are integral to some of the privacy protections they have announced (e.g., k-anonymity which was intended for late Q3 2023 but has yet to be released [52]). While some of our novel attacks leverage components or functionalities that are "temporary" until replacement components are deployed, other attacks will remain unaffected (see Table 3).

Crucially, while most of our attacks were disclosed *prior* to the public release of FLEDGE, Google opted to continue with the public release without any appropriate mitigations being put in place (apart from patching the issue that enabled our browser crash). As a result, users are currently facing significant additional privacy risks compared to the pre-FLEDGE ad auction ecosystem (e.g., arbitrary websites being able to infer part of the user's browsing history, or pollute their ad recommendations). We argue that mechanisms that aim to completely reshape an entire ecosystem should not be publicly deployed prior to implementing all announced safeguards or addressing major flaws that have been disclosed to the vendor.

K-anonymity. According to documentation, FLEDGE will employ k-anonymity to strengthen. For instance, *a "crowd of 50 users per creative over 7 days*" will be required for rendering the creative (i.e., ad). Moreover, requests will be routed through Oblivious HTTP, which prevents the server from linking requests to a specific client or identifying requests as having come from the same client [33]. Since attackers can trivially bypass that restriction by deploying numerous browser instances, and currently no robust mechanism exists for verifying that requests are from legitimate Chrome instances [53], users will be required to be logged into their Google accounts. In practice, however, this does not pose a major obstacle to attackers; prior work has demonstrated systems for automating the account creation process [54, 55], and solving CAPTCHAs [56, 57], and has studied underground markets that emerge for assisting attackers in passing challenging account verification constraints (e.g., phone verification [58]). As such, even if FLEDGE employs k-anonymity, it will not be sufficient for fully protecting users' privacy. Importantly, we also demonstrate tracking techniques that leverage fields that *will not* be protected by k-anonymity.

6 Related Work

To the best of our knowledge, our work presents the first in-depth investigation of FLEDGE, resulting in a series of novel attacks with severe privacy implications. Next, we provide an overview of prior research on web tracking and privacy-invasive attacks, as well as explorations of the ad ecosystem.

Privacy Sandbox. Browser vendors and consumer protection organizations have raised concerns about the privacy implications of Google's Privacy Sandbox. Recently, Ali et al. [59] presented an automated framework, CanITrack, for testing browser mechanisms as potential tracking vectors, and demonstrated various tracking techniques including two that misuse Privacy Sandbox APIs (i.e., Trust Token API, FLEDGE API). That study presents a tracking attack against FLEDGE that is conceptually similar to some of the attacks we present and to prior work in user tracking [60,61]. Their attack relied on collusion between multiple advertiser domains and only analyzed a single aspect of FLEDGE auctions, i.e., responses to unsuccessful auctions. Instead, our techniques leverage different FLEDGE functionalities. However, CanITrack cannot identify the 5 non-tracking attacks nor automatically design or find the 7 tracking attacks we present in §4. The framework requires the *manual* development of the client-side and server-side script snippets to identify the fields that we intend to target (e.g., biddingLogicURL, biddingWasmHelperUrl, etc.). Nonetheless, once those have been created it can identify the effectiveness and extent of the tracking potential (e.g., across third-party contexts, across regular and private browsing modes). Based on our analysis which covers these dimensions, all of our tracking attacks function cross-site, using embedded third-parties. Additionally, since FLEDGE APIs cannot be called in the private browsing mode, our attacks only work during regular browsing sessions. Finally, clearing all browsing data will also result in interest groups being cleared from the browser.

Furthermore, we conduct an extensive, in-depth analysis that uncovers a series of severe design and implementation flaws that enable several different classes of attacks. Previously, Berke and Calacci [62] studied Google's FLoC (which has been cancelled and replaced by "Topics"), a system intended to group users with common browsing behaviors, and found that the succession of FLoC's k-anonymous cohort IDs over time could lead to tracking. Beugin and McDaniel [63] analysed the Topics API using statistical models of the distribution of user behaviors, and reported weaknesses in the proposal's privacy guarantees that can leak user interests and also help trackers re-identify individual users.

Tracking. Numerous prior studies have explored and measured mechanisms and web practices that relate to tracking. Lerner et al. [64] used the Internet Archive to provide a retrospective analysis of third-party tracking over time,

while Englehardt and Narayanan [15] presented a large-scale comprehensive measurement of online tracking practices. Franken et al. [65] uncovered flaws in browsers' and browser extensions' implementations of various third-party cookie policies that enabled tracking and other cross-site attacks, while Dimova et al. [16] studied how CNAME DNS records were being used to bypass anti-tracking defenses. More recently, studies have demonstrated cookieless techniques for storing tracking identifiers [59], such as using HSTS policies [60] and favicons [60]. In a different line of work, numerous studies have explored various aspects of browser fingerprinting [66–76] as it can allow websites to track users based on unique characteristics of their devices.

Ad ecosystem. Tracking and advertising are inextricably connected and prior work has extensively explored and measured the complexities of the advertising ecosystem [3, 77–79]. Digital ad spaces are bought and sold through a real-time bidding process that incentivizes advertisers to gather granular user information to help them place competitive bids. Zeng et al. [80] gathered evidence of the use of individual user profiles in real-time bidding strategies. Papadopoulos et al. [81] presented a method to evaluate user profiles and their influence on advertising bids. Pachilakis et al. [82] studied the adoption of header bidding on the web and reported on the dominance of a few advertisers. In another study, Pachilakis et al. [83] observed that the availability of user demographics increased ad prices, explaining the incentives behind user tracking. Alternatively, Venkatadri et al. [84] demonstrated how Facebook's "custom audience" functionality could be misused for inferring users' PII and activities, and Vines et al. [9] showed how ad targeting could be used for tracking users' location. Accordingly, a large body of work has proposed techniques for detecting and blocking ads and trackers [85–89], while prior work has also proposed various schemes for privacy-preserving ads [25, 90–93].

7 Conclusion

Google recently announced plans to phase out support for third-party cookies in Chrome, with the goal of mitigating cross-site tracking and strengthening user privacy. However, Google's revenue stream relies *heavily* on the online ad ecosystem, thus introducing an obvious dilemma. Accordingly, Google has started rolling our the Privacy Sandbox, a collection of new browser mechanisms and standards that aim to provide privacy-preserving alternatives to existing processes and workflows in the online ad ecosystem. Due to Google's pivotal role and positioning in the web ecosystem (i.e., running the most prevalent browser, search engine, and ad display network), these plans have massive implications for online privacy. This has led to serious concerns being raised by other browser vendors and user protection organizations. Putting concerns about Google's monopoly aside, our in-depth empirical analysis of the FLEDGE API demonstrates that the Privacy Sandbox initiative is currently exposing users to significant privacy risks. We have responsibly disclosed our findings in an effort to assist Chrome in improving their system and better protecting users, and hope that our research will enable and motivate additional research into Chrome's emerging APIs.

Abstract

A type of traffic analysis, *website fingerprinting (WFP)*, aims to reveal the website a user visits over an encrypted and anonymized connection by observing and analyzing data flow patterns. Its efficiency against anonymization networks such as Tor has been widely studied, resulting in methods that have steadily increased in both complexity and power. While modern WFP attacks have proven to be highly accurate in laboratory settings, their real-world feasibility is highly debated. These attacks also exclude valuable information by ignoring typical user browsing behavior: users often visit multiple pages of a single website sequentially, e.g., by following links.

In this paper, we aim to provide a more realistic assessment of the degree to which Tor users are exposed to WFP. We propose both a novel WFP attack and efficient strategies for adapting existing methods to account for sequential visits of pages within a website. While existing WFP attacks fail to detect almost any website in real-world settings, our novel methods achieve F1-scores of 1.0 for more than half of the target websites. Our attacks remain robust against state-of-the-art WFP defenses, achieving 2.5 to 5 times the accuracy of prior work, and in some cases even rendering the defenses useless. Our methods enable to estimate and to communicate to the user the risk of successive page visits within a website (even in the presence of noise pages) to stop before the WFP attack reaches a critical level of confidence.

1 Introduction

Over the past two decades, more and more of users' daily activities have moved online. As a result, online privacy has become increasingly important. While encryption helps protect the confidentiality of user data exchanged over the Internet, it does not hide the identities (i.e., IP addresses) of the communicating parties and the relationship between them. The latter is often abused by corporations to profile and track Internet users, by repressive governments to engage in nationwide censorship, and even to track and persecute individuals exercising their fundamental right to freedom of speech and expression. In response, several methods for anonymous communication have been proposed [31,47]. Today, Tor [15] is the most popular low-latency anonymization network. To provide anonymity, it uses the principle of onion routing, where users build a virtual tunnel via a chain of three volunteer nodes, called onion relays (ORs), and send their data encrypted in multiple layers. This design ensures that no OR in the path knows both the user and the destination at the same time.

Despite Tor's promise to hide the relationship between users and their destinations from a *local passive observer* (located on the link between the Tor user and the first anonymization node, i.e., the entry node), e.g., an Internet service provider—one of the weakest attackers in the Tor's adversarial model [15], Tor leaks information about the number, direction, and timing of packets transmitted. This can be exploited for sophisticated attacks such as website fingerprinting (WFP) [24,37,39,45]. WFP is a type of traffic analysis that aims to reveal the website a user is visiting by observing and analyzing data flow patterns. Over the years, a large number of studies [24,38,41,43,45,48] has systematically showed the continuous improvement in the effectiveness of WFP attacks. Today, modern WFP methods achieve a classification accuracy of more than 90% in laboratory settings. However, their real-world efficiency is highly controversial because they rely on unrealistic assumptions and have unknown scalability due to the huge universe size of the World Wide Web (WWW).

The main limitation of existing WFP attacks is their focus on detecting *individual pages* (typically index pages) via *isolated* page visits, rather than the websites that an accessed page belongs to. First, these attacks omit valuable information by ignoring typical user browsing behavior, where users usually visit multiple pages of a single website in sequence [11], e.g., by following links. Second, fingerprinting only individual pages within the entire WWW universe results in attacks with severely limited scalability in practice as websites are comprised of numerous pages, making the size of the universe even larger. Although previous research [24, 38, 41, 43, 45] assumes silently that detecting the index page of a website is

sufficient to recognize this website as users always access the website's content through it, the validity of this assumption often does not align with the current user browsing habits. For instance, users frequently access various websites' content through browser-cached URLs [11] or URLs received via email or instant messaging, bypassing the index pages of those websites. Even if the attacker attempts to enumerate all individual pages of a given website, this is often practically impossible due to their vast number. However, if the attacker can exploit the additional information leaked by the set of individual pages belonging to the same website and visited by a user in sequence, WFP will become significantly more accurate and scalable, and thus more dangerous than assumed.

In this paper, we provide a more realistic assessment of the degree to which Tor users are exposed to WFP and propose both a novel WFP attack and efficient strategies for adapting existing classifiers to account for sequential visits to pages of a single website. Our novel methods do not require knowing the order of pages visited, making WFP even more realistic. We show that two, at most three, clicks within a website allow the attacker to increase the accuracy by more than 20% in a closed-world scenario, bringing it into the alarming range. Using our collected dataset, we investigate the limitations of our methods in real-world settings and show that our attacks achieve F1-scores of 1.0 for more than half of the websites of interest, while existing techniques fail to detect almost any website. Our attacks remain robust against state-of-the-art WFP defenses, achieving up to five times the accuracy of prior work, and in some cases even rendering the defenses useless. Overall, our analysis shows that detecting websites based on sequential page visits, rather than individual pages, poses a more serious threat to Tor users in the real world, and appeals for research to rethink the existing assumptions in the attacker model and to reconsider existing evaluations and WFP defenses. The contribution of this paper is as follows:

1. We perform the first systematic analysis of the suitability of existing classifiers for *website* fingerprinting (i.e., detecting websites by analyzing patterns from their individual pages). We evaluate several strategies and conclude that naive methods of adapting webpage classifiers for website fingerprinting are insufficient. Specifically, we observe a 20 to 30% decrease in accuracy for *website* fingerprinting compared to webpage fingerprinting.
2. We design a novel dedicated set-aware method for website fingerprinting based on multiple instance learning, which can naturally handle the set of pages visited by a user sequentially. We further propose several efficient voting-based strategies to adapt existing WFP classifiers to take into account the set of pages of a website. We analyze the effectiveness of both our strategies and our set-aware WFP attack in an open-world scenario and show that WFP poses a serious threat to users who click on multiple links within the same website.
3. We evaluate the effectiveness of state-of-the-art defenses in preventing our novel WFP methods. We show that WFP defenses are up to five times less effective than expected, or even useless in some cases. Thus, considering sets of pages is a powerful tool to successfully enhance the WFP attack even in the context of newer defenses.

Finally, we discuss the limitations of classifiers, the weaknesses of existing defenses, and the need for further research.

2 Threat Model

Unlike most previous research [4, 43, 45, 46], which has concentrated on fingerprinting individual pages (mainly the index pages of websites), we examine an attacker whose goal is to identify the *website* visited by a user, regardless of the specific page accessed on that website. We strictly distinguish between a *website* and a *page*. A website comprises pages, hosted under the same domain and identifiable by a unique URL. We focus on the worst-case scenario from user's perspective, in which users browse a website in a single tab, visiting multiple pages in sequence by following links. Crichton et al. [11] have recently shown that specific user groups frequently exhibit this browsing behavior in their daily routine. Thus, we believe that some Tor users also choose to use this strategy, in part for better performance. Nonetheless, we examine the impact of including pages in the set of visited pages that do not belong to the target website and discuss the effects of multi-tab browsing on our WFP methods in Section 6.4.

For our analysis, we assume that the attacker specifies a set of targeted websites and retrieves a certain number of pages from them. For each page, multiple traffic traces are collected to extract potentially significant patterns, i.e., *features*, needed to train a supervised machine learning (ML) method and to create a model. The model is then used to detect an accessed website, which corresponds to an unknown trace of a real user. WFP is examined through two threat models: *closed* and *open* world. In a closed-world scenario, the user is restricted to access a limited set of websites, and the attacker has patterns for these websites. In an open-world scenario, the attacker has only traces for *foreground* websites of interest, while the user can visit an unlimited *background* set of websites.

Finally, we assume the attacker is a passive observer who does not decrypt, modify, or interrupt transmitted packets. He is positioned either between the user and the entry node or at the entry node itself, and monitors traffic exchanged with a Tor user and is aware of its IP address. Similarly to other works [24, 38, 41, 43, 45], the attacker can identify the start and end of each page load [50].

3 Related Work

Unlike our work, most previous research has focused on developing attacks **fingerprinting individual pages**.

Traditional ML-based Attacks. Herrmann et al. [25] studied the first WFP attack on Tor utilizing packet size distributions

to train a Multinomial Naïve Bayes classifier. Their results showed a detection rate of less than 3%. Panchenko et al. [40] enhanced the attack accuracy to nearly 55% by using Support Vector Machines (SVM) and multiple feature sets based on packet volume, time, and direction. They also presented the first open-world analysis of WFP. Dyer et al. [17] proposed a variable n-gram classifier and analyzed new feature sets based on time and bandwidth. However, their accuracy did not exceed [40]. Cai et al. [7] used a SVM classifier that employed Damerau-Levenshtein edit distance between fingerprints and increased the accuracy to over 80%. This attack was further improved by removing Tor management cells from traffic traces and using a new set of distance-based metrics to distinguish between fingerprints [49]. Despite achieving a substantial accuracy improvement, these methods were rendered impractical due to their high computational costs.

In response, a new generation of attacks was developed. The k-Nearest Neighbor (k-NN) classifier [48] relies on a large and diverse feature set and attained an accuracy of 91% in a closed world and an 85% detection rate when using over 5,000 background pages in an open world. The CUMUL classifier [39] relies on a feature set comprising the cumulative sizes of transmitted packets for a given page load and SVM. By sampling cumulative packet sequence, it implicitly considers the page load pattern in its feature space. The k-FP method [24] uses a random decision forest classifier to produce feature vectors and a k-NN classifier for classification. Like CUMUL, k-FP achieved an accuracy of more than 90% in a closed world. Gálvez et al. [19] studied the use of clustering in the WFP domain. Unlike our work, where we employ clustering to partition multiple pages within a website, Gálvez et al. apply clustering to detect index pages of websites.

DL-based Attacks. More recent studies have examined the use of deep learning (DL) to enable automated selection and fine-tuning of features. The first DL-based WFP attack [2] was based on a stacked denoising autoencoder and achieved 88% accuracy in a closed world. Rimmer et al. [42] analyzed three different DL methods enhancing the accuracy of the previous attack to 96%. They showed that features generated automatically by certain DL methods are more resilient to constantly evolving web content. Still, these methods required a much larger number of training samples than traditional ML classifiers. Sirinam et al. [45] first tackled this problem with deep fingerprinting (DF). DF is based on a convolutional neural network (CNN) with activation functions specifically adapted to WFP and a number of precautions against overfitting. Var-CNN [4] is built using a Residual Neural Network with automated feature extraction and a set of handcrafted features. It achieves higher accuracy than DF by including direction and timing data from packets, especially when working with limited training data. Tik-Tok [41] represents another DL-based attack that uses both packet directions and timing of bursts in raw data. Recently, Shen et al. [43] proposed robust fingerprinting (RF) comprising a traffic representation method for capturing fine-grained features and a CNN-based classifier. RF has shown an improved capability to overcome defenses. Oh et al. [38] employed unsupervised DL methods solely for automated feature extraction. They showed that traditional ML-based classifiers (e.g., k-NN, CUMUL, k-FP) improved in accuracy when fed with features derived automatically.

Other studies have tackled the challenge of applying WFP with limited data. Triplet fingerprinting [46] is based on N-shot learning and requires only a few traffic traces per page to train a model. However, building a model for the feature extractor using large training sets remains a necessary step in extracting features from the raw data in its pre-training phase. GANDaLF [37] employs a semi-supervised attack through a generative adversarial network (GAN), which produces a large set of synthetic traces for training a deep neural network. It requires only a small labeled dataset, but needs a more extensive second dataset for GAN training.

Fingerprinting Websites. A limited number of studies have focused on detecting websites. Cai et al. [7] attempted to fingerprint websites by analyzing multiple pages within the same domain and the impact of clicking on embedded links. They used a Hidden Markov Model (HMM) to simulate a typical user behavior and obtained high accuracy by examining only two websites. Zhuo et al. [54] used a Profile HMM—an extended HMM capable of, e.g., zero transitions—to model websites. However, the assumption of having prior knowledge of the order of pages accessed by the user questions the scalability of these attacks in practice.

Panchenko et al. [39] analyzed the effectiveness of CUMUL using a small dataset when the attacker aims to detect a visited website regardless of the specific page accessed by the user. Oh et al. [37] performed similar evaluation on GANDaLF, where the attack achieved an accuracy of up to 62% in a closed world. In this work, we continue the research of [37, 39] and perform the first systematic analysis of webpage classifiers for detecting websites. We identify multiple strategies how to adapt these methods to achieve effective website fingerprinting attacks. Our work is the first to examine the risks of WFP when users sequentially browse multiple pages of a single website. Once a website has been detected by our methods, existing works such as [36, 44] can be used to pinpoint the exact pages that were visited by the user.

Criticism on Existing WFP Attacks. WFP attacks have been criticized for making impractical assumptions. Juarez et al. [29] argued that prerequisites such as non-changing web content and use of same vantage point, made by previous work, do not necessarily hold in real world. Panchenko et al. [39] demonstrated that current methods for fingerprinting individual pages do not scale in realistic settings, i.e., for every page there are at least several others that look similar to the classifier and cause confusion. Cherubin et al. [10] analyzed the potential of WFP attacks in the operational Tor network. By observing real user traffic, they achieved a high detection rate for a limited number of pages, but observed

a significant drop in accuracy as the number of monitored pages increased. Our work tackles the scalability issue of existing attacks through fingerprinting websites, instead of individual pages, and using additional information obtained by sequential visits to multiple pages belonging to a single website.

Multi-tab Website Fingerprinting. Some research has designed WFP attacks for multi-tab setting. A few studies [21, 51, 52] have focused mainly on retrieving and analyzing only those portions of transmitted packets that correspond to single page traffic. Other works [12, 22] have used majority voting and attention scoring to differentiate traffic chunks of concurrently loaded pages and to classify them. In contrast, we use different voting strategies for multiple pages to detect the website visited. Recently, Deng et al. [14] took a different approach to tackle the usage of multiple tabs. They considered it as a multi-label classification problem and proposed a transformer model that uses several short traffic patterns extracted from each page loaded in a tab. While these attacks show feasibility of WFP even when using multiple tabs, our novel methods are able to further boost these attacks and overcome their limitations. Further implications of multi-tab browsing on our WFP methods are discussed in Section 6.4.

4 Our Novel Fingerprinting Methods

The novelty of our WFP attacks is their ability to incorporate previously ignored leakage obtained from a user's sequential browsing activity across multiple pages within a website. Thus, our methods can more accurately detect the visited website, regardless of the individual pages accessed, resulting in increased scalability in the real world. We first suggest strategies to empower existing webpage classifiers to deal with websites and, then, introduce our novel set-aware method.

4.1 Our Novel Voting-based Strategies

Consecutive page visits can expose valuable information, which can be combined with individual page predictions made by webpage classifiers, to identify websites. We examine six different voting-based strategies that incorporate predictions for individual pages within a given website, without even the need to consider their visiting order. For all of our strategies, we assume the usage of a webpage classifier that is trained on multiple website classes and can compute a set of probability values for each testing page, determining the likelihood of the given page to originate from each of these websites.

Our most basic strategy, *majority voting*, counts the number of pages predicted to be associated with each website class and selects the most frequently predicted website class as the final choice. If two or more website classes have equal numbers of predictions, we randomly select one of them as the final prediction. In *probability voting*, we multiply the probabilities assigned by the classifier to each page in the testing set. For each website class, we compute a probability for each testing set of pages and the website class with the highest probability is then chosen as the final prediction. The *mean voting* is similar to probability voting, except that it entails adding the probabilities of the testing pages instead of multiplying them.

Contrary to the methods above, we propose three additional strategies that account for varying levels of confidence in separate predictions. The *weighting methods* employed in these strategies ensure that predictions of individual pages within a testing set, which stem from a decision made with high confidence, carry more weight in the final prediction than predictions based on less certain classifier's decisions. We use three metrics to weight each probability value when computing the average for our mean voting strategy: (i) variance, (ii) standard deviation, and (iii) Gini coefficient [9, 34]. We refer to the corresponding voting-based strategies as *variance-weighted mean voting*, *standard deviation-weighted mean voting*, and *Gini-weighted mean voting*, respectively. The metrics are computed over the list of probability values assigned to a given page indicating the likelihood that the page belongs to each of the target websites. High values for one or more of these metrics indicate significant discrepancy between probability values for different website classes of a given page and point out strong confidence in the classifier's decision.

4.2 Multiple Instance Learning for WFP

Our voting-based strategies strongly depend on the efficacy of the underlying webpage classifiers that were not specifically tailored to fingerprint websites. Alternatively, we propose to apply a special branch of supervised learning, called *multiple instance learning (MIL)* [8]. In MIL, a group of instances is referred to as a *bag* and is treated as a single instance similar to the classical instance-based methods. The main goal is to extract features that capture essential patterns of the entire set and to train a classifier capable of predicting a single label for each bag, rather than separate labels for the individual instances. In our work, we propose a MIL-based WFP attack that employs an architecture inspired by a state-of-the-art attention-based MIL approach [27]. Our MIL-based attack utilizes weights to identify particular pages in each bag, which can improve the confidence of the classifier's decision and, thus, increase the accuracy of associating a given set of pages with a given website. The novelty of our method is its flexible, multi-layered neural network that computes the weighted average from the traffic traces of all pages in a bag.

Figure 1 illustrates the architecture of our method. Initially, the method is provided with several website classes containing a subset of pages. We adhere to the data representation used in previous work [42, 45, 46], where each traffic trace comprises a sequence of $+1$ and -1, indicating outgoing and incoming packets, respectively, and excludes the size and timestamps of those packets. Similar to [4, 45, 46], the traffic traces are

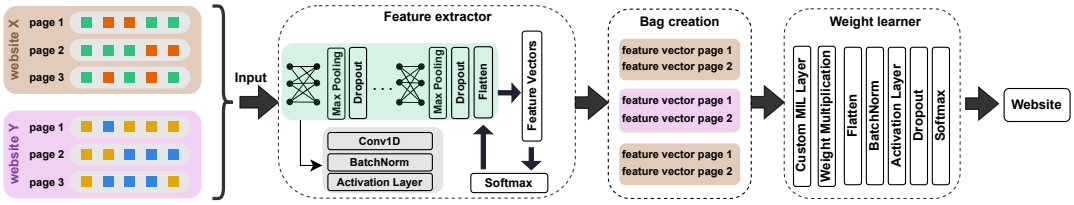

Figure 1: A general overview of the architecture of our MIL-based WFP attack.

either truncated or padded with zeroes to conform to a fixed packet length of 5,000. The traffic traces are then inputted into the *feature generator*, which closely corresponds to the CNN model developed in DF [45]. The feature generator includes eight convolutional layers, followed by batch normalization and activation functions to prevent overfitting. It also includes four max-pooling layers for input data reduction and four dropout layers for overfitting mitigation during the reduction. Instead of using a fixed learning rate drop-off scheme with a fixed number of epochs, as done in [45], we employ a learning rate that varies and adjusts during training based on the performance of the validation set. Finally, we replace the fully connected layers and output prediction previously developed in DF with a single softmax layer, permitting intermediate evaluation of the data in reduced dimension.

Once the dimensions of the initial traffic traces have been reduced, our method proceeds to *bag creation*. During this stage, the traces are grouped into multiple bags and each bag is labeled with the corresponding website class to which the pages belong. We ensure that each bag contains traces of different pages. If the initial website class has multiple traces from a single page, they are distributed to multiple bags. The resulting bags are fed into the final stage of our method, called *weights learner*. To develop the weights learner, we first introduce a custom layer that computes and optimizes the weights derived from traces in a single bag. Similar to [27], this layer implements the hyperbolic tangent function to consider incoming and outgoing packets in separate traces. The activation function softmax is utilized to ensure all page weights in a bag sum to one, avoiding the influence of different bag sizes. The computed weights are then employed in the following layer for the multiplication with the initial traces in a bag and the output is flattened. Before making predictions for the final website label, additional measures are taken to prevent overfitting in this stage. We use batch normalization and dropout techniques and also employ a variable learning rate that is adjusted during training. Further details regarding the architecture of our MIL-based WFP attack, data dimensions, and selection of hyperparameters are provided in Appendix A.

4.3 Use of Hidden Markov Model

While our preceding set-aware methods account for successive visits to multiple pages within a website, they do not consider their exact visiting order. To check whether this additional leakage can further improve the accuracy of the attack, we create another set-aware method based on an HMM. Although Cai et al. [7] previously used an HMM to model certain user behavior, their study was limited in scope, failing to analyze the effect of the number of pages within a website accessed by the user or the impact of different user behaviors. While we rely on different sources to obtain potential page visiting orders, it is worth noting that such browsing patterns are very user-specific and we argue that it is unrealistic to fully exploit such leakage. As shown in Section 6.2, high accuracies can be obtained by using merely sets of pages without regard to their visiting order.

We create an individual HMM model for each website, where the pages correspond to different states and the state transition probabilities indicate the likelihood of a user moving from one page to another. As most websites comprise a large number of pages, implementing a separate state for each individual page does not scale. Thus, we use clustering to group multiple pages that share similar appearances and link connectivity with other pages on the same website into a single HMM state. To account for varying number of clusters across different websites, we implement the DBSCAN clustering method [18], which does not require any prior knowledge of the number of clusters. The resulting clusters represent hidden states in our HMM model. A separate webpage classifier is then trained on each of these clusters.

Beside the set of hidden states, we also need to define the set of observations, the set of transition probabilities indicating the likelihood of generating a given observation upon transitioning to a certain hidden state, the set of initial probabilities, and the set of observation probabilities to complete the HMM model for each website. The set of observations corresponds to the set of cluster labels predicted for each testing page. To derive the set of transition probabilities, we use two sources of data: a sitemap graph of each website containing available pages with the link relationships between them, and automatically-generated user browsing sessions describing sequences of pages (see Appendix B). The set of start probabilities is the frequency of clusters, counted for a set of training sessions, containing the first page in a session. The set of observation probabilities contains the probability values obtained by the webpage classifier and indicating the likelihood that a given testing page belongs to each of the possible classes. Then, we apply the Viterbi algorithm to find the most likely sequence of hidden states given the sequence

of observations in the HMM for each website. Finally, we sum the predicted probability values of each page for each website and multiply the aggregated probabilities of the pages in the sequence. The website class with the highest likelihood is our final prediction.

4.4 Strengthening Webpage Classifiers

While increasing the number of pages per website and traces per page improves the accuracy of traditional ML-based WFP attacks (see Section 6.1), they only achieve moderate accuracy when fingerprinting websites instead of individual pages. This may be because the manual feature sets used by these methods are not suitable for detecting websites, or since there are too many page types within a single website class, leading to divergent traffic patterns interfering with the classifiers.

To verify our first assumption, we extended our feature generator, presented in Section 4.2, to enable the independent storage of extracted feature vectors in files. We have opted for the set of 100 features per traffic trace as a good choice for our evaluation. Although we explored the use of the autoencoder suggested by Oh et al. [38] and a variational autoencoder, we were unable to achieve any improvement with the features extracted from these methods in our evaluation settings.

To validate our second assumption, we suggest the use of clustering. We cluster training traces of pages that belong to a single website prior to inputting them into a webpage classifier. Intuitively, traces assigned to a single cluster share a high level of similarity. Each of the clusters then forms a separate class for training the classifier. During testing, if a test trace is predicted to belong to a particular cluster, it is assigned to the website associated with that cluster. We tested several clustering methods, including DBSCAN [18], OPTICS [3], ShiftMean [28], Gaussian Mixture Model [53], k-Means [23]. Based on our empirical analysis, we identify k-Means as the most suitable clustering method for our evaluation.

5 Experimental Setup

We present our evaluation setup to allow for verifiable results.

Datasets. Our analysis requires a set of multiple websites, each represented by its respective pages. As there is no such existing dataset, we compiled a new dataset including 100 websites from the Alexa Top list of the most popular websites [16]. To confirm the representativeness of our Alexa list and the soundness of our findings, we created a second validation dataset comprising 100 websites[1] from the latest Tranco Top list of the most popular websites [33]. Both samples contain websites from various categories (e.g., news, social media, online shops) with diverse layouts and content from many regions worldwide. For each website, we selected 80 unique URLs of accessible pages by following links from the index page and using the method presented in [39]: We choose a link with a probability of 0.5 from the first, 0.25 from the second, 0.125 from the third, and 0.0625 from the fourth and fifth result pages of that website. As websites can be accessed from different sources, e.g., visting a browser-cached URL or performing a search engine query [11, 32], we used the same method from [39] to query Google—one of the most popular search engines—and further retrieved ten unique URLs of accessible pages per website. In total, we gathered the URLs of index pages from 100 unique websites, and the URLs of 90 unique non-index pages for each of these websites. We refer to the datasets as `ALEXA-WSC-FG` and `TRANCO-WSC-FG`.

We also visited the 5,000 most popular Alexa websites, excluding the 100 websites in `ALEXA-WSC-FG`, and collected nine unique pages for each website using the same method from [39]. We call this dataset `ALEXA-WSC-BG` and mainly use it for our open-world analysis. The last dataset we created for evaluating our HMM-based method is called `ALEXA-WSC-HMM`. While it includes the same websites as those in `ALEXA-WSC-FG`, `ALEXA-WSC-HMM` comprises URLs of 50 unique non-index pages per website and uses a sitemap graph for each website and automatically-generated user browsing sessions to record the exact page visiting order. Due to space constraints, we refer the reader to Appendix B for details regarding the creation of sitemap graphs and user sessions.

Network Traffic Collection. As in related work [39,42,45], we excluded page loads denying requests coming from Tor, showing a CAPTCHA, having no content, or pointing to a client or server error. We also omitted pages that require user authentication to access their content, as they are usually not compatible with Tor's default configuration[2]. The attacker is not interested in fingerprinting such page loads as none of them can be considered successful in accessing the content. We used the automated approach presented in [39] to gather metadata, such as TCP packet sizes, their direction and timing, for all pages in our datasets. Then, we reconstructed the Tor cells using a data extraction method from [39]. We used the Tor Browser 7.5.6 for all `ALEXA-*` datasets and the latest Tor Browser 12.5.3 for gathering `TRANCO-WSC-FG`. The validation of our results across different Tor Browser versions is essential to establish their soundness (see Section 6.4). In total, we collected 90 traffic traces for each non-index page and 20 traffic traces for each index page in `ALEXA-WSC-FG`, and one traffic trace for each page in `ALEXA-WSC-BG` and `TRANCO-WSC-FG`. We further gathered 10 user sessions per website from `ALEXA-WSC-HMM`, with each session consisting of 10 pages and 20 traffic traces per page.

Evaluation Setup. We use four modern webpage classifiers: CUMUL [39], k-FP [24], DF [45], and Var-CNN [4]. We refer the reader to the original papers for more details on them. For all experiments, unless otherwise stated, we conduct 10-fold cross-validation (CV) based on either the number

[1] https://tranco-list.eu/download/X53GN/500

[2] As Tor often changes the exit node, and, hence, the IP address visible for these pages, this causes the pages to activate their security mechanisms.

of traces per page or the number of pages per website.

6 Evaluation and Discussion

This section analyzes the efficacy of our novel WFP methods. We consider two main evaluation strategies. In the first strategy, called *website with known pages*, we assume that the attacker can obtain fingerprints of all pages belonging to a target website, i.e., traces from all pages of a website are used for training a classifier. In this strategy, we conduct the CV based on the number of available traces per page for each website. While this strategy is suitable for websites with a small number of pages that seldom change, fingerprinting each page of a large website with many pages that frequently change content is practically unfeasible. Thus, we consider a second strategy, called *website with unknown pages*, in which the attacker can only use a portion of the pages available on a website to train a classifier, while the testing is conducted on pages that the classifier has not yet encountered. Here, we conduct the CV based on the number of available pages per website. We computed the *accuracy*, i.e., the probability of a correct prediction (either a true positive or a true negative), for our closed-world analysis and the *F1-score*, i.e., the harmonic mean of precision and recall, for our open-world experiments.

Section 6.1 begins with identifying a suitable training strategy and amount of data for state-of-the-art webpage classifiers for our threat model to enable a fair comparison with our methods. Section 6.2 provides insights into the efficiency of our novel fingerprinting methods in both closed- and open-world scenarios. Section 6.3 presents the level of security provided by state-of-the-art WFP defenses when our novel WFP methods are employed. In Section 6.4, we summarize our main takeaways and discuss potential limitations and future work.

6.1 Webpage versus Website Fingerprinting

Webpage Classifiers for Website Fingerprinting. First, we examine the efficacy of existing webpage classifiers in detecting websites in a closed world, using our dataset `ALEXA-WSC-FG`. Similar to previous work [4,39,45], we chose to use 90 traces for each website class. Beside the classical webpage detection done in previous research that we call *individual page*, we also study another evaluation scenario, where traces of a different page, not seen by the classifier before, are used for testing. We further distinguish between two training strategies. While the first strategy, called *website with single page training*, entails a classifier learning a single page per website, the second strategy, called *website with milti-page training*, involves a classifier being trained on multiple pages of a single website (with one trace per page)[3]. As shown in Table 1 (rows one and two), the accuracy of all methods decreases by around 50% when using a single page for training and aiming to detect a website. This drop indicates that existing attacks lack the robustness needed to make them viable. The use of only one page per website for training is particularly highly insufficient for identifying websites. On the other hand, training the classifiers on multiple pages per website, while keeping the same number of traces per website class (row three in Table 1), leads to an accuracy increase from about 20% (for CUMUL and Var-CNN) to nearly 30% (for k-FP and DF). Overall, the classification results of webpage classifiers, obtained in our more realistic evaluation setting, remain notably lower than expected, demanding dedicated methods to fingerprint websites.

[3] Both cases correspond to our strategy *website with unknown pages*.

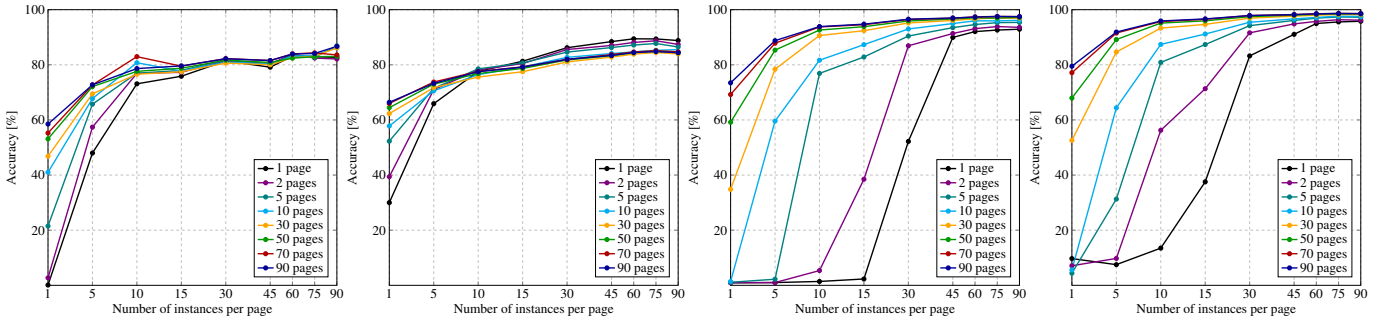

Table 1: Accuracy (in %) of webpage classifiers for fingerprinting individual pages vs. websites.

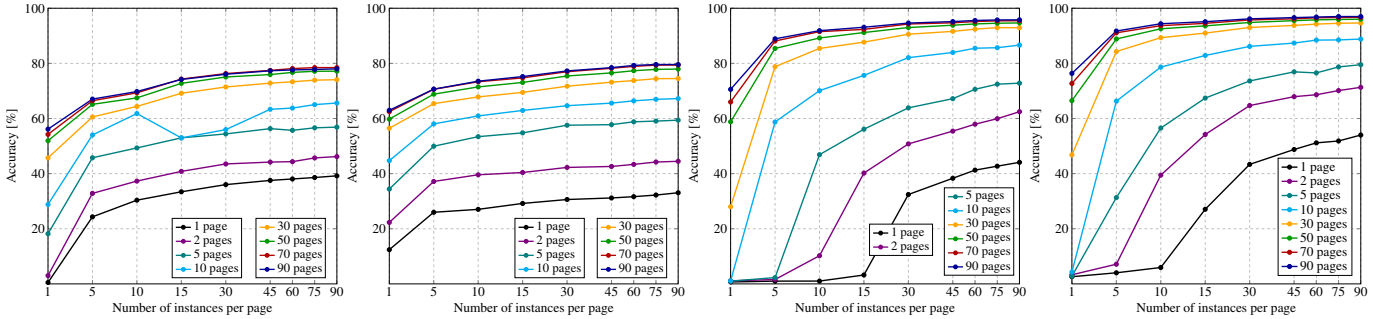
Scenario	CUMUL	k-FP	DF	Var-CNN
Individual page	82.75	88.81	92.91	95.80
Website with single page training	39.20	33.06	44.10	54.00
Website with multi-page training	56.14	62.98	70.57	76.36

Number of Available Pages for Website Fingerprinting. Next, we examine how the number of available pages for each site impacts the accuracy of the webpage classifiers. For our *website-with-known-pages* strategy, Figure 2 shows that all methods attain higher accuracy with a larger number of pages per site and traces per page in a closed world. Both DL-based attacks can learn a website and achieve over 90% accuracy already with 30 pages, each containing 10 traces. When using even more traces for these pages, the accuracy improves to over 96% for DF and 98% for Var-CNN. Contrariwise, the traditional ML-based methods CUMUL and k-FP achieve around 10% less accuracy than DF and Var-CNN when training on a larger number of pages and traces per page.



For our *website-with-unknown-pages* strategy, Figure 3 shows an overall lower accuracy for all attacks, compared to the first strategy. It is especially significant when the classifiers learn fewer than 10 pages per website. Although increasing the number of traces for this set of pages improves accuracy by roughly up to 40% for DF and Var-CNN and up to 20% for CUMUL and k-FP, the highest achieved detection rate for the attacks remains below 60% for CUMUL and k-FP, around 70% for DF, and less than 80% for Var-CNN. All webpage classifiers require a minimum of 50 pages per website, each containing at least 10 traces, to effectively learn websites. This indicates a substantial rise in the amount of data needed to train these classifiers, requiring about 500 or more traces per class instead of 90. While the DL-based methods DF and Var-CNN can achieve over 95% accuracy with a large number of pages per site and traces for them, both traditional ML-based methods CUMUL and k-FP attain an accuracy of less than 80% for all sets of pages and traces per page. Still, none of these attacks scales when used to detect websites in real-world settings (see Section 6.2.3).

More Training Pages vs. More Training Traces per Page. We assess the importance of the number of pages vs. the num-

(a) CUMUL (b) k-FP (c) DF (d) Var-CNN

Figure 2: Existing WFP methods with varying number of pages per website and traces per page for *website with known pages*.

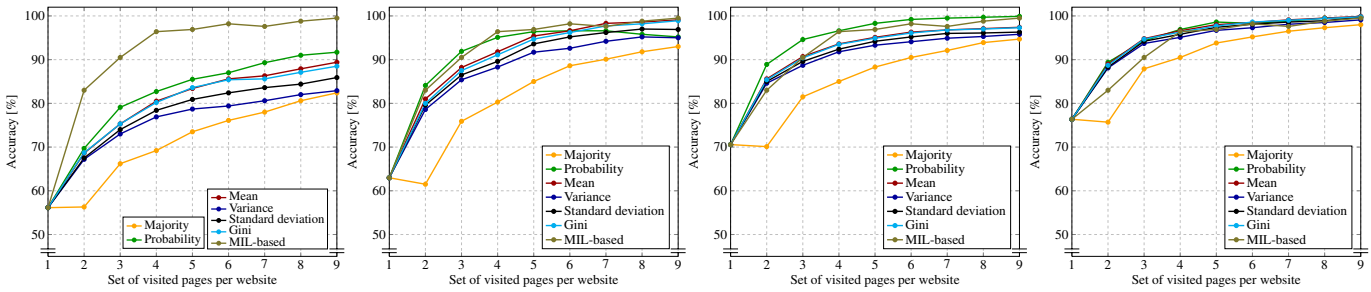

Figure 3: Existing WFP methods with varying number of pages per website and traces per page for *website with unknown pages*.

ber of traces per page to achieve higher accuracies. We only consider the results from Figures 2 and 3 that are obtained when the classifiers cumulatively rely on the same number of training samples, but with varying numbers of pages and traces per page, e.g., 10 pages per site with 90 traces per page vs. 30 pages per site with 30 traces per page. The trend of improved accuracy with the use of larger number of pages noted in Table 1 is less evident, when the size of the training data increases. Thus, we conclude that a variety of training pages per site is crucial when dealing with smaller datasets.

Index Pages for Training. We evaluated whether the use of the index pages is particularly important to detect websites, as doubted in [39]. Based on our analysis (see Appendix C), we conclude that the inclusion of index pages in training does not affect the accuracy of the attacks in either evaluation strategy.

Timing Information for Website Fingerprinting. Two of the evaluated classifiers, k-FP and Var-CNN, rely not only on packet order and size, but also on timing information. As shown in Figures 2 and 3, both classifiers achieve higher accuracy for very small datasets, i.e., less than 10 pages per site and less than 10 traces per page. The increase in accuracy is particularly evident in the results for k-FP. The k-FP's accuracy surpasses 40% for our *website-with-known-pages* strategy and is more than 20% higher than the accuracies of the other attacks when the *website-with-unknown-pages* strategy is used. Although Var-CNN has only a slightly increased accuracy for very small datasets, it still achieves over a 30% higher accuracy when using 5 pages per site and 5 traces per page than its DL-based competitor DF. As the number of pages per site and the number of traces per page increase, the effect of additional timing information on accuracy disappears.

Strengthening Traditional ML-based Classifiers. As stated in Section 4.4, the moderate accuracy of both traditional ML-based attacks can be attributed to suboptimal feature sets or too dissimilar traffic patterns across distinct pages of a website. We analyze whether the use of new feature sets or applying clustering methods in these attacks to account for diverse website structures can enhance their effectiveness. We conducted multiple experiments using our strategy *website with unknown pages* and a dataset of 90 pages per website with 15 traces per page. The dataset size is suitable for this evaluation as the attacker can already achieve high accuracy in detecting websites using both DL-based competitors with such a dataset. While the first experiment involved learning all training pages of a given site in a single class (as previously done), the second experiment included grouping the training pages into multiple clusters and learning each cluster separately (see Section 4.4). Both experiments are performed using the original features of the corresponding webpage classifiers. Then, we replicated these experiments, but this time with the feature set produced by our feature generator (see Section 4.4). Table 2 shows the results obtained. Regardless of the feature set used, the use of clustering does not improve the accuracy of both classifiers. However, the newly generated

(a) Voting (CUMUL) vs. MIL-based (b) Voting (k-FP) vs. MIL-based (c) Voting (DF) vs. MIL-based (d) Voting (Var-CNN) vs. MIL-based

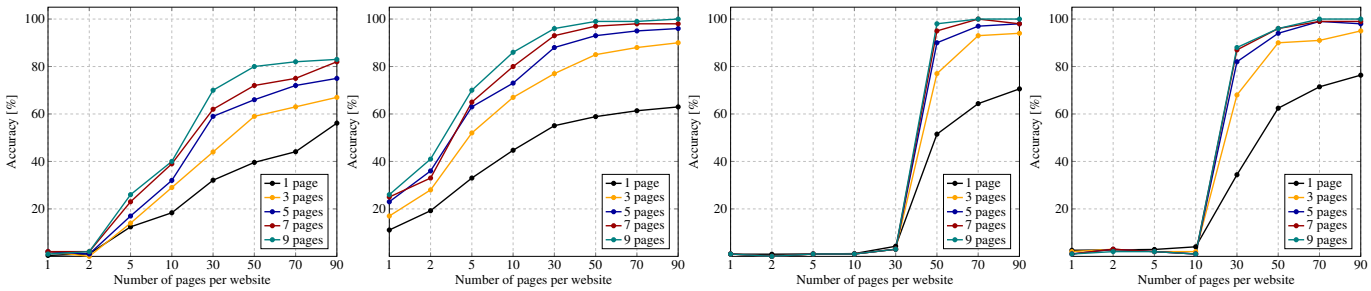
Figure 4: Accuracy achieved by our voting-based strategies with state-of-the-art webpage classifiers and our MIL-based method.

Table 2: Accuracy (in %) of traditional ML-based classifiers in combination with clustering and new feature sets.

		Without clustering		With clustering			
		Original feature set	New feature set	Original feature set	New feature set	DF	Var-CNN
Website with known pages	CUMUL	79.59	95.73	77.35	95.78	94.74	96.65
	k-FP	79.18	93.62	78.56	93.50		
Website with unknown pages	CUMUL	74.17	93.83	70.43	93.86	93.11	95.11
	k-FP	75.21	91.69	74.50	91.46		

features increase their accuracy by almost 20%, making them as efficient as the DL-based methods. This suggests that the original feature sets may not be suitable for detecting websites as opposed to individual pages, and thus need to be revised.

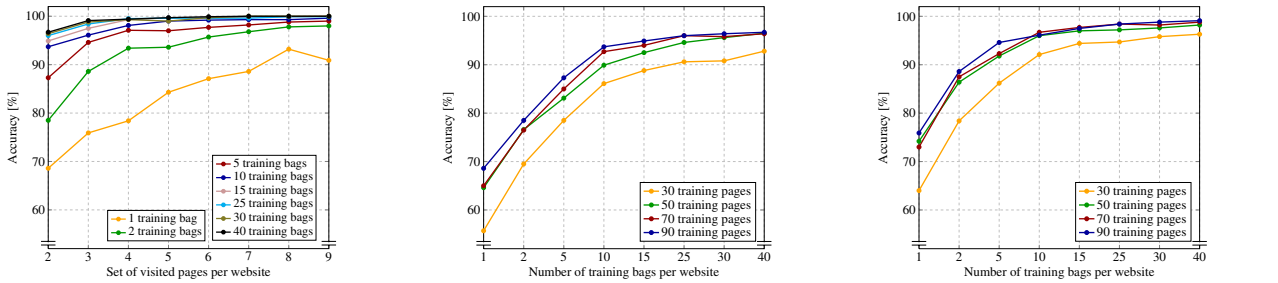
6.2 Analysis of Our Fingerprinting Methods



This section evaluates the efficiency of our novel fingerprinting methods, proposed in Section 4.1 and 4.2. We focus on our more realistic and, at the same time, more difficult evaluation strategy *website with unknown pages*. We assume that the attacker uses multiple pages per website to train a classifier. We consider the results from Table 1, row three, as the baseline for our closed-world analysis and use the same dataset consisting of 90 pages per website and one trace per page.

6.2.1 Use of Voting-based Strategies

Efficiency of Different Voting-based Strategies. Figure 4 shows the accuracies achieved by combining each webpage classifier with each of our voting-based strategies. Regardless of the chosen strategy, we observe an overall significant increase in the detection rates of all webpage classifiers as the number of successively visited pages belonging to a single website increases. We further notice that the majority voting—our simplest strategy—already provides a significant increase in accuracy (up to 90%) for three of the classifiers (k-FP, DF, and Var-CNN) for six consecutive page visits. Still, for short sets of visited pages we observe only a slow increase in accuracy, while for two consecutive pages the accuracy of three of the classifiers (k-FP, DF, and Var-CNN) even slightly decreases. The main reason is that more often there is no predominant website class in a set of two pages, and the final decision should practically be guessed in controversial cases.



When the mean voting is used, all classifiers experience a boost in accuracy of roughly 10% to 20% compared to majority voting as the number of visited pages increases. For k-FP, this increase is notably evident for a set of two page visits where we see a detection rate over 20% higher compared to the one obtained with majority voting. The accuracies attained by the variance, standard deviation, and Gini-weighted mean strategies closely approximate those achieved by mean voting. The Gini-weighted mean strategy performs better than the other two strategies on most sets of pages, but the differences in accuracy compared to mean voting are negligible. When employing the probability voting, a notable boost in accuracy is evident among all classifiers in comparison to the other strategies discussed above. The probability voting differs from majority voting in that it only requires two clicks on a website for nearly 90% accuracy using DF and Var-CNN. With one more click, both DL-based classifiers improve to a detection rate of 95% accuracy and k-FP achieves more than 90%. Additionally, DF and Var-CNN achieve an accuracy of almost 100% for sets of more than seven page visits. Although probability voting has shown higher detection rates than the other voting-based strategies when used with CUMUL, DF, and Var-CNN, accuracy degradation occurs with k-FP when test sets contain more than five pages. This may arise because k-FP produces zero probabilities for website classes, which can harm the computation of probability voting. Therefore, we selected probability voting as the most effective voting-based strategy for CUMUL, DF, and Var-CNN in all subsequent experiments. Mean voting was selected for k-FP.

Impact of Different Training Tactics. We also examine how the number of training pages per website impacts the accuracy of our best voting strategy employed with every webpage classifier. We conduct experiments where we change the number of training pages, ranging from one to 90 pages per website, while maintaining the same testing set as mentioned above. As shown in Figure 5, achieving a higher accuracy requires more user clicks per website when the number of training pages decreases. When there are 90 training pages available, the user can be deanonymized with nearly 95% accuracy when

(a) CUMUL (b) k-FP (c) DF (d) Var-CNN

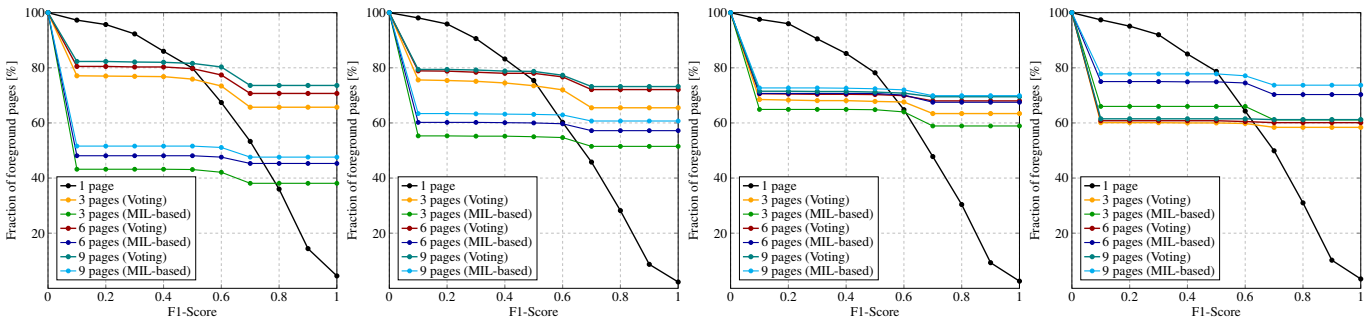
(c) Test bag of three pages with increasing training pages and bags per website.

Figure 6: Accuracy achieved by our MIL-based attack in different evaluation settings.



visiting only three pages on a website using k-FP, DF, and Var-CNN. However, this number increases for k-FP and Var-CNN to five pages, and for DF to seven pages, when relying on 50 training pages. When using only 30 training pages, the attacker needs up to nine pages for k-FP and Var-CNN to achieve a similar detection rate. It can be also seen that 70 training pages are enough to obtain the same accuracies for all the classifiers as those obtained with 90 training pages. Further training tactics are discussed in Appendix D.

6.2.2 Our MIL-based Attack

We proceed with the evaluation of our MIL-based method. Figure 4 shows the accuracy achieved by it compared to our voting-based strategies. Similar to the voting-based methods, we see a significant increase in the accuracy of our MIL-based attack as the number of sequentially accessed pages within a website increases. In particular, it achieves an efficiency that is comparable to that of our voting-based strategies when four or more pages per website are accessed. Still, this increase is smaller for a set of two or three pages per website. While the number of training bags used by our MIL-based method is always the same in all experiments, we have fewer traces per bag due to the smaller number of pages accessed per website, which reduces the accuracy for smaller numbers of user clicks.

Number of Training Bags per Website. In response, we examine the influence of the number of training bags on the accuracy of our MIL-based attack. For this analysis, we use a variable number of training bags for our weight learner while maintaining the same testing set as in the previous experiment. In addition, our feature generator is trained with all possible traces that can be found in the training bags, eliminating any potential bias in our results. As shown in Figure 6a, we see that one training bag is already sufficient to obtain a detection rate of over 90% when accessing eight or more pages within a website. As the number of training bags increases, the number of pages that need to be consecutively visited to achieve high accuracy decreases. In particular, just one additional training bag is necessary to reduce the set of observed user clicks to four and to still reach over 90% accuracy. Overall, the use of two training bags increases the detection rate by nearly 20% for sets of up to four pages, and by about 10% for larger sets of five or more pages. While the accuracy of smaller sets, up to four pages, is boosted by almost 10% when using five training bags, this boost begins to degrade gradually for larger numbers of training bags. Concurrently, our MIL-based attack achieves 100% accuracy for bigger sets consisting of seven, eight, or nine pages when using 15 training bags or more.

Number of Training Pages per Website. Finally, we analyze how the number of training pages per website affects the accuracy of our MIL-based attack. In particular, we examine how many training bags are needed for different number of training pages per website to achieve a high accuracy. Similar to the experiments above, we use an increasing number of training bags for each set of training pages, while keeping the test set the same. We also focus on the detection rates achieved when the user accesses two and three pages consecutively (in Section 6.2.1, we discovered that two, at most three,

(a) 500 background websites (b) 1000 background websites (c) 2000 background websites (d) 5000 background websites

Figure 7: F1-score for our MIL-based attack and out best voting stategy compared to the F1-score for webpage fingerprinting.

user clicks are sufficient to achieve more than 90% accuracy with our voting-based strategies). As shown in Figure 6b, the attacker can deanonymize a user with nearly 70% accuracy by observing only two consecutive pages that a user visits and solely two training bags for a training set of 30 pages per website. Figure 6c also shows that an additional user click can boost this accuracy by around 10%. While this result is similar to the one achieved by using a combination of k-FP with our voting-based methods and an equal number of training pages per website and testing user clicks, it is about 10% and 20% greater than the detection rates obtained for Var-CNN and CUMUL, respectively. Moreover, it is up to sixteen times higher than the accuracy obtained for DF. In particular, we see that for a set of 30 training pages per website, the attacker can achieve almost up to 93% and 97% accuracy when using 25 or more training bags. Furthermore, we observe that the detection rate of our MIL-based attack improves by about 7% to 10% for all sets of training bags when the attacker uses a set of 50 training pages per website. For larger numbers of training pages per website, the accuracy increase is negligible. Overall, it is evident from Figures 6b and 6c that the accuracy of our MIL-based attack is primarily affected by the number of training bags, rather than the number of different training pages per website.

6.2.3 Open-World Evaluation

This section assesses the efficiency of both our best voting-based strategy and our MIL-based method in an open world. For our experiments, we train a separate classifier for each foreground website (taken from `ALEXA-WSC-FG` as in the previous experiments) that the attacker aims to detect and use an increasing number of websites from `ALEXA-WSC-BG` as background, representing the universe. As described in Section 5, each background website comprises nine pages, resulting in a universe size of up to 45,000 traffic traces—a magnitude commonly used in related work [43, 45]. For the baseline and our voting-based strategy, we report only those classification results obtained with the best performing webpage classifier due to space constraints. Based on our analysis in Section 6.2.2, we further choose to use 40 training bags for each foreground website for our MIL-based method. Figure 7 illustrates the obtained results. We see that for the largest number of background websites, only three clicks are sufficient to deanonymize a user with a F1-score of 1.0 for roughly 60% of the foreground websites, while traditional webpage fingerprinting cannot detect almost any website. As the number of consecutive page visits increases, the percentage of foreground websites detected with a F1-score of 1.0 increases to almost 75%. This huge gain in the detection rate through our methods remains also for smaller values of F1-score. Using our novel fingerprint methods, the percentage of websites detected with a 90% or higher F1-score increases by over 50%. Overall, despite the increasing background sizes, both our best voting-based strategy and our MIL-based method achieve a steady and constant F1-score.

6.2.4 Evaluation of our HMM-based Strategy

Finally, we analyze our HMM-based method, proposed in Section 4.3. To do this, we use the dataset `ALEXA-WSC-HMM` and combine the worst-performing classifier CUMUL (cf. Section 6.1) with our HMM-based method. As our evaluation shows, such classifiers benefit most from observing the sequence of visited pages. In the first evaluation strategy, we assume that the attacker can learn all user sessions, i.e., the HMM contains transition information for all possible user sessions. This strategy is an adapted version of *website with known pages*, where we test WFP attacks using different traces of the known pages per website. As shown in Figure 8, the accuracy increases significantly for all test sets of pages of length of two or higher. In the second evaluation strategy, we assume that user sessions used for testing are unknown to the attacker. In most of the cases, this scenario leads to testing on pages per website that are also unknown to both CUMUL and HMM. The accuracy decreases slightly compared to the scenario when the sessions are known. Still, we see a similar positive trend from the use of sequence of pages. The negative effect of unknown sessions is prominent for short sets of pages and decreases when using longer sessions. For

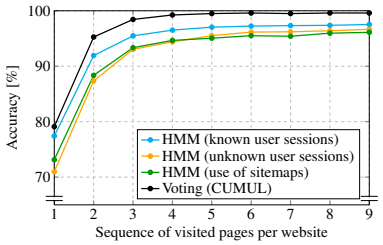


Figure 8: Accuracy achieved by our HMM-based strategy.

a session of nine pages, the accuracy is 96.8% compared to 97.8% when all sessions are known. Finally, instead of learning transition probabilities from user sessions for HMM, we use the sitemap graphs of the target websites. As shown in Figure 8, the use of sitemap graphs to compute the transition probabilities is beneficial for user sessions of at most four pages. Still, the differences in accuracy across the different use cases are negligible. Despite the improvements in accuracy, our HMM-based method is not able to surpass our best voting strategy, leading to the conclusion that knowing the exact order of the visited pages does not primarily affect the classifier's accuracy.

6.3 Effectiveness against WFP Defenses

This section analyzes the robustness of our novel fingerprinting attacks against WFP defenses. We consider six state-of-the-art methods: Tamaraw [6], CS-Buflo [5], WTF-PAD [30], TrafficSliver-Net [13], FRONT [20], and RegulaTor [26]. While TrafficSliver-Net currently stands as one of the most effective and prominent practical defenses [35], CS-Buflo and Tamaraw are among the state-of-the-art methods that result in one of the lowest accuracies for WFP attacks, despite being developed only as a simulation. WTF-PAD refers to a group of WFP defenses that offer easy practical deployment while having a lower level of security. FRONT and RegulaTor are newer WFP defenses that promise both increased security and low implementation costs. For our analysis, we created defended traces for each defense using their public implementations with the optimal performing parameters reported in the original papers. We also used the `ALEXA-WSC-FG` dataset, which consists of 90 pages per website, with 15 traces per page and considered the evaluation strategy *website with unknown pages*. We train the webpage classifiers with a sufficiently large number of traces, ensuring that we achieve high accuracy for our baseline. As shown in Table 3, the accuracy of our novel methods increases when the user sequentially browses multiple pages on a website despite the use of a WFP defense. Although the detection rate for the strong defense Tamaraw remains under 20%, the increase is still concerning, having risen almost fivefold (i.e., from 4.61% to nearly 20%). CS-BUFLO shows a similar increase in accuracy as Tamaraw. Even worse, here the attacker's accuracy is over 50% for a set of nine sequentially accessed pages. For all sets of visited pages, the attacker achieves about a 10% higher detection rate with RegulaTor compared to CS-BUFLO. Although the accuracy achieved for the different sets of pages in the case of TrafficSliver-Net is still below 50%, it has approximately doubled. Both defenses WTF-PAD and FRONT become practically useless when the number of user clicks within a website increases. These results indicate that our attacks are not only more realistic, but also more dangerous.

Table 3: Accuracy (in %) of our attacks against WFP defenses.

Defense	Classifier	Set of pages								
		1	2	3	4	5	6	7	8	9
Tamaraw	Voting	4.61	7.20	9.93	12.47	12.67	14.07	16.27	17.80	18.93
	MIL-based	–	5.37	7.25	8.81	10.79	12.19	13.77	14.73	16.36

	MIL-based	–	86.41	94.82	97.70	98.85	99.38	99.55	99.77	99.86

6.4 Discussion and Limitations

Unlike previous research that aim at detecting only individual pages via isolated page loads, our methods are able to (i) account for sequential visits to pages of a single website and (ii) detect the website a user visits, regardless of the page accessed within that website. If further desired, existing works such as [36, 44] can be used to conduct webpage detection in a secondary step, once our methods have detected the website. We present a more realistic assessment of the degree to which Tor users are vulnerable to WFP, in contrast to previous work that downplays the threat of WFP in Tor and gives an overestimated impression of the level of security provided.

Limitations. The main limitation of our work is the assumption that the attacker can distinguish and segregate consecutive visits to multiple pages associated with a given website. We argue that this is the worst-case scenario for a Tor user who is fixated on the content of a single website, and the segmentation of the visited pages from said website is also possible (e.g., using [50]). We further evaluate what happens if this assumption does not hold, i.e., how noise pages impact the accuracy of our methods. Noise pages refer to one or more pages in the set of visited pages that do not belong to the target website. Similar to Section 6.2, we examine the *website-with-unknown-pages* strategy, use multiple pages per website (excluding noise pages) to train a classifier, and use the dataset comprising 90 pages per site and one trace per page. We compute the accuracy for a set of nine accessed (i.e., testing) pages in a closed world, while the number of randomly selected noise pages in this set ranged from one to four. As shown in Table 4 (rows one and two), the more noise pages are present, the lower accuracy our methods achieve. Still, the accuracy of our best voting-based method is only minimally

Table 4: Accuracy (in %) of our MIL-based method and our voting-based stategies for increasing number of noise pages.

Classifier	Pages from a website + noise pages				Pages from a website			
	8+1	7+2	6+3	5+4	8	7	6	5
MIL-based	96.30	92.90	77.50	68.80	98.80	97.60	98.20	96.90
Our best voting	99.50	98.30	93.20	80.80	99.70	99.50	99.20	98.30
Gini-weighted mean voting	99.40	99.10	98.40	97.00	99.40	99.00	98.60	97.70

impacted when up to three noise pages are present in the set, resulting in no more than a 6% decrease. On the other hand, our MIL-based method is slightly more affected with a 5% reduction in accuracy for two noisy pages and almost a 20% decrease for three noisy pages. In case of four noise pages, the accuracies of both methods notably decrease, i.e., by around 20% for our best voting-based method and almost 30% for our MIL-based method. However, it should be noted that in the latter case the four noise pages are already almost half of the whole set of visited pages, which is a significant amount of noise. It is also noteworthy that according to research on user browsing behavior [11], on average users navigate to the first noise page after clicking five times within the target website, which is already enough for our methods to detect that target website without any confusion from noise pages (see Figure 4). We also check whether one of our three voting-based strategies using weighting methods are the better choice for this evaluation setting. As shown in row three in Table 4, the use of the Gini-weighted mean voting is already sufficient to filter out all possible noise pages and, thus, not negatively affect the accuracy of the attack. We believe that—in future work—the performance our MIL-based method can be further optimized.

Our work further focused on a scenario where a user visits websites in a single tab—the worst case from user's perspective. However, there are user groups that browse the web in multiple tabs. As our voting-based strategies are classifier-independent, they can be combined with existing webpage classifiers [21, 51, 52] that focus on multi-tab detection of individual pages, thus boosting their otherwise limited accuracy for website fingerprinting. Based on the lessons learned from [14], our MIL-based method can be further improved to account for more appropriate patterns for detecting websites in a multi-tab environment, which we leave for future work.

Different Datasets & Tor Browser Versions. To validate the soundness of our evaluation results, we repeated some of our key experiments using the dataset `TRANCO-WSC-FG` collected with the Tor Browser 12.5.3. Our verification shows no significant difference in the evaluation results, which again confirms our findings. Worse, we observe higher accuracies achieved with `TRANCO-WSC-FG` compared to `ALEXA-WSC-FG`. We refer the reader to Appendix E for more details.

Takeaways. In a closed world, existing state-of-the-art DL-based webpage classifiers can detect a website with high accuracy without considering the set of visited pages of that website at the cost of using a huge amount of training data. In contrast to our novel fingerprinting methods, they require for website fingerprinting five times or more traces for training—often unavailable in practice—than reported in the original papers for webpage fingerprinting. Further, existing state-of-the-art traditional ML-based webpage classifiers can only achieve moderate classification results, regardless of the number of training traces, when applied to detecting websites. While the use of clustering did not improve the accuracy of the original implementations, the newly created features increase the accuracy of the classifiers by about 20%, making them competitive with the state-of-the-art DL-based WFP attacks. Despite these closed-world results, all existing webpage classifiers fail to detect almost any website in real-world settings. Contrary to that, we have shown that both our voting-based strategies and our MIL-based attack are effective measures to enhance WFP and increase its feasibility in the real world. Our novel methods achieve F1-scores of 1.0 for more than 60% of the target websites. Although previous work [10, 39] showed limited scalability of WFP attacks in the real world, our results suggest the need to reconsider these evaluations in the context of our revisited evaluation settings.

We have shown that the worse the performance of the webpage classifier is, the more its performance can be improved by considering a set of visited pages and using our voting-based strategies. Hence, webpage classifiers trained with little data (or not so efficient ones) benefit significantly from our methods. The use of training traces corresponding to different pages of a website is also critical when dealing with small datasets, regardless of the fingerprinting methods used. Finally, the effectiveness of state-of-the-art defenses is drastically hampered by our improved attacks. Defenses with lower deployment costs, which make them attractive candidates for adoption in Tor, are particularly affected by our methods.

7 Conclusion

Understanding the feasibility and limitations of WFP attacks is crucial to assess the degree of protection offered to Tor users. Prior work mainly focused on detecting individual pages via isolated page loads, rather than websites, and ignored information regarding consecutive user visits to pages within a website. In response, we proposed both a novel WFP attack and effective strategies that leverage information on consecutive page visits within a website and aim at detecting websites, regardless of the specific page accessed. With our methods, we showed that merely two, at most three, clicks within a website are sufficient to successfully deanonymize a Tor user with nearly 100% accuracy in a closed world. In real-world settings, our methods achieve F1-scores of 1.0 for over half of the target websites, whereas existing classifiers fail to detect nearly any website. Finally, we showed that our novel methods remain robust against WFP defenses, achieving 2.5

to 5 times the accuracy of prior work, and in some cases even rendering the defenses useless. Overall, our work showed that WFP presents a much greater risk to the privacy of Tor users who visit multiple pages within a website and the need for further research to provide adequate protection. The source code of our methods is available online [1].

A Selection of Hyperparameters and Implementation of our MIL-based Method

We used Tensorflow[4] to implement our MIL-based method. Similar to [43,45], we relied on the extended candidate search method to identify the optimal hyperparameters for our model. For the hyperparameter tuning, we divided the dataset into training, validation, and testing with an 8:1:1 ratio using 10-fold CV and executed multiple experiments in a closed-world scenario utilizing the validation accuracy (i.e., the probability of a correct prediction in the validation set) as the performance metric. Table 5 summarizes the search ranges for the different hyperparamers and the values selected for them.

[4] https://www.tensorflow.org/

Table 5: Hyperparameter selection for our MIL-based method.

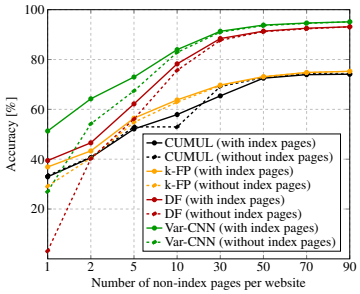
Hyperparameters	Search Range	Selected Value
Dimension of input traces	[5000]	5000
Optimizer	[Adam, Adamax, SGD]	Adamax
Training epochs	[10, ..., 70]	60
Learning rate	[0.001, ..., 0.01]	[0.002, 0.003]
Weight decay	[0.0001, ..., 0.01]	0.0001
Batch size	[100, ..., 300]	128
Activation Functions	[Tanh, ReLU, ELU]	Tanh, ELU, ReLU
Dropout	[0, ..., 0.5]	[0.1, 0.5]
Regularizer	[L1, L2, L1L2]	L2

Both the feature generator and the weights learner were trained using a weight decay of 0.0001, a batch size of 128, and initial learning rates of 0.002 and 0.003, respectively. We further identified the use of up to 60 training epochs as a good trade-off between classification accuracy and training time. For the convolutional layers in our feature generator we used 32, 64, 128, and 256 filters, respectively, and applied a dropout rate of 0.1. For our weights learner, we utilized a dropout rate of 0.5 and the regularizer L2. Finally, we used the Adam optimizer to minimize the loss function in our experiments.

B Creating Sitemap Graphs and User Sessions

For each website in `ALEXA-WSC-HMM`, we create a sitemap graph to collect automatically-generated user sessions.

Generating Sitemap Graphs. We create a sitemap graph per website containing data about available pages with the link relationship between them. Although some websites offer a hierarchical overview documents of their pages, these documents do not always provide data on page linkability and, thus, cannot be used to create our sitemap graphs. In response, we use a different strategy to collect the sitemap graphs. First, for each website, we gather the URLs of its index page and four additional, popular pages of it that were found from Google, i.e., to simulate that users access a website not only through its index page but also through an already known link, using a bookmark or by querying a search engine [32]. Starting from one of these five pages, we then extract all URLs from that page referring to the same website. We group the collected URLs based on their position on the page, i.e., whether they are located in the navigation section or in the footer, and exclude groups of URLs that are typically less visited by users, e.g., privacy policy and legal notice pages. From the remaining groups, we randomly select ten groups of URLs, fetch one random URL from each of these groups to simulate a user click, and repeat the procedure described above to decide on the next click. The crawling of URLs terminates once we reach a depth of ten pages for each website and have gathered at least 2000 unique pages. Finally, we build a directed graph where each node represents a URL and an edge between two nodes corresponds to a link between these URLs. For this graph, we consider all seen URLs regardless whether they were selected by the sampling for further steps or not.



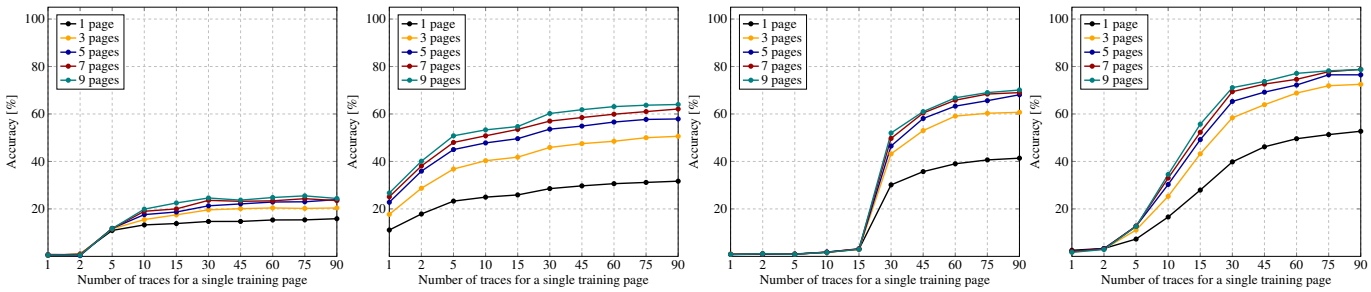


Figure 9: Accuracy achieved by the webpage classifiers with and without the use of index pages for training.

Generating User Sessions. Although a stored browser history would be a reliable source of real user sessions, it can reveal confidential data about users and usually is kept private. Thus, we use the gathered sitemap graphs to synthetically create a set of user sessions while ensuring that they exhibit realistic characteristics, as described by Kumar et al. [32]. As users can access a website in different ways, we use either the index page or one of the four additional pages of a site to start a user session. As Miller et al. [36], we execute a random walk over the sitemap graph of that website to sample the rest of the user session, whereas we prefer pages that have been visited neither in the current nor in any previously generated session. The latter increases the diversity between different sessions (and, thus, complicates the WFP attack).

C Use of Index Pages for Training

We evaluate whether the use of the index pages is particularly important to detect websites, as doubted in [39]. To achieve this, we conducted several experiments using our *website-with-unknown-pages* strategy in a closed world where each website was represented (i) by either 20 traces of its index page and multiple traces of other non-index pages belonging to the same website, (ii) or by its non-index pages only. In the first case, index pages are used solely for training and never for testing. Figure 9 illustrates the classification results obtained for a dataset containing 15 traffic traces per non-index page and a varying number of non-index pages, ranging from 1 to 90. As we can see, the difference in classification accuracy achieved when using index pages for training versus not using them is negligible for a set of 10 or more non-index pages for all classifiers. Although the difference is higher for smaller sets (i.e., less than 10) of non-index pages, particularly for both DL-based classifiers DF and Var-CNN, this is mainly due to the fact that the classifiers receive more training data through the use of index pages, which improves their accuracy. Similar results were obtained for different numbers of traces per non-index page (i.e., other than 15), which were omitted due to space constraints. Thus, we conclude that the use of index pages for training does not affect the accuracy of the

(a) CUMUL (b) k-FP (c) DF (d) Var-CNN

Figure 10: Accuracy achieved by our best voting strategy per classifier, when the number of traces of the training page increases.

attacks in either evaluation strategy and do not distinguish between using index and non-index pages in our evaluation.

D Additional Training Tactics

We also assess to what extent our voting strategies enhance the accuracy of webpage classifiers trained with a single page per website that is represented by an increasing number of traces. To accomplish this, we use the same test set as in Section 6.2.1, but adjusting the number of traces available per training page that represent a particular website. Figure 10 shows the obtained results. Unlike the results in Figure 5, where k-FP accuracy can increase by 40%, using a single page for training reduces this increase by about 30%. However, the opposite scenario is observed for DF. If the classifier is trained on a single page per website, probability voting achieves about 30% higher detection rate compared to the approximately 25% increase when using multiple pages per website. Nevertheless, the overall accuracy of all classifiers remains significantly lower than that of multiple training pages.

E Different Datasets & Tor Browser Versions

All evaluation results presented in Section 6 were obtained using a single set of websites and an old version of the Tor Browser. To verify that our results are generalizable to different sets of websites and newer Tor Browser versions, we repeated the experiments from Figure 4 using the `TRANCO-WSC-FG` dataset and computing only the best voting-based strategy for all webpage classifiers. Table 6 summarizes the results obtained. As we can see, the trend towards improved accuracy is evident with an increase in the number of sequentially visited pages per website. Overall, we achieve higher detection rates for both our voting-based methods and our MIL-based attack with all sets of pages when using the `TRANCO-WSC-FG` dataset in conjunction with the latest Tor Browser 12.5.3. Thus, we confirm the soundness of our findings.

Table 6: Accuracy (in %) of our fingerprinting methods for different datasets and Tor Browser versions.

Classifier	Set of pages								
`TRANCO-WSC-FG` & Tor Browser 12.5.3									
	1	2	3	4	5	6	7	8	9
Voting (with CUMUL)	71.76	85.20	91.50	93.70	95.10	96.00	95.80	96.40	96.80
Voting (with k-FP)	66.56	83.60	90.10	93.60	94.80	96.30	97.40	98.50	98.80
Voting (with DF)	87.36	98.00	99.40	99.60	99.80	99.90	99.90	99.90	100.00
Voting (with Var-CNN)	87.42	97.90	99.60	99.80	99.80	100.00	100.00	100.00	100.00

Abstract

Federated Learning (FL) is a collaborative machine learning technique where multiple clients work together with a central server to train a global model without sharing their private data. However, the distribution shift across non-IID datasets of clients poses a challenge to this one-model-fits-all method hindering the ability of the global model to effectively adapt to each client's unique local data. To echo this challenge, personalized FL (PFL) is designed to allow each client to create personalized local models tailored to their private data.

While extensive research has scrutinized backdoor risks in FL, it has remained underexplored in PFL applications. In this study, we delve deep into the vulnerabilities of PFL to backdoor attacks. Our analysis showcases a tale of two cities. On the one hand, the personalization process in PFL can dilute the backdoor poisoning effects injected into the personalized local models. Furthermore, PFL systems can also deploy both server-end and client-end defense mechanisms to strengthen the barrier against backdoor attacks. On the other hand, our study shows that PFL fortified with these defense methods may offer a false sense of security. We propose *PFedBA*, a stealthy and effective backdoor attack strategy applicable to PFL systems. *PFedBA* ingeniously aligns the backdoor learning task with the main learning task of PFL by optimizing the trigger generation process. Our comprehensive experiments demonstrate the effectiveness of *PFedBA* in seamlessly embedding triggers into personalized local models. *PFedBA* yields outstanding attack performance across 10 state-of-the-art PFL algorithms, defeating the existing 6 defense mechanisms. Our study sheds light on the subtle yet potent backdoor threats to PFL systems, urging the community to bolster defenses against emerging backdoor challenges.

1 Introduction

Conventional federated learning (FL) techniques encounter the challenge of addressing data heterogeneity issues arising from non-IID data distributions among local devices in real-world scenarios [35]. For example, when using FL to develop a language model for mobile keyboards, clients from diverse demographic groups may demonstrate distinct usage patterns due to cultural, linguistic, and generational disparities. To address this challenge, Personalized Federated Learning (PFL) has emerged as a recent technological advancement. Unlike conventional FL, which relies on a single global model, PFL introduces personalized local models that effectively adapt to the unique data distribution of each client, thereby enhancing classification accuracy for individual clients.

Various PFL strategies have been explored [33], which can be categorized into full model-sharing methods [11, 14, 19, 23, 38, 42, 45] and partial model-sharing methods [10, 25]. Full model-sharing methods involve globally aggregated models that clients adapt through techniques such as fine-tuning with local data [38, 42], meta-learning [11, 14], parallel global and local model training [23], global model regularization during local training [19, 24], or the weighted average of global and local models for local training initialization [45]. In partial model-sharing methods, only part of the classifier model is shared among different clients. [10] shares the feature encoder while keeping the classification head private for each client. Similarly, [25] globally aggregates model parameters except for batch normalization layers for each client. As reported in these works, PFL outperforms traditional FL by creating personalized local models with significantly higher classification accuracy on each client's local data in non-IID scenarios.

Customizing personalized local models for clients is both a blessing and a curse. While PFL methods enhance classification accuracy for clients, they concurrently open the door to backdoor attacks. Adversaries can seamlessly transfer backdoor triggers to personalized local models by optimizing the backdoor poisoning effect in the globally shared model. Previous works [2, 3, 37, 41, 46] highlight traditional FL's vulnerability to backdoor attacks orchestrated by adversary-controlled clients. These malicious clients submit carefully crafted local models to establish trigger-target mappings in the global model, thereby manipulating it to output the adver-

sary's desired label for backdoor data. However, compared to traditional FL, PFL introduces additional barriers against backdoor attacks due to the personalization process adopted by benign clients, which fine-tunes the global model to better fit individual client data. Even if backdoors are successfully injected into the global model, personalization techniques can mitigate the backdoor poisoning effects in the personalized local models using backdoor-free data. For instance, local fine-tuning [38, 42] is one such personalization technique that utilizes the client's backdoor-free data to tune the global model. Fine-tuning global models with backdoor-free data can disrupt the presence of the backdoor trigger in personalized local models, leading to catastrophic forgetting of the trigger [16], thereby mitigating backdoor poisoning effects on these models. Therefore, executing successful backdoor attacks in PFL requires not only maintaining stealthiness to evade defenses deployed at the central server or local clients but also ensuring the persistence of backdoor poisoning effects throughout the personalization process. However, the specific threat posed by backdoor attacks within the personalization context of PFL remains relatively underexplored.

Our study aims to fill this gap by exploring the potential threat of backdoor attacks in PFL systems and demonstrating their feasibility to mainstream PFL techniques, covering both state-of-the-art full and partial model sharing PFL methods [10, 11, 14, 19, 23–25, 38, 42, 45]. Traditional backdoor attacks on FL encounter three primary bottlenecks when targeting PFL. **First**, in full model-sharing PFL methods, fine-tuning the global model with clean local training data can weaken the backdoor poisoning effect. **Second**, in partial model-sharing PFL methods, only the globally shared layers of a neural network are aggregated at the server, while each client customizes the remaining layers using their clean local training data. Adversaries can only inject backdoor poisoning effects into the globally shared layers. It remains uncertain whether these backdoor poisoning effects can persist in the personalized local model, which consists of the poisoned globally shared layers and privately owned local layers. Empirical observations in Section 5.2 confirm PFL systems' resilience to backdoor attacks on clients' personalized local models. For instance, Table 1 shows that the existing backdoor attacks cannot succeed in inserting the backdoor trigger into personalized local models, whether from partial or full model-sharing PFL algorithms on the Fashion-MNIST dataset.

Furthermore, PFL systems can deploy both server-end and client-end countermeasures against backdoor attacks to enhance their resilience to model integrity threats. The central server can leverage robust aggregation algorithms [4, 32, 34, 44] to counteract the poisoning effects introduced by malicious clients. Simultaneously, local clients can utilize backdoor mitigation methods [27, 36] on their local devices to remove potential backdoor triggers.

Despite these challenges, our research reveals that the flourishing of PFL approaches fortified with various defense mechanisms is a false sense of comfort in the face of the threat of backdoor poisoning attacks. To substantiate this backdoor threat, we introduce a novel backdoor attack method, *PFedBA*, and evaluate its effectiveness against mainstream PFL approaches in different scenarios. Experimental results show that *PFedBA* can perform successful attacks against mainstream PFL approaches, circumventing state-of-the-art server-end and client-end defense methods.

Our design of *PFedBA* is inspired by the recent advancements in understanding the training dynamics of deep neural networks. First of all, [13] has shown that deep neural networks trained using gradient descent can be mathematically equivalent to a Gaussian process equipped with neural tangent kernels (NTKs). According to the theory of NTK, the similarity between the decision boundaries of two neural network models can be quantified by measuring the degree of alignment between the gradient vectors of the two models. Besides, [1, 30] reveal that the loss landscape of a neural network training process nearly contains one single basin at convergence. By strategically manipulating the training data, It is possible to guide two neural network models to converge towards the same loss basin, ultimately leading to similar classification boundaries, a.k.a Machine Teaching [30]. With these concepts in mind, our intuition is: if we align the gradient of the backdoor task with that of the main learning task, and align the classification loss of the two tasks into the same loss basin, we will obtain a backdoor-poisoned model whose classification boundary closely resembles that of the backdoor-free model trained with clean data. Maintaining consistency in classification boundaries enables the backdoor poisoning effects to persist during the personalization process and evade the defense mechanisms deployed at both local clients and the central server.

More specifically, we formulate the backdoor attack method against PFL as a joint optimization problem, where the backdoor trigger and poisoned model parameters are simultaneously optimized during the global training phase. Our goal is twofold: minimizing the classification loss on the backdoor input by alternately optimizing the trigger and model parameters while minimizing the Euclidean distance between the gradient of the backdoor task and the gradient of the main task in each attack iteration. In this way, we align the gradients and losses of the main and backdoor tasks, making the decision boundary of the backdoor poisoned model very similar to that of the clean model. In Section 4, we elaborate on how *PFedBA* persists within PFL algorithms, and this persistence holds true even in the presence of defense mechanisms.

We conduct a comprehensive empirical study to demonstrate the effectiveness of our proposed *PFedBA* attack against PFL systems on 4 large-scale datasets: Fashion-MNIST, CIFAR-10, CIFAR-100, and N-BaIoT. *PFedBA* successfully injects backdoor triggers into personalized local models generated with 10 popular PFL algorithms, including 8 full model-sharing methods [11, 14, 19, 23, 38, 42, 45] and 2 partial

model-sharing methods [10, 25]. In comparison to *PFedBA*, we evaluate 5 prevalent backdoor attack methods—*Sybil attack* [17], *Model replacement attack* [2], *PGD attack* [37], *Neurotoxin* [46], *CerP* [29]—as attack baselines. To gauge attack effectiveness against countermeasures, we consider 6 state-of-the-art defense methods, including 4 server-end defenses [4, 32, 34, 44] in FL and 2 client-end backdoor mitigation techniques [27, 36]. Our experimental results reveal that *PFedBA* achieves high attack success rates on personalized local models while maintaining accuracy in the main task. Even in scenarios where robust FL methods and backdoor mitigation techniques are implemented, *PFedBA* outperforms the attack baselines. These findings underscore the attack effectiveness of *PFedBA* based on gradient and loss alignments.

The key contributions in our study can be summarized in the following perspectives:

- We expose the backdoor poisoning vulnerabilities in PFL systems by introducing an effective distributed backdoor attack targeting PFL systems. We highlight a critical security concern regarding model integrity and reliability in practical PFL applications. This issue, while rarely explored in mainstream PFL solutions, demands attention from the security community.
- We formulate the *PFedBA*-driven attack as a joint optimization problem to simultaneously generate the backdoor trigger and optimize the poisoned models to align the main and backdoor tasks. The goal is to maintain the backdoor poisoning effect during the personalization stage while maximizing the attack performance against the server-end and client-end defense mechanisms.
- Our study organizes a large-scale and comprehensive evaluation of the backdoor threat in PFL systems on 4 benchmark datasets, utilizing 10 mainstream PFL methods, 6 backdoor attack methods (including *PFedBA*), and 6 defense mechanisms. Our results provide a convincing argument for the attack effectiveness of *PFedBA*.

2 Related Work

2.1 Personalized Federated Learning

Our work focuses on the state-of-the-art PFL methods, which includes full model-sharing [11, 14, 19, 23, 38, 42, 45] and partial model-sharing [10, 25] methods.

In full model-sharing PFL methods, local clients jointly optimize the global model and use it as a reference to adapt their personalized local models. *Local fine-tuning* [38, 42] is the most straightforward PFL technique of this kind. It first updates the global model by aggregating clients' local model updates globally. After that, each client uses the global model as an initialization for local training and fine-tunes their local model with their own data. Beyond the simple fine-tuning strategy, *SCAFFOLD* [19] regularizes the difference between the global model update and individual local model updates, which aims to reach a balance of generalization and diversity of local models. Furthermore, PFL methods based on meta-learning [11, 14] train a meta global model to facilitate few-shot fine-tuning of local models. *Per-FedAvg* [14] is a direct extension of the vanilla *FedAvg*, incorporating Model-Agnostic Meta-Learning (MAML) [15] into the global model training stage. *pFedMe* [11] further extends the learning framework by integrating Moreau envelopes and the L2-norm regularization to tune the trade-off between local model adaptation to the local training data and generalization performance on data beyond the local training set.

In parallel, *Ditto* [23] introduces a multi-task learning framework for personalized local models, considering two tasks: global model learning and local model learning. To relate these tasks, *Ditto* incorporates a regularization term that encourages the personalized local models to stay close to the optimal global model. Other PFL methods [28, 45] propose to adapt the local models by customizing the initialized model parameters for local training. For example, instead of using the shared global model directly for initializing local models, *FedALA* [45] proposes to learn a client-specific weighted average of the global and local model derived from the past global training iteration as each client's initialized local model.

In partial model-sharing PFL methods, each personalized local model is composed of the globally shared layers and privately owned local layers. Though both sets of layers are updated via local training at local clients, only the globally shared layers are submitted to the central server for model aggregation. Different clients utilize the globally shared layers while adapting the privately owned local layers to their data. In *FedBN* [25], clients keep the Batch Normalization layers of the learned model as the privately owned local layers, while the remaining layers of the model are globally updated following the standard *FedAvg* protocol. Similarly, *FedRep* [10] divides the model into a globally shared feature encoder and a local classification head. Clients jointly learn the feature encoder and share the same feature embedding space, while tuning their classification heads to better fit their local data.

2.2 Distributed Backdoor Attacks to FL

Several studies [2, 3, 9, 17, 37, 41, 46] have highlighted the vulnerability of FL to distributed backdoor attacks launched by malicious clients in FL systems. Pioneering efforts in this domain, such as the *Sybil attack* [17], *Model Replacement attack* [2], and *DBA* [41], organize distributed backdoor attacks by having malicious clients independently train and submit the poisoned local model. *Sybil attack* [17] involves malicious clients submitting backdoor-poisoned local models directly targeting FedAvg-based aggregation rules that aggregate model parameters from both benign and malicious clients. *Model Replacement attack* [2] strengthens significantly the attack strength by scaling up the poisoned model updates submitted by malicious clients, effectively achieving

its attack objective in very few global aggregation iterations. Since the model parameters submitted by malicious clients are distinguished from those submitted by benign clients, both attacks can be easily mitigated by Byzantine-robust FL methods. Besides, *DBA* [41] divides a global trigger into multiple local triggers and distributes them to all malicious clients. However, it is challenging to embed the complete trigger into the global model since partial-participation FL cannot ensure the selection of all malicious clients for model aggregation.

Other distributed backdoor attack methods focus on improving the attack performance against robust FL aggregation methods. [3] attempts to evade the robust FL aggregation rules by constraining the parameters of poisoned local models within the parameter value range observed in benign local models. *PGD attack* [37] utilizes the projected gradient descent to update the poisoned local models, aiming to keep their local models relatively close to the global model. Similarly, *Neurotoxin* [46], to increase the durability of the poisoning effect, adopts a coordinate-wise project gradient descent approach, focusing on the parameters that are rarely updated during benign local training, to learn the backdoor model. *CerP* [29] slightly fine-tunes the backdoor trigger with an L2-ball constraint and explicitly controls malicious model bias to improve the attack effectiveness and stealthiness.

Effective as they are, these distributed backdoor attack methods are designed to poison only the globally shared model in FL systems. It remains an open question whether embedded backdoor effects persist in personalized local models. Nonetheless, from these studies, we can gain insights from two perspectives. First, optimizing the learning process of backdoor poisoned local models by constraining or regularizing gradient updates can narrow the gap between the backdoor and clean models, aiding in evading the robust FL methods without compromising backdoor attack performance. Second, as suggested by [29], it is feasible for the adversary to adapt the trigger pattern to improve attack performance, yet guarantee the high utility of the backdoor model.

Our study is guided by these insights learned from previous works. We increase the flexibility of our attack by generating carefully crafted triggers to force gradient alignment and loss alignment of the main and backdoor tasks. This design facilitates the seamless transfer of backdoor effects from the globally shared model to locally personalized models while keeping the attack undetected facing robust FL methods.

It is worth noting that our work focuses on exploring the vulnerabilities to backdoor attacks in PFL systems that incorporate both global training and local personalization, encompassing both partial and full model-sharing PFL methods. In contrast, [43] focuses solely on attacks targeting partial model-sharing PFL systems, where only the classification head is fine-tuned locally, while the feature encoder is globally shared among all clients. Furthermore, [21] focuses on the HyperNetFL system, which employs a neural network hosted by the server to generate local model parameters for each client using the client-specific descriptor and parameters of a special shared model as inputs. Backdooring this HyperNetFL model resembles backdooring traditional FL systems, where a specially crafted model embedded with backdoors is shared among all clients. This differs from the PFL system examined in our study, which incorporates a local personalization process.

2.3 Backdoor Defense Methods

Server-end Backdoor Defenses. State-of-the-art robust FL methods leverage a variety of anomaly detection techniques to filter out abnormal local model updates or introduce random noise to the model, thus mitigating the impact of backdoor attacks. *Trimmed mean* [44], a coordinate-wise aggregation rule, sorts n local model updates for parameters in each dimension and excludes the largest and smallest β values. The remaining $n-2\beta$ values are then averaged as the corresponding coordinate of the global model update. *Multi-Krum* [4] selects multiple local model updates with the closest Euclidean distance to the nearest $n-m-2$ local model updates (where m is the number of malicious clients in FL) and computes their average as the global model update. *DnC* [34] first computes the principal component of local model updates and then calculates the dot product of each local model update with the principal component. It removes the local model updates that deviate the most from the principal component. *FLAME* [32] utilizes the model clustering method HDBSCAN [5] to identify potentially poisoned local models. It then clips the parameter values of the remaining local models and introduces the random Gaussian noise to the aggregated global model. *FLTrust* [6] allows the central server to maintain a small, poison-free dataset sampled from a distribution similar to the entire training dataset. The server utilizes this dataset to train a global reference model and computes a linear combination of local models weighted by the score, measured by the cosine similarity between the global reference model and local models. *FedRecover* [7] is a model recovery method capable of leveraging historical information to restore clean global models from poisoning attacks. *FLCert* [8] constructs an ensemble of global models by randomly selecting k out of n clients to produce N global models. The label for a testing input is predicted based on the majority vote among these derived global models.

Client-end Backdoor Defenses. Current strategies addressing backdoor attacks in centralized machine learning can be classified into three main categories: pre-training defense, in-training defense, and post-training defense, as outlined in [39]. Pre-training defense methods, like *Februus* [12], focus on identifying and removing poisoned data samples before the model training phase. However, these methods are not practical in FL systems due to privacy-preserving protocols. In-training defense mechanisms, exemplified by *anti-backdoor learning techniques* [26], aim to mitigate the impact

of backdoor poisoning during the model training process. Nevertheless, this approach faces challenges in FL because the distributed nature of FL restricts the defender from overseeing the local training processes of individual clients. Post-training defense methods concentrate on eliminating or mitigating the backdoor poisoning effects in already-trained models. For instance, *Neural Cleanse* (NC) [36] functions by reversing the trigger on clean data instances and subsequently removing the backdoor through unlearning-based deep neural network patching or neuron pruning. Another approach, *Neural Attention Distillation* (NAD) [27], achieves backdoor mitigation by pruning neurons highly correlated with the backdoor trigger.

Our study explores whether these state-of-the-art server-end and client-end defense methods can enhance the resilience of the PFL system against the proposed backdoor attack when adopted by both the server and benign clients. Our key insight lies in the alignment of losses and gradients between backdoor and main tasks, offering a two-fold advantage in evading these defense methods. Firstly, it reduces model bias between backdoor-poisoned and clean models, facilitating bypass the server-end defenses. Secondly, aligning the main task with the backdoor task narrows the gap between the decision boundaries of the backdoor model and the clean model, enabling the circumvention of client-end defenses.

3 Problem Definition and Threat Model

3.1 Problem Definition

Suppose we have N clients in the PFL system. Each client possesses a local dataset $D_i = \left\{ \{x_{i,j} \in R^m, y_{i,j}\}_{j=1}^{d_i} \right\}$, where $d_i = |D_i|$ and $\{x_{i,j}, y_{i,j}\}$ represents the feature vector and class label of each data instance hosted by the client i. We highlight that the local datasets of different clients are non-IID. The PFL system aims to collaboratively use the private datasets $D_1, \cdots, D_N$ to find the optimal set of the personalized local models $[\omega_1, \cdots, \omega_N]$ that better fit these local datasets. The PFL problem can be formulated as:

$$\min_{W=[\omega_1,\omega_2,\cdots,\omega_N]} F_P(W) = \min_{\omega_i, i\in[N]} \sum_{i=1}^{N} p_i f_i(\omega_i) \tag{1}$$

where $F_P(\cdot)$ is the global objective of PFL, and $p_i \geq 0$ is the aggregated weight of client i.

In this study, we focus on both full and partial model-sharing based PFL methods. All of these PFL methods involve two stages: a global aggregation stage and a local model adaptation stage, which runs sequentially or jointly. More specifically, the global aggregation stage follows the standard FL protocol. During each global aggregation iteration, the server aggregates local model updates from the selected clients to update the globally shared model, which is then shared back with all clients. While or after the global aggregation stage, local clients utilize the globally shared model to fine-tune their personalized local models ω_i, thereby capturing the data distribution of each client.

3.2 Threat Model

Attack Goal. The objective of backdoor attacks in PFL differs from those in traditional FL [2, 3, 37, 41, 46]. While backdoor attacks against traditional FL aim to induce misclassification in the global model for trigger-embedded inputs, adversaries targeting PFL aim to introduce backdoor poisoning effects into personalized local models. The poisoned personalized local models should produce the adversary-desired output for trigger-embedded inputs while functioning normally for inputs without triggers. Our focus further extends to stealthy backdoor attacks, designed to bypass both server-end and client-end defenses while ensuring the success of the attacks.
Attack Capability. We assume the adversary has control C out of N clients ($C \ll N$) in the PFL system. The adversary can access and arbitrarily manipulate the local data, labels, training status, and the local model training process hosted by malicious clients. The adversary can leverage the local datasets from malicious clients to create a dataset denoted as D^{mal} for generating the optimized trigger. It is important to note that the adversary cannot collect any auxiliary data for use in the attack or compromise the central server. Furthermore, the adversary cannot access or tamper with the local datasets, the local model training process, and the personalization process of benign clients.
Attack Knowledge. The adversary has complete access to the local datasets, local training, and personalization processes of malicious clients to conduct backdoor attacks. Nevertheless, the adversary remains entirely unaware of any information concerning the benign clients and the central server. Furthermore, the adversary is unaware of the defense techniques implemented on the server or clients in the PFL system.

In this study, we aim to unveil the feasibility of backdoor attacks in practical PFL systems, where the adversary can only manipulate compromised local clients and remains agnostic to the learning strategy adopted by the central server and other benign clients. As such, our work is based on a logical premise within our threat model: if an adversary can successfully execute backdoor attacks with such limited knowledge and attack capabilities, the potential for even more severe threats to model integrity increases when the adversary possesses greater attack capabilities and richer knowledge of the target PFL system. Our findings provide insights into the vulnerability of real-world PFL applications to backdoor attacks.

4 The PFedBA-based attack method

The workflow and the pseudo codes of the proposed *PFedBA* attack are given in Figure 1 and Algorithm 1. In the t-th poisoned federated training iteration, the pipeline of *PFedBA* consists of two stages: alignment-optimizing driven trigger

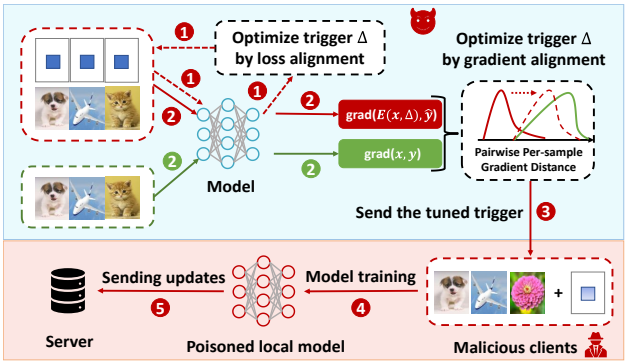

Figure 1: Illustration of our *PFedBA* attack.

generation and backdoor poisoned local training. In the trigger generation stage, the adversary uses the training data D^{mal} owned by the adversary-controlled malicious clients to generate the backdoor trigger Δ^t by enforcing the loss alignment and gradient alignment between the backdoor and the main task. After obtaining the optimized trigger, the adversary sends the trigger Δ^t to the malicious clients. In the backdoor poisoned local training stage, the malicious clients embed the optimized trigger Δ^t into their local training data and train the backdoor local models. Finally, the selected malicious clients send the poisoned model updates to the central server. Both the backdoor and clean local model updates are aggregated at the server to update the global model.

4.1 The Design of PFedBA

Our *PFedBA* attack is formulated as a distributed optimization problem with the objective function defined in Eq.2. In the t-th training iteration, the adversary launches the attack via jointly optimizing Eq.2 with the malicious clients selected to join the global model aggregation:

$$\begin{aligned} &\omega_i^{*,t} = \arg\min_{\omega_i^t} \sum_{j \in D_i^{mal}} \mathcal{L}_{\omega_i^t}(E(x_{i,j}, \Delta^{*,t}), \hat{y}) + \sum_{j \in D_i^{nor}} \mathcal{L}_{\omega_i^t}(x_{i,j}, y_{i,j}) \\ &\text{s.t. } \Delta^{*,t} = \arg\min_{\Delta^t} AL(\Delta^t, \omega^{t-1}, D^{mal}) \end{aligned} \tag{2}$$

where $\mathcal{L}_{\omega_i^t}(x,y)$ denotes the classification loss function given the data instance (x,y) and the backdoored local model ω_i^t of the malicious client i. ω^{t-1} represents the aggregated model obtained from the previous federated training iteration $t-1$, which the adversary uses to optimize the task-specific backdoor trigger. Specifically, in full model-sharing PFL methods, ω^{t-1} represents the global model aggregated at the previous FL training iteration $t-1$, which serves as the initialized local model for local clients at iteration t. In partial model-sharing PFL methods, ω^{t-1} refers to the initialized local model of the malicious client specified by the adversary at iteration t, comprising both the globally shared layers and the privately owned local layers. Notably, if the adversary chooses to inject backdoors from the t-th federated training iteration onwards, ω^{t-1} remains backdoor-free, while ω_i^t is injected with the backdoor trigger. As the attack progresses, the backdoor is embedded in the model ω^t. D_i^{mal} and D_i^{nor} represent the backdoor and the clean training data hosted by the malicious client i, respectively. $\hat{y}$ indicates the adversary-desired classification output. $D^{mal} = \{D_i^{mal}\}$ denotes the union of all the backdoor local training datasets owned by malicious clients. *In our study, we assume the adversary can manipulate all the training samples hosted by the malicious clients. However, she cannot collect any auxiliary data.*

The function $AL(\cdot)$ in Eq.2 of *PFedBA*, as defined in Eq.3, represents the module responsible for generating the task-specific backdoor trigger Δ^t using the dataset D^{mal} and the model ω^{t-1}. The parameter λ, which can take values of either 1 or 0, determines the optimization method: when set to 1, optimization prioritizes gradient alignment; when set to 0, it emphasizes loss alignment. In *PFedBA*, the trigger is

Algorithm 1 PFedBA

        Patch $x, x \in D_i^{mal}$ with Δ^t by Eq.4;
        Train the backdoor poisoned local model ω_i^t through Eq.2;
        Send the poisoned local model update $\Delta\omega_i^t = \omega_i^t - \omega^{t-1}$ to the server.
      end for
    end Stage
  end if
end for

optimized using gradient alignment and loss alignment by adjusting λ accordingly. Specifically, in the first attack iteration, the adversary initially optimizes the backdoor trigger by minimizing Eq.3 with $\lambda = 0$. Then, the adversary tunes the optimized trigger by minimizing Eq.3 with $\lambda = 1$. For all subsequent attack iterations, the adversary solely minimizes Eq.3 with $\lambda = 1$ to further optimize the trigger.

$$AL = \begin{cases} \lambda \sum\limits_{l \in D^{mal}} \|\nabla_{\omega^{t-1}} \mathcal{L}(E(x_l, \Delta^t), \hat{y}) - \nabla_{\omega^{t-1}} \mathcal{L}(x_l, y_l)\|_2 \\ \\ +(1-\lambda) \sum\limits_{l \in D^{mal}} \mathcal{L}_{\omega^{t-1}}(E(x_l, \Delta^t), \hat{y}) \end{cases} \tag{3}$$

$E(\cdot)$ defined in Eq.4 represents the function that embeds a trigger Δ into the original data sample x. m is a matrix called the mask, deciding how much the trigger can overwrite the original data sample. Values in the mask are 0 or 1. $m_{i,j} = 0$ means the feature is not modified at all, and $m_{i,j} = 1$ means the trigger completely overwrites the feature ($x_{i,j} = \Delta_{i,j}$). In our work, the mask m designed by the adversary is fixed. The symbol $\odot$ represents element-wise multiplication.

$$E(x, \Delta) = x \odot (1 - m) + \Delta \odot m \tag{4}$$

Next, we describe the details of the proposed *PFedBA* attack, which consists of two steps: *alignment-optimizing driven trigger generation* and *backdoor poisoned local training*.

4.1.1 Alignment-Optimizing driven Trigger Generation

The common way of backdoor attack is to train the model using the trigger-embedded data, in order to force the model to memorize the association between the trigger-embedded input with the adversary-desired classification output. However, the backdoor poisoning effect embedded in the globally shared model can be diluted during the personalization process. In this process, the globally shared model is further fine-tuned with clean training data hosted by local clients. Due to the catastrophic forgetting phenomenon unveiled in neural networks, the poisoning effect becomes significantly weaker with more rounds of local model tuning. Besides, injecting an arbitrary trigger may cause excessive malicious model bias [29]. The backdoor poisoned local models may thus be easily detected by the server-end defense mechanisms during the global aggregation stage of PFL. At the personalization stage, benign clients can also deploy client-end backdoor mitigation methods to detect and mitigate the backdoor trigger in the local model. To address these bottlenecks, we consider both the trigger and the global model parameters as optimization variables in *PFedBA*. We propose to generate task-specific triggers to align the backdoor task with the main task. The proposed trigger generation module, given in Eq.3, is designed to achieve *gradient alignment* and *loss alignment* simultaneously between the main learning task and the backdoor task.

Objective of Gradient Alignment. This alignment term (the first term of Eq.3) is designed to adapt the backdoor trigger Δ such that it can directly align the gradients of the backdoor and main tasks along the same direction, i.e. we minimize the Euclidean distance between the two gradient vectors. Both of these gradient vectors mentioned above are computed by the adversary using the model ω^{t-1}, the poison-free data D^{mal} and the corresponding backdoor training samples $\hat{D}^{mal}$. Intuitively, minimizing the Euclidean distance serves to bring the gradient of the backdoor task closer to that of the main task. As benign clients adapt the model using clean training data through gradient descent, the memory of the mapping between the trigger-embedded input and the adversary-desired class label in the personalized local model is strengthened due to the consistent gradient direction of the main task and the backdoor task. Therefore, this gradient alignment term prevents the erasure of triggers during the personalization stage.

Furthermore, the idea of introducing gradient alignment into our attack is also inspired by theoretical breakthroughs in Neural tangent kernels (NTKs) [13]. Originally introduced to explain the evolution of deep neural networks using gradient descent during training, NTK theory allows us to measure the similarity between the decision boundaries of two neural network models based on the inner product between the gradients of the two neural network models for given inputs. The greater the inner product (reflecting closer alignment between the gradients), the more similar the decision boundaries of these two models are. Building upon this theory, we enforce alignment between the gradients of the backdoor task and the main task, with the goal of making the decision boundary of the backdoor model as similar as possible to the decision boundary of the backdoor-free model. The enhanced closeness between the decision boundaries of the backdoor model and the backdoor-free model helps the trigger evade the client-end defense methods [27, 36].

The enhanced closeness between the decision boundaries of the backdoor model and the backdoor-free model also helps our attack evade the server-end defense methods [4, 32, 34, 44] that are designed to detect Byzantine clients following the spirit of anomaly detection. Performing the gradient alignment reduces the model bias between the backdoor local models and the backdoor-free local models, which makes the server-end defense methods unable to differentiate the backdoor local models from the backdoor-free ones.

Objective of Loss Alignment. The loss alignment between the main and backdoor tasks is formulated as a bi-level optimization problem, described in Eq.2. In the outer-layer optimization, our aim is to minimize classification losses for both tasks by adjusting local model parameters while keeping the trigger fixed. In the inner-layer optimization (the second term of Eq.3), we freeze the model and optimize the trigger to minimize the classification loss of the backdoor task on the model ω^{t-1}, while ensuring the classification loss of the main task remains unchanged. Intuitively, if a model well-trained on backdoor-free data can achieve a low classification loss on backdoored data, the attack objective is achieved without sig-

nificantly altering the model parameters, thereby mitigating malicious model bias caused by trigger injections. Therefore, the objective of loss alignment is to align the classification loss for the backdoor task with that of the main task through trigger optimization, bringing them into the same loss landscape on the model without changing the model parameters.

The idea of trigger generation using the loss alignment can find its origin in the concept of Machine Teaching [30]: given a testing set, fine-tuning the training data can calibrate the decision boundary of a classifier and help the classifier produce the desired classification outputs for the test data. We follow the spirit of Machine Teaching and minimize the backdoor classification loss, thus achieving loss alignment between the main task and the backdoor task on the model. This alignment helps minimize the divergence in decision boundaries between the backdoor and backdoor-free models. Therefore, the client-end backdoor mitigation methods [36] may be ineffective in removing adversary-specified backdoor triggers, since these methods cannot distinguish between the decision boundaries in backdoor and backdoor-free models.

Additionally, according to [1], the loss landscape of deep neural network training typically exhibits a few equivalent basins with similar model parameters at convergence. Aligning the loss landscape of the backdoor task with that of the main task forces the backdoor model to converge to the same basin area of the backdoor-free model, which can effectively reduce the model bias between backdoor models and backdoor-free models, thereby allowing the trigger to evade the server-end defense methods.

In summary, we generate the optimized trigger in the way that the classification boundary of the backdoor model is aligned as much as possible to that of the backdoor-free model. Deploying the optimized trigger in attack not only preserves the backdoor effects in the personalization process, but also circumvents the server-end and client-end defense methods.

4.1.2 Backdoor Poisoned Local Training

By optimizing Eq.3 using the training data owned by malicious clients, the adversary obtains an optimized trigger Δ^t for attacks, and sends Δ^t to all malicious clients. The malicious clients embed the optimized trigger Δ^t into the poisoned local training dataset D_i^{mal} via Eq.4. Then, the malicious clients train local models based on D_i^{mal} and D_i^{nor} and send their poisoned local model updates to the central server.

5 Empirical Evaluation

5.1 Experimental Settings

Datasets, Triggers, and Model Structures. *CIFAR-10* [20] and *CIFAR-100* [20] are color image classification datasets, each consisting of 50,000 training instances and 10,000 testing instances, all with a size of 32×32. We use ResNet [18] as the model architecture. The trigger is an 8×8 pixel pattern placed at the center of the image. For *CIFAR-10*, the target class label for the poisoned input instances is set as *airplane*, and for *CIFAR-100*, it is designated as *apple*. *Fashion-MNIST* [40] is a 10-class classification dataset with 60,000 training instances and 10,000 testing instances, each of size 28×28. We use LeNet [22] as the model structure. The trigger, a 10×10 pixel pattern, is positioned at the center of the image. The target class label for the poisoned input instance is set as *T-shirt*. The *N-BaIoT* [31] dataset is a botnet dataset that provides authentic traffic data gathered from 9 commercial IoT devices. The dataset consists of 7 million data instances, each with 115 features, supporting an 11-class classification task. We create a trigger using 23 features, with the target class label for the poisoned input instance set as *gafgyt_combo*. The model structure we employ is a 4-layer fully connected network.

For each dataset, we employ a non-IID data distribution. Specifically, we utilize the Dirichlet distribution [41] to sample the data instances allocated to each client, thereby introducing complexity and diversity into the data distribution across clients. For the Fashion-MNIST and N-BaIoT datasets, we set the α value of the Dirichlet distribution to 0.1, while for CIFAR-10 and CIFAR-100, the α value is set to 0.5.

The PFL System Settings. In this work, we focus on the following 10 PFL algorithms: *FedAvg-FT* [38], *FedProx-FT* [24], *SCAFFOLD* [19], *Per-Fedavg(FO)* [14], *Per-Fedavg(HF)* [14], *pFedMe* [11], *Ditto* [23], *FedBN* [25], *FedRep* [10], and *FedALA* [45]. For all datasets, we assume a total of $N = 100$ clients in the PFL system. In each global aggregation iteration, the central server randomly selects $N_p = 10$ clients to participate in the global aggregation. During the personalization stage, for *FedAvg-FT*, *FedProx-FT*, *Per-FedAvg(FO)*, and *Per-FedAvg(HF)*, we adapt the global model generated by these methods with 1 epoch (Fashion-MNIST and N-BaIoT) or 5 epochs (CIFAR-10 and CIFAR-100) of stochastic gradient descent using the local training data to produce personalized local models. For the rest 6 PFL methods, we create personalized local models for clients based on the hyperparameters suggested by the original research papers. See the Appendix A for more detailed PFL system settings.

Baseline Attacks and Attack Settings. To organize a comparative study, we involve the following 5 baseline backdoor attacks. *ModelRe* [2] scales up the poisoned local model updates with a factor λ before sending them to the central server. We set λ to 20 for all the datasets. *PGD attack* [37] employs projected gradient descent to train the poisoned local models. It periodically project the parameters of the local poisoned models on a small ball of radius $\eta = 0.001$ centered around the global model of the previous iteration. This method thus poses the constraint that the poisoned local models stay relatively close to the global model to bypass Byzantine-resilient FL aggregation. *Sybil attack* [17] controls multiple malicious clients to independently train their poisoned local

models. *Neurotoxin* [46] targets model parameters with minimal magnitude changes during benign local training to insert durable backdoor triggers into the global model. We maintain a 1% ratio for masked gradients, following the original paper. *CerP* [29] enhances the stealthiness of backdoor attacks by optimizing triggers and explicitly controlling trigger-induced model deviations. By default, we assume that 10% of clients are malicious for all the backdoor attack methods.

Defense Methods. We study the attack performance of various backdoor attacks against different defense techniques. We evaluate the effectiveness of backdoor attack methods against a range of defense techniques implemented on the central server, which include *Multi-Krum* [4], *Trimmed mean* [44], *DnC* [34], and *FLAME* [32]. Specifically, following [32], we set $\lambda = 0.001$ (representing the amount of adaptive noise used in *FLAME*) for CIFAR-10, CIFAR-100, and Fashion-MNIST, and $\lambda = 0.01$ for B-NaIoT. Additionally, we evaluate the performance of backdoor attacks when clients utilize the widely adopted backdoor mitigation methods *NC* [36] and *NAD* [27].

Evaluation Metrics. We consider two metrics to evaluate jointly the effectiveness of backdoor attacks against PFL. *ACC* denotes the average clean test accuracy of benign clients' personalized local models on their clean test data. *ASR* measures the average backdoor accuracy of benign clients' personalized local models on their trigger-embedded test data. A successful backdoor attack against PFL is expected to produce as high as possible ACC and ASR on the personalized local models of benign clients. Given similar ACC levels, the attack methods reaching higher ASR are considered more effective.

5.2 Experimental Results

We provide a comprehensive analysis of the threat posed by backdoor attacks on the PFL system across 4 datasets. We present ACC and ASR for 6 backdoor attacks and a no-attack scenario under various conditions. More specifically, we present the attack performance of all the backdoor attacks and the no-attack scenario under 10 PFL algorithms without any defenses on N-BaIoT, Fashion-MNIST, CIFAR-10, and CIFAR-100 in Table 1. Tables 2– 4, and 7 illustrate the attack performance of all the backdoor attacks and the no-attack scenario for 10 PFL algorithms equipped with various server-end defense methods on Fashion-MNIST, N-BaIoT, CIFAR-10, and CIFAR-100, respectively. Due to space constraints and similar results derived on different datasets, we present the results for Fashion-MNIST, CIFAR-10, and N-BaIoT in this section, with results for CIFAR-100 available in Appendix B. Moreover, Table 5 presents the ACCs and ASRs of various backdoor attacks against client-end defense methods across 10 PFL methods. In each table, we use bold fonts to highlight the highest ASR value achieved among all the attack methods (including *PFedBA*), facing different defensive mechanisms. We also evaluate the sensitivity of the *PFedBA*'s attack performance with respect to different alignment terms on Fashion-MNIST and CIFAR-10, shown in Tables 8 and 9. The impacts of several parameters within PFL on *PFedBA* are shown in Figures 2, 3, 4– 6.

The experimental results show that *PFedBA* outperforms the other baseline attack methods in terms of attack effec-

tiveness across all the discussed scenarios. Further detailed observations and discussions are provided below.

(1) Attack performance without any defenses. As indicated in Table 1, across all 10 PFL algorithms without any defense mechanisms, our *PFedBA* exhibits outstanding attack performance on personalized local models, while still maintaining the model's performance on the main learning task. In contrast, the other baseline attacks face challenges when attempting to inject triggers into personalized local models, even in scenarios where PFL systems do not employ defenses.

For instance, *PFedBA* consistently achieves ASR values exceeding 80% for all 10 PFL algorithms across the 4 datasets, while maintaining ACC values similar to the non-attacked model (NoAttack). However, the attack baselines often struggle to successfully inject backdoor triggers into personalized local models. For Fashion-MNIST, the ASR values for all the attack baselines are below 47% against *Per-Fedavg(FO)*, *pFedMe*, and *FedRep*, while *PFedBA* achieves ASR values exceeding 93%. On CIFAR-10 and N-BaIoT, under *Per-FedAvg(HF)*, none of the baseline attacks can achieve ASR values exceeding 60%, whereas *PFedBA* achieves ASR values exceeding 82%. Similarly, the ASR values of the baseline attacks are lower than 51% against *pFedMe* on CIFAR-100, while *PFedBA* obtains a 98.9% ASR value.

The personalization process forces the personalized local models to forget the trigger-target mappings by adapting the local models with backdoor-free local training data. These attack baselines are designed without considering the impact of the personalization process with clean data on the backdoor effects. Therefore, embedding triggers into personalized local models within PFL systems becomes challenging for these baseline attacks. *PFedBA*, on the contrary, proactively aligns the gradients of the backdoor and main tasks by optimizing the trigger. This design enables the model to exploit as much trigger-related information as possible from the gradient of the main task. Moreover, by aligning the main task with the backdoor task, the backdoor model exhibits the decision boundary that closely resembles that of the clean model, so that the trigger can persist in personalized local models.

(2) Attack performance against server-end defenses. As shown in Tables 2–4 in this section and Table 7 in Appendix B, *PFedBA* achieves significantly high ASR values against the server-end defenses under 10 PFL algorithms on 4 datasets without harming the accuracy of the main task.

For instance, on Fashion-MNIST, *PFedBA* consistently achieves ASR values exceeding 87% against all defenses across all PFL algorithms, except *Per-Fedavg(HF)*. Even against *Per-Fedavg(HF)*, *PFedBA* still obtains more than 73% of ASR values against all the defenses. Notably, the ACC values of the main task on the personalized local models attacked by *PFedBA* remain very close to those of unattacked models. However, none of the attack baselines can achieve an ASR higher than 58%. For N-BaIoT, *PFedBA* achieves ASR values greater than 93% against *Multi-Krum* and *FLAME* under *Per-Fedavg(FO)* and *pFedMe*, while the attack baselines fail to attain ASR values higher than 37%. Similarly, on CIFAR-

10, *PFedBA* achieves ASR values higher than 94% against *Trimmed mean* under *FedAvg-FT* and *FedProx-FT*, outperforming other attack baselines with ASR values lower than 40%. For CIFAR-100, on *pFedMe*, *PFedBA* obtains a 98.1% ASR value against *FLAME*, which is at least 34% higher than the ASR values achieved by all the other attack baselines.

These attack baselines fail to minimize the trigger-induced model bias, which makes them difficult to bypass defense methods deployed at the central server. Although *CerP* can adapt a pre-specified trigger to reduce malicious model biases, which help bypass the server-end defenses. However, this method is restricted from two perspectives. Firstly, it can only slightly change the given trigger with a strict L2-ball constraint posed to the trigger optimization. In contrast, *PFedBA* offers significantly greater tuning flexibility by allowing the adversary to generate and optimise the task-specific trigger. Second, *PFedBA* enforces both gradient and loss alignment objectives to explicitly narrow down the gap between the gradient descent trajectories of the backdoor and clean models. Furthermore, the loss alignment enables the models to learn the trigger without significantly changing the model parameters. Consequently, *PFedBA* outperforms the other attacks by producing higher ASR facing the deployed server-end defense methods. For example, on Fashion-MNIST, the ASR value of *PFedBA* is at least 40% higher than that of other attack baselines. The results confirm that *PFedBA* performs well in evading the server-end defense methods and retaining more backdoor poisoning effects than the other baselines.

(3) Attack performance against client-end defenses. Table 5 presents the ACCs and ASRs of various attack methods against *NC* and *NAD*. Our findings reveal that backdoor mitigation techniques applied by benign clients are unable to remove the trigger embedded in personalized local models by *PFedBA*. ASR of *PFedBA* consistently exceeds 70% against *NC* and *NAD* across all 10 PFL methods on Fashion-MNIST and B-NaIoT. Conversely, backdoor triggers introduced by the other attack baselines are identified and removed by *NC* and *NAD*. For example, on Fashion-MNIST and B-NaIoT, all the attack baselines against *NC* achieve a maximum ASR value of only 39.9%. However, *PFedBA* can achieve an ASR value of at least 70%, successfully embedding the trigger into the personalized local models. Similarly, against *NAD* on Fashion-MNIST, all the attack baselines achieve an ASR value of no more than 61%.

The explanation behind can be summarized in the followings. On one hand, the baseline attacks cause significant differences in the decision boundaries between backdoor and backdoor-free models. The client-end backdoor mitigation methods can exploit the gap and thus effectively eliminate the backdoor poisoning effect. On the other hand, the gradient and loss alignment optimization adopted in *PFedBA* brings the decision boundary of the backdoor model as close as possible to that of the backdoor-free model. Therefore, *NC* and *NAD* cannot distinguish the backdoor model from the backdoor-free models, allowing *PFedBA* to bypass these client-end defense mechanisms.

Table 4: ACC/ASR against PFL with server-end defenses on CIFAR-10.(%) Standard Deviation Range: 0.5%-5%.

(4) Ablation Study of PFedBA. *PFedBA* optimizes the trigger through both gradient alignment and loss alignment to enhance its attack effectiveness against PFL systems. As detailed in Section 4.1, the parameter λ determines the method of trigger optimization. In *PFedBA*, we consider only two cases for λ: $\lambda = 0$ or $\lambda = 1$, representing gradient alignment or loss alignment for trigger optimization, respectively. In this section, we evaluate the effectiveness of both alignment modules utilized in *PFedBA* on CIFAR-10 and Fashion-MNIST. Due to space limitations, we show the results on Fashion-MNIST and CIFAR-10 in Tables 8 and 9 in Appendix C.

By observing the results, we find that both gradient alignment and loss alignment modules are necessary to ensure the success of *PFedBA*. Removing any of these modules significantly decreases the ASR value of *PFedBA*. For example, on Fashion-MNIST, *PFedBA* achieves ASR values exceeding 87% against *DnC* and *FLAME* under *FedRep*. In contrast, the variant of *PFedBA* without gradient alignment (referred to as No-Gradient) yields an ASR value of less than 27%. Besides, on Fashion-MNIST, *PFedBA* attains ASR values over 89% against *Multi-Krum* and *DnC* under *Per-Fedavg(HF)*. However, the variant of *PFedBA* without loss alignment (referred to as No-Loss) fails to conduct a successful attack, with ASR values below 11%. Similarly, on CIFAR-10, the absence of any alignment module reduces the ASR values of *PFedBA*, especially under *pFedMe* and *FedRep*. These results underline the necessity of both the gradient alignment and loss alignment modules in the *PFedBA* attack framework.

In summary, *PFedBA* consistently and effectively injects backdoor triggers into personalized local models across various PFL scenarios. Optimizing triggers to align the backdoor task with the main task is crucial for successful backdoor attacks against PFL systems.

(5) Impact of Personalized FL Parameters. We study the impact of several parameters in PFL on *PFedBA*, such as the degree of non-IID data distribution, the percentage of malicious clients, the total number of clients, the trigger size, and the target class.

Impact of the Degree of Non-IID Data Distribution. Figure 2 illustrates the impact of varying degrees of non-IID data distribution on the attack performance of *PFedBA* against PFL on CIFAR-10 and Fashion-MNIST. Smaller α values indicate a higher degree of non-IIDness in the data distribution. We find that *PFedBA* can obtain high ASR values under different degrees of non-IID data distribution. For instance, on both datasets, the ASR values of *PFedBA* against all the PFL algorithms with varying degrees of non-IID data distribution are above 80%. Furthermore, even though the server deploys multiple defense methods, our attack is still able to successfully embed backdoor triggers into the personalized local model, achieving ASR values above 70% across all the 10 PFL algorithms under different non-IID data distributions on both two datasets. These results indicate that *PFedBA* raises challenges to the PFL system with different non-IID data distributions.

Impact of the Percentage of Malicious Clients. Figure 3 depicts the change in ASR of *PFedBA* as the percentage of

malicious clients increases from 5% to 20% on CIFAR-10 and Fashion-MNIST. We observe that *PFedBA* can successfully execute backdoor attacks with just a small fraction of malicious clients. On both the Fashion-MNIST and CIFAR-10 datasets, even with only 5% of malicious clients, *PFedBA* can achieve an ASR value of over 70%, regardless of whether the server deploys defensive measures. These results illustrate that *PFedBA* can maintain strong attack performance even with a limited number of malicious clients.

Impact of the Total Number of Clients. Figure 4 in Appendix D shows the *PFedBA*'s ASR changes as the total number of clients ranges from 50 to 200 on N-BaIoT and Fashion-MNIST, with 10% of clients being malicious. The results demonstrate that *PFedBA* achieves ASR values exceeding 70% across 10 PFL algorithms, regardless of the total number of clients or the presence of the defense mechanisms on the server. More details are available in Appendix D.

Impact of the Trigger Size. In Appendix E, Figure 5 illustrates the attack performance of *PFedBA* using various trigger sizes on the CIFAR-10 and N-BaIoT datasets. The results indicate that the *PFedBA* attack consistently achieves ASR values exceeding 70% across all the 10 PFL algorithms, regardless of the trigger sizes used by adversaries. Further details are provided in Appendix E.

Impact of the Target Class. Figure 6 in Appendix F shows the attack performance of *PFedBA* on the CIFAR-10 and N-BaIoT datasets with different target classes. The results demonstrate that *PFedBA* consistently achieves ASR values above 80% across various target classes on 10 PFL algorithms. For further details, please refer to Appendix F.

6 Takeaways

As revealed in our study, we can summarize the vulnerability of PFL facing backdoor attacks from two perspectives:

Compared to conventional FL, PFL gains more resilience to backdoor attacks by the personalization process and defense methods deployed on both the central server and local clients. First, the personalized local model forgets the knowledge of triggers during the personalization process by learning information from clean local datasets. Second, defense methods employed at the central server can minimize the impact of malicious local model updates on the global model during the global aggregation stage. Finally, backdoor mitigation methods deployed on benign clients can eliminate the presence of backdoor triggers in the personalized local model. Consequently, the integration of the personalization process and defense mechanisms enhances PFL's resilience to backdoor attacks.

Aligning the backdoor task with the main task is the key-to-success in embedding the triggers into the personalized local models in PFL. Despite the strong resilience of PFL against backdoor attacks, we can still carry out successful and stealthy backdoor attacks by enforcing the loss alignment and the gradient alignment between the main task and the backdoor task. On the one hand, enforcing both alignments can decrease the expected backdoor classification loss in the local model of benign clients during the personalization process, thus preventing the personalized local model from forgetting the embedded backdoor triggers. On the other hand, aligning the main task and the backdoor task narrows the gap between

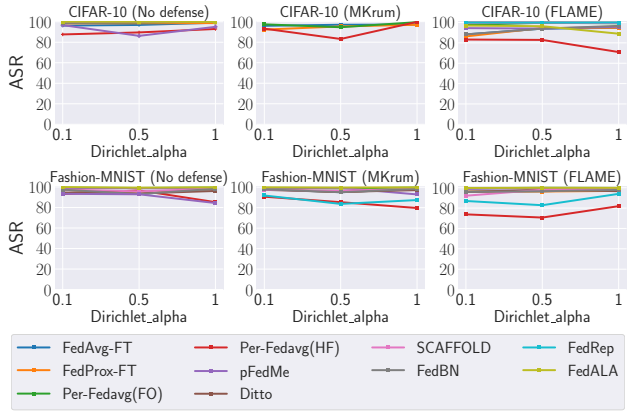

Figure 2: ASR for PFedBA against 10 PFL algorithms with the various degrees of non-IID data distribution on CIFAR-10 and Fashion-MNIST.

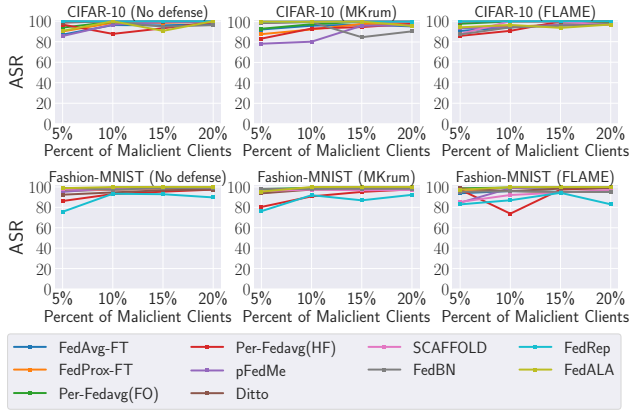

Figure 3: ASR for PFedBA against 10 PFL algorithms with various percentages of malicious clients on CIFAR-10 and Fashion-MNIST.

the decision boundary of the backdoor model and that of the backdoor-free model. This alignment enables the adversary to circumvent the defense methods implemented on the server or local clients and embed the backdoor into the personalized local model. This backdoor attack raises a severe security concern regarding model integrity in practical PFL applications. Therefore, we appeal to the security community to devise mitigation strategies that can effectively counter these risks.

7 Conclusion

This study presents a comprehensive analysis of the threat posed by backdoor attacks on the PFL system. Our findings illustrate that the PFL system can mitigate the backdoor poisoning effect by using its unique personalization process. Additionally, deploying defense mechanisms on both the central server and local clients can further enhance the PFL system's resistance to backdoor attacks. Nonetheless, we introduce a new backdoor attack method called *PFedBA*, which utilizes the alignment of loss and gradient between the main learning task and the backdoor learning task to highlight the vulnerabilities of robust-enhanced PFL systems. Our extensive experiments demonstrate that *PFedBA* can effectively inject backdoor triggers into personalized local models, circumventing defense methods within the PFL system. The effectiveness of raises more significant concerns about the PFL system's integrity than previously anticipated. In future work, our aim is to develop a defense method inspired by the concept of randomized smoothing. This method will adaptively optimize the magnitude of added noise to mitigate backdoor poisoning effects while preserving the performance of the main task to the greatest extent possible.

Appendix A The PFL System Settings

In this work, we focus on the following 10 PFL algorithms: *FedAvg-FT* [38], *FedProx-FT* [24], *SCAFFOLD* [19], *Per-Fedavg(FO)* [14], *Per-Fedavg(HF)* [14], *pFedMe* [11], *Ditto* [23], *FedBN* [25], *FedRep* [10], and *FedALA* [45]. For all datasets, we assume a total of $N = 100$ clients in the PFL system. In each global aggregation iteration, the central server randomly selects $N_p = 10$ clients to participate in the global aggregation. During the personalization stage, for *FedAvg-FT*, *FedProx-FT*, *Per-FedAvg(FO)*, and *Per-FedAvg(HF)*, we adapt the global model generated by these methods with 1 epoch (Fashion-MNIST and N-BaIoT) or 5 epochs (CIFAR-10 and CIFAR-100) of stochastic gradient descent using the local training data to produce personalized local models. For the rest 6 PFL methods, we create personalized local models for clients based on the hyperparameters suggested by the original research papers.

Additionally, for CIFAR-100 and CIFAR-10, the local learning rate is set to 0.1 for all the PFL algorithms. For Fashion-MNIST and N-BaIoT, the local learning rate is set to 0.1 for all the PFL algorithms except *Per-FedAvg(FO)*, *Per-FedAvg(HF)*, and *pFedMe*, for which the local learning rate is set to 0.01. The batch size is consistently set at 64 for all datasets, except for N-BaIoT, where a batch size of 128 is employed. For N-BaIoT, Fashion-MNIST, CIFAR-10, and CIFAR-100, the total number of global training iterations is set to 100, 150, 200, and 300, respectively. We summarize the settings in Table 6.

Appendix B Server-end Defenses on CIFAR-100

Table 7 displays the ACC and ASR values for various backdoor attack methods against the 10 PFL methods equipped with distinct defense mechanisms implemented at the central

Table 7: ACC/ASR against PFL with server-end defenses on CIFAR-100.(%) Standard Deviation Range: 0.6%-4.6%.

server on CIFAR-100. The results demonstrate the superior attack performance of *PFedBA*. On the CIFAR-100 dataset, for *pFedMe* with diverse defense mechanisms, *PFedBA* achieves ASR values exceeding 97%, which are at least 22% higher than the ASR values of the other baseline attack methods. Our gradient and loss alignment-based *PFedBA* method can successfully embed backdoor triggers into personalized local models, which is difficult for the other attack baseline methods.

Appendix C Ablation Study of PFedBA on CIFAR-10

The results in Tables 8 and 9 show the sensitivity of the *PFedBA*'s attack performance with respect to different alignment terms on Fashion-MNIST and CIFAR-10. The results validate the indispensability of both gradient alignment and loss alignment modules within the *PFedBA* attack framework.

Appendix D Impact of the Total Number of Clients

Figure 4 depicts the change of *PFedBA*'s ASR as the total number of clients varies from 50 to 200 on the N-BaIoT and Fashion-MNIST datasets, with 10% of clients being malicious. The results indicate that the attack performance of *PFedBA* remains consistent even when the number of clients increases.

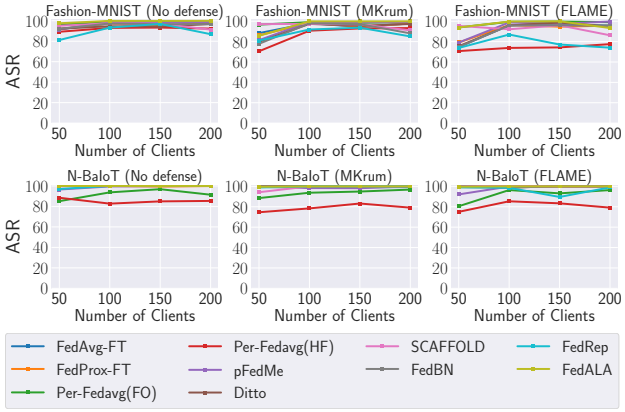

Figure 4: ASR for PFedBA against 10 PFL algorithms with the various total numbers of clients on N-BaIoT and Fashion-MNIST.

Appendix E Impact of the Trigger Size

Figure 5 illustrates the variation in ASR values for *PFedBA* across different trigger sizes in the N-BaIoT and CIFAR-10 datasets. The results consistently show that *PFedBA* achieves ASR values exceeding 70% across all 10 PFL algorithms in both datasets, irrespective of the trigger size. This confirms the effectiveness of *PFedBA*.

Abstract

In *Federated Learning (FL)*, a set of clients collaboratively train a machine learning model (called *global model*) without sharing their local training data. The local training data of clients is typically non-i.i.d. and heterogeneous, resulting in varying contributions from individual clients to the final performance of the global model. In response, many contribution evaluation methods were proposed, where the server could evaluate the contribution made by each client and incentivize the high-contributing clients to sustain their long-term participation in FL. Existing studies mainly focus on developing new metrics or algorithms to better measure the contribution of each client. However, the security of contribution evaluation methods of FL operating in adversarial environments is largely unexplored. In this paper, we propose the *first* model poisoning attack on contribution evaluation methods in FL, termed ACE. Specifically, we show that any malicious client utilizing ACE could manipulate the parameters of its local model such that it is evaluated to have a high contribution by the server, even when its local training data is indeed of low quality. We perform both *theoretical* analysis and *empirical* evaluations of ACE. Theoretically, we show our design of ACE can effectively boost the malicious client's perceived contribution when the server employs the widely-used cosine distance metric to measure contribution. Empirically, our results show ACE effectively and efficiently deceive five state-of-the-art contribution evaluation methods. In addition, ACE preserves the accuracy of the final global models on testing inputs. We also explore six countermeasures to defend ACE. Our results show they are inadequate to thwart ACE, highlighting the urgent need for new defenses to safeguard the contribution evaluation methods in FL.

1 Introduction

Federated learning (FL) [35] enables a set of clients to collaboratively train a machine learning model, denoted as the *global model*, using their local training data in an iterative manner. At each communication round, a cloud server first broadcasts the current global model to the clients. Each client then adopts the global model as its local model, locally minimizes an empirical loss function (e.g., cross-entropy function) over its local training data to compute a *local model update*, and finally sends the local model update to the server. The server aggregates the local model updates from the clients according to an aggregation rule (e.g., FedAvg [35]) to update the current global model. FL has been widely deployed in real-world cross-silo settings where data is spread across multiple isolated organizations [33, 44].

In practice, the local training data possessed by the clients in FL is non-i.i.d. and heterogeneous [30, 49, 69], and thus inherently of varying qualities. Therefore, it is crucial to understand and evaluate the contribution of each client toward the performance (e.g., accuracy on testing inputs) of the global model. Accurate contribution evaluation facilitates the designs of incentive mechanisms to encourage the clients, especially those owning high-quality data, to participate into FL [13, 18, 60], which could further enhance the performance of the global model. To this end, contribution evaluation methods in FL has been extensively studied [46]. The existing studies [13, 18, 32, 51, 54, 60, 67] primarily focus on the development of novel metrics or algorithms to measure the contributions of clients in FL. At present, however, the security of contribution evaluation methods in FL remains largely unexplored.

Our Contribution. In this paper, we propose the *first* model poisoning attack on contribution evaluation methods in FL. We term this attack as ACE. We consider that an attacker owns a subset of clients in FL, denoted as malicious clients. These malicious clients are evaluated as low-contributing participants by the server. Specifically, the malicious clients manipulate the parameters of their local models, with the objective of elevating their contributions evaluated by the server. Accomplishing this attack goal can result in monetary advantages for the attacker when contribution-based incentive mechanisms are employed in FL. For example, the FL server may distribute a certain amount of budget to the clients in propor-

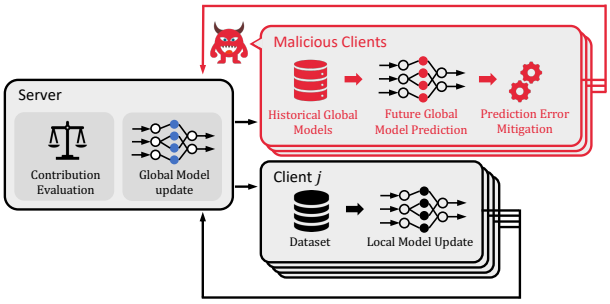

Figure 1: An illustration of ACE consisting of two components: future global model prediction and prediction error mitigation.

tion to their individual contributions in order to encourage clients with high contributions to remain in the FL [38]. The attack studied in this paper can boost the contributions of malicious clients, and thus increase their shares of the budget. This lowers the shares available to the other clients, thereby jeopardizing their interests.

We highlight that the attack goal of ACE is significantly different from existing attacks in FL, including untargeted poisoning attacks [8, 14, 43] and backdoor attacks [1, 2, 52, 56, 68]. In particular, existing untargeted poisoning attacks and backdoor attacks aim to make the global model exhibit low performance for indiscriminate testing inputs or predict an attacker-chosen target class for any inputs embedded with a backdoor trigger [23]. By contrast, ACE aims to deceive the contribution evaluation method employed by the server to increase the contributions of malicious clients (with low-quality local training data). Our empirical studies demonstrate that ACE retains the performance of the global models in different settings. We defer the detailed discussion on the difference to Section 8.

A major challenge in developing ACE is how the malicious clients should strategically manipulate the parameters of malicious clients' local models to increase the perceived contribution by the server. Our insight to address this challenge is that the FL procedure provides the malicious clients information on the global model as shown in Figure 1, allowing the malicious client to predict how the global model evolves over communication rounds. Therefore, the malicious clients can craft local model updates to better align with the prediction of the global model, making them more likely to be perceived by the server as having higher contributions. ACE uses the Cauchy mean value theorem [27] to predict the global model at each communication round. We show that predicting the global model significantly reduces the computation complexity for the malicious clients compared to iteratively learning local model updates from the local training datasets, allowing ACE to boost the perceived contributions at negligible cost.

We *theoretically* analyze the effectiveness of ACE when the server measures contributions using cosine distance. We prove that ACE allows the malicious clients to always increase the perceived contribution by appropriately scaling up the predicted global model. We further *empirically* evaluate the effectiveness and efficiency of ACE using five state-of-the-art contribution evaluation methods in FL [34, 54, 59, 60, 67]. We compare ACE with four baselines using three models across three datasets including MNIST [12], CIFAR-10 [26], and Tiny-ImageNet [28]. We show that ACE consistently outperforms all baselines when the local training data of clients is non-i.i.d., yielding the highest perceived contribution by the FL server. This demonstrates the severity of ACE on contribution evaluation methods in FL. We evaluate ACE against countermeasures including extended Multi-Krum [3] and Trimmed-Mean [63], which have been widely used in FL. Our empirical evaluations demonstrate that these countermeasures are not effective against ACE. These results underscore the need for the development of new defenses to thwart ACE.

To summarize, this paper makes the following major contributions:

- We propose the first model poisoning attack on contribution evaluation methods in FL, termed as ACE.
- We present theoretical analysis and perform extensive empirical evaluations of ACE to demonstrate its effectiveness and efficiency.
- We investigate the countermeasures to mitigate ACE. We show that ACE can remain stealthy against the existing mitigation strategies, highlighting the needs for new defense mechanisms.

2 Background and Related Work

In this section, we present background on federated learning and contribution evaluation methods in FL.

2.1 Federated Learning

We consider an FL setting where N clients collaboratively train a machine learning model, called *global model*. Let $\mathcal{D}_i$ represent the local training dataset of the i-th client and $|\mathcal{D}_i|$ denote its size, where $i = 1, 2, \cdots, N$. We denote the set of clients as Γ, and thus the joint training dataset can be represented as $\mathcal{D} = \cup_{i\in\Gamma}\mathcal{D}_i$. To learn the global model, the set of clients collaboratively minimizes a loss function over their local training datasets as follows:

$$\min_{\mathbf{w}} \sum_{i\in\Gamma} L(\mathcal{D}_i; \mathbf{w}),$$

where $\mathbf{w}$ represents the parameters of the global model and $L(\mathcal{D}_i; \mathbf{w})$ is the empirical loss (e.g., cross-entropy loss) evaluated using the global model with parameters $\mathbf{w}$ on the local training dataset $\mathcal{D}_i$. The clients iteratively solve the optimization problem through multiple communication rounds with

an FL server. Specifically, there are three steps at each communication round t, which are detailed below.

Step I. The server broadcasts the current global model, denoted as $\mathbf{w}^t$, to the clients.

Step II. For each client i, it first uses the global model $\mathbf{w}^t$ to initialize its local model, and then uses the local training dataset $\mathcal{D}_i$ to update its local model by minimizing the empirical loss function L, i.e., $\mathbf{w}_i^{t+1} = \mathbf{w}^t - \eta_i \nabla L(\mathcal{D}_i; \mathbf{w}^t)$, where η_i is the learning rate and $\nabla L(\mathcal{D}_i; \mathbf{w}^t) = \frac{\partial L(\mathcal{D}_i; \mathbf{w}^t)}{\partial \mathbf{w}^t}$. Finally, it sends the *local model update* $\mathbf{g}_i^t = \mathbf{w}^t - \mathbf{w}_i^{t+1}$ back to the server. Note that it is equivalent for the client to send the local model update or local model due to the above relationship.

Step III. The server aggregates the local model updates from the clients, and updates the global model of the $(t+1)$-th communication round as $\mathbf{w}^{t+1} \leftarrow \mathbf{w}^t - \mathbf{g}^t$, where $\mathbf{g}^t = \mathcal{A}(\mathbf{g}_1^t, \mathbf{g}_2^t, \cdots, \mathbf{g}_N^t)$ is the global model update at communication round t and $\mathcal{A}$ is an aggregation rule. A typical example of $\mathcal{A}$ is FedAvg [35], defined as $\mathcal{A}(\mathbf{g}_1^t, \mathbf{g}_2^t, \cdots, \mathbf{g}_N^t) = \sum_{i \in \Gamma} \frac{|\mathcal{D}_i|}{|\mathcal{D}|} \mathbf{g}_i^t$.

2.2 Contribution Evaluation Methods in FL

Contribution evaluation in FL aims to quantify the *contribution* made by each client to the performance (e.g., accuracy on testing inputs) of the global model. Following previous studies [32, 46], we divide the existing contribution evaluation methods in FL into three categories: *self-reporting based contribution evaluation* [64, 65], *individual performance based contribution evaluation* [11, 18, 25, 34, 47, 59, 60], and *game theory based contribution evaluation* [19, 24, 32, 51, 53, 54, 67].

Self-Reporting based Contribution Evaluation. The methods in this category utilize the information reported by each client to measure its contribution. For instance, Zeng et al. [65] propose to use self-reported local data size and communication bandwidth to evaluate the contribution. Yu et al. [64] proposed to use the data quantity and quality (e.g., measured by the marginal revenue generated by the global model) reported by each client to measure its contribution. Since those methods heavily rely on self-reported information, they are susceptible to malicious clients who can untruthfully report their information to the server.

Individual Performance based Contribution Evaluation. This category of methods proposes some performance metrics defined on the local model updates of clients to measure their contributions. Some studies [11, 34] assume the server has a clean validation dataset in order to calculate the proposed performance metrics. For instance, Lyu et al. [34] evaluate the contribution of a client at each communication round using the validation accuracy of its local model on the validation dataset of the server. Chen et al. [11] propose to quantify the contribution of a client at each individual communication round by computing the mutual cross-entropy loss between the local model of the client and the global model on the validation dataset. However, these methods assume the server has a clean, small validation dataset, which has been shown to be impractical [42]. When the server does not have any validation data, existing studies propose to utilize the distance (e.g., cosine distance [25, 47, 59, 60] and Euclidean distance [18]) between the global model and the local model of a client to measure its contribution at each communication round. The key assumption is that a client whose local model is more similar to the aggregated global model makes more contribution to it. Therefore, the contribution of a client is smaller if the distance becomes larger.

Game Theory based Contribution Evaluation. This category of methods formulates the FL as a cooperative game, where all clients collaboratively learn a global model using their local training data. Then the aggregated contribution of the clients is represented by the utility of the game (e.g., accuracy [32] or empirical loss [51, 67] of the global model on testing inputs), and the contribution of each individual client is modeled by its payoff received in this game.

Wang et al. [51] propose to quantify the contribution (averaged over all communication rounds) of each client in FL using its marginal loss, which is defined as the utility difference when the client joins the game as opposed to not joining the game. Similarly, Zhang et al. [67] measure the contributions of clients at each communication round using their marginal performance loss evaluated on a held-out validation dataset. However, these methods are sensitive to the order in which the clients join the game, and may not yield consistent results for contribution evaluation when the order changes.

To eliminate the effect from the order of joining the FL, Shapley value (SV) is adopted to measure the contribution of each client under the cooperative game framework [19, 24]. Wang et al. [54] propose the federated SV (FedSV) to quantify the contribution of each client at each communication round, which retains the key features of the traditional SV without introducing additional communication costs. However, computing SVs is generally computationally expensive. Consequently, numerous efforts have been made to reduce the computation complexity of SV [32, 53].

3 Problem Formulation

In this section, we characterize the threat model by presenting the capabilities, background knowledge, and goals of an attacker. We then formally formulate the model poisoning attack on contribution evaluation methods in FL. We finally describe the design goals of the attack.

3.1 Threat Model

Attacker's capabilities and background knowledge. We consider an attacker owns a set of clients, referred to as *malicious clients*. As a result, the attacker could (1) access the

local training datasets of malicious clients and the global model sent by the server, (2) control the training processes of local models of malicious clients, and (3) manipulate the parameters of the malicious clients' local models before sending the local model updates to the server. However, the attacker lacks the necessary background knowledge (e.g., local training datasets) of all other clients and the capabilities to manipulate parameters in other clients' local models. Moreover, we assume the attacker knows the contribution evaluation method employed by the server. This assumption is realistic in practice since the server normally shares such information with all clients for transparency and trustworthiness purposes during the initiation of the FL system [14, 35]. However, we consider that the attacker does not know the hyperparameters of the contribution evaluation method and thus does not know the contributions of malicious clients computed by the server in each communication round. For example, the server may use a validation dataset to evaluate the local model of a client, and use the validation accuracy as the contribution of the client, which is not broadcast to the clients [34, 54]. We also assume that the attacker possesses some storage capacity to retain the global models broadcast by the server in the previous m (e.g., $m = 3$) communication rounds.

Attacker's goal. Suppose the server employs a contribution evaluation method (as reviewed in Section 2) to quantify the contribution of each client. We consider that the goal of the attacker is to elevate the malicious clients' contributions computed by the server, compared to truthfully sending the local model updates learned using their local training data to the server. By accomplishing the attack goal, the attacker can get extra rewards from the existing incentive mechanisms deployed in FL [13, 34], even though it holds low-quality local training data. For instance, in a cross-silo FL system where multiple banks collaborate to jointly learn a global model for commercial purposes [33], if the profit earned using the global model is distributed among the banks based on their contributions, the bank launching `ACE` can gain extra profit while reducing the shares of others. Such malicious behavior further discourages the long-term participation of banks possessing high-quality training data and undermines the fairness of the federated learning system.

3.2 A Model Poisoning Attack on Contribution Evaluation Methods in FL

In what follows, we formally formulate the model poisoning attack on contribution evaluation methods in FL. We denote the set of malicious clients as $\hat{\Gamma}$. For each malicious client $i \in \hat{\Gamma}$, we use $\mathbf{g}_i^t$ to denote the local model update learned using the local training data without attacks. Moreover, we denote the manipulated parameters of the local model update from client i at communication round t as $\hat{\mathbf{g}}_i^t$. We use $\mathcal{E}$ to denote the contribution evaluation method deployed by the server, where $\mathcal{E}(\mathbf{g}_i^t)$ (or $\mathcal{E}(\hat{\mathbf{g}}_i^t)$) denotes the contribution calculated by the server when the client i sends the local model update $\mathbf{g}_i^t$ (or $\hat{\mathbf{g}}_i^t$) to the server. The goal of the attacker is to craft $\hat{\mathbf{g}}_i^t$ for each malicious client $i \in \hat{\Gamma}$ such that the accumulated contribution $\sum_{i\in\hat{\Gamma}} \mathcal{E}(\hat{\mathbf{g}}_i^t)$ (or equivalently $\sum_{i\in\hat{\Gamma}}(\mathcal{E}(\hat{\mathbf{g}}_i^t) - \mathcal{E}(\mathbf{g}_i^t))$) is maximized. We call such an attack *model poisoning attack on contribution evaluation methods in FL*. Formally, we formulate the attack as the following optimization problem in the t-th communication round:

$$\{\hat{\mathbf{g}}_i^t | i \in \hat{\Gamma}\} = \underset{\{\mathbf{g}_i | i\in\hat{\Gamma}\}}{\operatorname{argmax}} \sum_{i\in\hat{\Gamma}} \mathcal{E}(\mathbf{g}_i). \tag{1}$$

3.3 Design Goals

We aim to design a model poisoning attack on contribution evaluation methods in FL. In particular, we aim to accomplish the following goals in our attack design:

Effective. Our first goal is that the attack should be effective, i.e., it could significantly increase the contributions of malicious clients calculated by the server, compared to the scenario without attacks (i.e., the malicious clients learn their local model updates using the local training datasets).

Efficient. Our second goal is that the attack should be efficient, i.e., it should incur small computation and communication costs, compared to the baseline when there is no attack. The reason for incorporating efficiency into the design goals is that clients in FL are often resource-constrained, e.g., mobile phones and IoT devices [35, 37].

Performance Preserving. We note that the attacker's goal is not to disrupt the convergence or performance of the final global model learned from FL. Thus, we aim to design an attack that preserves the performance of the final global model. As a result, the malicious clients, who own low-quality local training data, could obtain a global model with comparable performance to the one learned without attacks.

Aggregation Rule Independent. We note that many aggregation rules [3, 35, 60, 63] have been proposed to aggregate local models in FL. We aim to design an attack that is agnostic to the aggregation rules such that our attack is generalizable to a wide range of FL systems.

4 Description of `ACE`

4.1 Overview of `ACE`

A key challenge in solving the optimization problem in Eq. (1) is that an attacker does not know $\mathcal{E}(\hat{\mathbf{g}}_i^t)$ for an arbitrary local model update $\hat{\mathbf{g}}_i^t$. The reason is that the attacker lacks necessary information such as the local models of other clients or validation dataset of the server that is utilized to calculate contribution (see Section 2.2 for details). To address the challenge, our key insight is that a client is more likely to have a high contribution if its local model is more similar to the aggregated global model in each communication round. The

reason is that the aggregated global model is obtained from local models learned on local training datasets of all clients, including those whose local training data is considered more valuable by the server. Based on this insight, we propose ACE, a poisoning attack on contribution evaluation methods in FL.

ACE consists of two components: *future global model prediction* and *prediction error mitigation*. The future global model prediction component aims to predict the global model in each communication round based on the historic global models (i.e., the global models in previous communication rounds) received by the attacker. We note that the attacker could incur certain prediction errors and they would accumulate over communication rounds, resulting in low contributions for the malicious clients. In response, we further propose two strategies to mitigate the impact of errors in our prediction error mitigation component. We further discuss how ACE can improve the attack effectiveness on certain contribution evaluation methods. Finally, we analyze both the time and space complexities of ACE. Our analysis shows ACE incurs negligible computation and storage costs. The reason is that it is very efficient to predict the future global model and ACE only requires saving a few snapshots of historic global models.

4.2 Detailed Design of ACE

We first describe the *future global model prediction* component, followed by the *prediction error mitigation* component. Then, we discuss how to adapt ACE to further enhance the effectiveness of our attack.

4.2.1 Future Global Model Prediction

In what follows, we describe how the malicious clients predict the global model update. Note that given the predicted global model update, the predicted global model could be obtained by adding the predicted global model update and the current global model together.

Predicting the Global Model Updates using the Cauchy Mean Value Theorem. We use $\hat{\mathbf{g}}^t$ to denote the predicted global model update at communication round t. According to the Cauchy mean value theorem [27], the *predicted global model update* $\hat{\mathbf{g}}^t$ at communication round t is calculated as

$$\hat{\mathbf{g}}^t = \mathbf{g}^{t-1} + H^t(\mathbf{w}^t - \mathbf{w}^{t-1}), \tag{2}$$

where $\mathbf{g}^{t-1}$ is the global model update in the communication round $t-1$, $\mathbf{w}^t$ (or $\mathbf{w}^{t-1}$) is the global model at communication round t (or $t-1$), and $H^t = \int_0^1 H(\mathbf{w}^{t-1} + z(\mathbf{w}^t - \mathbf{w}^{t-1}))dz$ is an *integrated Hessian matrix*. Based on Eq. (2), predicting the global model update only requires the current and previous global models, the integrated Hessian matrix, and the previous global model update. Although each malicious client has background knowledge on the previous global model update, previous global model, and current global model, computing the integrated Hessian matrix, however, is computationally expensive. In light of this, we utilize the L-BFGS algorithm [4, 5], which is widely used to approximate the integrated Hessian matrix.

Approximating the Integrated Hessian Matrix via the L-BFGS Algorithm. We approximate the integrated Hessian matrix H^t using the L-BFGS algorithm [4, 5], as outlined in Algorithm 1 in Appendix B. The L-BFGS algorithm takes two buffers $\Delta\mathbf{W}^t = [\Delta\mathbf{w}^{t-m}, \Delta\mathbf{w}^{t-m+1}, \cdots, \Delta\mathbf{w}^{t-1}]$ and $\Delta\mathbf{G}^t = [\Delta\mathbf{g}^{t-m}, \Delta\mathbf{g}^{t-m+1}, \cdots, \Delta\mathbf{g}^{t-1}]$ as inputs, and approximates the integrated Hessian matrix, where $\Delta\mathbf{w}^t = \mathbf{w}^t - \mathbf{w}^{t-1}$ is the change in the global model and $\Delta\mathbf{g}^t = \mathbf{g}^t - \mathbf{g}^{t-1}$ is the change in global model update. In practical implementation [5], the L-BFGS algorithm consumes an additional vector $\mathbf{v}$ of appropriate dimension as an input, and returns a product $H^t\mathbf{v}$, termed *Hessian-vector product*, as the output. This is sufficient for the malicious clients to predict the global model update since Eq. (2) only requires a Hessian-vector product $H^t(\mathbf{w}^t - \mathbf{w}^{t-1})$ to predict the global model update $\hat{\mathbf{g}}^t$. In the remainder of this paper, we represent the L-BFGS algorithm as $\text{L-BFGS}(\Delta\mathbf{W}^t, \Delta\mathbf{G}^t, \mathbf{v})$. We note that the L-BFGS algorithm is employed by the server to estimate clients' local models, as countermeasures against model poisoning attacks in FL in existing studies [9, 66]. This paper, however, considers scenarios where malicious clients use the L-BFGS algorithm to estimate the global model, thereby elevating their contribution evaluated by the server.

4.2.2 Prediction Error Mitigation

Insufficiency of Future Global Model Prediction. We remark that it is inadequate for the malicious clients to only predict the global model update. The reason is that the L-BFGS algorithm may incur large prediction errors, i.e., the deviation between the predicted global model update and its true value, at some communication rounds. As we will demonstrate in Section 6, the prediction error results in low contribution evaluated by the server for the malicious clients. We identify two major reasons for prediction errors. The first issue arises because the L-BFGS algorithm requires historical information from past global models and their updates to construct buffers $\Delta\mathbf{W}^t$ and $\Delta\mathbf{G}^t$. To compensate for the absence of this historical information, we adopt a strategy used in previous studies [9, 20], *preliminary iteration*, during the initial communication rounds, where malicious clients either learn from their local datasets or use the previous round's global model updates as proxies for their current local updates. In the meantime, the malicious clients collect the global models and global model updates to construct the buffers $\Delta\mathbf{W}^t$ and $\Delta\mathbf{G}^t$. After that, the malicious clients proceed with the L-BFGS algorithm as discussed in Section 4.2.1. The second reason for prediction errors is the potential accumulation of errors over successive communication rounds. To address this, we develop a *threshold-based filtering* strategy to mitigate the impact of error accumulation.

Threshold based Filtering. As the L-BFGS algorithm cannot predict the exact global model update, it is unavoidable that there would be prediction errors. Moreover, those errors could accumulate over communication rounds, which could lower the contributions of the malicious clients. We note that the malicious clients may not be aware when a large prediction error occurs since it does not have access to the true global model update for the future communication rounds, and thus cannot calculate the prediction errors. To tackle this challenge, we develop a threshold based filtering strategy to estimate whether the predicted global model update incurs a large prediction error. Our intuition is that the prediction error is more likely to be larger if the magnitude of the Hessian-vector product is larger. Therefore, if the ℓ_2-norm of the Hessian-vector product is less than a threshold, i.e.,

$$\|\text{L-BFGS}(\Delta\mathbf{W}^t, \Delta\mathbf{G}^t, \mathbf{w}^t - \mathbf{w}^{t-1})\| \leq \tau, \tag{3}$$

where $\|\cdot\|$ represents ℓ_2-norm and τ is a threshold (we defer the detailed discussion on it), we consider that the prediction error is tolerable, and thus the malicious clients use the predicted global model update as their local model updates. Otherwise, each malicious client calculate its local model update by using its local training dataset or utilizing the global model update from the previous communication round.

A key question in our design is how to set the threshold. Our idea is that the magnitude of the predicted global model update should be on a similar scale as the previous global model updates. Thus, we set the threshold τ as $l\|\mathbf{w}^t - \mathbf{w}^{t-1}\|$, where l is a positive coefficient that can be tuned by each malicious client to control its tolerance on prediction errors. Our experimental results show that $l = 1$ is sufficient to mitigate prediction errors.

4.2.3 Strategies to Enhance ACE

In this subsection, we discuss how to adapt ACE to further enhance its effectiveness when certain a contribution evaluation method is employed by the server.

Adaptation to Contribution Evaluation Methods using Cosine Distance. In the following, we discuss how to adapt ACE when the server uses the cosine distance between the local model and global model to measure each client's contribution. This class of methods is widely used in existing studies [25, 47, 59, 60] since cosine distance is efficient to calculate. In this case, we can rewrite the optimization in Eq. (1) as the following equivalent formulation:

$$\{\hat{\mathbf{g}}_i^t | i \in \hat{\Gamma}\} = \underset{\{\mathbf{g}_i | i \in \hat{\Gamma}\}}{\text{argmax}} \sum_{i \in \hat{\Gamma}} (1 - \cos(\mathbf{g}_i, \mathbf{g}^t)). \tag{4}$$

Here, $\cos(\mathbf{a}, \mathbf{b}) = 1 - \frac{\mathbf{a} \cdot \mathbf{b}}{\|\mathbf{a}\|\|\mathbf{b}\|}$ is the cosine distance function, where $\mathbf{a} \cdot \mathbf{b}$ represents the inner product between vectors $\mathbf{a}$ and $\mathbf{b}$. Global model update $\mathbf{g}^t$ is obtained following the aggregation rule (Step III in Section 2.1).

According to Eq. (4), we note that the malicious clients can enhance the attack effectiveness by sending an amplified prediction of the global model update $c\hat{g}_i^t$ to the server as their local model updates, where $c > 1$ is an amplifying coefficient. The insight is that increasing the magnitude of the predicted global model update will make it more dominant compared with other clients' local model updates. As a result, the angle deviation between the predicted global model update and the aggregated global model update decreases, leading to a smaller cosine distance between them. Furthermore, such dominance effects will accumulate over communication rounds, thereby elevating the malicious clients' contributions perceived by the server. We finally remark that introducing the coefficient c does not lower the accuracy of the global model, which will be demonstrated in Section 6.

Adaptation to Contribution Evaluation Methods with Validation Dataset. Some contribution evaluation methods [11, 34, 51, 54, 67] require the server to have a validation dataset, and use the validation accuracy or loss of local models to measure contributions. In this case, the malicious clients can execute the L-BFGS algorithm multiple times within one communication round. We term this operation as the *local evolution*. The insight behind local evolution is to mimic the normal training process over multiple epochs at one communication round. When the L-BFGS algorithm yields limited prediction error, the local evolution will allow the malicious clients to craft local model updates of higher validation accuracy and hence increase the associated contributions.

4.3 Complete Algorithm

Algorithm 2 in Appendix B shows our complete algorithm for attacking contribution evaluation methods in FL. The attacker can initiate attack at any communication round t. If communication round t is a preliminary iteration, then the malicious clients compute their local model updates by learning from the local training data or sending the previous global model update to the server (see Section 4.2.3). If communication round t is not a preliminary iteration, then the malicious clients leverage the L-BFGS algorithm to predict the next global model update (see Section 4.2.1). Given the predicted global model update, the malicious clients estimate whether the prediction error can be tolerated or not using the threshold based filtering as shown in Eq. (3). If the prediction error is tolerable by the malicious clients (Eq. (3) holds true), then they set the prediction of global model update to be their local model updates which will be sent to the server. Otherwise, the malicious clients compute the local model updates using their local training data or the previous global model update.

4.4 Complexity Analysis

Time Complexity. According to [5], the time complexity to calculate the Hessian-vector product using Algorithm 1

is $O\left(m^3\right)+6mp+p$, where p is the model size and m is the buffer length. If the malicious clients does not launch the attack and learn the local model update using the local training dataset over e epochs, then the time complexity of learning the local model update using the local training dataset $\mathcal{D}_i$ over e epochs is $6|\mathcal{D}_i|eR(p)$, where $R(p)$ is the time complexity for forward propagation [21]. Although the expression of $R(p)$ is architecture dependent, we note that the time complexity of ACE is in general significantly less than that of learning the local model update using local training data [16], achieving the design goal of being efficient in Section 3.3. For instance, when the global model is a CNN (see our report [62] for the detailed architecture), the computation time of ACE using an RTX 6000 Ada GPU is 0.004s per communication round. By contrast, training the same model using the local training dataset of a client takes 1.10s, which is 270× slower compared to ACE.

Space Complexity. The space complexity for each malicious client is $O(mp)$ when it launches ACE. Note that in practice, we typically choose $m=2$ or $m=3$. Therefore, the proposed attack in this paper imposes a small storage constraint on the malicious clients. For instance, when $m=3$ and the architecture of the global model is CNN, our attack only requires 42.43MB of additional storage space.

5 Theoretical Analysis

In this section, we characterize the strategies to enhance the attack effectiveness. Specifically, we focus on the cases where cosine distance is used by the server to measure contributions. All the proofs can be found in Appendix C. The effectiveness of amplifying the predicted global model update with coefficient c is stated as follows.

Proposition 1. *Let* $\mathbf{g}'=\mathcal{A}(\mathbf{g}_1,\cdots,c\hat{\mathbf{g}}_i,\cdots,\mathbf{g}_N)$ *and* $\mathbf{g}=\mathcal{A}(\mathbf{g}_1,\cdots,\hat{\mathbf{g}}_i,\cdots,\mathbf{g}_N)$ *be the global model updates obtained using the predicted global model update* $c\hat{\mathbf{g}}$ *and* $\hat{\mathbf{g}}$*, respectively. When* $c\geq 1$*, we have the following relationship:*

$$\cos(\mathbf{g}',c\hat{\mathbf{g}}_i)\leq\cos(\mathbf{g},\hat{\mathbf{g}}_i). \tag{5}$$

Remark 1. *Proposition 1 shows that the cosine distance between the amplified global model update* $c\mathbf{g}_i$ *and the global model update* $\mathbf{g}'$ *is no larger than the cosine distance before applying the amplification with coefficient* $c\geq 1$*. Therefore, our strategy developed for contribution evaluation using cosine distance will not degrade the attack effectiveness.*

Proposition 1 yields the following corollary.

Corollary 1. *Let* $\mathbf{g}'$ *and* $\mathbf{g}$ *be defined as in Proposition 1. If* $\cos(\mathbf{g},\hat{\mathbf{g}}_i)\leq\cos(\mathbf{g},\mathbf{g}_j)$*, then* $\cos(\mathbf{g}',c\hat{\mathbf{g}}_i)\leq\cos(\mathbf{g}',\mathbf{g}_j)$*.*

Remark 2. *Corollary 1 indicates that if a malicious client* i *surpasses the contribution of another client* j *by sending the predicted global model update as its local model update, then amplifying the predicted global model update will not make the contribution of malicious client* i *less than client* j*. Therefore, the malicious client* i *is always perceived as a high-contributing client compared to client* j *(note that a smaller cosine distance means a higher contribution).*

We finally show that the parameter c can be tuned such that the contributions of malicious clients become larger than any arbitrary client.

Proposition 2. *Let* $\mathbf{g}'$ *and* $\mathbf{g}$ *be defined as in Proposition 1. Suppose that* $\cos(\mathbf{g},\hat{\mathbf{g}}_i)>\cos(\mathbf{g},\mathbf{g}_j)$ *holds for some client* j *and malicious client* i*, and* $\mathcal{A}(\mathbf{g}_1,\cdots,\mathbf{g}_N)=\sum_{j\in\Gamma}\alpha_j\mathbf{g}_j$*, where* $\alpha_j\in[0,1]$ *is a weight coefficient and* $\sum_{j\in\Gamma}\alpha_j=1$*. If the malicious client* i *chooses the coefficient* c *such that* $c\geq\frac{\|\hat{\mathbf{g}}_i\|\mathbf{g}\cdot\mathbf{g}_j-\|\mathbf{g}_j\|\mathbf{g}\cdot\hat{\mathbf{g}}_i}{\alpha_i\|\hat{\mathbf{g}}_i\|(\|\mathbf{g}_j\|\|\hat{\mathbf{g}}_i\|-\hat{\mathbf{g}}_i\cdot\mathbf{g}_j)}+1$*, then* $\cos(\mathbf{g}',c\hat{\mathbf{g}}_i)\leq\cos(\mathbf{g}',\mathbf{g}_j)$*.*

Remark 3. *Proposition 2 focuses on servers that utilize linear combinations as the aggregation rule, which are widely used in practice [3, 35, 60, 63]. Proposition 2 shows that even if the predicted global model may not be sufficient for a malicious client* i *to surpass the contribution of another client* j*, choosing a proper coefficient* c *allows the malicious client* i *to make a higher contribution (evaluated by the server) compared to client* j*.*

6 Empirical Evaluations

We perform extensive experiments to evaluate ACE. In Section 6.1, we show the experimental setup. Section 6.2 presents the results. Ablation analysis is presented in Section 6.3.

6.1 Experimental Setup

Datasets and Models. We consider three benchmark datasets MNIST [12], CIFAR-10 [26], and Tiny-ImageNet [28]. Specifically, MNIST is a 10-class digit image classification dataset, which contains 60,000 training images and 10,000 testing images of dimension 28×28 in grayscale. CIFAR-10 is a 10-class dataset with 50,000 training images and 10,000 testing images uniformly distributed across the classes, where the size of each image is $32\times 32\times 3$. Tiny-ImageNet is a color image classification dataset covering 200 classes, with 100,000 training images, 10,000 validation images, and 10,000 testing images. Each image in Tiny-ImageNet is of dimension $64\times 64\times 3$. We use two Convolution Neural Network (CNN) variants on MNIST and CIFAR-10 datasets respectively, and a pre-trained VGG11 model [48] on Tiny-ImageNet. Details can be found in our report [62].

Data Partition. For each dataset, we consider one homogeneous data partition (denoted as UNI) and two heterogeneous data partitions (denoted as POW and CLA) among clients by following previous studies on contribution evaluation methods in FL [34, 59, 60]. The heterogeneous data partitions yield non-i.i.d. data distributions, as detailed below.

- **UNI**: This data partition uniformly splits the training images in each dataset among all clients, yielding an i.i.d. data distribution among the clients.
- **POW**: Following [34, 59, 60], the sizes of local training datasets of all clients are sampled from a parameterized power law distribution. We set the parameter of power law distribution as two. This leads to a data-size heterogeneous setting among the clients. For example, on MNIST, the numbers of training images of 10 clients are 110, 219, 328, 437, 546, 655, 764, 873, 982, and 1,086, respectively. The details for the power law distribution can be found in our report [62].
- **CLA**: Following [34, 59, 60], we use CLA to create a class imbalance setting where the local training datasets of different clients cover heterogeneous numbers of classes. For example, on MINST, the local training datasets of 10 clients contain training images from 6, 6, 7, 7, 8, 8, 9, 9, 10, and 10 classes, respectively. We show the details in our report [62].

FL Setup. By default, we assume there are $N = 10$ clients. Note that we set $N = 10$ since some contribution evaluation methods calculate the Shapley value to measure contributions, whose computation cost grows exponentially as the number of clients increases. As some contribution evaluation methods require the server to have a validation dataset to compute contributions, we reserve 20% of the data samples from the training images of MNIST, CIFAR-10, and Tiny ImageNet as the validation dataset. Each client uses stochastic gradient descent (SGD) to update its local model for ε epochs with a batch size of 128. We set $\varepsilon = 3$ for MNIST and CIFAR-10, and $\varepsilon = 5$ for Tiny-ImageNet, considering that the classification tasks on MNIST and CIFAR-10 are easier than that on Tiny-ImageNet. Following previous studies [30, 56, 69], we set the learning rate η as 0.03 for MNIST, 0.05 for CIFAR-10, and 0.001 for Tiny-ImageNet, with the learning rate exponentially decaying at rate $\gamma = 0.995$. The total number of communication rounds is $T = 60$.

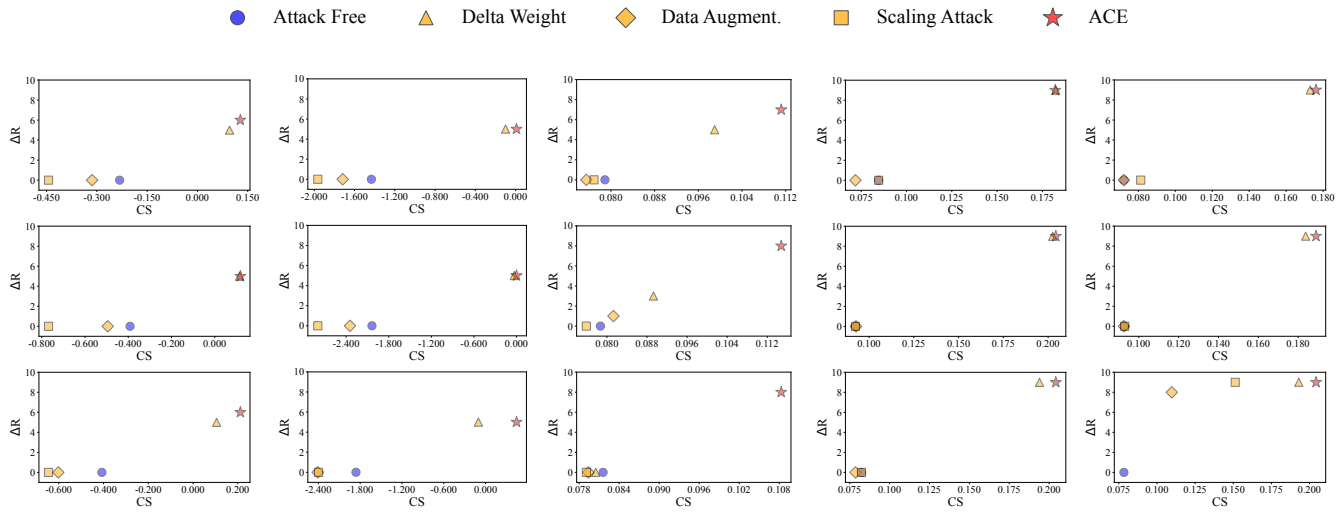
Evaluation Metrics. We define the following two metrics to demonstrate the effectiveness of ACE. The first metric is called *contribution score*, which measures the fraction of contribution from each individual client. Formally, the contribution score for the client i is computed as follows:

$$CS_i = \frac{\sum_{t=1}^{T} e_i^t}{\sum_{j\in\Gamma}\sum_{t=1}^{T} e_j^t}, \tag{6}$$

where Γ is the set of all clients and e_i^t (or e_j^t) is the contribution computed by the server using a contribution evaluation method for the client i (or j) in the t-th communication round.

We note that elevation in the contribution scores does not necessarily imply that the malicious clients' contributions can surpass those of other clients. Therefore, we propose the second metric named *rank gain* to measure the change in the ranks of a client's contribution score with and without attacks. Formally, the rank gain for the client i is computed as follows:

$$\Delta R_i = \widehat{R}_i - R_i, \tag{7}$$



where $\widehat{R}_i$ and R_i represent the ranking (in ascending order) of the contribution score of the client i among all clients with and without attack, respectively. An attack is more effective when CS_i and ΔR_i are larger for a malicious client i.

We use *ACC* to measure the performance preserving property of ACE. In particular, ACC measures the classification accuracy of the final global model on testing inputs. Additionally, we will compare the computation cost of ACE with the attack free setting (i.e., a malicious client uses its local training dataset to learn a local model update) to demonstrate the efficiency of ACE.

Compared Baselines. We note that there are no existing studies on attacking contribution evaluation methods in FL. In response, we generalize several existing methods as baselines [1, 31, 61]. First, we consider the scenario where the malicious clients do not launch any attack and follow the procedure outlined in Section 2.1 to learn their local model updates (denoted as *Attack Free*). In addition to Attack Free, we compare ACE with the following three baselines [1, 31, 61]:

- **Delta Weight**: In this baseline [31], the malicious client i crafts local model updates as $\mathbf{g}_i^t = \mathbf{w}^{t-1} - \mathbf{w}^t + \delta$, where $\mathbf{w}^{t-1} - \mathbf{w}^t$ is the global model update in the previous communication round and each entry of δ follows a zero-mean Gaussian distribution with a standard deviation $\sigma = 5 \times 10^{-5}$.
- **Data Augment**: This baseline utilizes data augmentation to increase the sizes of local training datasets of the malicious clients. In particular, each malicious client randomly rotates, scales, and crops the data samples from its local training dataset to form a new dataset, and then merges the newly generated dataset with the original one. At each communication round, each malicious client learns its local model update using the augmented dataset, aiming to increase its contribution [61].
- **Scaling Attack**: In this baseline, each malicious client first learns a local model update using its local training dataset. Then the magnitudes of these local model updates are amplified using a scaling attack [1]. In our experiments, the scaling factor is set to 2.

Contribution Evaluation Methods. We consider five state-of-the-art contribution evaluations that can be employed by the server, including **FedSV** [54], **LOO** [54, 67], **CFFL** [34], **GDR** [60], and **RFFL** [59]. Specifically, FedSV and LOO are game theory based methods, whereas CFFL, GDR, and RFFL are individual performance based methods.

(a) FedSV (b) LOO (c) CFFL (d) GDR (e) RFFL

Figure 2: Comparing the contribution score *CS* and rank gain ΔR of the attacker when using ACE and baselines under three datasets, i.e., MNIST (first row), CIFAR-10 (second row), and Tiny-ImageNet (third row), and five contribution evaluation methods, i.e., FedSV, LOO, CFFL, GDR, and RFFL. The data partition method is CLA (a heterogeneous setting). Our results show ACE is more effective than baselines. The results for data partition POW are in Figure 3 of Appendix A.

ACE Setup. By default, we consider a single malicious client. We note that when a client has a high contribution even if there is no attack, it is very challenging to improve the ranking of its contribution score. In response, by default, we select a client whose contribution is the lowest without attacks as the malicious client. Unless otherwise mentioned, the buffer length is set to $m = 3$, the threshold is chosen as $l = 1$ to mitigate prediction error, and the tunable amplifying coefficient is set as $c = 1$. When the server employs contribution evaluation methods using cosine distance (GDR and RFFL) and validation datasets (FedSV, LOO, and CFFL), we set the local evolution rounds to one and two, respectively. During the preliminary iteration and when the L-BFGS algorithm incurs a large prediction error, the malicious client executes the delta weight attack (using the global model update in the previous communication round with Gaussian noise). In Section 6.3, we perform ablation analysis and evaluate alternative strategies when the L-BFGS incurs a large prediction error.

6.2 Experimental Results

We evaluate ACE using the metrics in Section 6.1. When the context is clear, we drop the subscript i for the attacker.

ACE is Effective and Aggregation Rule Independent. Figure 2 and 3 (in Appendix A) compare the contribution score and rank again of the malicious client when using ACE and baselines. We have the following key observations. First, the contribution score and rank gain of ACE consistently outperform those of all baselines. For example, when the server employs CFFL [34] as the contribution evaluation method and the data partition is CLA, the malicious client is perceived with contribution score 0.108 and rank gain 8 by the server for the classification task on Tiny-ImageNet dataset. This moves the malicious client from being the lowest-contributing to becoming the second highest-contributing client. All the baselines in this case, however, give rank gain zero, indicating that the malicious client is still evaluated as the lowest-contributing client by the server under those baseline attacks. Our second observation is that under non-i.i.d. data distribution, some baselines yield the same rank gain as ACE, e.g., when the server employs RFFL and the data partition is CLA. However, we note that the malicious client attains the highest contribution score using ACE in these scenarios. Therefore, ACE is more effective compared with all baselines under non-i.i.d. data distributions.

We note that ACE is effective across all contribution evaluation methods in Figure 2, which utilize different aggregation rules. This indicates that ACE is independent of the aggregation rules used in FL.

ACE Preserves the Performance. We show the accuracy on testing inputs of the final global model in Table 1. We observe that the accuracy of the final global model under ACE remains within a negligible 1% deviation from highest ACC in the worst-case. Therefore, ACE preserves the performance of the final global model learned in FL. Note that ACE can potentially lead to the higher ACC under some contribution evaluation methods than Attack Free, e.g., FedSV, CFFL, and GDR. The reason is that ACE replaces the malicious clients' original local model updates (that should have been learned from their low-quality local training data) with the predicted global model

Table 1: This table summarizes the ACC of the final global model learned with ACE and all baselines, evaluated under three data partitions (UNI, POW, and CLA), three datasets (MNIST, CIFAR-10, and Tiny ImageNet), and five contribution evaluation methods (FedSV, LOO, CFFL, GDR, and RFFL). The accuracy of the final global model under ACE remains within a negligible 1% deviation from highest ACC in the worst-case. Thus ACE preserves the accuracy of the final global model.

Contribute Evaluation	Attack	MNIST UNI	MNIST POW	MNIST CLA	CIFAR-10 UNI	CIFAR-10 POW	CIFAR-10 CLA	Tiny-ImageNet UNI	Tiny-ImageNet POW	Tiny-ImageNet CLA

	ACE	96.64%	96.87%	92.30%	70.72%	70.90%	57.36%	51.75%	52.31%	46.54%

Table 2: This table shows the ratio between the computation costs of using a local training dataset to learn a local model update and ACE. The data partition method is UNI. We observe that ACE is significantly more efficient.

Dataset	FedSV	LOO	CFFL	GDR	RFFL
MNIST	30.88×	30.88×	7.48×	16.15×	18.26×
CIFAR-10	270.81×	270.81×	21.25×	86.48×	101.44×
Tiny-ImageNet	35.35×	35.35×	13.26×	29.22×	24.79×

update which integrates updates from other clients learned using local training data of higher qualities.

ACE is Efficient. We compare the computation cost of ACE with Attack Free (when the malicious client utilizes its local training dataset to learn a local model update). Table 2 shows the ratio between the computation cost of learning a local model update using a local training dataset and ACE, i.e., (computation cost of learning a local model update)/(computation cost of ACE). Our key observation is that ACE is significantly more efficient than learning a local model update using the local training dataset. The reason is that it is very efficient to predict the future global model. Note that ACE does not incur extra communication cost since the malicious client simply replaces its local model update with the predicted global model update.

6.3 Ablation Analysis

We perform ablation analysis on the CIFAR-10 dataset under CFFL and RFFL contribution evaluation methods. Here CFFL and RFFL are chosen as the representative contribution evaluation methods for servers with and without validation datasets, respectively.

Effect of the Threshold Based Filtering. We evaluate the effect of the threshold based filtering discussed in Section 4.2.2, which is used when ACE potentially incurs high prediction error. We compare the ACC, CS, ΔR with and without the threshold based filtering in Table 3. We observe that when the data distribution is non-i.i.d. (e.g., POW data partition), the threshold based filtering can significantly improve the attack effectiveness and the accuracy of the final global model (ACC) under CFFL. Hence, the threshold based filtering is necessary to the design of ACE.

Effect of Amplifying Coefficient c. In Table 4, we evaluate the effect of the amplifying coefficient c. We observe that as

Table 3: This table shows the effect of the threshold based filtering. We compare the ACC, *CS*, and ΔR of ACE with and without the threshold based filtering. We observe that solely relying on future global model prediction is not sufficient for attack effectiveness. The prediction error mitigation with threshold based filtering is necessary to guarantee the effectiveness of ACE.

Contri. Eval.	Metric	UNI		POW		CLA	
		with	without	with	without	with	without
CFFL	ACC	70.44%	70.50%	62.03%	56.87%	52.45%	52.51%
	CS	0.1051	0.1049	0.1055	0.0526	0.1148	0.1149
	ΔR	9	9	8	0	8	8
RFFL	ACC	70.72%	70.72%	70.90%	70.90%	57.36%	57.36%
	CS	0.1917	0.1917	0.1963	0.1963	0.1890	0.1890
	ΔR	9	9	9	9	9	9

Table 4: This table presents the effect of amplifying coefficient c when the server employs RFFL as the contribution evaluation method under all data partitions. The contribution score of the malicious client increases as the amplifying coefficient increases. AF is the abbreviation of Attack Free.

Data Partition	Metric	AF	$c = 1$	$c = 1.5$	$c = 2$	$c = 2.5$
UNI	ACC	71.78%	70.72%	70.90%	70.83%	70.59%
	CS	0.096	0.192	0.199	0.205	0.207

we increase the coefficient c, the contribution score of the malicious client increases under all data partitions when the server utilizes cosine distance to measure the contributions (RFFL). This observation aligns with our theoretical analysis in Section 5. Moreover, ACE preserves the ACC under all data partitions with different choices of amplifying coefficient c.

More Experiments. Due to space constraint, we defer the results of the attack effectiveness under POW data partition under all datasets to Figure 3 in Appendix A. We also show experimental results when the attacker does not know the contribution evaluation methods deployed by the server in Appendix A. Additional experimental results on the effects of strategies for preliminary iteration and threshold based filtering, buffer length, local evolution, the fraction of clients selected by the server in each communication round, and the fraction of malicious clients can be found in our report [62]. In summary, our results show that ACE is relatively insensitive to these factors, and is effective in boosting the malicious clients' contributions perceived by the server.

7 Countermeasures to ACE and Evaluations

7.1 Countermeasures to ACE

We focus on defense developed for FL against model poisoning attacks to thwart ACE. According to [45], existing defenses against model poisoning attacks can be divided into three categories: *performance based defense* [7, 10, 29, 58], *distance based defense* [3, 6, 15, 17, 55, 66] and *statistics based defense* [22, 36, 41, 57, 63]. As demonstrated in Section 6, ACE successfully deceives the methods that utilize validation accuracy to measure contribution (e.g., FedSV and LOO), which invalidates the performance based defenses. We thus mainly focus on distance and statistics based defenses. In particular, we choose Multi-Krum [3], Trimmed-Mean [63], FABA [55], Sniper [6], and Foolsgold [17] as representative countermeasures. These defenses do not require a validation dataset in the server and are commonly employed by the community to defend against poisoning and Sybil attacks in FL.

- **Multi-Krum [3].** We choose Multi-Krum [3] from the category of distance based defense as the first countermeasure to ACE, which has been widely used to mitigate model poisoning attacks in FL. Multi-Krum focuses on identifying and eliminating local model updates from malicious clients by analyzing the distance between local model updates from different clients. We extend it to defend against ACE. In particular, the server computes the Euclidean distance between each pair of local model updates at each communication round to measure how similar or dissimilar the local model updates are to each other. The server then considers the k most dissimilar local model updates, i.e., k local model updates that has the largest sum of distance to other local model updates, to be sent by the malicious clients.

- **Trimmed-Mean [63].** We extend Trimmed-mean from the class of statistics based defense as the second countermeasure to ACE. In each communication round, Trimmed-Mean first sorts each dimension of the local model updates from all clients. Subsequently, it identifies the largest k and smallest k entries for each dimension in the sorted local model updates, considering these entries to be potentially sent by malicious clients. Finally, the top k clients that are identified by the server most frequently across all dimensions are considered to be malicious by the server.

- **FABA [55].** We apply FABA [55], an efficient defense algorithm against Byzantine attacks in FL as the third countermeasure. In each communication round, the server first computes the mean of local model updates, and then computes the difference between the mean and each local model update. The server subsequently identifies the local model update with the largest difference from the mean as malicious.

- **Sniper [6].** We consider a clustering-based approach, Sniper, to defend against ACE. Sniper clusters benign local model updates by solving a maximum clique problem in each communication round. Specifically, the server first calculates the Euclidean distances between each pair of local model updates, then constructs a graph such that each local model update is a vertex in the graph. An edge exists if the Euclidean distance between two local model updates is smaller than a pre-determined threshold. In the end, the server finds the maximum clique in the graph and identifies vertices (local model updates) in the clique as benign. The remaining local model updates are identified as malicious.
- **Foolsgold [17].** We evaluate ACE against Foolsgold [17], a Sybil detection countermeasure. Foolsgold maintains aggregate historical updates of local model updates from each client to better estimate the similarity of the overall contributions made by clients. Foolsgold detects malicious clients by calculating the pairwise cosine similarity of historical updates as a representation of how strongly two clients are acting similarly. The clients with high pairwise cosine similarity are identified as malicious.
- **Random Guess.** The last countermeasure considered in this paper is Random Guess. In particular, the server randomly selects k local model updates as manipulated by the malicious clients.

We note that k is a hyper-parameter for those countermeasures. We consider a strong defense scenario where the server knows the total number of local model updates (which is used to set k) from the malicious clients.

7.2 Evaluations of Countermeasures to ACE

We empirically evaluate the countermeasures against ACE under our default setting.

Evaluation Metrics. We use three metrics, **precision**, **recall**, and **F1-Score** to evaluate the detection performance of countermeasures when the attacker launches ACE.

- **Precision.** Precision is defined as the fraction of local model updates that are indeed from the malicious clients among all predicted ones.
- **Recall.** Recall is the fraction of local model updates from the malicious clients that are successfully predicted by a countermeasure.
- **F1-Score.** F1-Score measures the harmonic mean of precision and recall, i.e., F1-Score $= 2 \cdot \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}}$.

We note that each defense will detect local model updates from the malicious clients in each communication round. Thus, we report the average precision, recall, and F1-Score overall all communication rounds.

Table 5: This table summarizes the precision, recall, and F1-score when Multi-Krum, Trimmed-Mean, FABA, Sniper, Foolsgold, or Random Guess is employed to mitigate ACE under both i.i.d. (i.e., UNI) and non-i.i.d. (i.e., POW and CLA) data distributions. We observe that none of these countermeasures are effective and adequate to defend ACE. None of these countermeasures are effective and adequate to defend ACEin all data distributions. If Precision and Recall are 0, F1-Score is not defined and denoted as N/A.

Data Partition	Countermeasure	CFFL			RFFL		
		Precision	Recall	F1-Score	Precision	Recall	F1-Score
UNI	Multi-Krum	0.017	0.017	0.017	0.017	0.017	0.017
	Trimmed-Mean	0.017	0.017	0.017	0.017	0.017	0.017
	FABA	0.017	0.017	0.017	0	0	N/A
	Sniper	0.017	0.017	0.017	0	0	N/A
	Foolsgold	0	0	N/A	0	0	N/A
	Random Guess	0.100	0.100	0.100	0.100	0.100	0.100
POW	Multi-Krum	0.017	0.017	0.017	0.017	0.017	0.017
	Trimmed-Mean	0.017	0.017	0.017	0.017	0.017	0.017
	FABA	0.017	0.017	0.017	0.017	0.017	0.017
	Sniper	0.022	0.033	0.027	0	0	N/A
	Foolsgold	0	0	N/A	0	0	N/A
	Random Guess	0.100	0.100	0.100	0.100	0.100	0.100
CLA	Multi-Krum	0.017	0.017	0.017	0.017	0.017	0.017
	Trimmed-Mean	0.017	0.017	0.017	0	0	N/A
	FABA	0.017	0.017	0.017	0.017	0.017	0.017
	Sniper	0.022	0.033	0.026	0	0	N/A
	Foolsgold	0	0	N/A	0	0	N/A
	Random Guess	0.100	0.100	0.100	0.100	0.100	0.100

Evaluation Results. We report the precision, recall, and F1-score when the server utilizes the countermeasures in Section 7.1 to mitigate ACE in Table 5 on CIFAR-10, where the contribution evaluation methods are CFFL and RFFL. For UNI data distribution, we observe that the malicious client is rarely detected by any of these countermeasures, indicating that none of these are effective and adequate to thwart ACE. In particular, the performances of these detection methods are worse than the naive Random Guess. The reason is that the local model updates sent by the malicious client do not significantly diverge from the global model update, leading the server to perceive the malicious client as a benign client. For POW and CLA, two more realistic data partitions, there is only a marginal increase in detection performance. However, the performance remains worse than Random Guess, highlighting the stealthiness of ACE in non-i.i.d. settings. We defer the evaluation results when parameter $c \geq 1$ to Appendix A.

The insights of detecting malicious clients behind Multi-Krum, Trimmed Mean, FABA, Sniper, and Foolsgold can be classified into two categories, whereas neither of these was adequate to detect ACE. The inadequacy of Multi-Krum, Trimmed Mean, FABA, and Sniper can be attributed to their insight that malicious clients likely to send local model updates significantly different from other clients' updates. Foolsgold identifies malicious clients whose local model updates are too similar to others as malicious. However, as discussed in Section 3.2, ACE does not exhibit either excessive similarity or dissimilarity to benign clients, and thus can evade detection by all these countermeasures. This highlights the urgent need to develop new mitigation strategies to defend against ACE.

8 Discussion and Limitation

Untargeted Poisoning and Backdoor Attacks in FL. Attacks against FL have been extensively studied, such as untargeted poisoning attacks [8, 14, 43, 50] and backdoor attacks [1, 2, 52, 56, 68]. For image classification tasks, the final global model of FL learned under untargeted poisoning attacks produces incorrect predictions indiscriminately on the testing inputs, whereas the global model learned under backdoor attacks outputs attacker-chosen class when the inputs are embedded with the attacker-chosen triggers. We note that the untargeted poisoning attacks have a different goal from our attack. Scaling Attack [1] is a state-of-the-art backdoor attack. We extend it to attack contribution evaluation methods in FL. Our experimental results in Section 6 demonstrate that ACE consistently outperforms Scaling Attack. The reason is that backdoor attacks are not designed to improve the contribution of a malicious client.

Defenses against Untargeted Poisoning and Backdoor Attacks in FL. To mitigate these attacks, various defenses have been proposed [3, 7, 9, 17, 36, 39, 40, 42, 63] to identify and remove the local model updates from malicious clients. However, most of these defenses are ineffective to mitigate ACE. The reason is that these existing defenses identify the malicious clients by detecting abnormal local model updates from the clients. For example, FLTrust [7] assigns a trust score to each local model update by comparing its direction with the global model update. As the deviation in the directions between the local model update and the global model increases, the client's trust score decreases, indicating that it is more likely to be malicious. Our design of ACE, however, does not lead to abnormal local model updates. Instead, the manipulated local model updates sent by the malicious clients using ACE tend to be similar to the global model update in order to elevate their contributions. This makes ACE particularly challenging to be detected as shown in Section 7.

Limitation of ACE. One limitation of ACE is how to select the *optimal* parameters and strategies for ACE. Evaluation results in our report [62] show that the effectiveness of ACE is relatively insensitive to these choices under most of the cases with different datasets, data partitions, and contribution evaluation methods. In order to further enhance the attack effectiveness of ACE, a future direction is to explore efficient techniques to compute the optimal parameters and strategies.

9 Conclusion and Future Work

In this paper, we proposed a new model poisoning attack called ACE on contribution evaluation methods in federated learning (FL). We showed that the malicious clients in FL could utilize ACE to predict the future global model update with small errors, and elevate their contributions evaluated by the server in FL. We empirically evaluated ACE using five state-of-the-art contribution evaluation methods with three datasets and three data partition methods. Our results showed that ACE effectively increased the contributions of malicious clients with negligible costs, and it preserved the performance of the final global model learned from FL. We also evaluated ACE against six countermeasures, and showed that none of them can effectively mitigate ACE. An interesting future work is to develop new mitigation strategies against our attack.

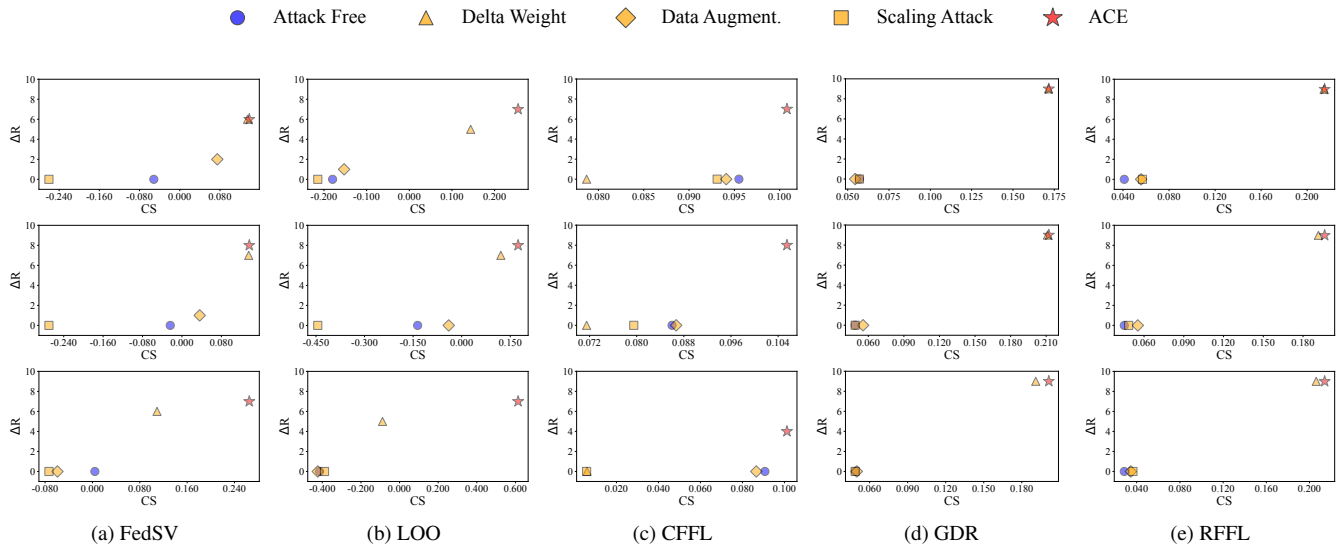
Appendix A Additional Experimental Results



ACE is Effective under POW data partition. We show the contribution score versus the rank gain in Figure 3 under POW data partition. We observe that ACE consistently outperforms all baselines when the data distribution is non-i.i.d..

Effect of Different c on Defense Performances. We present the precision, recall and F1-score when the server utilizes Multi-Krum, Trimmed-Mean, FABA, Sniper, Foolsgold to mitigate ACE in Table 6, where we apply ACE under UNI data partition with RFFL contribution evaluation method employed. We observe that the performance of defense methods do not improve as c increases. This indicates the stealthiness of ACE towards the choice of c.

Experimental Results When the Attacker is Unware of the Contribution Evaluation Methods. In Figure 4, we evaluate the scenario where the attacker does not know the specific contribution evaluation method used by the server. Specifically, the attacker makes a guess on the contribution evaluation method used by the server, which may not necessarily be identical to the method employed. Our results indicate that the client launching ACE can still successfully elevate its contribution evaluated by the server even when it is unaware of the contribution evaluation method.

Table 6: This table shows the effect of values of c on defense performance under UNI data partition. The contribution evaluation method is RFFL. We observe that the defense methods show marginal performance gain as c increases. This indicates the stealthiness of ACE towards the choice of c. If Precision and Recall are 0, F1-Score is not defined and denoted as N/A.

Detection	Metric	$c=1$	$c=1.5$	$c=2$	$c=2.5$
Multi-Krum	Precision	0.017	0.017	0.017	0.017

(a) FedSV (b) LOO (c) CFFL (d) GDR (e) RFFL

Figure 3: Comparing the contribution score *CS* and rank gain ΔR of attacker when using ACE and baselines under three datasets, i.e., MNIST (first row), CIFAR-10 (second row), and Tiny-ImageNet (third row), and five contribution evaluation methods, i.e., FedSV, LOO, CFFL, GDR, and RFFL, with POW data partition. Our results show ACE is more effective than baselines.

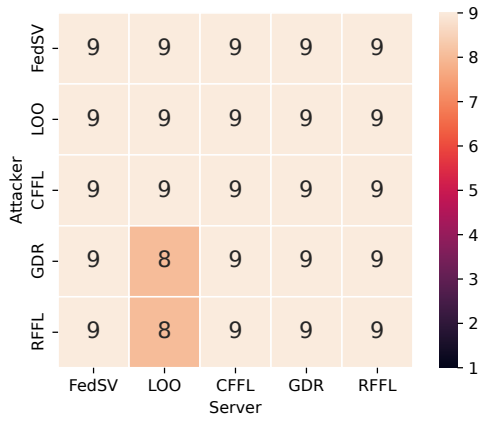

Figure 4: This figure shows the rank gain ΔR when the attacker is unaware of the contribution evaluation method applied by the server. The *y*-axis represents the attacker's guess on the contribution evaluation method used by the server, while the *x*-axis represents the actual contribution evaluation method. We observe that the client launching ACE successfully elevates its contribution evaluated by the server even when it is unaware of the contribution evaluation method.

Appendix B Algorithm Details

We summarize the L-BFGS algorithm in Algorithm 1 and the complete algorithm of ACE in Algorithm 2.

Since the dimension of the integrated Hessian matrix grows quadratically as the size of the global model increases, it is memory demanding for the malicious clients to store the integrated Hessian matrix. To this end, in practical implementation [5], the L-BFGS algorithm consumes an additional vector $\mathbf{v}$ of appropriate dimension as an input, and returns a product $H^t\mathbf{v}$, termed *Hessian-vector product*, as the output. This is sufficient for the malicious clients to predict the global model update since Eq. (2) only requires a Hessian-vector product $H^t(\mathbf{w}^t - \mathbf{w}^{t-1})$ to predict the global model update $\hat{\mathbf{g}}^t$. Then the malicious clients can predict the global model update by replacing the Hessian-vector product in Eq. (2) with the output of the L-BFGS algorithm. Finally, the malicious clients can set their local model updates as the predicted global model update, and send the manipulated local model updates to the server. Note that when there are multiple malicious clients, they can further add a zero-mean Gaussian noise to their local model updates to reduce the probabilities of being detected by the server.

Appendix C Proofs of Section 5

Proof of Proposition 1. Since $\cos(\mathbf{g}', c\cdot\hat{\mathbf{g}}_i) = \cos(\mathbf{g}', \hat{\mathbf{g}}_i)$,

$$\cos(\mathbf{g}, \hat{\mathbf{g}}_i) - \cos(\mathbf{g}', c\cdot\hat{\mathbf{g}}_i) = \cos(\mathbf{g}, \hat{\mathbf{g}}_i) - \cos(\mathbf{g}', \hat{\mathbf{g}}_i)$$
$$= (1 - S_c(\mathbf{g}, \hat{\mathbf{g}}_i)) - (1 - S_c(\mathbf{g}', \hat{\mathbf{g}}_i)) = S_c(\mathbf{g}', \hat{\mathbf{g}}_i) - S_c(\mathbf{g}, \hat{\mathbf{g}}_i)$$

Algorithm 1: L-BFGS Algorithm

Input: $\Delta\mathbf{W} = [\Delta\mathbf{w}_0, \Delta\mathbf{w}_1, \cdots, \Delta\mathbf{w}_{m-1}]$, $\Delta\mathbf{G} = [\Delta\mathbf{g}_0, \Delta\mathbf{g}_1, \cdots, \Delta\mathbf{g}_{m-1}]$, and a vector $\mathbf{v}$.
Output: Approximation of Hessian-vector product $\hat{H}\mathbf{v}$.

$\mathbf{A} = \Delta\mathbf{W}^T\Delta\mathbf{G}$
$\mathbf{D} = \text{diag}(\mathbf{A})$ {Diagonal matrix of $\mathbf{A}$}
$\boldsymbol{L} = \text{tril}(\boldsymbol{A})$ {Lower triangular matrix of $\mathbf{A}$}
$\sigma = \left(\Delta\mathbf{g}_{m-1}^T\Delta\mathbf{w}_{m-1}\right) / \left(\Delta\mathbf{w}_{m-1}^T\Delta\mathbf{w}_{m-1}\right)$
$\mathbf{p} = \begin{bmatrix} -\mathbf{D} & \mathbf{L}^T \\ \mathbf{L} & \sigma\Delta\mathbf{W}^T\Delta\mathbf{W} \end{bmatrix}^{-1} \begin{bmatrix} \Delta\mathbf{G}^T\mathbf{v} \\ \sigma\Delta\mathbf{W}^T\mathbf{v} \end{bmatrix}$
return $\sigma\mathbf{v} - [\Delta\mathbf{G} \quad \sigma\Delta\mathbf{W}]\mathbf{p}$

  end if
end for

$$= \frac{\mathbf{g}' \cdot \hat{\mathbf{g}}_i}{\|\mathbf{g}'\|\|\hat{\mathbf{g}}_i\|} - \frac{\mathbf{g} \cdot \hat{\mathbf{g}}_i}{\|\mathbf{g}\|\|\hat{\mathbf{g}}_i\|} = \frac{\|\mathbf{g}\|\mathbf{g}' \cdot \hat{\mathbf{g}}_i - \|\mathbf{g}'\|\mathbf{g} \cdot \hat{\mathbf{g}}_i}{\|\mathbf{g}'\|\|\mathbf{g}\|\|\hat{\mathbf{g}}_i\|}.$$

We denote by $\mathbf{g}' = \mathbf{g} + (c-1)\alpha_i\hat{\mathbf{g}}_i$. For $\mathbf{g} \cdot \hat{\mathbf{g}}_i \ge 0$, we have:

$$\begin{aligned}
&\cos(\mathbf{g}, \hat{\mathbf{g}}_i) - \cos(\mathbf{g}', c \cdot \hat{\mathbf{g}}_i) \\
&\ge \frac{\|\mathbf{g}\|(\mathbf{g} + (c-1)\alpha_i\hat{\mathbf{g}}_i) \cdot \hat{\mathbf{g}}_i - (\|\mathbf{g}\| + \|(c-1)\alpha_i\hat{\mathbf{g}}_i\|)\mathbf{g} \cdot \hat{\mathbf{g}}_i}{\|\mathbf{g}'\|\|\mathbf{g}\|\|\hat{\mathbf{g}}_i\|} \\
&= \frac{(c-1)\alpha_i\|\mathbf{g}\|\|\hat{\mathbf{g}}_i\|^2 - (c-1)\alpha_i\|\hat{\mathbf{g}}_i\|\mathbf{g} \cdot \hat{\mathbf{g}}_i}{\|\mathbf{g}'\|\|\mathbf{g}\|\|\hat{\mathbf{g}}_i\|} \ge 0.
\end{aligned}$$

The first inequality uses Triangle Inequality, and the second inequality holds because $c > 1$ and $\|\mathbf{g}\|\|\hat{\mathbf{g}}_i\| \ge \|\mathbf{g} \cdot \hat{\mathbf{g}}_i\| \ge \mathbf{g} \cdot \hat{\mathbf{g}}_i$.

Similarly, for $\mathbf{g} \cdot \hat{\mathbf{g}}_i \le 0$, we have:

$$\begin{aligned}
&\cos(\mathbf{g}, \hat{\mathbf{g}}_i) - \cos(\mathbf{g}', c \cdot \hat{\mathbf{g}}_i) = \frac{\|\mathbf{g}\|\mathbf{g}' \cdot \hat{\mathbf{g}}_i - \|\mathbf{g}'\|\mathbf{g} \cdot \hat{\mathbf{g}}_i}{\|\mathbf{g}'\|\|\mathbf{g}\|\|\hat{\mathbf{g}}_i\|} \\
&= \frac{\|\mathbf{g}' - (c-1)\alpha_i\hat{\mathbf{g}}_i\|\mathbf{g} \cdot \hat{\mathbf{g}}_i + (c-1)\alpha_i\|\mathbf{g}\|\|\hat{\mathbf{g}}_i\|^2 - \|\mathbf{g}'\|\mathbf{g} \cdot \hat{\mathbf{g}}_i}{\|\mathbf{g}'\|\|\mathbf{g}\|\|\hat{\mathbf{g}}_i\|} \\
&\ge \frac{(\|\mathbf{g}'\| + \|(c-1)\alpha_i\hat{\mathbf{g}}_i\|)\mathbf{g} \cdot \hat{\mathbf{g}}_i + (c-1)\alpha_i\|\mathbf{g}\|\|\hat{\mathbf{g}}_i\|^2 - \|\mathbf{g}'\|\mathbf{g} \cdot \hat{\mathbf{g}}_i}{\|\mathbf{g}'\|\|\mathbf{g}\|\|\hat{\mathbf{g}}_i\|} \\
&= \frac{(c-1)\alpha_i\|\hat{\mathbf{g}}_i\|\mathbf{g} \cdot \hat{\mathbf{g}}_i + (c-1)\alpha_i\|\mathbf{g}\|\|\hat{\mathbf{g}}_i\|^2}{\|\mathbf{g}'\|\|\mathbf{g}\|\|\hat{\mathbf{g}}_i\|} \ge 0.
\end{aligned}$$

Combining the above two cases, we have:

$$\cos(\mathbf{g}, \hat{\mathbf{g}}_i) - \cos(\mathbf{g}', c\hat{\mathbf{g}}_i) \ge \frac{(c-1)\alpha_i\|\hat{\mathbf{g}}_i\|(\|\mathbf{g}\|\|\hat{\mathbf{g}}_i\| - |\mathbf{g} \cdot \hat{\mathbf{g}}_i|)}{\|\mathbf{g} + (c-1)\alpha_i\hat{\mathbf{g}}_i\|\|\mathbf{g}\|\|\hat{\mathbf{g}}_i\|} \ge 0.$$

Therefore, $\cos(\mathbf{g}', c \cdot \hat{\mathbf{g}}_i) \le \cos(\mathbf{g}, \hat{\mathbf{g}}_i)$.

Proof of Corollary 1. Since $\cos(\mathbf{g}, \hat{\mathbf{g}}_i) \le \cos(\mathbf{g}, \mathbf{g}_j)$, we have:

$$\begin{aligned}
&\cos(\mathbf{g}, \mathbf{g}_j) - \cos(\mathbf{g}, \hat{\mathbf{g}}_i) = S_c(\mathbf{g}, \hat{\mathbf{g}}_i) - S_c(\mathbf{g}, \mathbf{g}_j) \\
&= \frac{\mathbf{g} \cdot \hat{\mathbf{g}}_i}{\|\mathbf{g}\|\|\hat{\mathbf{g}}_i\|} - \frac{\mathbf{g} \cdot \mathbf{g}_j}{\|\mathbf{g}\|\|\mathbf{g}_j\|} = \frac{\|\mathbf{g}_j\|\mathbf{g} \cdot \hat{\mathbf{g}}_i - \|\hat{\mathbf{g}}_i\|\mathbf{g} \cdot \mathbf{g}_j}{\|\mathbf{g}\|\|\hat{\mathbf{g}}_i\|\|\mathbf{g}_j\|} \ge 0.
\end{aligned}$$

Since $\|\mathbf{g}\|\|\hat{\mathbf{g}}_i\|\|\mathbf{g}_j\| \ge 0$, the numerator $\|\mathbf{g}_j\|\mathbf{g} \cdot \hat{\mathbf{g}}_i - \|\hat{\mathbf{g}}_i\|\mathbf{g} \cdot \mathbf{g}_j \ge 0$. Denote $\mathbf{g}' = \mathbf{g} + (c-1)\alpha_i\hat{\mathbf{g}}_i$, we have:

$$\begin{aligned}
&\cos(\mathbf{g}', \mathbf{g}_j) - \cos(\mathbf{g}', c\hat{\mathbf{g}}_i) = \cos(\mathbf{g}', \mathbf{g}_j) - \cos(\mathbf{g}', \hat{\mathbf{g}}_i) \\
&= \frac{\mathbf{g}' \cdot \hat{\mathbf{g}}_i}{\|\mathbf{g}'\|\|\hat{\mathbf{g}}_i\|} - \frac{\mathbf{g}' \cdot \mathbf{g}_j}{\|\mathbf{g}'\|\|\mathbf{g}_j\|} = \frac{\|\mathbf{g}_j\|\mathbf{g}' \cdot \hat{\mathbf{g}}_i - \|\hat{\mathbf{g}}_i\|\mathbf{g}' \cdot \mathbf{g}_j}{\|\mathbf{g}'\|\|\hat{\mathbf{g}}_i\|\|\mathbf{g}_j\|} \\
&\ge \frac{(c-1)\alpha_i(\|\mathbf{g}_j\|\hat{\mathbf{g}}_i \cdot \hat{\mathbf{g}}_i - \|\hat{\mathbf{g}}_i\|\hat{\mathbf{g}}_i \cdot \mathbf{g}_j)}{\|\mathbf{g}'\|\|\hat{\mathbf{g}}_i\|\|\mathbf{g}_j\|} \ge 0.
\end{aligned}$$

The inequality holds because $\|\mathbf{g}_j\|\mathbf{g} \cdot \hat{\mathbf{g}}_i - \|\hat{\mathbf{g}}_i\|\mathbf{g} \cdot \mathbf{g}_j \ge 0$. Therefore, we have $\cos(\mathbf{g}', \mathbf{g}_j) \ge \cos(\mathbf{g}', c\hat{\mathbf{g}}_i)$.

Proof of Proposition 2. The definition of cosine distance yields

$$\begin{aligned}
&\cos(\mathbf{g}', \mathbf{g}_j) - \cos(\mathbf{g}', c\hat{\mathbf{g}}_i) = \cos(\mathbf{g}', \mathbf{g}_j) - \cos(\mathbf{g}', \hat{\mathbf{g}}_i) \\
&= \frac{\mathbf{g}' \cdot \hat{\mathbf{g}}_i}{\|\mathbf{g}'\|\|\hat{\mathbf{g}}_i\|} - \frac{\mathbf{g}' \cdot \mathbf{g}_j}{\|\mathbf{g}'\|\|\mathbf{g}_j\|} = \frac{\|\mathbf{g}_j\|\mathbf{g}' \cdot \hat{\mathbf{g}}_i - \|\hat{\mathbf{g}}_i\|\mathbf{g}' \cdot \mathbf{g}_j}{\|\mathbf{g}'\|\|\hat{\mathbf{g}}_i\|\|\mathbf{g}_j\|} \\
&= \frac{\|\mathbf{g}_j\|(\mathbf{g} + (c-1)\alpha_i\hat{\mathbf{g}}_i) \cdot \hat{\mathbf{g}}_i - \|\hat{\mathbf{g}}_i\|(\mathbf{g} + (c-1)\alpha_i\hat{\mathbf{g}}_i) \cdot \mathbf{g}_j}{\|\mathbf{g}'\|\|\hat{\mathbf{g}}_i\|\|\mathbf{g}_j\|} \ge 0.
\end{aligned}$$

Since $\cos(\mathbf{g}, \hat{\mathbf{g}}_i) > \cos(\mathbf{g}, \mathbf{g}_j)$, we have $\|\mathbf{g}_j\|\|\hat{\mathbf{g}}_i\| - \hat{\mathbf{g}}_i \cdot \mathbf{g}_j > 0$, and hence $c \ge \frac{\|\hat{\mathbf{g}}_i\|\mathbf{g} \cdot \mathbf{g}_j - \|\mathbf{g}_j\|\mathbf{g} \cdot \hat{\mathbf{g}}_i}{\alpha_i\|\hat{\mathbf{g}}_i\|(\|\mathbf{g}_j\|\|\hat{\mathbf{g}}_i\| - \hat{\mathbf{g}}_i \cdot \mathbf{g}_j)} + 1$.

BackdoorIndicator: Leveraging OOD Data for Proactive Backdoor Detection in Federated Learning

Abstract

In a federated learning (FL) system, decentralized data owners (clients) could upload their locally trained models to a central server, to jointly train a global model. Malicious clients may plant backdoors into the global model through uploading poisoned local models, causing misclassification to a target class when encountering attacker-defined triggers. Existing backdoor defenses show inconsistent performance under different system and adversarial settings, especially when the malicious updates are made statistically close to the benign ones. In this paper, we first reveal the fact that planting subsequent backdoors with the same target label could significantly help to maintain the accuracy of previously planted backdoors, and then propose a novel proactive backdoor detection mechanism for FL named BackdoorIndicator, which has the server inject indicator tasks into the global model leveraging out-of-distribution (OOD) data, and then utilizing the fact that any backdoor samples are OOD samples with respect to benign samples, the server, who is completely agnostic of the potential backdoor types and target labels, can accurately detect the presence of backdoors in uploaded models, via evaluating the indicator tasks. We perform systematic and extensive empirical studies to demonstrate the consistently superior performance and practicality of BackdoorIndicator over baseline defenses, across a wide range of system and adversarial settings.

1 Introduction

Federated learning (FL) [36] is an emerging collaborative training paradigm, which enables the use of computing resources from multiple data owners to jointly train a global model under the coordination of a center server. For every global round in FL, decentralized clients locally train models using private training data, and then provide the server with these model updates, instead of their raw data, for aggregation to generate the global model for the next round. Despite of respecting participants' privacy, FL systems have shown to be vulnerable to a series of malicious attacks, especially poisoning attacks [2, 3, 12, 15, 16, 40, 57].

Adversaries could participate in the training procedure of FL to upload carefully designed updates to manipulate the global model's performance. Poisoning attacks can be categorized into untargeted attacks [7, 12, 18, 45] and backdoor attacks [2, 3]. While untargeted attackers aim to compromise the overall performance of the global model, backdoor attackers try to have the model misclassify to a particular target label only when encountering predefined triggers. Previous works have successfully planted backdoors in FL models. For instance, Bagdasaryan et *al.* [2] replace the global model with the backdoor model, through uploading a poisoned model whose parameters are scaled up to cancel the effect of benign updates during model aggregation; Wang et *al.* [52] propose to plant edge-case backdoors utilizing data which lives in the tail of the input distribution, to enhance the backdoor's durability and stealth. Compared with untargeted attacks, backdoor attacks are especially destructive due to their stealthy nature, as they do not influence the model behavior when backdoor triggers are not present. This makes effectively defending backdoor injection a challenging problem.

Previous methods to defend against backdoor attacks in FL mainly rely on modification and scrutinisation on the received model updates, and fall into two categories: 1) influence reduction [5, 37, 39, 49, 56] and 2) detection and filtering [4, 14, 38, 41, 43, 46, 53, 58]. Influence reduction based methods generally assume that backdoor updates are the minority compared to benign updates. Thus, the influence of backdoor updates on the global model can be restricted by either constraining the norm of model updates to an agreed bound, or adding a sufficient amount of noise to the global model. These methods can slow down the rate of the backdoor injection. However, a strong attacker who can keep participating in the training procedure, or can control multiple clients in a single global round can still effectively inject the backdoor [49, 57]; Detection and filtering methods build upon the assumption that introducing backdoor tasks makes the uploaded model

*The two authors contributed equally to this work.

different from benign updates in the parameter space. These methods focus on designing mechanisms to identify backdoor updates, based on certain distance metrics evaluated on received model parameters [15,41]. Several methods (e.g., [43]) also try to detect backdoor updates through manually defined fine-grained features. Uploaded models with abnormal values in these features are marked as suspicious, and then ruled out from aggregation.

Table 1: Detection performance of FLAME when the attacker adopts different poisoned learning rates (plrs). The performance is evaluated through true positive rate (TPR), false postive rate (FPR) and backdoor accuracy (BA).

plr	TPR	FPR	BA
0.01	0.0	44.2	83.0
0.025	1.6	44.0	88.1
0.04	38.8	40.1	90.8
0.055	100.0	33.6	13.0

Detecting and suppressing backdoors by purely examining and comparing model parameters may fall short, under certain system settings and adversarial strategies. For instance, for a highly non-IID data distribution, the poisoned update from some backdoor attack with a small learning rate can be even closer to a benign update in parameter space, compared with other benign updates, making it impossible to detect this poisoned update. We empirically demonstrate the insufficiency of the current backdoor defenses through training a CIFAR10 [28] model on an FL system with 100 clients. The dataset is partitioned onto the clients following a non-IID fashion, using Dirichlet sampling [21] with parameter $\alpha = 0.2$. In each global round, 10 clients are randomly selected to contribute to model update. Each benign client locally trains for 2 iterations with a learning rate of 0.05. A vanilla backdoor attacker controlling a single client tries to inject pixel-pattern backdoor [17] into the global model, through locally training the model on the dataset containing backdoor samples. We evaluate the detection performance of FLAME [41], the state-of-the-art (SOTA) FL backdoor defense method, using the metrics of true positive rate (TPR): the ratio between the number of detected backdoor updates and the total number of backdoor updates; false positive rate (FPR): the ratio between the number of incorrectly detected benign updates and the total number of benign updates; and backdoor accuracy (BA). As shown in Table 1, while FLAME successfully detects all backdoor updates when the attacker uses a comparable poisoned learning rate (plr) of 0.055, the TPR decays quickly to 0 as the attacker reduces its learning rate. This leads to a backdoor accuracy of more than 80%, rendering the FLAME defense ineffective. Also, the FPRs across all settings are quite high. We note that the case could be even worse if the attacker plants more stealthy backdoors, e.g., edge-case backdoor [52], and Chameleon [10]. *Considering the inherent limitation of the detection frameworks based on the examination and comparison of model parameters, a new detection paradigm is needed to provide consistent defense performance across different settings of FL training.*

In this work, we first conduct investigation on the effects of multiple backdoors on each other when planted sequentially. We observe that planting subsequent backdoor task with the same target label could help to maintain the persistence of the previously planted backdoors, once the misleading effect caused by batch normalization (BN) statistics shift is eliminated. Motivated by this observation, we propose a proactive backdoor detection method, *BackdoorIndicator*, through utilizing the intrinsic property of backdoor tasks, which is that backdoor samples are out-of-distribution (OOD) samples with respect to benign samples from the target class. Specifically, the server will first prepare an indicator dataset using OOD data. At the beginning of each global round, the server injects an indicator task into the global model based on the indicator dataset, and then broadcasts the global model to selected clients. After receiving model updates from clients, the server checks the accuracy of the indicator task after correcting the BN statistics shift. The server marks those updates, whose indicator accuracy is above some threshold, as suspicious, and rules them out from aggregation.

We provide extensive experimental results on three image datasets EMNIST [9], CIFAR10 and CIFAR100 [28], with three model architectures VGG16 [48], ResNet18, and ResNet34 [19]. We evaluate the performance of BackdoorIndicator under various adversarial scenarios, where the attacker could control either a single or multiple clients, upload different types of backdoors using different training algorithms, and adopt different poisoned learning rates. We also perform experiments for different non-IID degrees of the FL system. We compare with several SOTA detection methods to demonstrate the consistent superiority of BackdoorIndicator. We further explore the influence of several key hyper-parameters on the detection performance of the proposed method, showing that BackdoorIndicator is easy to implement, and does not exert much computation overhead to the FL system.

In summary, our contribution is of three folds: 1) We reveal the effect that subsequently planted backdoors could help to maintain the accuracy of previously planted backdoors, which sheds light on a new paradigm to design backdoor detection methods; 2) We propose a novel proactive backdoor detection mechanism for FL, BackdoorIndicator, through utilizing the intrinsic property of backdoor tasks and leveraging OOD data to identify backdoor updates; 3) We provide extensive empirical results to show that BackdoorIndicator consistently outperforms five SOTA backdoor detection methods across various adversarial and system scenarios.

2 Background

2.1 Federated Averaging

FedAVG [2] is the baseline algorithm for implementing FL systems. Specifically, we assume that each client i holds a local dataset D_i. FedAVG aims to minimize the summation of the local empirical losses $\sum_{i=1}^{K} \mathcal{L}_i(\theta)$ of K participating clients in a decentralized manner, where we denote $\mathcal{L}_i$ as the cross-entropy loss over D_i, and θ as the global model. In each global round t, the server first broadcasts the current global model θ^t to a subset S_t of randomly selected clients. Each selected client then trains the local model θ_i^t based on θ^t through optimizing $\mathcal{L}_i$ over its local dataset D_i, and then sends θ_i^t backdoor to the central server. After receiving all updates from clients, the server then aggregates all updates through $\theta^{t+1} = \frac{1}{|S_t|} \sum_{i \in S_t} \theta_i^t$ to get the global model for the next round. In the rest of the paper, we use FedAVG for FL training.

2.2 Backdoor Training Algorithms in FL

A backdoor attacker could choose different malicious training algorithms to inject the backdoor model. The attacker could simply replace a part of benign samples with constructed backdoor samples, and perform mini-batch stochastic gradient descent on the mixed training data. We denote this method as the vanilla backdoor algorithm. Based on the vanilla method, previous works have proposed more advanced methods to escape from defenses. The attacker could train the backdoor model using projected gradient descent (PGD) [49], where in each iteration the backdoor model is trained and then projected onto an ℓ_2 ball around the model of the previous iteration. This could help to escape from the norm-clipping defense which regularizes the norm of each received model update within a norm bound. The attacker could also adopt Neurotoxin [57] or Chameleon [10] to inject more durable backdoors in FL. To implement Neurotoxin, the attacker first computes gradients over its benign dataset, and identifies the top-k% coordinates of benign gradients that are frequently updated by benign samples; the attacker proceeds to exclude these parameters from backdoor training, through projecting the backdoor model, initially trained in an unconstrained way, onto the bottom-(1-k%) parameters. Chameleon tries to enhance the backdoor durability in FL through utilizing sample relationships. It identifies two types of samples which dominate backdoor persistence in FL, and utilizes contrastive learning to adjust the distance between backdoor samples and these two types of samples in feature space. Without modifying the model architecture, it proceeds to train the classifier of the model while freezing the feature encoder.

Previous studies have also proposed customized backdoor attacks, for attackers who control multiple clients. Specifically, to plant pixel-pattern backdoors in a distributed manner, DBA [54] is designed to decompose the global trigger into separate local patterns, which are then embedded into the datasets of multiple corrupted clients. 3DFed [30] is a recently proposed backdoor attack that achieves SOTA performance against various defense mechanisms. It proposes to camouflage the backdoor model through backdoor training with constrained loss, noise mask, and decoy model. The method first trains the backdoor model through adding a constraining term, which is proportional to the Euclidean distance between the trained backdoor model and the global model, to the loss function. It then adds each backdoor model with some noise to hide features that can be identified by the central server. The sum of these noise masks is zero so that the global model will not be influenced if all backdoor updates are accepted into aggregation. For detection mechanisms which apply dimensionality reduction techniques, e.g., principal component analysis (PCA), 3DFed proposes to upload extra decoy models to fool such mechanisms to select garbage dimensions on which backdoor updates are not separated from benign ones. The hyper-parameters of these three modules can also be dynamically adjusted through acquiring feedback from indicators planted in previous rounds.

2.3 Backdoor Defenses in FL

We proceed to introduce several SOTA backdoor detection mechanisms in the following.

Multi-Krum [4] is a byzantine-robust aggregation protocol which is initially proposed to ensure the convergence of distributed stochastic gradient descent, under untargeted attackers. Specifically, for n participating clients with IID data, Multi-Krum could effectively ensure convergence with f malicious clients in a single round, as long as $2f+2 < n$. For every received model update, the server first identifies $n-f-1$ closest updates in Euclidean distance, and then summarizes them to compute a score. The update with the lowest score is added to the candidate set. The server then iterates to perform selection with the rest of the updates until m updates are selected. The global model for the next round is computed through aggregating the updates from the candidate set.

Deepsight [43] attempts to identify backdoor updates through measuring the fine-grained difference between model updates. It generally assumes that the training data of backdoor models exhibits less heterogeneity than that of benign models. Thus, it proposes several metrics, including Division Differences (DDifs) and Normalized Energy Updates (NEUPs), to reveal the distribution of labels in the used training data. While DDifs measures the difference between the predicted scores of the local and global models, NEUPs analyzes the total magnitude of the updates for the individual neurons of the output layer. After computing these metrics, the method divides all received updates into clusters based on DDifs, NEUPs, and cosine similarity. Subsequently, it marks all updates with considerably low NEUPs as poisoned, and high NEUPs as benign. The method then accepts all updates in the cluster with suf-

ficient amount of benign models. Deepsight also enforces a maximal ℓ_2 norm of all updates and clip them to the agreed bound if necessary. Finally, the final accepted updates are aggregated to the new global model.

Foolsgold [15] assumes that the diversity of the model updates can be utilized to separate malicious updates from benign ones, as benign clients have unique data distributions while attackers share the same objective. Specifically, the method maintains a history of updates from each client, and computes cosine similarity between pair-wise historical updates. Instead of directly ruling out suspicious updates, Foolsgold mitigates attacks through assigning low weight for updates with large cosine similarity with others during aggregation.

RFLBAT [53] assumes that the difference between benign and backdoor updates can be amplified and further identified through dimensionality reduction. The server adopting RFLBAT filters out suspicious updates in two rounds. For the first round, the server performs PCA on all received updates w_i to get dimension-reduced updates w_i'. The server then computes pair-wise Euclidean distance based on w_i', and filters out outliers. For the second round, the server divides these accepted updates into clusters using K-means [1], and selects the optimal cluster based on cosine similarity. The server proceeds to exclude outliers in the optimal cluster using pair-wise Euclidean distance to get finally accepted updates.

FLAME [41] estimates and injects sufficient amount of noise to eliminate backdoors. The amount of noise needed is minimized through dynamically filtering out backdoor updates and restricting update norms. Specifically, the method first carries out model clustering to identify and filter out suspicious updates with large deviation. The accepted updates are then imposed a maximal ℓ_2 norm, and are then clipped to the median of the norm of all accepted updates m. Finally, the server adds a Gaussian noise $\mathcal{N}(0,\sigma^2)$ to each update, where $\sigma = \frac{m}{\varepsilon} \cdot \sqrt{2\ln\frac{1.25}{\delta}}$ for some privacy budgets ε and δ.

2.4 Motivation and Overview of Solution

We highlight that the above FL backdoor detection and removal methods are based on computing some statistics of the uploaded model parameters. This basic approach of examining model statistics makes these methods inherently ineffective, in scenarios where attackers can fabricate backdoor updates that are statistically close or even identical to the benign ones, as demonstrated by our motivating experiments in Introduction. As a major contribution of this work, we propose a fundamentally different principle in designing backdoor defenses in FL, based upon two key observations: 1) all backdoor samples are essentially out-of-distribution (OOD) data to the benign dataset; and 2) subsequently injected backdoors on the same target label (not necessarily the same trigger) can help to maintain the accuracy of the previously injected backdoors. Consequently, we propose a novel FL backdoor defense mechanism BackdoorIndicator, which has the server train the global model on OOD data as an indicator task before sending it to the clients, and detect for any potential backdoor injections via evaluating the indicator task. In contrast to statistical defenses, BackdoorIndicator remains effective across all FL settings and adversarial strategies, as the leveraged observations hold true as long as there is a backdoor attempt, for arbitrary data distributions across clients.

3 BackdoorIndicator

3.1 Threat Model

We begin to formalize the setting through defining the threat model in terms of the goal and capability of both the attacker and the defender.

Attacker's Goal and Capability. The attacker aims to inject backdoors into the FL model by corrupting local clients, making the model misbehave when encountering certain backdoor triggers while leaving other tasks uninfluenced. Once the attacker successfully corrupts a client, it has full control over the client's training and model uploading process. In this paper, we focus on targeted backdoor attackers who aim to make the model misclassify all images with the backdoor trigger into a specific class, denoted as the *target class*. The attacker could begin the poisoning from any global round in a continuous fashion. Notably, we leave it free for the attacker to choose different types of backdoors for injection. We also do not make constraints on the number of participating clients the attacker could corrupt in every global round. As far as we know, our paper assumes the strongest attacker ever among all backdoor detection works, which makes the setting much more realistic and challenging for successful defense.

Defender's Goal and Capability. The defender intends to detect backdoors embedded in uploaded local models through certain defense protocol, and rules out potential malicious models from aggregation. The defender does not have access to either the raw data or the data distribution of local clients, but does have white-box access to models uploaded from participating clients. We assume that the defender has no access to data which is in the same distribution with the raw data of local clients.

3.2 Key Intuition

We illustrate the key intuition behind our proposed defense, through experimentally exploring the effects of multiple backdoors on each other, when planted sequentially. We focus on investigating how the subsequent backdoor task influences those who have been planted in the model.

In the following, we consider a centralized setting where an attacker has white-box access to the training process. Specifically, we assume that the adversary is running an image classification task on CIFAR10 using ResNet18. While training the main task, the adversary tries to *sequentially inject two*

different backdoors, which are the car-with-vertically-striped-walls-in-the-background semantic backdoor [2] as task $\mathcal{A}$, and the pixel-pattern backdoor [17] as task $\mathcal{B}$, into the model. The backdoor poisoning is done by mixing up benign images (x_b, y_b) and backdoor images (x_p, y_p) to construct the malicious training dataset $D_1 = \{\{(x_b, y_b)^i\}_{i=1}^N, \{(x_p, y_p)^j\}_{j=1}^M\}$ with N benign images and M backdoor images. The attacker first injects backdoor $\mathcal{A}$ into the model starting from iteration $t_{\mathcal{A}}$. When the training iteration reaches $t_{\mathcal{B}}$, backdoor $\mathcal{A}$ will not be further injected. Instead, images from backdoor $\mathcal{B}$ will be supplemented to construct malicious training dataset $D_2 = \{\{(x_b, y_b)^i\}_{i=1}^N, \{(x_p^{\mathcal{B}}, y_p^{\mathcal{B}})^j\}_{j=1}^M\}$. Notably, two backdoor tasks share the same target label, i.e., $y_p^{\mathcal{A}} = y_p^{\mathcal{B}}$. To better illustrate the influence of injecting backdoor $\mathcal{B}$ on the backdoor $\mathcal{A}$, we also consider another scenario where backdoor $\mathcal{B}$ will no longer be introduced after iteration $t_{\mathcal{B}}$. The variation of accuracy with training iteration for different tasks is shown in Figure 1. While the accuracy of backdoor $\mathcal{A}$ gradually declines to 0 after the adversary stops poisoning, planting subsequent backdoor $\mathcal{B}$ has marginal effect in maintaining the accuracy of $\mathcal{A}$, compared to stopping injecting $\mathcal{B}$ after iteration $t_{\mathcal{B}}$.

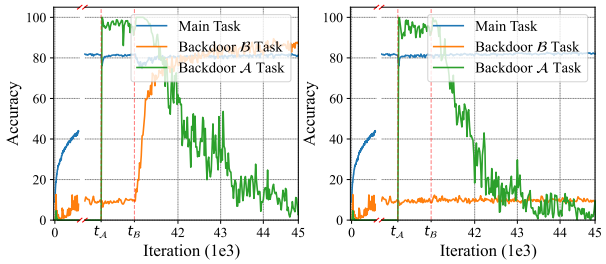

Figure 1: Accuracy of backdoor $\mathcal{A}$ task with (**Left**) and without (**Right**) backdoor $\mathcal{B}$ task involved after iteration $t_{\mathcal{B}}$.

Nevertheless, we find that the maintaining effect shown in Figure 1 is rather misleading due to *batch normalization (BN) statistics shift*. BN [23] is a widely employed technique to facilitate and stabilize model training. During training, for each training batch, the BN layer normalizes the output of the former layer, utilizing the empirical mean and variance computed from the batch. A running average of the mean and the variance across all batches is utilized for normalization during inference. In such a case, due to change of the training data, the estimated mean and variance after iteration $t_{\mathcal{B}}$ gradually deviate from those of task $\mathcal{A}$, and are thus no longer applicable in evaluating the maintaining effect. To overcome such *BN statistics shift*, we save the estimated running mean $\mu_{t_{\mathcal{B}}-1}$ and variance $\sigma_{t_{\mathcal{B}}-1}$ in iteration $t_{\mathcal{B}}-1$, and further replace the estimated BN statistics with $\mu_{t_{\mathcal{B}}-1}$ and $\sigma_{t_{\mathcal{B}}-1}$ in evaluating task $\mathcal{A}$. As it is shown in Figure 2, *planting the subsequent backdoor task with the same target label significantly helps to maintain the accuracy of the previously planted backdoor.* In contrast, the accuracy of backdoor $\mathcal{A}$ task quickly fades when there is no subsequent backdoor injected after iteration $t_{\mathcal{B}}$.[1]

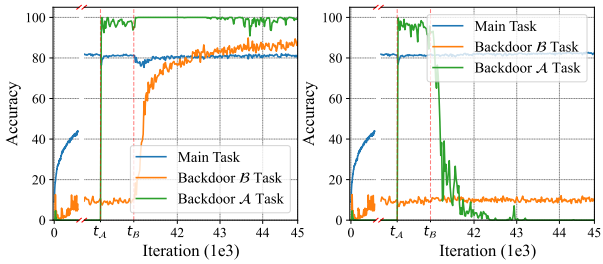

Figure 2: Accuracy of backdoor $\mathcal{A}$ with (**Left**) and without (**Right**) backdoor $\mathcal{B}$ involved after iteration $t_{\mathcal{B}}$. BN statistics are replaced with the estimated statistics in iteration $t_{\mathcal{B}}-1$.

These experimental results reveal the fact that under appropriate evaluation, the persistence of the previously injected backdoor could be tremendously enhanced by the subsequently planted backdoor. The reason behind the maintaining effect touches the intrinsic property of backdoor tasks - **backdoor samples are out-of-distribution (OOD) samples with respect to benign samples from the target class.** Training backdoor tasks generally constructs OOD mappings between backdoor samples and the target class, while keeping the original in-distribution (ID) mappings between benign samples and the target class unaffected. When the adversary stops training backdoor tasks, only ID mappings are introduced and the OOD mappings are gradually erased. In such a case, injecting subsequent backdoor helps to maintain the previous OOD mappings, thanks to the shared OOD characteristics relative to the ID data, even for different backdoor triggers and types, and hence the accuracy of the previously planted backdoor can be preserved.

The above observations motivate us to design a novel backdoor detection mechanism which does not rely on statistical comparison of received updates. The idea is that the server in FL can inject certain "backdoor task", termed as the indicator task, before broadcasting the global model to the clients. The accuracy of the designed indicator task is expected to quickly fade under benign training at the clients, but will be maintained by backdoors injected at adversarial clients. After receiving all uploaded models, the server can then check the accuracy of the indicator task after correcting the BN statistics shift. All updates with high accuracy on the indicator task are considered suspicious and filtered out from aggregation. The major challenge here is that the server, in the FL setting, is completely *agnostic* of the unknown backdoors potentially injected by adversarial clients, and we need to design an indicator task, whose accuracy is well maintained by any unknown backdoors. We achieve this goal by proposing a novel backdoor detection mechanism in FL, BackdoorIndicator, who leverages OOD data to construct the indicator task.

[1] Note that the observations made here are for this particular example to motivate our design, but may not hold for arbitrary backdoor combinations.

We next proceed to describe the details of BackdoorIndicator.

3.3 Detailed Methodology

Algorithm 1: BackdoorIndicator

Input: Indicator Dataset D_o, number of training iterations and learning rate in training the indicator task: E, η, weight of the regularization term λ and suspicious threshold ε_I. set of the selected local client at round t: S_t.
Output: Global model at global round $t+1$: G^{t+1}

```
// Server initialize at global round t
```
The server saves estimated running mean and variance as μ_M and σ_M. $w_{ind} \leftarrow G^t$
for $e = 1, ..., E$ **do**
  The indicator model $w_{ind} = w_{ind} - \eta\nabla(\mathcal{L}_{task}(w_{ind}, D_o) + \lambda||w_{ind} - G^t||_2)$
end
The server saves estimated running mean and variance as μ_I and σ_I.
The server replace the BN statistics in w_{ind} with μ_M and σ_M.
The server broadcasts w_{ind}
```
// Clients perform local training
```
Clients initialize with w_{ind}
for *client* $i \in S_t$ **do**
  for $e_i = 1, ..., E_i$ **do**
    Local model $L_i = L_i - \eta_i\nabla\mathcal{L}_{task}(L_i, D_b^i)$
  end
end
Clients update $\Delta w_i = L_i - w_{ind}$ to the server
```
// Server checks indicator accuracy and aggregates
```
$A \leftarrow []$
for $i \in S_t$ **do**
  $L_i \leftarrow w_{ind} + \Delta w_i$
  $L_i \leftarrow$(replace BN statistics with μ_I and σ_I)
  $\{\alpha_1, \alpha_2, ..., \alpha_N\} \leftarrow$ (check the accuracy of the indicator task on L_i)
  $\alpha_m = max(\{\alpha_1, \alpha_2, ..., \alpha_N\})$
  if $\alpha_m < \varepsilon_I$ **then**
    $A \leftarrow [A; i]$ /* Accept update i */
  end
end
$G^{t+1} = w_{ind} + \frac{1}{|A|}\sum_{i \in A}\Delta w_i$

To implement BackdoorIndicator, the server first needs to prepare some OOD data and corresponding indicator task. In each FL training round, the server starts with saving the BN statistics of the global model from the last round, denoted as μ_M and σ_M. Then the server trains over the OOD data to inject the indicator task, and records the estimated running means μ_I and variances σ_I in BN layers. Afterwards, the server replaces the BN statistics in the trained model with μ_M and σ_M to alleviate any influence of indicator task on the main task performance, and broadcasts the indicator-injected global model to the selected clients.

After the clients finish local training and upload local models back to the server, the server first replaces BN statistics in received models with μ_I and σ_I, and then checks the accuracy of the indicator task. Any received model with the accuracy exceeding certain threshold is considered suspicious and will be ruled out from aggregation. Detailed algorithm is shown in Algorithm 1. We next elaborate details in each step.

Indicator Task Selection. The server faces two crucial challenges when designing the indicator task: the server is agnostic of 1) the types and triggers; and 2) the target labels of potentially injected backdoors.

To tackle the first challenge, the selected indicator task should be effective for all potential backdoors, which means that the OOD mapping introduced by the indicator task should be maintained by any type of injected backdoor. Inspired by the fact that all backdoor samples are essentially OOD samples with respect to the benign samples of the target class, we choose a certain amount of *out-of-distribution* samples, which have distinct real labels with samples from the benign dataset, to construct the indicator dataset. For example, we could sample data from EMNIST dataset or from CIFAR100 dataset to construct the indicator dataset for the training on CIFAR10. Specifically, let (x_b, y_b), (x_o, y_{ro}) be the benign and indicator feature-label pair respectively, where y_{ro} represents the real label of x_o. Also, we denote $\mathcal{Y}_b$, $\mathcal{Y}_{ro}$ as the benign and indicator label space separately. The server should inject the indicator task which satisfies $\mathcal{Y}_b \cap \mathcal{Y}_{ro} = \emptyset$ to achieve decent detection performance. Notably, such indicator data is easy to acquire as it does not require access to the in-distribution data. The server could adopt public datasets, generated samples or simply randomly generated noise masks.

To address the second challenge, while the server does not know the target labels of potential backdoors, it should uniformly sample labels from the benign label space, and assign the label to each of the indicator samples. That is, the construction of the indicator dataset D_0 is done such that

$$D_o = \{(x_o^i, y_o^i)\}_{i=1}^N, \quad y_o^i \sim U(\mathcal{Y}_b). \tag{1}$$

Injecting Indicator Task. At the beginning of every FL global round t, the server first saves the estimated running mean μ_M and running variance σ_M of the global model G^t. The server proceeds to train the indicator task using the constructed indicator dataset, via optimizing the cross-entropy loss $\mathcal{L}_{task}$. To control the influence of injecting the indicator task on the main task, we add a regularization term to punish updates which deviate too much from the original model. Specifically, let w_{ind} be the indicator model, the server minimizes the following loss with respect to D_o.

$$\mathcal{L} = \mathcal{L}_{task} + \lambda||w_{ind} - G^t||_2, \tag{2}$$

where λ denotes the weight of the regularization term. After the server finishes training the indicator task, it records the estimated running mean μ_I and variance σ_I of the indicator model, and then replaces the BN statistics with previously saved μ_M and σ_M. This can help to reduce the influence brought by injecting the indicator task on the main task accuracy, caused by the difference in the data distribution between the indicator dataset and main task dataset. The server then broadcasts the indicator model to selected clients, who then conduct local training using their private datasets, and upload the updated local model back to the server.

Inspecting Indicator Accuracy. After receiving models from clients, the server proceeds to inspect the performance of the indicator task on each model. As the first step, the server replaces BN statistics of each received model with the saved μ_I and σ_I, correcting the BN statistics shift. Next, the server evaluates the accuracies of samples belonging to different labels in the indicator dataset. Specifically, suppose that the main task has $N = \mathcal{Y}_b$ classes, the server computes an accuracy array $Acc = \{\alpha_1, \alpha_2, ..., \alpha_N\}$, where α_i represents the test accuracy of all data samples assigned label i in the indicator dataset D_o. The server then selects the maximum value α_m in Acc, and regards it as the indicator accuracy. If the indicator accuracy α_m of a local model exceeds the suspicious threshold ε_I, the model will be marked as backdoor model and excluded from aggregation. The corresponding label m is considered to be the backdoor target label of the attacked model.

4 Evaluation

In this section, we provide extensive experimental results to demonstrate the effectiveness of BackdoorIndicator, by comparing its backdoor detection performance with several SOTA backdoor detection mechanisms, including Multi-Krum [4], Deepsight [43], Foolsgold [15], RFLBAT [53] and FLAME [41]. Specifically, we consider scenarios where an adversary launches backdoor attacks of different types, using different malicious training algorithms, and starting from different global rounds. We also consider the scenarios where the attacker could train the backdoor model using different poisoned learning rates (plrs), and control either a single client or multiple ones in each global round. We further conduct experiments in FL systems with different non-IID degrees to demonstrate the universal superiority of BackdoorIndicator. Finally, we reveal how several key hyper-parameters influence the detection performance of BackdoorIndicator. Our code is available at https://github.com/ybdai7/Backdoor-indicator-defense.

4.1 Experiment Setup

Our experiment implements an FL system running image classification tasks using FedAVG [36], on a single machine using an NVIDIA GeForce RTX 4090 GPU with 24GB memory. We evaluate the performance of the proposed method on three computer vision datasets: CIFAR10, CIFAR100 [28], and EMNIST [9] with three model architecture: VGG16 [48], ResNet18, and ResNet34 [19]. During the training process, 10 out of total 100 clients are randomly selected to contribute to aggregation in every global round. For all three datasets, we randomly split the dataset over clients in a non-IID fashion utilizing Dirichlet sampling [21]. The sampling parameter α is set to 0.2 by default to represent a challenging setting of severe data heterogeneity. We also evaluate BackdoorIndicator under different non-IID settings.

Evaluation Metric. We evaluate the detection performance through a set of metrics: true positive rate (TPR), false positive rate (FPR), and backdoor accuracy (BA). TPR suggests how well the detection mechanism identifies adversarial backdoors, which is computed as the ratio of correctly identified malicious updates to the total number of malicious updates. FPR indicates how well the detection mechanism discriminates backdoor updates with benign updates. It is computed as the ratio of benign clients who are mistakenly classified as malicious to the total number of benign updates. As the true negative rate (TNR) and false negative rate (FNR) can be computed as 1 minus FPR and TPR respectively, we only show results of TPR and FPR to evaluate different backdoor defenses methods. BA is the accuracy of the backdoor task on the global model when the attacker stops poisoning.

Attack Settings. We validate the defense performance of our proposed method through considering an attacker who aims to inject *different types of backdoor* using *different malicious training algorithms*. Malicious training algorithms and backdoor types are considered as main factors that influence the strength and stealth of the injected backdoor. *Pixel-pattern backdoors* [17] are the most widely evaluated backdoor in FL settings, which overlay fixed pixel-patterns over the original image as the backdoor trigger. The backdoor trigger chosen for *Blendeded backdoors* [6] is randomly generated noise map sampled from uniform distribution, which is mixed up with benign images to construct backdoor samples. While aforementioned backdoors need to modify benign images to construct backdoor images, *semantic backdoors* [2] can be chosen as any naturally occurring feature of the physical world, and do not require the attacker to modify original images. Specifically, we choose the semantic backdoor to be the car-with-vertically-striped-walls-in-the-background [2] in CIFAR10. *Edge-case backdoors* [52] proceed to poison the model using data that lives in the tail of the input distribution. Model updates trained utilizing such data are considered to be less likely to conflict with other benign updates. This results in a more durable backdoor model against the vanishing backdoor effect [10, 57], and also a more stealthy model which can escape from backdoor detection.

As for the malicious training algorithm, an *Vanilla* backdoor attacker first constructs a malicious training dataset

Table 2: Detection performance of all evaluated methods under single client attack with different settings on CIFAR10. The performance is evaluated through the triplet of TPR/FPR(BA). The poisoning lasts for 250 global rounds.

through mixing up backdoor samples with benign samples; the backdoor model is then trained on the constructed dataset through optimizing the cross-entropy loss. *PGD* backdoor attacker, however, trains the backdoor model using projected gradient descent (PGD) [49], which periodically projects the model parameters on a ball centered around the model of the previous iteration, to escape the norm-clipping defense that mitigates the effect from abnormally large updates. We also consider two malicious training algorithms, *Neurotoxin* [57] and *Chameleon* [10], which aim to plant more durable backdoors. While Neurotoxin tries to inject the backdoor using parameters which are not frequently updated by benign clients, Chameleon enhances the backdoor durability through utilizing sample relationships, and trains the backdoor model using supervised contrastive learning [26].

We consider scenarios where the backdoor attacker can choose to either corrupt a single or multiple clients in every global round, and train the backdoor model with different poi-

soned learning rates (plr). We additionally evaluate two more malicious training algorithms, *DBA* [54] and *3DFed* [30], designed especially for multiple client attacks. DBA decomposes a global pixel-pattern trigger into separated local patterns, and then embeds them into the dataset of multiple corrupted clients for local poisoning to achieve a more persistent and stealthy backdoor. 3DFed proposes to camouflage backdoor models through three well-designed evasion modules, and dynamically adjust the hyper-parameters through obtaining feedback from previous global round.

Also, we do not impose constraints on the global round at which the attacker initiates poisoning. Specifically, we assume that the attacker may start poisoning from global rounds 400, 800, or 1200, representing distinct training stages of the main task. Once the poisoning begins, the attacker consistently participates and injects backdoor models for a specified number of global rounds, determined according to specific tasks.

Baseline Defenses. We compare with multiple SOTA backdoor detection methods described in Section 2.3, which are Multi-Krum [4], Deepsight [43], Foolsgold [15], RFLBAT [53] and FLAME [41]. Specifically, as Foolsgold assigns weight for different model updates instead of directly ruling out suspicious updates, we choose updates whose assigned weights are smaller than 0.5 to compute the TPR and FPR.

Indicator Settings. To successfully implements BackdoorIndicator, the server needs to sample a certain number of OOD data to construct the indicator dataset. We randomly select samples from CIFAR100 to construct the indicator dataset for CIFAR10 task. While for CIFAR100 and EMNIST task, the indicator dataset is built by samples from CIFAR10. We set the size of the indicator dataset to 800 by default. For detailed hyper-parameter settings, the weight of the regulation term λ in (2) is set to 0.1, and the suspicious threshold is set to 95 for CIFAR10 and EMNIST tasks, and 85 for CIFAR100 tasks. At the beginning of every global round, the server trains the indicator task for 200 iterations. We also vary the source, size of the indicator dataset, and several key hyper-parameters to reveal their influence on the detection performance.

4.2 Detection Performance

Performance under single client attack. Table 2 presents the detection performance of all evaluated methods on CIFAR10 under single client attack with various adversarial settings. Compared with other detection mechanisms, BackdoorIndicator achieves both the lowest backdoor accuracy and the highest TPR under all considered adversarial settings. We can also see that the FPR of BackdoorIndicator is only about the half of the method with the second highest TPR. For vanilla attackers with the intention to inject pixel-pattern backdoors, BackdoorIndicator successfully identifies over 95% of all malicious updates and limits the backdoor accuracy at around 10%. Specifically, for the attacker who starts poisoning at 1200 global rounds, BackdoorIndicator achieves 99.2% TPR and 15.5% BA, and only misclassifies 15.0% of benign updates as backdoor updates. Foolsgold has 44.9% BA and 71.2% TPR, which is the second highest of all evaluated methods. However, to achieve such detection performance, Foolsgold misclassifies over half of the benign updates as backdoor updates, which is three times higher than that of BackdoorIndicator.

Table 3: Detection performance of all evaluated methods on CIFAR100 and EMNIST under single client attack. The malicious training algorithm and the backdoor type are Vanilla and pixel-pattern. The adversary starts poisoning from 1200 global round. The poisoning lasts for 250 global rounds.

methods	CIFAR100	EMNIST
No defense	0.0/0.0 (84.5)	0.0/0.0 (91.8)
Multikrum	0.0/44.3 (87.8)	5.0/43.5 (99.1)
Deepsight	6.4/2.7 (61.3)	19.0/12.8 (51.4)
Foolsgold	0.0/0.0 (84.4)	52.0/46.4 (73.6)
RFLBAT	0.4/9.7 (85.5)	1.0/10.0 (90.4)
FLAME	0.4/44.2 (87.8)	41.0/39.6 (97.6)
Indicator	**85.2**/15.8 (**7.3**)	**99.0**/35.4 (**9.6**)

BackdoorIndicator can effectively detect more stealthy backdoors injected by vanilla adversaries. Specifically, BackdoorIndicator could identify blended backdoors with 83.9% TPR and 7.2% BA, and edge-case backdoors with 73.2% TPR and 12.1% BA. However, Foolsgold can only successfully detect 28.4% and 23.6% of backdoor updates for blended backdoor and edge-case backdoor respectively, resulting 74.3% and 42.4% BA for these two backdoors.

BackdoorIndicator can also successfully identify backdoor updates trained with more advanced algorithms. For PGD attackers who inject pixel-pattern backdoor from 1200 global rounds, BackdoorIndicator filters out 94.0% of all backdoor updates to achieve 12.3% BA, while the largest TPR of the rest methods is 71.6% with 56.2% BA. BackdoorIndicator achieves the best performance for pixel-pattern backdoor updates trained using Neurotoxin and Chameleon from 1200 global rounds, with the TPR/FPR (BA) triplet as 90.0/20.6 (5.2) and 81.6/19.4 (18.0) respectively.

BackdoorIndicator can identify backdoor planted from different training stages. Vanilla attackers can successfully plant blended backdoors against other methods through poisoning model starting from 400 global rounds, which is the early training stage. The highest TPR and the lowest BA for all evaluated methods is 3.6% and 56.2%, compared with BackdoorIndicator which detects 63.6% of backdoor updates and achieves 29.8% BA. Attackers could also adopt more advanced algorithm to increase BA for blended backdoor. Chameleon attackers achieve a BA higher than 75% against other methods. However, they still fail to bypass BackdoorIndicator, which achieve 53.2% TPR and 29.7% BA. These results not only demonstrate the strong capability of

Table 4: Detection performance of all evaluated methods on CIFAR10 under single client attack with different non-IID settings and poisoned learning rate (plr). The malicious training algorithm and the backdoor type are Vanilla and pixel-pattern. The adversary starts poisoning from 1200 global round. The performance is evaluated through the triplet of TPR/FPR (BA). The poisoning lasts for 250 global rounds.

BackdoorIndicator in identifying backdoors, but also suggests that it can effectively discriminate between backdoor and benign updates. This could help to protect the global model from backdoor poisoning, while maintaining a fast and accurate training of the main task.

BackdoorIndicator can still effectively reduce the backdoor accuracy, even when its detection performance declines as adversaries inject backdoors in the early training stage. For blended backdoor updates trained using Neurotoxin, the TPR of BackdoorIndicator drops from 70% to 44.0% if the attacker starts poisoning from 400 global rounds rather than 800. However, BackdoorIndicator still achieves a lower BA of 26.1% with 44.0% TPR. We argue that it is due to the difficulty of injecting backdoors into a model that is far from convergence: in the following training process, benign updates are more likely to conflict with backdoor updates, resulting in a slow increase of BA even when there is no defense.

Table 2 also reveals that, BackdoorIndicator's ability of precisely distinguishing backdoor updates and benign updates gets stronger if the attack happens later in the training stage. To defend a vanilla pixel-pattern backdoor attack, the FPR of BackdoorIndicator decreases from 25.7% to 22.2%, and further to 15.0% as the attack starts later. This is because benign updates becomes smaller in magnitude and closer to each other in distance, resulting in a lower false alarm rate.

We find that all evaluated methods except for BackdoorIndicator and Foolsgold fails to detect backdoor updates. We argue that it is because of the challenging adversarial training setting and non-IID degree of the data. It is hard for these methods to effectively detect backdoor models trained using a small learning rate in highly non-IID settings. We follow up to study their influence on the detection performance.

An interesting observation in Table 2 is that the utilization of alternative backdoor detection techniques, such as FLAME, would unexpectedly lead to an improvement in backdoor accuracy. This is because the considered attackers could fabricate poisoned models to make them statistically close to the benign ones by using small learning rate. In such scenarios, statistical methods, like FLAME, fail to detect any backdoor updates, while still mark and filter out around 44% benign updates. This will lead to a decrease in the number of accepted updates, and consequently an increase in the aggregation weights of backdoor updates, which is computed as one divided the total number of accepted updates. This eventually leads to an improvement in backdoor accuracy compared with scenarios without any defenses.

We also compare the detection performance on more datasets. We present a part of results in Table 3 and the full results in Appendix A. The proposed method still achieves the lowest BA, and the highest TPR for both CIFAR100 and EMNIST. Specifically, BackdoorIndicator identifies 85.2% of backdoor updates, which restricts backdoor accuracy at 7.3%, and only misclassifies 15.8% benign models as malicious on CIFAR100. However, other evaluated methods fail to filter out backdoor updates, among which Deepsight achieves the highest TPR as 6.4% and the lowest BA as 61.3%. The performance of these methods improves on EMNIST with the highest TPR as 52.0% and the lowest BA as 51.4%. Nevertheless, BackdoorIndicator still achieves the best performance with the TPR/FPR (BA) triplet as 99.0%/35.4% (9.6%). This further demonstrates the universal effectiveness of ackdoorIndicator across different datasets.

Performance under different non-IID degrees and poisoned learning rates. Table 4 exhibits detection performance of all evaluated methods under different non-IID degrees and multiple poisoned learning rates (plr). BackdoorIndicator can stably identify malicious updates regardless of the change in plr. For the highly non-IID setting of $\alpha = 0.2$, BackdoorIndicator detects 98.0% backdoor updates when plr equals 0.01, and also achieve 97.6% TPR with 0.055 plr. However, the change in plr substantially influences the performance of the other methods. FLAME and Multi-Krum can effectively identify backdoor updates trained using large plr while fail to detect any malicious update trained using small plr. This is

Table 5: Detection performance of all evaluated methods on CIFAR10 under multiple client attack. The backdoor type are Vanilla and pixel-pattern. The adversary starts poisoning from global round 1200 for CIFAR100, and 400 for EMNIST. The performance is evaluated through the triplet of TPR/FPR (BA). The poisoning ends until 360 backdoor models are injected.

Table 6: Performance on different model architectures under single client attack for CIFAR10 task. The backdoor type are Vanilla and pixel-pattern. The adversary starts poisoning from 1200 global round, and continues for 250 rounds.

architecture	ResNet34	VGG16
No defense	0.0/0.0 (77.3)	0.0/0.0 (76.7)
Multikrum	0.7/44.1 (88.4)	0.7/44.1 (86.6)
Deepsight	11.3/6.5 (42.2)	6.7/4.3 (56.4)
Foolsgold	61.3/46.8 (31.7)	21.3/35.0 (76.2)
RFLBAT	0.0/14.0 (61.4)	0.7/12.3 (79.2)
FLAME	0.0/44.0 (91.4)	1.3/43.9 (85.2)
Indicator	**91.9**/38.0 **(14.3)**	**95.3**/10.5 **(13.6)**

because that these two methods identify potential malicious updates based on certain distance measure, and updates with abnormal distance features will be marked as outliers. In such a case, it is much harder for these methods to detect backdoor models trained using small plr which makes the backdoor models closer to the global model. In contrast, Foolsgold and Deepsight show weaker detection ability as the plr increases. Specifically for Foolsgold, as it assigns lower weights for updates that have strong similarity with others, backdoor updates trained using larger plr exhibit larger differences from benign updates, making them harder for Foolsgold to identify.

We also note that BackdoorIndicator consistently performs well under different non-IID settings, with an average TPR of over 90%. For the rest methods, Foolsgold exhibits weaker performance in more IID setting, while Deepsight shows stronger sensitivity in identifying backdoor updates when α grows larger. FLAME shows better performance as non-IID degree gets stronger. Under the setting where plr equals 0.055, FLAME achieves 100% TPR when α equals 0.2 and 54.5% TPR when α equals 0.9.

Performance under multiple client attack. Table 5 presents the detection performance when attackers control multiple malicious clients in every global round. We find that the proposed method can successfully defend against backdoor attacks even when 60% of the clients are malicious. BackdoorIndicator achieves over 93% TPR and limits BA at around 10% in all the evaluated tasks. We also note that Foolsgold can identify over 99% of backdoor updates in all evaluated multiple client attack settings, which shows stronger detection ability compared with when facing single client attack. However, the FPRs of Foolsgold are still about twice compared with the FPR of BackdoorIndicator. This indicates that BackdoorIndicator can precisely discriminate between benign and backdoor updates even under multiple client attack.

Performance for different model architectures. We also conduct experiments to demonstrate the effectiveness of BackdoorIndicator on different model architectures. As is shown in Table 6, the detection performance of BackdoorIndicator remains the strongest for both ResNet34 and VGG16, yielding the lowest BA among all evaluated methods.

Table 7: Main task accuracy **(LEFT)** when applying BackdoorIndicator, and **(RIGHT)** when not applying any defense mechanism, under single client attack with different malicious training algorithms, backdoor types, and injection rounds on CIFAR10. The poisoning lasts for 250 global rounds.

BackdoorIndicator does not degrade main task accuracy. As it is shown in Table 7, we further provide the main task accuracy with the same setting in Table 2, when applying BackdoorIndicator and when not applying any defense mechanism. We can see that although the proposed defense slightly impacts the main task accuracy in some cases, applying BackdoorIndicator achieves almost identical main task accuracy for most settings to when not applying any defenses.

4.3 Impact of Hyper-parameters

We proceed to reveal the influence of several key hyper-parameters on the performance of BackdoorIndicator. In the

following experiments, we assume that vanilla attackers start to inject backdoors from 1200 global rounds, and keep poisoning for 100 global rounds. We repeat each task for 5 times, and present the mean value and the standard deviation.

Table 8: Performance of BackdoorIndicator which collects data from different sources to construct the indicator dataset. MA* indicates the main task accuracy without replacing BN statistics with the main BN statistics after injecting the indicator task. The size of the indicator dataset is 800.

source	TPR/FPR	MA*	MA
CIFAR100	95.6±3.7/22.4±3.6	84.3±2.4	84.8±1.4
EMNIST	93.0±4.2/32.3±1.7	72.7±3.1	87.0±1.3
300k random	95.8±1.7/19.0±1.4	84.1±3.0	83.1±1.0
random noise	90.0±7.0/41.3±8.6	69.6±4.2	85.2±1.7

Influence of the source of indicator dataset. Table 8 provides the performance of the proposed method which collects data from different sources to build the indicator dataset. We find that *the detection performance is rather insensitive to the data source that is used to construct the indicator dataset*. Constructing the indicator dataset using data from EMNIST and even uniformly sampled random noise can achieve 93.0% TPR and 90.0% TPR respectively. However, the FPR in these scenarios, which are 32.3% and 41.3%, increases substantially compared to 22.4% FPR and 19.0% FPR, in which case the defender samples data from CIFAR100 and 300k random images [20] to build the indicator dataset respectively.

We also note that BN statistics is crucial in correctly evaluating the main task accuracy (MA). For the indicator dataset which consists of data sampled from EMNIST and random noise, the MA, without replacing BN statistics with the main BN statistics after injecting the indicator task, is around 72.7% and 69.6% respectively; while the MAs are about 87.0% and 85.2% when using main BN statistics. On the other hand, the influence of whether replacing BN statistics with the main BN statistics is relatively negligible for indicator dataset with CIFAR100 and 300K random data. Utilizing the BN statistics from the indicator dataset may cause degradation of the main task, especially for an indicator dataset that is considerably different from the main dataset. Thus, it is crucial for the defender, who is agnostic to the data distribution of the main task, to replace BN statistics with the main BN statistics to avoid potential drop of MA.

Table 9: Performance of BackdoorIndicator with different sizes of the indicator dataset.

size	TPR/FPR
100	96.6±4.8/53.2±4.2
200	88.6±10.7/23.5±2.3
500	93.2±6.8/23.7±2.7
800	95.6±3.7/22.4±3.6
1100	96.2±3.6/19.3±2.3

Influence of the size of indicator dataset. We provide experiments to explore how the size of the indicator dataset influences the detection performance. As is shown in Table 9, the decrease in the size of the indicator dataset causes negligible influence in identifying the backdoor updates. With merely 100 samples in the indicator dataset, BackdoorIndicator is able to identify around 96.6% of all malicious updates. Nevertheless, the FPR with 100 samples is around 53.2%, indicating a weak ability in precisely discriminating between benign and malicious updates. This problem can be effectively addressed through having 200 samples in the indicator dataset. In such a case, BackdoorIndicator achieves around 23.5% FPR, which is about the same performance when the size equals 800. This suggests that the defender does not need to collect a large number of indicator data to implement BackdoorIndicator.

For main tasks with more classes, the defender generally needs to construct a relatively large indicator dataset to ensure sufficient number of samples for all potential adversary-chosen labels. However, evaluation results in Table 3 show that implementing BackdoorIndicator with the indicator dataset of 800 samples can secure the CIFAR100 main task from backdoor attacks with the TPR/FPR (BA) triplet as 85.2/15.8 (7.3). The detection performance with approximately 8 OOD-samples-per-class for CIFAR100 is comparable to applying the indicator dataset with 200 samples in Table 9 for CIFAR10, which corresponds to 20 OOD-samples-per-class. This is because the indicator task is much easier to be forgotten by the benign updates, when there are more classes. Therefore, to achieve comparable difference between the indicator task accuracies of the benign and backdoor updates (and hence similar backdoor detection performance), the task with a dataset of more classes can afford to use a smaller number of OOD samples per class. This also suggests that the size of the indicator dataset does not need to increase linearly with the number of classes, further demonstrating the practicality of BackdoorIndicator.

Table 10: Performance of BackdoorIndicator with different numbers of training iterations.

training iterations	TPR/FPR
10	95.0±1.4/16.0±2.8
200	95.6±3.7/22.4±3.6

Influence of indicator training iterations. We also provide experiments to show that implementing the proposed method does not add too much computation overhead to the FL system. Table 10 shows that training the indicator task for 10 iterations can achieve around 95.0% TPR and 16.0% FPR, which is comparable with training for 200 iterations.

The above set of experiments demonstrates that the indicator dataset is easy to construct: no strict requirements on the data source (even random noise suffices), and only a few hundred samples are needed; and the training of indicator task is lightweight: only a few iterations are needed. These features make the deployment of BackdoorIndicator widely

feasible in practical FL systems.

Table 11: Performance of BackdoorIndicator with different values of λ.

λ	TPR/FPR	MA
0	89.0±3.7/20.7±5.7	76.1±8.2
0.01	96.3±2.3/19.3±4.8	81.0±3.4
0.1	95.6±3.7/22.4±3.6	84.8±1.4
0.2	94.7±3.3/18.8±7.8	86.8±0.4
0.3	97.0±1.6/14.9±3.6	86.0±2.2

Influence of λ in training the indicator task. Table 11 illustrates the performance of the proposed method with different λ, which is the weight of the regularization term in training the indicator task. We observe a sizable decrease in MA as λ decreases. Specifically, BackdoorIndicator achieves around 76.1% MA when we exclude the regularization term from training. The MA gradually increases to 84.8% and further to 86.8% as λ is increased to 0.1 and 0.2 respectively. Without proper regularization in the change of the model parameter, the model gradually forgets the main task, causing a drop in the MA. Thus, a sufficiently large λ needs to be chosen to make BackdoorIndicator effective.

Influence of the suspicious threshold ε_I. A proper suspicious threshold needs to be chosen to achieve a decent performance in both identifying backdoor updates and discriminating with benign updates. For the same task, decreasing ε_I undoubtedly boosts TPR and FPR simultaneously, resulting in a stronger ability in detecting malicious updates while a weaker ability in distinguishing benign updates. For different tasks, as is shown in Table 2 and 3, BackdoorIndicator achieves comparable performance for CIFAR100 with $\varepsilon_I = 85$ and CIFAR10 with $\varepsilon_I = 95$ under the same adversarial setting. This is because that the maintaining effect of clients' backdoors on the indicator task is weaker when there are more classes, which causes the accuracy of the indicator task to decline and a relatively smaller ε_I is needed.

5 Resilience to Adaptive Attacks

Knowing how BackdoorIndicator operates, adversaries may adopt adaptive attacks to bypass the detection. We consider such attack settings and strategies utilizing *pre-training*.

Pre-training. As shown in Table 4, the increase in the poisoned learning rates results in the decrease of the detection performance of BackdoorIndicator. This is because the indicator task is forgotten more quickly when the attacker trains a backdoor model with a larger learning rate. Thus, adaptive attackers could pre-train the model using its benign dataset to first erase the indicator task, and then train the model using the constructed backdoor dataset to escape from the detection of BackdoorIndicator.

We proceed to demonstrate the performance of the above adaptive attack against BackdoorIndicator. We assume that an adaptive attacker first trains the model using the benign dataset for 10 iterations with 0.05 learning rate. The attacker then trains the backdoor model using the constructed malicious dataset with a plr of 0.025. We assume that the attacker adopts a vanilla training algorithm and intends to inject pixel-pattern backdoors. We repeat each task for 3 times, and report the mean value and the standard deviation. The evaluated dataset is CIFAR10.

Table 12: Performance of BackdoorIndicator w./wo. norm clipping defense (NCD) against adaptive attack.

method	TPR/FPR (BA)
Indicator wo. NCD	53.0±9.6/19.3±4.2 (39.1±15.1)
Indicator w. NCD	75.3±8.0/13.6±8.2 (9.9±1.8)

As is shown in Table 12, BackdoorIndicator only identify 53.0% of all malicious updates and achieves around 39.1% BA, indicating the effectiveness of the adaptive attack. To this end, we further modify the proposed defense to improve resilience to the above adaptive attack. Specifically, for the pre-training step to be effective, the uploaded local model of an adaptive attack needs to be sufficiently different from the global model with indicator task injected. Motivated by this, we propose to leverage norm clipping defense (NCD), which clips the norm of each received update to a fixed bound, to mitigate the forgetting of the indicator task, potentially introduced by adaptive attackers through pre-training. We observe from Table 12 that BackdoorIndicator equipped with NCD can now effectively detect around 75% of backdoor updates, and limit the BA to merely around 9.9%.

6 Discussion

The proposed BackdoorIndicator can be composed with other statistical defenses for FL, further improving effectiveness. For example, BackdoorIndicator can replace the dynamic clustering component in FLAME to serve as a more precise backdoor detector, which could help to further minimize the amount of noise needed in FLAME. Given that the design principle of BackdoorIndicator based on detection of OOD task injection is orthogonal to those of statistical methods, incorporating BackdoorIndicator is expected to provide multiplicative gains on defense performance. Nevertheless, while it is not the focus of this paper, we envision that future works could seek to combine BackdoorIndicator with other detection methods to build stronger FL backdoor defense mechanisms.

Despite the effectiveness of BackdoorIndicator corroborated by empirical evaluations, it is also important to understand the theoretical explanation behind the maintaining effect on injected backdoors. We envision that future research could provide theoretical analysis to further facilitate the understanding of BackdoorIndicator, guiding the development of stronger backdoor detection mechanisms.

7 Related Work

Federated Learning. Multiple variants of FedAVG are proposed to tackle the data heterogeneity problem in FL. FedProx [31] argues that simply adding a proximal term to constrain local updates from deviating from the global model could help to enhance the performance under non-IID setting. SCAFFOLD [25] tries to mitigate the statistical heterogeneity through correcting client drifts using control variates. Another line of work, named personalized FL, attempts to handle the heterogeneity through training distinct models for different clients. Per-FedAVG [11] utilize the Model-Agnostic Meta-Learning (MAML) framework to find an initial global model that local clients can easily adapt to their dataset through performing a few steps of gradient descent. pFedMe [50] formulates the problem in a bi-level way, and solve it using Moreau envelops as clients' loss function, which achieves better performance compared with Per-FedAVG.

Backdoor attack is an emerging security threat in training deep neural networks (DNNs). Except for the BadNets [17], which first reveal the vulnerability of DNNs against backdoor attack, a series of works proposes more stealthy backdoor attacks to escape from detection algorithms. The adversarial backdoor embedding algorithm [47] not only optimizes the original loss function of the model, it also seeks to maximize the indistinguishability of the hidden representations of poisoned data and clean data. Composite attacks [33] proposes to use backdoor triggers composed from existing benign features of multiple labels to elude detection. Li *et al.* [32] explores sample-specific backdoor attack, where the backdoor trigger for each sample is distinct. The method only needs to modify a small amount of perturbation to original images, which makes the trigger invisible. Apart from the successful implementation of backdoor attacks in poisoning DNNs, it has also been shown to effectively attack other deep learning paradigms. In continual learning setting, Kang *et al.* [24] shows that attacker could plant an input-aware backdoor to stealthily promote forgetting on the previous task while retaining high accuracy at the current task. Yang *et al.* [55] shows that multi-modal models are also vulnerable to poisoning attacks.

Backdoor defenses in training deep learning neural networks can be mainly categorized into: pruning-based defenses, trigger synthesis based defenses, and saliency map based defenses. For pruning based methods, Liu et al. [34] proposes to prune backdoor-related neurons to remove backdoors based on the observation that these neurons are usually dormant during the inference process. Neural cleanse [51] is the first proposed trigger synthesis based method, which first obtains potential backdoor trigger for each class, and proceeds to reconstruct the final trigger and its target label through anomaly detection. The following work [42] argues acquiring the entire trigger distribution is essential for effective defending against backdoor attacks. Thus, the method adopts generative modeling to recover the whole trigger distribution. For saliency map based defenses, SentiNet [8] utilizes the Grad-CAM [44] to extract critical regions from input, and then locate the trigger regions based on the boundary analysis. NeuronInspect [22] exhibits a similar idea through identifying the existence of backdoor attacks by generating heatmaps from the output layer. The method proceeds to extract key features and apply an anomaly detector to identify backdoor updates.

Backdoor attacks and defenses in FL. We further review several recent works on backdoor attacks and defenses in FL, which are not evaluated in this paper. F3BA [13] tries to mount backdoor attacks through only compromising a small fraction of least important parameters, and further optimize the trigger to improve effectiveness. CerP [35] casts the distributed backdoor attack as a joint optimization process to reduce the bias between benign and backdoor updates. These two works try to fabricate malicious updates to make them statistically close to benign ones to escape from backdoor detection, which utilize the inherent weakness of statistical backdoor defenses as revealed in our paper. However, the proposed backdoor samples are still OOD samples with respect to benign ones from the target class. Planting these backdoors will still maintain the indicator accuracy, and eventually be identified and filtered out by BackdoorIndicator.

A recent work [27] proposes a novel backdoor attack method, AutoAdapt, which leverages the Augmented Lagrangian method for constraint optimization to create backdoor models which can automatically adapt to various defense metrics to evade detection. However, AutoAdapt is not applicable in attacking BackdoorIndicator. This is because the indicator dataset is kept secret in the server, and is agnostic to the attacker, which renders the attacker impossible from computing the defense metric to adapt backdoor models to evade the BackdoorIndicator detection.

For other backdoor defense mechanisms in FL, BayBFed [29] relies on a Bayesian statistical method to filter out backdoor updates, which still suffers from the inherent weakness of statistical backdoor defenses. ADFL [59] utilizes GAN to revise the global model and eliminate the planted backdoors. However, this method requires the server to access a part of clean training data, which is rather impractical in FL.

8 Conclusion

We propose a novel proactive backdoor detection method BackdoorIndicator, to detect potential backdoors injected to the clients' updates in federated learning. BackdoorIndicator builds upon the maintaining effect of subsequent backdoors on the previous ones and the fact that backdoor samples are OOD samples compared to benign samples from the target class, designs indicator task leveraging OOD samples to identify and rule out backdoor updates. Extensive experiments show the superior performance and practicality of BackdoorIndicator, under a wide range of system and adversarial settings.

Appendix

A Supplementary Experiments

We provide supplementary experimental results to show the effectiveness of BackdoorIndicator under various adversarial and system settings on CIFAR100 and EMNIST. As it is shown in Table 13, 14, 15, 16, BackdoorIndicator consistently achieves the best performance across all evaluated settings.

Table 13: Detection performance of all evaluated methods under single client attack with different settings on CIFAR100. The performance is evaluated through the triplet of TPR/FPR(BA). The poisoning lasts for 100 global rounds.

UBA-Inf: Unlearning Activated Backdoor Attack with Influence-Driven Camouflage

Abstract

Machine-Learning-as-a-Service (MLaaS) is an emerging product to meet the market demand. However, end users are required to upload data to the remote server when using MLaaS, raising privacy concerns. Since the right to be forgotten came into effect, data unlearning has been widely supported in on-cloud products for removing users' private data from remote datasets and machine learning models. Plenty of machine unlearning methods have been proposed recently to erase the influence of forgotten data. Unfortunately, we find that machine unlearning makes the on-cloud model highly vulnerable to backdoor attacks. In this paper, we report a new threat against models with unlearning enabled and implement an Unlearning Activated Backdoor Attack with Influence-driven camouflage (UBA-Inf). Unlike conventional backdoor attacks, UBA-Inf provides a new backdoor approach for effectiveness and stealthiness by activating the camouflaged backdoor through machine unlearning. The proposed approach can be implemented using off-the-shelf backdoor generating algorithms. Moreover, UBA-Inf is an "on-demand" attack, offering fine-grained control of backdoor activation through unlearning requests, overcoming backdoor vanishing and exposure problems. By extensively evaluating UBA-Inf, we conclude that UBA-Inf is a powerful backdoor approach that improves stealthiness, robustness, and persistence.

1 Introduction

Emerging large deep models like GPT [56] and ViT [17] have exacerbated the tension between the rapid growth of data and the relative lack of computing resources, making it difficult for individual users and small companies to deploy large models locally [57]. To ease resource constraints and data barriers, vendors like Google and Microsoft have moved deep models onto cloud platforms as API services for advantages like accessibility, cost-effectiveness, and scalability [7]. Such a Machine-learning-as-a-Service (MLaaS) trend has gained significant momentum in recent years [20]. MLaaS service providers (SPs) establish cloud platforms for data collection, model training, and inference service provision. The MLaaS of Google AI [1], Microsoft Azure AI [2], and Amazon SageMaker [4] have made successful cases.

MLaaS users are commonly required to upload data to the remote server for training or inferring on-cloud models, raising serious privacy concerns [11, 30]. With users' private data learned by on-cloud models, MLaaS is at risk of various threats like inference attacks [31, 77], data reconstruction attacks [47, 55], and poisoning attacks [48, 64]. Besides, privacy regulations like the European GDPR [7] allow users to revoke their personal data from learning models as part of the right to be forgotten. In such circumstances, machine unlearning [8, 22, 71] emerges as a promising solution for addressing the privacy concerns of MLaaS users [29, 72]. For instance, Google Analytics 4 facilitates the utilization of the User Deletion API [6]. Other companies like OpenAI and Meta also allow data deletion requests in their AI products [3, 5]. However, some factual cases [24, 42] indicate that influence caused by learning may persist in the model, like backdoors.

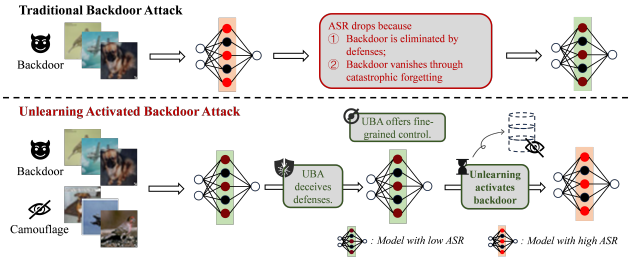

Figure 1: Differences between conventional backdoor and unlearning activated backdoor approaches.

Backdoor attacks [18, 44, 51, 61] compromise the deep models by embedding adversary-specified hidden triggers during the learning process. The adversary can exploit embedded backdoors in on-cloud models to manipulate the predictions by putting pre-defined triggers in input data, posing a security risk to MLaaS. Fortunately, feasible defense methods have been widely studied since backdoor threats against MLaaS were identified. Model scanners reveal potential backdoors

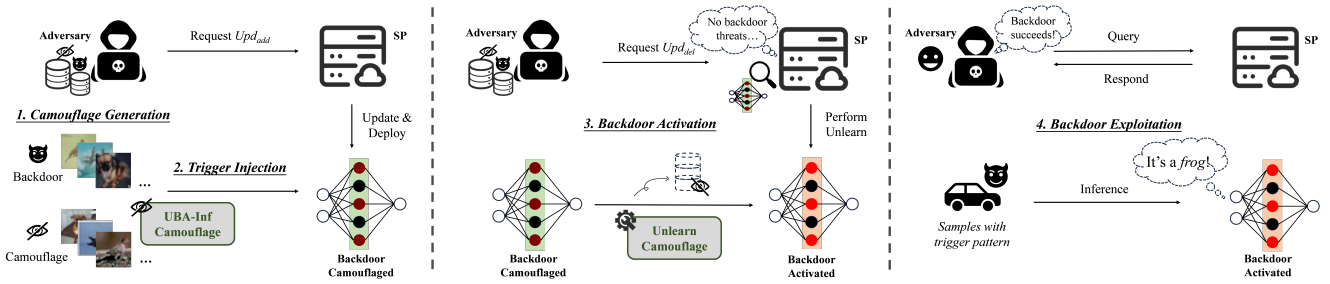

Figure 2: Attack workflow of our unlearning activated backdoor attack.

through reverse engineering [62, 67]. Outlier filters cast malicious samples out from the training dataset [13, 25]. Model reconstructors modify model weights directly to eliminate backdoor threats [40, 81]. Besides, backdoor attacks also suffer from natural flaws like the vanishing problem [59, 80].

On the other hand, recent works have exposed potential vulnerabilities in machine unlearning, like over-unlearning [29], slow-down unlearning [49], and camouflage attacks [16, 78]. Camouflage attacks inspire an unlearning activated backdoor attack (UBA), enhancing the stealthiness of data poisoning, which is illustrated in Figure 1. However, backdooring MLaaS with camouflage attacks is rather challenging considering complicated conditions like continuous learning and restricted data access strategy of unlearning. Recent camouflage attacks either require strong assumptions with a white box setting [16] or suffer from limitations in flexibility and effectiveness [78]. The existing work also overlooks the diversity of unlearning algorithms. In light of these limitations, we take a step forward and propose an alternative backdoor approach through unlearning with an enhanced camouflage algorithm based on data influence [33].

Rethinking the frustrations of backdoor attacks, we summarize the challenges of UBA. ① Existing backdoor approaches lack fine-grained control, as on-cloud models are poisoned in offline training but exploited in online inference, leading to unstable conditions of the injected backdoor. ② Backdoor cannot persist in continuous learning. When MLaaS enables continuous learning, the injected backdoor faces a catastrophic forgetting problem. ③ Backdoor should be stealthy and robust enough to defeat defenses like scanning, filtering, and reconstruction. ④ UBA should be practical and effective, requiring the ability to construct camouflage with limited knowledge and adaptability to different backdoor generating algorithms and machine unlearning algorithms.

Our contributions. It is rather tricky to design a satisfying backdoor approach considering the challenges ① and ② mentioned above. Because conventional backdoor approaches have natural drawbacks. Having observed vulnerabilities introduced by machine unlearning in MLaaS, we propose leveraging unlearning requests to develop an unlearning activated backdoor attack. Our attack involves concealing backdoor traces in the learning process and activating the backdoor on-demand by unlearning requests. Since machine unlearning removes camouflage representations from the original model, the backdoor activated in this way persists much longer than conventional backdoors (obtaining 4x improvement in the evaluation). To meet the challenge ③ and ④, we propose an influence [33] driven camouflage sample generation algorithm, which covers backdoor traces effectively (the ratio of camouflage sample amount to backdoor sample amount reaches 1:4). Additionally, the camouflage can evade existing defenses including detectors and filters, and withstand model transformations. It is also compatible with various backdoor generating algorithms and machine unlearning algorithms. Putting them together, we offer an unlearning activated backdoor attack with influence-driven camouflage (UBA-Inf). The attack workflow is illustrated in Figure 2.

In conclusion, we have made the following contributions:

- We introduce a new backdoor approach named UBA-Inf, which provides fine-grained control and better persistence of the backdoor through machine unlearning.
- We implement UBA-Inf for different MLaaS scenarios, including one-time learning and continuous learning, with both exact and approximate unlearning strategies.
- UBA-Inf is compatible with existing backdoor generating algorithms, enhancing them in MLaaS scenarios.
- UBA-Inf has been evaluated comprehensively. Evaluation results show that UBA-Inf achieves 4x persistence improvement with limited poisoning samples (2% of the total training samples). The resistance to different defense methods has also been verified.

2 Preliminaries

This section will review essential concepts appearing throughout the literature, including MLaaS, machine unlearning, and backdoor attacks.

2.1 MLaaS

In recent years, cloud computing service providers have begun to launch on-cloud machine learning services with public APIs [20, 44], known as *Machine-Learning-as-a-Service* **(MLaaS)**. For conciseness, we consider two parties in MLaaS, i.e., the **service provider (SP)** who provides the service, and the **users** who use the service [29].

Let $\mathcal{X}$ denote the input feature space and $\mathcal{Y}$ denote the output space. A data point is an element of $\mathcal{Z} = \mathcal{X} \times \mathcal{Y}$ and

we denote $\mathcal{Z}^*$ as the universal space of the dataset. SP commonly builds training dataset $D_{trn} \in \mathcal{Z}^*$ by adopting third-party datasets or directly collecting from users [44,52]. In this paper, users' adding training data into the on-cloud model is represented as an update request $Upd_{add}(D), D \in \mathcal{Z}^*$ [29,57]. Generally, SP trains a model $\theta^* \in \Theta$ on training data D_{trn} with a deep learning algorithm $A : \mathcal{Z}^* \to \Theta$, aiming to minimize the empirical loss $\ell \in \mathcal{L} : \mathcal{Z} \times \Theta \to \mathcal{R}^+$ on D_{trn} by solving an optimizing problem: $\theta^* = \underset{\theta}{argmin} \frac{1}{|D_{trn}|} \sum_{z_i \in D_{trn}} \ell(z_i, \theta)$. After training, SP deploys the well-trained model θ^* with a set of service APIs ψ for users to invoke.

If SP supports users' data updating through Upd_{add}, we call the service Continuous-Training MLaaS (CT-MLaaS), updating the model on an input data stream [52,59]. Once the amount of data collected reaches a predefined threshold c, SP updates the model by $\theta^* = A_{ct}(\theta^*, D_{tsk})$, where $D_{tsk} \in \mathcal{Z}^*$ is the newly incoming dataset with size c and $A_{ct} : \Theta \times \mathcal{Z}^* \to \Theta$ is a continuous learning algorithm. We call a cycle of data collection, model updating, and deployment a *task*. If we denote by $D_{tsk,i}, i \in [1,n]$ the dataset collected in the i-th task from the very beginning, the training dataset can be seen as a superset of all task datasets, i.e., $D_{trn} = \bigcup_{i=1}^{n} D_{tsk,i}$.

Table 1: The category of different MLaaS.

Categories of MLaaS	
Does MLaaS employ continuous learning?	
YES	Continual Training MLaaS (CT-MLaaS)
NO	One-time-Training MLaaS (OT-MLaaS)
Does MLaaS have full access to D_{trn} during unlearning process?	
YES	Full Access MLaaS (FA-MLaaS)
NO	Restricted Access MLaaS (RA-MLaaS)

We assume task datasets in CT-MLaaS are from either a similar distribution [52, 59], or different domains in which each task has the same data label space but different feature distributions, also known as *Domain-Incremental-Learning* [68]. Instead of CT-MLaaS, One-time-Training MLaaS (OT-MLaaS) is another approach commonly used with only one-time data collection and model training [57], which will be also studied in our work. Table 1 demonstrates the details of various MLaaS.

2.2 Machine Unlearning

Given a subset $D_{rm} \in \mathcal{Z}^*$ to be unlearned, accessible remaining data $D'_{trn} \in \mathcal{Z}^*$, and the original model $\theta^* \in \Theta$, the unlearning algorithm $U : \mathcal{Z}^* \times \mathcal{Z}^* \times \Theta \to \Theta$ erases the influence of D_{rm} from θ^* and returns the model $\theta^*_u \in \Theta$ after unlearning. The objective of unlearning is to minimize the empirical loss $\frac{1}{|D_{trn} - D_{rm}|} \sum_{z_i \in D_{trn} - D_{rm}} \ell(z_i, \theta^*_u)$ just like D_{rm} has not shown ever. In other words, the model after unlearning should be indistinguishable from the model trained with $D_{trn} - D_{rm}$ from scratch. The accessible remaining data D'_{trn} of unlearning in MLaaS can vary from an $\emptyset$ to D_{trn}, depending on the data access policy of the SP [29].

For brevity, let Full-Access MLaaS (FA-MLaaS) refer to MLaaS where the SP is always granted full access to the original training data [9, 16] and Restricted-Access MLaaS (RA-MLaaS) refer to MLaaS where the SP cannot access to the original training dataset once the model is well-trained [29]. Similar to the learning request, the unlearning request can be defined as $Upd_{del}(D_{rm}), D_{rm} \in \mathcal{Z}^*$ for unlearning service in MLaaS [57, 72]. The SP is supposed to respond to unlearning request Upd_{del} by running a specific unlearning algorithm. Generally, unlearning algorithms can be divided into two types: *exact unlearning* and *approximate unlearning*, the former of which employs caching and re-scheduling to enhance efficiency [9, 72], and the latter of which removes data influence through mathematical tools like inverse hessian matrix [33, 69, 70], gradient-based model optimization through tailored loss functions [63, 69, 74].

Table 2: A comparison of commonly used unlearning algorithms.

	Need For D_{trn}	**FA-MLaaS**	**RA-MLaaS**	**CT-MLaaS**
Exact Unlearning				
full retrain	●	✓	-	-
SISA [9]	●	✓	-	-
Approximate Unlearning				
PUMA [70]	●	✓	-	-
GBU [69]	○	✓	✓	✓
LIRF [74]	○	-	-	✓

As shown in Table 2, some unlearning algorithms are designed for FA-MLaaS so that $D'_{trn} = D_{trn}$ [9, 70]. Most exact unlearning algorithms like SISA [9] and some approximate algorithms that calculate the Hessian matrix [70] belong to this type. Some other approximate algorithms like first-order gradients based method [69, 74] can unlearn with $D'_{trn} = \emptyset$. In this paper, we will consider both exact unlearning and approximate unlearning under the most commonly discussed unlearning circumstance, i.e., unlearning by samples [72].

2.3 Backdoor Attacks

The backdoor attack on deep learning is an emerging attack where the adversary embeds a backdoor into the victim model by injecting maliciously crafted samples into the training dataset [21,44]. Backdoor attacks are highly threatening since any legal MLaaS user can be the adversary, tempering the model with training data through data updating. The backdoor procedure $B : \mathcal{Z} \to \mathcal{Z}$ induces the victim model θ^*_v to misclassify all samples with the backdoor trigger into a target class y_{tgt}. Generally, B consists of a feature transformation $B_{\mathcal{X}} : \mathcal{X} \to \mathcal{X}$ and a label transformation $B_{\mathcal{Y}} : \mathcal{Y} \to \mathcal{Y}$.

The feature transformation $B_{\mathcal{X}}$ takes as input a clean example and embeds the pre-designed backdoor trigger. A satisfying backdoor trigger should be imperceptible but mislead model predictions with a small portion of data poisoned, satisfying stealthiness and effectiveness [14, 37, 44]. The adversarial capability of backdoor attacks varies in data accessibility and model accessibility. Some studies assume that the adversary has full access to the victim model and data in a white-box setting [32, 50], while others use input and output pairs in a black-box setting [43, 75]. Some additional assumptions

like auxiliary datasets and surrogate models [43, 50, 75] are also commonly used for improving the attack performance.

The label transformation $B_{\mathcal{Y}}$ differs in dirty-label and clean-label attacks [44, 75]. In dirty-label attacks [14, 21, 37], the adversary sets labels of backdoor samples to y_{tgt}. In clean-label attacks [65, 66, 75], poisoning examples are directly selected from class y_{tgt} and maintain their original labels.

For backdoor attack evaluation, a high benign accuracy (**BA**) on benign samples and a high attack success rate (**ASR**) on target samples with triggers are desired simultaneously. Furthermore, for the stealthiness concern, the trigger's perturbation and the poisoning data amount are also critical metrics.

3 Problem Formalization and Threat Model

MLaaS offers online services where SP receives requests from users and updates the model when needed. We consider both OT-MLaaS and CT-MLaaS. OT-MLaaS gathers data once before training, while CT-MLaaS supports continual learning and updates the model even after release. Both cases can support machine unlearning, enforcing the right to be forgotten. MLaaS allows users to revoke specific data on demand and updates the on-cloud model. Therefore, an MLaaS user can send data adding request $Upd_{add}(D)$ and data deleting request $Upd_{del}(D)$, $D \in \mathcal{Z}^*$. Any legal MLaaS user can be a UBA attacker, capable of sending requests of learning and unlearning. This threat model is widely used in existing backdoor attacks [32, 48, 64] and unlearning attacks [16, 29, 54, 78]. Please note that CT-MLaaS commonly supports unlimited adding and deleting requests, while OT-MLaaS only supports one-time adding and limited deleting requests.

The UBA can be defined as a composition of four stages as indicated in Figure 2, including *camouflage generation*, *trigger injection*, *backdoor activation*, and *backdoor exploitation*.

1. The camouflage generation stage is a key improvement of UBA. In conventional backdoor attacks, only backdoor samples are generated. In UBA, camouflage samples are crafted along with backdoor samples for fine-grained activation control and stealthiness purposes.
2. The trigger injection stage is the same as conventional backdoor attacks. Backdoor samples are fed into the target model through data uploading or learning requests, i.e., $Upd_{add}(D)$ in our definition.
3. Different from the existing backdoor attacks on MLaaS, UBA uses an explicit backdoor activation stage to enable the backdoor instead of assuming the backdoor is alive all the time. In this stage, the adversary uses unlearning requests to remove the camouflage, i.e., $Upd_{del}(D)$ in our definition.
4. The backdoor exploitation stage is the same as conventional backdoor attacks. Samples with triggers can exploit the backdoor simply by querying the model through users' interface ψ.

Adversarial goal. Unlike conventional backdoor attacks, whose goal is to maintain the backdoor's availability all the time, the adversarial goal of UBA is to activate the backdoor at the right time while keeping it imperceptible before the activation. If we interpret the adversarial goal in evaluation metrics, conventional backdoor attacks' goal is to keep a high ASR and a high BA at the same time. Instead, UBA's goal is to keep the ASR as low as possible for stealthiness before launching the attack. When the injected backdoor is activated, UBA has the same requirements for ASR and BA as usual.

Adversarial capability. We assume that the adversary can pose as a legitimate MLaaS user to manipulate the victim model θ_v^*. The adversary can poison the training data of SP through data collection or continual learning requests. In OT-MLaaS, the adversary injects poisoning samples into the training dataset at once. In CT-MLaaS, the adversary can adaptively inject poisoning samples during continual learning. Besides, the adversary can influence the victim model by unlearning specific samples through unlearning requests.

We assume that the SP has collected a clean dataset $\mathbb{D}_{cl}$ in MLaaS and $\theta_v^* \in \Theta$ is the victim model learned on $\mathbb{D}_{cl}$. The adversary has adequate background knowledge of the learning task so that an auxiliary dataset $D_{atk} \sim \mathbb{D}_{cl}$ can be sampled from public datasets of the same learning task, e.g., image classification or object detection. Furthermore, the adversary can construct a surrogate model θ_s^* using auxiliary data and methods like inference attack, model inversion attack, and some backdoor attacks [28, 66, 75, 79]. For example, the victim model θ_v^* is trained on CIFAR-10 [35] while θ_s^* is pre-trained on ImageNet [15]. Besides, the on-cloud model of MLaaS can be seen as a blackbox to the adversary. Please note that UBA's adversary capability is the same as the existing backdoor attacks [66, 75]. No additional assumptions are made.

Defense and evaluation. Nowadays, MLaaS is commonly protected by backdoor defense methods. It is critical to take into account UBA performance under available defense strategies, including model sanitizing and input detection. Defense solutions for MLaaS are widely studied in different types of MLaaS. Meanwhile, when SP adopts defense solutions, the cost introduced should also be considered for practical concerns. Therefore, we assume that the SP will deploy defense solutions for MLaaS regarding different types of MLaaS. In OT-MLaaS, the SP can extensively apply backdoor defenses to eliminate the backdoor before the service is online. However, in CT-MLaaS, defenses applied in each task are unnecessary and time-consuming because the model is continuously updated. The SP could deploy backdoor defenses like anomaly detection before responding to learning and unlearning requests in CT-MLaaS.

UBA will be evaluated in multiple metrics, including backdoor effectiveness, stealthiness, persistence, and resistance to defenses. From the effectiveness perspective, UBA is expected to be immediately activated by unlearning, achieving a

high ASR and a high BA. For stealthiness, UBA should have a low ASR while keeping a high BA. Besides, both camouflage and backdoor samples can deceive detection methods. From the persistence perspective, the adversary expects the backdoor to stay alive as long as possible after it is activated, which suffers from catastrophic forgetting previously. As for resistance to defenses, the backdoor injected should not be eliminated by model sanitizing or transforming in MLaaS.

4 Unlearning Activated Backdoor Attack

Motivated by the backdoor vanishing phenomenon in MLaaS, we have intensively investigated available approaches to maintaining or recovering the backdoor's influence. Besides, on-demand attacks need the backdoor to be activated at the right time. Fortunately, machine unlearning emerges and gives us inspiration. If the adversary injects an inactivated backdoor into the MLaaS model and activates it when necessary, the adversary will be capable of attacking the on-cloud model stealthily in fine-grained control, acquiring activation control and the resistance to backdoor vanishing. We note that there is concurrent work of *Unlearning-activated Backdoor Attacks* (UBAs) [78]. However, we are the first to formalize the definition of UBA with a well-defined threat model. Furthermore, our attack achieves a new state-of-the-art result on CIFAR-10, acquiring 93.26% BA and 100% ASR through unlearning 200 camouflage samples after 400 backdoor samples are injected in total.

4.1 UBA-Inf Design Rationale

Before proposing a UBA design, it is essential to be aware of the underlying challenges of UBA designs. ① Similar to conventional backdoor attacks, there is a natural trade-off between acquiring effectiveness and stealthiness in UBA designs. ② Since MLaaS provides online learning and unlearning requests, it is difficult to ensure the robustness and persistence of the backdoor after model updating and sanitizing. ③ Various defensive strategies have been proposed to mitigate the backdoor's influence in MLaaS. Proposing a UBA design with resistance to multiple defensive strategies will be rather challenging.

To address these challenges, we propose a camouflage-aided backdoor attack. The intuition is straightforward: in addition to injecting backdoor samples, the attacker introduces carefully crafted camouflage samples into the victim model. Hence, an important stage of UBA is to generate proper camouflage samples. Our approach is inspired by [16], which employs gradient matching during victim model training for data poisoning camouflage. We extend this concept to backdoor attacks on MLaaS, adhering to strict adversary constraints in a practical black-box setting. Please also note there is a concurrent study [78] that applies camouflage idea [16] to BadNets [21]. Unlike dedicating to retraining-based unlearning [78], UBA-Inf is designed for various backdoor generating algorithms and different unlearning strategies. To enhance the UBA attack further, we derive two techniques from machine learning, i.e., the label correction [67] and influence function [33]. By adopting these two techniques, UBA-Inf achieves better stealthiness and attack performance than [78].

We note that our UBA-Inf has its limitations. The fine-grained backdoor control is provided by unlearning. If the SP does not provide an unlearning function, UBA-Inf cannot be implemented. Our work focuses on the mechanism design of unlearning-enabled backdoor attacks. Backdoor sample generating algorithms are orthogonal to our work, and we will show that UBA-Inf is effective with different backdoor generating algorithms. Advanced backdoor generating methods can also improve UBA-Inf performance. Meanwhile, natural flaws (like visual anomaly) of backdoor generating methods cannot be fixed by UBA-Inf. We also note these limitations are interesting topics to study further.

4.2 Camouflage Generation

The critical part of UBA-Inf is the camouflage generation. Inspired by label correction [67] and influence function [33] techniques in machine learning, we propose an iterative optimization method for searching satisfying camouflage samples. In backdoor defense studies, a reverse-engineering method is used to extract adversarial perturbations, recovering backdoor samples [67]. After that, the defender updates the victim model by tuning with correctly labeled backdoor samples that have been recovered. Having noticed this label correction method can not only sanitize the victim model but also mitigate the backdoor's influence, we use it in a totally different way for camouflage effects in UBA-Inf.

Firstly, the adversary selects from the auxiliary dataset D_{atk} and clean samples $D_{cm,cl} \subset D_{atk}$ that don't belong to the target class y_{tgt}, such that

$$D_{cm,cl} = \left\{(x,y)\middle|(x,y) \in D_{atk} \wedge y \neq y_{tgt}\right\}, \tag{1}$$

and transforms them using the backdoor generation function $B(\cdot) : \mathcal{Z} \to \mathcal{Z}$ but remains their correct labels, i.e.,

$$D_{cm,0} = \left\{(B_{\mathcal{X}}(x),y)\middle|(x,y) \in D_{cm,cl}\right\}, \tag{2}$$

in which $B_{\mathcal{X}}(\cdot) : \mathcal{X} \to \mathcal{X}$ adds the backdoor trigger to the image. Meanwhile, backdoor samples are generated beforehand for trigger injection as

$$D_{bd} = \left\{B((x,y))\middle|(x,y) \in \mathcal{Z}\right\}. \tag{3}$$

The adversary then combines the auxiliary dataset with camouflage and backdoor samples as

$$D_{atk,0} = (D_{atk} \setminus D_{cm,cl}) \cup D_{cm,0} \cup D_{bd}. \tag{4}$$

Next, the adversary iteratively optimizes the camouflage effect of D_{cm} through surrogate model fine-tuning and influence-driven camouflage perturbation. The influence function is a method calculating the influence on a statistical model when a

specific sample is up-weighted or perturbed. Although the theory behind influence functions may not hold for non-convex and non-differentiable models, approximations of influence functions can still offer valuable insights to analyze the direction of camouflage perturbation that makes the model as unresponsive as possible to the backdoor trigger [33]. Influence can be computed in a complete black-box setting using a surrogate model, making UBA-Inf more feasible than the gradient matching based approach [16], which demands an exact white-box setting. We note that our influence-enhanced camouflage generation algorithm can improve the UBA from two perspectives: concealing the backdoor effectively in training and recovering the backdoor by unlearning very few samples, which considerably outweigh related work [78].

The influence function reveals how the perturbation δ on a certain training data point $z \in \mathcal{Z}$ would impact the prediction of a specific samples $z' \in \mathcal{Z}$ such that

$$\begin{aligned} &I_{pert,loss}(z,z') \overset{def}{=} \nabla_\delta \ell(z', \theta_{z_\delta,-z}) \\ &= -\nabla_\theta \ell(z',\theta)^\top (\frac{1}{|D_{trn}|} \sum_{i=1}^{|D_{trn}|} \nabla_\theta^2 \ell(z_i,\theta))^{-1} \nabla_x \nabla_\theta \ell(z,\theta)), \end{aligned} \tag{5}$$

where ℓ denotes the loss function, $z = (x,y)$ denotes the original training point, δ denotes a small perturbation on the image x, and $\theta_{z_\delta,-z}$ denotes parameters trained on the dataset that replaces z with the perturbed one $z_\delta = (x+\delta, y)$. Thus, $[I_{pert,loss}(z,z')]\delta$ tells us the approximate effect caused by replacing z with z_δ on the loss at the test point z'. By setting δ in the direction of $I_{pert,loss}(z,z')$, we can construct local perturbations of z that maximize the loss at z'. In our design, we let $z' \in D_{bd}$ for trigger injection and then perturb samples in D_{cm} to maximize the loss at backdoor samples based on influence functions for inactivation in the training process.

To this end, the adversary first fine-tunes the surrogate model θ_s^* with auxiliary clean samples D_{atk}, since θ_s^* may be trained on public data from different distributions,

$$\theta_{s,0}^* = finetune(\theta_s^*, D_{atk}), \tag{6}$$

where $finetune : \Theta \times \mathcal{Z}^* \to \Theta$ refers to the fine-tuning function that adjusts the last fully connected layers of the model. In the i-th tuning epoch, $i \in [1,N]$, the adversary fine-tunes $\theta_{s,0}^*$ with the auxiliary dataset $D_{atk,i-1}$, and gets $\theta_{s,i}^*$.

$$\theta_{s,i}^* = finetune(\theta_{s,0}^*, D_{atk,i-1}), i \in [1,N]. \tag{7}$$

Given the surrogate model $\theta_{s,i}^*$, camouflage samples can be updated through the influence function $I_{pert,loss}$, increasing their concealing effects on the backdoor. In particular, for a camouflage sample $\widetilde{z} \in D_{cm,i-1}$, we define $I_{pert,loss}(\widetilde{z}, D_{bd})$ as

$$\begin{aligned} &I_{pert,loss}(\widetilde{z}, D_{bd}) = \mathop{\mathbf{E}}_{z' \in D_{bd}} (I_{pert,loss}(\widetilde{z}, z')) \\ &= -\mathop{\mathbf{E}}_{z' \in D_{bd}} (\nabla_\theta \ell(z', \theta_{s,i}^*)^\top)(\frac{1}{m} \sum_{k=1}^{m} \nabla_\theta^2 \ell(z_k, \theta_{s,i}^*))^{-1} \nabla_x \nabla_\theta \ell(\widetilde{z}, \theta_{s,i}^*), \end{aligned} \tag{8}$$

where m is the size of the auxiliary dataset i.e. $m = |D_{atk,i-1}|$, and $z_k \in D_{atk,i-1}, k \in [1,m]$.

Given the influence, the adversary perturbs $\widetilde{z}$ with $I_{pert,loss}(\widetilde{z}, D_{bd})$ iteratively,

$$\begin{aligned} &\widetilde{z}^j = \Pi_{\varepsilon,\widetilde{z}_0}(\widetilde{z}^{j-1} + \alpha\, sign(I_{pert,loss}(\widetilde{z}^{j-1}, D_{bd}))), \\ &\widetilde{z}^0 := \widetilde{z}\ and\ j \in [1,n], \end{aligned} \tag{9}$$

where n denotes the iteration times, α is a step size while Π projects onto the set of valid images that share the same 8-bit representation with $\widetilde{z}$ and ε is the offset bound such that $\widetilde{z}^j - \widetilde{z}_0$ is no larger than ε. $\widetilde{z}_0$ is the non-perturbed version from $D_{cm,0}$ because the perturbation should not be overwhelming to guarantee stealthiness.

At the end of the optimization, we get influence-enhanced camouflage sample $\widetilde{z}^n$ such that

$$\widetilde{z}^n = \Pi_{\substack{\varepsilon,\widetilde{z}_0 \\ j=0}}^{n}(\widetilde{z}^j + \alpha\, sign(I_{pert,loss}(\widetilde{z}^j, D_{bd}))). \tag{10}$$

By applying the algorithm to all samples in $D_{cm,i-1}$, the adversary gets $D_{cm,i}$ such that

$$D_{cm,i} = \left\{ \widetilde{z}^n \middle| \widetilde{z} \in D_{cm,i-1} \right\}, \tag{11}$$

which is the camouflage result of epoch i. The auxiliary dataset is thus updated with $D_{cm,i}$, i.e., $D_{atk,i} = (D_{atk,i-1} \setminus D_{cm,i-1}) \cup D_{cm,i}$. After N epochs, the adversary generates the final influence-enhanced camouflage samples $D_{cm} = D_{cm,N}$, where N is the total iteration epochs. The complete camouflage generation algorithm is summarized in Algorithm 1.

4.3 UBA-Inf Implementation

Having camouflage generation accomplished, we now introduce practical UBA-Inf implementations in both OT-MLaaS and CT-MLaaS, attacking on-cloud models with interfaces Upd_{add}, Upd_{del}, and ψ. To interpret implementation differences between the conventional backdoor approach and a UBA-Inf approach, we give demos in Figure 3 and Figure 4.

1. Camouflage generation stage. Since backdoor generation and camouflage generation are offline processes, things are the same in both OT-MLaaS and CT-MLaaS. The adversary generates backdoor samples D_{bd} with a selected backdoor trigger and camouflage samples D_{cm} through Algorithm 1 beforehand.
2. Trigger injection stage. In OT-MLaaS, the adversary uploads all crafted samples through $Upd_{add}(D_{bd} \cup D_{cm})$ and waits for the SP to train and deploy the victim model θ_v^*. In CT-MLaaS, the adversary can inject backdoor and camouflage samples in continuous learning tasks. For brevity, we assume that the adversary injects both backdoor and camouflage samples through

Algorithm 1 IBAU Camouflage Generation Algorithm

Input: θ_s^* (pre-trained surrogate model)
D_{bd} (backdoor samples)
D_{atk} (auxiliary samples)
B_X, y_{tgt} (backdoor trigger and target class)
N (total iteration epochs)
n, ε, α (adversarial perturbation parameters)
Output: D_{cm} (UBA-Inf camouflage samples)

$\theta_{s,0}^* \leftarrow finetune(\theta_s^*, D_{atk})$
$D_{cm,cl} \leftarrow \{ (x,y) | (x,y) \in D_{atk} \wedge y \neq y_{tgt} \}$
$D_{cm,0} \leftarrow \{ (B_X(x), y) | (x,y) \in D_{cm,cl} \}$
$D_{atk,0} = (D_{atk} \setminus D_{cm,cl}) \cup D_{bd} \cup D_{cm,0}$
for each iteration $i \in [1, N]$ **do**
  $\theta_{s,i}^* \leftarrow finetune(\theta_{s,0}^*, D_{atk,i-1})$
  $D_{cm,i} \leftarrow \emptyset$
  for $\widetilde{z} \in D_{cm,i-1}$ **do**
    $\widetilde{z}^0 \leftarrow \widetilde{z}$
    for each perturbation $j \in [1, n]$ **do**
      $I_{pert,loss}(\widetilde{z}^{j-1}, D_{bd}) \leftarrow \mathop{\mathbf{E}}_{z' \in D_{bd}} (I_{pert,loss}(\widetilde{z}^{j-1}, z'))$
      $\widetilde{z}^j \leftarrow \Pi_{\varepsilon, \widetilde{z}_0}(\widetilde{z}^{j-1} + \alpha sign(I_{pert,loss}(\widetilde{z}^{j-1}, D_{bd})))$
    end for
    $D_{cm,i} \leftarrow D_{cm,i} \cup \{\widetilde{z}^n\}$
  end for
  $D_{atk,i} \leftarrow (D_{atk,i-1} \setminus D_{cm,i-1}) \cup D_{cm,i}$
end for
$D_{cm} \leftarrow D_{cm,N}$
return D_{cm}

$Upd_{add}(D_{bd,p} \cup D_{cm,p}), i \leq p < k$, while in the subsequent tasks, only backdoor samples can be injected by $Upd_{add}(D_{bd,p}), k \leq p \leq j$.

3. Backdoor activation stage. Having the backdoor and camouflage samples injected, the adversary can choose the right time to activate the backdoor by unlearning camouflage samples. Generally, the adversary can revoke camouflage samples through $Upd_{del}(D_{cm})$ in both OT-MLaaS and CT-MLaaS. However, θ_v^* is continuously updated on clean samples in CT-MLaaS. Therefore, the adversary can observe the behavior of θ_v^* through the query API ψ and choose the activation timing, e.g., when ASR is about to decrease below a certain threshold.
4. Backdoor exploitation stage. After the backdoor is activated and enhanced by unlearning, the adversary can utilize the backdoor in θ_v^* at any time. The backdoor can be simply exploited by the adversary through the query API ψ in both OT-MLaaS and CT-MLaaS.

5 Evaluation

We will evaluate the effectiveness, stealthiness, persistence, and resistance to defenses of UBA-Inf in different MLaaS scenarios. Before showing the results, we will introduce the learning setting, backdoor attacks and defenses, unlearning algorithms, and UBA-Inf configurations.

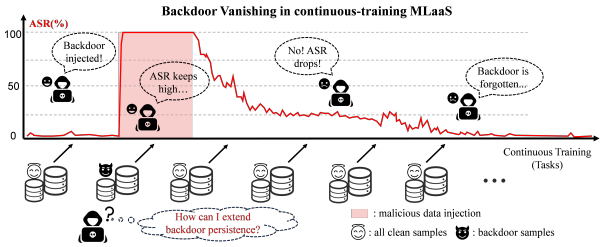

Figure 3: An illustration of backdoor vanishing.

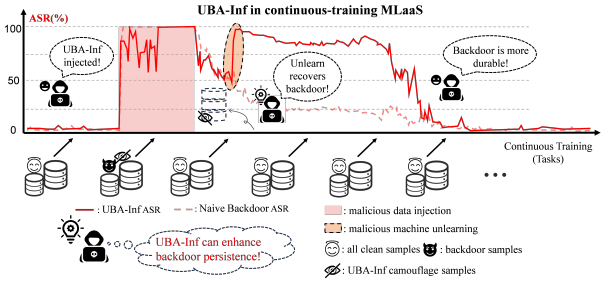

Figure 4: An overview of UBA-Inf workflow in CT-MLaaS.

5.1 Experiment Settings

Datasets and models. We conduct experiments on widely-adopt image classification datasets, including CIFAR-10 [35], GTSRB [60], MNIST [36] and Tiny-ImageNet [34] (Tiny for short), covering a wide range of image classification with different learning complexities. We use 3 popular deep models for experiments, namely PreactResNet-18 [27] (PARN-18 for short), VGG-16 [41] and ResNet-34 [26]. For the CIFAR-10 dataset, we use all three models for the experiment[1], while for MNIST, GTSRB, and Tiny, we use PARN-18 only since all three models perform similarly on these three datasets.

Learning settings. By default, models are all trained for 120 epochs on 4 datasets using a stochastic gradient descent (SGD) optimizer with a momentum of 0.9, an initial learning rate of 0.1, a weight decay factor of 1e-4, and a batch size of 128. Specifically, models on Tiny are trained without optimization techniques like data augmentation, resulting in a relatively low BA of around 55%. As a result, the attack performance on Tiny may not be as strong as on the other datasets, where BA exceeds 90%.

CT-MLaaS uses a specific data setting. We assume that data for each learning task in CT-MLaaS is 30% of the original training set, which is uniformly and randomly sampled. We consider domain-incremental learning for CT-MLaaS. To form datasets for different domain-incremental tasks, we use the random rotation transformations as Rotated-MNIST [46] for CIFAR-10 and MNIST.

Backdoor attacks and defenses. Since UBA-Inf is orthogonal to backdoor generation algorithms, we will use differ-

[1] If not specified, PARN-18 will be used for further evaluations like defense evaluations on CIFAR-10.

ent backdoor attacks for evaluation, including 2 dirty-label attacks, namely BadNets [21] and Blended [14], and 2 clean-label attacks, namely LC [66], and Sig [65]. In fact, UBA-Inf can be improved by advanced backdoor generation methods like Narcissus [75]. On the other hand, multiple backdoor defenses will be used to evaluate the resistance of UBA-Inf. We group them by defense techniques, namely *anomaly detectors*, including NC [67], Pixel-Backdoor [62], and AEVA [23], *outlier filters*, including Spectre [25], ABL [38], and D-BR [13], *model reconstructors*, including standard fine-tuning, Fine-pruning [40], CLP [81], and NAD [39]. All backdoor attacks and defenses are implemented by following the instructions in the original papers. However, since learning settings and scenarios are different, their performance may vary from the original results.

Unlearning algorithms. We use 4 advanced unlearning algorithms, including SISA [9], PUMA [70], GBU [69] and LIRF [74]. Table 2 demonstrates the applicable cases of these algorithms, which cover the most unlearning strategies and MLaaS scenarios. For all unlearning algorithms, we use the suggested settings in the original papers. Some unlearning algorithms rely on empirically set unlearning rates [69, 70, 74] tailored for MLaaS needs. Under these circumstances, all unlearning rates in this work fall within the recommended ranges from the original sources [69, 70, 74].

- **SISA** [9]. A popular exact unlearning algorithm based on training data separation, known as sharding and slicing, generates results through the aggregation of sub-models.
- **PUMA** [70]. An approximate unlearning algorithm based on data removal through samples' influence and an optimized up-weighting strategy.
- **GBU** [69]. A first-order approximate unlearning algorithm by leveraging irrelevant samples with perturbations to overwrite unlearned samples.
- **LIRF** [74]. A recoverable unlearning algorithm specifically designed for CT-MLaaS, which fine-tunes the target model on randomly labeled unlearned samples with a combination of cross-entropy loss and filtered attention distillation loss.

Recently, defense methods have been proposed for unlearning [78], We will deploy model-uncertainty (MU) for all unlearning algorithms and sub-model similarity (SMS) for SISA algorithms.

UBA-Inf configurations. We separate 10% of the training dataset as an auxiliary dataset D_{atk}, which has been widely used in related studies [39, 40, 67]. We use ConvNeXt-tiny [45] pre-trained on ImageNet [15] as an off-the-shelf surrogate model, which is publicly available on PyTorch website [53]. We set total iterations $N = 8$, tuning epochs $E = 60$, perturbation iterations $n = 40$, perturbation limit $\varepsilon = 2/255$, perturbation stepsize $\alpha = 0.5/255$. As for backdoor configurations, we assume that the total number of D_{bd} and D_{cm} is less than 5% of the total training data, while the ratio of camouflage samples to backdoor samples is no greater than 2. That means $|D_{cm}| + |D_{bd}| < 0.05 * |D_{trn}|$ and $|D_{cm}|/|D_{bd}| \leq 2$ if without any explanations. We compare UBA-Inf with related work BAMU [78], which is implemented based on BadNets for retraining based unlearning.

5.2 Effectiveness Evaluation

Unlike conventional backdoor attacks, UBA-Inf maintains a low ASR in a camouflage state and is expected to activate the backdoor by machine unlearning for fine-grained control. In brief, camouflage samples in UBA-Inf are used to enhance backdoor stealthiness and robustness, improve persistence in continual learning, and provide fine-grained backdoor activation control. Therefore, we will evaluate the camouflage effectiveness first and evaluate backdoor effectiveness in various unlearning scenarios as shown in Table 2.

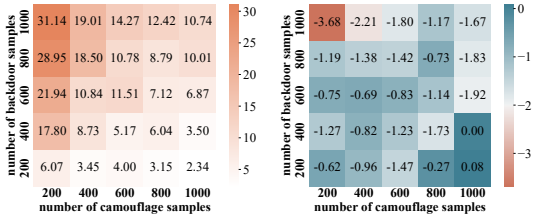

Figure 5: ASR (left figure) and NC anomaly index (right figure) of UBA-Inf for different numbers of backdoor and camouflage samples. Backdoors are detected by NC with an anomaly index below -2 [67].

We first evaluate camouflage effectiveness by checking the ASR of UBA-Inf with BadNets (left of Figure 5). We train CIFAR-10 models in 25 settings (5 amounts of backdoor samples times 5 amounts of camouflage samples). The ASR remains at 31.94% even with 5 times more backdoor samples. By increasing the camouflage sample amount, UBA-Inf can achieve ASR as low as 2.34%.

NC [67] detects backdoors with an anomaly index below -2. The right of Figure 5 shows UBA-Inf protects backdoors from detection with enough camouflage samples. Models with an ASR below 30% typically evade NC detection with an anomaly index greater than -2. We can conclude that UBA-Inf has better camouflage effectiveness and attack performance than existing work like [78].

5.2.1 UBA-Inf Activation Effectiveness in FA-MLaaS

In FA-MLaaS, all training samples are accessible to the SP for unlearning. As indicated in Table 2, we can evaluate UBA-Inf through multiple unlearning algorithms in this setting, including full retrain, SISA, and PUMA[2].

Table 3 and 4 show the results of BA and ASR before and after the camouflage samples are removed by full retraining and SISA [9], respectively. Different backdoor attacks are evaluated. The ASR varies from 0.02% to 29.42% when

[2]The injection rate of evaluations can be found in Appendix A. We suppose all samples are exactly unlearned at once. Appendix D demonstrates evaluations on different unlearning batch sizes.

Table 3: Backdoor effectiveness evaluation for full retrain. Italic numbers with underlines indicate backdoor ASR after unlearning.

backdoors are concealed. After unlearning, backdoors are activated, and ASR rises sharply to nearly 100% in most cases.

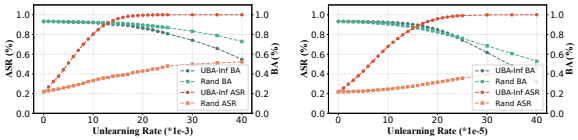

Figure 6: Unlearn UBA-Inf camouflage (UBA-Inf) and Random clean samples (Rand) by PUMA [70] (left figure) and GBU (right figure) [69] with different unlearning rate on a CIFAR-10 model.

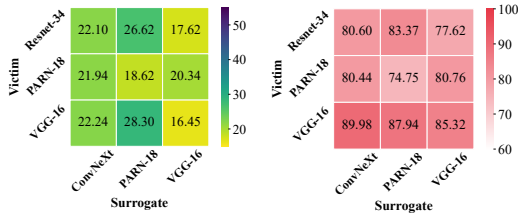

Figure 7: The ASR before unlearning (left figure) and after PUMA unlearning (right figure) with different UBA-Inf surrogate models and target models.

The evaluation results of UBA-Inf with PUMA are shown in Table 5. We find that for all cases after unlearning, the ASR rises above 80% with BA dropping less than 4%. This indicates that UBA-Inf can suit PUMA very well. Unlike full retrain and SISA, the unlearning rate in PUMA is an important hyper-parameter since it can affect PUMA performance significantly. Thus, we evaluate the effects of unlearning rates on BA and ASR for PUMA in the left of Figure 6. By observing the effects on BA when unlearning clean samples, we can tell that the unlearning rate should not exceed 3e-2, in which case ASR can keep above 90% if camouflage samples are unlearned.

5.2.2 UBA-Inf Activation Effectiveness in RA-MLaaS

In RA-MLaaS, the access to original training data during unlearning is highly restricted [29], and only data to be removed is available. In RA-MLaaS, GBU [69][3] is a gradient-based unlearning algorithm. By adopting GBU in RA-MLaaS, the data to be removed will be replaced by perturbed data for unlearning. The results of UBA-Inf with GBU are shown in Table 6. Similar to the results of UBA-Inf with PUMA, unlearning through GBU makes ASR increase from around 22% to above 80%, with BA dropping less than 4% in all cases. The right of Figure 6 presents the effects of unlearning rates for UBA-Inf with GBU. When the unlearning rate is no larger than 1e-4, unlearning clean samples has a negligible effect on BA, while unlearning camouflage samples can increase ASR to around 70%.

5.2.3 Effectiveness Comparisons with BAMU

Like UBA-Inf, BAMU [78] uses unlearning camouflage samples to activate backdoors. However, Table 7 shows UBA-Inf surpasses BAMU in camouflage effectiveness and activation effectiveness. With the same injection rate, UBA-Inf's ASR is at least 10% lower than BAMU's before unlearning, showing that UBA-Inf can provide better camouflage effectiveness. After exact unlearning like full retraining, the ASR after unlearning largely depends on the backdoor trigger instead of the camouflage-generating algorithm, so the ASR is similar for both methods. Meanwhile, BAMU doesn't support approximate unlearning algorithms, so we reproduced it with PUMA and GBU following its original idea. After unlearning using PUMA [70] and GBU [69], UBA-Inf's ASR is about 20% higher than BAMU's, indicating UBA-Inf's adaptability and superior attack performance in different unlearning strategies.

5.2.4 Evaluation of the Surrogate Model

We evaluate UBA-Inf with different surrogate model settings. Figure 7 demonstrates attack results of UBA-Inf on CIFAR-10 with different surrogate models and different victim models. The ASR before unlearning keeps lower than

[3] Here we only evaluate on the first-order GBU [69]. We further evaluate the second-order GBU [69] in Appendix B.

† BAMU fails in MNIST with ASR higher than 80%, which completely has no camouflage effect.

30% while rising to at least around 75% after PUMA unlearning, which means UBA-Inf achieves satisfactory camouflage effectiveness and activation effectiveness under different surrogate model settings. In other words, the attack performance of UBA-Inf is not depended on a specific surrogate model setting.

5.3 Stealthiness Evaluation

Having noticed backdoor threats, the SP deploys backdoor defenses to protect MLaaS from suspicious backdoor samples, including outlier filter defenses [13, 25, 38] and model scanner defenses [23, 62, 67]. Furthermore, recent studies provide the SP with defenses against UBA [78] in particular. We will demonstrate the stealthiness of our UBA-Inf by evaluating the deceiving result of conventional backdoor defenses and UBA defenses in comparison with BAMU [78]. In previous experiments, we have evaluated different backdoor generation algorithms on multiple datasets, from which we can conclude that BadNets is suitable for further evaluation as a typical generation method to simplify the discussion.

5.3.1 Evaluation of Outlier Filter Defense

Outlier filters defend MLaaS against backdoor attacks by filtering out suspicious samples in the training and inference processes. Three popular outlier filters, Spectre [25], D-BR [13], and ABL [38], are used for evaluating the stealthiness of camouflage samples in UBA-Inf. We use outlier filters to detect suspicious samples and present the result of poisoning samples in Figure 8. It shows that Spectre, ABL (with isolation rate equal to 10%), and D-BR filter about half of and almost backdoor samples generated by naive BadNets, respectively. However, only about 10% UBA-Inf backdoor samples under camouflage are correctly detected by Spectre and ABL. In the worst case, D-BR detects about 30% UBA-Inf backdoor samples on GTSRB. Even so, the rest samples are enough for the attack according to the effectiveness evaluation. We find that UBA-Inf's ASR is around 20% before unlearning and rises to over 85% after unlearning under outlier filters like Spectre and D-BR. UBA-Inf also protects more poisoning samples from detection than BAMU [78], providing better stealthiness.

5.3.2 Evaluation of Model Scanner Defense

Model scanners verify whether the model has potential backdoor threats and attempt to reverse-engineer the backdoor trigger. Three popular model scanner defenses and corresponding anomaly indexes are used for the evaluation, i.e.,

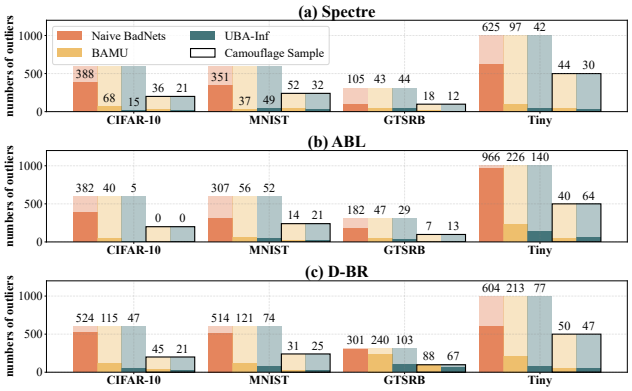

Figure 8: Filtered suspicious samples in backdoor and camouflage by Spectre, ABL, and D-BR. Bars without and with a border represent backdoor and camouflage samples, respectively. Bars in light and dark colors indicate all and detected samples, respectively.

NC [67], PB [62], and AEVA [23]. SP can employ model scanners before and after unlearning. However, frequent scanning after each unlearning request is overwhelmingly time-consuming.

Figure 9 demonstrates different anomaly indexes of one target class before unlearning. The more negative the anomaly indexes, the more likely a class has backdoors. With naive BadNets, all three scanners detect the backdoor in the target class with highly negative anomaly indexes. However, with UBA-Inf camouflage, these indexes become less negative or even positive. Using the -2.0 threshold from [67], none of the scanners can detect the backdoor injected by UBA-Inf, while BAMU camouflages still get detected. We have only listed the target class because other classes are irrelevant to the backdoor attack. In Figure 10, we show an example of reverse-engineering a backdoor trigger using NC, from which we can easily conclude that UBA-Inf camouflage protects backdoor triggers from being revered effectively compared with naive BadNets and BAMU.

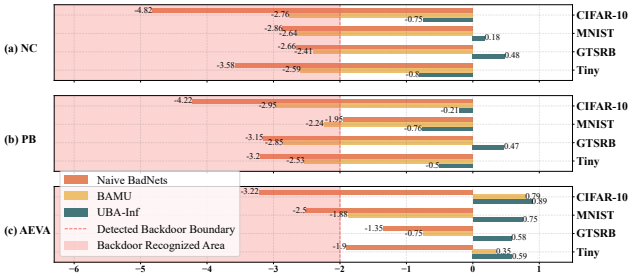

Figure 9: Anomaly indexes of one class (the 6th class in all datasets) calculated by NC, PB, and AEVA before unlearning.

When SP scans the model after unlearning, UBA-Inf with BadNets may be detected by backdoor scanners. However, UBA-Inf offers better flexibility with diverse backdoor generating algorithms and can evade detection by employing appropriate methods like Narcissus [75]. We compared BAMU with UBA-Inf using BadNets and UBA-Inf using Narcissus.

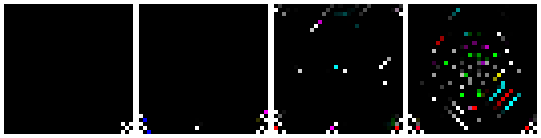

Figure 10: From left to right is the true trigger and the reversed trigger of naive BadNets, BAMU [78] and UBA-Inf, respectively. The camouflage of UBA-Inf is more effective.

Figure 11 demonstrates that BadNets-based UBA-Inf is vulnerable to post-unlearning defenses, UBA-Inf with Narcissus effectively eludes these scanners with anomaly indexes above -0.67 or even positive. This suggests UBA-Inf's resilience to model scanning persists even after unlearning, leveraging suitable backdoor generating methods.

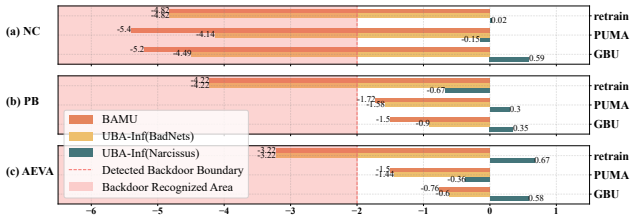

Figure 11: Anomaly indexes of one class (the 6th class in CIFAR-10 [35]) calculated by NC, PB, and AEVA after full retrain, PUMA [70] and GBU [69] unlearning.

5.3.3 Evaluation of UBA Defense

In a recent study [78], defenses dedicated to UBA have been proposed. In particular, model uncertainty (MU) for deep learning models and sub-model similarity (SMS) for SISA models are calculated to distinguish malicious samples from clean ones and reject suspicious unlearning requests[4]. Figure 12 indicates that MU fails to distinguish UBA-Inf samples from clean samples on all 4 datasets because the Gini impurity distribution of malicious samples generated by UBA-Inf is very similar to that of clean samples, which makes it impossible to define a proper threshold for identifying malicious samples. Table 8 shows UBA-Inf effectiveness when considering stealthiness under MU defense. If MU allows 10% false negative, which means 90% clean samples can pass MU defense, a large portion of malicious samples can also escape the defense and increase the ASR to over 80% in most cases through unlearning. Meanwhile, MU defenses cast more BAMU camouflage samples with the same 10% false negative. After unlearning, BAMU reaches lower ASRs against MU defenses, which is around 60% in most cases. This concludes that UBA-Inf is more stealthy and effective compared with BAMU, and MU cannot prevent UBA-Inf effectively.

Experimental results of SMS defense are given in Figure 13, showing the variance of the predicted value of SISA sub-models. On CIFAR-10 and Tiny, the distribution of UBA-Inf malicious samples looks very similar to the one of clean

[4]Here we only evaluate UBA-Inf against the MU defense and the SMS defense. More defenses designed for other unlearning vulnerabilities are represented in Appendix C.

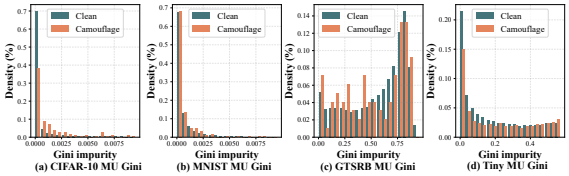

Figure 12: MU measured by Gini impurity on different datasets.

† Please note that BAMU does not have a masking effect on the MNIST dataset.

samples. Thus, most malicious samples generated by UBA-Inf can escape SMS defense when considering a reasonable false negative ratio. However, UBA-Inf malicious samples on MNIST and GTSRB can be effectively distinguished by SMS, which means most malicious samples generated by UBA-Inf will be rejected by SMS. Table 9 gives UBA-Inf effectiveness when considering stealthiness under SMS defense. The backdoor can be successfully activated and exploited on CIFAR-10 and Tiny while probabilistically activated on MNIST and GTSRB when using 5 shards for SISA. In the worst case, UBA-Inf can hardly succeed on GTSRB shen using 3 shards for SISA because most unlearning requests are rejected by SMS. We have observed that UBA-Inf effectiveness under SMS defense gets better when the shard number increases. Actually, practical applications commonly use more shards way beyond demo cases, which means UBA-Inf can cause practical threats when SISA uses more than 5 shards.

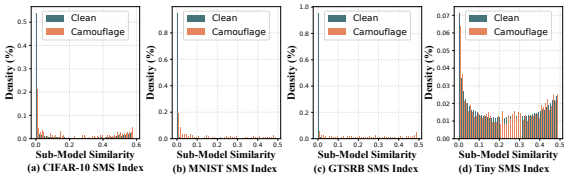

Figure 13: SMS measured by sub-model prediction variance for 3-shard SISA.

5.4 Evaluation of Resistance to Reconstruction

Model sanitizing or transforming modifies model parameters to eliminate potential backdoor threats. Such model reconstruction may affect the activation of UBA-Inf. Three model reconstructors are used for UBA-Inf resistance evaluation, i.e., naive fine-tuning (FT), fine-pruning (FP) [40], and neural attention distillation (NAD) [39]. Please note that since exact unlearning algorithms retrain model parameters on contaminated datasets, they invalidate previous model reconstruction defenses. Thus, we will focus on the evaluation of approximate unlearning like PUMA and GBU. Like model scanning, SP can employ a model reconstructor before or after model updating. However, reconstruction defenses after each unlearning inevitably bring significant time overheads.

Table 10: UBA-Inf evaluation after model reconstruction.

Table 10 gives the results of UBA-Inf effectiveness after model reconstruction before unlearning, from which we can tell that model reconstruction certainly increases the robustness of the target model, lowering ASR of UBA-Inf than without reconstructing, as shown in Table 5 and Table 6. Even so, UBA-Inf gives satisfying ASRs on CIFAR-10, MNIST, and GTSRB. Even in the worst case of Tiny, the ASR of UBA-Inf exceeds 40%, still posing high backdoor risks.

Table 11: Backdoor evaluations of BAMU, UBA-Inf(BadNets), and UBA-Inf(Narcissus) against FT, FP, and NAD defenses after full retrain, PUMA, GBU unlearning, respectively.

Method	Unlearn algorithm	After unlearn		FT after unlearn		FP after unlearn		NAD after unlearn	
		BA(%)	ASR(%)	BA(%)	ASR(%)	BA(%)	ASR(%)	BA(%)	ASR(%)
BAMU	full retrain	93.48	100.00	91.89	10.14	91.83	7.86	92.59	9.24
	PUMA	89.50	50.10	91.88	11.49	91.58	5.02	91.81	7.74
	GBU	90.11	52.53	91.90	11.71	91.56	5.16	90.89	7.52
UBA-Inf (BadNets)	full retrain	93.48	100.00	91.89	10.14	91.83	7.86	92.59	8.24

	GBU	90.77	84.52	93.84	53.61	93.74	54.61	93.62	50.90

As discussed in model scanning, when SP will perform defenses at any cost after unlearning, UBA-Inf using BadNets can be mitigated. In this case, UBA-Inf can use suitable triggers like Narcissus to resist post-unlearning model reconstruction. We compared BAMU with UBA-Inf using BadNets and UBA-Inf using Narcissus. Table 11 shows UBA-Inf's resilience to defenses after unlearning. While BAMU's ASR drops to around 10%, UBA-Inf maintains at least 50% ASR by switching the trigger from BadNet to Narcissus. For models with full retraining, UBA-Inf's ASR stays above 80% with Narcissus. This suggests that UBA-Inf can withstand model

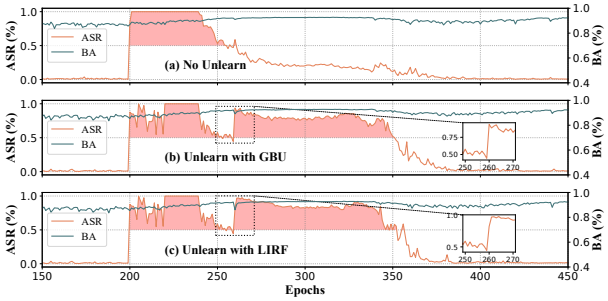

Figure 14: Persistence evaluation on CIFAR-10.

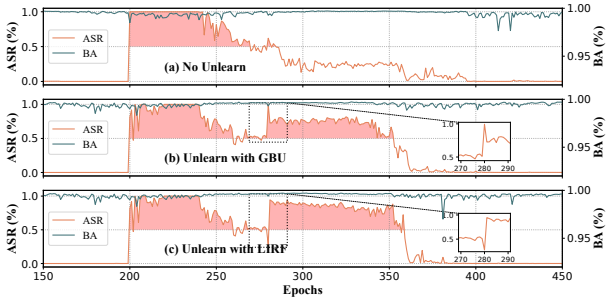

Figure 15: Persistence evaluation on Rotated-MNIST.

reconstruction even after unlearning when leveraging proper backdoor triggers.

5.5 Persistence Evaluation

Unlike OT-MLaaS, CT-MLaaS continuously updates the on-cloud model with newly coming training data [58, 59]. Thus, we should consider the persistence of the injected backdoor. The adversary of UBA-Inf expects the injected backdoor to keep away from backdoor vanishing caused by catastrophic forgetting [68]. We will evaluate the backdoor persistence after being activated using two unlearning methods as indicated in Table 2, i.e., GBU [69] and LIRF [74].

Assuming new training data comes in tasks, we use CIFAR-10 for continuous learning in the same domain [52], and Rotated-MNIST [46] for domain incremental learning where training data in different tasks comes from different domains [68, 82]. In either case, we train a PRAN-18 model with clean samples for 10 tasks (200 epochs) before injecting malicious samples and with malicious samples for 2 tasks (40 epochs), after which the model will learn continuously with only clean samples. For naive BadNets, the adversary injects 400 backdoor samples in 2 tasks (epoch 200 to 240). As for UBA-Inf, 400 backdoor samples are injected in the same way, while 200 camouflage samples will also be injected from epoch 200 to 220. UBA-Inf achieves backdoor activation through unlearning instead of learning. Hence, the criteria is timing for unlearning. Better ASR is achieved with earlier unlearning before catastrophic forgetting. UBA-Inf can significantly prolong the backdoor effect even if unlearning occurs when the ASR drops to 50%, which corresponds to epoch 260 for CIFAR-10 and epoch 280 for Rotated-MNIST.

The first row of Figure 14 and Figure 15 demonstrates the ASR trends of naive BadNets in continuous learning on CIFAR-10 and Rotated-MNIST respectively, which drop below 50% in about 20 epochs after backdoor samples have been injected. The last two rows of Figure 14 and Figure 15 show the ASR of UBA-Inf with GBU unlearning and the ASR of UBA-Inf with LIRF unlearning, respectively. ASRs of the last two rows share a similar dropping to below 50% before unlearning, just like the naive BadNets. However, when the adversary activates the backdoor through unlearning camouflage samples, ASRs of UBA-Inf rise to a new peak immediately. Moreover, ASRs of UBA-Inf remain around 70% to 80% and drop below 50% after 80 epochs, which significantly extends the persistence of the backdoor's effect. Compared with the conventional backdoor attack, UBA-Inf enhances the backdoor persistence after activation by about 4 times.

6 Related work

6.1 Backdoor Attacks and Defenses

Neural backdoor attack embeds backdoors into DNNs to induce twisted predictions evoked by the trigger pattern. [44]. BadNets [21] leverages a small patch as the trigger pattern. LC [66] combines BadNets with adversarial perturbations to perform a clean-label attack effectively. Blended [14] directly blends a cartoon image or a random pattern with the input. Sig [65] injects a sinusoidal signal pattern on images, which is a strip-like pattern. Narcissus [75] optimizes the trigger pattern in a way that points towards the inside of the target class. More backdoor generating methods have been proposed for better effectiveness and stealthiness [37, 76].

Recent works have shown the worrying threat of more complicated backdoor attack workflows. For example, latent backdoor attacks conceal backdoors initially but then activate it with fine-tuning [50] or exact machine unlearning [78]. The comparison between recent backdoor activation approaches is given in Table 12. Existing approaches either require full control of the training process for poisoning [32, 50] or depend on replayed backdoor injection [82]. Meanwhile, recent works also expose the backdoor vanishing problem in continuous learning [32, 82]. However, UBA-Inf can achieve the same adversarial goals under more restrictions, including continuous learning, making it a more disturbing attack on MLaaS.

Various defenses have been proposed against backdoor attacks. Generally, backdoor defenses can be categorized as 1) *model scanners* [23, 62, 67], which conduct reverse engineering to decide whether a certain class has been poisoned and identify the potential backdoor triggers, 2) *outlier filters* [13, 25, 38], which detect malicious training data and gives them up during training or fine-tunes the model to mitigate backdoor after training; and 3) *model reconstructors* [39, 40, 81], which reconstruct the victim model through

Table 12: Different properties and applicable scenarios of existing latent backdoor approaches.

methods like neuron pruning [40] or channel shuffling [81]. We will show that UBA-Inf in the camouflage state is immune to these defense solutions, calling for more robust backdoor defenses and more secure MLaaS mechanisms.

6.2 Machine Unlearning

Machine unlearning aims to remove sensitive samples from the MLaaS model [72]. Intuitively, full retraining is the most naive solution, but it costs too much time and resources [29].

Exact machine unlearning is based on model retraining. SISA [9] reorganizes the training data in sharding and slicing to reduce the execution time of retraining. It aggregates the results of sub-models as the final result. Many exact unlearning solutions inherit SISA. ARCANE [73] designed an efficient architecture for exact unlearning. A study [10] introduced SISA into recommendation systems. Another work [12] adopted SISA to graph data. All of these exact unlearning algorithms require full access to the training dataset.

Approximate unlearning algorithms exploits feasible ways to speed up the unlearning process [72]. Some works exploit the second-order Hessian matrix, which requires full access to training data for unlearning. For instance, PUMA [70] relies on influence functions [33] and re-weighting methods to remove data without compromising model performance. Some works exploit first-order gradients [63, 69] or tailored loss functions [74] instead. Gradient-Based Unlearning (GBU) [69] replaces a data sample with the adversarially perturbed one through first-order or second-order gradient-decent optimization. Fine-tuning has been widely used as an empirical unlearning baseline in existing works [19, 63, 72]. Besides, LIRF [74] is tailored to recoverable knowledge removal in continual learning. It assumes that the upper layers have completely transferred to new knowledge and only modifies the lower layers through a tailored loss function combined with the cross-entropy loss and the filtered attention distillation loss on randomly labeled samples.

Recent studies have exposed vulnerabilities in machine unlearning, such as slowdowns caused by malicious data removal [49], degradation in model performance on clean data [29, 54], and latent attacks that confuse defenders [16, 78]. Some solutions have been proposed to counter malicious unlearning. For instance, Zhang et al. [78] utilized Gini impurity and sub-model similarity to identify malicious unlearning, assuming that malicious samples exhibit larger prediction uncertainty and poor generalization across sub-models. Additionally, other defenses like hashing [29] or medoid optimization [54] have been explored. However, we demonstrate that our UBA-Inf method can bypass these defenses, underscoring the need for more robust and effective unlearning defenses.

7 Conclusion

Our work presents a novel approach to implementing effective and stealthy backdoor attacks on MLaaS platforms using machine unlearning. We introduce an influence-enhanced unlearning-activated backdoor attack method, which can not only strengthen backdoor robustness but also improve backdoor persistence in continuous learning, thus shedding light on the vulnerabilities of current unlearning procedures in MLaaS contexts. Through extensive evaluations, we demonstrate UBA-Inf's resistance to defenses across various MLaaS scenarios, achieving high attack success rates with improved stealthiness and robustness compared to existing approaches.

Note that our work gives an alternative backdoor approach with fine-grained control of backdoor activation. However, dedicated backdoor designs are orthogonal to our work, which means this approach can also be applied to advanced backdoor triggers in the future. Meanwhile, we should also note that novel defenses may mitigate UBA-Inf in the future. In this case, the adversary could take novel defenses into camouflage optimization process as constraints if defense strategies are known. Moreover, UBA is an example of leveraging unlearning for attacks. Other types of attacks, like poisoning and inference, may be of interest in future work.

APPENDIX

A Discussion of Injection Ratio

Intuitively, a high injection ratio of backdoor samples to camouflage samples brings a high ASR. However, this is bad for backdoor stealthiness. Thus, UBA-Inf aims at low injection ratios of both backdoor samples and camouflage samples. Table 13 gives injection ratios used in full retrain (shard=1), SISA (shard=3,5), and approximate unlearning algorithms (e.g., PUMA and GBU). Please note these injection ratios are relatively lower than existing studies.

Table 13: Injection ratios of backdoor(b) and camouflage(c) samples.

Shards	BadNets		Blended		LC		Sig	
	b(%)	c(%)	b(%)	c(%)	b(%)	c(%)	b(%)	c(%)
CIFAR-10								
shard=1†	1.20‡	0.40	0.50	1.00	6.00	1.00	1.20	0.40
shard=3	1.20	0.60	1.20	2.40	6.00	1.80	1.20	0.40
shard=5	2.00	1.00	2.00	4.00	10.00	3.00	3.00	1.00
MNIST								
shard=1†	0.40	1.00	0.40	0.80	8.00	1.00	8.00	1.00
shard=3	0.40	1.00	0.40	0.80	8.00	1.00	8.00	1.00
shard=5	0.40	1.00	0.40	0.80	8.00	1.00	8.00	1.00
GTSRB								
shard=1†	0.80	0.25	0.80	2.00	0.95	0.10	0.95	0.10
shard=3	0.80	0.25	0.80	2.00	0.95	0.10	0.95	0.10
shard=5	0.80	0.25	0.80	2.00	0.95	0.10	0.95	0.10
Tiny								
shard=1†	1.00	0.50	0.80	2.00	0.50	0.50	0.50	1.00
shard=3	1.00	0.50	0.80	2.00	0.50	0.50	0.50	1.00
shard=5	1.00	0.50	0.80	2.00	0.50	0.50	0.50	1.00

† shard=1 represents injection rates for full retrain, PUMA and GBU.
‡ When BadNets attacks VGG-16 trained on CIFAR-10, backdoor ratio is 0.4% instead of 1.2%.

B Effectiveness on Second-Order GBU

In 5.2.2, we evaluate the effectiveness of UBA-Inf in RA-MLaaS with the first-order GBU unlearning algorithm [69]. The first-order GBU uses a first-order Taylor Series of model θ^* to derive the gradient updates. Here, we use $D_{rm} \subset D_{trn}$ to denote the set of targeted unlearning data and $\widetilde{D}_{rm} = \{\widetilde{z} \mid \widetilde{z} = (x+\delta, y), (x,y) \in D_{rm}\}$ where $x+\delta$ compose a perturbed version for unlearning. Then the model parameters are modified as $\theta^u \leftarrow \theta^* - \eta(\sum_{\widetilde{z}\in\widetilde{D}_{rm}} \nabla\ell(\widetilde{z},\theta^*) - \sum_{z\in D_{rm}}(z,\theta^*))$ where η is a pre-defined unlearning rate, ℓ is the loss function and θ^u denotes the unlearned model. Meanwhile, work [69] also proposed a second-order GBD algorithm. This second-order method uses the inverse Hessian matrix of the second-order partial derivatives to change the original model's parameters to obtain the unlearned model. The unlearned model can be formulated as $\theta^u \leftarrow \theta^* - H_{\theta^*}^{-1}(\sum_{\widetilde{z}\in\widetilde{D}_{rm}} \nabla\ell(\widetilde{z},\theta^*) - \sum_{z\in D_{rm}}(z,\theta^*))$ where $H_{\theta^*}^{-1}$ is the inverse Hessian matrix. As Table 6 demonstrates, Table 14 indicates second-order GBU unlearning camouflage samples make ASR increases from around 22% to above 80% with BA dropping less than 4% in all cases. As a result, we claim UBA-Inf can work with both first-order and second-order GBU algorithms.

Table 14: Backdoor effectiveness evaluation for Second-Order GBU.

Datasets	Models	conceal		unlearn	
		BA(%)	ASR(%)	BA(%)	ASR(%)
CIFAR-10	PARN-18	93.26	**21.94**	91.12	***80.86***

Tiny	PARN-18	55.56	**16.57**	51.02	***68.78***

C Discussion of Related Unlearning Defenses

Besides UBA defenses which we discuss in Section 5.3.3, work [29, 54, 78] also proposed possible defenses against malicious unlearning requests. Unlike UBA defenses, which are deliberately designed for unlearning camouflage samples, work [29, 54] consider a similar yet different threat model, in which the adversary perturbs some training samples and requests to unlearn these perturbed samples to corrupt the victim model. They reveal the risk of malicious unlearning and propose related unlearning defenses.

The authors of work [29] suggest *hashing* can effectively avoid malicious unlearning requests in their threat model because the samples for malicious unlearning are deliberately perturbed and different from the real ones in training. SP stores the hash value of each training sample and rejects the malicious unlearning requests if he finds that the hash values of the unlearned sample do not match the stored hash value. UBA-Inf can easily bypass the hashing defense because all camouflage samples the adversary needs to unlearn are already in the training dataset.

Work [54] finds that attackers can exploit influence function [33] to maliciously perturb training samples and mislead the victim model to make wrong predictions through unlearning. They discovered the perturbed samples for malicious unlearning are way different from clean samples in the gradient space. Therefore, instead of directly rejecting unlearning requests, they drop the corrected malicious samples that have a different gradient compared to other instances in their class. In order to find the corrected malicious samples, they can find

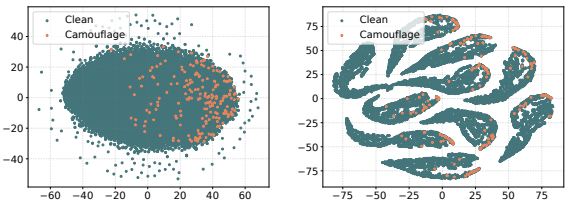

Figure 16: The t-SNE of clean and camouflage samples in the gradient space generated by the bottom layer (left one) and the top layer (right one) in the target model.

the medoids of each class in the gradient space. Such medoid-based defense fails to defeat UBA-Inf because camouflage samples share a similar gradient distribution with clean samples. Figure 16 indicates the t-SNE of clean and camouflage samples in the gradient space generated by both the bottom and top layers. The camouflage samples are completely mixed with clean samples in the gradient space, and one cannot separate them for successful medoid-based defenses.

In conclusion, there are few effective defenses against UBA-Inf, and the design of robust unlearning defenses is worryingly difficult. Firstly, recent unlearning defenses are particularly targeted at one specific risk, and such defenses often fail to defeat different unlearning attacks. This emphasizes the urge to design universal solutions to defend against various unlearning attacks. Secondly, recent defenses rely heavily on some important parameters like the threshold in [78] and the number of medoids in [54]. Setting such hyper-parameters requires a subtle balance between usability and security, which requires careful parameter tuning in real practice.

D Discussion of Unlearning Batch Size

In machine unlearning services, users remove certain data by unlearning requests. In former evaluations, we assume SP performed unlearning completely as the adversary requested, exactly removing all camouflage samples altogether. However, in some cases, SP may remove samples by batches [9, 72]. SP aggregates several small requests and divides large requests into batches for unlearning.

In exact unlearning, which is based on model re-training, batch size has little influence on UBA-Inf effectiveness because the unlearned model is essentially trained on the dataset with camouflage samples removed. However, different removal ratio (RR) of camouflage samples affects the UBA-Inf effectiveness. Table 15 demonstrates that when more camouflage samples are unlearned from the model, ASR becomes higher. When camouflage samples are completely removed, the ASR reaches nearly 100%. For better UBA-Inf effectiveness, the adversary should remove as many camouflage samples as possible.

In approximate unlearning like PUMA [70] and GBU [69], batch size of unlearn requests affects the removal of camouflage samples. If the unlearned batch size is large, camouflage samples are unlearned together with some extra clean samples.

Table 15: UBA-Inf effectiveness evaluation for full retrain with different removal ratios.

Dataset	CIFAR-10 [35]		MNIST [36]		GTSRB [60]	
$(\|D_{bd}\|, \|D_{cm}\|)$	(600,200)		(240,600)		(314,99)	
RR	BA(%)	ASR(%)	BA(%)	ASR(%)	BA(%)	ASR(%)
0	93.26	21.94	99.50	22.42	99.34	18.15
0.1	93.37	18.31	99.52	23.43	98.15	29.37
0.2	93.51	24.26	99.53	28.37	98.24	35.31
0.3	93.03	26.45	99.47	34.92	98.45	37.07
0.4	93.28	29.36	99.47	47.65	98.37	40.86
0.5	93.68	32.81	99.43	58.76	98.11	46.67
0.6	93.12	36.36	99.53	63.55	98.62	57.81
0.7	93.33	52.27	99.61	64.74	98.22	61.55
0.8	93.29	70.59	99.56	72.21	98.30	77.71
0.9	93.19	86.92	99.53	88.00	98.07	86.92
1.0	93.48	100.00	99.64	100.00	97.85	99.89

Table 16 indicates the UBA-Inf effectiveness with different unlearning batch sizes. There are 200 camouflage samples in total, and other unlearned data are randomly sampled from the clean samples. Statistics show that the UBA-Inf backdoor is successfully activated by unlearning camouflage samples mixed with some extra clean data, with ASR over 70% and BA over 85%. However, with a larger unlearning batch size, the ASR and BA become lower after unlearning.

Table 16: UBA-Inf effectiveness evaluation with different unlearning batch sizes.

	PUMA [70]		GBU [69]	
$(\|D\_bd\|, \|D\_cm\|)$	(600,200)		(600,200)	
Unlearning batch size	BA(%)	ASR(%)	BA(%)	ASR(%)
200	89.50	80.44	90.53	83.60
400	88.71	75.59	89.25	83.50
600	88.37	75.29	88.89	80.98
800	88.41	72.75	88.96	75.42
1000	88.08	74.83	88.56	67.71
2000	88.59	72.68	86.60	53.50
5000	85.55	67.13	84.51	19.71

Table 17: UBA-Inf effectiveness evaluation for multiple unlearning with small batch size.

	GBU [69]				
Unlearn times	0	1	2	3	4
BA(%)	93.26	92.76	93.28	93.31	91.20
ASR(%)	21.94	51.45	17.15	24.4	76.99
	PUMA [70]				
Unlearn times	0	1	2	3	4
BA(%)	93.26	93.26	92.14	88.22	90.33
ASR(%)	21.94	25.91	41.38	82.18	76.68

Meanwhile, when the unlearning batch size is too small, the camouflage samples need to be unlearned multiple times. If the batch size is 50, then the 200 camouflage samples should be removed in 4 batches. We evaluate the UBA-Inf effectiveness each time 50 camouflage samples are unlearned, and the results are displayed in Table 17. The UBA-Inf backdoor is activated after 4 times unlearning, with BA over 90% and ASR over 75%. In conclusion, UBA-Inf can be activated with different unlearning batch sizes, making it a more risky threat in practical MLaaS applications.
