Message from the USENIX Security '24 Program Co-Chairs

On behalf of USENIX, we welcome you to the proceedings of the 33rd USENIX Security Symposium.

It has been a great honor to serve as program chairs for the conference, and a privilege to work together with the amazing team that made the 2024 Symposium a great success.

This year set a new record for the number of submitted papers: 2176 valid submissions (not counting the 100 papers who did not follow the submission policies and that were therefore desk-rejected without reviews), divided in 488 submissions we received during the summer cycle, 946 in the fall, and 742 in the winter. Overall, this was a stunning 53% increase over the record number of submissions received by the conference in 2023.

To cope with the increased workload, we worked on two fronts. First, we increased the number of vice-chairs to six: Tiffany Bao (Arizona State University), Alexandra Dmitrienko (University of Wuerzburg), Qi Li (Tsinghua University), Giancarlo Pellegrino (CISPA Helmholtz Center for Information Security), Chen Yan (Zhejiang University), and Yupeng Zhang (University of Illinois at Urbana–Champaign). This conference would not be possible without their invaluable commitment, enthusiasm, and crucial role in supervising the review process and in guiding the online discussion.

Second, we increased the members of the technical program committee (TPC) to include 356 researchers from academia, industry, and government organizations. This number, reached after a progressive increase over the three submission cycles, reflects our substantial effort to maintain diversity across different aspects, including scientific background, experience, seniority, gender, and geographical location. TPC members were selected among those who served in previous years, those who were recommended to us by fellow researchers, and those who self-nominated by using the available online form. Our selection was driven by two goals: maximize review quality and align as much as possible the TPC expertise with the distribution of topics in the submitted papers.

The combined effort of this team resulted in 382 accepted papers and 35 papers still undergoing a major revision, and that might therefore be accepted by the reviewers to appear in the conference next year. This places the acceptance rate for the papers submitted in the three cycles of 2024 between 17.6% to 19.1%. The 382 already accepted papers, combined with 35 major revisions originally submitted in 2023, constitutes the 417 papers that are part of this proceedings and that are presented at the conference this year in Philadelphia.

The review process we followed this year is the result of the continuous improvements and refinements applied by the chairs that came before us. This starts with the three cycles of submissions, with deadlines in June 2023, October 2023, and February 2024. The authors were required to declare prior submissions and include previous reviews along with an explanation of how the different comments were addressed in the current document. To avoid introducing biases, this information was only revealed to the reviewers after they completed their review.

In each cycle, the double-blind review process was divided in two rounds. Papers that did not receive any positive support from the first two reviewers were rejected at the end of round one, thus giving the authors immediate feedback and the possibility to improve their work and submit elsewhere. At the end of the second round, the authors had the opportunity to first write a rebuttal to answer the comments of the reviewers, and then engage in an interactive (and anonymous) online discussion to further clarify additional aspects of their work and answer new questions from the reviewers.

In parallel to the regular reviews, those papers who raised potential ethical concerns were also reviewed by at least two members of a special Research Ethics Committee (REC) led by Rikke Bjerg Jensen. The feedback of these additional experts were then provided to the reviewers and everyone participated in the online discussion to make sure that the research followed proper ethical guidelines and that ethical aspects were included in the final feedback to the authors and/or in the revision criteria. The REC committee consisted of Anjo Vahldiek-Oberwagner, Hao Chen, Franziska Roesner, Thorsten Holz, Nathan Malkin, Tadayoshi Kohno, Giovanni Vigna, Zakir Durumeric, and Ruba Abu-Salma.

For the papers that received a revision decision we continued with the anonymous online shepherding process introduced in 2023. This allowed the authors to interact with their shepherds, discuss possible options to address the requirements, and eventually get the revised version of their paper accepted either within the same cycle or in one of the following cycles. Overall, after tens of thousands of hours of work from the TCP members the review process resulted in 6688 reviews and 23287 comments posted for the online discussion.

In addition to papers submitted to USENIX Security '24, as we mentioned above, this proceedings also contain 35 papers that were still under Major Revision from USENIX Security '23. With respect to them, we continued the practice of having these papers managed by the previous year's co-chairs, along with their shepherds and the original reviewers.

This year we decided to recognize roughly 5% of accepted papers with a Distinguished Paper Award. Since the number of candidate papers was high and the topics very diverse, we divided them into six separate groups according to their main topic (Network & Web, System Security, Privacy & Usability, Machine Learning, and Applied Cryptography) and asked a subset of the awards committee to rank the papers in each category. We then assembled the final list by aggregating the rankings and balancing the different areas. This year's Awards Committee included Dan Boneh, David Brumley, Yanjiao Chen, Kevin Fu, Guofei Gu, Xiaoyu Ji, Zhiqiang Lin, Catherine Meadows, Hamed Okhravi, Michel van Eeten, David Wagner, Qian Wang, Moti Yung, Daniel Zappala, and Yupeng Zhang. In addition, USENIX also assembled a separate Test of Time Awards Committee which is lead by Kevin Fu and consists of Dan Boneh, Joseph Calandrino, Srđan Čapkun, Lorrie Cranor, Nick Feamster, Fabian Monrose, David Wagner, and Wenyuan Xu to recognize papers that have had a lasting impact on the security field.

Since 2020, papers accepted at the USENIX Security Symposium had the option to get their artifact evaluated through a separate procedure, which this year was supervised by Phani Vadrevu and Anjo Vahldiek-Oberwagner. The 140 members of the artifact evaluation committee evaluated the artifacts of 141 papers, all of which received an 'Artifact Available' badge, 126 received an 'Artifact Functional' badge, and 98 received a 'Results Reproduced' badge. A special thanks also to the 2024 Poster Session Co-Chairs, Andrea Continella and Yuan Tian, who accepted 46 posters to be presented at the conference.

We could not have done all this, if not by standing on the shoulders of the giants who came before us. In particular, 2023 Program Co-Chairs Joseph Calandrino and Carmela Troncoso defined most of the process we followed this year and were always available to provide feedback and share their experience with us.

Last but not least, we want to share our immense gratitude to the fantastic USENIX team for their guidance and suggestions, for their availability and endless patience, and most of all for the invaluable help they provided in all phases of the organization. A special thanks to USENIX Executive Director Casey Henderson, to William Enck for serving as our USENIX Board liaison, and to USENIX Staff Kara Arias, Cathy Bergman, Arnold Gatilao, Jessica Kim, Mo Moreno, Camille Mulligan, Jasmine Murcia, Simone Richmond-Burden, Heidi Sherwood, Ginny Staubach, Sarah TerHune, and Karen Wong, who spent countless hours preparing these proceedings and guiding the authors in the preparation of their final presentations.

Our time as Program Co-Chairs is now over. We had an unforgettable experience, and we are deeply honored to be part of our community. We now pass the role to Lujo Bauer and Giancarlo Pellegrino, who will be responsible for the technical program of USENIX Security '25. We have no doubts the conference will continue to grow and improve under their guidance and we are looking forward to reading the 2025 proceedings.

Davide Balzarotti, *Eurecom*

Endokernel: A Thread Safe Monitor for Lightweight Subprocess Isolation 145
Fangfei Yang, *Rice University;* Bumjin Im, *Amazon.com;* Weijie Huang, *Rice University;* Kelly Kaoudis, *Trail of Bits;* Anjo Vahldiek-Oberwagner, *Intel Labs;* Chia-Che Tsai, *Texas A&M University;* Nathan Dautenhahn, *Riverside Research*

HIVE: A Hardware-assisted Isolated Execution Environment for eBPF on AArch64 163
Peihua Zhang, *SKLP, Institute of Computing Technology, CAS; University of Chinese Academy of Sciences;* Chenggang Wu, *SKLP, Institute of Computing Technology, CAS; University of Chinese Academy of Sciences; Zhongguancun Laboratory;* Xiangyu Meng, *Northwestern Polytechnical University;* Yinqian Zhang, *Southern University of Science and Technology;* Mingfan Peng, Shiyang Zhang, and Bing Hu, *SKLP, Institute of Computing Technology, CAS; University of Chinese Academy of Sciences;* Mengyao Xie, *SKLP, Institute of Computing Technology, CAS;* Yuanming Lai and Yan Kang, *SKLP, Institute of Computing Technology, CAS; University of Chinese Academy of Sciences;* Zhe Wang, *SKLP, Institute of Computing Technology, CAS; University of Chinese Academy of Sciences; Zhongguancun Laboratory*

BUDAlloc: Defeating Use-After-Free Bugs by Decoupling Virtual Address Management from Kernel 181
Junho Ahn, Jaehyeon Lee, Kanghyuk Lee, Wooseok Gwak, Minseong Hwang, and Youngjin Kwon, *KAIST*

Page-Oriented Programming: Subverting Control-Flow Integrity of Commodity Operating System Kernels with Non-Writable Code Pages 199
Seunghun Han, *The Affiliated Institute of ETRI, Chungnam National University;* Seong-Joong Kim, Wook Shin, and Byung Joon Kim, *The Affiliated Institute of ETRI;* Jae-Cheol Ryou, *Chungnam National University*

Network Security I: DDoS

SMARTCOOKIE: Blocking Large-Scale SYN Floods with a Split-Proxy Defense on Programmable Data Planes 217
Sophia Yoo, Xiaoqi Chen, and Jennifer Rexford, *Princeton University*

Loopy Hell(ow): Infinite Traffic Loops at the Application Layer 235
Yepeng Pan, Anna Ascheman, and Christian Rossow, *CISPA Helmholtz Center for Information Security*

Zero-setup Intermediate-rate Communication Guarantees in a Global Internet 253
Marc Wyss and Adrian Perrig, *ETH Zurich*

Towards an Effective Method of ReDoS Detection for Non-backtracking Engines. 271
Weihao Su, Hong Huang, and Rongchen Li, *Key Laboratory of System Software* (*Chinese Academy of Sciences*) *and State Key Laboratory of Computer Science, Institute of Software, Chinese Academy of Sciences; University of Chinese Academy of Sciences;* Haiming Chen, *Key Laboratory of System Software* (*Chinese Academy of Sciences*) *and State Key Laboratory of Computer Science, Institute of Software, Chinese Academy of Sciences;* Tingjian Ge, *Miner School of Computer & Information Sciences, University of Massachusetts, Lowell*

ML I: Federated Learning

FAMOS: Robust Privacy-Preserving Authentication on Payment Apps via Federated Multi-Modal Contrastive Learning 289
Yifeng Cai, *Key Laboratory of High Confidence Software Technologies* (*PKU*), *Ministry of Education; School of Computer Science, Peking University;* Ziqi Zhang, *Department of Computer Science, University of Illinois Urbana-Champaign;* Jiaping Gui, *School of Electronic Information and Electrical Engineering, Shanghai Jiao Tong University;* Bingyan Liu, *School of Computer Science, Beijing University of Posts and Telecommunications;* Xiaoke Zhao, Ruoyu Li, and Zhe Li, *Ant Group;* Ding Li, *Key Laboratory of High Confidence Software Technologies* (*PKU*), *Ministry of Education; School of Computer Science, Peking University*

Efficient Privacy Auditing in Federated Learning 307
Hongyan Chang, *National University of Singapore;* Brandon Edwards, *Intel Corporation;* Anindya S. Paul, *University of Florida;* Reza Shokri, *National University of Singapore*

Defending Against Data Reconstruction Attacks in Federated Learning: An Information Theory Approach 325
Qi Tan, *Department of Computer Science and Technology, Tsinghua University;* Qi Li, *Institute for Network Science and Cyberspace, Tsinghua University;* Yi Zhao, *School of Cyberspace Science and Technology, Beijing Institute of Technology;* Zhuotao Liu, *Institute for Network Science and Cyberspace, Tsinghua University;* Xiaobing Guo, *Lenovo Research;* Ke Xu, *Department of Computer Science and Technology, Tsinghua University*

Lotto: Secure Participant Selection against Adversarial Servers in Federated Learning 343
Zhifeng Jiang and Peng Ye, *Hong Kong University of Science and Technology;* Shiqi He, *University of Michigan;* Wei Wang, *Hong Kong University of Science and Technology;* Ruichuan Chen, *Nokia Bell Labs;* Bo Li, *Hong Kong University of Science and Technology*

Security Analysis I: Source Code and Binary

Ahoy SAILR! There is No Need to DREAM of C: A Compiler-Aware Structuring Algorithm for Binary Decompilation 361
Zion Leonahenahe Basque, Ati Priya Bajaj, Wil Gibbs, Jude O'Kain, Derron Miao, Tiffany Bao, Adam Doupé, Yan Shoshitaishvili, and Ruoyu Wang, *Arizona State University*

A Taxonomy of C Decompiler Fidelity Issues 379
Luke Dramko and Jeremy Lacomis, *Carnegie Mellon University;* Edward J. Schwartz, *Carnegie Mellon University Software Engineering Institute;* Bogdan Vasilescu and Claire Le Goues, *Carnegie Mellon University*

D-Helix: A Generic Decompiler Testing Framework Using Symbolic Differentiation 397
Muqi Zou, Arslan Khan, Ruoyu Wu, Han Gao, Antonio Bianchi, and Dave (Jing) Tian, *Purdue University*

SymFit: Making the Common (Concrete) Case Fast for Binary-Code Concolic Execution 415
Zhenxiao Qi, Jie Hu, Zhaoqi Xiao, and Heng Yin, *UC Riverside*

Crypto I: Secret Key Exchange

K-Waay: Fast and Deniable Post-Quantum X3DH without Ring Signatures. 433
Daniel Collins and Loïs Huguenin-Dumittan, *EPFL;* Ngoc Khanh Nguyen, *King's College London;* Nicolas Rolin, *Spuerkeess;* Serge Vaudenay, *EPFL*

Diffie-Hellman Picture Show: Key Exchange Stories from Commercial VoWiFi Deployments 451
Gabriel K. Gegenhuber and Florian Holzbauer, *University of Vienna;* Philipp É. Frenzel, *SBA Research;* Edgar Weippl, *University of Vienna and Christian Doppler Laboratory for Security and Quality Improvement in the Production System Lifecycle* (*CDL-SQI*)*;* Adrian Dabrowski, *CISPA Helmholtz Center for Information Security*

Formal verification of the PQXDH Post-Quantum key agreement protocol for end-to-end secure messaging 469
Karthikeyan Bhargavan, *Cryspen;* Charlie Jacomme, *Inria Nancy Grand-Est, Université de Lorraine, LORIA, France;* Franziskus Kiefer, *Cryspen;* Rolfe Schmidt, *Signal Messenger*

Swoosh: Efficient Lattice-Based Non-Interactive Key Exchange 487
Phillip Gajland, *Max Planck Institute for Security and Privacy, Ruhr University Bochum;* Bor de Kock, *NTNU - Norwegian University of Science and Technology, Trondheim, Norway;* Miguel Quaresma, *Max Planck Institute for Security and Privacy;* Giulio Malavolta, *Bocconi University, Max Planck Institute for Security and Privacy;* Peter Schwabe, *Max Planck Institute for Security and Privacy, Radboud University*

Social Issues I: Phishing and Password

PhishDecloaker: Detecting CAPTCHA-cloaked Phishing Websites via Hybrid Vision-based Interactive Models . . . 505
Xiwen Teoh, *Shanghai Jiao Tong University; National University of Singapore;* Yun Lin, *Shanghai Jiao Tong University;* Ruofan Liu, Zhiyong Huang, and Jin Song Dong, *National University of Singapore*

Less Defined Knowledge and More True Alarms: Reference-based Phishing Detection without a Pre-defined Reference List 523
Ruofan Liu, *Shanghai Jiao Tong University/National University of Singapore;* Yun Lin, *Shanghai Jiao Tong University;* Xiwen Teoh, *National University of Singapore;* Gongshen Liu, *Shanghai Jiao Tong University;* Zhiyong Huang and Jin Song Dong, *National University of Singapore*

In Wallet We Trust: Bypassing the Digital Wallets Payment Security for Free Shopping 541
Raja Hasnain Anwar, *University of Massachusetts Amherst;* Syed Rafiul Hussain, *Pennsylvania State University;* Muhammad Taqi Raza, *University of Massachusetts Amherst*

The Impact of Exposed Passwords on Honeyword Efficacy. 559
Zonghao Huang, *Duke University;* Lujo Bauer, *Carnegie Mellon University;* Michael K. Reiter, *Duke University*

Side Channel I: Transient Execution

InSpectre Gadget: Inspecting the Residual Attack Surface of Cross-privilege Spectre v2. 577
Sander Wiebing, Alvise de Faveri Tron, Herbert Bos, and Cristiano Giuffrida, *Vrije Universiteit Amsterdam*

Shesha: Multi-head Microarchitectural Leakage Discovery in new-generation Intel Processors 595
Anirban Chakraborty, Nimish Mishra, and Debdeep Mukhopadhyay, *Indian Institute of Technology Kharagpur*

BeeBox: Hardening BPF against Transient Execution Attacks 613
Di Jin, Alexander J. Gaidis, and Vasileios P. Kemerlis, *Brown University*

SpecLFB: Eliminating Cache Side Channels in Speculative Executions 631
Xiaoyu Cheng, *School of Cyber Science and Engineering, Southeast University, Nanjing, Jiangsu, China; Jiangsu Province Engineering Research Center of Security for Ubiquitous Network, China;* Fei Tong, *School of Cyber Science and Engineering, Southeast University, Nanjing, Jiangsu, China; Jiangsu Province Engineering Research Center of Security for Ubiquitous Network, China; Purple Mountain Laboratories, Nanjing, Jiangsu, China;* Hongyu Wang, *State Key Laboratory of Power Equipment Technology, School of Electrical Engineering, Chongqing University, China; Wiscom System Co., LTD, Nanjing, China;* Zhe Zhou and Fang Jiang, *School of Cyber Science and Engineering, Southeast University, Nanjing, Jiangsu, China; Jiangsu Province Engineering Research Center of Security for Ubiquitous Network, China;* Yuxing Mao, *State Key Laboratory of Power Equipment Technology, School of Electrical Engineering, Chongqing University, China*

Mobile Security I

Towards Privacy-Preserving Social-Media SDKs on Android. 647
Haoran Lu, Yichen Liu, Xiaojing Liao, and Luyi Xing, *Indiana University Bloomington*

UIHash: Detecting Similar Android UIs through Grid-Based Visual Appearance Representation 665
Jiawei Li, *Beihang University; National University of Singapore;* Jian Mao, *Beihang University; Tianmushan Laboratory; Hangzhou Innovation Institute, Beihang University;* Jun Zeng, *National University of Singapore;* Qixiao Lin and Shaowen Feng, *Beihang University;* Zhenkai Liang, *National University of Singapore*

Racing for TLS Certificate Validation: A Hijacker's Guide to the Android TLS Galaxy 683
Sajjad Pourali and Xiufen Yu, *Concordia University;* Lianying Zhao, *Carleton University;* Mohammad Mannan and Amr Youssef, *Concordia University*

DVa: Extracting Victims and Abuse Vectors from Android Accessibility Malware 701
Haichuan Xu, Mingxuan Yao, and Runze Zhang, *Georgia Institute of Technology;* Mohamed Moustafa Dawoud, *German International University;* Jeman Park, *Kyung Hee University;* Brendan Saltaformaggio, *Georgia Institute of Technology*

Web Security I

SoK: State of the Krawlers – Evaluating the Effectiveness of Crawling Algorithms for Web Security Measurements . . .719
Aleksei Stafeev and Giancarlo Pellegrino, *CISPA Helmholtz Center for Information Security*

Vulnerability-oriented Testing for RESTful APIs. 739
Wenlong Du and Jian Li, *School of Electronic Information and Electrical Engineering, Shanghai Jiao Tong University;* Yanhao Wang, *Independent Researcher;* Libo Chen, Ruijie Zhao, and Junmin Zhu, *School of Electronic Information and Electrical Engineering, Shanghai Jiao Tong University;* Zhengguang Han, *QI-ANXIN Technology Group;* Yijun Wang and Zhi Xue, *School of Electronic Information and Electrical Engineering, Shanghai Jiao Tong University*

Web Platform Threats: Automated Detection of Web Security Issues With WPT 757
Pedro Bernardo and Lorenzo Veronese, *TU Wien;* Valentino Dalla Valle and Stefano Calzavara, *Università Ca' Foscari Venezia;* Marco Squarcina, *TU Wien;* Pedro Adão, *Instituto Superior Técnico, Universidade de Lisboa, and Instituto de Telecomunicações;* Matteo Maffei, *TU Wien*

Rise of Inspectron: Automated Black-box Auditing of Cross-platform Electron Apps. 775
Mir Masood Ali, Mohammad Ghasemisharif, Chris Kanich, and Jason Polakis, *University of Illinois Chicago*

LLM for Security

KnowPhish: Large Language Models Meet Multimodal Knowledge Graphs for Enhancing Reference-Based Phishing Detection 793
Yuexin Li, Chengyu Huang, and Shumin Deng, *National University of Singapore;* Mei Lin Lock, *NCS Cyber Special Ops-R&D;* Tri Cao, *National University of Singapore;* Nay Oo and Hoon Wei Lim, *NCS Cyber Special Ops-R&D;* Bryan Hooi, *National University of Singapore*

Exploring ChatGPT's Capabilities on Vulnerability Management 811
Peiyu Liu and Junming Liu, *Zhejiang University NGICS Platform;* Lirong Fu, *Hangzhou Dianzi University;* Kangjie Lu, *University of Minnesota;* Yifan Xia, *Zhejiang University NGICS Platform;* Xuhong Zhang, *Zhejiang University and Jianghuai Advance Technology Center;* Wenzhi Chen, *Zhejiang University;* Haiqin Weng, *Ant Group;* Shouling Ji, *Zhejiang University;* Wenhai Wang, *Zhejiang University NGICS Platform*

Large Language Models for Code Analysis: Do LLMs Really Do Their Job? 829
Chongzhou Fang, Ning Miao, and Shaurya Srivastav, *University of California, Davis;* Jialin Liu, *Temple University;* Ruoyu Zhang, Ruijie Fang, Asmita, Ryan Tsang, and Najmeh Nazari, *University of California, Davis;* Han Wang, *Temple University;* Houman Homayoun, *University of California, Davis*

PentestGPT: Evaluating and Harnessing Large Language Models for Automated Penetration Testing 847
Gelei Deng and Yi Liu, *Nanyang Technological University;* Víctor Mayoral-Vilches, *Alias Robotics and Alpen-Adria-Universität Klagenfurt;* Peng Liu, *Institute for Infocomm Research (I2R), A*STAR, Singapore;* Yuekang Li, *University of New South Wales;* Yuan Xu, Tianwei Zhang, and Yang Liu, *Nanyang Technological University;* Martin Pinzger, *Alpen-Adria-Universität Klagenfurt;* Stefan Rass, *Johannes Kepler University Linz*

Fuzzing I: Software

OptFuzz: Optimization Path Guided Fuzzing for JavaScript JIT Compilers 865
Jiming Wang and Yan Kang, *SKLP, Institute of Computing Technology, CAS & University of Chinese Academy of Sciences;* Chenggang Wu, *SKLP, Institute of Computing Technology, CAS & University of Chinese Academy of Sciences & Zhongguancun Laboratory;* Yuhao Hu, Yue Sun, and Jikai Ren, *SKLP, Institute of Computing Technology, CAS & University of Chinese Academy of Sciences;* Yuanming Lai and Mengyao Xie, *SKLP, Institute of Computing Technology, CAS;* Charles Zhang, *Tsinghua University;* Tao Li, *Nankai University;* Zhe Wang, *SKLP, Institute of Computing Technology, CAS & University of Chinese Academy of Sciences & Zhongguancun Laboratory*

Fuzzing BusyBox: Leveraging LLM and Crash Reuse for Embedded Bug Unearthing 883
Asmita, *University of California, Davis;* Yaroslav Oliinyk and Michael Scott, *NetRise;* Ryan Tsang, Chongzhou Fang, and Houman Homayoun, *University of California, Davis*

Towards Generic Database Management System Fuzzing 901
Yupeng Yang and Yongheng Chen, *Georgia Institute of Technology;* Rui Zhong, *Palo Alto Networks;* Jizhou Chen and Wenke Lee, *Georgia Institute of Technology*

HyperPill: Fuzzing for Hypervisor-bugs by Leveraging the Hardware Virtualization Interface 919
Alexander Bulekov, *EPFL, Boston University, and Amazon;* Qiang Liu, *EPFL and Zhejiang University;* Manuel Egele, *Boston University;* Mathias Payer, *EPFL*

Differential Privacy I

Less is More: Revisiting the Gaussian Mechanism for Differential Privacy 937
Tianxi Ji, *Texas Tech University;* Pan Li, *Case Western Reserve University*

Relation Mining Under Local Differential Privacy 955
Kai Dong, Zheng Zhang, Chuang Jia, Zhen Ling, Ming Yang, and Junzhou Luo, *Southeast University;* Xinwen Fu, *University of Massachusetts Lowell*

Gradients Look Alike: Sensitivity is Often Overestimated in DP-SGD 973
Anvith Thudi and Hengrui Jia, *University of Toronto and Vector Institute;* Casey Meehan, *University of California, San Diego;* Ilia Shumailov, *University of Oxford;* Nicolas Papernot, *University of Toronto and Vector Institute*

DPAdapter: Improving Differentially Private Deep Learning through Noise Tolerance Pre-training 991
Zihao Wang, Rui Zhu, and Dongruo Zhou, *Indiana University Bloomington;* Zhikun Zhang, *Zhejiang University;* John Mitchell, *Stanford University;* Haixu Tang and XiaoFeng Wang, *Indiana University Bloomington*

Deepfake and Synthesis

Double Face: Leveraging User Intelligence to Characterize and Recognize AI-synthesized Faces 1009
Matthew Joslin, Xian Wang, and Shuang Hao, *University of Texas at Dallas*

SoK: The Good, The Bad, and The Unbalanced: Measuring Structural Limitations of Deepfake Media Datasets . . .1027
Seth Layton, Tyler Tucker, Daniel Olszewski, Kevin Warren, Kevin Butler, and Patrick Traynor, *University of Florida*

Can I Hear Your Face? Pervasive Attack on Voice Authentication Systems with a Single Face Image. 1045
Nan Jiang, Bangjie Sun, and Terence Sim, *National University of Singapore;* Jun Han, *KAIST*

dp-promise: Differentially Private Diffusion Probabilistic Models for Image Synthesis 1063
Haichen Wang and Shuchao Pang, *Nanjing University of Science and Technology;* Zhigang Lu, *James Cook University;* Yihang Rao and Yongbin Zhou, *Nanjing University of Science and Technology;* Minhui Xue, *CSIRO's Data61*

Hardware Security II: Architecture and Microarchitecture

DmaAuth: A Lightweight Pointer Integrity-based Secure Architecture to Defeat DMA Attacks 1081
Xingkai Wang, Wenbo Shen, Yujie Bu, Jinmeng Zhou, and Yajin Zhou, *Zhejiang University*

Bending microarchitectural weird machines towards practicality 1099
Ping-Lun Wang, Riccardo Paccagnella, Riad S. Wahby, and Fraser Brown, *Carnegie Mellon University*

GoFetch: Breaking Constant-Time Cryptographic Implementations Using Data Memory-Dependent Prefetchers . . . 1117
Boru Chen, *University of Illinois Urbana-Champaign;* Yingchen Wang, *University of Texas at Austin;* Pradyumna Shome, *Georgia Institute of Technology;* Christopher Fletcher, *University of California, Berkeley;* David Kohlbrenner, *University of Washington;* Riccardo Paccagnella, *Carnegie Mellon University;* Daniel Genkin, *Georgia Institute of Technology*

CacheWarp: Software-based Fault Injection using Selective State Reset 1135
Ruiyi Zhang, Lukas Gerlach, Daniel Weber, and Lorenz Hetterich, *CISPA Helmholtz Center for Information Security;* Youheng Lü, *Independent;* Andreas Kogler, *Graz University of Technology;* Michael Schwarz, *CISPA Helmholtz Center for Information Security*

System Security II: OS Kernel

Moat: Towards Safe BPF Kernel Extension 1153
Hongyi Lu, *Research Institute of Trustworthy Autonomous Systems, Southern University of Science and Technology, and Hong Kong University of Science and Technology;* Shuai Wang, *Hong Kong University of Science and Technology;* Yechang Wu and Wanning He, *Southern University of Science and Technology;* Fengwei Zhang, *Southern University of Science and Technology and Research Institute of Trustworthy Autonomous Systems*

SeaK: Rethinking the Design of a Secure Allocator for OS Kernel 1171
Zicheng Wang, *University of Colorado Boulder & Nanjing University;* Yicheng Guang, *Nanjing University;* Yueqi Chen, *University of Colorado Boulder;* Zhenpeng Lin, *Northwestern University;* Michael Le, *IBM Research;* Dang K Le, *Northwestern University;* Dan Williams, *Virginia Tech;* Xinyu Xing, *Northwestern University;* Zhongshu Gu and Hani Jamjoom, *IBM Research*

Take a Step Further: Understanding Page Spray in Linux Kernel Exploitation 1189
Ziyi Guo, Dang K Le, and Zhenpeng Lin, *Northwestern University;* Kyle Zeng, Ruoyu Wang, Tiffany Bao, Yan Shoshitaishvili, and Adam Doupé, *Arizona State University;* Xinyu Xing, *Northwestern University*

SafeFetch: Practical Double-Fetch Protection with Kernel-Fetch Caching 1207
Victor Duta, Mitchel Josephus Aloserij, and Cristiano Giuffrida, *Vrije Universiteit Amsterdam*

Network Security II: Attacks

LanDscAPe: Exploring LDAP Weaknesses and Data Leaks at Internet Scale 1225
Jonas Kaspereit and Gurur Öndarö, *Münster University of Applied Sciences;* Gustavo Luvizotto Cesar, *University of Twente;* Simon Ebbers, *Münster University of Applied Sciences;* Fabian Ising, *Fraunhofer SIT and National Research Center for Applied Cybersecurity ATHENE;* Christoph Saatjohann, *Münster University of Applied Sciences, Fraunhofer SIT, and National Research Center for Applied Cybersecurity ATHENE;* Mattijs Jonker, *University of Twente;* Ralph Holz, *University of Twente and University of Münster;* Sebastian Schinzel, *Münster University of Applied Sciences, Fraunhofer SIT, and National Research Center for Applied Cybersecurity ATHENE*

FakeBehalf: Imperceptible Email Spoofing Attacks against the Delegation Mechanism in Email Systems. 1243
Jinrui Ma, Lutong Chen, and Kaiping Xue, *University of Science and Technology of China;* Bo Luo, *The University of Kansas;* Xuanbo Huang, Mingrui Ai, and Huanjie Zhang, *University of Science and Technology of China;* David S.L. Wei, *Fordham University;* Yan Zhuang, *University of Science and Technology of China*

Rethinking the Security Threats of Stale DNS Glue Records 1261
Yunyi Zhang, *National University of Defense Technology and Tsinghua University;* Baojun Liu, *Tsinghua University;* Haixin Duan, *Tsinghua University, Zhongguancun Laboratory, and Quan Cheng Laboratory;* Min Zhang, *National University of Defense Technology;* Xiang Li, *Tsinghua University;* Fan Shi and Chengxi Xu, *National University of Defense Technology;* Eihal Alowaisheq, *King Saud University*

EVOKE: Efficient Revocation of Verifiable Credentials in IoT Networks 1279
Carlo Mazzocca, *University of Bologna;* Abbas Acar and Selcuk Uluagac, *Cyber-Physical Systems Security Lab, Florida International University;* Rebecca Montanari, *University of Bologna*

ML II: Fault Injection and Robustness

DNN-GP: Diagnosing and Mitigating Model's Faults Using Latent Concepts 1297
Shuo Wang, *Shanghai Jiao Tong University;* Hongsheng Hu, *CSIRO's Data61;* Jiamin Chang, *University of New South Wales and CSIRO's Data61;* Benjamin Zi Hao Zhao, *Macquarie University;* Qi Alfred Chen, *University of California, Irvine;* Minhui Xue, *CSIRO's Data61*

Yes, One-Bit-Flip Matters! Universal DNN Model Inference Depletion with Runtime Code Fault Injection 1315
Shaofeng Li, *Peng Cheng Laboratory;* Xinyu Wang, *Shanghai Jiao Tong University;* Minhui Xue, *CSIRO's Data61;* Haojin Zhu, *Shanghai Jiao Tong University;* Zhi Zhang, *University of Western Australia;* Yansong Gao, *CSIRO's Data61;* Wen Wu, *Peng Cheng Laboratory;* Xuemin (Sherman) Shen, *University of Waterloo*

Tossing in the Dark: Practical Bit-Flipping on Gray-box Deep Neural Networks for Runtime Trojan Injection . . 1331
Zihao Wang, Di Tang, and XiaoFeng Wang, *Indiana University Bloomington;* Wei He, Zhaoyang Geng, and Wenhao Wang, *SKLOIS, Institute of Information Engineering, Chinese Academy of Sciences*

Forget and Rewire: Enhancing the Resilience of Transformer-based Models against Bit-Flip Attacks 1349
Najmeh Nazari, Hosein Mohammadi Makrani, and Chongzhou Fang, *University of California, Davis;* Hossein Sayadi, *California State University, Long Beach;* Setareh Rafatirad, *University of California, Davis;* Khaled N. Khasawneh, *George Mason University;* Houman Homayoun, *University of California, Davis*

Security Analysis II: Program Analysis

What IF Is Not Enough? Fixing Null Pointer Dereference With Contextual Check 1367
Yunlong Xing, Shu Wang, Shiyu Sun, Xu He, and Kun Sun, *George Mason University;* Qi Li, *Tsinghua University*

Unleashing the Power of Type-Based Call Graph Construction by Using Regional Pointer Information 1383
Yuandao Cai, Yibo Jin, and Charles Zhang, *The Hong Kong University of Science and Technology*

Practical Data-Only Attack Generation 1401
Brian Johannesmeyer, Asia Slowinska, Herbert Bos, and Cristiano Giuffrida, *Vrije Universiteit Amsterdam*

Don't Waste My Efforts: Pruning Redundant Sanitizer Checks by Developer-Implemented Type Checks 1419
Yizhuo Zhai, Zhiyun Qian, Chengyu Song, Manu Sridharan, and Trent Jaeger, *University of California, Riverside;* Paul Yu, *U.S. Army Research Laboratory;* Srikanth V. Krishnamurthy, *University of California, Riverside*

Zero-Knowledge Proof I

Two Shuffles Make a RAM: Improved Constant Overhead Zero Knowledge RAM. 1435
Yibin Yang, *Georgia Institute of Technology;* David Heath, *University of Illinois Urbana-Champaign*

Notus: Dynamic Proofs of Liabilities from Zero-knowledge RSA Accumulators 1453
Jiajun Xin, Arman Haghighi, Xiangan Tian, and Dimitrios Papadopoulos, *The Hong Kong University of Science and Technology*

Practical Security Analysis of Zero-Knowledge Proof Circuits. 1471
Hongbo Wen, *University of California, Santa Barbara;* Jon Stephens, *The University of Texas at Austin and Veridise;* Yanju Chen, *University of California, Santa Barbara;* Kostas Ferles, *Veridise;* Shankara Pailoor, *The University of Texas at Austin and Veridise;* Kyle Charbonnet, *Ethereum Foundation;* Isil Dillig, *The University of Texas at Austin and Veridise;* Yu Feng, *University of California, Santa Barbara, and Veridise*

Formalizing Soundness Proofs of Linear PCP SNARKs 1489
Bolton Bailey and Andrew Miller, *University of Illinois at Urbana-Champaign*

Measurement I: Fraud and Malware and Spam

Guardians of the Galaxy: Content Moderation in the InterPlanetary File System 1507
Saidu Sokoto, *City, University of London;* Leonhard Balduf, *TU Darmstadt;* Dennis Trautwein, *University of Göttingen;* Yiluo Wei and Gareth Tyson, *Hong Kong Univ. of Science & Technology (GZ);* Ignacio Castro, *Queen Mary, University of London;* Onur Ascigil, *Lancaster University;* George Pavlou, *University College London;* Maciej Korczyński, *Univ. Grenoble Alpes;* Björn Scheuermann, *TU Darmstadt;* Michał Król, *City, University of London*

True Attacks, Attack Attempts, or Benign Triggers? An Empirical Measurement of Network Alerts in a Security Operations Center 1525
Limin Yang, Zhi Chen, Chenkai Wang, Zhenning Zhang, and Sushruth Booma, *University of Illinois at Urbana-Champaign;* Phuong Cao, *NCSA;* Constantin Adam, *IBM Research;* Alexander Withers, *NCSA;* Zbigniew Kalbarczyk, Ravishankar K. Iyer, and Gang Wang, *University of Illinois at Urbana-Champaign*

DarkFleece: Probing the Dark Side of Android Subscription Apps 1543
Chang Yue, *Institute of Information Engineering, Chinese Academy of Sciences, China; School of Cyber Security, University of Chinese Academy of Sciences, China;* Chen Zhong, *University of Tampa, USA;* Kai Chen and Zhiyu Zhang, *Institute of Information Engineering, Chinese Academy of Sciences, China; School of Cyber Security, University of Chinese Academy of Sciences, China;* Yeonjoon Lee, *Hanyang University, Ansan, Republic of Korea*

Into the Dark: Unveiling Internal Site Search Abused for Black Hat SEO 1561
Yunyi Zhang, *National University of Defense Technology; Tsinghua University;* Mingxuan Liu, *Zhongguancun Laboratory;* Baojun Liu, *Tsinghua University; Zhongguancun Laboratory;* Yiming Zhang, *Tsinghua University;* Haixin Duan, *Tsinghua University; Zhongguancun Laboratory;* Min Zhang, *National University of Defense Technology;* Hui Jiang, *Tsinghua University; Baidu Inc;* Yanzhe Li, *Baidu Inc;* Fan Shi, *National University of Defense Technology*

Side Channel II: RowHammer

ABACuS: All-Bank Activation Counters for Scalable and Low Overhead RowHammer Mitigation 1579
Ataberk Olgun, Yahya Can Tugrul, Nisa Bostanci, Ismail Emir Yuksel, Haocong Luo, Steve Rhyner, Abdullah Giray Yaglikci, Geraldo F. Oliveira, and Onur Mutlu, *ETH Zurich*

SledgeHammer: Amplifying Rowhammer via Bank-level Parallelism 1597
Ingab Kang, *University of Michigan;* Walter Wang and Jason Kim, *Georgia Tech;* Stephan van Schaik and Youssef Tobah, *University of Michigan;* Daniel Genkin, *Georgia Tech;* Andrew Kwong, *UNC Chapel Hill;* Yuval Yarom, *Ruhr University Bochum*

ZenHammer: Rowhammer Attacks on AMD Zen-based Platforms 1615
Patrick Jattke, Max Wipfli, Flavien Solt, Michele Marazzi, Matej Bölcskei, and Kaveh Razavi, *ETH Zurich*

Go Go Gadget Hammer: Flipping Nested Pointers for Arbitrary Data Leakage 1635
Youssef Tobah, *University of Michigan;* Andrew Kwong, *UNC Chapel Hill;* Ingab Kang, *University of Michigan;* Daniel Genkin, *Georgia Tech;* Kang G. Shin, *University of Michigan*

Forensics

00SEVen – Re-enabling Virtual Machine Forensics: Introspecting Confidential VMs Using Privileged in-VM Agents. 1651
Fabian Schwarz and Christian Rossow, *CISPA Helmholtz Center for Information Security*

WebRR: A Forensic System for Replaying and Investigating Web-Based Attacks in The Modern Web 1669
Joey Allen, *Palo Alto Networks;* Zheng Yang, Feng Xiao, and Matthew Landen, *Georgia Institute of Technology;* Roberto Perdisci, *Georgia Institute of Technology and University of Georgia;* Wenke Lee, *Georgia Institute of Technology*

AI Psychiatry: Forensic Investigation of Deep Learning Networks in Memory Images 1687
David Oygenblik, *Georgia Institute of Technology;* Carter Yagemann, *Ohio State University;* Joseph Zhang, *University of Pennsylvania;* Arianna Mastali, *Georgia Institute of Technology;* Jeman Park, *Kyung Hee University;* Brendan Saltaformaggio, *Georgia Institute of Technology*

Cost-effective Attack Forensics by Recording and Correlating File System Changes. 1705
Le Yu, Yapeng Ye, Zhuo Zhang, and Xiangyu Zhang, *Purdue University*

ML for Security

Automated Large-Scale Analysis of Cookie Notice Compliance 1723
Ahmed Bouhoula, Karel Kubicek, Amit Zac, Carlos Cotrini, and David Basin, *ETH Zurich*

Detecting and Mitigating Sampling Bias in Cybersecurity with Unlabeled Data 1741
Saravanan Thirumuruganathan, *Independent Researcher;* Fatih Deniz, Issa Khalil, and Ting Yu, *Qatar Computing Research Institute, HBKU;* Mohamed Nabeel, *Palo Alto Networks;* Mourad Ouzzani, *Qatar Computing Research Institute, HBKU*

Code is not Natural Language: Unlock the Power of Semantics-Oriented Graph Representation for Binary Code Similarity Detection 1759
Haojie He, *School of Electronic Information and Electrical Engineering, Shanghai Jiao Tong University;* Xingwei Lin, *Ant Group;* Ziang Weng and Ruijie Zhao, *School of Electronic Information and Electrical Engineering, Shanghai Jiao Tong University;* Shuitao Gan, *Laboratory for Advanced Computing and Intelligence Engineering;* Libo Chen, *School of Electronic Information and Electrical Engineering, Shanghai Jiao Tong University;* Yuede Ji, *University of North Texas;* Jiashui Wang, *Ant Group;* Zhi Xue, *School of Electronic Information and Electrical Engineering, Shanghai Jiao Tong University*

VulSim: Leveraging Similarity of Multi-Dimensional Neighbor Embeddings for Vulnerability Detection 1777
Samiha Shimmi, Ashiqur Rahman, and Mohan Gadde, *Northern Illinois University;* Hamed Okhravi, *MIT Lincoln Laboratory;* Mona Rahimi, *Northern Illinois University*

LLM I: Attack and Defense

An LLM-Assisted Easy-to-Trigger Backdoor Attack on Code Completion Models: Injecting Disguised Vulnerabilities against Strong Detection 1795
Shenao Yan, *University of Connecticut;* Shen Wang and Yue Duan, *Singapore Management University;* Hanbin Hong, *University of Connecticut;* Kiho Lee and Doowon Kim, *University of Tennessee, Knoxville;* Yuan Hong, *University of Connecticut*

REMARK-LLM: A *R*obust and *E*fficient Water*mark*ing Framework for Generative Large Language Models 1813
Ruisi Zhang, Shehzeen Samarah Hussain, Paarth Neekhara, and Farinaz Koushanfar, *University of California, San Diego*

Formalizing and Benchmarking Prompt Injection Attacks and Defenses 1831
Yupei Liu, *The Pennsylvania State University;* Yuqi Jia, *Duke University;* Runpeng Geng and Jinyuan Jia, *The Pennsylvania State University;* Neil Zhenqiang Gong, *Duke University*

Instruction Backdoor Attacks Against Customized LLMs 1849
Rui Zhang and Hongwei Li, *University of Electronic Science and Technology of China;* Rui Wen, *CISPA Helmholtz Center for Information Security;* Wenbo Jiang and Yuan Zhang, *University of Electronic Science and Technology of China;* Michael Backes, *CISPA Helmholtz Center for Information Security;* Yun Shen, *NetApp;* Yang Zhang, *CISPA Helmholtz Center for Information Security*

Software Vulnerability Detection

FIRE: Combining Multi-Stage Filtering with Taint Analysis for Scalable Recurring Vulnerability Detection . . . 1867
Siyue Feng, *National Engineering Research Center for Big Data Technology and System, Services Computing Technology and System Lab, Hubei Key Laboratory of Distributed System Security, Hubei Engineering Research Center on Big Data Security, Cluster and Grid Computing Lab; School of Cyber Science and Engineering, Huazhong University of Science and Technology;* Yueming Wu, *Nanyang Technological University;* Wenjie Xue and Sikui Pan, *National Engineering Research Center for Big Data Technology and System, Services Computing Technology and System Lab, Hubei Key Laboratory of Distributed System Security, Hubei Engineering Research Center on Big Data Security, Cluster and Grid Computing Lab; School of Cyber Science and Engineering, Huazhong University of Science and Technology;* Deqing Zou, *National Engineering Research Center for Big Data Technology and System, Services Computing Technology and System Lab, Hubei Key Laboratory of Distributed System Security, Hubei Engineering Research Center on Big Data Security, Cluster and Grid Computing Lab; School of Cyber Science and Engineering, Huazhong University of Science and Technology; Jinyinhu Laboratory;* Yang Liu, *Nanyang Technological University;* Hai Jin, *National Engineering Research Center for Big Data Technology and System, Services Computing Technology and System Lab, Hubei Key Laboratory of Distributed System Security, Hubei Engineering Research Center on Big Data Security, Cluster and Grid Computing Lab; School of Computer Science and Technology, Huazhong University of Science and Technology*

Inference of Error Specifications and Bug Detection Using Structural Similarities 1885
Nora Dossche and Bart Coppens, *Ghent University*

A Binary-level Thread Sanitizer or *Why Sanitizing on the Binary Level is Hard* 1903
Joschua Schilling, *CISPA Helmholtz Center for Information Security;* Andreas Wendler, *Friedrich-Alexander-Universität Erlangen-Nürnberg;* Philipp Görz, Nils Bars, Moritz Schloegel, and Thorsten Holz, *CISPA Helmholtz Center for Information Security*

ORANalyst: Systematic Testing Framework for Open RAN Implementations 1921
Tianchang Yang, Syed Md Mukit Rashid, Ali Ranjbar, Gang Tan, and Syed Rafiul Hussain, *The Pennsylvania State University*

Cryptographic Protocols I: Multi-Party Computation

Scalable Multi-Party Computation Protocols for Machine Learning in the Honest-Majority Setting 1939
Fengrun Liu, *University of Science and Technology of China & Shanghai Qi Zhi Institute;* Xiang Xie, *Shanghai Qi Zhi Institute & PADO Labs;* Yu Yu, *Shanghai Jiao Tong University & State Key Laboratory of Cryptology*

Lightweight Authentication of Web Data via Garble-Then-Prove 1957
Xiang Xie, *PADO Labs;* Kang Yang, *State Key Laboratory of Cryptology;* Xiao Wang, *Northwestern University;* Yu Yu, *Shanghai Jiao Tong University and Shanghai Qi Zhi Institute*

Holding Secrets Accountable: Auditing Privacy-Preserving Machine Learning 1975
Hidde Lycklama, *ETH Zurich;* Alexander Viand, *Intel Labs;* Nicolas Küchler, *ETH Zurich;* Christian Knabenhans, *EPFL;* Anwar Hithnawi, *ETH Zurich*

Secure Account Recovery for a Privacy-Preserving Web Service 1993
Ryan Little, *Boston University;* Lucy Qin, *Georgetown University;* Mayank Varia, *Boston University*

Thursday, August 15

User Studies II: At-Risk Users

Navigating Traumatic Stress Reactions During Computer Security Interventions 2011
Lana Ramjit, *Cornell Tech;* Natalie Dolci, *UW-Safe Campus;* Francesca Rossi, *Thriving Through;* Ryan Garcia, *UW-Safe Campus;* Thomas Ristenpart, *Cornell Tech;* Dana Cuomo, *Lafayette College*

Exploring digital security and privacy in relative poverty in Germany through qualitative interviews 2029
Anastassija Kostan and Sara Olschar, *Paderborn University;* Lucy Simko, *The George Washington University;* Yasemin Acar, *Paderborn University & The George Washington University*

"But they have overlooked a few things in Afghanistan:" An Analysis of the Integration of Biometric Voter Verification in the 2019 Afghan Presidential Elections 2047
Kabir Panahi and Shawn Robertson, *University of Kansas;* Yasemin Acar, *Paderborn University;* Alexandru G. Bardas, *University of Kansas;* Tadayoshi Kohno, *University of Washington;* Lucy Simko, *The George Washington University*

Understanding How to Inform Blind and Low-Vision Users about Data Privacy through Privacy Question Answering Assistants 2065
Yuanyuan Feng, *University of Vermont;* Abhilasha Ravichander, *Allen Institute for Artificial Intelligence;* Yaxing Yao, *Virginia Tech;* Shikun Zhang and Rex Chen, *Carnegie Mellon University;* Shomir Wilson, *Pennsylvania State University;* Norman Sadeh, *Carnegie Mellon University*

Assessing Suspicious Emails with Banner Warnings Among Blind and Low-Vision Users in Realistic Settings . . . 2083
Filipo Sharevski, *DePaul University;* Aziz Zeidieh, *University of Illinois at Urbana-Champaign*

Side Channel III

INVALIDATE+COMPARE: A Timer-Free GPU Cache Attack Primitive 2101
Zhenkai Zhang, *Clemson University;* Kunbei Cai, *University of Central Florida;* Yanan Guo, *University of Rochester;* Fan Yao, *University of Central Florida;* Xing Gao, *University of Delaware*

Peep With A Mirror: Breaking The Integrity of Android App Sandboxing via Unprivileged Cache Side Channel . . . 2119
Yan Lin, *Jinan University;* Joshua Wong, *Singapore Management University;* Xiang Li and Haoyu Ma, *Zhejiang Lab;* Debin Gao, *Singapore Management University*

Indirector: High-Precision Branch Target Injection Attacks Exploiting the Indirect Branch Predictor 2137
Luyi Li, Hosein Yavarzadeh, and Dean Tullsen, *UC San Diego*

Intellectual Property Exposure: Subverting and Securing Intellectual Property Encapsulation in Texas Instruments Microcontrollers 2155
Marton Bognar, Cas Magnus, Frank Piessens, and Jo Van Bulck, *DistriNet, KU Leuven*

ML III: Secure ML

AutoFHE: Automated Adaption of CNNs for Efficient Evaluation over FHE 2173
Wei Ao and Vishnu Naresh Boddeti, *Michigan State University*

Fast and Private Inference of Deep Neural Networks by Co-designing Activation Functions 2191
Abdulrahman Diaa, Lucas Fenaux, Thomas Humphries, Marian Dietz, Faezeh Ebrahimianghazani, Bailey Kacsmar, Xinda Li, Nils Lukas, Rasoul Akhavan Mahdavi, and Simon Oya, *University of Waterloo;* Ehsan Amjadian, *University of Waterloo and Royal Bank of Canada;* Florian Kerschbaum, *University of Waterloo*

OblivGNN: Oblivious Inference on Transductive and Inductive Graph Neural Network 2209
Zhibo Xu, *Monash University and CSIRO's Data61;* Shangqi Lai, *CSIRO's Data61;* Xiaoning Liu, *RMIT University;* Alsharif Abuadbba, *CSIRO's Data61;* Xingliang Yuan, *The University of Melbourne;* Xun Yi, *RMIT University*

MD-ML: Super Fast Privacy-Preserving Machine Learning for Malicious Security with a Dishonest Majority . . . 2227
Boshi Yuan, Shixuan Yang, and Yongxiang Zhang, *Shanghai Jiao Tong University, China;* Ning Ding, Dawu Gu, and Shi-Feng Sun, *Shanghai Jiao Tong University, China; Shanghai Jiao Tong University* (*Wuxi*) *Blockchain Advanced Research Center*

Accelerating Secure Collaborative Machine Learning with Protocol-Aware RDMA 2245
Zhenghang Ren, Mingxuan Fan, Zilong Wang, Junxue Zhang, and Chaoliang Zeng, *iSING Lab@The Hong Kong University of Science and Technology;* Zhicong Huang and Cheng Hong, *Ant Group;* Kai Chen, *iSING Lab@The Hong Kong University of Science and Technology and University of Science and Technology of China*

Measurement II: Network

CalcuLatency: Leveraging Cross-Layer Network Latency Measurements to Detect Proxy-Enabled Abuse 2263
Reethika Ramesh, *University of Michigan;* Philipp Winter, *Independent;* Sam Korman and Roya Ensafi, *University of Michigan*

6Sense: Internet-Wide IPv6 Scanning and its Security Applications 2281
Grant Williams, Mert Erdemir, Amanda Hsu, Shraddha Bhat, Abhishek Bhaskar, Frank Li, and Paul Pearce, *Georgia Institute of Technology*

A Flushing Attack on the DNS Cache 2299
Yehuda Afek and Anat Bremler-Barr, *Tel-Aviv University;* Shoham Danino, *Reichman University;* Yuval Shavitt, *Tel-Aviv University*

SnailLoad: Exploiting Remote Network Latency Measurements without JavaScript 2315
Stefan Gast, Roland Czerny, Jonas Juffinger, Fabian Rauscher, Simone Franza, and Daniel Gruss, *Graz University of Technology*

An Interview Study on Third-Party Cyber Threat Hunting Processes in the U.S. Department of Homeland Security 2333
William P. Maxam III, *US Coast Guard Academy;* James C. Davis, *Purdue University*

ML IV: Privacy Inference I

A Linear Reconstruction Approach for Attribute Inference Attacks against Synthetic Data 2351
Meenatchi Sundaram Muthu Selva Annamalai, *University College London;* Andrea Gadotti and Luc Rocher, *University of Oxford*

Did the Neurons Read your Book? Document-level Membership Inference for Large Language Models 2369
Matthieu Meeus, *Imperial College London;* Shubham Jain, *Sense Street;* Marek Rei and Yves-Alexandre de Montjoye, *Imperial College London*

MIST: Defending Against Membership Inference Attacks Through Membership-Invariant Subspace Training . . . 2387
Jiacheng Li, Ninghui Li, and Bruno Ribeiro, *Purdue University*

Inf^{2}Guard: An Information-Theoretic Framework for Learning Privacy-Preserving Representations against Inference Attacks 2405
Sayedeh Leila Noorbakhsh and Binghui Zhang, *Illinois Institute of Technology;* Yuan Hong, *University of Connecticut;* Binghui Wang, *Illinois Institute of Technology*

Property Existence Inference against Generative Models 2423
Lijin Wang, Jingjing Wang, Jie Wan, and Lin Long, *Zhejiang University;* Ziqi Yang and Zhan Qin, *Zhejiang University, ZJU-Hangzhou Global Scientific and Technological Innovation Center*

Fuzzing II: Method

SDFuzz: Target States Driven Directed Fuzzing 2441
Penghui Li, *The Chinese University of Hong Kong and Zhongguancun Laboratory;* Wei Meng, *The Chinese University of Hong Kong;* Chao Zhang, *Tsinghua University and Zhongguancun Laboratory*

Critical Code Guided Directed Greybox Fuzzing for Commits 2459
Yi Xiang, *Zhejiang University NGICS Platform;* Xuhong Zhang, *Zhejiang University and Jianghuai Advance Technology Center;* Peiyu Liu, *Zhejiang University NGICS Platform;* Shouling Ji, Xiao Xiao, Hong Liang, and Jiacheng Xu, *Zhejiang University;* Wenhai Wang, *Zhejiang University NGICS Platform*

Toward Unbiased Multiple-Target Fuzzing with Path Diversity 2475
Huanyao Rong, *Indiana University Bloomington;* Wei You, *Renmin University of China;* XiaoFeng Wang and Tianhao Mao, *Indiana University Bloomington*

SymBisect: Accurate Bisection for Fuzzer-Exposed Vulnerabilities 2493
Zheng Zhang and Yu Hao, *UC Riverside;* Weiteng Chen, *Microsoft Research;* Xiaochen Zou, Xingyu Li, Haonan Li, Yizhuo Zhai, and Zhiyun Qian, *UC Riverside;* Billy Lau, *Google*

Data Coverage for Guided Fuzzing 2511
Mingzhe Wang, Jie Liang, Chijin Zhou, Zhiyong Wu, Jingzhou Fu, and Zhuo Su, *Tsinghua University;* Qing Liao, *Harbin Institute of Technology;* Bin Gu, *Beijing Institute of Control Engineering;* Bodong Wu, *Huawei Technologies Co., Ltd;* Yu Jiang, *Tsinghua University*

Crypto II: Searchable Encryption

I/O-Efficient Dynamic Searchable Encryption meets Forward & Backward Privacy 2527
Priyanka Mondal, *University of California, Santa Cruz;* Javad Ghareh Chamani, *HKUST;* Ioannis Demertzis, *University of California, Santa Cruz;* Dimitrios Papadopoulos, *HKUST*

FEASE: Fast and Expressive Asymmetric Searchable Encryption 2545
Long Meng, Liqun Chen, and Yangguang Tian, *University of Surrey;* Mark Manulis, *Universität der Bundeswehr München;* Suhui Liu, *Southeast University*

***d*-DSE: Distinct Dynamic Searchable Encryption Resisting Volume Leakage in Encrypted Databases. 2563**
Dongli Liu and Wei Wang, *Huazhong University of Science and Technology;* Peng Xu, *Huazhong University of Science and Technology, Hubei Key Laboratory of Distributed System Security, School of Cyber Science and Engineering, JinYinHu Laboratory, and State Key Laboratory of Cryptology;* Laurence T. Yang, *Huazhong University of Science and Technology and St. Francis Xavier University;* Bo Luo, *The University of Kansas;* Kaitai Liang, *Delft University of Technology*

MUSES: Efficient Multi-User Searchable Encrypted Database 2581
Tung Le, *Virginia Tech;* Rouzbeh Behnia, *University of South Florida;* Jorge Guajardo, *Robert Bosch Research and Technology Center;* Thang Hoang, *Virginia Tech*

Query Recovery from Easy to Hard: Jigsaw Attack against SSE 2599
Hao Nie and Wei Wang, *Huazhong University of Science and Technology;* Peng Xu, *Huazhong University of Science and Technology, Hubei Key Laboratory of Distributed System Security, School of Cyber Science and Engineering, JinYinHu Laboratory, and State Key Laboratory of Cryptology;* Xianglong Zhang, *Huazhong University of Science and Technology;* Laurence T. Yang, *Huazhong University of Science and Technology and St. Francis Xavier University;* Kaitai Liang, *Delft University of Technology*

Social Issues II: Surveillance and Censorship

GFWeb: Measuring the Great Firewall's Web Censorship at Scale 2617
Nguyen Phong Hoang, *University of British Columbia and University of Chicago;* Jakub Dalek and Masashi Crete-Nishihata, *Citizen Lab - University of Toronto;* Nicolas Christin, *Carnegie Mellon University;* Vinod Yegneswaran, *SRI International;* Michalis Polychronakis, *Stony Brook University;* Nick Feamster, *University of Chicago*

Snowflake, a censorship circumvention system using temporary WebRTC proxies 2635
Cecylia Bocovich, *Tor Project;* Arlo Breault, *Wikimedia Foundation;* David Fifield and Serene, *unaffiliated;* Xiaokang Wang, *Tor Project*

SpotProxy: Rediscovering the Cloud for Censorship Circumvention 2653
Patrick Tser Jern Kon, *University of Michigan;* Sina Kamali, *University of Waterloo;* Jinyu Pei, *Rice University;* Diogo Barradas, *University of Waterloo;* Ang Chen, *University of Michigan;* Micah Sherr, *Georgetown University;* Moti Yung, *Google and Columbia University*

Bridging Barriers: A Survey of Challenges and Priorities in the Censorship Circumvention Landscape 2671
Diwen Xue, Anna Ablove, and Reethika Ramesh, *University of Michigan;* Grace Kwak Danciu, *Independent;* Roya Ensafi, *University of Michigan*

Fingerprinting Obfuscated Proxy Traffic with Encapsulated TLS Handshakes 2689
Diwen Xue, *University of Michigan;* Michalis Kallitsis, *Merit Network, Inc.;* Amir Houmansadr, *UMass Amherst;* Roya Ensafi, *University of Michigan*

AR and VR

When the User Is Inside the User Interface: An Empirical Study of UI Security Properties in Augmented Reality. . 2707
Kaiming Cheng, Arkaprabha Bhattacharya, Michelle Lin, Jaewook Lee, Aroosh Kumar, Jeffery F. Tian, Tadayoshi Kohno, and Franziska Roesner, *University of Washington*

Can Virtual Reality Protect Users from Keystroke Inference Attacks? 2725
Zhuolin Yang, Zain Sarwar, Iris Hwang, Ronik Bhaskar, Ben Y. Zhao, and Haitao Zheng, *University of Chicago*

Remote Keylogging Attacks in Multi-user VR Applications 2743
Zihao Su, *University of California, Santa Barbara;* Kunlin Cai, *University of California, Los Angeles;* Reuben Beeler, Lukas Dresel, Allan Garcia, and Ilya Grishchenko, *University of California, Santa Barbara;* Yuan Tian, *University of California, Los Angeles;* Christopher Kruegel and Giovanni Vigna, *University of California, Santa Barbara*

That Doesn't Go There: Attacks on Shared State in Multi-User Augmented Reality Applications 2761
Carter Slocum, Yicheng Zhang, Erfan Shayegani, Pedram Zaree, and Nael Abu-Ghazaleh, *University of California, Riverside;* Jiasi Chen, *University of Michigan*

Penetration Vision through Virtual Reality Headsets: Identifying 360-degree Videos from Head Movements. . . . 2779
Anh Nguyen, Xiaokuan Zhang, and Zhisheng Yan, *George Mason University*

User Studies III: Privacy I

"I'm not convinced that they don't collect more than is necessary": User-Controlled Data Minimization Design in Search Engines 2797
Tanusree Sharma, *University of Illinois at Urbana-Champaign;* Lin Kyi, *Max Planck Institute for Security and Privacy;* Yang Wang, *University of Illinois at Urbana-Champaign;* Asia J. Biega, *Max Planck Institute for Security and Privacy*

The Effect of Design Patterns on (Present and Future) Cookie Consent Decisions. 2813
Nataliia Bielova, *Inria research centre at Université Côte d'Azur;* Laura Litvine and Anysia Nguyen, *Behavioural Insights Team* (*BIT*)*;* Mariam Chammat, *Interministerial Directorate for Public Transformation* (*DITP*)*;* Vincent Toubiana, *Commission Nationale de l'Informatique et des Libertés* (*CNIL*)*;* Estelle Hary, *RMIT University*

Unpacking Privacy Labels: A Measurement and Developer Perspective on Google's Data Safety Section 2831
Rishabh Khandelwal, Asmit Nayak, Paul Chung, and Kassem Fawaz, *University of Wisconsin-Madison*

Dissecting Privacy Perspectives of Websites Around the World: "Aceptar Todo, Alle Akzeptieren, Accept All..." . . . 2849
Aysun Ogut, Berke Turanlioglu, Doruk Can Metiner, Albert Levi, Cemal Yilmaz, and Orcun Cetin, *Sabanci University, Tuzla, Istanbul, Turkiye;* Selcuk Uluagac, *Cyber-Physical Systems Security Lab, Florida International University, Miami, Florida, USA*

Data Subjects' Reactions to Exercising Their Right of Access. 2865
Arthur Borem, Elleen Pan, Olufunmilola Obielodan, Aurelie Roubinowitz, and Luca Dovichi, *University of Chicago;* Michelle L. Mazurek, *University of Maryland;* Blase Ur, *University of Chicago*

ML V: Backdoor Defense

Neural Network Semantic Backdoor Detection and Mitigation: A Causality-Based Approach. 2883
Bing Sun, Jun Sun, and Wayne Koh, *Singapore Management University;* Jie Shi, *Huawei Singapore*

On the Difficulty of Defending Contrastive Learning against Backdoor Attacks 2901
Changjiang Li, *Stony Brook University;* Ren Pang, Bochuan Cao, Zhaohan Xi, and Jinghui Chen, *Pennsylvania State University;* Shouling Ji, *Zhejiang University;* Ting Wang, *Stony Brook University*

Mudjacking: Patching Backdoor Vulnerabilities in Foundation Models 2919
Hongbin Liu, Michael K. Reiter, and Neil Zhenqiang Gong, *Duke University*

Xplain: Analyzing Invisible Correlations in Model Explanation 2937
Kavita Kumari and Alessandro Pegoraro, *Technical University of Darmstadt;* Hossein Fereidooni, *Kobil;* Ahmad-Reza Sadeghi, *Technical University of Darmstadt*

Verify your Labels! Trustworthy Predictions and Datasets via Confidence Scores 2955
Torsten Krauß, Jasper Stang, and Alexandra Dmitrienko, *University of Würzburg*

ML VI: Digital Adversarial Attacks

More Simplicity for Trainers, More Opportunity for Attackers: Black-Box Attacks on Speaker Recognition Systems by Inferring Feature Extractor 2973
Yunjie Ge, Pinji Chen, Qian Wang, Lingchen Zhao, and Ningping Mou, *Wuhan University;* Peipei Jiang, *Wuhan University; City University of Hong Kong;* Cong Wang, *City University of Hong Kong;* Qi Li, *Tsinghua University;* Chao Shen, *Xi'an Jiaotong University*

Transferability of White-box Perturbations: Query-Efficient Adversarial Attacks against Commercial DNN Services 2991
Meng Shen and Changyue Li, *School of Cyberspace Science and Technology, Beijing Institute of Technology, China;* Qi Li, *Institute for Network Sciences and Cyberspace, Tsinghua University, China;* Hao Lu, *School of Computer Science and Technology, Beijing Institute of Technology, China;* Liehuang Zhu, *School of Cyberspace Science and Technology, Beijing Institute of Technology, China;* Ke Xu, *Department of Computer Science, Tsinghua University, China*

Adversarial Illusions in Multi-Modal Embeddings 3009
Tingwei Zhang and Rishi Jha, *Cornell University;* Eugene Bagdasaryan, *University of Massachusetts Amherst;* Vitaly Shmatikov, *Cornell Tech*

It Doesn't Look Like Anything to Me: Using Diffusion Model to Subvert Visual Phishing Detectors 3027
Qingying Hao and Nirav Diwan, *University of Illinois at Urbana-Champaign;* Ying Yuan, *University of Padua;* Giovanni Apruzzese, *University of Liechtenstein;* Mauro Conti, *University of Padua;* Gang Wang, *University of Illinois at Urbana-Champaign*

Invisibility Cloak: Proactive Defense Against Visual Game Cheating 3045
Chenxin Sun, Kai Ye, Liangcai Su, Jiayi Zhang, and Chenxiong Qian, *The University of Hong Kong*

Security Analysis III: Protocol

Logic Gone Astray: A Security Analysis Framework for the Control Plane Protocols of 5G Basebands 3063
Kai Tu, Abdullah Al Ishtiaq, Syed Md Mukit Rashid, Yilu Dong, Weixuan Wang, Tianwei Wu, and Syed Rafiul Hussain, *Pennsylvania State University*

SPF Beyond the Standard: Management and Operational Challenges in Practice and Practical Recommendations . . 3081
Md. Ishtiaq Ashiq and Weitong Li, *Virginia Tech;* Tobias Fiebig, *Max-Planck-Institut für Informatik;* Taejoong Chung, *Virginia Tech*

A Formal Analysis of SCTP: Attack Synthesis and Patch Verification 3099
Jacob Ginesin, Max von Hippel, Evan Defloor, and Cristina Nita-Rotaru, *Northeastern University;* Michael Tüxen, *FH Münster*

Athena: Analyzing and Quantifying Side Channels of Transport Layer Protocols 3117
Feiyang Yu, *Duke University;* Quan Zhou and Syed Rafiul Hussain, *Pennsylvania State University;* Danfeng Zhang, *Duke University*

Shaken, not Stirred - Automated Discovery of Subtle Attacks on Protocols using Mix-Nets 3135
Jannik Dreier, *Université de Lorraine, CNRS, Inria, LORIA;* Pascal Lafourcade and Dhekra Mahmoud, *Université de Clermont Auvergne, LIMOS*

Cryptographic Protocols II

Rabbit-Mix: Robust Algebraic Anonymous Broadcast from Additive Bases 3151
Chongwon Cho and Samuel Dittmer, *Stealth Software Technologies Inc.;* Yuval Ishai, *Technion;* Steve Lu, *Stealth Software Technologies Inc.;* Rafail Ostrovsky, *UCLA*

PerfOMR: Oblivious Message Retrieval with Reduced Communication and Computation 3169
Zeyu Liu, *Yale University;* Eran Tromer, *Boston University;* Yunhao Wang, *Yale University*

Fast RS-IOP Multivariate Polynomial Commitments and Verifiable Secret Sharing. 3187
Zongyang Zhang, Weihan Li, Yanpei Guo, and Kexin Shi, *Beihang University;* Sherman S. M. Chow, *The Chinese University of Hong Kong;* Ximeng Liu, *Fuzhou University;* Jin Dong, *Beijing Academy of Blockchain and Edge Computing*

Abuse Reporting for Metadata-Hiding Communication Based on Secret Sharing 3205
Saba Eskandarian, *University of North Carolina at Chapel Hill*

SOAP: A Social Authentication Protocol 3223
Felix Linker and David Basin, *Department of Computer Science, ETH Zurich*

User Studies IV: Policies and Best Practices I

How WEIRD is Usable Privacy and Security Research? 3241
Ayako A. Hasegawa and Daisuke Inoue, *NICT;* Mitsuaki Akiyama, *NTT*

Security and Privacy Software Creators' Perspectives on Unintended Consequences 3259
Harshini Sri Ramulu, *Paderborn University & The George Washington University;* Helen Schmitt, *Paderborn University;* Dominik Wermke, *North Carolina State University;* Yasemin Acar, *Paderborn University & The George Washington University*

Engaging Company Developers in Security Research Studies: A Comprehensive Literature Review and Quantitative Survey. 3277
Raphael Serafini, Stefan Albert Horstmann, and Alena Naiakshina, *Ruhr University Bochum*

"What Keeps People Secure is That They Met The Security Team": Deconstructing Drivers And Goals of Organizational Security Awareness 3295
Jonas Hielscher, *Ruhr University Bochum;* Simon Parkin, *Delft University of Technology*

Unveiling the Hunter-Gatherers: Exploring Threat Hunting Practices and Challenges in Cyber Defense 3313
Priyanka Badva, Kopo M. Ramokapane, Eleonora Pantano, and Awais Rashid, *University of Bristol*

Side Channel IV

Pixel Thief: Exploiting SVG Filter Leakage in Firefox and Chrome 3331
Sioli O'Connell, *The University of Adelaide;* Lishay Aben Sour and Ron Magen, *Ben Gurion University of the Negev;* Daniel Genkin, *Georgia Institute of Technology;* Yossi Oren, *Ben-Gurion University of the Negev and Intel Corporation;* Hovav Shacham, *UT Austin;* Yuval Yarom, *Ruhr University Bochum*

Sync+Sync: A Covert Channel Built on fsync with Storage 3349
Qisheng Jiang and Chundong Wang, *ShanghaiTech University*

What Was Your Prompt? A Remote Keylogging Attack on AI Assistants 3367
Roy Weiss, Daniel Ayzenshteyn, Guy Amit, and Yisroel Mirsky, *Ben Gurion University of the Negev*

NetShaper: A Differentially Private Network Side-Channel Mitigation System 3385
Amir Sabzi, Rut Vora, Swati Goswami, Margo Seltzer, Mathias Lécuyer, and Aastha Mehta, *University of British Columbia*

SoK: Neural Network Extraction Through Physical Side Channels 3403
Péter Horváth, Dirk Lauret, Zhuoran Liu, and Lejla Batina, *Radboud University*

Cloud Security

ACAI: Protecting Accelerator Execution with Arm Confidential Computing Architecture 3423
Supraja Sridhara, Andrin Bertschi, Benedict Schlüter, Mark Kuhne, Fabio Aliberti, and Shweta Shinde, *ETH Zurich*

***ChainPatrol*: Balancing Attack Detection and Classification with Performance Overhead for Service Function Chains Using Virtual Trailers 3441**
Momen Oqaily and Hinddeep Purohit, *CIISE, Concordia University;* Yosr Jarraya, *Ericsson Security Research;* Lingyu Wang, *CIISE, Concordia University;* Boubakr Nour and Makan Pourzandi, *Ericsson Security Research;* Mourad Debbabi, *CIISE, Concordia University*

HECKLER: Breaking Confidential VMs with Malicious Interrupts 3459
Benedict Schlüter, Supraja Sridhara, Mark Kuhne, Andrin Bertschi, and Shweta Shinde, *ETH Zurich*

Stateful Least Privilege Authorization for the Cloud 3477
Leo Cao, Luoxi Meng, Deian Stefan, and Earlence Fernandes, *UC San Diego*

GraphGuard: Private Time-Constrained Pattern Detection Over Streaming Graphs in the Cloud 3495
Songlei Wang and Yifeng Zheng, *Harbin Institute of Technology;* Xiaohua Jia, *Harbin Institute of Technology and City University of Hong Kong*

Blockchain I

Mempool Privacy via Batched Threshold Encryption: Attacks and Defenses 3513
Arka Rai Choudhuri, *NTT Research;* Sanjam Garg, Julien Piet, and Guru-Vamsi Policharla, *University of California, Berkeley*

Speculative Denial-of-Service Attacks In Ethereum 3531
Aviv Yaish, *The Hebrew University;* Kaihua Qin and Liyi Zhou, *Imperial College London, UC Berkeley RDI;* Aviv Zohar, *The Hebrew University;* Arthur Gervais, *University College London, UC Berkeley RDI*

GuideEnricher: Protecting the Anonymity of Ethereum Mixing Service Users with Deep Reinforcement Learning . . 3549
Ravindu De Silva, Wenbo Guo, Nicola Ruaro, Ilya Grishchenko, Christopher Kruegel, and Giovanni Vigna, *University of California, Santa Barbara*

All Your Tokens are Belong to Us: Demystifying Address Verification Vulnerabilities in Solidity Smart Contracts . . 3567
Tianle Sun, *Huazhong University of Science and Technology;* Ningyu He, *Peking University;* Jiang Xiao, *Huazhong University of Science and Technology;* Yinliang Yue, *Zhongguancun Laboratory;* Xiapu Luo, *The Hong Kong Polytechnic University;* Haoyu Wang, *Huazhong University of Science and Technology*

Using My Functions Should Follow My Checks: Understanding and Detecting Insecure OpenZeppelin Code in Smart Contracts 3585
Han Liu, *East China Normal University, Shanghai Key Laboratory of Trustworthy Computing;* Daoyuan Wu, *The Hong Kong University of Science and Technology;* Yuqiang Sun, *Nanyang Technological University;* Haijun Wang, *Xi'an Jiaotong University;* Kaixuan Li, *East China Normal University, Shanghai Key Laboratory of Trustworthy Computing;* Yang Liu, *Nanyang Technological University;* Yixiang Chen, *East China Normal University, Shanghai Key Laboratory of Trustworthy Computing*

ML VII: Adversarial Attack Defense

Correction-based Defense Against Adversarial Video Attacks via Discretization-Enhanced Video Compressive Sensing 3603
Wei Song, Cong Cong, Haonan Zhong, and Jingling Xue, *UNSW Sydney*

Rethinking the Invisible Protection against Unauthorized Image Usage in Stable Diffusion 3621
Shengwei An, Lu Yan, Siyuan Cheng, Guangyu Shen, Kaiyuan Zhang, Qiuling Xu, Guanhong Tao, and Xiangyu Zhang, *Purdue University*

Splitting the Difference on Adversarial Training 3639
Matan Levi and Aryeh Kontorovich, *Ben-Gurion University of the Negev*

Machine Learning needs Better Randomness Standards: *Randomised Smoothing* and PRNG-based attacks 3657
Pranav Dahiya, *University of Cambridge;* Ilia Shumailov, *University of Oxford;* Ross Anderson, *University of Cambridge & University of Edinburgh*

PATCHCURE: Improving Certifiable Robustness, Model Utility, and Computation Efficiency of Adversarial Patch Defenses 3675
Chong Xiang, Tong Wu, and Sihui Dai, *Princeton University;* Jonathan Petit, *Qualcomm Technologies, Inc.;* Suman Jana, *Columbia University;* Prateek Mittal, *Princeton University*

Language-Based Security

GHunter: Universal Prototype Pollution Gadgets in JavaScript Runtimes 3693
Eric Cornelissen, Mikhail Shcherbakov, and Musard Balliu, *KTH Royal Institute of Technology*

MetaSafe: Compiling for Protecting Smart Pointer Metadata to Ensure Safe Rust Integrity 3711
Martin Kayondo and Inyoung Bang, *Seoul National University;* Yeongjun Kwak and Hyungon Moon, *UNIST;* Yunheung Paek, *Seoul National University*

RustSan: Retrofitting AddressSanitizer for Efficient Sanitization of Rust 3729
Kyuwon Cho, Jongyoon Kim, Kha Dinh Duy, Hajeong Lim, and Hojoon Lee, *Sungkyunkwan University*

FV8: A Forced Execution JavaScript Engine for Detecting Evasive Techniques 3747
Nikolaos Pantelaios and Alexandros Kapravelos, *North Carolina State University*

Donapi: Malicious NPM Packages Detector using Behavior Sequence Knowledge Mapping 3765
Cheng Huang, Nannan Wang, Ziyan Wang, Siqi Sun, Lingzi Li, Junren Chen, Qianchong Zhao, Jiaxuan Han, and Zhen Yang, *Sichuan University;* Lei Shi, *Huawei Technologies*

Zero-Knowledge Proof II

Election Eligibility with OpenID: Turning Authentication into Transferable Proof of Eligibility 3783
Véronique Cortier, Alexandre Debant, Anselme Goetschmann, and Lucca Hirschi, *Université de Lorraine, CNRS, Inria, LORIA, France*

Reef: Fast Succinct Non-Interactive Zero-Knowledge Regex Proofs 3801
Sebastian Angel, Eleftherios Ioannidis, and Elizabeth Margolin, *University of Pennsylvania;* Srinath Setty, *Microsoft Research;* Jess Woods, *University of Pennsylvania*

Scalable Zero-knowledge Proofs for Non-linear Functions in Machine Learning 3819
Meng Hao, Hanxiao Chen, and Hongwei Li, *School of Computer Science and Engineering, University of Electronic Science and Technology of China;* Chenkai Weng, *Northwestern University;* Yuan Zhang and Haomiao Yang, *School of Computer Science and Engineering, University of Electronic Science and Technology of China;* Tianwei Zhang, *Nanyang Technological University*

ZKSMT: A VM for Proving SMT Theorems in Zero Knowledge 3837
Daniel Luick, John C. Kolesar, and Timos Antonopoulos, *Yale University;* William R. Harris and James Parker, *Galois, Inc.;* Ruzica Piskac, *Yale University;* Eran Tromer, *Boston University;* Xiao Wang and Ning Luo, *Northwestern University*

SoK: What Don't We Know? Understanding Security Vulnerabilities in SNARKs 3855
Stefanos Chaliasos, *Imperial College London;* Jens Ernstberger; David Theodore, *Ethereum Foundation;* David Wong, *zkSecurity;* Mohammad Jahanara, *Scroll Foundation;* Benjamin Livshits, *Imperial College London & Matter Labs*

Measurement III: Auditing and Best Practices I

SecurityNet: Assessing Machine Learning Vulnerabilities on Public Models 3873
Boyang Zhang, Zheng Li, Ziqing Yang, Xinlei He, Michael Backes, Mario Fritz, and Yang Zhang, *CISPA Helmholtz Center for Information Security*

How does Endpoint Detection use the MITRE ATT&CK Framework? 3891
Apurva Virkud, Muhammad Adil Inam, Andy Riddle, Jason Liu, Gang Wang, and Adam Bates, *University of Illinois Urbana-Champaign*

Digital Discrimination of Users in Sanctioned States: The Case of the Cuba Embargo 3909
Anna Ablove, Shreyas Chandrashekaran, Hieu Le, Ram Sundara Raman, and Reethika Ramesh, *University of Michigan;* Harry Oppenheimer, *Georgia Institute of Technology;* Roya Ensafi, *University of Michigan*

A Broad Comparative Evaluation of Software Debloating Tools 3927
Michael D. Brown and Adam Meily, *Trail of Bits;* Brian Fairservice, Akshay Sood, and Jonathan Dorn, *GrammaTech;* Eric Kilmer and Ronald Eytchison, *Trail of Bits*

Hardware Security III: Signals

LaserAdv: Laser Adversarial Attacks on Speech Recognition Systems 3945
Guoming Zhang, Xiaohui Ma, Huiting Zhang, and Zhijie Xiang, *Shandong University;* Xiaoyu Ji, *Zhejiang University;* Yanni Yang, Xiuzhen Cheng, and Pengfei Hu, *Shandong University*

MicGuard: A Comprehensive Detection System against Out-of-band Injection Attacks for Different Level Microphone-based Devices. 3963
Tiantian Liu, Feng Lin, Zhongjie Ba, Li Lu, Zhan Qin, and Kui Ren, *Zhejiang University and Hangzhou High-Tech Zone (Binjiang) Institute of Blockchain and Data Security*

***VoltSchemer*: Use Voltage Noise to Manipulate Your Wireless Charger 3979**
Zihao Zhan and Yirui Yang, *University of Florida;* Haoqi Shan, *University of Florida, CertiK;* Hanqiu Wang, Yier Jin, and Shuo Wang, *University of Florida*

VibSpeech: Exploring Practical Wideband Eavesdropping via Bandlimited Signal of Vibration-based Side Channel 3997
Chao Wang, Feng Lin, Hao Yan, and Tong Wu, *Zhejiang University;* Wenyao Xu, *University at Buffalo, the State University of New York;* Kui Ren, *Zhejiang University*

System Security III: Memory I

CAMP: Compiler and Allocator-based Heap Memory Protection 4015
Zhenpeng Lin, Zheng Yu, Ziyi Guo, Simone Campanoni, Peter Dinda, and Xinyu Xing, *Northwestern University*

GPU Memory Exploitation for Fun and Profit 4033
Yanan Guo, *University of Rochester;* Zhenkai Zhang, *Clemson University;* Jun Yang, *University of Pittsburgh*

SLUBStick: Arbitrary Memory Writes through Practical Software Cross-Cache Attacks within the Linux Kernel 4051
Lukas Maar, Stefan Gast, Martin Unterguggenberger, Mathias Oberhuber, and Stefan Mangard, *Graz University of Technology*

Detecting Kernel Memory Bugs through Inconsistent Memory Management Intention Inferences 4069
Dinghao Liu, Zhipeng Lu, and Shouling Ji, *Zhejiang University;* Kangjie Lu, *University of Minnesota;* Jianhai Chen and Zhenguang Liu, *Zhejiang University;* Dexin Liu, *Peking University;* Renyi Cai, *Alibaba Cloud Computing Co., Ltd;* Qinming He, *Zhejiang University*

Web Security II: Privacy

Near-Optimal Constrained Padding for Object Retrievals with Dependencies 4087
Pranay Jain, *Duke University;* Andrew C. Reed, *United States Military Academy;* Michael K. Reiter, *Duke University*

PURL: Safe and Effective Sanitization of Link Decoration 4103
Shaoor Munir and Patrick Lee, *University of California, Davis;* Umar Iqbal, *Washington University in St. Louis;* Zubair Shafiq, *University of California, Davis;* Sandra Siby, *Imperial College London*

Fledging Will Continue Until Privacy Improves: Empirical Analysis of Google's Privacy-Preserving Targeted Advertising 4121
Giuseppe Calderonio, Mir Masood Ali, and Jason Polakis, *University of Illinois Chicago*

Stop, Don't Click Here Anymore: Boosting Website Fingerprinting By Considering Sets of Subpages 4139
Asya Mitseva and Andriy Panchenko, *Brandenburg University of Technology* (*BTU Cottbus, Germany*)

ML VIII: Backdoors and Federated Learning

Lurking in the shadows: Unveiling Stealthy Backdoor Attacks against Personalized Federated Learning 4157
Xiaoting Lyu, *Beijing Jiaotong University;* Yufei Han, *INRIA;* Wei Wang, Jingkai Liu, and Yongsheng Zhu, *Beijing Jiaotong University;* Guangquan Xu, *Tianjin University;* Jiqiang Liu, *Beijing Jiaotong University;* Xiangliang Zhang, *University of Notre Dame*

ACE: A Model Poisoning Attack on Contribution Evaluation Methods in Federated Learning 4175
Zhangchen Xu, Fengqing Jiang, and Luyao Niu, *University of Washington;* Jinyuan Jia, *Pennsylvania State University;* Bo Li, *University of Chicago;* Radha Poovendran, *University of Washington*

BackdoorIndicator: Leveraging OOD Data for Proactive Backdoor Detection in Federated Learning 4193
Songze Li, *Southeast University;* Yanbo Dai, *HKUST*(*GZ*)

UBA-Inf: Unlearning Activated Backdoor Attack with Influence-Driven Camouflage 4211
Zirui Huang, Yunlong Mao, and Sheng Zhong, *Nanjing University*

Software Security + ML 1

Racing on the Negative Force: Efficient Vulnerability Root-Cause Analysis through Reinforcement Learning on Counterexamples 4229
Dandan Xu, *SKLOIS, Institute of Information Engineering, Chinese Academy of Sciences, China, and School of Cyber Security, University of Chinese Academy of Sciences, China;* Di Tang, Yi Chen, and XiaoFeng Wang, *Indiana University Bloomington;* Kai Chen, *SKLOIS, Institute of Information Engineering, Chinese Academy of Sciences, China, and School of Cyber Security, University of Chinese Academy of Sciences, China;* Haixu Tang, *Indiana University Bloomington;* Longxing Li, *SKLOIS, Institute of Information Engineering, Chinese Academy of Sciences, China, and School of Cyber Security, University of Chinese Academy of Sciences, China*

Uncovering the Limits of Machine Learning for Automatic Vulnerability Detection 4247
Niklas Risse and Marcel Böhme, *MPI-SP, Germany*

Improving ML-based Binary Function Similarity Detection by Assessing and Deprioritizing Control Flow Graph Features 4265
Jialai Wang, *Tsinghua University;* Chao Zhang, *Tsinghua University and Zhongguancun Laboratory;* Longfei Chen and Yi Rong, *Tsinghua University;* Yuxiao Wu, *Huazhong University of Science and Technology;* Hao Wang, Wende Tan, and Qi Li, *Tsinghua University;* Zongpeng Li, *Tsinghua University and Quancheng Labs*

TyGr: Type Inference on Stripped Binaries using Graph Neural Networks 4283
Chang Zhu, *Arizona State University;* Ziyang Li and Anton Xue, *University of Pennsylvania;* Ati Priya Bajaj, Wil Gibbs, and Yibo Liu, *Arizona State University;* Rajeev Alur, *University of Pennsylvania;* Tiffany Bao, *Arizona State University;* Hanjun Dai, *Google;* Adam Doupé, *Arizona State University;* Mayur Naik, *University of Pennsylvania;* Yan Shoshitaishvili and Ruoyu Wang, *Arizona State University;* Aravind Machiry, *Purdue University*

Crypto III: Password and Secret Key

MFKDF: Multiple Factors Knocked Down Flat 4301
Matteo Scarlata and Matilda Backendal, *ETH Zurich;* Miro Haller, *UC San Diego*

LaKey: Efficient Lattice-Based Distributed PRFs Enable Scalable Distributed Key Management 4319
Matthias Geihs, *Torus Labs;* Hart Montgomery, *Linux Foundation*

Exploiting Leakage in Password Managers via Injection Attacks. 4337
Andrés Fábrega, Armin Namavari, and Rachit Agarwal, *Cornell University;* Ben Nassi, *Cornell Tech, Technion - Israel Institute of Technology;* Thomas Ristenpart, *Cornell University, Cornell Tech*

OPTIKS: An Optimized Key Transparency System 4355
Julia Len, *Cornell Tech;* Melissa Chase, Esha Ghosh, Kim Laine, and Radames Cruz Moreno, *Microsoft Research*

Social Issues III: Social Media Platform

Understanding the Security and Privacy Implications of Online Toxic Content on Refugees 4373
Arjun Arunasalam, *Purdue University;* Habiba Farrukh, *University of California, Irvine;* Eliz Tekcan and Z. Berkay Celik, *Purdue University*

Understanding Help-Seeking and Help-Giving on Social Media for Image-Based Sexual Abuse 4391
Miranda Wei, *University of Washington / Google;* Sunny Consolvo and Patrick Gage Kelley, *Google;* Tadayoshi Kohno, *University of Washington;* Tara Matthews and Sarah Meiklejohn, *Google;* Franziska Roesner, *University of Washington;* Renee Shelby, Kurt Thomas, and Rebecca Umbach, *Google*

Enabling Contextual Soft Moderation on Social Media through Contrastive Textual Deviation 4409
Pujan Paudel, Mohammad Hammas Saeed, Rebecca Auger, Chris Wells, and Gianluca Stringhini, *Boston University*

The Imitation Game: Exploring Brand Impersonation Attacks on Social Media Platforms 4427
Bhupendra Acharya, *CISPA Helmholtz Center for Information Security;* Dario Lazzaro, *University of Genoa;* Efrén López-Morales, *Texas A&M University-Corpus Christi;* Adam Oest and Muhammad Saad, *PayPal Inc.;* Antonio Emanuele Cinà, *University of Genoa;* Lea Schönherr and Thorsten Holz, *CISPA Helmholtz Center for Information Security*

Wireless Security I: Cellular and Bluetooth

Hermes: Unlocking Security Analysis of Cellular Network Protocols by Synthesizing Finite State Machines from Natural Language Specifications **4445**
Abdullah Al Ishtiaq, Sarkar Snigdha Sarathi Das, Syed Md Mukit Rashid, Ali Ranjbar, Kai Tu, Tianwei Wu, Zhezheng Song, Weixuan Wang, Mujtahid Akon, Rui Zhang, and Syed Rafiul Hussain, *Pennsylvania State University*

On the Criticality of Integrity Protection in 5G Fronthaul Networks. **4463**
Jiarong Xing, *Rice University;* Sophia Yoo, *Princeton University;* Xenofon Foukas, *Microsoft;* Daehyeok Kim, *The University of Texas at Austin;* Michael K. Reiter, *Duke University*

SIMurai: Slicing Through the Complexity of SIM Card Security Research **4481**
Tomasz Piotr Lisowski, *University of Birmingham;* Merlin Chlosta, *CISPA Helmholtz Center for Information Security;* Jinjin Wang and Marius Muench, *University of Birmingham*

Finding Traceability Attacks in the Bluetooth Low Energy Specification and Its Implementations. **4499**
Jianliang Wu, *Purdue University & Simon Fraser University;* Patrick Traynor, *University of Florida;* Dongyan Xu, Dave (Jing) Tian, and Antonio Bianchi, *Purdue University*

Mobile Security II

Defects-in-Depth: Analyzing the Integration of Effective Defenses against One-Day Exploits in Android Kernels . . . **4517**
Lukas Maar, *Graz University of Technology;* Florian Draschbacher, *Graz University of Technology and A-SIT Austria, Graz;* Lukas Lamster and Stefan Mangard, *Graz University of Technology*

Exploring Covert Third-party Identifiers through External Storage in the Android New Era **4535**
Zikan Dong, *Beijing University of Posts and Telecommunications;* Tianming Liu, *Monash University/Huazhong University of Science and Technology;* Jiapeng Deng and Haoyu Wang, *Huazhong University of Science and Technology;* Li Li, *Beihang University;* Minghui Yang and Meng Wang, *OPPO;* Guosheng Xu, *Beijing University of Posts and Telecommunications;* Guoai Xu, *Harbin Institute of Technology, Shenzhen*

PURE: Payments with UWB RElay-protection **4553**
Daniele Coppola, Giovanni Camurati, Claudio Anliker, Xenia Hofmeier, Patrick Schaller, David Basin, and Srdjan Capkun, *ETH Zurich*

***Do You See How I Pose?* Using Poses as an Implicit Authentication Factor for QR Code Payment.** **4571**
Chuxiong Wu and Qiang Zeng, *George Mason University*

Measurement IV: Web

Simulated Stress: A Case Study of the Effects of a Simulated Phishing Campaign on Employees' Perception, Stress and Self-Efficacy **4589**
Markus Schöps, Marco Gutfleisch, Eric Wolter, and M. Angela Sasse, *Ruhr University Bochum*

Arcanum: Detecting and Evaluating the Privacy Risks of Browser Extensions on Web Pages and Web Content . . . **4607**
Qinge Xie, Manoj Vignesh Kasi Murali, Paul Pearce, and Frank Li, *Georgia Institute of Technology*

Smudged Fingerprints: Characterizing and Improving the Performance of Web Application Fingerprinting **4625**
Brian Kondracki and Nick Nikiforakis, *Stony Brook University*

Does Online Anonymous Market Vendor Reputation Matter? **4641**
Alejandro Cuevas and Nicolas Christin, *Carnegie Mellon University*

LLM II: Jailbreaking

LLM-Fuzzer: Scaling Assessment of Large Language Model Jailbreaks **4657**
Jiahao Yu, *Northwestern University;* Xingwei Lin, *Ant Group;* Zheng Yu and Xinyu Xing, *Northwestern University*

Don't Listen To Me: Understanding and Exploring Jailbreak Prompts of Large Language Models **4675**
Zhiyuan Yu, *Washington University in St. Louis;* Xiaogeng Liu, *University of Wisconsin, Madison;* Shunning Liang, *Washington University in St. Louis;* Zach Cameron, *John Burroughs School;* Chaowei Xiao, *University of Wisconsin, Madison;* Ning Zhang, *Washington University in St. Louis*

***Malla*: Demystifying Real-world Large Language Model Integrated Malicious Services** **4693**
Zilong Lin, Jian Cui, Xiaojing Liao, and XiaoFeng Wang, *Indiana University Bloomington*

Making Them Ask and Answer: Jailbreaking Large Language Models in Few Queries via Disguise and Reconstruction 4711
Tong Liu and Yingjie Zhang, *Institute of Information Engineering, Chinese Academy of Sciences and School of Cyber Security, University of Chinese Academy of Sciences;* Zhe Zhao, *RealAI;* Yinpeng Dong, *RealAI and Tsinghua University;* Guozhu Meng and Kai Chen, *Institute of Information Engineering, Chinese Academy of Sciences and School of Cyber Security, University of Chinese Academy of Sciences*

Fuzzing III: Network

ResolverFuzz: Automated Discovery of DNS Resolver Vulnerabilities with Query-Response Fuzzing 4729
Qifan Zhang and Xuesong Bai, *University of California, Irvine;* Xiang Li, *Tsinghua University;* Haixin Duan, *Tsinghua University; Zhongguancun Laboratory; Quan Cheng Laboratory;* Qi Li, *Tsinghua University;* Zhou Li, *University of California, Irvine*

Understanding Ethereum Mempool Security under Asymmetric DoS by Symbolized Stateful Fuzzing 4747
Yibo Wang and Yuzhe Tang, *Syracuse University;* Kai Li, *San Diego State University;* Wanning Ding and Zhihua Yang, *Syracuse University*

Atropos: Effective Fuzzing of Web Applications for Server-Side Vulnerabilities 4765
Emre Güler and Sergej Schumilo, *Ruhr University Bochum;* Moritz Schloegel, Nils Bars, Philipp Görz, and Xinyi Xu, *CISPA Helmholtz Center for Information Security;* Cemal Kaygusuz, *Ruhr University Bochum;* Thorsten Holz, *CISPA Helmholtz Center for Information Security*

***From One Thousand Pages of Specification to Unveiling Hidden Bugs:* Large Language Model Assisted Fuzzing of Matter IoT Devices 4783**
Xiaoyue Ma, Lannan Luo, and Qiang Zeng, *George Mason University*

Differential Privacy II

DAAP: Privacy-Preserving Model Accuracy Estimation on Unlabeled Datasets Through Distribution-Aware Adversarial Perturbation 4801
Guodong Cao, *Wuhan University;* Zhibo Wang, *Zhejiang University;* Yunhe Feng, *University of North Texas;* Xiaowei Dong, *Wuhan University*

Closed-Form Bounds for DP-SGD against Record-level Inference Attacks 4819
Giovanni Cherubin, *Microsoft Security Response Center;* Boris Köpf, *Microsoft Azure Research;* Andrew Paverd, *Microsoft Security Response Center;* Shruti Tople, *Microsoft Azure Research;* Lukas Wutschitz, *Microsoft M365 Research;* Santiago Zanella-Béguelin, *Microsoft Azure Research*

PrivImage: Differentially Private Synthetic Image Generation using Diffusion Models with Semantic-Aware Pretraining 4837
Kecen Li, *Institute of Automation, Chinese Academy of Sciences and University of Chinese Academy of Sciences;* Chen Gong, *University of Virginia;* Zhixiang Li, *University of Bristol;* Yuzhong Zhao, *University of Chinese Academy of Sciences;* Xinwen Hou, *Institute of Automation, Chinese Academy of Sciences;* Tianhao Wang, *University of Virginia*

"What do you want from theory alone?" Experimenting with Tight Auditing of Differentially Private Synthetic Data Generation 4855
Meenatchi Sundaram Muthu Selva Annamalai, *University College London;* Georgi Ganev, *University College London and Hazy;* Emiliano De Cristofaro, *University of California, Riverside*

Friday, August 16

User Studies V: Policies and Best Practices II

"I Don't Know If We're Doing Good. I Don't Know If We're Doing Bad": Investigating How Practitioners Scope, Motivate, and Conduct Privacy Work When Developing AI Products 4873
Hao-Ping (Hank) Lee, *Carnegie Mellon University;* Lan Gao and Stephanie Yang, *Georgia Institute of Technology;* Jodi Forlizzi and Sauvik Das, *Carnegie Mellon University*

Towards More Practical Threat Models in Artificial Intelligence Security 4891
Kathrin Grosse, *EPFL;* Lukas Bieringer, *QuantPi;* Tarek R. Besold, *TU Eindhoven;* Alexandre M. Alahi, *EPFL*

"There are rabbit holes I want to go down that I'm not allowed to go down": An Investigation of Security Expert Threat Modeling Practices for Medical Devices 4909
Ronald E. Thompson, Madline McLaughlin, Carson Powers, and Daniel Votipka, *Tufts University*

"*Belt and suspenders*" or "*just red tape*"?: Investigating Early Artifacts and User Perceptions of IoT App Security Certification 4927
Prianka Mandal, Amit Seal Ami, Victor Olaiya, Sayyed Hadi Razmjo, and Adwait Nadkarni, *William & Mary*

TAPFixer: Automatic Detection and Repair of Home Automation Vulnerabilities based on Negated-property Reasoning. 4945
Yinbo Yu, *National Engineering Laboratory for Integrated Aero-Space-Ground-Ocean Big Data Application Technology, School of Cybersecurity, Northwestern Polytechnical University, China; Research & Development Institute of Northwestern Polytechnical University in Shenzhen, China;* Yuanqi Xu, Kepu Huang, and Jiajia Liu, *National Engineering Laboratory for Integrated Aero-Space-Ground-Ocean Big Data Application Technology, School of Cybersecurity, Northwestern Polytechnical University, China*

User Studies VI: Privacy II

Co-Designing a Mobile App for Bystander Privacy Protection in Jordanian Smart Homes: A Step Towards Addressing a Complex Privacy Landscape 4963
Wael Albayaydh and Ivan Flechais, *University of Oxford*

"I really just leaned on my community for support": Barriers, Challenges, and Coping Mechanisms Used by Survivors of Technology-Facilitated Abuse to Seek Social Support 4981
Naman Gupta, *University of Wisconsin–Madison, Madison Tech Clinic;* Kate Walsh, *University of Wisconsin–Madison;* Sanchari Das, *University of Denver;* Rahul Chatterjee, *University of Wisconsin–Madison, Madison Tech Clinic*

From the Childhood Past: Views of Young Adults on Parental Sharing of Children's Photos. 4999
Tania Ghafourian, *Indiana University Bloomington;* Nicholas Micallef, *Swansea University;* Sameer Patil, *University of Utah*

ATTention Please! An Investigation of the App Tracking Transparency Permission. 5017
Reham Mohamed and Arjun Arunasalam, *Purdue University;* Habiba Farrukh, *University of California, Irvine;* Jason Tong, Antonio Bianchi, and Z. Berkay Celik, *Purdue University*

Voice App Developer Experiences with Alexa and Google Assistant: Juggling Risks, Liability, and Security. 5035
William Seymour, *King's College London;* Noura Abdi, *Liverpool Hope University;* Kopo M. Ramokapane, *University of Bristol;* Jide Edu, *University of Strathclyde;* Guillermo Suarez-Tangil, *IMDEA Networks Institute;* Jose Such, *King's College London & Universitat Politecnica de Valencia*

Measurement V: App

Swipe Left for Identity Theft: An Analysis of User Data Privacy Risks on Location-based Dating Apps 5053
Karel Dhondt, Victor Le Pochat, Yana Dimova, Wouter Joosen, and Stijn Volckaert, *DistriNet, KU Leuven*

Spill the TeA: An Empirical Study of Trusted Application Rollback Prevention on Android Smartphones 5071
Marcel Busch, Philipp Mao, and Mathias Payer, *EPFL*

A Decade of Privacy-Relevant Android App Reviews: Large Scale Trends 5089
Omer Akgul, *University of Maryland;* Sai Teja Peddinti and Nina Taft, *Google;* Michelle L. Mazurek, *University of Maryland;* Hamza Harkous, Animesh Srivastava, and Benoit Seguin, *Google*

Tickets or Privacy? Understand the Ecosystem of Chinese Ticket Grabbing Apps 5107
Yijing Liu and Yiming Zhang, *Tsinghua University;* Baojun Liu, *Tsinghua University; Zhongguancun Laboratory;* Haixin Duan, *Tsinghua University; Quancheng Laboratory;* Qiang Li, *Qihoo 360;* Mingxuan Liu, *Zhongguancun Laboratory;* Ruixuan Li and Jia Yao, *Tsinghua University*

PixelMod: Improving Soft Moderation of Visual Misleading Information on Twitter 5125
Pujan Paudel and Chen Ling, *Boston University;* Jeremy Blackburn, *Binghamton University;* Gianluca Stringhini, *Boston University*

Network Security III: Detection

Learning with Semantics: Towards a Semantics-Aware Routing Anomaly Detection System 5143
Yihao Chen, *Department of Computer Science and Technology & BNRist, Tsinghua University;* Qilei Yin, *Zhongguancun Laboratory;* Qi Li and Zhuotao Liu, *Institute for Network Sciences and Cyberspace, Tsinghua University; Zhongguancun Laboratory;* Ke Xu, *Department of Computer Science and Technology, Tsinghua University; Zhongguancun Laboratory;* Yi Xu and Mingwei Xu, *Institute for Network Sciences and Cyberspace, Tsinghua University; Zhongguancun Laboratory;* Ziqian Liu, *China Telecom;* Jianping Wu, *Department of Computer Science and Technology, Tsinghua University; Zhongguancun Laboratory*

Enhancing Network Attack Detection with Distributed and In-Network Data Collection System 5161
Seyed Mohammad Mehdi Mirnajafizadeh and Ashwin Raam Sethuram, *Wayne State University;* David Mohaisen, *University of Central Florida;* DaeHun Nyang, *Ewha Womans University;* Rhongho Jang, *Wayne State University*

You Cannot Escape Me: Detecting Evasions of SIEM Rules in Enterprise Networks 5179
Rafael Uetz, Marco Herzog, and Louis Hackländer, *Fraunhofer FKIE;* Simon Schwarz, *University of Göttingen;* Martin Henze, *RWTH Aachen University & Fraunhofer FKIE*

MAGIC: Detecting Advanced Persistent Threats via Masked Graph Representation Learning 5197
Zian Jia and Yun Xiong, *Shanghai Key Laboratory of Data Science, School of Computer Science, Fudan University, China;* Yuhong Nan, *School of Software Engineering, Sun Yat-sen University, China;* Yao Zhang, *Shanghai Key Laboratory of Data Science, School of Computer Science, Fudan University, China;* Jinjing Zhao, *National Key Laboratory of Science and Technology on Information System Security, China;* Mi Wen, *Shanghai University of Electric Power, China*

CellularLint: A Systematic Approach to Identify Inconsistent Behavior in Cellular Network Specifications 5215
Mirza Masfiqur Rahman, Imtiaz Karim, and Elisa Bertino, *Purdue University*

ML IX: Model Extraction and Watermark

SoK: All You Need to Know About On-Device ML Model Extraction - The Gap Between Research and Practice . . 5233
Tushar Nayan, Qiming Guo, and Mohammed Al Duniawi, *Florida International University;* Marcus Botacin, *Texas A&M University;* Selcuk Uluagac and Ruimin Sun, *Florida International University*

Unveiling the Secrets without Data: Can Graph Neural Networks Be Exploited through Data-Free Model Extraction Attacks? 5251
Yuanxin Zhuang, Chuan Shi, and Mengmei Zhang, *Beijing University of Posts and Telecommunications;* Jinghui Chen, *The Pennsylvania State University;* Lingjuan Lyu, *SONY AI;* Pan Zhou, *Huazhong University of Science and Technology;* Lichao Sun, *Lehigh University*

ClearStamp: A Human-Visible and Robust Model-Ownership Proof based on Transposed Model Training 5269
Torsten Krauß, Jasper Stang, and Alexandra Dmitrienko, *University of Würzburg*

***DeepEclipse*: How to Break White-Box DNN-Watermarking Schemes 5287**
Alessandro Pegoraro, Carlotta Segna, Kavita Kumari, and Ahmad-Reza Sadeghi, *Technical University of Darmstadt*

ModelGuard: Information-Theoretic Defense Against Model Extraction Attacks 5305
Minxue Tang and Anna Dai, *Duke University;* Louis DiValentin, Aolin Ding, and Amin Hass, *Accenture;* Neil Zhenqiang Gong, Yiran Chen, and Hai "Helen" Li, *Duke University*

Fuzzing IV: Hardware and Firmware

SHiFT: Semi-hosted Fuzz Testing for Embedded Applications 5323
Alejandro Mera and Changming Liu, *Northeastern University;* Ruimin Sun, *Florida International University;* Engin Kirda and Long Lu, *Northeastern University*

Cascade: CPU Fuzzing via Intricate Program Generation 5341
Flavien Solt, Katharina Ceesay-Seitz, and Kaveh Razavi, *ETH Zurich*

MultiFuzz: A Multi-Stream Fuzzer For Testing Monolithic Firmware 5359
Michael Chesser, *The University of Adelaide and Data61 CSIRO, Cyber Security Cooperative Research Centre;* Surya Nepal, *Data61 CSIRO, Cyber Security Cooperative Research Centre;* Damith C. Ranasinghe, *The University of Adelaide*

WhisperFuzz: White-Box Fuzzing for Detecting and Locating Timing Vulnerabilities in Processors 5377
Pallavi Borkar, *Indian Institute of Technology Madras;* Chen Chen, *Texas A&M University;* Mohamadreza Rostami, *Technische Universität Darmstadt;* Nikhilesh Singh, *Indian Institute of Technology Madras;* Rahul Kande, *Texas A&M University;* Ahmad-Reza Sadeghi, *Technische Universität Darmstadt;* Chester Rebeiro, *Indian Institute of Technology Madras;* Jeyavijayan Rajendran, *Texas A&M University*

EL3XIR: Fuzzing COTS Secure Monitors 5395
Christian Lindenmeier, *FAU Erlangen-Nürnberg;* Mathias Payer and Marcel Busch, *EPFL*

Crypto IV: Position and Elections

GridSE: Towards Practical Secure Geographic Search via Prefix Symmetric Searchable Encryption 5413
Ruoyang Guo, Jiarui Li, and Shucheng Yu, *Stevens Institute of Technology*

Abuse-Resistant Location Tracking: Balancing Privacy and Safety in the Offline Finding Ecosystem 5431
Harry Eldridge, Gabrielle Beck, and Matthew Green, *Johns Hopkins University;* Nadia Heninger, *University of California, San Diego;* Abhishek Jain, *Johns Hopkins University*

Security and Privacy Analysis of Samsung's Crowd-Sourced Bluetooth Location Tracking System 5449
Tingfeng Yu, James Henderson, Alwen Tiu, and Thomas Haines, *School of Computing, The Australian National University*

The Decisive Power of Indecision: Low-Variance Risk-Limiting Audits and Election Contestation via Marginal Mark Recording. 5467
Benjamin Fuller, Rashmi Pai, and Alexander Russell, *University of Connecticut - Voting Technology Research Center*

ElectionGuard: a Cryptographic Toolkit to Enable Verifiable Elections 5485
Josh Benaloh and Michael Naehrig, *Microsoft Research;* Olivier Pereira, *Microsoft Research and UCLouvain;* Dan S. Wallach, *Rice University*

Measurement VI: Human Behavior and Security

A High Coverage Cybersecurity Scale Predictive of User Behavior 5503
Yukiko Sawaya, *KDDI Research Inc.;* Sarah Lu, *Massachusetts Institute of Technology;* Takamasa Isohara, *KDDI Research Inc.;* Mahmood Sharif, *Tel Aviv University*

Biosignal Authentication Considered Harmful Today 5521
Veena Krish, *Stony Brook University;* Nicola Paoletti and Milad Kazemi, *King's College London;* Scott Smolka and Amir Rahmati, *Stony Brook University*

GlobalConfusion: TrustZone Trusted Application 0-Days by Design 5537
Marcel Busch, Philipp Mao, and Mathias Payer, *EPFL*

PointerGuess: Targeted Password Guessing Model Using Pointer Mechanism 5555
Kedong Xiu and Ding Wang, *Nankai University*

Hardware Security IV: Firmware

FFXE: Dynamic Control Flow Graph Recovery for Embedded Firmware Binaries 5573
Ryan Tsang, Asmita, and Doreen Joseph, *University of California, Davis;* Soheil Salehi, *University of Arizona;* Prasant Mohapatra and Houman Homayoun, *University of California, Davis*

***CO3*: Concolic Co-execution for Firmware 5591**
Changming Liu, Alejandro Mera, and Engin Kirda, *Northeastern University;* Meng Xu, *University of Waterloo;* Long Lu, *Northeastern University*

Unveiling IoT Security in Reality: A Firmware-Centric Journey 5609
Nicolas Nino, *School of Computing, University of Georgia;* Ruibo Lu and Wei Zhou, *School of Cyber Science and Engineering, Huazhong University of Science and Technology;* Kyu Hyung Lee, *School of Computing, University of Georgia;* Ziming Zhao, *Khoury College of Computer Sciences, Northeastern University;* Le Guan, *School of Computing, University of Georgia*

Your Firmware Has Arrived: A Study of Firmware Update Vulnerabilities 5627
Yuhao Wu, Jinwen Wang, Yujie Wang, Shixuan Zhai, and Zihan Li, *Washington University in St. Louis;* Yi He, *Tsinghua University;* Kun Sun, *George Mason University;* Qi Li, *Tsinghua University;* Ning Zhang, *Washington University in St. Louis*

Mobile Privacy

Abandon All Hope Ye Who Enter Here: A Dynamic, Longitudinal Investigation of Android's Data Safety Section 5645
Ioannis Arkalakis, Michalis Diamantaris, Serafeim Moustakas, and Sotiris Ioannidis, *Technical University of Crete;* Jason Polakis, *University of Illinois Chicago;* Panagiotis Ilia, *Cyprus University of Technology*

***iHunter*: Hunting Privacy Violations at Scale in the Software Supply Chain on iOS 5663**
Dexin Liu, *Peking University and Alibaba Group;* Yue Xiao and Chaoqi Zhang, *Indiana University Bloomington;* Kaitao Xie and Xiaolong Bai, *Alibaba Group;* Shikun Zhang, *Peking University;* Luyi Xing, *Indiana University Bloomington*

Is It a Trap? A Large-scale Empirical Study And Comprehensive Assessment of Online Automated Privacy Policy Generators for Mobile Apps 5681
Shidong Pan and Dawen Zhang, *CSIRO's Data61 & Australian National University;* Mark Staples, *CSIRO's Data61;* Zhenchang Xing, *CSIRO's Data61 & Australian National University;* Jieshan Chen, Xiwei Xu, and Thong Hoang, *CSIRO's Data61*

A New Hope: Contextual Privacy Policies for Mobile Applications and An Approach Toward Automated Generation 5699
Shidong Pan and Zhen Tao, *CSIRO's Data61 and Australian National University;* Thong Hoang, *CSIRO's Data61;* Dawen Zhang, *CSIRO's Data61 and Australian National University;* Tianshi Li, *Northeastern University;* Zhenchang Xing, *CSIRO's Data61 and Australian National University;* Xiwei Xu, Mark Staples, and Thierry Rakotoarivelo, *CSIRO's Data61;* David Lo, *Singapore Management University*

Network Security IV: Infrastructure

CDN Cannon: Exploiting CDN Back-to-Origin Strategies for Amplification Attacks 5717
Ziyu Lin, *Fuzhou University and Tsinghua University;* Zhiwei Lin, *Sichuan University and Tsinghua University;* Ximeng Liu, *Fuzhou University;* Jianjun Chen and Run Guo, *Tsinghua University;* Cheng Chen and Shaodong Xiao, *Fuzhou University*

You Can Obfuscate, but You Cannot Hide: CrossPoint Attacks against Network Topology Obfuscation 5735
Xuanbo Huang, Kaiping Xue, Lutong Chen, and Mingrui Ai, *University of Science and Technology of China;* Huancheng Zhou, *Texas A&M University;* Bo Luo, *The University of Kansas;* Guofei Gu, *Texas A&M University;* Qibin Sun, *University of Science and Technology of China*

Cross the Zone: Toward a Covert Domain Hijacking via Shared DNS Infrastructure. 5751
Yunyi Zhang, *National University of Defense Technology; Tsinghua University;* Mingming Zhang, *Zhongguancun Laboratory;* Baojun Liu, *Tsinghua University; Zhongguancun Laboratory;* Zhan Liu and Jia Zhang, *Tsinghua University;* Haixin Duan, *Tsinghua University; Zhongguancun Laboratory;* Min Zhang, Fan Shi, and Chengxi Xu, *National University of Defense Technology*

CAMP: Compositional Amplification Attacks against DNS 5769
Huayi Duan, Marco Bearzi, Jodok Vieli, David Basin, Adrian Perrig, and Si Liu, *ETH Zürich;* Bernhard Tellenbach, *Armasuisse*

LLM III: Abuse

Moderating Illicit Online Image Promotion for Unsafe User Generated Content Games Using Large Vision-Language Models 5787
Keyan Guo, Ayush Utkarsh, Wenbo Ding, and Isabelle Ondracek, *University at Buffalo;* Ziming Zhao, *Northeastern University;* Guo Freeman, *Clemson University;* Nishant Vishwamitra, *The University of Texas at San Antonio;* Hongxin Hu, *University at Buffalo*

Deciphering Textual Authenticity: A Generalized Strategy through the Lens of Large Language Semantics for Detecting Human vs. Machine-Generated Text. 5805
Mazal Bethany, *The University of Texas at San Antonio and Secure AI and Autonomy Lab;* Brandon Wherry, *The University of Texas at San Antonio, Secure AI and Autonomy Lab, and Peraton Labs;* Emet Bethany, *The University of Texas at San Antonio and Secure AI and Autonomy Lab;* Nishant Vishwamitra and Anthony Rios, *The University of Texas at San Antonio;* Peyman Najafirad, *The University of Texas at San Antonio and Secure AI and Autonomy Lab*

Prompt Stealing Attacks Against Text-to-Image Generation Models. 5823
Xinyue Shen, Yiting Qu, Michael Backes, and Yang Zhang, *CISPA Helmholtz Center for Information Security*

Quantifying Privacy Risks of Prompts in Visual Prompt Learning 5841
Yixin Wu, Rui Wen, and Michael Backes, *CISPA Helmholtz Center for Information Security;* Pascal Berrang, *University of Birmingham;* Mathias Humbert, *University of Lausanne;* Yun Shen, *Netapp;* Yang Zhang, *CISPA Helmholtz Center for Information Security*

Security Analysis IV: OS

Pandawan: Quantifying Progress in Linux-based Firmware Rehosting 5859
Ioannis Angelakopoulos, Gianluca Stringhini, and Manuel Egele, *Boston University*

DeepType: Refining Indirect Call Targets with Strong Multi-layer Type Analysis 5877

"I feel physically safe but not politically safe": Understanding the Digital Threats and Safety Practices of OnlyFans Creators

Ananta Soneji
Arizona State University

Adam Doupé
Arizona State University

Allison McDonald
Boston University

Elissa M. Redmiles
Georgetown University

Abstract

OnlyFans is a subscription-based social media platform with over 1.5 million content creators and 150 million users worldwide. OnlyFans creators primarily produce intimate content for sale on the platform. As such, they are distinctly positioned as content creators and sex workers. Through a qualitative interview study with OnlyFans creators (n=43), building on an existing framework of online hate and harassment, we shed light on the nuanced threats they face and their safety practices. Additionally, we examine the impact of factors such as stigma, prominence, and platform policies on shaping the threat landscape for OnlyFans creators and detail the preemptive practices they undertake to protect themselves. Leveraging these results, we synthesize opportunities to address the challenges of sexual content creators.

1 Introduction

The exponential growth of OnlyFans since its founding in 2016 has transformed it into a prominent social media platform with over 1.5 million creators, who primarily create erotic content, and 150 million "fans" [71]. OnlyFans creators, like other professional content creators, navigate a complicated landscape of content creation, monetization strategies, and fan management, and need to engage in extensive off-platform advertisement to draw followers. The prominence that comes with being a content creator, regardless of the platform, brings specific security and privacy risks such as obsessive fans, online harassment, and stalking [30, 91].

OnlyFans creators face additional sources of risk stemming from sex work stigma [30]. Those who create and sell sexual content are sex workers; they exchange erotic services for money [69]. However making, distributing, or even possessing certain kinds of sexual content is legislated in a variety of ways across different countries [84]. Although millions of people worldwide work in the sex industry, sex workers globally face significant stigma, discrimination, violence, and harassment [23, 67, 82]. Therefore, OnlyFans' sexual content creators must manage risks such as censorship of sexual expression, platform precarity [30], refusal of service from banking institutions [77], and digital account loss [15]. Despite these risks, OnlyFans provides a level of flexibility, accessibility, and control that draws creators to the platform [47].

Drawing on the contextual risk factors outlined by Warford et al. [99], OnlyFans creators are at-risk—"anyone who experiences heightened digital-safety threats"—due to their *prominence* as well as the *stigma* associated with sex work. With this work, we respond to the call of Thomas et al. [90]—"responding to each class of hate and harassment requires a unique strategy"—by identifying the online risks to and protective measures taken by sexual content creators.

Through semi-structured interviews with 43 OnlyFans creators,[1] we investigate their online risks and the protective strategies they employ to mitigate them. In particular, we recruited both participants who were new to creating sexual content and those with previous sex industry experience, capturing a broad spectrum of experience and stages of learning about digital safety. We investigate three research questions:

RQ1: How well does the existing online hate and harassment framework [90] capture the threats experienced or perceived by sexual content creators?

RQ2: How do contextual risk factors [99]—stigma and prominence—relate to the threats faced by sexual content creators?

RQ3: What is the role of platforms in sexual content creators' digital safety?

We analyze our interviews with OnlyFans creators through the lens of Thomas et al.'s online hate and harassment framework [90]. We do so for two primary reasons, to: (i) support a growing effort to use unifying language and frameworks [99] across research of hate, harassment, and safety issues and (ii) validate the framework in the context of the combination of contextual risk factors we study—prominence and stigma. This approach further allows us to juxtapose our participants'

[1] Hereafter, when we use the term 'OnlyFans creators,' we refer to creators producing sexual content on the platform.

experiences with those of previously studied populations: general internet users [100], at-risk users [99] and professional non-sexual content creators [81, 91].

We find that OnlyFans creators contend with two existing threats from Thomas et al.'s online hate and harassment framework—toxic content and content leakage—and two sources of risk not included in the Thomas et al. framework: platform precarity and censorship (e.g., shadowbanning[2] and deplatforming[3]). Whereas prior work finds that non-sexual content creators find toxic content to be the most prominent threat [91], our participants were more concerned about platform-related risks than they were about toxic content and content leakage. In response, we find participants diversified the platforms they used and practiced self-censorship to avoid being deplatformed.

The OnlyFans creators we study face many of the same toxic content attacks as non-sexual content creators [91]. While they use some of the same strategies to address such toxic content—"ignoring haters" and engaging in self-censorship [91]—our participants also establish strong boundaries with their fans, extensively use platforms' blocking features to counter harassment, and draw strength and support from the broader community of sexual content creators.

Given the intimate nature of content produced as part of sexual content creation, our analysis emphasizes the prevalent and seemingly unavoidable threat of intimate content leakage—constituting both content theft and non-consensual distribution of intimate content where the creator did not intend to share it [68]—a consequence our participants often associated with the online sharing of explicit content.

While prior work on non-sexual content creators finds a reactive approach to digital safety [81], we find that sexual content creators are uniquely proactive and prepared to defend against digital threats. *All* of our participants adopted at least one protective practice before joining OnlyFans, compared to only one-third of participants in prior work focused on non-sexual content creators. This preparedness is vital due to the essential requirement for cross-platform promotion to earn money on OnlyFans. Without internal promotion mechanisms on OnlyFans, creators must drive traffic to their page from other platforms. This increases creator visibility and subjects them to heightened risks such as outing and doxxing[4] [81]. Participants point to the role of sex work stigma in influencing their proactive stance toward digital safety.

[2] Shadowbanning refers to platforms silently suppressing a user and/or their content, reducing their visibility. Users may be unaware they have been shadowbanned until they experience unusually low engagement.

[3] Deplatforming refers to the removal of a creator's account from a platform, often without transparency or recourse [16].

[4] Doxxing refers to revealing someone's real name, home address, workplace, phone number, or other personal information for harassment and financial harm.

2 OnlyFans Background

We begin with an overview of the platform, creator interactions with the platform and fans, and noteworthy platform policy changes impacting creator experiences.

OnlyFans and creators. OnlyFans is a fast growing (70% per month [38]) social media platform with two types of user: creator and fan. All users must confirm that they are over 18, with additional identity verification checks for creators[5]—name, date of birth, address, government photo ID, selfie, social media handles, payment details—and consent checks when content features more than one creator.

Creators can host both free and paywalled pages. Users must have an OnlyFans account to view free pages. Creators can also generate income through pay-per-view content, custom content requested by individual fans, paid direct messages—where creators can set a per-message fee or flat fee to set up messages for their fans [14]—and fan tips. Creators earn 80% of all payments. OnlyFans creators manage their payouts and are responsible for chargebacks from fans, a model termed "digital patronage" [18]. OnlyFans limits the type of content creators can share and sets guidelines for language in private messages [72].

Notably, the platform lacks internal discoverability, necessitating creators to drive traffic internally (when creators promote each other) or externally (from social media platforms or personal websites) [6], fostering "multi-platform practices" [44]. This boosts the platform's public visibility, and OnlyFans' brand recognition has further grown by "celebrity hype" [47] and extensive mainstream news media coverage [78], particularly during the COVID-19 pandemic. Additionally, Hamilton et al. argue that OnlyFans' unique design has not only spurred its growth but has also attracted a diverse range of sexual content creators, including those with existing sex industry experience and newcomers [47].

Policy changes and known creator risks. Due to its association with erotic content [42], OnlyFans creators are exposed to the prevailing stigma attached to sex work [53] and the challenges stemming from platform policies. Notably, Bhalerao et al. point out that platform policies, created without subject matter knowledge or sufficient understanding of its effects, can inadvertently harm sex industry workers [13], as demonstrated by a proposed sexual content ban by OnlyFans in August 2021. The platform attributed the ban to banking-related issues [42] and despite being reversed, resulted in creators suffering financial and subscriber losses [8, 13]. The utilization of online platforms by sex workers for both work and daily activities is significantly affected by policies that are stigmatizing and overly restrictive [13]. These policies may lead to deplatforming and reduced platform accessibility, highlighting the precarious nature of sex work platforms [5, 13, 17]. Such circumstances can have profound financial and emotional im-

[5] https://onlyfans.com/transparency-center/verification

pacts on marginalized content creators [4]. Furthermore, the structural design of OnlyFans necessitates off-platform advertising, subjecting creators to the policy changes and associated risks of other platforms.

Additionally, since OnlyFans uses third-party services for user verification and monitoring for minor content on the platform, breaches of OnlyFans or its third-party services are sources of risk for creators [85]. In a case study, Ford highlights the absence of preventive measures against screenshots or screen recording on OnlyFans, creating a risk of unauthorized distribution of creators' material, constituting both service theft and image-based sexual abuse [34].

3 Related Work

We discuss prior literature on online risks and safety practices of content creators and sex workers.

Content creators. Across social media platforms, content creators produce content for financial benefits [56, 93], self-expression [19, 65, 70, 73], socialization [65, 73, 93], and popularity (e.g., to create "media brands") [26]. However, prior work explored the multifaceted challenges that content creators face. For instance, Uttarapong et al. investigated the harassment experiences of women and LGBTQ streamers on Twitch, revealing difficulties in coping real-time with negativity from fans [96]. While Jhaver et al. describe how YouTube creators benefit from using collaborative keyword filtering to manage hate and harassment [52], community self-moderation requires significant emotional and relational work [96]. Further, such labor may not fall equally. Haimson et al. found that content moderation may lead to disproportionate censorship of trans people and certain racial identities (e.g., Black), despite following platform policies [43].

In a survey of 135 social media creators, Thomas et al. explored online risks, including targeted attacks, hate speech, threats of violence, impersonation, account hijacking, stalking, and false reporting [91]. To cope, creators often resort to self-censorship or may choose to leave a platform entirely. Samermit et al. in a recent interview study with 23 content creators, found that prominence, social norms, marginalization, and access to sensitive resources were reasons for online risks, including toxic content, harms to family, stalking, privacy risks, impersonation, and account hijacking or false reporting [81]. To cope, creators maintained privacy, employed moderation techniques, and sought advice from other creators, but found platform support and legal aid hard to reach.

Sex workers. Sex work encompasses a diverse spectrum of sexual labor, including stripping, pornography, and outdoor full-contact sex work [60]. Digitally-mediated sex work, defined as "the Internet-mediated exchange of sexual commodities and/or services" [53, 82], is performed by sex workers who organize and market their labor through digital platforms [12, 53, 75]. This form of sex work may offer increased safety, a more appealing labor environment, better wages, efficient advertising, and client vetting methods [27, 53].

Digitally-mediated sex work includes both digital-mediation of in-person work (e.g., digital communication with clients for in-person sex work) and online-only sex work like OnlyFans or web-camming "in which cam models sell interactive computer-mediated sex online" [54]. Jones and Campbell, respectively, discuss challenges in digitally-mediated in-person sex work, namely lack of control on digital identities [53], under- or non-payment for services, online harassment including persistent unwanted contact, verbal abuse, surveillance, and hesitance in seeking law enforcement help against harms given the non-existent legalization of crimes on digital platforms [23]. Sanders et al. discover that U.K.-based sex workers mitigate such digital risks by using aliases, filtering clients, and utilizing social media to connect with friends and ensure their safety [82]. In a recent study, McDonald et al. highlighted that in-person sex workers faced risks coming from clients, deficient legal protections, and hostile digital platforms, which participants mitigate by covering for a friend or colleague, vetting clients, and managing digital identities [67]. Strohmayer et al. studied how sex workers use digital technologies to report harassment such as boundary pushing and violence, and use such tools to proactively avoid violent or disrespectful clients [87, 88].

In analyzing the largest UK-based adult entertainment platform, Rand [75] finds that although digital platforms enable flexibility and choice, sex workers become dependent on those platforms. As a consequence, workers may pay higher intermediary fees and must constantly diversify and engage with consumers to stay profitable in a competitive market.

The traffic to online adult websites grew [39] during the COVID-19 pandemic outbreak and associated lockdowns, providing a source of income for both sex workers and those without prior sex work experience [45, 47, 78]. Hamilton et al. found that the in-person sex workers who shifted to online-only sex work during the COVID-19 pandemic experienced increased digital exposure and faced platform loss (deplatforming), stalking, harassment, and content theft [45]. Rubattu et al. performed a media analysis post COVID-19 pandemic, finding that those new to sex work experienced outing and harassment online [78], echoing pre-pandemic observations [53, 54, 82].

Apart from the aforementioned challenges, sex workers also face risks stemming from different legislatures and social norms across countries. Sex work legality varies from country to country and even within individual countries. Prior work finds that American legislation and social attitudes lead platforms (including payment processors) to censor sexual expression and sex work to shield from liability and protect their corporate image—regardless of the legal status of the censored expression or labor in the U.S. or in the user's country [1, 9]. To do so, platforms may use algorithmic shadowbanning[2] [15, 92], place blanket bans in their terms of service

(ToS) against the use of their services for any sex work-related activities [9, 13, 15, 16], or over-censor potentially objectionable content [4]. Stardust et al. theorize that sex work stigma is a key driver for such policies and practices and argue for anti-discrimination protections for sex workers [86].

Beyond censoring expression and work, prior work also finds that sex workers themselves may be systematically identified and de-platformed based purely on their identity as sex workers, regardless of whether they are using the platform for that work [9, 16, 67]. Such censorship can lead to diminished financial stability, safety, and community access [7, 17].

OnlyFans, a UK-based platform, operates where many types of sex work are legal and primarily facilitates pornographic services, which are legal in the US. Our work contributes to the broader literature on both professional content creation and online sex work as we investigate creator security and privacy on OnlyFans, a web-based social media platform focused primarily on sexual content and with a unique combination of attributes including lack of internal searchability that requires cross-platform advertising and interaction, a greater level of mainstream visibility than other sexual-content focused platforms [45,47], and a variety of subscription, paywall and direct interaction models of creator-fan interaction [79].

4 Methods

We conducted 43 semi-structured interviews with OnlyFans creators in two cohorts: 1) at the onset of the COVID-19 pandemic and 2) between September and October 2021. Additional questions regarding the impacts of policy changes were incorporated into our questionnaire in response to OnlyFans' announcement and subsequent retraction of the ban on explicit content in August 2021 (§ 2). Here, we provide an overview of our participant recruitment, data collection, and data analysis approach, along with the ethical practices followed throughout this multi-phase interview study.

4.1 Participant Recruitment

We recruited participants with a variety of backgrounds including those with and without prior experience in sex work on social media, through the researchers' personal networks, and for the second phase of recruitment, with printed flyers in coffee shops, grocery stores and on university campuses in multiple U.S. cities.

The link and QR code on the recruitment graphic led participants to a screening survey in Qualtrics (Appendix A). We employed Qualtrics' quota function with filters for age, gender, and ethnicity to achieve a diverse sample, encompassing various identities that could impact participants' experiences on the platform. Given that OnlyFans does not publish demographic data about its creators and the inherent limitation of smaller sample sizes in interview studies, our aim was to prioritize a diverse sample rather than pursuing a "representative" one. We therefore used the quota function to ensure demographic diversity amongst those we recruited. Qualification for the study was limited to those over 18 and currently or recently (within 6 months) creating content on OnlyFans. Participants that qualified through the screening survey questions were invited to self-schedule an interview through Calendly, which allows for anonymous sign-up.

Participant demographics. We had a diverse sample of participants across many identities with a median age of 30 years ($\sigma = 5.37$); self-reported genders[6] of woman (25), non-binary (15), man (4), and trans (3); and self-reported race/ethnicity of: white alone (26), Black (5), Asian (4), Hispanic and white (3), Asian and white (1), and other (4). 26 of 43 participants were disabled (3 choose not to answer). Of the first cohort of participants, all were LGBTQ+ and we did not ask the second cohort to specify. We did not ask the first cohort about their highest level of education or their income on OnlyFans. Most of the second cohort had at least some college education but no degree, with the rest having additional qualifications. Among those who disclosed their OnlyFans income earned to date, the reported income ranged between $135 and $332,000 ($\sigma = \$83,974.24$). Out of 43 participants, 24 had prior sex work experience, 19 did not, and three had recently left the platform before the interview.

Not all of our participants disclosed their number of followers; but those who did disclose ranged from creators with tens to those with tens of thousands of fans. The web-use skills [48] of our 43 participants ranged from 1.33 to 5 with a mean of 3.57 ($\sigma = 1.21$).

4.2 Data Collection

Before starting the interview, interviewers explained the study goals and answered any questions regarding confidentiality, the research team and data use, and reminded participants that they could skip any question. We then re-affirmed consent to record. We used a semi-structured interview protocol, starting with background questions about their prior works and their comparisons to OnlyFans experience, content creation, business model, safety and privacy, impacts of changes in ToS, platform use, and overall OnlyFans experience. The relevant interview questions for this paper can be found in Appendix A. All interviews were conducted online in English via video, voice, or chat. They were transcribed and any identifying information was removed. Participants were compensated $50 through PayPal or Amazon gift card.

4.3 Data Analysis

Study researchers employed thematic analysis [20] to gain insights into the online experiences of OnlyFans creators. After becoming familiar with the collected data, the primary

[6] We report genders following the HCI Guidelines for Gender Equity and Inclusivity: www.morgan-klaus.com/gender-guidelines.html

coder inductively created an initial codebook [25] from a random selection of five transcripts. This initial codebook was then cross-referenced with the online hate and harassment framework [90] to add any missing themes and align the terminology of the inductive codes with the framework where applicable. Two coders used this codebook to independently analyze five new transcripts and test the coverage of codes. They met to discuss code applications extensively and made necessary refinements to the codebook, mainly developing the codes into themes. After independently coding three more transcripts, the coders achieved a substantial inter-coder reliability score for Cohen's Kappa ($\kappa > 0.7$) [58] and refined the codebook until any minor disagreements were resolved. Coders used the final codebook to independently code the remaining transcripts, evenly dividing them between both.

We primarily report our findings qualitatively using participant quotes, shared experiences, and incidents to describe and interpret the themes that emerged from the interviews. While reporting, we occasionally provide counts (i.e., how many participants reported each risk or safety practice) of overall themes to demonstrate the prevalence of certain patterns and ensure transparency in our data analysis.

4.4 Ethics

The research procedures were approved by the institutional ethics boards of the researchers. At every stage of the research, we undertook great care to provide the highest possible level of protections for participants' data privacy and anonymity. We used end-to-end encrypted platforms for the interviews (paid Webex) and no systems required legal information or login. The interviews were scheduled using Calendly and we provided advice on signing up with an encrypted email address if preferred. The payment options could both be anonymous (Amazon gift card) or to any address (PayPal).

Research justice. We employed a sex worker to transcribe the interviews. A copy of the published research will be sent to all participants who requested it. We also employed OnlyFans creators to work as consultants on designing the study (including the interview protocol) and they circulated the recruitment graphic within their networks. The authors' commitment to research justice contributes to their trust capital as researchers of a population with research fatigue. This trust capital is essential in such research with a marginalized community.

Positionality. To design the study, recruit participants, and write the interview protocol, the research team included OnlyFans creators as consultants. The data analysis and writing of this paper were carried out by researchers who are scholars of technology and sex work but who are not OnlyFans creators. The OnlyFans creator consultants who assisted in the study design were not participants.

Limitations. OnlyFans is an extremely competitive market. Whilst we felt our participants were very honest with us, it is important to note that due to the nature of the work and the industry in general, some participants might have preferred to omit relevant information. OnlyFans has a global reach, and has creators and fans from many countries. We conducted interviews with creators only from the Global North in English, which limits generalizations regarding other territories. By focusing on our participants' shared (positive or negative) experiences, some insights might have been missed from those with contrasting opinions, however our participants' varied experiences on the platform might have balanced out the bias. Lastly, the participant demographics include creators with genders or ethnicities which were not reflected in the interview or research team, limiting our insight into that data.

5 Results

After analyzing interviews with 43 OnlyFans creators through the lens of the online hate and harassment framework [90], we now delve into their perceived and experienced risks and how they defend against those risks.

5.1 Platform Risks

Participants were most concerned (29 participants) about risks from platform precarity and censorship.

Platform precarity. The policy of banning sexual content from OnlyFans, which was later reversed (§ 2), had a lasting impact on our participants. The impacts of this ToS change were not only financial: "people were not re-billing or re-subscribing" (P11), but also emotional:

> *When you deplatform creators you take away their community and that's violence. You are isolating people and as we all know from this last year isolation leads to severe mental health consequences.*

P9 reported that the change in ToS and resulting media coverage elevated the platform's visibility, leading to increased harassment toward creators: "we didn't even get to find out from the platform itself, we found out from news outlets and I think it also exposed us to a lot of harassment on the internet from people who don't like sex work."

OnlyFans explained the ToS change as being a result of pressure from financial institutions [77]. Some participants shared this view, explaining that "banking institutions are now deciding what is moral and what is not moral to purchase... it directly impacts people on OnlyFans" (P11). Others ascribed intentionality and responsibility to OnlyFans. 14 participants felt that OnlyFans "is uncomfortable with being a platform that hosts sex work" (P12), "is trying really hard to say no, there are no sex workers... it's mostly chefs and fitness influencers" (P39), and was "cleaning up their image" by banning sexual content (P26). P22 felt that "what happened with the ToS revealed that OnlyFans simply does not believe sex workers to be their primary creative force, which I think

they are." After the ban, 14 participants—new to creating sexual content—expressed feeling less safe due to the increased platform precarity. P6 stated:

> *In terms of like the decisions that the platform's making... they just use sex workers and then will sell them out. I feel physically safe you know, but like not as politically safe as I did at first if that makes sense.*

Platform censorship. Since OnlyFans lacks internal discoverability, creators work cross-platform to drive fans to their accounts. These platforms may remove, block or restrict the content they share, shadowban their accounts, or deplatform creators, even if the platform's ToS are not violated.

Twitter does not ban pornography and other forms of consensually produced adult content when marked "sensitive" [35]. But P32 experienced shadowbanning on Twitter for "overly promoting OnlyFans." Although platforms by and large hide the criteria for shadowbanning content [4], our participants have identified behaviors that seem to impact their reach. They perceive that the likelihood of shadowbanning while promoting on other platforms increases when creators using automation tools are perceived as bots (P27), when they use hashtags often (P25, P31, P33, P38), or send the same message with an OnlyFans link too many times in a period of time (P23). Creators become aware of their content being shadowbanned from platforms only when they observe less engagement or income generation. P23 described how fear of shadowbanning creates cascading promotional challenges because "other colleagues don't tend to retweet you when you're promoting your OnlyFans, probably out of fear of getting shadowbanned themselves."

Prior work on professional non-sexual content creators [81] notes that creators are highly aware that violation of platform norms comes at a high cost—losing access to the platform and its associated audience. Our participants similarly feared violating OnlyFans' and other platforms' ToS. 13 of the 22 participants in our second cohort reported that they had either read or skimmed through the ToS. P9 explained their proactivity in carefully reading the ToS: "they [OnlyFans] often ban people and they [the creators] don't get their pending balance. It's not a risk that I'm willing to take."

Even when a post does not violate ToS, censorship occurs due to factors such as co-moderation (where other users participate in moderation by blocking and reporting other people) [15], discrimination against expression of sexuality, sexual identity [15], poor implementation of not-safe-for-work (NSFW) moderation [92], or when creators post content that is legally sensitive—deemed criminal in some countries [4] or perceived as advocating against policies and laws [15].

In line with prior work on racial, gender and body size variance in platform censorship of sexual expression [36, 43, 66], participants underscored the variance in censorship across creators. P39 explained: "I was so heavily censored... I had a photo of me and my friend that was clothed, and we were kissing, and we were two Asian women, I'm South Asian, she's Asian, and that got deleted right away... similar photos of my white counterparts weren't censored... more explicit photos." Conversely, P30 described his experience:

> *My risk of being censored is a lot lower as a male performer, and as a white performer. So I'm quite amazed my Instagram is still available and intact while other people have lost their account a thousand times in that same time period.*

Participants tried to hypothesize about the cause of such censorship, pointing to co-moderation (P42: "I'm trying to figure out if it's someone reporting me or if it's Instagram itself" and P9: "TikTok is huge for that [censorship]... since they have a user-based report system") and suppression of sexual expression (P27: "I feel like the algorithm interprets that [pictures in panties] as little less human").

Fear of violating platform norms can lead to creators proactively silencing themselves or leaving content creation [91]. P39 explained how the disproportionate impacts of platform censorship can end up silencing some more than others:

> *It's frustrating to be constantly living censored both on Twitter and Instagram. It's a systematic way of silencing people of color and queer folks so we just give up and stop posting which essentially is what happens. It's effective, because it's exactly what happened. I gave up.*

To make platform moderation more equitable for marginalized social media users, Haimson et al. suggest platforms collaborate with marginalized communities and develop censorship policies and enforcement mechanisms that better reflect the voices and needs of the community [43].

5.1.1 Defenses

To defend against platform precarity and censorship, participants diversified the platforms they used to sell content and/or engaged in self-censorship on the platforms they already used.

Platform diversification. 12 participants diversified the platforms on which they created and sold content. While for some, like P10, diversification was purely to defend against precarity ("the reason I'm building out on another platform is just in case something like that [sexual content ban] happens again, I definitely want to be diversified even more"), others diversified to avoid violating ToS. P12 publishes "prohibited content to another [sex work] platform [that allows it] instead." Participants chose platforms for diversification based on their longevity (P18) or recommendations from other creators (P3, P4, P15). While some participants actively used the accounts they created on other platforms, others username squatted—created accounts with their preferred username to reserve it in case they were deplatformed or OnlyFans ceased to exist in the future—but did not actively use their other accounts.

Self-censorship and Algospeak. Participants self-censored on social media platforms to reduce platform harms ($n = 24$,

§ 5.1) and manage their identity ($n = 22$, § 5.3.2).

P29 created a cheat-sheet to help them self-censor on OnlyFans: "when I started I wrote everything on paper that we can't use, so I'm always looking at that sheet for like okay, this I can, this I can['t]." On advertising platforms (e.g., social media), participants also invested significant effort to ensure that they comply with all non-adult-content related regulations and ToS (e.g., P33 avoids posting with music that "could potentially be flagged for copyright").

Algorithm Speak (Algospeak) encompasses strategies of abbreviations, deliberate misspelling, or substitution of words to avoid automated content moderation systems [2]. This approach is commonly employed by social media users to circumvent platform censorship [55]. To circumvent censorship, our participants "try to be vague as possible to make account[s] last as long as possible" (P25) or used acronyms: "if I tweet about OnlyFans, I'll use the acronym *OF*..." (P8). P41 told us: "there are many words that are forbidden [on OnlyFans]... obviously the words can be taken out of context and not always mean that thing." Therefore, our participants use different spellings (P41, P39, P28) or emojis, symbols, or synonyms for restricted words (P23, P26) to not get *flagged or blocked* on-platform when they are posting or chatting. In some cases, using Algospeak was too cumbersome and participants instead engaged with clients off-platform:

> *Once, I got a request to write a dirty story for a client and I had to drop it in the chat and every fourth word was a word that could not go through on OnlyFans... I ended up emailing the story. (P42)*

Finally, some tweaked their profile attributes to avoid bias in the censorship process. P34, who intentionally changed their gender (to male) on Instagram explains how it reduced their experiences of censorship: "I've been kind of pushing the envelope with Instagram but I haven't had anything taken down in a while... it's really sad but [changing my gender] made a huge difference."

5.2 Toxic Content

Like at-risk users [90] and other professional content creators [81, 91], 26 of our participants described dealing with different forms of toxic content such as harassment and online hate from fans directly on OnlyFans as well as from other platforms that caused varying degrees of emotional harm. Echoing professional non-sexual content creators' expressions that such hate and harassment is unavoidable [91], our participants noted that toxic content is "just part of being on the platform" (P20) and there are "just clients that have no idea how to message people" (P39).

Harassment and bullying. Participants commonly ($n = 19$) experienced *boundary pushing* where fans become "overly persistent"—exceeding or violating personal or professional limits set by the creators—and P17 indicates that "it's a fine line between being overly insistent and obsession." P1, who provides messaging service on OnlyFans, was tired of people "pushing to learn more to get a little more familiar." P13 experiences mental distress when fans repeatedly push boundaries and "be disrespectful," making it "complicated" (P25) for creators to effectively manage fan interactions.

Boundary pushing can extend beyond requesting additional information or content, reaching into demands for more of the creator's time. For example, P39 said "people were expecting instant replies all the time from me" and P40 added "you had to be online 24-7, every time you're not answering you're missing out on money and I did not like the stress of that."

8 participants mentioned experiencing other forms of harassment and general bullying on the internet, on OnlyFans, and in-person as a result of their work on OnlyFans. P11 described one of the rude comments: "some people just say that... you're just a cheap whore... why would anyone want to date you if they can just see you for free." These negative experiences take a mental toll (P20) on creators and can do psychological harm [10, 64, 83]: "online harassment is going to affect [me] more mentally than anything else" (P11).

Online hate. Six participants faced online hate based on their appearance, race, or gender. P12 observed "people being transphobic or racist" and like P31, P21 said "a lot of women of color and trans people who are not thin and white, experience the brunt of hate." P31 emphasized the mental toll of increased hate online relating to more visibility:

> *With online work, because of how many more people you're seeing, you're exposed to a lot more trolls and time wasters than you would in person because it's just the volume and number of people, especially if you're not white or thin or cis.*

P21 noted varying types of hate on different social media platforms, attributing it to the demographics of both users and creators. For example, they perceived Reddit to have an audience "dominated primarily by white American men" and who preferred content from "thin white women" whereas "Twitter is much more diverse with its user base."

5.2.1 Defenses

To address hate and harassment, participants established clear rules ($n = 18$) or blocked ($n = 13$) attackers. Additionally, some participants call on community support (P22: "if someone posted something *mean* I would just retweet it and then the entire internet would ask to delete their account") or respond directly to their harasser themselves (P22: "I'm very skilled at handling [hate and harassment] because I'm sassy"). Others simply ignore the harassment: "I have a really really thick skin from working in this industry for a long time" (P11). This strategy is similar to how other populations manage harassment [81, 90, 91].

Boundary setting with fans. To address the most common form of harassment, boundary pushing, participants made significant efforts to establish *strong* boundaries with fans. P10

received uncomfortable messages and pricing negotiations on their free page, but when they observed that individuals on their paid account exhibited comparatively more polite communication, they deleted the free page. To avoid repeated requests, P4 has added a statement to their bio: "you are welcome to send requests but... I have every right to deny them." During the interview, P2 said, "I mean people are rude for sure sometimes but there isn't a rating system like in so many gig work apps." P38 increased their prices to "weed out assholes" and P36 shared that "they [fans] always wanted the cheaper, the best, even free... I don't have to give them what the broke boys want." P30 clearly communicates their boundaries to fans, but they acknowledge that "expressing boundaries can be hard work and really difficult." For P18, not having to negotiate their established boundaries and saying that "these are boundaries for a reason" gives them a sense of privacy.

Blocking. 13 participants indicated that they employ the platform's block feature when encountering spamming or harassing clients. Upon receiving uncomfortable requests, some participants first tried to warn the fans about their boundaries but would also "restrict them or block them depending on the severity... how aggressive they're being with it" (P9). Similarly, P4 does not react instantly to repeated requests but "ends up blocking people who just kind of go out of hand."

P43 found it easier to handle fan issues online as compared to in-person sex work: "[there] was nothing I couldn't solve by blocking." P11 emphasized the significance of blocking, stating, "if someone is being really crappy towards you, just block them... OnlyFans work is also the biggest privilege within sex work." According to P19, "the only safe thing OnlyFans offers is blocking." P10 further elaborated on the convenience and practicality of the blocking feature:

> *I've blocked way more accounts on these two OnlyFans accounts I've had for a year and a half or two years... once they [fans] start pushing I'm just like no, blocked. I'm not even going to deal with you. It's like no is a full sentence.*

When engaging in off-platform advertising, creators, like P18, "made heavy use of block buttons" to manage heightened harassment due to sex work stigma.

5.3 Content Leakage

Content leaks [90] were the next most common ($n = 24$) risk our participants reported. Although creator content on OnlyFans is paywalled (§ 2), it can be illicitly captured in violation of the ToS and the creators' consent by screenshotting and downloading. Additionally, OnlyFans itself can be hacked: in February 2020, an estimated 1.4 to 4 terabytes of OnlyFans videos and photos were shared across social media [28].

Multiple participants viewed content leaks as inevitable: "there's always a possibility for that [content leak]" (P4), "no matter what you do leaks are inevitable" (P21), "it's [content is] going to eventually get stolen"(P27), and "it's just something that unfortunately is part of the job" (P31).

Prior work on image-based sexual abuse finds that perpetrators may leak content in order to raise their own social status, using the content they non-consensually obtain and distribute as a form of social currency [31, 49]. In line with this, P36 describes their perception that:

> *The usual porn user is kind of like a hoarder of porn, they save all the porn and try to put them again on platforms to share them around like if they were kind of football cards.*

In the transactional context of OnlyFans, content theft deprives creators of income. Attackers may thus be motivated to engage in content leaks to obtain content for free or to leverage fraudulently obtained content to profit financially, as detailed next.

5.3.1 Harms of Content Leakage

Content leakage can cause harm in a variety of ways, and enable additional attacks.

Privacy violation & image-based sexual abuse. While OnlyFans creators consent to post and share their intimate content within the platform's transactional context, they do not consent to it being further shared nor viewed outside the context of this platform and transaction. Thus, leaks of creators' intimate content are a form of image-based sexual abuse [49, 90]. Such abuse is a violation in itself and has significant emotional and psychological consequences [49, 80, 100]. The permanence of intimate content leaks (e.g., P41 describes fearing their leaked content "being on the internet forever") and severity of consequences from such leaks make them a "severe" form of hate and harassment, as defined by prior work [90].

Outing. Attacker motivations for content leaks may vary. Attackers may also non-consensually distribute others' intimate content as a *targeted* form of abuse by doxxing creators and/or outing them as members of stigmatized communities (e.g., the sex worker and/or LGBTQ+ community). Attackers may do so by leaking creators' content and linking it to their personal information [22], which they can discover through a variety of means including using "facial recognition software... [to] find your old [pictures] from high school and... your name and where you grew up" (P9). Such attacks can cause relationship, reputational, and physical harms [83]. Similar to 13 other participants, safety to P11 is:

> *...being able to do what I do and not worry about being doxxed and having stalkers and people showing up at my house to potentially do harm to me.*

P9 mentioned the potential "safety risk" of "families kicking [creators] out of the house" if they found out about their work, while P22 linked "getting outed as a sex worker" to "receiving professional retribution." P1 fears how permanent content leaks could impact their ability to get other jobs in the future after they finish their schooling, because the "engineering world does not look too highly upon OnlyFans."

Chargebacks. Chargebacks happen when a purchaser falsely disputes a product charge, often by reporting credit card fraud or claiming they do not recognize the payments on a bank statement. The sex industry has particularly high chargeback rates due to the discreet and stigmatized nature of purchasing sexual content [21, 86, 94, 105]. For OnlyFans creators, chargebacks are passed on directly to creators, meaning a client gets access to their content without ultimately paying for it, violating their consent and impacting their revenue. Four participants in our work described being victimized by chargebacks. P23 explains:

> *So, if a guy gives you loads and loads of money and then decides to report that he got his credit card stolen, then you don't get that money back.*

P7 similarly described their experiences with "the people who come in and drop a whole bunch of money and then back track it." However, they proactively started charging extra for content they particularly wanted to protect and told us: "it would be nice if OnlyFans fixed that loophole."

Catfishing. Catfishing[7] is an impersonation attack [90] in which an attacker creates a fake online profile to trick people, usually for financial gain. In the context of OnlyFans, catfishing means someone copying creators' videos or posts to impersonate their OnlyFans identify elsewhere and engage in fraud. P9 described that scammers create fake Instagram accounts using OnlyFans creators' content to deceive fans, which damages creators' reputations and harms their followers. P12 and P22 shared instances where they found catfish profiles made using their images on Grindr. Additionally, P11 encountered their stolen images on Reddit, where the account attempted to defraud their fans. Fortunately, they were able to have these accounts taken down as they had watermarked their images (see below).

5.3.2 Defenses

In response to the threat of content leakage and its cascading attacks, our participants employed a variety of protections. P9 mentioned how an OnlyFans creator has to engage in adversarial thinking and "get in the minds of people who could potentially want to harm you." They summarized some of the technical protection strategies they were aware of:

> *There's a lot of services out there that will get your name scrubbed off of voter records or at least your address so no one can show up at your house... be very careful with not having your Snapchat location [on]... photos taken on iPhone have your information encrypted inside of them.*

Limiting prominence (and profit). Seven of our less prominent participants intentionally aimed to limit their popularity, motivated by the fear of having their location discovered or having their non-OnlyFans professional progress hindered. P4 and P7 expressed contentment with not having a significantly large following as the "stress from that is not great." Given their limited prominence, P7 was confident that their content would not be widely shared, while bigger accounts have to "deal with large chargebacks and take the heat." P23 was worried that increased visibility could impact their interpersonal relationships and privacy:

> *It exposes me to much more... there's much more exposure, there's not much privacy, any ex-boyfriend or stalker can look at my OnlyFans and they're seeing my sex work in a way they couldn't before.*

On the other hand, because OnlyFans lacks internal discovery and creators engage in cross-platform advertising, managing off-platform prominence becomes challenging: "my advertising is everywhere, and I know TikTok advertises more wherever your SIM card is based and I'm just using my regular phone so they're pushing my videos out more locally" (P24).

Internet presence monitoring. 17 participants actively implemented internet presence monitoring schemes to check for leaked content. P40 said: "the likelihood of it [content] getting leaked was giving me anxiety, OnlyFans leaks are very common and I was constantly googling if my shit got leaked." P2 searches variations of their name on Google to see "what's out there and delete-able." P35 does the same, and also checks PornHub and XVideos for stolen content to "not have videos out there for free." P9 uses image search to look for their leaked content on Reddit and Google. They also leverage a subscription service that searches for their name and scrubs identifiable information from the internet.

11 participants reported using DMCA takedown services[8] to remove stolen content from the internet. However, some participants hesitated to use these services either because of skepticism (P27: "it's not even like a guarantee"), the service's convoluted process and potential non-responsiveness (P33: "this might be really complicated, what if they don't respond?"), or the financial burden (P40: "this would take a lot of cash").

Two participants (P12, P22) who experienced catfishing received help from others in reporting catfishers. For example, when P22's photos were used to create a fake Grindr account, they made their fans aware of the catfish by tweeting and asking people to report the account.

During the interview, P8 and P40 mentioned the feature on OnlyFans that supposedly prevents users from taking screenshots or recording content. P8 described the similarity to platforms like Netflix, where attempting to screenshot results in a black screen, adding "I never actually tried it out to see if it works, I sort of just trusted it." However, OnlyFans does not currently have any features in place to prevent screen

[7] Prior literature has sometimes referred to similar attacks using an attacker term of art—"eWhoring"—to specify catfishing fraud conducted using "sexualized images" [51]. The use of the term "whore" is however disrespectful and therefore we opt not to use it [97].

[8] A DMCA takedown happens when the owner of content claims a copyright violation and requests a platform remove the content, https://www.dmca.com/

recording. This highlights the misconceptions that can exist in participants' mental models of platform-provided security tools.

Watermarking. Six participants relied on OnlyFans' in-platform content watermarking to deter content theft (§ 5.3). However, 14 participants practiced proactive watermarking to protect their content from theft and unauthorized use, as well as to trace specific people who stole the content via personalized watermarks. OnlyFans does not challenge intellectual property infringement on behalf of its creators, and so the responsibility for recovery is left to individuals. Prominence also influences creators' decisions about how to protect their content. P43 deems the extensive efforts of watermarking "probably not worth it at my level of visibility." P11, P20, and P37 recognize that leaked watermarked content also serve as a kind of promotion, as people can identify the creators through the username on the content, which potentially helps recover lost income.

Keeping online identities separate. Similar to online account management strategies of in-person sex workers [67], many participants ($n = 22$) kept their personal social media accounts separate from their OnlyFans accounts or the social media accounts used to promote OnlyFans. P25 keeps their social media accounts separate to prevent platforms from suggesting their profile to unwanted individuals. P33 reduced their posts on social media after an incident:

> *While I was on holiday I posted a picture of myself on the beach on my main Instagram which my friends and family see and on my porn Instagram, and I tagged my location, and then someone found the main, and I was like that was so dumb, I can't believe I did that.*

Participants' efforts to separate their online identities exist on a spectrum. Seven participants who were already open about their sex work in their personal lives did not worry about the risk of getting outed. For example, P32 said "I was already face out, so I wasn't necessarily concerned about clients taking screenshots of private photos that were revealing my face and sharing them and outing me." One participant (P34) even switched their personal Instagram account to a sex work account and deliberately outed themselves.

Saving username on different platforms. To minimize impersonation risk, five participants strategically saved their usernames on other platforms. To that end, P33 said: "I did worry that someone would want to impersonate me on there which is why I thought it'd make sense to get the username [on another site]." Creators sometimes encounter challenges in securing their usernames, as highlighted by P16: "someone took my username, some cis guy from UK who doesn't even do anything, he just watches people, he doesn't post anything, he doesn't stream. It's just really annoying."

Limiting identifying information on OnlyFans. Our study participants employed various strategies to hide any identifying information online, as P7 mentioned: "Sex workers are more at risk as soon as they put nudity online... I do more to keep my identity hidden on my OnlyFans account rather than my personal accounts."

To that end, 10 participants concealed their faces in their posts to maintain anonymity. For instance, P4 angles their camera to exclude their face in nude content, but reveals their face when portraying a cosplay character. P1 hesitates to use blurring software to conceal their face due to concerns about potential de-blurring, and instead opts to physically cover and crop their face before posting for "double security." P33 shared an incident where they did not hide their face in the "most clever way":

> *Sometimes I hide the top part of my face and sometimes I hide the bottom half of my face, and I had a guy who had stitched together the top half and the bottom half and he sent it to me like look, I've made a picture of your face, this is what you look like!*

P3 avoids posting identical content on their OnlyFans and NSFW Twitter accounts to mitigate the risk of reverse image searches linking pictures of their face across platforms.

16 participants proactively used aliases to protect their legal name. P13, a cosplayer, mentioned: "...with cosplayers, it's so easy to get people who are just creepy and trying to find my Facebook account. Then, they were finding out where I worked, where I lived... going by a different name adds a layer of security to anything that I do."

18 participants concealed their location on OnlyFans using security-focused tools such as VPNs. P17 felt "super secure" using VPNs because "just in case somebody was to get a weird idea to try to figure out my location it wouldn't even ping off to what state I am in." P18, on using a VPN, said "I'm assuming I'm not the only one who's heard horror stories. So like just making sure to have like a level of semi-anonymity in there." Some participants further hid their location by, e.g., avoiding taking photos near identifiable landmarks (P9, P10), turning off geo-location from images and videos (P10, P17, P19), and removing image meta-data (P16).

Managing outness offline. 16 participants proactively avoided disclosing ("a polite omission" - P12) their OnlyFans work with certain people in their life, primarily because of the stigma around sex work (P1: "this person has no dignity, no morals") or to reduce relationship harm (P11: "I don't think that they [parents] would even understand what is going on") [83]. Maintaining secrecy posed challenges for some; P10 consistently faced stress while upholding a "cover story." Similar to 13 participants, P8 opted to identify as a *content creator* to navigate interpersonal and professional relationships without revealing their OnlyFans association.

5.4 Adopting Digital Safety Practices

In contrast to prior work on non-sexual professional content creators [81], where two-thirds of participants adopted protec-

tive practices only *reactively*, we observe that before joining OnlyFans, all of our participants adopted one or more protective practices to avoid content leakage (§ 5.3.2). While most participants focused on protective practices to preemptively keep their online identities separate, some also preemptively limited their prominence, set up internet presence monitoring tools, watermarked content, limited identifying information on OnlyFans, and managed outness about OnlyFans work offline. Additionally, some participants became early adopters of strong boundaries to defend against toxic content (§ 5.2.1).

Learning sources. Participants learned these initial practices from fragmented sources of digital safety advice [76] and from their own "common sense" (P10) and technical skills, like "tech nerd" P16 and "Google queen" P20. For example, P8 engaged in preliminary research on OnlyFans' safety mechanisms to assess the platform's security features:

> *So the types of like encryption that they use or how they watermark photos... definitely didn't research in depth but like very slightly like legality and making a claim in your account about like if people were to redistribute it [content].*

Friends also served as sources of knowledge. For example, P13 learned their safety practices through a friend's doxxing experience in addition to their own stalking experience as a younger cosplayer, and P22 received information from friends about general internet safety. P4 on the other hand learned to watermark any content they share from observing their friend's experience of content leaks, and seeing their friend use watermarks to help trace who had leaked their content.

As reported in prior work [7, 87, 88, 95], our participants also learned certain safety mechanisms from OnlyFans and online sex-work-specific communities. 16 participants derived reassurance and support from being an active member of a strong and closely-knit online community of content creators, where they learned about safety and privacy, content creation and marketing strategies, and other OnlyFans-related experiences. P13 felt from the beginning that they could establish boundaries about the type of content they create when they saw others opting out of creating very explicit content. From being part of the OnlyFans community, P36 learned tips to grow as an online sex worker, perseverance, as well as boundary setting ("they taught me that I don't have to cater to what the boys want"). Likewise, P21 learned about "basic things such as knowing your boundaries, to not feel uncomfortable, how to protect yourself online, and a little bit of anonymity" through a sex work industry video.

Preparedness. Participants mentioned that they learned to be proactive in their defensive approach because of the societal stigma around sex work: "there's definitely a little bit of a stigma... I can't exactly go on my Instagram and start broadcasting or I'm gonna get a label [for] myself" (P1). Recognizing potential risks, P9 advocated for proactive preparation, stating, "ignorance is not bliss in this situation."

While participants were very proactive in their security posture, they also engaged in ongoing learning. To that end, 13 participants actively monitor Twitter and Reddit to learn about safety tips on OnlyFans: "I follow like keywords for safety and security on OnlyFans" (P13), "there's a subreddit and there's a lot of really knowledgeable creators on there that can tell you what to do and how to stay safe" (P9), and "I check reddit, check top content creators, see how they feel about safety... they will post scammer IDs and stuff like that so you can go ahead and pre-block them" (P7).

6 Discussion

Through 43 semi-structured interviews with sexual content creators on OnlyFans, we documented creators' online threats and safety strategies. In this section, we synthesize our results using our research questions as a guide. We conclude with an exploration of the opportunities for better security affordances.

6.1 Creators' Threat Landscape: A Hate and Harassment Framework Perspective

We used Thomas et al.'s online hate and harassment framework [90] as a lens to understand the threat landscape of OnlyFans creators (RQ1). Our analysis reveals that OnlyFans creators experience digital risks common to other "at-risk" users—toxic content and content leakage—as well as more unique risks from platform censorship and precarity.

Similar to non-sexual content creators [81, 91], our participants experienced a high volume and expressed a high degree of concern about hate and harassment attacks. In contrast with non-sexual content creators who prior work finds predominantly face attacks related to toxic content [91], our participants experienced the most frequent and concerning threats from platform censorship and precarity.

Prior work finds that some non-sexual content creators worry about violating platform ToS and resulting platform censorship [81]. Our participants expressed such concerns in greater volume and with greater concern, and additionally raised concern about platform censorship as a result of biased moderation of ToS-compliant content due to the explicit and stigmatized nature of the content they share. Further, our participants expressed significant concern about the precarity of OnlyFans as a platform. Combined with threats creators face from people—of toxic content and content leakage—the threats of platform censorship and precarity foster a strong sense of insecurity among creators (§ 5.1).

6.2 Role of Stigma and Digital Prominence in Creators' Threat Landscape

Our results show that awareness of sex work stigma prompts OnlyFans creators to proactively anticipate and prepare for

online risks (§ 5.4), in contrast to non-sexual content creators who tend to approach digital safety in a more reactive fashion [81]. Participants often turned to their community, either passively through following community-members on social media, or actively by seeking out support from friends and community members. Our findings support prior work illustrating the influence of stigma on digital communities, where shared experiences of stigma foster a strong sense of solidarity and collective support [7, 33, 63]. Together this highlights the role of stigma in digital security education and offers evidence for its influence on differential threat models and protective behaviors between otherwise similar groups of end users (e.g., between digital content creators who do and do not do stigmatized work).

Stigma also intersects with prominence, influencing creators' online risks. Prior research revealed that social media content creators, even without the added layer of sex work stigma, faced increased risks with growing popularity [81]. Experts advise general Internet users to approach online participation with a minimalist mindset [100]. However, the content creation industry inherently requires information sharing for monetary gain, rendering a minimalist mindset impractical. Particularly on OnlyFans, which lacks internal searchability, off-platform information sharing becomes a necessity for creators to promote their content, attract subscribers, and generate revenue.

OnlyFans creators actively strive to maintain separate online identities to overcome challenges posed by stigma and balance the necessity of increased prominence with preservation of personal privacy. However, effectively maintaining privacy while prominently engaging online remains a challenge. Future work may seek to address this challenge by developing privacy-preserving technology to better support persona management [46]. Such work can help non-sexual professional content creators [81] who must manage their identities due to prominence, recreational content creators who are especially at-risk because of a stigmatized identity [61], and professional sexual content creators such as the OnlyFans creators we study who are at risk due to both prominence and stigmatized labor.

6.3 Platforms' Impacts on Creator Risks

Experts recommend using platform-provided tools to moderate abusive messages online [100]. However, both sexual and non-sexual content creators are skeptical about the support offered by platform tools. Although non-sexual content creators used keyword blocklists and manual reviewing to address hate and harassment, they expressed skepticism about the effectiveness of reporting users [91].

Similarly, while OnlyFans offers reporting options for addressing hate and harassment, our participants predominantly opted for *blocking* fans in response to such incidents, which provided them a sense of empowerment[9] and avoided reliance on the platform for justice. We hypothesize that our participants prefer not to rely on the platform due to experiences of platform precarity. For example, when OnlyFans suddenly banned explicit content (this ban was later reverted, see § 2), creators were left with a sense of helplessness (§ 5.1).

Additionally, some platform policies increased participants' apprehension that the platform would adequately safeguard their interests. For example, chargebacks pose a significant challenge in the sex industry. OnlyFans passes such risk on to creators directly: the community guidelines on chargebacks state that "any amounts that users seek to refund or chargeback will be reported to the creator and will be removed from the creator's income" [24]. This places a considerable financial burden on the creators, treating them as de-facto e-commerce merchants without affording them control over payments—typical to an e-commerce merchant—or the ability to contest chargebacks effectively.

Beyond OnlyFans itself, our participants experienced and/or perceived that mainstream platforms may be biased toward shadowbanning their content or deplatforming them due to the stigmatized nature of their labor and the content they share (§ 5.1). Consequently, they might be reluctant to depend on reporting tools provided by platforms they perceive as indifferent to their safety.

6.4 Suggestions for Solutions

Affordances for diversification. Our participants practiced platform diversification strategies (e.g., saving usernames on other platforms) to avoid sole dependence on a single source, such as OnlyFans, for income (§ 5.1.1). The precarious nature of sex work platforms also means that an account and all data within—photos, videos, messages, connections with fans—could be deleted arbitrarily and without notice [4]. However, diversification can be extremely challenging. It requires a significant time commitment and effort to maintain multiple-platform account activities effectively [44]. For instance, during OnlyFans' ban on sexual content (§ 2), participants expressed a desire for sufficient time to retrieve pending deposits and "safely delete content or transfer it [content] to other platform" (P4). Moving to alternative platforms requires critical evaluation based on factors such as popularity (in comparison to OnlyFans) and fan engagement. Only half of P11's fans were willing to move to other platform and P12 said "creators did not experience the same success that they had on OnlyFans" when creating new accounts, attributing it to the differing audience presence.

There have been various attempts to increase consumer control over personal data. For example, the General Data Protection Regulation (GDPR) Article 20 [37] asserts individuals' right to "receive their personal data in a machine-readable format and transfer that directly from one data controller to

[9] "If someone is being really crappy towards you, just block them" - P11

another (wherever possible)." This *right to data portability*, in theory, offers consumers significantly reduced costs for switching between digital service providers [57], and could play a crucial role in enabling OnlyFans creators to diversify their online presence and mitigate risks associated with platform dependence.

Despite the fact that the GDPR has been in force for several years, the right to data portability is still, in practice, largely unusable [89]. Requests can be cumbersome, data can be in unusual formats, and new platforms rarely have a method for ingesting data from another. With further advancements in enforcement and usability, data portability can offer creators stability and facilitate seamless content and data transfer.

Internet monitoring. OnlyFans' ToS recognize redistribution of content by fans on other platforms as a violation, but it neither prevents users from recording their screen nor enforces intellectual property rights on behalf of creators [34].

To search for and take down leaked content, participants practiced extensive "internet monitoring" (§ 5.3.2). This practice is time-consuming and emotionally draining, taking creators' time away from running a profitable business and limiting freedom of self-expression. Although the platform provides a free watermarking service to creators and actively scans the internet to identify external websites hosting large amounts of stolen content from its creators [74], there remain opportunities for OnlyFans to proactively prevent unauthorized content capture. For instance, OnlyFans could implement features that mimic the behavior of streaming websites like Netflix, which detect screen recording and cause the screen to turn black. Additionally, leveraging existing digital rights management approaches, such as content fingerprinting [59,98], could help automate the detection of unauthorized content use. Such advancements would also streamline the process of issuing automated takedown notices [41].

Catfish prevention. Prior work has described various types of catfishing attacks. For example, romance scams involve an attacker using stolen photographs and false identities to develop a fake romantic relationship with their victim to defraud them of large sums of money [50, 102]. Other attacks involve selling photos and videos with sexual content of another person to third parties, sometimes while pretending to be the subject [51].

Preventative mechanisms from this area of research could be translated to help OnlyFans creators cope with catfishing (§ 5.3): 1) automatic detection and blocking of impersonators through a hashed image dataset shared across social media and dating sites; 2) verification processes where creators could apply their verified status on OnlyFans to other platforms, or adding a layer of security through physical assets (one-time-passwords on cellular devices); 3) active and regular reporting of catfishers (by verified accounts and OnlyFans automatically generating reports to platforms like Twitter, Facebook, or Grindr, requesting investigation into reported catfish or scam accounts); and 4) asking creators to link their genuine social media accounts and report fraudulent accounts. These mechanisms align with established phishing detection and mitigation techniques: content classification and blocklisting [62, 101, 103, 104], user training and education [29], content take-down [3], and direct reports from users [40].

Chargebacks and financial harm reduction. Although only four participants discussed the unique risk of chargebacks in our study (§ 5.3), chargebacks on OnlyFans are common largely because of sex work stigma [11]. For example, a fan may request a refund for their OnlyFans transactions to hide it from their spouse on their bank statement. To free creators from bearing the brunt of chargeback liability, OnlyFans could challenge chargebacks on behalf of their creators or implement a platform currency: fans purchase tokens from OnlyFans, and then use the tokens to pay creators (who are then, in turn, paid proportional to the tokens they earn). The streaming platform Twitch has already implemented a similar system to challenge chargebacks [32].

7 Conclusion

We interviewed 43 OnlyFans creators with and without prior sex work experience to understand their online risks on- and off-platform. Creators were most concerned about platform risks of shadowbanning and deplatforming from platform censorship and precarity which affected their creativity and emotional and financial safety. Despite facing a substantial amount of online hate and harassment, they demonstrated preparedness to handle toxic content by proactively setting strong boundaries with fans and blocking abusive fans. Creators found intimate content leaks prevalent and unavoidable and employed a range of protective measures from limiting prominence to keeping their online identities separate. Our study emphasizes the significance of platform risks which are concerning for sexual, non-sexual, and marginalized creators. By incorporating platform-specific risks, we can better understand the challenges faced by at-risk populations and enhance security measures to promote safer online environments.

Acknowledgements

We thank the anonymous reviewers as well as our major revision shepherd for their valuable feedback. We extend our sincere gratitude to the participants of this study. This work was supported in part by the Max Planck Institute for Software Systems, the U.S. National Science Foundation awards CNS-2206950 and 1663651, and a Google Security & Privacy Research Award for Research into at-risk users and creator safety. A portion of this work was completed while the last author was at the Max Planck Institute for Software Systems.

Abstract

Content creators are exposed to elevated risks compared to the general Internet user. This study explores the threat landscape that creators in Pakistan are exposed to, how they protect themselves, and which support structures they rely on. We conducted a semi-structured interview study with 23 creators from diverse backgrounds who create content on various topics. Our data suggests that online threats frequently spill over into the offline world, especially for gender minorities. Creating content on sensitive topics like politics, religion, and human rights is associated with elevated risks. We find that defensive mechanisms and external support structures are non-existent, lacking, or inadequately adjusted to the sociocultural context of Pakistan.

Disclaimer: This paper contains quotes describing harmful experiences relating to sexual and physical assault, eating disorders, and extreme threats of violence.

1 Introduction

Online content creators express themselves, reach broad audiences, raise awareness, or build careers [22,54] using services such as TikTok, Instagram, and YouTube. They cater to large audiences, share a sizable volume of private data and are consequently exposed to elevated risks [87]. Prior research explored the threats to US-based content creators [79,87] and the ways in which sensitive topics – such as sex work – affect the security and privacy of creators [38,62]. While it is estimated that approximately an equal number of men and women engage in content creation work [50], a survey by Thomas et al. [87] found that U.S. content creators who identify as women are more likely to experience sexual harassment, excessive negative reviews, stalking, spreading of rumors, and surveillance than those who identify as men. Furthermore, outside of content creation, a growing body of work establishes how gender impacts the digital security and privacy experiences [25,76–78,96]. In the global south [6,77,78,91], women are structurally disadvantaged and face unique threats, often tied to their socioeconomic status and literacy [6,70,78].

In this paper, we present a study with 23 semi-structured interviews investigating the intersectional marginalization for content creators across genders in Pakistan. Pakistan is a particularly interesting country in this regard: It ranks second to last in terms of gender parity [35]. Due to cultural and religious factors, the access to the regular labor markets is limited for women [19] as is their presence in public spaces in comparison to men [68]. To navigate these constraints many women choose to migrate to online spaces for forming social connections and for work and business opportunities [97]. Prior work reveals the vital importance of online communities in countries like Pakistan for women to discuss taboo narratives, find work, explore identities and form connections [11,97].

In contrast to general social media users, content creators are especially vulnerable and constitute a special case in two ways: (1) They cater to a large audience, and depending on the type of content they produce can (be perceived to) threaten social norms and structures.[1] (2) They *have to* stay online and maintain public profiles and personas to keep their business/activism going and thus cannot rely on affordances available to other users who have private profiles and are not dependent on making money as content creators.

Anecdotal evidence reports instances of women content creators in Pakistan facing severe harassment [21], group assault [31], or getting killed [55,82]. The prominent case of Qandeel Baloch demonstrates how content creation can be a powerful way for women from low socioeconomic backgrounds in Pakistan to emancipate themselves, but who also face lethal consequences when family, friends or extended relatives start to feel threatened or dishonoured by their presence in online spaces, particularly when their private data (identity) is leaked [55]. Additionally, content creators - both men and women - who engage with sensitive topics such as religion, sexuality or politics face harassment [21,45], may be forced to leave the country temporarily [3], and have even been killed for their work [47]. These stories showcase the elevated risk to which Pakistani content creators are exposed and under-

[1] Blasphemy laws in Pakistan carry severe penalties up to death [59].

score the critical need for research into how to best protect these marginalized content creators.

Our qualitative study investigates the security context of digital content creation in Pakistan including the threat landscape, how creators navigate concrete negative experiences, defensive mechanisms, and what support structures they rely on. Accordingly, we defined the following research questions:

RQ1: What does the threat landscape for content creators in Pakistan look like?

RQ2: What defensive mechanisms do Pakistani content creators implement to stay safe and secure? Which resources do they rely on?

RQ3: What gaps are present in existing security and privacy measures? Which interventions would be needed that are specific to the Pakistani social media ecosystem?

We find that the online and offline threat landscape is tightly connected, with online threats frequently manifesting in offline harm. The degree of both online and offline threats are severe and in the socio-political context of Pakistan can become lethal, especially if content revolves around religion, sexuality, or politics. Online threats are accounted for with a mixture of *technical* and *behavioral defenses*. While defenses exist for prominent threat categories like *toxic content*, participants are dissatisfied with options to deplatform attackers. However, certain threat categories such as *impersonation* lack any defensive mechanisms, while exposing victims to severe threats. Our findings inform the further development of inclusive safety tooling for social media platforms tailored to different populations and risks that are specific to those populations. Moreover, our findings contribute to the improvement of information sources for at-risk populations.

2 Background and Related Work

2.1 Sociocultural Background of Pakistan

Pakistan is a particularly interesting country to study the challenges of publicly exposed figures such as content creators and frontiers of security and privacy measures given its complex patriarchal and religious landscape. In the recent 2022 gender gap report by the World Economic Forum Pakistan places second to last (Afghanistan is last) in terms of gender parity [35]. In Pakistan, offline and online privacy behaviors are heavily influenced by religious and conservative values and patriarchal norms. Notions of community, family honor, and piety as well as Islamic values heavily influence legal, political, and social norms [37]. Pakistan is a culturally and linguistically diverse country with significant region-specific differences within the country. It is also deeply class-based where wealth is not equally distributed, and the reality of high-income citizens is very different from those of low-income citizens [4]. There exists an educational divide between rural and urban citizens, and the majority of women have no formal education [1]. Mobile phones are equally available to both rural and urban households, however, rural households are three times less likely to have access to a computer or internet [1]. Islam is the state religion with approximately 95-98% of the population identifying as Muslim. The Islamic principles of *Purdah* and gender segregation often bleed into digital spaces as well. *Purdah* is broadly defined as the segregation of genders, and involves both modesty of the heart and the eye [40]. The practice of Islam in Pakistan values modesty, the segregation of genders and the covering of women's bodies [40]. These values also impact women's access to formal labor markets, public spaces, and digital spaces [56]. Prior work highlights the ways in which women in Pakistan navigate constraints on mobility, social networks, access to labor markets, and social support by leveraging digital spaces [69, 97]. Online spaces are a particularly critical pathway for women to access vital resources and gain financial independence. However, prior work also highlights the ways in which these spaces fail women in Pakistan [70].

Since 2013, the Pakistani national identity cards have a third gender category [2], and since 2018, Pakistan's Transgender Persons (Protection of Rights) Act theoretically strengthened the rights of transgender people. Although the transgender community – locally referred to as the *Khwaja Sira* – are officially recognized, they continue to face severe discrimination, are often excluded from the conventional job market, and are seen as beggars in public [71]. Despite legal recognition and a Supreme Court ruling allowing transgender people to be identified as a third gender, systemic social support is still lacking. Prominent representatives of the *Khwaja Sira* community argue that the Western LGBTQ+ acronym does not adequately capture their unique experiences, and they emphasize the separation of gender identity and sexual orientation [48]. In Pakistan, there are two main social attitudes towards the *Khwaja Sira*: conservative groups marginalize them for not conforming to a binary gender, while the liberal population often understands trans rights but through Western ideals [9].

2.2 Security and Privacy of Content Creators

In 2022, Thomas et al. [87] conducted a survey with 135 U.S. content creators from different platforms (esp. YouTube, Instagram, and TikTok) with a focus on quantifying the extent of negative experiences, reactions to attacks, and perceived gaps in protective solutions provided by platforms. They found that content creators in the U.S. are structurally exposed to risk, with one in three being the target of attacks and 95% experiencing hate or harassment at least once. In response, many content creators chose to ignore attacks, while others engaged in self-censorship, or leaving platforms altogether. A recent interview study by Samermit et al. [79] explored threats relevant to U.S. creators, and their protective practices. They found diverse threat models apply for creators, and that defenses are often adopted only after negative expe-

riences. While these works offer insight into experiences of content creators in the US, a full understanding of content creator safety and security requires an understanding of the experiences of non-WEIRD (Western, Educated, Industrialized, Rich, and Democratic [44]) creators. Centering the most marginalized users allows us to ensure that we fully capture the risks faced by content creators in designing interventions; as McDonald et al. [63] explain, "often, the privacy risks of vulnerable populations are not fully considered in the design of systems because those risks and potential harms are not fully understood (nor necessarily prioritized) by those responsible for research and design." For instance, recent work has begun to explore the unique safety and security experiences of digital sex workers. These content creators exist at the intersection between digital content creation and sex work; they utilize social media to create monetized adult content as well as connect with other creators and engage in community support [34, 38, 39, 89]. In addition to negative experiences faced by content creators at large [87], digital sex workers are also subject to social stigma and strict content moderation policies [17], producing additional negative outcomes like being de-platformed from social media sites [16, 38]. In general, algorithmic fairness is an issue for marginalized creators [26, 33, 49]. For instance, creators with disabilities face challenges with demonetization [49] and transfeminine TikTok creators need to navigate visibility traps [33].

2.3 Research beyond WEIRD populations

Prior works exploring the privacy and security concerns of non-WEIRD populations reveal the deeply gendered ways in which privacy is understood, enacted and preserved [15, 70, 77, 78]. In these studies religion, literacy and gender play a pivotal role in privacy perceptions and behaviours. In the Pakistani context, studies reveal the ways in which women negotiate the creation of gendered women-only spaces online as a way of protecting their modesty from unfamiliar men, as prescribed by Islamic teachings [70, 97]. A recent study on young Pakistanis' perceptions on security and cyber crime found that men and women prioritize threats differently, and form networks to cope with lacking platform affordances [15]. Studies exploring Arab Gulf citizens' privacy behaviours reveal Arabic social media users frequently establish private online accounts to uphold personal or familial honor, in line with social norms [5]. Prior work also reveals low-income, low-literate women in Pakistan, India, and Bangladesh associate privacy with *western values* [78] or with shame [70], often believing privacy is only for people who have done something that they want to hide. These studies highlight the mechanisms women in Pakistan, India and Bangladesh employ to protect themselves including but not limited to avoidance, deletions, limited lists, private profiles, multiple accounts and the use of private modes [70, 77, 78]. In contrast to these populations our work focuses on a particularly vulnerable group, content creators, who due to the nature of their online engagement are unable to use many of the provided platform affordances like private modes, limited lists, private profiles or avoidance.

2.4 Research on Vulnerable Populations

We place our work in the broader context of populations exposed to elevated risks. In both the HCI and security communities researchers have identified the need to study vulnerable populations to understand the structural threat landscape these people are exposed to, and to investigate possible shortcomings in protective means [63, 94]. In a meta study, Warford et al [94] identified *contextual risk factors* that can be used to categorize at-risk populations. *Societal factors* describe how users are at-risk due to their cultural and social embeddedness and public roles they take on. Examples of people facing elevated risk due to taking legal or political action include, but are not limited to, people involved with political campaigns in the US [28], activists [30, 51, 57, 85], and journalists [64–66]. Moreover, research focused on vulnerable marginalised groups such as LGBTQ+ people [20, 53, 80], sex workers [18, 84], and populations that are at-risk due to low socioeconomic status (e.g., non-Western woman [32, 77, 78, 92], people in developing regions [7, 67, 74, 91], and people in developed regions [27, 72, 73, 93]). Apart from that, Warford et al. [94] identified the *relationships* of people (e.g., intimate partner abuse [24, 36, 41, 60]), and the *personal circumstances* (e.g., underserved accessibility needs [8, 46, 58]) as potential risk factors. In our study we find that content creators who use their voice to make political statements, or otherwise comment on societal norms such as religion or sexuality are exposed to elevated risk in the context of Pakistan.

3 Methodology

We conducted a qualitative semi-structured interview study ($n = 23$) to explore content creators' security and privacy perceptions, needs, and practices in the socio-cultural context of Pakistan. The following sections detail our recruitment, interview procedure, pilot tests, and analysis.

3.1 Recruitment and Participants

Our target population are content creators matching the following criteria: (1) living and working in Pakistan, (2) generating some form of income from their content (e.g., monetary or through compensation with physical goods). We recruited Pakistani content creators across platforms (YouTube, Instagram, TikTok, Facebook, Twitter, Snapchat, Spotify) and targeted a diverse sample across several dimensions (income level, literacy, gender, follower count, content type) to ensure we captured a range of relevant experiences. For recruitment, we manually compiled short lists of creators of different genders based on profile data[2] ensuring broad coverage of the above

[2] In Pakistan, few people openly disclose their gender online. We validated our assumption with participants' self-reported gender data.

demographics. Recruitment followed an exploratory, iterative approach. We used the results of the ongoing qualitative analysis to expand the shortlists with candidates that could bring new perspectives to the study. For example, we found that content creators frequently engage in self-censorship to protect themselves. To complement our perspective, we then specifically targeted people who post content on sensitive topics that other content creators avoid, such as gender and politics, but also people who only post seemingly uncritical content, such as food or pets. Moreover, after each interview, we asked the participant if they knew someone whom we should interview for this study. We reached out through content creators' designated contact channels and asked them to fill out a three-minute screening survey to ensure they fit our criteria. The screening survey collected personal information (like age, location information, gender, disabilities, education, and income), and platform information (where they create content, compensation for content creation, description of content topic, posting habit, and follower count). The positive response rates per shortlist were: 21.4% *woman*, 30% *man*, 100% *Khwaja Sira*.

3.2 Interviews

Two interviewers conducted 23 one-hour semi-structured interviews in Pakistan from December 2022 to May 2023. This resulted in a total of 1261 minutes, with a median of 56 minutes. We compensated each participant with PKR 5000 (USD 19.02), resulting in a median hourly wage of PKR 5258 or USD 20.37. To comply with socio-cultural norms, the interviewers were a man and a woman Pakistani co-author who respectively spoke to the men and women participants. Khwaja Sira chose their interviewer. This practice was intended to create a room where participants could feel safe and talk openly. We conducted interviews in English and Urdu, depending on the participants' preferences. Interviews took place in person or online via Zoom.

We developed the interview guideline with our exploratory research questions in mind. We also took the results of previous studies into account [87], building on them while exploring the topic broadly through semi-structured interviews. Figure 2 in Appendix B provides an overview of the interview flow and contents. We describe the interview sections below and provide the interview guideline in the supplementary material. Each interview started with a fixed introduction that established the purpose and procedure of the interview and allowed the participant to ask organizational questions. Afterward, we obtained the participant's consent to record the interview and proceeded with the interview guideline. The interview was structured as follows:

Verification Section: We revisit questions from the screening survey about the scope of content creation. This serves both as opening questions to get participants talking and to re-verify that creators fall within our target population and are, indeed, the creators we reached out to. No participants were screened out.

Defining Their Work: This section establishes our participants' context and content creation habits. In the beginning, participants define their job title (e.g., *content creator* vs. *influencer*) by which we address them throughout the interview. Further, they describe posting habits and the type of content they create. We provide an overview of participants' background information in Section 4.1.

Negative Experiences: We ask participants to describe their personal definition of safety and privacy in relation to content creation. Then, we ask about their biggest digital and physical security and safety concerns. To make the conversation more tangible, we focus on concrete negative experiences that participants encountered in connection to their content creation work. Moreover, we ask who they identified as potential adversaries, and how they protected themselves in these scenarios. Based on this, we categorize the negative experience of content creators in Pakistan in Section 4.2.

Defense and Mitigation Strategies: We explore how participants aim to prevent these threats from occurring via *behavioral* (e.g., adjustment of content types, or leaving platforms) and *technical* defenses (e.g., platform features, or authentication schemes). Then, we explore any additional support structures participants relied on to cope with negative experiences. Finally, we explore (gaps in) participants' sociotechnical approaches to mitigating harm from the negative experiences they have endured (see Section 4.3).

3.3 Pilot Testing

To pilot test the interview guideline, one researcher took on the persona of a Pakistani content creator and we conducted two pilot tests, one with each interviewer. We tested the flow of the interview guideline in terms of the overall structure and order of questions. In response, we restructured minor parts of the interview guideline to remove redundancies. As the study progressed, we further developed the interview guideline by incorporating participant feedback. Changes included minor rewording to make questions more open-ended and changes to the question order. No substantial changes were made to the interview guideline.

3.4 Analysis

We transcribed the interview recordings manually and using a GDPR-compliant transcription service (Amberscript). Urdu parts were first transcribed and then translated into English by the researchers of our team. Four researchers were involved in the coding process: the two co-authors from Pakistan who conducted the interviews and two co-authors with German and U.S. backgrounds, respectively. Three of them are computer scientists; one is a social scientist. We conducted a thematic analysis where data collection (interviewing) and analysis was

an iterative process. Our goal was to collect a set of threat patterns which are associated with in-depth data about individual experiences. Researchers used a combination of "top-down" qualitative content analysis [52, 61, 75, 81, 90] (informed by previous frameworks [86]) and "bottom-up" analysis inspired by "open coding" [23, 29, 83] allowing for emerging themes. Three researchers jointly established a first codebook taking into account a male and female interview. We followed an iterative approach where at least two researchers coded one interview independently. Then they discussed and resolved all disagreements and updated the codebook accordingly. As we coded, we wrote summaries and memos to collect and systematize potential themes. Once coding was complete, we jointly discussed themes by revisiting memos and grouping codes in the codebook. Thereby we identified five axial categories (negative experiences, concerns, attackers, defense practices, support). We reached stability in threat patterns after having interviewed 16 men and women. We continued interviewing but focused recruitment efforts on Khwaja Sira creators, to explore if (individuals of) this gender experienced additional threat patterns (because we found that gender is likely an influencing factor on negative experiences). However, we did not find additional threat patterns in the last six interviews (two Khwaja Sira and four men/women), although we learned about extreme instances of already known threats. Therefore, we closed data collection and concluded reaching thematic saturation [42, 43] with respect to threat patterns after 16 interviews. The final codebook contains 495 codes.

3.5 Limitations

Interview studies are limited by self-reported data, which may lead to under- or over-reporting. To address this, we designed the interview guideline to focus on specific experiences and provided prompts to aid memory recall. Participants sometimes felt uncomfortable reporting negative incidents, and we respected their decision. Therefore, we acknowledge that our findings may not fully capture extreme negative experiences. To mitigate social desirability bias, we reassured participants that we were interested in their experiences as content creators and would not judge their actions or responses to threats. Given the strict social gender norms in Pakistan (Section 2.1), we conducted interviews in a same-gender setting (selected gender for Khwaja Sira) to create a safe space for discussing sensitive topics. Our convenience sample does not necessarily represent the wider population of Pakistani content creators. While qualitative studies like ours do not strictly require representation, we made deliberate efforts to recruit diverse participants. We defined recruitment criteria based on previous research and anecdotal evidence to identify potential high-risk populations [2, 37], resulting in a diverse sample that includes Khwaja Sira creators. However, future work should quantitatively validate our findings. Moreover, our sample does not include participants who decided to withdraw from creating content, or who faced lethal consequences.

Ethical Considerations We obtained approval for this study by Saarland University's ethical review board. This research touches upon critical negative experiences, thus potentially bringing up past trauma. To obtain informed consent, we thoroughly explained the process of the study, including how we recorded, anonymized, and stored the collected data according to GDPR. We paid special attention to anonymizing participant quotes and present only aggregated demographical information to avoid potential harm due to de-anonymization.

4 Results

Findings are illustrated with participants quotes (Gx); x denotes the participant id within the gender group G (**M**an, **W**oman, **K**hawaja **S**ira).

4.1 Sample Descriptives

We recruited 12 women, 9 men, and 2 Khwaja Sira (see Section 2.1). Participants are young with 83% ages 18-24 and 17% ages 25-34; and educated with highest degree high school (48%) or University (48%). One person was still pursuing a high school degree. 56% of interviews contained answers in both English and Urdu, 26% were solely conducted in English, and 17% in Urdu alone. 48% of participants have 10k - 50k total followers across platforms, while the biggest creator has between 300k - 400k followers. Everyone earned some form of income from content creation, but only 36% were comfortable sharing annual income details. 48% of participants reported earning upwards of 100k PKR annually. Table 2 in the Appendix reports demographics; Table 3 presents a breakdown of the platforms participants create content on. All participants use Instagram, followed by TikTok (65%), and Youtube (61%). Participants post various content topics: from fashion and lifestyle to awareness of socio-political issues. Some participants posted multiple types of content which fall into a common broader category, e.g., fashion, lifestyle, etc. Most commonly participants create lifestyle content (39%), followed by fashion (35%), comedy (17%), and music, life stories, vlogs, and socio-political and human rights issues (13% each). It is important to note that socio-political issues include topics on gender, sexuality, and religious minorities, politics, and human rights include topics like women and trans rights. Two of our participants posted dance videos. The remaining categories include makeup, food, mentoring, photography, pets/animals, family content, and documentaries (4.3% each).

4.2 Threat Landscape and Negative Experiences

We structured the threat landscape of Pakistani creators following Thomas et al.'s taxonomy of online hate and harassment attacks [86] and expanded it towards offline threats. Threats were identified based on the axial categories *negative experiences*, *concerns*, and *attackers*. Figure 1 provides an

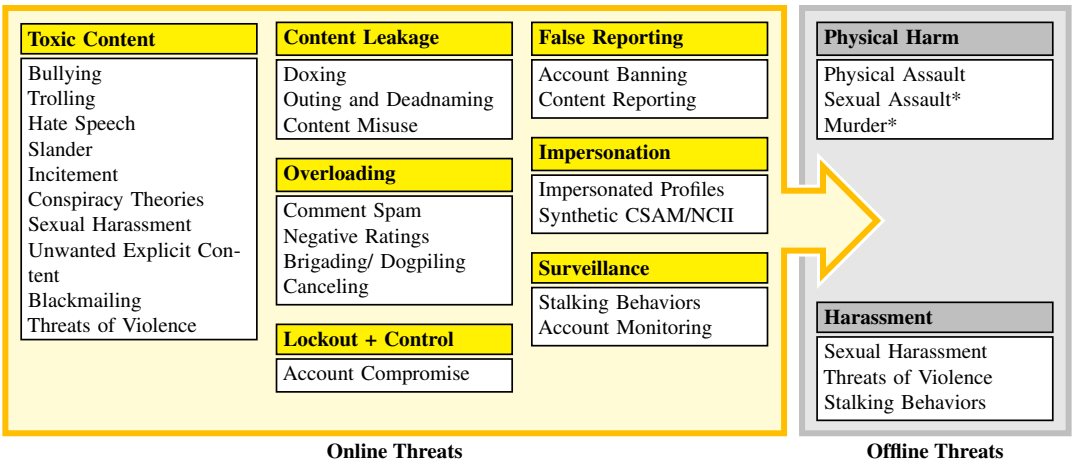

Figure 1: Spillover effect from online (yellow) to offline threats (gray) for content creation in Pakistan, grouped by categories. A * denotes threats explicitly mentioned (but not experienced); all other threats were experienced by at least one participant.

overview of online and offline threat categories, including associated attacks that emerged in the interviews. Throughout our results, we compare our findings to prior work on U.S. creators [79, 87] and the general Pakistani population [15], however, we do not provide comparative statements for all findings due to differences in analysis lense.

4.2.1 Toxic Content

This category includes online attacks that are intended to be seen by the creator, often with the goal to intimidate, harass, influence, or silence them. In line with our work, research on U.S. creators found these attacks impact emotional safety [79].

Bullying and Trolling. The boundaries between *bullying* and *trolling* are fluid, and attacks are prevalent across genders [w:11 | m:6 | k:2]. Women report instances of body (W7, W8, W11) and skin tone (W1) shaming, with one participant developing an eating disorder as an outcome (W7). Similarly, men are also shamed for their bodies, such as for not growing facial hair (M3). Participants are also targeted if they are in positions of power; for instance, W9 works as a civil servant and experienced bullying and harassment due to attackers' belief that she does not deserve a good life while the local population lives in poverty. In general, *marginalization* is a risk factor [94] that applies to U.S. creators, too. Attackers focus on identity characteristics such as gender or religion, with intersectional identities (e.g., woman, overweight) compounding risk [79].

Hate Speech. In our sample, all genders report experiencing *hate speech*, although it was most prevalent among woman and Khwaja Sira [w:10 | m:3 | k:2]. Extreme cases of hate speech and harassment are associated with specific content topics, such as religion (W9), politics (K1), and discussion of social issues such as rights for women and/or transgender people (W9, K1, K2). As W9 puts it, activism can be dangerous, as people start targeting you based on the minorities you speak up for: *"When I talk about Ahmadis [religious sect] or religious minorities in general, people would just tag me an Ahmadi. [...] If I talk about women, they would just spew slurs at me just randomly. They would curse me, saying I'm a feminist. It's a curse word itself. March is just upon us and Women's Day is here. The whole cycle just starts every single year. The other kind of harassment that I face is when I talk about transgenders. They would just say that I am promoting gay marriages just because I'm talking about the protection of transgenders"* (W9). Outside of religious, political, and social issues-centric content, even pictures with friends in a mixed-gendered group can lead to harassment: *"I remember posting a group picture with my friends and they were, five or six girls and there were two guys in the picture [...]. For some reason, I received a lot of backlash on that post. 'Why are you promoting Western ideals in Pakistan? [...] She's Western propaganda.' Even though it was literally just a couple of friends standing together and there was nothing problematic about it"* (W3).

Slander, Incitement, and Conspiracy Theories. *Slander* is a distinct type of toxic content meant to harm the reputation of creators. It is particularly dangerous in Pakistan, as people – especially women – need to comply with strict cultural norms of *pardah/modesty* and *honor* [88]. Among our participants, all genders [w:3 | m:3 | k:2] fell victim to the spread of disinformation – not only those who produce content associated with heightened risk (e.g., religion, politics, social issues), but also those of non-sensitive content types. For instance, W12 owns a pet account, and a competing account that did not grow as quickly as hers spread disinformation that she abused her animals. Slander may lead to *incitement* [w:2 | m:3 | k:2], either when creators decide to remain associated with someone who got canceled (W2), or if their content is controversial or sensitive (K1). *Incitement*

can easily lead to online (W2, W9, M4, M5) and offline (K1) harassment, for instance K1 reports of online articles speculating about her gender that led to religious sects showing up at her home (K1). The boundaries between *slander* and *conspiracy theories* are fluid, and the potential for harm is great if the creators reputation is damaged. We identified four instances of *conspiracy theories* [w:1 | m:1 | k:2] that were all trying to explain creators behavior with hidden political agendas: *"If these individuals are sitting and saying that I'm an American agent working on a conspiracy to promote LGBT rights in Pakistan"* (K1).

Sexual Harassment. Among our participants, only women and Khwaja Sira reported experiencing online sexual harassment [w:2 | m:0 | k:2]. One prominent experience involved religious figures leaving sexualized comments on the (non-sexual) picture of a woman creator. Being targeted by religious figures can escalate the incident into the religious realm where the victim becomes a target for a broader audience that often is willing to resort to offline violence [55].

Unwanted Explicit Content. The majority of women in our sample receive unsolicited messages [w:9 | m:2 | k:1], often containing explicit content. In one incident, a friend sent the unwanted content (M2), but usually attackers are unknown as the messages are sent from throw-away accounts: *"This guy was DMing me really sexual stuff, pictures, unsolicited pictures of himself [...]. I blocked him from so many different accounts and he would just keep making new accounts to do that"* (W7).

Blackmailing. Few participants report being *blackmailed* with the majority identifying as men [w:1 | m:3 | k:1]. Attackers can come from within their inner circle; for example, former friends threatened to leak a participant's identity (W11). Other attackers are anonymous and threaten participants for attention or personal gain: *"The most extreme level of it is when someone reaches out to you and basically asks you for [...] a shout out, [...] a reply, it can be anything like that and if you don't do it, then they threaten people that you love"* (M9).

Threats of Violence. Some participants report receiving *threats of violence* [w:2 | m:2 | k:2] through comments and direct messages (M2). Attackers are usually anonymous, although participants sometimes link them to known opponents of them (e.g., influential industrialists (K1)). Threats can also be a result of *hate* and *canceling* campaigns (M4). The goal is to intimidate or silence the creator, and may target the creator's family and close ones as well (M4). Participants report that content on topics like religion and gender lead to more extreme (sexualized) threats of violence (K1,K2, M2, W9). In general, creators think that *"mostly girls [...] receive perverted comments"*(M2). In our data set only woman and Khwaja Sira received comments regarding sexualized violence: *"Whenever I talk about religion, these kinds of things happen. I believe that [...] the concept of religion that has been propagated by different Madrasas is the ultraconservative version of a religion that I'm talking about. They do not see women or random creators talking about religion. They believe that religion is something that only they can talk about. Just because a person [...] is in westernized attire, [they are] not Muslim enough to talk about the religion. That's when I got some rape threats"* (W9). Participants did not report any threats of violence that were realized offline.

4.2.2 Content Leakage

Content leakage summarizes attacks in which private data or content is leaked by a third party. This was done to threaten, embarrass, or shame our participants.

Doxing. Most woman creators were concerned about or experienced *doxing*, where personal information is exposed to a greater audience [w:5 | m:2 | k:2]. Attackers can come from the inner circle (W11), or engage in social engineering to obtain personal information such as phone numbers (W4). Through *doxing* creators and their loved ones become targets for offline attacks (e.g., *stalking behaviors*, *physical harm*), but also because people surrounding them might feel threatened or dishonoured. In the context of Pakistan, leakage of personal information such as family details are therefore severe threats, and deanonymization has led to the murder of a woman creator in the past [55]. Brands can also be a threat as they obtain participants' information to send PR packages; one participant had a brand give out her home address to a fan who was a relative of the brand's owner (W7).

Deadnaming. Another form of leaking personal information and disrespecting the victim is deadnaming a Khwaja Sira, which was reported in one instance: *"Dead naming me is a line for me [...]. When people [call me by my old name] to belittle me that I think is a line that I do not like being passed because <old name> is a very personal name."* (K1). Here, *deadnaming* was used to harass the creator, however this practice reveals sensitive gender information that might not be intended for a broader audience. In case of K1, gender-identity is part of her content.

Content Misuse. We expanded this category to also include unauthorized content use, which was a prominent concern across participants [w:5 | m:3 | k:1]. It is different from content leakage, as in this case the content was previously posted on a public profile. Unauthorized content use by third parties primarily leads to financial harm [38], but may also be used for *impersonation* that in some cases can result in *physical harm*. In Pakistan this is a severe threat to woman, as it damages their reputation: *"Being a Pakistani girl with a public account, there is always a little thing in your heart that anything can happen anytime, your pictures can be edited and transformed and a lot of other things can happen so social media is one of the most unsafe places, which we all know but still we use it"* (W1).

4.2.3 Overloading

Overloading refers to online attacks or interactions that overwhelm the creator by spamming communication channels

(e.g., comments or notifications), usually with the aim to silence or influence them. Non-malicious intentions, such as getting the creator's attention or showing fan affection were also reported (W12), but can equally be perceived as harassment. Attackers are groups of people, often entire communities, that coordinate to target a victim.

Comment Spam and Negative Ratings. Especially when it comes to religious content (M5), our participants face excessive negative engagement like hate comments and messages [w:7 | m:3 | k:1]. Comment spam can also be a way for people to get the attention of creators. Complementary, W12 describes out of the norm positive attention from fans as a form of harassment.

Canceling, Brigading, and Dogpiling. These attacks [w:3 | m:2 | k:1] are similar because they are all carried out by coordinated online communities, e.g., through comment spams. The goal is what makes them different: *Canceling* aims to silence and de-plotform creators (W2, M4, M7), *brigading* tries to disrupt the discourse (W2, W8, W9), and *dogpiling* aims to get victims to recant their views (K2).

4.2.4 Lockout and Control

These attacks aim to silence creators or de-platform them alltoghether by breaking into or leveraging privileged access to a targets' accounts or devices [87]. In our sample, attackers were never identified, but third-party reports highlight the risk of attackers from the inner circle of the victim [60, 78].

Account compromise. The threat of getting hacked is known to the majority of participants, and they deploy Two-Factor-Authentication (2FA) as a defense [w:12 | m:7 | k:2]. However, the concepts of attack vectors and recovery seem to be obscure: *"I couldn't access my account and I don't know why that happened"* (W12). M7 told us about the account deletion of a fellow creator, allegedly because the attacker did not like her content: *"Her account got deleted recently. And the kid who hacked it said that because he didn't like the content [...] he deleted it. If it's so simple for a kid like that to do something, I would say Instagram is not really a safe account. And you can't even appeal to anyone to help"* (M7). In our sample, three creators (W12, M9, K2) have fallen victim to hacks that resulted in account lockouts. None named details on who the attacker was or how their account got compromised. All were able to recover their account with the help of the platform's support system and external digital rights organization. Only after the hacks and on the platform's request, two of them switched to 2FA. Participants also expressed their concerns of account or content deletion, although nobody in our sample experienced it firsthand.

4.2.5 False Reporting

A platform's reporting function is intended to protect individuals and the community at large. However, due to its semi-automated handling, reporting can be misused to silence, de-platform, and financially harm creators or, more generally, demonstrate power. Attackers usually stay anonymous. We extended the taxonomy [86] to fit creators.

Account Banning and Content Reporting Participants were as concerned about attacks in this scenario as they were about hacking attempts. However, they were dissatisfied with the lack of defensive options. One participant experienced account loss through banning twice on TikTok (W8) but was able to recover from it. Another participant reported a similar incident of a fellow creator: *"Some random person [...] reported her account and got her banned from Instagram. There's nothing that she could do to get her account back. She had around 20,000 followers. The person who reported her account also told her, 'I don't agree with your content, and I think that you're annoying [so I took your platform], and I want you to apologize to me, then I'll give it back to you.' "* (W3). Similarly, some participants had their content wrongly taken down from platforms [w:1 | m:1 | k:0]. Attackers coordinated malicious reporting attacks to silence creators: *"Even though my videos did not have any sort of explicit content [dance], due to people reporting it, a lot of my videos got taken down. They still do to this day"* (W8). Generally, participants wished for transparency on how banning works from the platforms (W1, W3, W12).

4.2.6 Impersonation

This category involves using, altering, or artificially recreating content to impersonate a creator online. These kinds of attacks can do severe reputational damage. As a result, M9 reported offline harm such as physical assault and lethal threats.

Impersonated Profiles. Half of the woman creators in our sample were impersonated online [w:6 | m:1 | k:0]. Common platforms are dating profiles (W2, M9), and social media platforms (W1, W10). Attackers are unknown to participants, and motives are often unclear. Attackers deceived people to send them money (W2) or extract information from family members (W10). There was one case that led to offline harm: *"People started making fake Tinder and Bumble profiles. I don't know if it was something personal against me."* (M9). Even several years after the incident, the participant faces severe threats, as family members of the matches track him down and threaten to kill him. They are motivated by violations of strict cultural norms of *pardah/modesty* and *honor* [88].

Synthetic CSAM and NCII. Another form of impersonation, that was experienced by one woman in our sample, is synthetic non-consensual intimate imagery (NCII) or synthetic child sexual abuse material (CSAM). Participant W7 had synthetically-created pictures of her shared in an online community forum: *"I think to me the most unpleasant experience was the Reddit picture [...] where someone did something really weird on my picture. That was uncomfortable for me because that was more of a sexual nature. [...] I was 16. [...] someone sent me a screenshot of [the image]. I reported that and it got taken down because I [was] a minor "* (W7). Further, technologies such as Deepfakes generate content that is

harder to distinguish from reality, opening the door to harass the victim based on societal norms of decency.

4.2.7 Surveillance

Participants identified two types of attackers: (1) online contacts, such as fans or opponents, and (2) offline contacts, such as friends, family, or work-related acquaintances.

Stalking Behaviors. Stalking is a common experience among creators [w:4 | m:2 | k:2]. One participant reported being digitally stalked: *"There was a case with a house help of mine that got access to my accounts and then ended up stalking me from different accounts. That was a very big concern for me and a very unpleasant experience"* (W6). Stalking, especially if exerted by people close to the victim, directly or indirectly reduces the victim's physical or psychological integrity. Incidents of stalking may co-occur with physical threats, as was the case for this participant: *"I've had physical concerns in the sense that randomly, people 1-2 times have sent me messages: 'This was your car and this was the numberplate. We saw you take a u-turn from here.' "* (W5). Thereby stalking of creators is an example of a post-digital security issue [27], as it blurs the line between the online and offline worlds.

Account Monitoring. Similarly, female participants reported that they are concerned and annoyed that parents and other relatives monitor their account (W2, W3, W6, W9, W11, W12). This is in part due to socio-cultural norms of decency, as W9 puts it: *"People in our society are not accustomed to looking at pictures or videos of a woman on social media."* and W3: *"I know that a lot of people from my family have approached my mom in a way, saying you have absolutely no control over her daughter and she should be ashamed of what I was doing."*

4.2.8 [Offline] Physical Harm

The various online threats above can manifest into offline attacks causing physical harm to creators. Participants are especially concerned about influential Pakistani figures abusing their power and network to harm them. For U.S. creators physical-world harm was a top concern, however only few had personal experiences [79]. In our study 11 participants reported negative offline experiences, suggesting that they might be more prominent in the context of Pakistan.

Physical and Sexual Assault, Murder. The majority of participants were aware and concerned about the possibility of becoming targets in the real world. Three participants experienced physical assault [w:1 | m:1 | k:1]. M9 went through an extreme case of assault as a consequence of being impersonated on a dating profile: *"I was getting into my car and behind my car two cars came and parked. A person came out from one of the car and he held me by the collar pushed me against the wall and he pointed a gun to my head and he was you have done this and that to my sister."* K2 reported getting kidnapped. Mostly Khwaja Sira were concerned about sexual assault; none of our participants experienced it. Murder is real threat as is exemplified by M9 and past events [55].

4.2.9 [Offline] Harassment.

This category contains offline attacks that cause the victim to feel intimidated, dehumanized, or belittled.

Sexual Harassment. Sexual harassment like catcalling (W9) was not experienced by men [w:1 | m:0 | k:2]. Khwaja Sira faced severe instances of offline sexual harassment through cis-woman: *"As a trans woman interacting with a cis woman, the privilege lies with the cis women. Harassment at the hands of cisgender women, I have faced a lot, which can both be what I call sexual harassment and then harassment of a private nature where they ask me very, very intrusive and disgusting questions in the presence of other people"* (K1). She explains that in Pakistani patriarchy, women cannot harass cis-men, so they harass transgender people.

Threats of Violence. Another form of intimidation is threats of violence, such as threatening sexual assault (W9) or death (W9, M9, K2). Many participants are concerned about the possibility of somebody showing up at their address to threaten them. Creators are sometimes threatened to influence their posting behavior or delete content: *"Lucky for me it was not someone influential otherwise they would have forced me to delete it rather than asking politely and might have reached my house and telling me are you deleting it or we make you delete it"* (M1). Others will threaten to kill creators to restore honor (M9).

Stalking Behaviors. All genders experienced offline stalking behaviors [w:4 | m:3 | k:2]. While participants are generally open to take pictures and meet fans in public, some are concerned about having pictures and videos taken without their consent because of being public figures (W3). Similarly, creators reported instances where fans went to their house or current location to take pictures or meet them (W7). In contrast to the previous category, here the intention is not to threaten the creator, but to be near them. The close-knit communities within Pakistan simplify the process of obtaining creators' personal information for attackers (K1). This is especially the case in rural areas, and when the creator has great visibility [87], e.g., because of being Khwaja Sira (K2).

4.3 Coping with Threats

We categorize *defensive mechanisms* and *mindsets* of creators when handling threats described above in Section 4.2 and the *external support* they rely on. The results of this section contain a thematic analysis of the axial category *defense practices* and *support*. Table 1 relates the findings of this section to the previously described *threat categories*.

4.3.1 Defensive Mechanisms

Technical Defenses. All participants rely on **technical** defense mechanisms to protect their accounts, content, and

Table 1: Mapping of defensive mechanisms, mindsets, and external support to threat categories (c.f. Figure 1).

Threat Category	Defenses				Mindsets				External Support				
	Technical	Data Policies	Self-Censorship	Offline	Ignore	Comply	Fight	Fatalism	Information Sources	Platforms	Authorities	Social Suppport	Therapy
Toxic Content	●		●		●	●	●	●	●	●	●	●	●

Physical Harm		●	●	●			●	●	●			●	
Offline Harassment		●	●	●			●	●	●			●	

●: observed with one or more participants

manage their community. To battle *account lockout*, few participants use *authentication-related* defenses, such as password complexity rules (W1, M7), password managers (W1, W9), and login monitoring (F6). While some participants follow outdated security practices, such as changing passwords regularly (W1, W5, W6, M9), the majority use enhanced authentication schemes such as 2FA [w:12 | m:7 | k:2]. 2FA in particular is perceived as a strong security mechanism, however some participants only adopted it when the platform pushed it on them after account compromise (M9, W12), or they saw suspicious login attempts (W5). Similarly, U.S. creators adopt protective practices in response to attacks [79]. Moreover, most participants [w:12 | m:6 | k:2] rely on *community management* tools to prevent and *combat toxic content* and *overloading*. Mechanisms that restrict who can send messages or reply to content (W7) are used to silence attackers and perceived as effective. Yet, the majority of participants were not satisfied with the available comment moderation, blocking, and reporting tools platforms provide to prevent hate and harassment and de-platform attackers. Similar to how young Pakistanis collaborate to counteract impersonated profiles [15], creators rely on their community to mass-report attackers in the case of hate speech and impersonation. Some participants [w:5 | m:1 | k:0] use *content control* methods to protect against *content theft*. For example, creators sometimes use watermarks on their content (W11). However, these do not stop the content theft itself, but rather ensures that the source will be known (if the watermark is not removed entirely). Other creators completely separate content into private accounts to prevent it from being misused (W1, W2, W3, W12, M9). To prevent content being deleted after a hack, one creator curates backup accounts to which they can switch in case of a hack (W1). This purpose is also communicated to fans and they are encouraged to follow the backup account.

Data Policies. Most participants [w:12 | m:6 | k:2] report following personal data control policies to combat *content leakage*, *surveillance*, and offline threats. The underlying principle involves keeping personal data points private, such as details about family and friends, location data, daily activities, or means of transport. Some go as far as hiding their identity online or in real life (W9, W11, M9), or leaking false information to distract people (K1). These practices are universally perceived as effective strategies to preserve online and offline privacy among our participants.

Self-Censorship. Similarly to a study on U.S. creators [79], the majority [w:9 | m:9 | k:2] of our participants engage in self-censorship to protect from becoming the targets of online and offline hate and harassment. Self-censorship is a learned pattern of behavior that results from one's own or other people's experiences. Thereby, implicit or explicit social norms influence what may be said and done. While one participant acknowledges self-censorship as an effective strategy to prevent hate (W2), our data suggests that it does not prevent creators from harassment, particularly related to religion. Against this background, self-censorship is a fragile precaution: *"I also avoid political and religious discussions online because I know for a fact that will never end well. [...] The most precautionary thing is to extremely filter out everything that I say and do"* (W3).

Offline Protections. Several participants [w:1 | m:2 | k:2] report relying on offline defenses to protect from *physical harm* and *harassment*. They carry pepper spray and rely on physical protection from other people (W9). Khwaja Sira face increased risk of offline harassment and report being selective about the people they meet (K2) and avoid attending parties in response to their digital visibility: *"I'm a digital creator who was getting very famous, and if I'm inviting 20 people and 25 show up, at least eight of them are going to show off saying [...] we ran into her. [...] They will go post my pictures and then that becomes a whole shitstorm. Like they would say this person talks about Islam or Sufism and now you see them in short cloths"* (K1). In that way, for creators offline privacy invasions can feed into online harassment.

4.3.2 Coping Mindsets

Based on how participants reacted to negative experiences we derived four *coping mindsets*:

Ignore. When coping with online harassment participants had the sentiment that this is something that one simply has to *accept* and *ignore* [w:12 | m:8 | k:2]. A similar theme was identified by Samermit et al. when U.S. creators claimed to develop a "thick skin" [79]. In line with their work, we find

that creators do not want to give haters and trolls attention, hoping that this way the attack will die down. We identified an additional theme of Pakistani creators being concerned that by standing up for themselves they might confront someone influential who could target them in the real-world (M1). *Ignoring* is often informed by a sense of helplessness when creators feel they cannot defend against a threat. This resetting of safety expectations when facing elevated risk applies to U.S. creators, too [79]. We find this theme especially for *toxic content* type threats when creator's way of coping is to *"just get used to it"* (W7). Similarly, most could not imagine a world without online hate and harassment attacks. However, this does not mean that they do not deploy defensive mechanisms. Acceptance of risks was felt throughout our participants; for instance regarding impersonation, one participant noted they lacked adequate tools to deal with such attacks and therefore became desensitized: *"Impersonation happens a lot. Initially, I would get very scared about it. I would report the account and I would ask my friends [to report] them also. But then slowly, as the number of accounts increased, I got desensitized."* (W3).

Comply. One creator reports *complying with* attackers to stop hate and harassment, especially when facing cancelling. M4 apologized and changed his behavior and content. *"I uploaded three apology videos. [...] Did it once and deleted that account because I was getting too many death threats."* In that way, this coping mindset is connected to *self-censorship*.

Fight. Many creators [w:4 | m:3 | k:2] report fighting online hate and harassment, especially if other coping mechanisms like *ignoring* or *complying* fail: *"I try to ignore it as much as I can, but if I can't and if I lose [my mind], then I'll have to answer to that person back"* (M3). They speak up for themselves (M3, K2), call people out (W2, W5), respond to comments (K2), and sometimes harass people back - the latter also offline (K1). We found that fighting back is a coping strategy that all participants who create sensitive or controversial topics rely upon (K1, K2, W9). We theorize that creators who actively decide to put out controversial content are willing to fight for their voice. But also creators on seemingly uncritical topics easily become targets. When asked whether she ever considered leaving the platform due to the hate she faces, W12 responded: *"I think that would be the weakest I can do. I chose to fight, be brave, and to deal with it."*

Fatalism. Across genders [w:7 | m:7 | k:1] participants developed a fatalistic mindset towards online and offline threats: *"If it's harassment, that's something that I still haven't figured out how to deal with [...] Though, I don't know how I will [ever] figure out how to deal with that"* (W3). In response to online hate participants left platforms (W5, W9), or even fled the country (M9). The attacker who almost killed M9 advised him to leave the country even after being convinced that M9 was innocent: *"He's like, 'Today was me tomorrow it could be some other guy from that group who tries to do something like this.' I was like, 'What do you suggest I should do?' He's like 'I would honestly say, stay off the grid. If you can [...] leave the country for a while.' "* (M9). W8 stopped creating content on TikTok because her account kept getting reported.

4.3.3 External Support

Information Resources. Two participants (W9, K2) explicitly mentioned education as a critical step to maintaining their security and privacy: *"Everything is just changing so much and technology is advancing at a speed of light. I'm just trying to understand it first, and then I'll take some measures about it."* (W9). Participants got their information about how to defend against threats from fellow creators [w:7 | m:7 | k:0], people in their personal lives [w:10 | m:7 | k:2], search engines [w:2 | m:1 | k:1], platform guidelines [w:3 | m:2 | k:1], advertisements (M8), and organizations (e.g., Digital Rights Foundation) (K1, K2).

Platforms. Creators appreciate platforms having physical offices (M8) and help centers (W12). They rely on *platform support* to combat *impersonation* (W4), and recover from *account compromise* after being hacked (W12). Also, platforms are the only way to recover from account loss due to *false reporting* attacks. In the case of *impersonation* participants stress that they *"don't know any other way to deal with it"* (W4). Creators criticize the slow response time of some platforms (Instagram) when taking down *content misuse*, and highlight that others (YouTube) are doing a good job (W9). Wanted features are tools to check for re-posted and impersonated content (W2, W3, W4, W7), controls over who can view and screenshot content (W1, W3, M9), measures to counter spread of *slander* (W2), and involving real people to resolve conflict (W2, W6, W12, M2, M9), e.g. in the form of a help line (W2, W4, W6, W7, W9, M2). Moreover, they would appreciate transparency over how banning works (W1, W3, W12) and the formation of support communities (W5, W7, W9, W11, M7).

Authorities. Few participants reported *involving authorities* when dealing with online or offline threats. Creators rarely reached out to *government agencies*, and if they did it was not very effective (e.g., they got no response (W5)). W2 summarizes why: *"I think in Pakistan especially, like nobody really directly goes to authorities. It's usually through contacts. [...] I don't recall there being sort of easy access to authorities where it's like a helpline or something. Maybe there is one, but [...] it's not being advertised enough. Because I think there's also a general distrust in society, like in terms of authority. We don't really trust them because it's very hard to find authority that takes your word and actually brings justice"* (W2). Even creators who generally fight back against hate and harassment are reluctant to report attackers officially: *"[If] I lodge cases against them, I'm pretty certain things against me are going to go ballistic. It's a double edged sword. I will take an action, but that action is also probably going to cost me my life"* (K1). None of our participants mentioned involving authorities in response to offline threats. Other

participants reported being in contact with activist agencies (K1), or reaching out to lawyers (W2, K2) and experts (K2).

Social Support. To cope with negative experiences, especially hate and harassment, participant rely on *social support*. They commonly refer to family and friends for support and to get a reality check (M3), although W3 tends to hide negative experiences from her close family because *"they already won't approve of <content creation>, and they'll tell me to stop"*. Another popular form of support is to talk to fellow creators and receive advice on how they navigate negative experiences (W4).

Therapy. Last but not least, a few participants go to therapy to cope with the outcome of online hate and harassment. The vast majority of our participants report on how content creation and the threats they face negatively impacts their mental health. They question their self-worth (M4), and face depression (M4) and burnout (W12, K1). One participant reported becoming suicidal after facing severe online and offline harassment (M4).

5 Discussion

5.1 Risk Factors (RQ1)

We discuss factors that correlate with experiencing heightened risk based on the relative frequency of reported threat types (compare Table 4 in Appendix C), and the reasoning participants offered. These factors have to be quantitatively validated in future work.

Gender. Our data suggest that women and Khwaja Sira face heightened threats and are more likely to experience sexual harassment than men (average # of reported negative experiences: [w:7.33 | m:5 | k:17]); future work needs to validate this hypothesis. Women are pressured to adhere to social norms and face heightened risks in online spaces when identifiable as women (W12). Thomas et al. [87] found that woman creators in the U.S. statistically faced more threats than other genders; they did not find effects for transgender persons. In this study the threats Khwaja Sira faced were severe: Among others, they got kidnapped (K2), were sexually harassed online and offline (K1, K2), and experienced human-trafficing attempts (K2). Sexual harassment is an extremely sensitive topic. Victims are reluctant to speak up because of getting stigmatized, i.e., tainting their honor. Also, victims need to be cautious when acting against attackers. Confrontational responses like calling out people, especially if they are powerful (e.g., religious leaders) can become lethal [55]. Thus, technical solutions need to focus on victim protections; solutions such as blocking that draw attention on the actions of victims might not be suitable as it can provoke attackers.

Content Topic. Participants who create content on topics that are controversial face more negative experiences than those who do not. In contrast, in the U.S. content topics were not correlated with higher risk [87]. However, recent research identified content on sex work and nudity leads to de-platforming [13, 14] or shadowbanning [12]. In our study, examples of critical content topics are social issues and activism (W9), women's rights (W9), transgender rights (K1, K2), and sex and sexuality (K1, K2). Moreover, many participants report avoiding content on religion (W2), politics (M2), and influential people (W9) to avoid harm. On the contrary, creators in our sample whose content centers on topics like music (W4) and pets (W12) face fewer threats. Yet, seemingly harmless content such as pictures in a mixed-gendered group (W3), dance videos (W8), or wearing shorts (K1) can be *"stigmatized in [Pakistan's] society"* (W8), and bear the potential to be weaponized, especially against woman and Khwaja Sira. Thus, platforms need to take local cultural norms into consideration when deciding what classifies as "harmful" content and must not make assumptions based on Western views.

Platform and Audience. Some participants see a connection between the platform and the hate they receive. They suspect that the audiences differ between platforms, and that platforms with more low-literacy users (they name TikTok) harbor more potential for hate and harassment. Moreover, they think certain interaction features and affordances that allow direct contact with creators enable harassment. However, results are inconclusive, and this factor must be explored further in future work. Some creators reported that they started attracting hate only after reaching a bigger audience (W8). This is in line with Thomas et al. [87], who reports a correlation between hate and audience size. Moreover, Samermit et al. [79] describe *prominence* (in accordance to Warford et al. [94]) as a risk factor for creators in the US, e.g. when massive popularity and virality further amplify risk.

5.2 Gaps in Defenses and Support (RQ2+3)

Flawed Defenses. *Toxic content* is a prominent threat that a majority of our participants experience. It is also ranked a top priority by experts, and they advise *blocking*, *muting*, *reporting*, and *moderating* [95] which our participants also rely on. Platforms invest great effort into combating *toxic content*, and we find that participants use and appreciate moderation tools that help filter comments. However, they report that it is especially difficult to de-platform malicious actors, and criticise the lack in transparency and efficacy of reporting mechanisms. In line with this, other research discusses how reporting in Urdu is harder than reporting in English [88]. Work on U.S. creators found that involving platforms can be slow and opaque if the creator does not have a human contact at the platform [79]. In our sample creators often felt left alone with the responsibility to defend themselves. However, some active forms of defense, like speaking up and addressing hate, can have lethal consequences in Pakistan's tight social net when perpetrators in turn feel attacked and use their network to reach creators offline. Creators deliberate this when speaking up against hate; some may have a cause that they deem worth fighting for, e.g., activism for minorities, women and transgender rights. However, a policy brief by

UNESCO and the Digital Rights Foundation [88] discusses that posts on sensitive topics lead to less engagement, either because audiences self-censor too or because of algorithmic biases [10]. In general, all creators were aware of the risks associated with sensitive topics such as religion and politics, and thus most of our participants refer to self-censorship.

Missing Protections. Participants lacked any defenses against threats of *false reporting* and *impersonation*. A recent study by Wei et al. [95] in which experts ranked threat categories internet users should prioritize, threats that fall under the category *impersonation* and *false reporting* were assigned medium ranking and rarely identified as top threats. In contrast, we found that *impersonation* attacks likely lead to offline threats and are thus highly critical in Pakistan. In our data set, we had one participant who almost got killed due to being impersonated on an online dating app (M9). Regarding Pakistan, *impersonation* poses a high risk for (1) the reputation of the victim, but also (2) for the reputation of the person who falls for the scam, especially in the context of impersonated dating profiles. M9 still receives online and offline threats from family members of the scam victim, even several years after the incident. Threats are so severe, that even former attackers advise him to leave the country. This points out the potential for geographic biases when selecting generalized security advice [95] and highlights the need for targeted advice, especially for populations facing elevated threats. Critically, even for the general internet user experts identified a lack of effective advice to defend against *impersonation* [95]. Future research needs to work towards effective and feasible defensive mechanisms taking into account the needs of marginalized populations such as creators in Pakistan. Moreover, creators are lacking effective protections against *stalking behaviors*; they rely on *data policies* that are implicit rules to control which data they release. However, it is difficult to foresee which data points might result in *stalking behaviors* and retracting data that is published once, is hard or impossible. In this regard creators are different from young adult internet users in Pakistan [15], as they cannot rely on the same affordances (e.g. having private profiles).

Lacking Support. The socio-cultural context of Pakistan impacts availability of support structures, especially as content creation is unregulated and lacks protective legislation [15, 88]. First, there are gaps when it comes to official support structures for online harm. Participants were reluctant to approach authorities, or unaware of agencies that deal with online hate and harassment. Underscoring the problem, even the one participant in our sample who filed a report never heard back from the authorities. This issue is similar for marginalized content creators in the West such as sexual content creators who similarly report being unable to turn to authorities due to stigma and lack of respect [38]. For U.S. content creators, law enforcement can be helpful, but they are not always taken seriously [79]. Second, participants report a stigma that is attached to content creation in Pakistan, especially for women: in our sample they were concerned about their parents and close relatives monitoring their accounts. This in turn might constrain the *social support* resources women can rely on, if they do not feel they can approach their parents when being attacked. Similarly, young adults in Pakistan are reluctant to report cybercrimes because they do not want their families to worry, or women want to avoid being victim blamed [15].

5.3 Towards Solutions

Threat Modeling. There is a need to explore the design for flexible threat priorities where socio-economic context determines what are severe threats, as opposed to viewing threats as static across social contexts. Comparing our results (e.g. impersonation attacks leading to offline harm) to previous work focusing on Western populations where experts ranked threat categories that internet users should prioritize [95], we suggest that different socio-economic contexts influence the prioritisation of threats.

Technical Defenses. Creators in Pakistan are especially dependent on well-designed technological defenses because of missing social and societal protections (e.g. reluctance to approach authorities, involve families). Defenses need to take cultural norms into account when (1) detecting harmful content (e.g. pictures of mixed-gendered groups, comments by religious figures), (2) protecting victims (defensive mechanisms should not leave traces), as Pakistan's tightly-woven social-net allows attackers to reach creators offline, or mobilize a crowd to attack victims based on false claims (e.g. religious offense).

Tailored Information Sources. Creators expressed a desire for contextualized information sources. We suggest to consider factors that impact creators' threat experiences when generating advice. Based on our findings we identified gender, content topic, platform, (size of) audience, and broader social embeddedness including cultural background.

6 Conclusion

Creators in Pakistan and the US [87] face online threats in the same categories, however there are differences in risk surface and expected harms: (1) what classifies as harmful content depends on the cultural context, and (2) we observe that online threats can be expected to lead to offline harm, which was not reported for U.S. creators [79]. Here, threats like impersonation that are rated "moderate" by experts [95] lead to potentially lethal attacks. Hence, we hypothesize that although creators across the world face the same threat categories, the prioritization of threats changes across cultures. Finally, compared to young adults in Pakistan [15], the threats creators face are even amplified. Furthermore, countermeasures such as taking their profiles offline do not work for creators which suggests that they need protection mechanims for their specific needs.

Acknowledgements

We thank the content creators for sharing their experiences in this study. Moreover, we thank the reviewers and shepherd for offering constructive feedback. Adrian Dabrowski, thank you for fighting the TikZ dragons with your LaTeX magic. The fifth author conducted a portion of this work while supported by the Max Planck Institute for Software Systems and additionally acknowledges support from a Google Research award focused on "at-risk users and creator safety".

Investigating Moderation Challenges to Combating Hate and Harassment: The Case of Mod-Admin Power Dynamics and Feature Misuse on Reddit

Madiha Tabassum[1], Alana Mackey[2], Ashley Schuett[3], Ada Lerner[1]
[1]*Northeastern University,* [2]*Wellesley College,* [3]*George Washington University*

Abstract

Social media platforms often rely on volunteer moderators to combat hate and harassment and create safe online environments. In the face of challenges combating hate and harassment, moderators engage in mutual support with one another. We conducted a qualitative content analysis of 115 hate and harassment-related threads from r/ModSupport and r/modhelp, two major subreddit forums for this type of mutual support. We analyze the challenges moderators face; complex tradeoffs related to privacy, utility, and harassment; and major challenges in the relationship between moderators and platform admins. We also present the first systematization of how platform features (including especially security, privacy, and safety features) are misused for online abuse, and drawing on this systematization we articulate design themes for platforms that want to resist such misuse.

1 Introduction

Online platforms like Reddit provide social spaces to build diverse communities around many topics and interests. However, widespread use of these platforms has also given rise to online hate and harassment, such as hateful speech, sexual harassment, violence, trolling, and doxing. As of 2021, 41% of U.S. adults have personally experienced some harassment online [13]. Members of marginalized or minoritized identities were more likely to be harassed because of their physical appearance, gender, race or ethnicity, religion, sexual orientation, gender identity, or disability [8].

Social media platforms often rely on volunteer moderators to reduce online abuse and harassment and maintain community safety. Moderators are responsible for monitoring the behavior of community members and enforcing community rules. Multiple studies have looked at moderators' experiences and practices [14, 16, 22, 32, 49], moderators' activities and labors [21, 37], and their processes for identifying rule violators as they work toward sustaining online communities [16]. These studies have discovered that moderators face complex challenges, including being personally targeted by harassers on the internet [14, 46], emotional burnout [21, 52], and lack of support from the platform [22].

Though past work has identified moderation challenges in online communities, limited research has looked at moderation specifically through the lens of preventing hate and harassment. Moreover, these studies were mostly conducted via interviews and surveys. Our work complements these works by studying organic, unfiltered, and spontaneous conversations in situ from two online communities for moderators, Reddit's r/ModSupport, and r/modhelp subreddits, avoiding social desirability bias that can occur in more controlled settings like interviews. Moderators post moderation-related topics or queries to these communities to get answers and suggestions from fellow moderators and Reddit administrators.

We have conducted a qualitative content analysis of 115 threads with 2,740 comments mentioning hate and harassment attacks and abuse from these subreddits. We systematically analyzed moderators' discussions in these subreddits to understand the challenges and unwanted trade-offs they face in managing community safety and the needs that emerge from these challenges. We found these conversations emphasize a uniquely challenging and adversarial subset of moderation situations, which appear naturally in r/ModSupport and r/modhelp by their nature as places for moderators to seek support with issues that challenge the limits of their skills, tools, and resources. This emphasis on challenging scenarios enables a major novel theme of our results and discussion - adversarial misuse of platform features - since adversarial misuse causes many such challenging scenarios. Overall, Our contributions include:

- Insight into the breadth of challenges moderators face, including the misuse of platform features for harassment, inadequate and unclear moderation tools, lack of support for moderators' safety, vague platform policy and actions, etc., drawing on a found dataset that uniquely highlights moderation challenges.
- The first systematization of how platform features are

misused for hate and harassment, mapping how different features can be misused to facilitate attacks,, a novel contribution enabled by the unique nature of our in situ, challenge-dominated dataset. We generalized these misuses beyond Reddit, and articulated design themes for creating platform features that are more robust to adversarial misuse by toxic users.
- An analysis of the of the critical but rarely studied relationship between moderators and platform administrators and its role in preventing hate and harassment.

2 Background and Related Works

2.1 Harassment in Online Communities

Online hate and harassment have been steadily increasing in recent years, posing a grave challenge to the digital world's well-being and inclusivity [13]. This rise is influenced by the anonymity provided by the internet and the polarization of online spaces, where like-minded individuals gravitate towards echo chambers, reinforcing extremist beliefs and normalizing abusive behavior [19, 23]. Online hate and harassment manifest in different ways, ranging from dissemination of toxic content (e.g., hate speech, threats of violence, etc.) to surveillance and impersonation [55]. Users employ diverse protective strategies to limit such harassment, including reporting, blocking, and disengaging from online platforms [3, 13, 56].

In addition to user reporting, many major social media platforms such as Facebook, Reddit, and Twitch depend on volunteer moderators to enforce rules, monitor content, and identify and action offenders while fostering an engaging and respectful community [35, 42, 49]. According to the Reddit 2023 Transparency Report, 167.2 million pieces of content were removed from Reddit in the first half of 2023, 49.5% by volunteer moderators [6]. Our paper provides an in-depth analysis of salient challenges to this moderation work.

2.2 Moderation Challenges

User-driven volunteer moderation has been studied on various platforms from varying perspectives in recent years and has demonstrated the challenges faced by the moderators. One of the primary challenges moderators face is the sheer volume and scale of user-generated content they need to moderate and the labor required to do that [18, 37, 60]. In addition to that, moderators need to balance free speech with maintaining a respectful environment, which poses a persistent dilemma when defining the line between acceptable and inappropriate content [33, 44]. There have been some automated moderation tools, such as auto-moderator in Reddit, which can be employed to reduce the workload of the moderators. While these automated moderation tools are aimed at lightening the load, previous studies have revealed that such tools are limited in their comprehension of context, linguistic nuances, and the intricacies of social interaction [14, 26, 30, 36], making manual intervention by moderators necessary for nuanced, case-specific decisions, even with automated assistance [49].

Previous work has also looked at the psychological impacts of reviewing toxic content and handling harassing behavior for extended periods of time [21, 52]. Dosono et al. showcased the substantial emotional labor moderators experience as they engage in moderation tasks, meeting platform, and community expectations that ultimately lead to burnout [21]. Steiger et al. highlighted the arduous exercise of moderators in managing and maintaining personal boundaries, such as avoiding burnout and navigating complex interpersonal conflicts within the community [52]. Furthermore, Almerekhi et al. pointed out the targeted hate and harassment towards moderators by users actioned for violating community rules [11].

Several studies investigated transparency in moderation and highlighted the importance of providing explanations of moderation actions in building trust and accountability [15, 29]. However, moderators encounter challenges in delivering transparency as it requires more moderation effort and time to manually provide explanations [31]. More transparency could also escalate conflict and harm against moderators, leading to emotional burnout [25, 49]. Moderation gets even more complex with the diversity of platform contexts and communication mediums. For instance, Jiang et al. discussed the mechanisms of abuse within voice-based communities and the moderators' struggles in identifying and addressing violations during real-time, ephemeral interactions [32]. Wohn et al. underscored the difficulty of combating harassment within large, fast-paced live chat exchanges on platforms like Twitch, necessitating immediate moderation decisions [59].

Most of the previous works have explored challenges in specific moderation issues, i.e., content governance, emotional labor, transparency, etc. We extend the current literature by providing a comprehensive overview of the challenges moderators encounter in their moderation work by leveraging online discussion data (Reddit) among moderators. Our paper draws from forums specifically dedicated to moderator support, offering a particularly close view of the most challenging issues encountered by moderators.

2.3 Moderation on Reddit

Moderation on Reddit involves a combination of automated tools, volunteer subreddit moderators, and professional platform administrators. Each subreddit has volunteer moderators who enforce community rules. Moderators can remove posts or comments, issue warnings, or ban users who violate those rules. Reddit also has a small team of paid employees, called admins, who manage sitewide policies and legal matters and can issue sitewide bans. Reddit's sitewide automated tools include "automoderator", which assists mods by automatically identifying and removing abusive content [1]. Users can report rule violations and communicate with moderators

through modmail, a shared per-subreddit inbox that moderators use to communicate with each other and handle requests from community members [7]. The "modqueue" is a central, per subreddit listing of "all the pieces of content in the community that need to be reviewed by [moderators]—including user reports, filtered posts, and comments" [2].

3 Methods

In this section, we detail our approach to data collection, explaining how we selected the subreddits and threads to analyze. We then outline our analysis process.

3.1 Forum Selection and Data Collection

We looked for subreddits designed to assist moderators on Reddit's official moderator support page [5]. We have considered the following inclusion criteria for subreddits:

- Moderators can post in the subreddit (i.e., r/modnews was excluded because only Reddit admins can post).
- Subreddits specifically for moderators to discuss moderation-related topics (i.e., r/help was excluded because any Redditors can post any Reddit-related topic).
- Subreddit is not limited to a particular moderation topic or geographical area (i.e., r/AutoModerators was excluded because it only discusses automod, and r/FrMods was excluded because it only includes moderators from French-speaking communities).

Based on these criteria, we have decided to study r/ModSupport and r/modhelp.[1] r/ModSupport and r/modhelp subreddits are specifically designed for moderators to discuss diverse topics related to moderation (i.e., moderation issues, moderation tools, online abuse in community, etc.) and seek support and advice from admins and other moderators. These two forums have a large user base: r/modhelp, established in 2009, has 133k members (the largest community of moderators in Reddit), and r/ModSupport, established in 2015, has 92k members as of April 2024. Both are very active with over ten daily threads, providing a rich dataset for our study.

We downloaded a publicly available datset of all available threads[2] from these subreddits from inception to December 2022. We used pushshift.io, a platform that is used to maintain an up-to-date public archive for Reddit to download the threads[3]. We omitted threads where the posts were empty, deleted by the poster, or removed by moderators. The resulting corpus contains 41,256 threads: 12,345 threads from r/Modsupport with an average of 12.58 (SD: 47.46) comments per thread, and 28,911 threads from r/modhelp with an average of 5.82 (SD: 6.52) comments per thread.

[1]Table depicting how these subreddits were selected: https://osf.io/3hk8r

[2]A thread consists of the initial post and subsequent comments and replies.

[3]https://pushshift.io/. We collected our data in January 2023, prior to Reddit revoking Pushshift.io's API access in May 2023

3.2 Sampling a Set of Threads for Analysis

We focused on threads where moderators posted about hate, harassment, and abuse-related attacks towards their community or themselves, asking questions/suggestions about those and sharing challenges in keeping their community safe against those attacks. We used a broad definition of hate and harassment taken from Pew Research [13] and Thomas et al. [55] while sampling the threads: *"Hate, harassment, and abuse occur when an aggressor (either an individual or group) specifically targets another person (including moderators) or group to inflict harm: emotional, financial, or physical. In its milder forms, it creates a layer of negativity that people must shift through as they navigate their daily routines online. At its most severe, it can compromise users' privacy, force them to choose when and where to participate online, or even pose a threat to their physical safety, e.g., doxing and swatting."*

This section will describe the process of generating our dataset for the main analysis, which contains such threads.

Keyword Generation Process: We developed a set of keywords/key phrases to identify posts relevant to hate, harassment, and online abuse. Our initial list of 47 keywords/key phrases drew on Thomas et al.'s taxonomy [55] combined with the set of reasons related to hate and harassment (i.e., harassment, hate, spam, etc) that Reddit's report form offers users for describing content that breaks site rules. We included all hate and harassment-related attacks from Thomas et al.'s taxonomy in our keyword list, except for removing those irrelevant to our topic, such as "IoT manipulation" and "zoom bombing," via discussion among the authors.

We searched for threads in our corpus using those keywords/key phrases such as bullying, trolling, etc. We removed a term from our keyword list if there were no threads containing that term or some word form of that term. For example, we include "bully" in our keyword list if we find a thread with the terms "bully," "bullying," "bullied," or "bullies." After this process, we had a list of 29 keywords/key phrases.

We sought to keep threads where the post contained at least one of the 29 keywords/key phrases or some word form of those terms. The matching process was case-insensitive and was conducted at the word level rather than the character level to avoid mismatches like matching "troll" to "stroll." 6,550 threads contained at least one keyword/key phrase.

We drew a random sample of 1,000 threads from these 6,550. Reading through this sample, we realized that the posts with keyword "spam" were frequent but rarely relevant: 603 out of 1,000 posts contained the word "spam", but only 53 of those were relevant to our analysis. Of those 53, 83% also contained at least one other keyword from our list. Therefore, we removed the keyword "spam" from our keyword list as we did not want our final dataset to be dominated by threads containing such posts. We changed the word "hate" to "hateful" and "hatred," as the word "hate" triggered many false positives and the words "hateful" and "hatred" matched the discussion

on online attacks. We added seven more keywords, "racism," "bigot," "transphobic," "homophobic," "scam," "AEO," and "abuse," because we found relevant posts containing these keywords that were not triggered by any other keywords from our list. Finally, we removed the key phrase "report abuse" from our list to remove duplicates, as we included "abuse" in our keyword list. In the end, we had a list of 35 keywords and key phrases, provided in https://osf.io/3hk8r. Searching these keywords left us with 3,321 threads in our final dataset.

Final Sample: We randomly sampled and coded threads from our final dataset until we reached thematic saturation, following the guidelines in prior research [47]. At each stage of random sampling, two researchers manually reviewed and discussed each sampled thread. If it was a false positive (i.e., unrelated to online hate, harassment, and community safety), we replaced it with a new randomly sampled thread, ensuring that all coded threads were relevant to the study. In total, we coded and reached saturation with 115 relevant threads[4] (2740 comments) sampled from all 3321 threads.

3.3 Data Analysis

We used an inductive coding process to analyze the threads. Our analysis considered both the post and all the comments in each thread. First, three researchers went through 50 threads in multiple rounds to reveal initial codes. The research team met multiple times in this process to discuss the codes, clarify definitions, resolve disagreements, and establish an initial codebook with fifteen codes. Two researchers then coded sets of 20-25 codes at a time, meeting between sets to compare codes, resolve disagreements, and revise the codebook until no new code emerged. Seven new codes were added to the codebook in the process. After the 95th thread, no new codes appeared from the additional 20 threads. Therefore, it was deemed that the data collection had reached a saturation point at the 115th thread. In the end, there were 22 codes in our final codebook. The final codebook is provided in the Appendix A.1. Both coders coded and discussed the same set of threads and agreed on the codes, so we do not report inter-coder agreement. Then, we conducted a thematic analysis by revisiting all the threads and codes multiple times to identify common themes. The research team held regular meetings to review and discuss the analysis results and the generated themes .

3.4 Ethical Considerations

Our institution's Institutional Review Board determined that this study was out of scope for their oversight. Nevertheless, this work has significant ethical implications for the moderators whose words we studied and the communities they protect. The data we analyzed are direct quotes from Reddit moderators, many of whom are from marginalized communities. Though this content is publicly available to anyone, our aggregating it as a dataset and highlighting aspects of it in this manuscript could induce unwanted or dangerous attention (including hate and harassment) towards moderators and their communities. We took several steps to mitigate these dangers. We chose not to release the aggregated dataset publicly. We redact any usernames, specific subreddits (other than `/r/ModSupport` and `/r/modhelp`), or specific communities (e.g., when discussing subreddits associated with a physical city). Additionally, to increase the difficulty of re-identifying specific comments and commenters for targeted harassment, we have paraphrased all quotations that appear in the paper (one researcher paraphrased and another reviewed each paraphrase for fidelity to the original meaning).

[4]The sample is used in another paper of our authorship [54] to understand mutual support among moderators in mod-support communities.

3.5 Limitations

This study only focused on publicly available threads from Reddit moderator communities. Our future work will address this limitation directly by recruiting Reddit moderators as interviewees to discuss the in-depth and complex aspects of questions inspired by our findings. Another limitation is that we only analyzed communities primarily using English. The nature of our research left many variables unknown. We did not have access to any data on the demographics of the moderators we studied, so their gender, education level, occupation, age, and location remain unknown to us.

4 Results

In this section, we present the results of our analysis of the Reddit data from two moderator support communities, r/ModSupport and r/modhelp. Though we analyzed additional major themes (e.g., the types of support exchanged among moderators), we chose to narrow our presentation of results to those focused on moderation challenges. We made this choice because the forums we studied provide a particularly rich source of data on challenges. Since by their nature as venues for moderation support, moderators often post in them when facing tricky issues they were unable to handle on their own. Thus compared to other work, our findings likely represent more difficult, frustrating, or unusual challenges, while downplaying more common ones that are typically handled by standard procedures, solo problem solving, or moderation tools. We then present a set of complex tradeoffs that moderators identified as underlying many of these challenges.

4.1 Moderation Challenges

Moderators described various challenges they face as they fight hate, harassment, & abuse to maintain community safety.

4.1.1 Misuse of Platform Features

As moderators discussed challenges with harassment, one major theme that emerged was the frequent and creative misuse of platform features in ways that enabled toxic behavior, amplified its harms, or made it more difficult to moderate. While the misuse of platform features for hate and harassment has been noted before (e.g., on Discord [32] or Facebook [27]), we believe that we are the first to systematically describe and characterize it as a broader phenomenon. Table 1 summarizes all of the platform features that were mentioned as being misused in our dataset and how it affects moderation. We categorized these misused features into four categories:

- **Community engagement:** Ability to create, engage or interact with community (e.g., posting or creating subs).
- **Mod/admin engagement:** Ability to interact with Mods or admins about different issues including abuse (e.g., mailing mods or reporting abuse to mod/admin).
- **Privacy control:** Ability to control one's privacy, including controlling the persistence of as well as others' experience of one's content and account (e.g., blocking, the ability to create multiple throwaway accounts to keep anonymity and avoid association with the primary account or privacy aspects of general platform features such as a lack of edit history on posts and comments).
- **Tracking:** Ability to track and learn about someone else's activity (e.g., the fact that Reddit accounts have unconfigurably public post comment histories).

The categorization was devised by considering the primary purpose for which the users used these features in our dataset. We analyze these features in terms of the types of threats and harms they enable and the ways they make moderation more difficult in Section 5.2, where we also provide general lessons for thinking adversarially in the design of such features. We hope that our analysis will aid designers in more effectively evaluating and threat-modeling social systems against different types of adversarial misuse of platform features.

4.1.2 Complexity of Policy and Rules

Echoing some past work [38, 45], moderators often discussed situations where rules or policies aren't well-defined, or where their details or enforcement are subjective. For instance, one moderator said: *"The primary issue in this situation is that nobody, including the administrators, can clearly define or provide evidence of brigading.* [5] *This remains a persistent source of disagreement between the moderators and the administrators."* Reddit's policy on sharing personal information [6] was another source of confusion: *"Are we required to delete a bad review detailing a user's experience with their doctor? We were threatened with a lawsuit from someone claiming to be the doctor's attorney and one of our mods ended up having to find a lawyer to advise us. Handling this situation should not be the job of unpaid moderators!"*

A lack of admin clarification of policies was also a common complaint. For example, one wrote: *"When admins refuse to provide clarifications on the specific rules, it's unreasonable to expect people will adhere to them."* That said, a few moderators acknowledged the complexity of defining concrete policy, especially in the complicated landscape of online misconduct and harassment. For example, one moderator said: *"This is one aspect where I agree with admin regarding the necessity for making contextual judgments. Policies can't encompass every scenario, leaving room for someone to claim the rule is unclear and disagree with its application somewhere."*

Others noted that too much specificity in policy may enable harassers to follow the letter of the policy while subverting its spirit: *"r/<redacted> is a prime example of why admin avoids giving a straightforward definition as they did bare minimum to comply with it. Yet they would still facilitate their community to engage in invading, manipulating, and harassing content/users they disagreed with. When mods were told to forbid linking to content, they complied but direct people on how to find that same content by other means."*

The issue of opaqueness in moderation policy is not exclusive to Reddit. Singhal et al. found a lack of clear guidelines for content moderation policies on all the major social media platforms. Moreover, there is no consensus among social media platforms on what type of content should be moderated for some categories, such as sexual content [50].

4.1.3 Issues with AEO and Admins

Anti-Evil Operations (AEO) and Reddit administrators moderate Reddit by enforcing content policies, addressing rule violations, and taking action against rule-breaking content or users. Though they seek to support mods in maintaining a safe and respectful online environment, mods frequently mentioned challenges when dealing with AEO and admins.

Lack of Response and Action: A major concern of moderators was admin's perceived slow or inconsistent response to reports and queries. They complained of a lack of responses or of generic assurances such as *"we'll investigate"* from Reddit, even in situations demanding urgent attention, such as reports involving suicide, sexual abuse of minors, and organized attacks and harassment. One moderator wrote:

"Has anyone encountered issues with admin not replying to private messages? I mod a mental health subreddit, and attempting to contact admin since last week about a user who is actively encouraging our users to self-harm. One would expect that a serious matter such as this would receive a quick response, but it's now been over 72 hours with no response."

[5] Coordinated activity of a group of users on social media or online communities to manipulate or disrupt discussions, forums, or platforms, usually by flooding content with a specific agenda or engaging in harassment.

[6] The policy reads: *"Respect the privacy of others. Instigating harassment, for example by revealing someone's personal or confidential information, is not allowed. Never post or threaten to post intimate or sexually explicit media of someone without their consent [4]."*

Feature	How Misused	Example Quotation
Community Engagement Features		
Create account (Username & profile pic)	Create account with offensive username or profile pic	*"One account is following people with a slightly obscured racial slur for a username & a profile pic showing a black man being executed."*
Post & comment	Post and comment harassing content, misinformation, scam, etc	*"We are getting overwhelmed at r/<redacted> because of the World Series and at least one troll is actively creating new reddit accounts to post racial messages. It is getting difficult to manage."*
Flair (post categories & user tags)	Use harassing text as flair	*"A subscriber decided it would be a great idea to fill their flair with offensive, racist and homophobic language."*
Crosspost (sharing posts on subreddit)	Crosspost posts to trolling subreddits; Crosspost harassing posts to a subreddit	*"He is crossposting many of our sub's threads to troll sites. He doesn't even try to hide it because surprisingly, all of it is legal. There is no way to ban offensive cross posting. He crossposts then invites his troll buddies to harass me or other community members."*
Create subreddit	Create subreddits with the sole purpose of harassing	*"Individuals in my area who run hate groups on facebook are creating subs that direct users to sites spreading hate and misinformation."*
Direct message (DM)	Send harassing content	*"A user in our sub pointed out some hateful language on a post and now getting DMs filled with hateful/incendiary/harassing words."*
Gilding (purchase and give award)	Award people with account containing offensive username	*"A user with an offensive username now gilding others so that I remove the comment they gilded as it shows their offensive name. I doubt Reddit is going to take action against accounts that buy gold."*
Vote (upvote & downvote)	Mass downvoting	*"After investigating, we believe 2-3 former members of our sub are chronically downvoting. Now the majority of the posts on our subreddit's main page have no upvotes or negative karma, and someone pointed out that that it portrays the subreddit in a negative light."*
Mod/Admin Engagement Features		
Modmail	Send harassing content, spam Modmail	*"We were recently bombarded by a single user who sent us the same harassing Modmail 30 times within a minute."*
Report	False reporting posts/comments; Fill the 'text field' on the report feature with harassing text	*"I moderate a controversial sub & lot of the reports have anti-semitic, violent, threatening, homophobic and transphobic language in it. "* *"Currently, any user (including those banned for harassment) can false report your posts and cause site-wide suspension of your account."*
Privacy Control Features		
Edit	Harass and then edit content to evade penalty	*"I recently deleted an offensive image. The poster began commenting that I am a bully and should not be a mod and when I went to alert other mods, they changed their texts to a more rational response."*
Delete	Delete post or comment and/or delete account after harassment to avoid penalty	*"A user waits 3 days after everyone has seen his abusive posts, then deletes any trace of doxxing from his accounts. Admins do nothing after I submit a report because there is no evidence of harassment."*
Alt/throwaway account (extra or temporary account)	Create account to harass and evade ban	*"A user created a new account and spent 6 hours urging others in the sub to commit suicide. We used automod to pseudo-shadow-ban them, but they simply created a new account and did it again. "*
Block	Harass and block someone so they can no longer view or respond to discussions	*" Someone post an insulting comment and then immediately blocks the accused. This gives the impression that the accused user is wrong and does not want to respond to the insults made against them, but in reality, they are unable to even see the comment."*
Tracking Features		
User post & comment history	Follow someone throughout Reddit to harass	*"Someone's stalking me, they check my post history and inundate all of my posts with offensive comments, even resorting to doxxing by using personal info they've gathered about my real life."*
Follow	Follow with harassing usernames, profile pics; follow to track targets posts to harass	*"New users in our teen subreddit are being bombarded by followbots with names related to pedophilia. 13 year olds are being notified on their cellphones that convicted pedophiles are following them."*

Table 1: Summary of platform features abused for harassment from our dataset

Moderators also expressed their frustration with Reddit's failure to enforce its terms of service and policies when it comes to content and individuals who blatantly violate these rules. This encompasses trolling-focused subreddits, subreddits associated with organized attacks, offensive content, and comments targeting specific communities, among other violations. For example, one moderator shared:

"I manage multiple large subreddits and frequently see blatantly violent anti-Semitic or Islamophobic comments. Even though I handle these at the subreddit level, I find it perplexing that when reported to admins, they constantly say that the content does not violate Reddit's policies on hate speech."

One moderator also shared an example of how this lack of action escalated to hate and harassment offline:

"Look at r/<redacted> for an example of a subreddit illustrating admin's reluctance to ban a community that exhibited blatant hatefulness, destructiveness, and disruption on Reddit and contributed to real-world violence by right wing extremists. Admins only banned the sub after it moved off-site to continue their extremism elsewhere."

Mods also discussed a lack of effectiveness of admin actions. For example, one popular admin sanction is the shadowban, which allows a banned user to post and comment, but their activity is invisible to others, with the goal of not revealing the punishment to the banned user so they cannot evade it. Nonetheless, mods observed that shadowbanned users can still engage in harassment:

" Shadowbanning a user that utilizes private messaging to run scams or sell drugs is ineffective. Shadowbanning a user who inundates mods with hundreds of messages is also ineffective. I know first-hand that getting admin to address explicit violations of content policy is not possible when the account has already been shadowbanned. It's incredibly frustrating."

Some moderators claimed that when a single user is reported multiple times, Reddit often investigates only the first: *"I flagged two comments from the same user. Reddit decided to delete one of them, but declined to look into the other & it wasn't removed. They said: "We've already investigated this user based on another report about other content. After investigating, we determined that the reported user was in violation of Reddit's Content Policy and took action accordingly."*

Moderators don't seek only admin's practical support; many also valued acknowledgment and appreciation of their work: *"Being heard and recognized means a lot. The fact that admins do not acknowledge these problems is a major issue. Simply making the time to listen and acknowledge the issues with genuine interest and intention to help holds immense value and can go a long way in reducing frustration."*

Lack of Transparency about Admin Actions: Moderators expressed a desire for greater transparency about the actions that admin or AEO take or the reasons for those actions. Some wanted transparency in order to form a better model of unclear or subjective rules (see Section 4.1.2) and better align their moderation with it. For instance, after AEO removed a post that a moderator had approved, they said: *"If there was a legitimate reason for the removal, I would like to be informed of it. This way I know what we did wrong in our approval process and make better choices moving forward."* Others expressed surprise when receiving feedback that users they reported were banned, noting that typically they received only boilerplate with no details about what action was taken: *"I am fed up with constantly receiving this message: "After investigating, we've found that the reported content violates Reddit's Content Policy and have taken action."* Such frustrations were also observed in the prior research on moderation transparency in different platforms [38, 53].

Finally, some were frustrated by the way a lack of transparency made it difficult to contest decisions made by AEO or admin, as the appeal form requires an explanation of why it is an error and why the instance actioned was not a violation of Reddit policy. This is particularly important in instances where moderators are targeted by false reporting to ban their account. One moderator said: *"I was banned for 'harassment' with no explanation of what I did. I appealed and the decision was revoked, but the process was difficult considering I had no idea what I had supposedly done."*

Prior studies emphasized the significance of making moderators' actions [29, 31] and automated content moderation [15] transparent to users and content creators to foster trust and engagement. Our results expand to also examine the role of transparency between the platform and volunteer moderators.

Inconsistent and Inaccurate Actions: Moderators frequently complained that AEO's actions appeared arbitrary and inconsistent, both in failing to address violations and in taking action without cause. Such inconsistencies in action from algorithmic moderation systems have also been observed in other platforms such as Facebook [26, 57].

One moderator wrote: *"Taking isolated messages out of context and imposing penalties based on them undermines the value of our role as moderators, portraying us as ineffective and dispensable."* This quote touches on two themes. First, moderators prided themselves as experts of their community and moderating contextually. Second, one of the problems with inconsistent platform actions is that they see it as undermining their ability to moderate effectively.

Inconsistent platform actions also frustrated moderators who saw them as increasing their workload through the need to appeal erroneous suspensions or request that posts be reinstated. Some found the process for doing so particularly cumbersome: *"I should not have to put so much effort (numerous modmails) just to review an AEO removal."*

Unwarranted actions against moderators were seen as particularly harmful, both because a banned moderator can't moderate (leading to more toxicity in their community), and because some moderators were afraid to take moderation actions after seeing others be banned for doing so:

"A mod in my community was banned, ironically, for reporting abuse of the report button. Our users abuse the report

button regularly, and honestly I'm nervous to report them now, since apparently we can be banned for doing our jobs."

Moderators articulated various theories of why AEO exhibits these behaviors, such as believing it consists of third-party contractors in another country or a poorly designed automated bot. Actions perceived as inaccurate may thus aggravate a lack of transparency around admin actions (by creating & reinforcing potentially incorrect theories). Conversely, a lack of transparency around how AEO works may contribute to perceiving its actions as inconsistent or inaccurate.

4.1.4 Issues with Moderation Tools/Features

Reddit's moderation features include tools such as post/comment removal, user banning, content approval, etc. Two major themes about these tools emerged: misunderstood or unknown tools and inadequate feature sets.

Misunderstood or Unknown Moderation Tools: Moderators were sometimes entirely unaware of the existence of some moderation features, learning about them in response to posts in r/ModSupport or r/modhelp. Others knew about features but misunderstood their behavior. For example, one mod deleted a post containing a link to non-consensual intimate imagery, assuming that removing the text of the post would render the link inaccessible. However, such links remain active on Reddit, which they learned only when told by the victim. In another case, a moderator banned an offender from a subreddit, believing they would be entirely blocked from the subreddit. The mod later discovered that the offender could still view the subreddit, report content, and even give awards, leading to continued misuse of these features. Such misunderstandings may be due to incomplete documentation; Reddit's website outlines what a banned individual cannot do, but doesn't list actions they can still take.

A key action moderators take is to report violations of Reddit's central policies to the platform. Reddit offers several avenues for reporting offensive behavior, such as utilizing the report button under posts or comments, utilizing a dedicated report form, submitting a request for inquiry through Reddit help, and contacting the administrators via Modmail on the r/ModSupport subreddit. Moderators discussed all of these options, but were often unclear on how they differed and when to use them. Further, when reporting content, mods need to choose a category under which to report, such as "This is spam", "This is abusive or harassing", "Minor abuse", and more. Some mods felt there was a lack of clear explanation of the meaning or scope of these categories, which they said led to incorrect use and less effective responses to reports. For example, one moderator pointed out that the category "report abuse" could be misleading, as some individuals might interpret it hastily as *"I want to report this abuse"* rather than *"This user is abusing the report button"* (i.e., by reporting non-problematic content). Such confusion can have major consequences: this moderator attempt to report an abusive user comment, but instead inadvertently reported another mod who had already reported the same comment, resulting in the suspension of that moderator for misuse of the report button.

Another moderator noted that clarity and consistency of report categories could also serve a role of communicating site standards and Reddit's consistent enforcement of them: *"By presenting users with categories of what constitutes unacceptable behavior, Reddit can enhance clarity, demonstrating its commitment to upholding every aspect of its code of conduct and reinforcing these rules with its community members."*

Moderators also discussed uncertainty about how much and what kind of evidence is needed for reporting. For example, a common form of harassment involves mass (false) reporting of threads in a subreddit, which wastes moderator time by filling the modqueue with gratuitous reports. Moderators were unsure whether to report each false report or just a few, and whether or not to clear the modqueue or if they should leave it as evidence for administrators. In this case, admins responded to say that it is fine to report just a few cases of spam abuse and then clear all the abusive reports from the modqueue. Nevertheless, we saw that many other inquiries about misunderstood and under-documented moderation features went unanswered by admin. Past research found similar misunderstandings and confusion about the content moderation and appeal process among users on social media platforms [58].

Inadequate Features: Moderators are often unsatisfied with the lack of adequate features to prevent abuse and action offenders, even though they are held accountable for the safety of their community. They often named specific toxic behaviors, such as ban evasion and misuse of the report and block features, for which features were particularly insufficient: *"How do you think we're going to moderate block abuse if we can't see when people have blocked each other, and just have to take their word for it?"*

Reporting to admin was seen as one of the few options available in such cases, but this was more difficult when nonstandard approaches were used to harass, such as paying to gild a post while using an offensive username: *"The report categories don't include offensive username and/or gild giver name)."* Furthermore, deleted accounts can't be reported. Mods described harassers circumventing bans by creating a new account and deleting the old one. One said:

"We can't report most usernames through the report form due to the error it returns: 'this account does not exist'."

The inability to provide contextual information while reporting offenses frustrated some mods, who considered this particularly important when the harassment was in another language or used relied on tropes or dog whistles. For instance, one moderator said: *"I once encountered a subreddit promoting hate against the queer community and it was near impossible to report because most things posted were subtle. They weren't so obvious like 'trans people go die'.*

At times, limits in place to resist abuse can backfire. For example, Reddit limits users' rate of reporting to mitigate

report abuse, a limit that also applies to mods dealing with a surge of toxic content: *"When you have an uptick in report abuse in the queue, you have to spread out reporting across multiple moderators to quickly clear the queue."* Similarly, Reddit does not accept images as evidence for reports since they could be edited. However, offenders can edit or delete posts and comments at any time to conceal their actions. According to Reddit's 2013 privacy policy, Reddit retains only the most recent versions of posts and comments, making it nearly impossible to detect such offenses. This policy has not been mentioned in subsequent privacy policy updates, but many moderators believe that Reddit still follows this policy.

4.1.5 Non-Reddit Authorities

In extreme cases of harassment, mods discussed contacting authorities such as law enforcement, and internet service providers (ISPs). However many mods believed that law enforcement has a high bar for acting on online abuse, a claim justified by past work on intimate privacy [17]. Others saw the platform as a blocker to such action after contacting police about doxing: *"I was told by police that they've asked for information from Reddit, but it could be two to six months before they're sent the necessary info. This does not appear to be high priority for them."* In other cases, the international nature of the internet was the problem.

"The problem I'm facing is that the user at risk are located in the United States, while I am in Germany. If I reach out to the local authorities in Germany, they would be unable to take any action due to jurisdictional constraints."

Moreover, mods noted that law enforcement and ISP practices vary from country to country. While online harassment is treated seriously in some regions, it may not be elsewhere. Mods felt that without other support, victims often have two choices: leaving the community or enduring harassment.

4.1.6 Mod-Targeted Harassment and Burnout

Moderators on Reddit are more prone to targeted harassment due to their role in enforcing subreddit rules and decisions, their increased visibility, and the potential for disagreements with users, which often escalate into personal attacks in the relatively anonymous online environment [11]. Moderator mentioned harassing messages (i.e., death and rape threats toward mods and their families, threats of physical harm, threats of hacking and doxing, etc.), organized targeted attacks of false reporting and downvoting all their posts and comments, and being hacked, doxed, or stalked in campaigns that sometimes escalated to moderators' other social media accounts. In extreme cases, harassers persisted over months or even years.

"After banning a user in my sub he sent me a private message containing my phone #, family address, and other personal info, saying they would 'pay me a visit'. I moderate a local sub so the threat felt very real. I am unashamed to say I am still afraid of this person and I don't think I'll ever reach closure around this situation nor will I feel at peace."

To minimize these risks, some moderators discussed using separate accounts for moderating and personal Reddit activities. Some wanted the ability to seamlessly switch between their dedicated moderation account and regular user profile or recommended that Reddit should conceal moderators' identities when interacting with rule violators.

In addition to targeted harassment, moderators see more offensive and harassing content and behaviors, which leads to emotional burnout [52, 59]. One moderator said: *"Automod prevents the public from seeing this stuff, but I still see it."* Previous research with online content moderators [51] and community moderators [21] showed that moderators cope with burnout by taking various approaches, including peer support, separating moderation from home, engaging in physical exercise or distraction, and using tools such as muting audio, ceasing immediate viewing when content was confirmed as sexual abuse content, etc. to minimize impact.

Special Events: Special events relevant to a particular community can create temporary increases in toxic content, leading to increased moderation burden both practically and emotionally. Discussing Pride Month, a moderator of an LGBTQ community asked: *"Is anything being done to address the significant increase in hate and harassment towards LGBTQ users, moderators, and subreddits?"* Current events could lead to similar but unplanned surges, as described by a mod of a geographically focused subreddit after a local mass shooting: *"It turned out to be unexpectedly demanding in terms of time and emotional toll. We were immersed in the tragedy without any chance to take a break, and piled on top of that was the overwhelming toxicity from brigaders."* Reddit organizes mod reserves, which provide temporary extra moderators for such events, but moderators exercise caution when considering this option, since so much of moderation depends on understanding subtle context or familiarity with the community's culture and values, reinforcing findings from past work [43].

Some attributed inaction to financial causes. *"Reddit possesses the financial resources to offer an immediate response for mod support in local surges like these. They opt not to since mods will just suffer and do it without pay."*

4.2 Complex Trade-offs

Moderators identified complex tradeoffs involving conflicting pressures between welcomingness, privacy, free speech, and other factors when working to combat hate and harassment.

Accessibility vs. Harassment: Ban evasion—in which offenders create new accounts and continue problematic behavior—was a commonly discussed challenge. One common mitigation is to establish a minimum account age or karma requirement to prevent new accounts from participating in a subreddit. However, this also restricts genuine (i.e., non-ban-evading) new users from contributing, which is a

serious concern for some moderators: *"Because we mod a local sub, we do not want to set age or karma limits. It would prevent new posters from posting, thus creating an unwelcome environment for folks who, say, recently moved to our city."*

Another approach to reducing harassment is to make a community private, such that only users approved by moderators can view, post, or comment. This option seriously limits accessibility to new users, as well as necessitating extra mod effort to manually approve each user. *"Changing our sub to private was an option that we thought of, but the labor needed for that and the risk of losing members was of major concern. We would possibly lose existing members or genuine new subscribers who want to talk, grieve, or find info. "*

Harassers also sometimes misuse features to induce this tradeoff. Mods described harassers who create accounts with offensive usernames and gild target's posts, which causes the platform to display the gilder's (toxic) username alongside the post. Moderators cannot remove the gild giver's username from the comment—their only moderation options are to delete the entire comment, which silences the target and makes the community less accessible to them, or leave the post up still branded with the harasser's username.

Privacy vs. Harassment: Reddit allows users to remain relatively anonymous, which can be both a strength and a weakness. Anonymity can protect privacy and allow for open discussions [12, 39], but it can also shield harassment, hate speech, and trolling. A popular way to maintain anonymity on Reddit is by creating a throwaway account. Many people use throwaway accounts to ask sensitive questions, confess secrets, or share stories that they don't want to be associated with their regular Reddit account. However, throwaway accounts are also misused for harassment and evading bans. One way to prevent this is to verify the throwaway account to confirm that they are legitimate users using a formal verification method. However, such verification can undermine the purpose of using a throwaway account. One mod suggested: *"If you are having an issue with new accounts trolling your community, why not require them to message you from an established account to prove their throwaway is legitimate?"*. Another replied: *"I hope that solutions exist to preserve anonymity if a user has genuine fears about their Reddit identity being exposed. I don't believe throwaway accounts should trust or rely on mods to keep their identity confidential."*

Reddit stores only the latest version of edited posts or comments. Mods described abusers who post offensive comments, then edit them to appear benign to evade punishment by concealing evidence. However, this lack of edit history is also seen as a valuable privacy feature:

"The privacy implications could be drastic if this change was enacted. Redditors could more easily gather another's personal information. Ongoing disclosure and editing is part of Reddit's approach to privacy, which is why you can edit posts and comments even when your account is suspended."

Finally, for the sake of privacy and to deter moderators from misusing their authority to suppress legitimate reports of misconduct, Reddit doesn't reveal who reported an issue to moderators. Unfortunately, mods noted that this also protects those who abuse the report button, and many wished for a system that could hold spam reporters accountable without disclosing genuine reporters' identities to mods.

Transparency vs. Harassment: Similar to prior work [33], mods noted a tradeoff between transparency and harassment mitigation. Moderators discussed the need for clear and concrete rules and transparency on how the platform makes decisions on violations. Though this information would help moderators take moderation actions that align with platform policy, excessive transparency can inadvertently empower harassers by revealing patterns that help them evade detection and circumvent moderation measures [20, 33, 34]. One mod described a toxic sub with *"[a] desire for an explicit rule not to better prevent harassment, but so they could find a loophole. They followed the letter of the spelled out rules but still allowed harassment."*

5 Discussion

Our discussion draws out to major themes from our results. First, we discuss the understudied relationship between mods and admins, examining it in terms of power dynamics and placing moderator behavior and understanding of the platform in that context. Second, from our results detailing feature misuse for hate and harassment, we generate a taxonomy of such misuse, analyzing the ways feature misuse strengthens harassment and makes it more resilient to moderation. We then articulate design themes for creating platform features that are more difficult to misuse in these ways, in the process arguing for the value in this context of taking a security mindset-based approach to platform design.

5.1 The Relationship of Mods and Site Admins

In our investigation, the relationships between mods and admins came up often. In broad terms, both admins and moderators have similar goals to deter targeted attacks, harassment, and other negative behaviors on Reddit and foster a positive and safe environment for users. However, we observed complex and often discordant relationships between them.

Moderators' perceptions of their relationship with admins crossed many emotions: frustration about insufficient communication, confusion about unclear guidance, anger about perceived inconsistent or inappropriate actions, and fear about the possibility that they, their users, or their whole community might be punished or banned unfairly. Mods often view admins as capricious, unreliable, or arbitrary yet powerful entities. These inconsistent and arbitrary actions of admins affected moderators' ability to effectively moderate their community, the safety of community members, and the perceptions of Reddit as a place for positive engagement. For in-

stance, moderators get inaccurately banned for reporting violations, their posts arbitrarily get removed without explanation, and so on, affecting their ability to interact with and ensure the safety of their community. Despite these challenges, moderators often find themselves in a position where they need to be reliant on admins. We have observed this dependency on admins both in the high frequency with which moderators advised each other to escalate issues to admins and the frequency with which admins came up when discussing challenges. This dependency underscores the significant power disparity between admins, who wield ultimate authority, and moderators, who possess lesser status and authority. Moderators feel compelled to engage with admins frequently to ensure the growth and safety of their community despite many of the challenges they face being a result of admin actions. Yet, we observed moderators seldom receive reasonable responses or support, if any, from the admin. We encourage future work to explore the power dynamics of such relationships as they vary across platforms with different moderation structures and approaches, especially given that power relations of this sort are particularly likely to harm marginalized groups with less status and power, to begin with.

The relationship between moderators and admins may also be affected by the inconsistent role of admins in moderation. Massanari asserted, “There seems to be a deep reluctance on the part of the administrators to alienate any part of their audience, no matter how problematic, as it will mean less traffic and ultimately less revenue for Reddit [41]" after investigating the response of Reddit to a public case of non-consensual distribution of intimate images of a celebrity within the platform. Reddit administrators responded to the case by saying they: “feel it is necessary to maintain as neutral a platform as possible and to let the communities on Reddit be represented by the actions of the people who participate in them. [10]" Yet, we observed moderators perceived administrators actions as particularly untrustworthy and unfair for niche and marginalized communities. One possible avenue for future exploration could be clearly distinguishing between admins’ and moderators’ involvement and responsibilities in moderation. This would involve specifying the hierarchy of community moderation, identifying which parties are involved, outlining their duties, and establishing protocols for intervention. For instance, depicting the circumstances under which administrators would intervene and when they would defer to and respect community moderators judgment in matters of moderation.

Finally, in the midst of the tension between mods and admins, we noticed genuine appreciation from moderators when support was provided by admins and their recognition of moderators’ efforts. More attention from platforms and admins in publicly acknowledging moderators’ contributions, whether through shout-outs in newsletters, badges, or other forms of recognition, may help improve the admin-mod relationship.

5.2 Designing Against Adversarial Misuse

Table 1 summarizes the platform feature misuse moderators identified. The research team analyzed each type of feature misuse in terms of the abuse types it enabled (informed by our dataset) from Thomas et al.’s taxonomy of online hate and harassment [55]. Table 2’s left-hand seven columns summarize this analysis. Through an iterative process reviewing the coded segments for the ’feature misused for harassment’ code, two of the researchers arrived at eight capabilities enabled by the feature misuse. The same researchers annotated different types of feature misuse to determine whether or not they enabled any of the capabilities in our dataset, with the rest of the research team validating the annotations. The adversarial capabilities that emerged from the analysis include (1) amplifying harassment, (2) silencing/narrative control, and (3) making harassment more resilient to moderation (divided into six capabilities). Finally, based on our systematization and responding to Freed et al.’s call for frameworks to design against UI-bound adversaries [24] we articulate general lessons for designing less abusable features to guide designers of not just Reddit but all platforms.

5.2.1 Amplify Harassment

Some features empower potential adversaries to execute large-scale attacks or aid in escalating harassment. Crossposting enables attackers to share posts from one subreddit to another, expanding their reach to a broader, potentially hostile audience. This, in turn, can lead to instances of brigading and a heightened level of harassment directed at the original poster or the target subreddit. We have also observed malicious individuals establishing subreddits to orchestrate coordinated attacks against specific communities. Additionally, adversaries can generate unlimited alternative or throwaway accounts to intensify harassment directed at the target. Adversaries can follow targets, and whenever targets post, it appears in their feed, providing them easier and immediate access to the target’s posts to harass. Finally, post and comment history escalate harassment by enabling attackers to follow around the target and harass them everywhere they engage across Reddit. Beyond Reddit, adversaries can amplify harassment on any platform, allowing users to create radicalized communities without proper platform moderation.

5.2.2 Silence/Control Narrative

There are several methods commonly employed to stifle opposing voices on Reddit. One approach involves reporting the content as abusive and triggering platform tools like AEO to remove the content or suspend the poster’s account. Another widely used tactic is to downvote posts or comments, reducing their visibility to the audience. We have also observed adversaries employing a unique method to silence by creating offensive usernames and gilding specific comments. It forces

moderators to remove the comments entirely, as there's no way to remove only the offensive gild givers' names from the comments. Moderators have also discussed how adversaries misuse the block feature to disrupt a target's ability to participate on Reddit. For instance, if a user higher up in a comment thread blocks you on Reddit, you lose the ability to reply to any users below you, including those responding to your comment. Adversaries exploit this feature to lock out the target from the conversation. Moderators have also highlighted the consequences of such feature misuse in terms of controlling the narrative of a conversation. For example, someone can disseminate misinformation more effectively by silencing active Redditors who typically counter misinformation with factual information, taking advantage of the aforementioned features.

5.2.3 Making Abuse Harder to Moderate

Past work has viewed abuse from various lenses, such as vulnerability (e.g., of specific populations), design (e.g., nudging to reduce toxic behavior), human and cultural factors (e.g., the need for humans in the moderation loop), and prediction (e.g., automated detection of hate speech). We add another lens that has been little used to date: harassment as a *security problem*, wherein intelligent adversaries (harassers) misuse features to harass and to resist moderation. 13/16 of the misused features we identified could be used to make abuse more resistant to moderation. We argue for the value of this lens in borrowing existing design tools from technical security work—most fundamentally, the adversarial perspective-taking of the security mindset [48]—to inform the design of platform features hardened against adversarial misuse. The rightmost columns of Table 2 summarize the ways moderators in our dataset witnessed feature being misused to resist moderation of abusive behavior. The subsequent paragraphs elaborate on these ways. We then present a set of design themes to inform designers working to design or re-design platform features that are resistant to adversarial misuse by harassers resisting moderation.

Incapacitating Moderators: In this adversarial model, attacks directed against moderators can be viewed as incapacitating them by consuming their time, focus, or emotional energy or simply by getting their accounts banned. Feature abuse here includes spamming modmail, filling the modqueue with spurious reports to make it tedious to act on real ones, or trying to get moderators banned via false reporting. Any system that relies on volunteer or professional human moderation is potentially vulnerable to similar denial-of-service attacks. Beyond Reddit, a variety of types of features might be misused to this end, such as direct messaging inboxes, notifications, moderation queues, and any kind of automated or user-report driven moderation system that might be adversarially redirected towards spuriously banning moderators.

Non-Standard Delivery Mechanisms for Toxic Content: Harassers embedded toxic content in "non-standard" locations or fields, such as usernames or flairs, or delivered it to targets in "non-standard" ways, such as by following a target or gilding their messages to their insulting username in notifications or alongside targets' posts. These "non-standard" approaches contrast "standard" approaches, such as posting, commenting, or private messaging. Furthermore, malicious users misused their ability to edit content by including offensive language after the moderators approve their innocuous posts. Such non-standard mechanisms may make moderation more difficult for a variety of reasons, including a lack of first- or third-party tooling for efficiently viewing and moderating such complaints or a lack of platform moderation features for reporting such content (e.g., one moderator complained about the fact that there is no option to report users for having hateful usernames). Beyond Reddit, such non-standard delivery mechanisms might exist anywhere users can embed content (e.g., profiles, tags, customized URLs, profile pictures, emoji reactions, etc.) and anywhere they are able to cause content they control to be shown to targets or audiences (e.g., notifications, replies, re-blogging, profiles, etc.).

Hiding Content from Moderators and/or Admin: Moderators discussed a variety of ways in which harassers misused features in order to hide toxic content or evidence of harassment from moderators and admins, including editing a toxic post to be innocuous (or deleting it) after the target has seen the toxic content, sending toxic content via direct message, cross-posting a target's post to a trolling subreddit or creating a subreddit to harass a particular subreddit and it's users. In many cases, these misuses rely specifically on features of the platform that may be described as privacy features, such as the fact that the history of edited or deleted posts are not preserved, inducing challenging tensions for designers.

Hiding Content from the Target: In this attack, the content is hidden not from mods or a broader audience, but from the target themself. The harasser posts a toxic comment replying to the target, then immediately blocks them, making their comment invisible to the target and preventing them from responding. Mods noted that this attack not only prevents the target from responding to toxicity, but also portrays them to others as unable or unwilling to do so. They also noted the potential to create a seeming "consensus" about misinformation or toxic beliefs by preventing those most likely to debunk or combat those ideas from responding. Blocking is an archetypical privacy feature, and the design of Reddit's blocking feature is natural and expected, yet this attack is a striking example how protective features can be leveraged by clever attackers. Beyond Reddit, any feature that allows users to control the visibility of content, such as private posts or accounts, circles, visibility settings, and more may implicate this type of attack. One example can be seen on Twitter, where quote retweeting from a private account has come to be widely associated with toxic or harassing behavior [28].

Hide Attacker Identity: Two features enabled harassers to hide their identities more easily: the deletion of posts/comments/accounts and Reddit's liberal policy with

Misused Features	Types of Abuse from [55]							Adversarial Capabilities (this paper)							
										Resilience Against Moderation					
Community engagement: Ability to create, or engage with community. *Mod/Admin Engagement:* Ability to interact with Mod/Admin. *Privacy control:* Ability to control one's privacy, including controlling the persistence of as well as others' experience of one's content and account. *Tracking:* Ability to track or learn aboutsomeone else's activity. Table 2: Taxonomy of platform feature misuse for hate and harassment. The categorization on the left-most column depicts the primary purpose for which the users used these features in the context of our dataset. A ✓indicates the feature being exploited to conduct an attack, amplify harassment, silence the target, or develop resistance against moderation in our dataset.

alt/throwaway accounts to keep anonymity and avoid association with the primary account. To make matters worse, when a malicious user deletes their (alt/throwaway) account, the harassing posts and comments published from that account persist and are not automatically removed. More than our other categories of moderation resistance, this one induces difficult tradeoffs, given the particular value of privacy and anonymity, as discussed in Section 4.2. Beyond Reddit, any features that allow anonymous, pseudonymous, or multiple-username participation such as guest posting, allowing multiple accounts, or the ability to change usernames or other account details might raise similar challenges.

Platform Incentives: Above, we discussed gilding from accounts with toxic usernames as a non-standard delivery mechanism. Some mods saw this as effective not only because it is non-standard, but also because gilding is one of Reddit's revenue streams. They hypothesized pessimistically that monetary incentives would make the platform less likely to take action against accounts that spend money on gold, even for hostile purposes. Whether or not it changes Reddit's behavior, this certainly reduced trust in the platform by moderators. Given the importance of the relationship between mods and the platform shown in our results, such loss of trust has serious implications for user safety. Beyond Reddit, any feature perceived by users as creating incentives for the platform, including direct revenue streams (e.g., advertising, Important Blue Internet Checkmarks, API fees, premium subscriptions, etc.) or indirect ones that support revenue (e.g., anything that

increases engagement) may implicate such concerns.

5.2.4 Designing Platform Features to Resist Misuse

Our results show that many of the toughest challenges moderators face result from the misuse of features, and we have characterized above the particular ways that feature misuse works to enhance toxic behavior by amplifying its effects, silencing targets/controlling the narrative, and by hardening it against moderation in a variety of ways.

Freed et al. called for HCI researchers to create design frameworks for resisting UI-bound adversaries by adopting the abusers viewpoint to identify avenues for abuse [24]. Expanding their notion of UI-bound adversaries outside of the space of intimate partner violence, we take up their call to ask: how can we design platform features that "limit systems' abusability... while maintaining, or minimally impacting legitimate user experience" [24]. In analyzing the properties of feature misuse described above, we have derived four themes that can inform designers working towards this goal.

The Security Mindset: Popularized by security writer and cryptographer Bruce Schneier, the security mindset is a common attitude towards systems and their design that is broadly valued among technical security practitioners. Just as Freed suggests taking on the abuser's viewpoint, the security mindset emphasizing thinking like an attacker to reveal unexpected uses of a system or its features and enable their design or re-design into a less abusable form. We argue that this mindset is a perfect fit for hardening the features of online platforms like Reddit against misuse by harassers. Though issues of hate & harassment are often thought of under headings such as "Trust & Safety", they can be viewed, like technical security challenges, as potentially adversarial situations. Thinking of harassers as adversaries is not the only way to view them, and we are not arguing against past work that rightfully believes that toxic users are not inherently toxic and deploys techniques such as nudging to encourage better behavior [9, 40]. But the evidence from our results suggests that harassers frequently misuse features in ways that are explicitly adversarial, in that they intelligently attempt to make moderators' jobs more difficult, more burdensome, or subject to catch-22 tradeoffs. Though our taxonomy includes only the attacks and adversarial capabilities of features discussed by the moderators in our dataset, it is also important to consider how the exploitation of various features in combination gives an attacker even greater adversarial capability. For instance, an attacker might create multiple throwaway accounts with offensive usernames and harass the target by commenting on their post and following them. It forces the target to triage numerous notifications or comments, hindering their ability to engage fully online while also subjecting them to harassing content. We suggest that platforms would benefit from incorporating security mindset at all phases of the design process to identify and mitigate opportunities for adversarial misuse. As our results show, a good existing platforms might learn much from their users and, especially, their moderators, who are intimately familiar with misuse and could guide designers toward opportunities to harden the platform against them.

Tooling and Attack Surface: Attackers often used non-standard locations and methods to deliver toxicity. Just as database or web security practitioners consider every user-controlled value as potentially adversarial, we argue that designers should view any user-controlled data or actions as potential vectors for toxic behavior or its enhancement. Moderation tools should handle toxic usernames, profile pictures, gilding, or follows as easily as they handle "standard" vectors like posts and comments. And designers should include this full attack surface in security mindset analyses to identify potential challenges to moderation.

Trust: Much as conflict of interest rules require agents to mitigate not only actual conflicts of interest but also the appearance of them, platforms should be wary of losing user and moderator trust in situations where the platform's incentives appear to align against users. The unusual attack we identified—in which users create accounts with toxic usernames and then pay Reddit to attach those toxic usernames to targets' posts—are a striking example of this idea. Though Reddit may not show deference to paying harassers, moderators warily noted the obvious financial incentives. Platforms should watch for the ways that their incentives appear to users and moderators as they design their features and profit models, since the lost of trust in platforms could be a major problem for their ability to combat hate and harassment. Our results illustrate this by showing the importance of the relationship between admins and mods in supporting community safety.

Policy: Platform policy can be examined through these lenses and using the security mindset. For example, Reddit's liberal policy around alt accounts, as well as their privacy-preserving choice to discard edit history for posts, can be misused. As with technical features, misuse doesn't mean that a policy is wrong—these policies have broadly understood and proven benefits for legitimate users. However, as moderators suggest in their discussions of the nuances of such policies, exploring the design space of such policies holds great opportunities for mitigating misuse while retaining or even enhancing opportunities for legitimate benefits.

6 Conclusion

By exploring the challenges moderators face combating online hate and harassment, this paper revealed intricate power dynamics between moderators and platform administrators that complicate moderation; systematized ways that adversarial users can carry out attacks by misusing platform features without privileged access; and proposed a set of design themes for designing interfaces, incentive models, and platform policies using the security mindset to limit the potential for feature misuse while retaining functionality.

A Appendix

A.1 Final Codebook

Code	Definitions	Example Quotation
Lack of clarity on Platform rules	Lack of clarity on where reddit stands on rules in a particular situation.	*"I'm unsure if this is the forum to discuss this, but are license plates a piece of personal information? I know that some subs are more serious about it than others. Some have no restrictions against it. Is there a Reddit platform policy on this?"*
Lack of transparency of platform decision/action	Lack of transparency of how the platform or admins makes internal decision.	*"Recently, I received a permanent ban for "harassment" without any specific details provided, such as a link to the alleged offense or information on the recipient. Fortunately, the ban was overturned upon appeal. However, it was challenging to mount an appeal without knowing what I did wrong."*
Lack of clarity on platform tools/features	Lack of clarity on how the platform's tool/feature works.	*"I recently tested using an alternate account and was surprised to find that when you ban someone, they just can't post or comment. They can still access the subreddit, report content, award gold, and other god-knows-what."*
Lack of guidelines on reporting offenses	lack of clear guidelines on how to effectively record and report offenses and harassment.	*"When an individual submits 50 reports within a ten-minute timeframe, how should we notify the admins? Should we file a single report? Or should we report each instance separately?"*
Lack of clarity on third party tool	Lack of clarity of how a third party tool works.	*" I want to understand whether Safestbot bans people with activity on certain subs or if it bans those people with activity on my sub and the selected sub? Thank you."*
Lack of Mod safety guidelines	Lack of guidance for moderators in place to ensure their safety.	*"I used the same account for moderation and using Reddit. I shared artwork with my name on it. It did not occur to me that somebody might get hostile toward me for banning them. Dumb! "*
Lack of notification on feature/policy change	Poor communication from Reddit about new rules/tool/policy or updates of rules/tools/policy	*Reddit has obviously changed what they consider 'harassment'. Can mods get a clear definition on this and why there was a shift?*
Lack of tool/feature	The current tool or feature does not support needs. There is a need for additional or upgraded tools.	*"The current report form for hate based on identity or vulnerability lacks a text field for providing an explanation, unlike many other report categories. Consequently, it relies on the administrators' familiarity with all forms of hateful rhetoric."*
Issues with inconsistent/inaccurate AEO/Reddit/admin action	Moderators sharing challenges regarding inconsistent/inaccurate action from Reddit/AEO/Admin	*"The AEO/Admin team seems to turn a blind eye when users engage in doxxing against moderators, and they persistently misuse Google Translate to misconstrue harmless jokes and posts from our users as genuine threats or harassment, disregarding the context."*
Issues with lack of Reddit/admin response/action	Moderators sharing challenges regarding lack of response and actions from Reddit/AEO/Admin.	*"A close friend was a moderator and has endured persistent harassment for more than a year. Despite making numerous attempts to seek assistance from the admins, they never provided any help. Eventually, he reached a point of frustration and decided to leave Reddit altogether."*
Lack of/complexity of external support	Challenges with receiving support from external resources like police.	*"To file a police report, activities must constitute a "direct threat," and actions like stalking and doxxing alone do not meet this criterion. The individual in question does not know my whereabouts and has not explicitly threatened to engage in any illegal activities.*
Feature misused for harassment	The platforms features are being misused for harassment.	*"After investigating, we believe 2-3 former members of our sub are chronically downvoting. Now the majority of the posts on our subreddit's main page have no upvotes or negative karma, and someone pointed out that that it portrays the subreddit in a negative light."*
Harassment towards moderator	Moderators are receiving harassment and hate on Reddit either internally or harassment that escalates to other platforms.	*"We were recently bombarded by a single user who sent us the same harassing Modmail 30 times within a minute."*
Community Harassment	Harassment taking place in a subreddit that is affecting the whole subreddit, perpetrated by a group or individual (e.g., Massive downvoting, crossposting for the purpose of harassment, etc.)	*"Someone hacked our Discord server and misused moderator privileges through another alternate account within our subreddit, resulting in our community being temporarily shut down for a few days."*
Complex tradeoff	Moderators are in a situation where they have to compromise and make one choice, resulting in losing something, usually forgoing a benefit or opportunity.	*"C1: What purpose does a reporting system serve if it protects trolls (by hiding the name of reporters who abuse the report feature)? C2: What would be the point of having a reporting system if moderators could retaliate against those who use it?"*
Increase of Hate and Harassment during a special event	Moderators face and have to manage more hate and harassment-related attacks during special events such as Pride Month, voting, etc.	*"I mod of r/<redacted>, whenever something significant occurs, such as shootings or elections or something local, the situation often spirals out of control."*
Burn out	Moderators discussed being burned out and having to overextend their time and energy to manage community safety.	*"We've had moderators who resigned from their positions because it was adversely affecting their mental well-being and personal lives."*
Lack of options to share resources	The community members are unable to share resources with each other that could help the community.	*"Unfortunately, the document originates from a private subreddit, so I can't create an archive of the page. I'll attempt to contact one of the moderators to inquire if they're willing to authorize sharing any details from the post."*
Community norms	Moderators face challenges in creating and enforcing community standards, onboarding new mods, and dealing with internal issues.	*"The theme of my subreddit attracts nazis and those who perpetuate racism and transphobia. I edited our sidebar to reflect this message, I issued numerous bans, and I began soliciting mod applications so that we would have more help dispelling this type of behavior. Yet, I doubt that addressing this issue through bans will actually solve anything."*
Admin response	Admin's response to a thread.	*"We acknowledge that Pride month may attract increased trolling and harassment directed at LGBTQ users, moderators, and communities. Consequently, we are closely monitoring r/ModSupport write-ins pertaining to these issues, recognizing the severity of such harassment."*
Automod response	Automoderator's response to a thread.	*"It looks like you're asking about brigading. Brigading is when a group of users, generally outsiders to the targeted subreddit, "invade" a specific subreddit and flood it with posts, comments or downvotes, in order to troll, manipulate, or interfere with the targeted community. Your subreddit could be flooded by spam posts."*
Abusive moderator	Conversations about a moderator's abuse of power or someone citing a moderator as abusive.	*"Moderator from another subreddit is excessively utilizing the report function to spam, false accusations and is encouraging others to raid my subreddit."*

Abstract

As many as 8 in 10 adults share intimate content such as nude or lewd images. Sharing such content has significant benefits for relationship intimacy and body image, and can offer employment. However, stigmatizing attitudes and a lack of technological mitigations put those sharing such content at risk of sexual violence. An estimated 1 in 3 people have been subjected to image-based sexual abuse (IBSA), a spectrum of violence that includes the nonconsensual distribution or threat of distribution of consensually-created intimate content (also called NDII). In this work, we conducted a rigorous empirical interview study of 52 European creators of intimate content to examine the threats they face and how they defend against them, situated in the context of their different use cases for intimate content sharing and their choice of technologies for storing and sharing such content. Synthesizing our results with the limited body of prior work on technological prevention of NDII, we offer concrete next steps for both platforms and security & privacy researchers to work toward safer intimate content sharing through proactive protection.

Content Warning: *This work discusses sexual violence, specifically, the harms of image-based sexual abuse (particularly in Sections 2 and 6).*

1 Introduction

Sharing intimate content[1] is a common practice. While prevalence is difficult to measure, estimates suggest that as many as 8 in every 10 adults share intimate content [26, 76, 81]. Sharing intimate content can benefit relationship intimacy [6, 32, 51, 55, 76, 84], body positivity [10, 26, 37, 84], and offer employment [37, 70, 72].

Societal norms and a lack of technological mitigations put people at risk of experiencing sexual violence when they share intimate content. Image-based sexual abuse (IBSA) encompasses a spectrum of violence, including (1) the nonconsensual distribution of consensually-created intimate content (NDII) [67] and the threat of NDII, (2) the nonconsensual creation of intimate imagery (e.g., via hidden cameras, "upskirting," extortion, or AI) [25, 43, 53, 58], and (3) the unsolicited sharing of intimate content [5, 24]. Studies estimate that one-third of individuals have been subjected to IBSA [63] (similar to rates of other types of sexual violence [13]). However, it is difficult to accurately estimate prevalence, as victim-survivors[2] face significant stigma in reporting experiences and may not always be aware that content has been created or shared without their consent [43].

We answer calls from prior work [32, 42–44, 59, 84] to **focus specifically on proactive technological mitigation of NDII**, leaving nonconsensual creation of images and post-harm mitigation as inquiries for future work. Through a qualitative interview study with 52 Europeans adults who share intimate images for recreational (sexters) and commercial (sex workers) purposes we investigate the following as they relate to intimate content sharing:

- *Contexts* (Section 5), which include group and 1:1 sharing with recipients that the sharer has an established relationship, a casual relationship, no relationship (strangers), and/or a commercial relationship.
- *Threats* (Section 6) such as recipient resharing (NDII) and non-recipient threats such as data breaches & hacking, and unintentional discovery.
- *Technologies* used to share intimate content (Section 7) and how the contexts, threats, and other considerations we identify influence participant use of 40+ technologies including messaging platforms, social media, dating apps, fileshare platforms, email, and adult content platforms.
- *Defensive strategies* against the threats we identify (Section 8), including detailed inquiry into the role of existing safety and security features.

[1] We define intimate content as images that: show a nude or semi-nude subject, contain intimate body parts, and/or intend to arouse. Throughout the text of this paper, we use the term *images* to refer to photos and videos.

[2] We use the terminology victim-survivor to capture the range of ways in which people who have experienced IBSA may identify [43, 75, 90].

We conclude in Section 9 by synthesizing the results of our study with the state of the art to offer a set of concrete recommendations to platforms and S&P researchers on next steps to prevent NDII.

2 Related Work

We summarize work related to the focus of our study: consensual *and* nonconsensual distribution of intimate content.

Technology & Intimate Content. Work exploring this topic from a technological viewpoint is scarce [44]. Notably, Geeng et al. surveyed 247 U.S. adults quantifying their general sexting practices and security concerns [32]. Respondents' sexting concerns included regret after sharing content, unwanted sexual content, NDII, and data breaches. The authors found that their respondents managed their concerns by selecting platforms based on availability of specific features (e.g., expiring messages). Additionally, they found evidence of behavioral strategies used to fill in the gaps left by platforms: respondents reported limiting what they share depending on the recipient and establishing rules with recipients.

Relatedly, Waldman studied the behavioral mitigation strategies used by "917 mostly gay male and bisexual users of geosocial dating apps" and found that participants faced an implicit expectation to share intimate content in participating on the apps [84]. To mitigate risks, participants would delay sending images, avoid identifying features from photos, or select photos that they would be less embarrassed by in case of NDII. Finally, examining trust in platform features that accommodate sexting use cases, Roesner et al. found that despite media focus on Snapchat's expiring messages feature for sexting, less than 2% of their survey respondents used Snapchat primarily for sexting and fewer than 15% used the app for sexting at all [64] because they did not trust Snapchat nor its security practices and features.

We expand on these works, which provide a quantitative analysis of people's sexting practices and concerns, by using qualitative methods to focus on *how* people use specific strategies to defend against NDII-related threats and *why* and what gaps remain between their threat models and the defensive strategies available to them. In so doing, we answer Geeng et al.'s call for future work to "identify—and bridge—any gaps between the threat models [that platforms] securely support and the threat models important to individuals engaging in sexting" by systematically studying the "technological properties" offered by platforms; we additionally answer the call of criminology scholarship on NDII to specifically use qualitative methods to understand use of and potential for technological mitigation in this complex and nuanced space [42].

Lastly, multiple works have explored user perceptions of security in messaging apps (often used for sharing intimate content) [1–3, 23, 40, 61, 85]. They found that users had large misconceptions from inconsistencies in (or lack of) information on end-to-end encryption (E2EE). In lieu of reliable information, users may turn to folk theories to inform their decision-making [88] and develop a false sense of security or blanket mistrust. Our findings are consistent with these results and we expand on this literature by including user perceptions of secure messaging in this context.

Harms of IBSA. Existing literature on NDII is scarce. Thus, we include related work on both NDII and IBSA more broadly, with the understanding that NDII is a subcategory of IBSA.

IBSA is a wrong in and of itself: "regardless of the nature and extent of any further consequential harm...[IBSA] constitutes [a] breach of an individual's 'fundamental rights to dignity and privacy, as well as their freedom of sexual expression and autonomy'" [57]. In the largest qualitative study of IBSA victim-surivivors to date ($n = 75$), McGlynn et al. describe IBSA as "torture for the soul," specifically noting the devastating disruption to participants' lives, work, and selves as well as the permanence and "endlessness" of the abuse and its impacts [57].

Beyond the wrong of IBSA alone, victim-survivors can experience harmful mental health consequences ranging from high levels of stress to suicidal thoughts and diagnoses of post-traumatic stress disorder, depression, and anxiety [8, 24, 45]. IBSA victim-survivors are often subjected to further harms as they navigate the post-IBSA landscape by seeking justice, advice, legal assistance, and mental health support. A survey among 6,109 individuals from New Zealand, Australia, and the UK found that one-third of respondents expressed "victim-blaming sentiments," defined as attributing blame towards victims and suggesting that they are at least partially responsible if an intimate image ends up online [27]. Victim-blaming has been associated with poorer outcomes for victim-survivors, acting as a barrier for reporting and help-seeking, worsening victim-survivors' already-impacted mental health [60] [62]. Accordingly, approximately 73% of IBSA victim-survivors choose not to report out of fear or embarrassment [66].

Focusing on norms around perpetration, Hasinoff and Shepherd [39] explored young adults' privacy norms related to sharing intimate images they receive, finding that while "nearly all the respondents view maintaining privacy when sexting as an expected social norm," some felt it was acceptable to show intimate content they had received to others in person. Prior work finds that there is no one dominant motivation for IBSA perpetration; indeed perpetrators are often motivated to share by a desire to achieve social status – with intimate images serving as a "social currency" – rather than an intent toward revenge[3] against a particular individual [24, 43].

Literature on other digitally-mediated harms has identified NDII as a significant threat [79]. Prior work that addresses tech-facilitated intimate partner violence found that NDII was a common threat faced by victim-survivors [28]. A study on

[3] We note that, while this is commonly referred to as "revenge porn" this term is not preferred by victim-survivors, activists, or researchers of IBSA [52].

digital abuse in South Asia found that women censor their presence on social media to avoid synthetic creation of intimate images using their likeness [68]. Online harassment research finds that IBSA (and NDII) are growing concerns globally [73]. Prior work also illustrates how attackers exploit NDII to attack others [46].

Sex Work and IBSA. Sex workers are generally omitted from the discussion about IBSA, even though a large volume of intimate content is shared for commercial purposes. Waring describes sex workers as missing from IBSA-related literature due to academia, the law,[4] and even sex workers themselves regarding sex workers (like other victim-survivors) as at fault for uploading their own sexual imagery [87].

In mixed-methods studies of commercial content creators who experienced IBSA, Sanders et al. and Redman and Waring found that participants were significantly affected when nonconsensually shared content reached those they had hidden their sex work status from, outing them and putting them at financial and personal risk [70, 72]. Clients or strangers weaponized this by threatening to share their content. Participants feared de-platforming when contacting platforms for assistance and reported a lack of response when they did so. Hamilton et al. describe how the COVID-19 pandemic increased sex workers' digital exposure, including the volume of intimate content they share [36]. Redman and Waring directly connect this with an increase in IBSA against sex workers. In separate work, Hamilton et al. document the growth in commercial content creation as a result of the pandemic and the mainstreaming of the OnlyFans platform [37], underscoring the importance of studying both commercial and recreational sharers of intimate content, as we do in this work.

Legal Perspectives. More laws are being introduced globally to address NDII [20, 33, 48, 78, 82]. While legislation is an important avenue for justice and changing societal perceptions [15], legal scholars have described its many limitations. Legislation may evolve too slowly to keep up with ever changing digital threats or be too narrow to address international platforms [15]. Litigation is expensive and victim-survivors may not know who perpetrated the abuse, may fear retaliation, may not want to be in a courtroom with their abuser, or may not want to reveal their personal information to courts [14]. As a result, it is critical to explore interventions on the technological side, especially those that platforms can implement [42, 59].

3 Methodology

We conducted 52 semi-structured interviews (August-November 2022) with adults (over 18 years old) living in European countries [92] who had consensually shared intimate content in the past year: 24 with sex workers who produced their own digital content and 28 with those who shared for noncommercial purposes. 42% of all participants were victim-survivors of IBSA (predominantly NDII).[5]

Recruitment. We recruited participants through convenience sampling via social media, relevant community organizations and personal contacts. To recruit recreational sexters, two authors posted a recruitment graphic to their social media accounts. To recruit sex workers, we used a similar but sex-work specific graphic (see Appendix B.1). We contacted sex worker rights organizations to share it and the graphic was also posted in sex-worker only social media groups. The graphics included sign-up links that led to a Qualtrics survey that screened out individuals who are younger than 18 years old, had not sent intimate content in the past year, and/or were not living in a European country. At the end of the screening survey, eligible participants were asked to review and sign a consent form for the interview study. We interviewed participants until we reached saturation for each group: recreational non-victim-survivors, recreational victim-survivors, commercial non-victim-survivors, commercial victim-survivors. To capture different perspectives, participants were asked questions related to various dimensions of diversity in the screening survey (see Section 3.1). Participants were compensated €50 (or equivalent amount) through PayPal or Amazon giftcard.

Interview Data Collection. Four of the authors conducted the semi-structured interviews. Sex-working participants were asked about their commercial *and* recreational content, if applicable. The interview protocols included several topics related to sharing intimate content (see Appendix B.3). We asked about the contexts in which participants shared intimate content (e.g., with whom, their motivations) and the technologies they used for storing and sharing intimate content. We then asked questions on how they navigate trust with recipients, security and safety concerns, and their proactive practices. Based on existing literature and media advice on sharing intimate content discussed in Section 2, we selected a set of features that we explicitly asked about (listed in Appendix B.3). Lastly, we asked participants to imagine potential futures [38] for design changes and proposals for better technologies for intimate content. Although we asked victim-survivors about their experiences with NDII, the **focus of this work is on proactive mitigation**. We will analyze post-harm mitigation in follow-up work.

Analysis. We followed an open coding analysis process. We randomly selected 4 interviews (2 commercial, 2 recreational) that three authors independently coded. They each created a codebook of main themes based on these interviews. Four of the authors (including the coders) then met to create the codebook. As part of this process, we grouped smaller codes into larger themes. The coders then each randomly selected 4 interviews to code using the developed codebook. They reached

[4] In England and Wales, for example, when content has been consensually uploaded online it ceases to be actionable as an offense if misused [70].

[5] One participant had experienced the nonconsensual *creation* of intimate content.

"substantial" intercoder agreement (alpha= 0.72) as measured by Krippendorf's Alpha [50] and met to resolve any disagreements. They collectively finalized the codebook and then divided and independently coded the transcripts. Throughout the paper we provide a relative sense of the frequency of the themes we coded (e.g., that a theme was mentioned by half of participants) but emphasize the importance of not reducing "sensitivity to complex concepts and nuances in data" by viewing these data through a quantitative lens [56].

Ethics. This work was approved by our institution's ethics review board. We took great care to protect the privacy of participants, which we detail in Appendix B.2. Since 42% of the participants had experienced NDII, we warned all participants that discussing their experiences may be triggering and phrased questions to avoid re-traumatization. To ensure both participant and researcher protection, our team includes a clinical psychologist who reviewed the interview protocols, analyzed data, and supported the research team. We additionally asked our partner organization, the European Sex Workers Rights Alliance (ESWA), and a victim-survivor of NDII for feedback on the protocol. We followed trauma-informed best practices set forth by sexual violence researchers [12] that minimize risk to participants and center victim-survivors' choice, well-being, empowerment, and autonomy. Team members were trained in response techniques by a licensed clinical psychologist who specializes in sexual assault and trauma (e.g., offering to pause/stop the interview) and were prepared with resources (e.g., hotline information) to offer participants if needed. We note that sharing these experiences may also be a form of empowerment for victim-survivors [35].

Impacts and Research Justice. The interviews were transcribed by a sex worker (trained in transcription and compensated) as part of a research justice commitment to materially support communities we study. We published a white paper of this work through ESWA. We will share published research with participants who requested it and plan to develop a resource guide based on this work. In addition, we have been using these findings to advocate for platform changes and policies that may mitigate IBSA. We translated design recommendations from our participants into wireframes that we have presented to relevant platform product teams. We have also presented findings from this research to policymakers in the European Union, the United States, and Australia. Our partner organization, ESWA, has been using the white paper to conduct workshops on IBSA.

Positionality. This work was conducted by a team of researchers who collectively are scholars of technology, sex work, and sexual violence. This research focuses on adults living in Europe but only half of the research team is based in Europe. Given the diversity of our participants, our team does not completely reflect all of the genders, ethnicities, and sexual orientations of our participants. Therefore, there may have been some limitations in our interpretations of the data.

Limitations. Since we conducted interviews in English and it is not the primary language in many European countries, this may have limited or skewed participation to those in countries where English is more prevalent and/or to those who are more educated, who tend to have studied English. Although we reassured participants that we were interested in understanding their perspectives to advocate for safer technologies for intimate content and took care to phrase questions non-judgmentally, the existing stigma of sharing intimate content may have prevented participants from fully disclosing their behaviors. Since there was a set of features we specifically asked participants about (Appendix B.3), there may be more data on these features; however, each feature in this list was also independently mentioned by participants.

Participant Labeling. We intentionally did not distinguish between quotes from different participant groups and labeled all participants "P#." Given the stigmatization of sex work, we did not want quotes from sex workers to be dismissed or to be attributed as only relevant toward sex work (and we also asked sex workers about how they share intimate content in their personal lives). In general, there were many commonalities in the narratives shared across all participant groups and we offer Section 8.4 for comparisons between them.

Platform Blinding. With the exception of a few quotes, we replaced specific platforms with the type of platform mentioned in italics. A quote that says, "I use WhatsApp" would be replaced as, "I use [*messaging app*]." This is to draw focus away from specific platforms and emphasize that *intimate content is likely being shared across any and all platforms that enable the storing and/or sharing of images or videos.*

3.1 Demographics

When recruiting participants, we considered diversity across different dimensions. We present summaries of participant responses to various pre-interview survey questions below.

Geography. Participants resided in 14 countries: Belgium, France, Germany, Greece, Ireland, Latvia, North Macedonia, Norway, Poland, Portugal, Serbia, Spain, The Netherlands, and the United Kingdom.

Race. Participants were given the option to self-describe their race through text-entry. The majority of participants (65%) identified as Caucasian/White (e.g., "Caucasian," "White, Russian") including 2 mixed race individuals. Among those who did not (35%), 15 opted to self-describe their race: 3 participants identified as Black (e.g., "Black British," "Black African"), 3 identified as Latina/Latino/Latinx, 2 identified as mixed race, and 2 identified as "Brown" or "Southeast Asia, Brown." Other responses included "French-Moroccan," "...born in South America," "Eurasian."

Education. A majority (73%) of participants had completed a Bachelor's degree or higher education. 17% had completed

some college, 6% had completed high school (or equivalent), and 4% did not finish high school.

Disability. 56% of participants responded that they had a disability (physical, mental health, or neurodivergence) while 35% did not (10% did not answer).

Age. Participants spanned the birth years of 2000 to 1976 with a median birth year of 1994 (roughly 28 years old at time of interview).

Gender & Sexuality. Participants were asked to optionally self-describe their gender and sexual orientation. To present summary statistics, we categorized the free-form text responses we received. These categories therefore represent a close approximation for some responses and do not capture the full richness of responses.

How would you describe your sexual orientation?	%
Asexual/Bisexual/Gay/Lesbian/Pansexual/Queer	71%
Heterosexual	21%
Prefer Not to Answer	10%
How would you describe your gender?	**%**
Cis or Trans Woman	27%
Cis or Trans Man	38%
Non-Binary, Gender Fluid, Agender	19%
Prefer Not to Answer	13%
Other	2%

4 Summary of Findings

We conducted an interview study with 52 people in Europe who share intimate content (24 sex workers, 28 recreational sharers), 42% of whom were victim-survivors of IBSA. Our participants used 40+ technologies to share intimate content. They relied on a combination of heuristics to choose technologies for sharing but nearly half chose to use their default method of communication. Participants' threat models around NDII were focused on a recipient resharing their content but they were also concerned about data breaches, hacking, and unintentional content discovery. Echoing prior research, all emphasized that stigma exacerbated these threats. To protect themselves, participants implemented a maze of safety strategies that included technical features (e.g., expiring messages) and interpersonal strategies (e.g., setting rules). In sections 5 through 8, we detail sharing contexts, threat models, how participants chose technologies for sharing content, and defensive strategies. In Section 9, we include narratives on how technology could be improved to support digital intimacy/reduce NDII alongside recommendations for platforms and researchers.

5 Sharing Contexts

Our participants shared intimate content across a wide range of use cases that we describe to contextualize their threat models and defensive strategies. Participants shared **one-on-one** with a specific person and with **groups** of individuals in all of the contexts detailed below. The same individual may have multiple sharing contexts:

> "I've shared them with a lot of people. I've shared them with romantic partners, I've sent them to strangers on the internet, like, on [*social media*], I sometimes this search for people looking for [intimate content], and then just send them" (P3).

Established relationship. A vast majority of participants shared intimate content in the context of an established relationship (e.g., spouse, long-term client). In line with literature [19,51], participants frequently mentioned the importance of intimate content as a form of connecting with their partners, "intimate content is to keep a connection alive, it's part of a couple's sex life" (P48). Around a quarter of participants also shared content with friends as a form of bonding. "I have been in text groups with like, female friends, and we've sent photos of our bodies to each other, just for fun, or like, hey, I'm feeling sexy today, or look at this great photo I took" (P18).

Casual relationship. Participants also shared intimate content with short-term sexual partners. Many participants described sharing intimate content with someone they met on a dating app as a means of initiating or maintaining a sexual relationship. "It's something that comes after a few basic questions that are asked in a regular [*dating app*] conversation" (P3). Some shared in group contexts as well, such as "very small groups where everyone was in sexual contact with each other" (P2).

Strangers. Individuals may also share intimate content with those they do not know and with whom they are not intending to initiate a relationship. For example, participants shared content mutually with strangers (e.g., in online communities) or in a one-directional sharing relationship, such as with a social media audience. Our recreational participants were motivated by a desire to connect with others, express themselves artistically, receive body validation or express body positivity [51, 84]. For example, P26 shared that, "Early [in] my transition, I had the need to just share some pictures [to] feel more sexy...I created an account *[on a social media platform]* especially for that, that [account] is networked with mostly other trans women that also have accounts for the exact same purpose."

Commercial. Sex workers in personal relationships shared in all of the contexts above. Additionally, their commercial sharing contexts closely mirrored the personal. They shared with: *established clients*; *casual clients*—one-off clients or "clients I do not trust (like new ones, or people I feel are asking

me for a little too much without being vetted yet)" (P33); and *unknown clients* such as those who bought their content from a subscription or clip site. Like the recreational users initiating hook-ups through dating apps, sex workers also shared content to verify themselves and entice further sales, whether of content or in-person services, like P37: "because I'm doing escorting, I do share images with clients, not for sale, just to check me out." Finally, there were commercially-specific contexts like multi-service adult platforms: "the one that I use, you can do live camming, and then you have your gallery of private pictures, and you set your price" (P35).

6 Threats

Participants were concerned about NDII across different contexts. Primarily, they feared that a recipient would re-share their content. Many also had additional concerns about non-recipient attackers via data breaches & hacking as well as unintentional discovery (e.g., via device sharing, device theft/loss, or shoulder surfing). Finally, participants noted a unifying mechanism of harm across these threats: stigma, which we discuss in further detail at the end of this section.

6.1 Recipient Resharing

Despite many participants expressing that they trusted their recipients, they reported having passive or background fears about their content being reshared. P31 described, "[in] that moment before [I] fall asleep, [I feel] like 'Oh, shit,' all of this is out there. [I] have a bit of a panic. But most of the time, I would say I feel relatively confident that if it does come out, I [will] deal with it in a way that I find suitable." Particularly for those who had experienced NDII previously, recipient re-sharing was a primary concern. A participant explained: "I don't think there's ever been a time where I share content and I don't think about the harm that can be caused" (P35). Participants also reported secondary concerns such as not knowing they had been victimized: "I know there are groups on Telegram and WhatsApp where people send porn. And then you don't have any control over it. Because if you're not part of these groups, you don't know they're there" (P9). In addition, P3 noted the concern of aggregator pages further proliferating nonconsensual content by reposting it. News articles and research on the existence of anonymous forums and messaging groups that are dedicated to nonconsensually sharing intimate content support these fears [9, 41, 74]. Participants also spoke about fears of an ex-partner sharing intimate content after a breakup: [6] "I asked him to delete all my intimate images and videos, but I don't know if he really did because we had a hard break up" (P14).

Only five participants explicitly stated that they were not concerned about recipient resharing and NDII in general. A small number also expressed resignation toward the threat. Many sex-working participants expressed this privacy fatalism, such as P42, who had been warned by peers: "my colleagues in this told me, that you have to be prepared that in some point in your career, your photos will be in free pages." P39 added, "it's something that I just accept." This sentiment was also shared by some recreational participants, particularly those who had shared material widely, with a large number of recipients or over a long period of time. P31 summarized this, saying, "my ideal expectation is, of course they won't share it. But my realistic expectation is that it might happen anyway." In some cases, this led participants to adopt additional safety practices such as P4 who frequently shared images with new recipients but, "I've been sending the same three pictures since eight years" or P24 who expressed that, "it's very delusional to think that people have good intentions only so I only send what [I'm] comfortable sending and never show my face." We discuss security practices further in Section 8.

6.2 Non-Recipient Threats

Data Breaches & Hacking. Although many participants described hacking as "a hypothetical background fear" (P11), more than a third were concerned about it as a means of accessing their stored intimate content. They brought up risks on their personal devices (e.g., viruses, phishing scams, and malware) and the risk of their intimate content being leaked through a data breach or poor security practices/policies of a platform they had used for sharing (e.g. how content is stored, protected, deleted). People feared both technical and policy breaches; exemplifying the latter, P10 "read stories of [employees] who have set up programs to find [images] of women shirtless."

6.2.1 Unintentional Discovery

Device/Account Sharing. Almost a third of participants were concerned about others accidentally discovering intimate content while device sharing or using shared accounts. For example, P22 commented, "I have cousins, my mom, my grandma [around me at home]...they can take my phone any time and browse [my photo] gallery." Similarly, P4 stores content on a file share platform and "sometimes I give [my parents] access to some of my [*file share*] folders... So I make sure all the folders are well separated from each other. But I am always thinking twice when I'm giving access."

Shoulder Surfing. About a sixth of participants worried about shoulder surfing: others accidentally viewing intimate content that is visible on a sender's or recipient's screen. As P11 put it, "have I been concerned that someone has accidentally seen a photo because I've sent it at the wrong time? 100%." P12 described taking proactive action to prevent shoulder-surfing: "I bump [an image] up [by sending text messages after the

[6] See [18] for an in-depth analysis on how people manage intimate content after experiencing a breakup.

image], so that it wouldn't necessarily be the first thing that comes up on a screen."

Device Theft or Loss. More than a sixth feared that someone could access stored intimate content if a device were stolen or lost. This was often coupled with concerns of weak password security: "someone like could crack my code and take my pictures" (P30). P51 experienced such an incident and described, "once my phone was stolen, containing a lot, a lot, a lot of personal images and data... I was like, 'Oh, my [gosh]. Oh, my [gosh]'." Additionally, P38 asked a recipient to delete any intimate content prior to bringing a phone in for repair—a concern confirmed by cases of intimate content theft by customer service and technical support employees who were given device access [17, 29, 30].

6.3 Mechanism of Harm: Stigma

IBSA can lead to many forms of harm (see Section 2) that stigma and victim blaming can perpetuate. Due to stigma, participants feared awkward or even dangerous situations with family, friends, their communities, and/or places of work and study. P18 worried about the reactions of their colleagues in the event of NDII: "I would like to think that it would be a non issue, and the focus will be on the person who was nonconsensually sharing images of me. But unfortunately, there is a lot of victim blaming."

Consistent with prior work [24, 43, 70, 86, 87], the concerns described tended to depend on participant identity. For LGBTQ and sex-working participants, the risk was magnified if they or their partner were not out, or their identity was a personal risk to them or their recipient(s). For example, P10 took more precautions because, "[My ex-partner] was from a quite conservative religious family... it's always better to play safe, especially when your partner is closeted." In the context of sex work, P49 explained: "I'm afraid that if I do more content... that someone from my family would see that... It's the most stressful thing for me," and as P35 described, "I have another [non sex work] job and I [get] really scared that I will no longer get work... [despite my] paranoia, there's nothing I can really do about it, because I have to still do [sex work]." Cultural norms also magnified risks: "Turkey is a very conservative and traditional country. My parents are open-minded but I don't think they could handle this" (P14).

In contrast, several cisgender men felt that they faced fewer threats[7]: "as someone who presents as male, I think I'm less at risk from exposure than someone who presents as anywhere else on the gender spectrum, because I think my image is less likely to be shared around maliciously" (P2). Some also felt that if sharing intimate content were less stigmatized in their specific social community, they may receive more support if NDII occurred (though they may still have concerns about the response of those outside of that community). P26 commented that due to shared politics, they trusted "people at my workplace to not let [nonconsenusally shared intimate content] have a negative influence."

[7]We note that men are disproportionately affected by sextortion, another form of IBSA, in which individuals are targeted by fake online personas to begin a relationship. Once intimate content is exchanged, the content is used as leverage for financial extortion [86].

7 Technologies

In total, participants mentioned using 40+ different platforms for sharing and storing intimate content. We categorized them in Table 1, which also includes the use cases people mentioned in relation to each category of sharing method and the number of different platforms that were mentioned per category. This leads us to emphasize that any platform that enables the storing and sharing of photo/video content is likely being used for intimate content. In addition, each participant commonly used multiple technologies as summarized by P12:

> "...I've got like Telegram, I've got Signal, I've got WhatsApp, I've got Kik, you name it, I've got it... if there's something really large, that requires Dropbox... I'll do that".

With the exception of 5 participants, nearly all stored intimate content locally in their mobile device photo gallery, laptop, or desktop computer. More than half intentionally stored their content in a cloud/file share platform. The vast majority used multiple forms of storage: "I have everything stored everywhere, I have it in my phone, I have it in my hard-drive. I have some parts on the cloud" (P42).

Participants decided to use technologies based on a variety of factors that we detail below. While we discuss each heuristic in isolation, most participants used several heuristics. For example, P17 explained: "Encryption and security would be...number one. Number two, that is...convenience."

Sharing Method	Sharing Use Case	# of Platforms
Messaging	1-1 conversation or with groups of recipients	9
Social Media	1-1 conversations (DMs), groups (posting or DMs), for marketing (commercial)	10
Adult content platforms	Posting content to platforms, livecamming	11
Dating / hookup apps	Sharing in-app intimate content, posting semi-nude/lewd photos in profile	10
Cloud/file share platforms	Storing and directly sharing content with recipients	4
Email	Sharing larger files and/or links to files, occasionally used as an alternative to primary sharing technology	N/A

Table 1: Categories of sharing methods, use cases, and the number of platforms mentioned per category.

7.1 Convenience

Around half of our participants shared intimate content using the same messaging service that they were already using to communicate with others. Since participants often shared intimate content in the middle of a conversation, they emphasized the importance of conversation *continuity*: "...it's like at the heat of the moment... so to [choose another method and] make it longer... it just doesn't make any sense" (P43). About a quarter also commented on the importance of *usability* and highlighted different affordances that they valued such as fast message delivery, desktop integration, clean user interfaces, and familiarity. Therefore, individuals that prioritize convenience must make do with any existing safety tools available on the platforms they use for sharing intimate content.

7.2 Security

Anonymity. Slightly less than a quarter of our participants sought *anonymity* from platforms and their recipients, particularly strangers, commonly as a means of protecting themselves from identification and other downstream harms in the event of recipient resharing (Section 6.1). When meeting someone new from a dating app, P12 used a specific messaging app because "you have a user name instead of it being connected to a phone number. [...] there's...a degree of arm's length-ness about it." Others, particularly sex workers, preferred platforms that allowed anonymity due to concerns about platforms that make account recommendations using contacts, common connections, or shared location.

Security Feature Availability. Around a sixth of participants highlighted the importance having specific features available to defend against recipient resharing, such as P4 who used an app because it "prevents you from taking screenshots... With people I don't know, and people... I have no trust in, I only send pictures through [this app]." The features participants sought are discussed in greater depth in Section 8.

Data Control. It was important for under a quarter of participants to have *data control and transparency* to prevent non-recipient threats (Section 6.2) such as data breaches and the unintentional discovery of intimate content. They wanted to ensure that their content was not sent to a server they were unaware of (P2), that an app did not share images within its own parent ecosystem (P6), or the ability to select images an app had access to (P19).

Context Separation. Three participants selected platforms to be exclusively used for intimate content to provide *context separation* and prevent unintentional discovery (Section 6.2.1). P1 explained: "I'm afraid that I [will] click the wrong person to send content...that's why I prefer to use *[messaging app]* which is an app that I don't use that much."

Reputation. The reputation of technologies influenced a fifth of participants. People leaned on folk models [88] of "secure" or "insecure" platforms to make choices. Some felt unsafe using certain platforms based on information they encountered about them, such as corporate data breaches [22], systems breaches [22], or general business practices like data sharing with third parties. A few were concerned that specific platforms had reputations tied to illicit behavior that would affect their recipients' perception of them. These "social triggers" [21] led them to choose other platforms. P2 and P18 shared that they preferred popular platforms vs. a less well-known E2EE app that is "marketed as being more secure" (P2) since they "don't know anybody that uses [*that E2EE app*] unless they're using it for scandalous activities" (P18). Conversely, others felt *safer* using a sharing method because of a reputation associated with privacy. P31 used the same platform P2 was hesitant about because: "the ethos of the company...I know that is about privacy." We further discuss participant preferences around E2EE in Section 8.3

7.3 Interpersonal

Number of Active Users. About a sixth of our participants preferred not to use less popular platforms because they did not have enough recipients on that platform, which inhibited the *convenience* of use. For example, P9 tried an app that they felt was safer but "I only had two people there. So I deleted it." This can hinder adoption of platforms that participants may prefer for security reasons, like offering E2EE.

Preference of Recipient. In the context of direct messaging, more than a quarter of participants were open to or deferred to (sometimes feeling like they had to) the technology preferred by their recipient. Particularly when the recipient prefers an app with specific safety features, some participants were willing to accommodate them. Sex-working participants more commonly expressed that they needed to use technologies that felt more secure and convenient to their clients and also because in some cases, "they're not willing [to] download like another app or like check another website" (P32).

7.4 Commercial

Finally, for around half of sex-working participants, profitability and hospitability to their work were key considerations.

Profitability. A third of sex-working participants emphasized the *profit potential* of a technology, such as a platform's ability to grow their client base, flexibility in setting rates (P20) and/or easy processes for receiving and transferring payments (P9, P24). Exemplifying the strong influence of profitability factors, P42 remarked, "I think [*adult content platform*] is the worst in everything... But I use it a lot because it's the one that has the most people."

Hospitability. A quarter of sex-working participants valued a *platform's hospitability toward sex work*. For some, it was important for a platform to be made by sex workers and/or

create an inclusive environment for queer people, such as P48 who found a platform "more comfortable" even though they thought it was complicated because, "...it's made by sex workers, [and] it's more like a gay, kinky, queer environment."

8 Safety Maze: How People Try to Defend

All participants adopted at least one strategy but many relied on multiple. Since many prioritized convenience and the preference of a recipient, most participants leveraged any technological features available in the sharing platform and fill in significant gaps in availability of desired features (see Section 9.1) with interpersonal behavioral strategies and third-party tools. In this section, we describe participant strategies based on the threats they sought to defend against.

8.1 Defending Against Recipient Resharing

To prevent recipients from resharing intimate content, participants employed strategies across the timeline from first establishing trust with a recipient to after content had been shared.

8.1.1 Before Sharing

Prior to sharing intimate content, participants used interpersonal strategies to establish trust, communicate boundaries, and vet recipients: "with somebody new, I wouldn't necessarily send them something sexy until we've been on a couple of dates... until I knew that we were on the same page about privacy" (P29). With more established relationships, they commonly held an implicit expectation that their intimate content would be kept private. When sharing with friends, P31 explained, "trust was so established that it didn't feel like you needed to say [not to reshare]." In other settings, participants employed additional strategies that we now discuss.

Vetting. Vetting a potential recipient of intimate content was described by over a third of participants, such as speaking to recipients for some period of time prior to sharing content to assess whether they felt safe: "I kind of establish a rapport and talk to people... [I'm looking for] just acknowledgement of the kind of precarity of the situation" (P12). A few participants relied on their intuition even without a conversation, such as P51 who shared intimate images through a dating app and described developing "a sixth sense" that they used to "make a judgement based on various features on the profiles" to establish if the recipient would be unlikely to reshare content. Many sex workers relied on payment for vetting. If the worker had payment details, they could take them to be an implicit understanding that the content was for private use only.

Rule Setting. About half of participants explicitly asked recipients not to share or store intimate content. "...I asked them not to screenshot anything, just to [keep] it in chat. And that was kind of the ground rule" (P11). Sex workers were more likely to set explicit rules. P35 shared: "before I send images, I always just say that this image is between myself and yourself... No one else is paying for this except you." Recreational sexters mentioned that they would circumstantially ask for content not to be shared such as if they had friends in common (P4) or if there were identifying features in the content (P14). In addition, a few participants stated direct consequences if content were to be shared. For instance, P30 said, "I would just tell them, if you ever shared, I will come up to you, we will go to the police" whereas P34 sent reminders to clients about potential consequences: "I send them the penal law articles regarding sharing/publishing porn content."

On the other hand, a few participants were open to recipients sharing intimate content if they asked permission first or in specific contexts: "I have on occasion, given people permission to share it with other people, especially in the context of [initiating group sex]" (P12).

8.1.2 While Sharing

When sharing intimate content, participants were highly cognizant of the risks of NDII and the limitations of existing technical defenses: "yeah, I can secure the communication, I can secure the storage where the photo is in, but I don't think I can prevent anyone from actually getting pictures" (P26).

Rather than focusing on complete prevention, participants used various strategies because "any of these measures that I'm talking about [are] a form of harm reduction" (P46). They therefore sought out technical features as a means of creating friction and used a combination of tactics to create accountability in event of NDII. Lastly, they sought to reduce the reshare value of their content so that it is less likely to be of interest to other audiences and proliferate further.

Friction. To create friction and reduce opportunities for recipient resharing, participants used *expiring messages* that allow a sender to set a message expiration time. This was widely used by three-fifths of participants (mainly recreational) and many used it situationally with strangers or in higher-risk contexts: "when I go to [*country*], which is a more dangerous place for homosexuals, I use this expiring pic feature" (P4).

When available, a few participants also made use of *screenshot prevention* in which screenshots result in a blank screen or deterrence messaging from a platform. P15 described using a platform because, "you couldn't also take like screenshot, like it wasn't allowed like like how it is [on a banking app]." Since this feature was not readily available in most platforms used for sharing content (see Appendix A), it was also commonly mentioned by others as a feature they wished more platforms would implement it as a means of increasing friction, despite many noting that it could be bypassed (e.g. capturing content through another device).

Accountability. Participants also used available safety features to reinforce boundaries and create mechanisms of ac-

countability. For example, a third of participants used *screenshot notifications* (particularly recreational ones) primarily to calibrate trust and "make the confrontations and the discussions that you need to do to be safe" (P10). P2 added that, "[a screenshot notification] empowers [people] to make decisions about whether to continue sharing messages." This was exemplified by a scenario in which P5 asked a recipient to delete an image after receiving a screenshot notification.

Expiring messages were also used in this context to calibrate the sensitivity of the content (e.g. sharing more explicit content) and implicitly communicate boundaries around resharing: "it's a clear, unambiguous sort of caption that says I would prefer if you didn't hold on to this" (P2).

Similarly, participants added watermarks and messaging on content to imply that it should be kept private and/or to trace leaked content back to its source. For example, P31 used watermarks on commercial content and also wrote the name of their recipient onto an image in their personal life to 'put the accountability on the person... you sort of implicate them into it more." P41 wrote a recipient's username on content as a way of later identifying who shared it. Participants also used watermarks to proactively prepare for future removal of nonconsensually shared content since "when you report on social platforms, you have proof of ownership" (P1).

Lastly, a few participants shared in contexts where there was a mutual exchange of intimate content: "if someone has also shared content of themselves, it kind of makes me feel better to also share something" (P47). For P26 who shared *and received* content in a network of strangers (see Section 5), they "expect them to not share [my intimate content] because they're in the same situation as me."

Lowering Content Value. To prevent resharing was, participant made content less desirable to others aside from intended recipients. Avoiding identifying features (Section 8.2) not only gave participants more anonymity, but also made intimate content less valuable and possibly less likely to be reshared. Personalizing content (e.g. writing a recipient's name) served a similar purpose. Lastly watermarks, particularly in commercial contexts, because "if your content's watermarked, then other platforms won't allow it to be uploaded" (P35).

8.1.3 After Sharing

After content had been shared, participants used strategies to manage and revoke access to reflect changing dynamics of trust in a sharing context.

Deletion Request. Although in some contexts participants consented to their recipients storing their intimate content, almost a third had made an explicit deletion request at some point. Sex-working participants made these requests in their personal lives and with clients. With clients, P20 shared that this occurred "when I sent them something that I later reconsidered... some things that I'm not comfortable with." However, P1 pointed out that this may be difficult after a transaction, "I even offered to like refund but no, [the client] didn't [delete the content]." Across contexts, participants expressed that they were unsure if content was ultimately deleted, such as P50 who described an "emotionally charged" period where they were not sure if their former partner had deleted their intimate images after a breakup.

Retroactive Unsend. Around a quarter of participants manually deleted intimate content from messaging histories such as through using an "unsend" feature. P32 described waiting for a client to view an image. After they receive a read receipt, they delete the image from their conversation history. P5, who shared with strangers online, added that, "So sometimes if I feel like you know, a person's acting fishy, then I either delete the messages or delete the photos."

8.2 Defending Against Identification.

Participants proactively used strategies to prevent being identified in the event of NDII. This may be to create plausible deniability (e.g., against blackmail) and to protect against additional harm (e.g., doxxing, harassment). In many cases, participants employed these strategies with the understanding that once content was shared, it was out of their control. "I know that I don't have full control over where these images will go, if people can trace them back to me" (P26).

Avoiding Identifying Features. Half of participants avoided capturing identifying visual information when creating content or removed such information after creation. Most commonly, they chose not to include their face or tattoos by using photo editing tools (to crop, blur, or cover them) or bandages/clothing such as P37: "Because I have big tattoos on my legs, I wear high knee high socks." Participants also voiced concerns about being identified through the background in their image or video, "the language of a shampoo bottle, street signs/public places... are carefully edited out" (P33). Although more than a third of participants used photo editing tools (either in-app or third-party), there were a few security concerns since they would "have to upload my intimate images to that app as well. So it feels extremely unsafe" (P23). Aside from using photo editing tools, participants also chose neutral backgrounds, removed identifying items in their background prior to taking content, and/or frequently changed the location in which content was created.

Metadata Removal. Six participants used metadata removal to eliminate extra information that is added when an image is created (e.g., location, date/time of creation). However, they generally expressed that they would prefer for it to be automatically done by a platform: "[it] almost feels like that should be the default when you share any image anyway" (P6).

8.3 Defending Against Non-Recipients

Along with concerns about recipient resharing, participants sought to defend against those who may access or view their intimate content through data breaches, hacking, and/or unintentional discovery (Section 6.2).

Storage Strategies. To defend against storage-related (e.g., hacking, unintentional discovery, device theft), around half of our participants proactively deleted their own stored content: "my [*cloud storage*] will send me like, memories of [intimate content]... [when I'm] trying to sip my tea... That's where I'll be like, yeah, get out of here" (P46). A quarter were mindful about their authentication practices—choosing to use strong passwords, 2FA, biometric authentication, or password managers. Finally, a quarter of participants stored content in local storage (or disabled automatic backups) while another quarter used a hidden folder, which moves selected photos from a photo gallery into a designated folder (e.g., Apple [7], Samsung [69]) to prevent unintentional discovery.

Consent. Many participants mentioned the importance of consent prior to sharing intimate content. A few specifically mentioned asking for consent before sharing intimate content in order to check if a recipient was alone or in a private area to prevent shoulder surfing, "I'll always ask first and wait for their response before I send something because you never know what people are doing" (P29).

Masking Content. Another strategy a few participants used to protect themselves against shoulder surfers was to mask it upon sending it. For the two participants who used this feature, a recipient would receive a blurred image that they would then have to click on to reveal the contents. This would signal that the content was sensitive and should be viewed in a private location. Though this feature was not commonly mentioned, it is also not readily available in most platforms (see Section 9.1).

End-to-End Encryption. End-to-end encryption (E2EE) ensures that only a sender and their intended recipient(s) can view a message. Once an E2EE message has been delivered, it carries similar risks to unencrypted messages: the recipient can still store or share message contents (some platforms may auto-download images onto devices). Over a quarter of participants actively used E2EE or considered it to be useful (excluding those who happened to use platforms with E2EE but did not mention it). For a few, E2EE alleviated their concerns about unwanted access by a platform or government entity: "There are basically two possible attackers. Like either the person I'm sending this to or someone from the outside trying to break into systems... I mostly care about someone from the outside able to steal pictures" (P26). P10 added that they valued E2EE because, "if there's anything I don't want, it's the government knowing details of my personal life and seeing my tits." On the other hand, a sixth of participants did not trust E2EE, believing that it could be broken if needed: "If someone wants the data, they will get their hands on it anyway. And if that someone is the police, they will just force companies to give that to them. No matter how well encrypted it is" (P50).

8.4 Comparing Participant Groups

In our work, we purposefully included the perspectives of victim-survivors and sex workers. Among our 52 participants, 22 were victim-survivors (8 recreational, 14 commercial).

We encountered narratives in which experiencing harm had increased fears of NDII: that, "I'm just really paranoid... and there's nothing I can really do about it... Especially after it's already happened" (P35). We also observed that some victim-survivors implemented additional strategies after experiencing harm. As P21 explained, "What happened to me was forever... And so I was more knowledgeable about what was going on, about the privacy of these pictures." P43 shared, "future photos... were really less revealing than they used to... you cannot recognise me." Otherwise, we did not observe notable differences in practices. Since we interviewed victim-survivors who continued sharing intimate content, many expressed that they resolved not to let shame and stigma stop them (and for some sex workers, they were unable to due to financial reasons). For example, P18 shared:

> "I'm having fun. I'm an adult... I don't want to allow shame or stigma to prevent me from living my life and exploring my sexuality."

When comparing commercial and recreational participants, commercial participants shared content in all the same contexts along with specific platforms to sell content and/or advertise services. However, sex workers were more constrained by the preferences of their clients when selecting a sharing method. Commercial participants may also prefer sex work specific platforms since they may otherwise perceive or experience hostility. We also observed that sex workers were less worried about unintentional discovery, either since the people around them already knew they were sex workers or because they employed more strategies to prevent this.

Generally, we observed that while recreational participants adopted many strategies, sex-working participants adopted more (in particular, watermarking, removing metadata, and using safe storage methods). They were also more likely to set explicit boundaries around sharing or storing. This greater protective action may be due to both differences in threat models (e.g. greater personal/physical risk, stigma) as well as better advice and educational support (see Section 9.2).

9 Gaps in Defenses & Recommendations

While work on secure technology to address IBSA is limited, we are not the first to study this topic (see Section 2). Our results build on prior work, such as Geeng et al. [32]. Taking our results together, we see that participants use a

range of technologies spanning different contexts and have varied threats from NDII to accidental forms of content discovery. We also observe that users leverage technological features when available. In both our findings, the most common feature used was expiring messages, perhaps due to its wider availability across platforms and popularized use with Snapchat. This supports our recommendation for wider platform adoption of safety features (discussed below). Further, our work in conjunction with Waldman [84], demonstrates that individuals often rely on interpersonal strategies to supplement (or in lieu of sufficient) content-based strategies. We echo the prior [32] suggestion for platforms to investigate design patterns that assist users in negotiating boundaries like consent-based design [93] and the need for platforms to design for intimate content as a use case, rather than as misuse. In addition, our findings reveal new gaps and opportunities for technological improvements alongside research in order to create more robust solutions against NDII.

9.1 Technological Recommendations

Our 52 participants used over 40 platforms for intimate content. Thus, any platform that enables the storing or sharing of images is likely being used for intimate content. Platforms must re-evaluate the sensitivity with which image and video data is treated and how it is secured. We detail high-level user needs below. We emphasize that such features should be flexible, allowing people to adjust to different interpersonal strategies and contexts (Section 5). In conjunction, we also urge for additional research to understand the limitations of these features (discussed further in Section 9.2).

Availability & Visibility of Existing Features. Many participants felt that they could or should be doing more to protect themselves but the features they wanted were not always available. Further, using protective strategies is time consuming, as P33 noted, "I spend more time scrubbing personal info off my pictures, putting them in private folders, etc., than actually taking said pictures. The learning curve is steep." Participants also sometimes forgot to use features because of the burden of using them. As a result, a few expressed a sense of futility: "I do what I can... [but] I just sometimes think it's pointless" (P23). P9 added, "It's like I gave up my security... everything I have read, it seems too complicated."

Participants wanted a full suite of safety features in any platform that allows photo/video storage and sharing. Desired features included: hidden folders, password protections, automatic watermarking, retroactive delete/unsend, expiring messages, masking on send, options to disable automatic download or backup of content sent in a messaging app, and screenshot notification. As P12 described, "If you could take the anonymity of [*platform*], the disappearing thing that you get from [*another platform*]. And this security that you get from [*E2EE platform*], that would be quite cool."

In response to these narratives, we conducted a systematic analysis of 8 popular platforms (see Appendix A) of the availability of safety features participants desired. We found that none of them fully implement all of the features (or features were only available in a special mode/for paid users). We emphasize that wider adoption of features is needed, particularly in popularly used platforms, to protect the majority of sexters who prioritize convenience or defer to their recipient's choice.

Content-Level Data Control & Presets. Participants wanted variations of existing features for data control that better reflect how they navigate trust and to help separate contexts.

Specifically, participants desired modifications and/or expansions of existing features to operate on a per-message (or per content) basis: being able to make an specific message expire; allowing screenshots only a single piece of content; or applying a shared password that would be needed to open a specific piece of content[8] "to make sure that no one else except that certain someone opens it" (P28). To prevent shoulder surfing, P23 suggested clicking a button or a sticker to reveal intimate content, rather than displaying it in a message window.[9] Lastly, they wanted the guarantee that when they delete content, it is deleted for recipients and that platforms no longer store the content, "you can delete everything [*in messaging app*] for yourself and the other person... it's not stored anywhere, it's not backed up or anything" (P35).

However, manipulating features based on the content or interaction is cumbersome. Thus, participants suggested offering a preset "intimate picture mode" (P30) in messaging apps, or several modes with preset settings appropriate for interactions with different levels of trust. This suggestion aligns with best practice from academic privacy literature [49, 91], which recommends privacy presets based on user contexts or personas. Since increasing the granularity of control may make platforms more difficult to use, additional research is needed to balance this with maintaining ease of use.

Support Manual Strategies. Participants wanted more technological support for the strategies they already used by making features easier to use and introducing new ones to complement interpersonal strategies. For example, participants wanted to *automate existing manual content-level strategies* (e.g., automatic background removal or face blurring in standalone or in-messaging-app photo editing tools or automatic metadata removal when content is captured). Participants also suggested various *design patterns to support interpersonal strategies* such as behavioral nudging: "a reminder that if you share this image without the consent, you could be imprisoned for time, maybe an alert to a service to contact the the police or psychologist" (P30) or a guided process of mutual consent to turn on storage of content sent in messages (P12).

[8] While WhatsApp recently released the ability to lock individual conversations, to our knowledge, no technologies allow password protection of a single message [89]. Prior work [39] offers preliminary quantitative evidence that a majority of young adult sexters would use such a feature.

[9] Confide (https://getconfide.com/) offers such functionality; no participants in our study had heard of the application.

Secure Storage. Participants wanted more and better options for secure storage. Six participants wanted expanded options for secure local storage or encrypted storage. "If there would be an app or method intended for intimate image storage only, I would totally use it to prevent any security issues... something that isn't connected to the internet" (P14). Some emphasized wanting to ensure locally stored intimate content was not accessible to other apps.

A few participants suggested building a designated app for storing intimate content where content would be stored locally in an encrypted format and that they could then selectively share content from. Although this sounds similar to vault apps,[10] only one participant had used one. Similarly, a few others wanted a mechanism for sharing a photo album that they could easily revoke access to: "I have never seen any app...that would allow you to like, you know, sort of create a photo album inside of your conversation" (P7). This suggestion is similar to Grindr's Album feature [34], which multiple participants wished more platforms would adopt.

Increase Friction. As previously noted in Section 8.1, participants desired additional features for increasing friction since, "No matter how much features people put into safety, there's always always always going to be a risk of it...[but] as long as the features and the way you're doing it has the minimum level of safety that will [stop] most people" (P16). Such features included download notifications (for when recipients save content and/or designating content for which download should be offered) or screenshot deterrence. While these features are not without risk (discussed further in Section 9.2), allowing users to disable auto-downloading of images/videos in messaging platforms or remove the download option for designated content can be meaningful changes.

Improve Transparency. For each feature we investigated, some participants expressed valid concerns while others had misconceptions. Particularly with E2EE, misunderstandings about the scope of protection and inconsistent implementations led to wholesale distrust, which is consistent with findings from prior work on E2EE (Section 2). Users also wanted clarity on how data persisted on platform servers when using expiring messages or other mechanisms of deletion. For example, P51 expressed the concern that, "even if [a recipient] deletes [stored intimate content], you delete it from your phone or wherever, it will be stored somewhere in some server." When deleting content, P10 added, "in the ideal sense... I want to be able to send the image and then to have it be wiped off the face of the planet and off the data server that it's in." There is need for more transparency around protections offered in this high-risk context and new mechanisms for guaranteeing/verifying deletion.

[10] Vault apps are designated apps for storing sensitive content such as images or documents but may offer varying levels of security [65]. They are often disguised as other apps to avoid discovery when device sharing. See [31] for a more in-depth discussion on the use of vault apps for intimate content storage.

9.2 Research Directions

Concerns around Safety Features. Though technical features (e.g. screenshot notifications, expiring messages, watermarks) were widely used, this was often caveated with expectations that these protections could be bypassed. While watermarks served as protection against content theft and created accountability, many acknowledged that they could altered or "used against people like, oh, it's the same girl in all these photos, collect them and put them in a folder together."

For screenshot notifications, screenshot prevention, and mechanisms that provided ephemerality, participants acknowledged that content could still be captured by another device. Despite these caveats, participants desired these features as means of increasing friction. However, it is important that the limitations of these features are clearly communicated to users so as to not give false expectations around security.

In addition to these concerns, some participants feared that such features would incentivize the behavior they sought to prevent against. For example, P31 was concerned that expiring messages "sort of invite people trying to screenshot... [because] it almost creates this environment of, oh, this is secret, which sort of invites people to be like, Oh, I'm going to try and hold on to it" (P31). Further investigation is needed to understand if there are any contexts in which these features may promote the capturing and storage of intimate content.

Balancing Content Control with Harm Documentation. Participants wanted message ephemerality (e.g., expiring messages, unsending a message) for protection, especially in high-risk contexts. However, in the event of NDII, it may be useful (or necessary) to have a record of the sender, recipient, and content of messages for pursuing legal action or content removal. In the context of unsending messages, P38 suggested removing the content only for the recipient. This and other design ideas should be explored to resolve the desire for ephemerality while allowing senders to maintain documentation in case of harm. However, it is important that such designs support victim-survivors while not introducing potential mechanisms for censorship and/or other privacy violations.

Discovery of NDII. Many participants wanted more technologies for identifying nonconsensual sharing. P33 described this as "an image search built in that would notify us when our content is posted elsewhere." More specifically, P47 wanted "a way for the actual content shared through the app to be identifiable through some kind of hash signature." We broadly referred to this functionality as "digital fingerprinting" [83] with participants. Only three participants had heard of this and only one used something related: a facial recognition tool.

After being provided a high-level description (see Appendix B.3), participants had mixed reactions of both interest and skepticism. A few expressed enthusiasm about this functionality enabling them to more easily find NDII content and perpetrators but others had reservations around the security of fingerprint storage and whether the fingerprint itself could

be used to identify or otherwise violate the image owner's privacy: "what if it could be traced back to me?" (P10). Meanwhile, a few participants commented that identifying the content alone would not be useful since barriers exist to removing nonconsensually shared content on many platforms.

Organizations like StopNCII [77] and AmIInPorn [4] aim to offer such functionality but lack public implementation details, making it difficult to assess any risks. These services may rely on perceptual hashing, which produces the same hash for *similar* content, or facial recognition. Perceptual hashing has previously been vulnerable to attacks that recover partial information about the original image [71], justifying participant concerns. Both approaches can have high false positive rates [11, 71], which may mistakenly alert individuals that an image was shared nonconsensually, causing distress.

More work is needed to explore technical mechanisms for tracking and/or identifying NDII, specifically to: investigate security/utility tradeoffs, establish effective transparency mechanisms, establish design paradigms for integration into platforms, and further investigate user concerns. Our recommendation to further investigate such technologies should not be taken as an endorsement of these methods, especially when applied in other contexts [16, 47, 54, 71, 80].

Insufficient Education. Many recreational sexters had not ever encountered advice for sharing intimate content nor had they sought it out, because, "it's not something that's talked about too often" (P3). As a result, they stumbled across safety features and navigated mitigation strategies on their own.

Those who had not experienced NDII, were generally unfamiliar with post-harm mitigation strategies and resources. We asked non-victim-survivors for advice they would give to a hypothetical friend who had experienced NDII[11]. The most common response was to go to the police and/or seek legal action, which may be inaccessible options (see Section 2). A fifth mentioned reporting content to a platform. Only one to two participants mentioned looking for help online and seeking help from an organization. Many also admitted that they were unsure what to do in this situation.

In contrast, a majority of sex-working participants spoke about the vast resources available to them through online sex worker communities. They were able to access safety content made by sex workers, ask questions freely, and receive support. This resulted in sex-working participants implementing more strategies such as watermarking, removing identifying features, safe storage, and/or metadata removal.

Broadly, there is a need for visible and accessible resources for people to learn how to protect themselves against NDII. Presently, the most common advice participants received from society, media, and others was not to share any intimate content. This was viewed as impractical, stigmatizing, and responsible for creating a culture of victim blaming because:

> "everyone does it... it's a part of how we sort of sexually express ourselves, or make money... If something does happen, and it does go badly, then you feel like, 'Oh, well, everyone's just saying, I shouldn't have done it.'So somehow, it's my fault even though it's obviously not" (P31).

Research such as ours can facilitate the creation of accessible advice guides for end users, particularly with the inclusion of resources from sex workers (since they practice more strategies and have experience educating and disseminating safety practices). Future work should look toward establishing such resources, evaluating their efficacy, and work on making resources more discoverable since end users may not be actively searching for advice due to the reasons discussed.

9.3 Concluding Discussion

We conclude by observing the ways in which societal stigma is encoded by technology's lack of protection against NDII and the broader cultural changes needed to make progress toward reducing NDII.

Technology & Victim-Blaming. Participants repeatedly mentioned themes of personal responsibility. They acknowledged the risk "inherent" in sharing intimate content, expressed fear of exposure and desire for greater control and autonomy. They expressed a matter-of-fact recognition that responsibility for their safety had been displaced onto them and that platforms were notably absent as "capable guardians to intervene" [43]. Left to navigate safety on their own, participants must shoulder the burden of preventing NDII and other threats (see Section 8). The volume and stringency of security behaviors that our participants engaged in extends beyond the standard level of responsibility any individual sharing online content should be reasonably expected to assume. Despite the effort they put into security, participants critiqued themselves for not implementing enough behaviors. **We conceptualize this as a form of victim blaming enacted by the absence of protective technological design**, which communicates the belief that a victim of sexual violence is responsible for (preventing) the consequences. As a result, it is critical to **reallocate responsibility from individuals to platforms and technologists.** We need to reconsider how much personal responsibility individuals must assume when engaging in sharing intimate content and how much of that responsibility can be reallocated or alleviated by implementing technological features. When possible, we must prioritize making technology that works in favor of individuals' autonomy, and safety, and implement features that relieve the burden from users. Individuals should not have to pick between avoiding abuse and engaging in recreation or labor.

All of Us: Reduce Stigma, Bring Consent. Alongside platform changes and state-of-the-art technologies, participants expressed the desire for societal change. They vocalized want-

[11] Victim-survivors were not asked this question and instead asked about their experiences with NDII, which we plan to report on in future work.

ing educational change that focuses on harm reduction and a shift from punitive ways of addressing harms. They envisioned a future where asking consent to share is the norm. "We should get into a place of cultural [understanding] where if I send you a picture of my dick, and you show it to someone else, they're like, did they fucking consent to that?" (P38).

As some participants have had to address their own shame, they found comfort and "feel so much safer about my nudes when I think about how many people send nudes" (P49). And with how common it is, participants hoped for a future where there is no longer stigma attached to sharing intimate content:

> "I really hope that culture starts to change... enough people are sending sexually explicit messages that our next generation of politicians will all have nudes in the world. So hopefully it won't be a scandal. People will just be like, hey, nice tits, great" (P18).

Acknowledgments

We thank our participants for sharing their experiences with us. This work was supported in part by the European Sex Workers Rights Alliance, the Max Planck Institute for Software Systems, and the U.S. National Science Foundation under award CNS-2206950. Lucy Qin was additionally supported by the NSF Graduate Research Fellowship. We thank Allison McDonald for feedback on an earlier draft of this work.

A Feature Availability Across Platforms

We conducted an analysis of feature availability in 8 popular platforms in November 2023. We selected features based on what participants reported using and what they shared that they wanted in a platform for sharing intimate content. The results are displayed in Table 2. We designated a platform as providing a feature if it was available in some variant. This includes when it is only available in a specific mode, such

	Apple iMessage	Discord	Google Messages	Grindr	Instagram DM	Signal	Snapchat	WhatsApp
Screenshot Prevention	○	○	○	●	○	○	○	●
Download Prevention	○	○	○	●	●	●	●	●
Screenshot Notification	○	○	○	●	○	○	●	○
Watermarking	◐	○	○	○	○	◐	◐	◐
Mask on Send	○	◐	●	●	○	●	●	●
Metadata Removal	●	○	●	●	●	●	●	●
Blur Identifying Features	◐	○	○	○	○	●	◐	◐
Message Unsend	○	●	●	◐	●	●	●	●
Expiring Message	○	○	◐	◐	●	●	●	●

Table 2: Survey of feature availability in popular platforms used for sharing intimate content. ● represents the availability of some variant of a feature, although this may be isolated to a specific mode of the platform, such as "vanish mode" in Instagram. ◐ represents the partial availability of a feature due to it being available only to paid users or through using a different feature for an unintended purpose, such as creating using decorative stickers in photo editors to cover identifying features. ○ represents the unavailability of a feature in any form.

as "vanish mode" in Instagram or a hidden/locked chat in Whatsapp. To assess the availability of features, we relied on published documentation and user guides from the platforms themselves. In some cases, we directly downloaded and accessed the platforms we surveyed to confirm the availability/unavailability of a feature when needed.

B Methods (Continued)

B.1 Recruitment Graphics

The following recruitment graphics were used to recruit recreational participants (Figure 1) and commercial participants (Figure 2).

B.2 Privacy and Anonymity.

To protect the privacy and anonymity of the participants, we used end-to-end encrypted platforms for the interviews, provided advice on how to sign up with an encrypted (and anonymous) email address if preferred, and used Calendly to schedule interviews, which did not require any legal information or login. The payment options could be anonymously received as well. Interviews were end-to-end encrypted and conducted either using Webex or Zoom. Participants were given the option of conducting the interview as a video call, audio call, or text chat. Sex-working participants were given the option of being interviewed by a current or former sex worker.

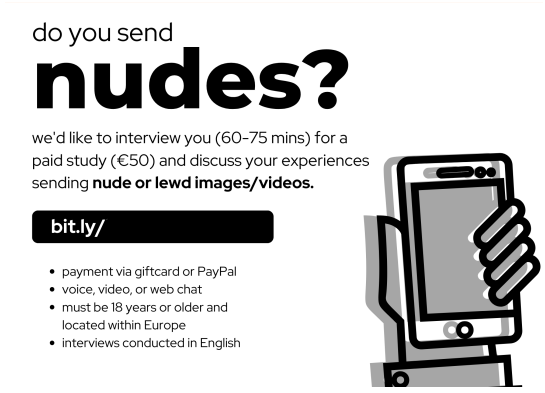

Figure 1: Recruitment graphic for recreational sexters

Figure 2: Recruitment graphic for sex workers

B.3 Interview Protocols

Our interview protocols are available at the following link along with our codebook:

`bit.ly/Tech-IBSA-Research-Protocols`

The audio and video interviews lasted an average of 47 minutes. During the interviews, we explicitly asked participants about the usefulness of a selected set of features based on prior work and existing media advice guides. These features included: end-to-end encryption, expiring messages, screenshot notifications, digital fingerprinting, watermarking, photo editing tools, and metadata removal. We wrote a high-level explanation of each feature that interviewers read to participants who had not previously heard of them or were only vaguely familiar with them. A document containing these explanations are included in the same repository.

AttackGNN: Red-Teaming GNNs in Hardware Security Using Reinforcement Learning

Vasudev Gohil[†], Satwik Patnaik[‡], Dileep Kalathil[†], Jeyavijayan Rajendran[†]

[†]{gohil.vasudev, dileep.kalathil, jv.rajendran}@tamu.edu, [‡]satwik@udel.edu

Abstract

Machine learning has shown great promise in addressing several critical hardware security problems. In particular, researchers have developed novel graph neural network (GNN)-based techniques for detecting intellectual property (IP) piracy, detecting hardware Trojans (HTs), and reverse engineering circuits, to name a few. These techniques have demonstrated outstanding accuracy and have received much attention in the community. However, since these techniques are used for security applications, it is imperative to evaluate them thoroughly and ensure they are robust and do not compromise the security of integrated circuits.

In this work, we propose *AttackGNN*, the first red-team attack on GNN-based techniques in hardware security. To this end, we devise a novel reinforcement learning (RL) agent that generates adversarial examples, i.e., circuits, against the GNN-based techniques. We overcome three challenges related to effectiveness, scalability, and generality to devise a potent RL agent. We target five GNN-based techniques for four crucial classes of problems in hardware security: IP piracy, detecting/localizing HTs, reverse engineering, and hardware obfuscation. Through our approach, we craft circuits that fool all GNNs considered in this work. For instance, to evade IP piracy detection, we generate adversarial pirated circuits that fool the GNN-based defense into classifying our crafted circuits as not pirated. For attacking HT localization GNN, our attack generates HT-infested circuits that fool the defense on all tested circuits. We obtain a similar 100% success rate against GNNs for all classes of problems.

1 Introduction

1.1 Threats Due to Globalized IC Supply Chain

Modern computing systems heavily rely on integrated circuits (ICs), which serve as their foundation. To achieve high performance and low power consumption in ICs, it is essential to have access to smaller and faster transistors, which are the basic components of ICs. The ongoing drive to continuously shrink transistors necessitates using cutting-edge fabrication facilities, commonly known as foundries. However, the cost of employing such advanced foundries is exorbitant. For instance, Samsung recently announced that it plans to invest $228 billion in a new semiconductor complex in South Korea, which will be the world's largest [50]. To address the challenges of design costs and overcome the tight time-to-market constraints, prominent IC design companies like NVIDIA and Apple operate under a fabless model. They outsource IC manufacturing to offshore third-party foundries, introducing potential trust concerns. In the U.S. Department of Defense's strategy for safeguarding critical defense supply chains in 2022, it was disclosed that a substantial 88% of microelectronic manufacturing takes place outside the U.S., thereby presenting a notable security concern [63]. This distributed supply chain arrangement has resulted in numerous security issues, including intellectual property (IP) piracy [7, 46] and the insertion of malicious logic called hardware Trojans (HTs) [2, 33, 43, 69, 76, 81, 87].

1.2 Impact of Hardware Security Problems

Hardware security problems such as IP piracy, HTs, and reverse engineering profoundly impact various aspects of technology and security. For instance, in 2018, as the U.S. Department of Justice reported, the global market for dynamic random-access memory (DRAM) was valued at nearly $100 billion. Micron, a major player in the DRAM industry holding a 20-25% market share, incurred an estimated loss of $8.75 billion due to IP piracy, underscoring the significant economic impact of IP piracy [25]. HTs are another serious threat to the security of ICs. HTs can cause denial-of-service, privilege escalation, or leak confidential information. For instance, researchers discovered a "backdoor" in a military-grade chip [72]. Researchers have also demonstrated HTs that can compromise the security of Intel's Ivy Bridge processors [12] or cause privilege escalation using capacitor-based HTs on fabricated chips [87]. The examples shown above

underscore the pernicious consequences of IP piracy and HTs, prompting research efforts by organizations like the Defense Advanced Research Projects Agency (DARPA) to counteract these threats using programs such as the Automatic Implementation of Secure Silicon program [1].

1.3 Graph Neural Networks in Hardware Security

As explained above, industry players, such as Intel, Qualcomm, Synopsys, Cadence, etc., and government agencies, such as DARPA, are investing a lot of effort into not only the power, performance, and area aspects of computing systems but also the security of those systems [14, 74, 80]. To aid this process of securing hardware, researchers have recently utilized graph neural networks (GNNs) for several hardware security-related tasks, showcasing state-of-the-art performance in identifying IP piracy [89], detecting and locating HTs [52, 88], reverse engineering circuits [11], and breaking hardware obfuscation techniques [9, 10], among others. However, there exists a crucial gap in using such GNN-based techniques for hardware security: these techniques have not been evaluated thoroughly. In particular, the threat of adversarial attacks on ML-based systems is extremely pernicious and must be understood and mitigated effectively. For instance, if a GNN that has not been thoroughly evaluated for adversarial robustness is used in detecting IP piracy, it can incorrectly classify a pirated circuit as not pirated, which can lead to a tremendous loss for the IP design house. Similarly, if a GNN that has not been thoroughly evaluated for adversarial robustness is used in detecting HTs, it can incorrectly classify an HT-infested circuit as HT-free, which can lead to disastrous consequences such as compromised encryption security.

1.4 Our Contributions

In this work, we address the above-mentioned research gap using *AttackGNN*, which performs a thorough evaluation of the GNN-based techniques in hardware security. To do so, we devise adversarial examples, i.e., circuits, against GNNs in hardware security for problems ranging from (i) detecting IP Piracy, (ii) detecting/localizing HTs, (iii) reverse engineering circuits, to (iv) breaking hardware obfuscation techniques for protecting circuit functionality. However, the threat model of devising adversarial examples places strict constraints (e.g., black-box access) on the attacker. The challenges for adversarial example generation are further exacerbated due to our field of application of GNNs, i.e., hardware security. Since we work with circuits, which need to obey design rule constraints, unlike arbitrary graphs, traditional perturbation-based adversarial example techniques, such as adding/deleting edges, injecting nodes, or modifying features, are not suitable in our case. Additionally, typical circuits consist of several thousands of gates, i.e., nodes, and even more wires, i.e., edges.

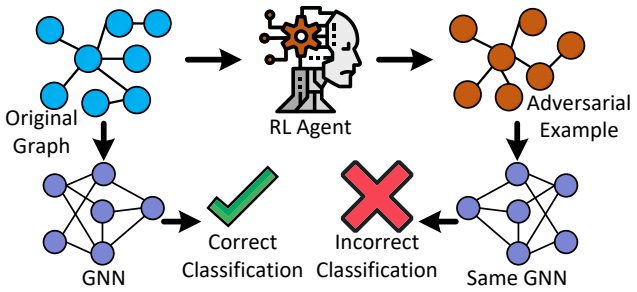

Figure 1: High-level overview of the proposed RL-based adversarial example attack against GNNs in hardware security.

Such a large design space of circuits makes the problem even more challenging. Simply brute-forcing all combinations of perturbations is clearly impossible. For instance, if we just restrict to perturbations that delete two edges in a graph with 1000 edges (a small circuit), the possible combinations are ${}^{1000}C_2 = 499,500$. Another practical consideration required when working with such large circuits is that performing operations on them is expensive. For instance, synthesizing or resynthesizing (i.e., compiling) large circuits can take several minutes. Thus, to ensure a practical technique, a balance needs to be struck in the trade-off between runtime and efficacy for such circuits. Likewise, testing adversarially-perturbed large circuits is also expensive since GNN-based tools require more time to analyze them. An appropriate trade-off must also be made in this regard (more details about this are provided in Sec. 4.4). Moreover, different circuits have vastly different structures. For instance, an encryption circuit will have very different gates and connections between them (convoluted operations for ensuring encryption security) compared to an adder circuit. This means that perturbations that work for one circuit may perform poorly for other circuits. These hurdles (large design space exploration and difficulty in generalizing to various circuits) make it challenging to devise successful adversarial examples.

We address these hurdles by modeling the adversarial example generation problem as a Markov decision process (MDP) and solving it using reinforcement learning (RL). RL has shown great promise in large design-space exploration by navigating unknown and uncertain problem spaces and finding optimal or near-optimal solutions. However, a straightforward application of RL is not sufficient to generate high-quality adversarial examples. Hence, we investigate and optimize the RL agent on three fronts: ❶ designing effective and generalizable actions, i.e., functionality preserving perturbations to the circuits, ❷ sparse rewards for faster training, i.e., ability to scale to larger circuits, and ❸ enabling multi-task learning using contextual MDPs, i.e., a single RL agent to generate successful adversarial examples against all GNNs. Incorporating all three optimizations results in an automated, generic, and practical method that evaluates the susceptibility of GNN-based techniques in hardware security to adversarial examples

Table 1: *AttackGNN* against GNNs used in hardware security.

Technique Type	Defense			Attack	
Security Problem	Detecting HTs	Localizing HTs	Detecting IP Piracy	Reverse Engineering	Hardware Obfuscation
Technique	GNN4TJ [88]	TrojanSAINT [52]	GNN4IP [89]	GNN-RE [11]	OMLA [9]
GNN Framework	Attention-based custom GCN	Graph attention network [79] (w. GraphSAINT [91] for sampling)	Attention-based custom GCN	Graph attention network [79] (w. GraphSAINT [91] for sampling)	Graph isomorphism network [84]
Claimed Efficacy	97% TPR	98% TPR, 96% TNR	94.61% Acc.	98.87% Acc.	89.55% Acc.
***AttackGNN* (This Work)'s Adversarial Success Rate**	100%	100%	100%	100%	100%

(details in Sec. 4). The primary contributions of this work are:

- We develop a first-of-its-kind RL-based adversarial example generation technique, *AttackGNN*,[1] for GNNs used in hardware security. Figure 1 illustrates the high-level concept of this work.
- *AttackGNN* is agnostic to the target GNN architecture and training process. In other words, it only assumes black-box access to the target GNN model.
- We develop custom optimizations to ensure the good performance of the underlying RL agent (Secs. 4.3 and 4.4).
- Using a contextual Markov decision process formulation, we perform multi-task learning, enabling a single RL agent to successfully generate adversarial examples against GNNs used for four different classes of hardware security problems (Sec. 4.5).
- Our results in Sec. 5 demonstrate that *AttackGNN* thwarts, i.e., successfully generates adversarial examples for all circuits against, GNN-based techniques for four classes of hardware security problems: IP piracy detection, detecting/localizing HTs, reverse engineering circuits, and breaking hardware obfuscation techniques (see Table 1).
- We demonstrate the ramifications of *AttackGNN*-generated adversarial examples through two practical, real-world attacks: fooling IP piracy detector on the `MIPS` and `IBEX` processors, and devising an HT that successfully leaks `AES` secret key by fooling an HT localization technique (Sec. 5.7).

2 Background

2.1 Graph Neural Networks

Graph neural networks (GNNs) have emerged as a powerful framework for analyzing and modeling structured data represented by graphs. Typically, GNNs used in classification tasks learn representations of nodes in a graph by repeatedly aggregating and transforming the information (i.e., features) from their neighbor nodes. After a fixed number of aggregation iterations, the aggregated features are reduced by taking their sums, averages, or maximums. The reduced outputs are passed to a classifier (e.g., a two-layer fully-connected network) for final classification. GNNs have proven successful in protein folding [73], social networks [30], and combinatorial optimization [16], among other fields.

2.2 GNNs' Applications in Hardware Security

Researchers have developed several GNN-based techniques for hardware security. Our selection of target GNN-based techniques ranges from the earliest techniques with high popularity, GNN4TJ [88] and GNN4IP [89], to the most recent one, TrojanSAINT [52]. We also select other GNNs, OMLA [9] and GNNRE [11], based on their high success rates and variety of underlying GNN frameworks (see Table 1). Overall, our selection represents a set of GNN-based techniques that use different frameworks and have demonstrated good performance for a variety of problems in hardware security.

GNN for Intellectual Property (IP) Piracy Detection. IP Piracy refers to the theft of the design IP by an adversary to develop competing devices without incurring research and development costs. GNN4IP is a GNN-based IP piracy detection technique that evaluates the similarity between two circuits [89]. It converts the two circuits into a graph representation and uses GCNs to obtain graph embeddings, which are passed through a fully connected layer that outputs a similarity score. If the similarity between the original and test circuits is high, GNN4IP flags the test circuit as pirated.

GNN for Hardware Trojan (HT) Detection. HTs are malicious modifications an adversary makes to disrupt the original functionality. GNN4TJ is a GNN-based detection technique targeting HTs inserted in third-party IPs [88]. Similar to GNN4IP, GNN4TJ converts a given circuit into a graph representation, which is passed through a GCN, resulting in graph embedding. A fully-connected layer decides if the circuit has an HT or not using the embedding.

GNN for Localizing HTs. TrojanSAINT is a GNN-based HT localization technique [52]. Similar to other techniques, given a circuit, TrojanSAINT operates on its graph representation and classifies each node as HT-free or HT-infested.

GNN for Reverse Engineering. Reverse engineering refers to identifying different parts of a circuit with the intent of duplicating them. Similar to previous techniques, GNN-RE converts circuits into graphs and uses GCN layers followed

[1] To enable future research on the practicality of GNNs in hardware security, we have open-sourced our adversarial examples to the community here.

by a fully connected network to classify gates into different modules/classes such as adders, multipliers, control logic, etc [11]. GNN-RE achieves an average accuracy of 98.82% on benchmark circuits [11].

GNN for Hardware Obfuscation. Hardware obfuscation is a design-for-trust scheme that promises protection throughout the IC supply chain by obfuscating certain circuit regions using key-controlled gates. OMLA is a GNN-based attack on hardware obfuscation that uses the structural information around the key-controlled gates to recover the correct key bits, thus breaking the security offered by the obfuscation [9]. OMLA achieves a high key-prediction accuracy (as high as >90%), outperforming prior works on all benchmarks [9].

The aforementioned techniques report very high success rates and show great potential in addressing their respective hardware security problem. However, they all lack in terms of a crucial aspect: thorough evaluation of robustness to adversarial examples. Evaluation of these GNN-based techniques, and any machine learning technique in general, against adversarial examples is absolutely essential because adversarial examples can have drastic impacts. For instance, [29] devised adversarial examples against image classification neural networks, resulting in misclassification of the "STOP" sign as a speed limit sign, which can cause a disaster in self-driving vehicles that use such image classifiers. The need for adversarial evaluation is especially pressing in these GNNs that target security applications. We develop *AttackGNN* as a framework to red-team these GNNs.

2.3 Reinforcement Learning

RL is a powerful framework in the field of artificial intelligence that enables an agent to learn and make sequential decisions in dynamic environments through interaction and feedback. Rooted in the concept of learning from rewards, RL employs an iterative process where an agent interacts with an environment, receives feedback in the form of rewards, and adjusts its behavior to maximize cumulative rewards over time. By learning an optimal policy (a function that maps state-action pairs to probabilities of selecting a particular action in a given state), the RL agent aims to make informed decisions in different states to maximize its long-term rewards. This learning paradigm is particularly well-suited for solving Markov decision processes (MDPs), which are mathematical models used to represent decision-making problems with sequential interactions. RL has demonstrated remarkable success in various domains, including robotics, game playing, and resource management [56, 60, 61].

3 Threat Model

We consider a standard and widely-used threat model of adversarial example generation [24, 49, 54, 62, 82, 93]. To that end, we make the following assumptions about the attacker.

Attacker's Capacity. The adversarial attack happens after the model has been trained. The model is fixed and the adversary cannot change the model parameters or structure. In particular, the attacker cannot poison the model and inject backdoors in the model.

Attacker's Abilities. The attacker can introduce arbitrary perturbations, albeit those perturbations cannot change the functionality of the circuit, and he/she cannot violate circuit design rules. These perturbations include, but are not limited to, any combination of adding/deleting edges, injecting nodes, etc. as long as the final perturbed circuit maintains the original functionality and does not violate circuit design rules.

Attacker's Knowledge. Attacker's knowledge refers to the amount of information known to the attacker about the model he/she aims to attack. We assume a black-box setting. The attacker does not have access to the model's parameters or training labels. He/she can only perform black-box queries for output scores or labels.

Attacker's Goal. The attacker aims to generate input samples (i.e., circuits) that result in misclassification by the target GNN model. For instance, when the target model is GNN4IP [89] (GNN-based technique for detecting IP piracy between two input circuits), given any original circuit, the attacker aims to create a pirated version of the circuit (by perturbing the original circuit) so that GNN4IP is fooled into classifying the perturbed circuit as "not pirated".

Note. The objective of this work is not to propose a new technique for inserting/detecting hardware Trojans (HTs), detecting/evading IP piracy, or reverse engineering. In other words, *AttackGNN* is not an attack or a defense on hardware security techniques. Rather, as mentioned in Table 1, it is an attack on GNNs used in hardware security, be they used for performing malicious acts or for benevolent acts.

4 Methodology

We now demonstrate how prior works have generated adversarial examples against general GNNs using perturbations and how these techniques are not applicable in our case with circuits (Sec. 4.1). Then, using GNN4IP [89] (a GNN-based technique for detecting IP piracy) as a representative example, we devise a novel approach to fool GNNs in hardware security by formulating the problem of finding adversarial examples as an RL problem (Sec. 4.2). However, this preliminary formulation suffers from generalization and performance issues which we overcome in Secs. 4.3 and 4.4. Additionally, for practicality and scalability, we devise a formulation that allows a single RL agent to generate successful adversarial examples against all GNNs (Sec. 4.5). Ultimately, we tie everything together in Sec. 4.6.

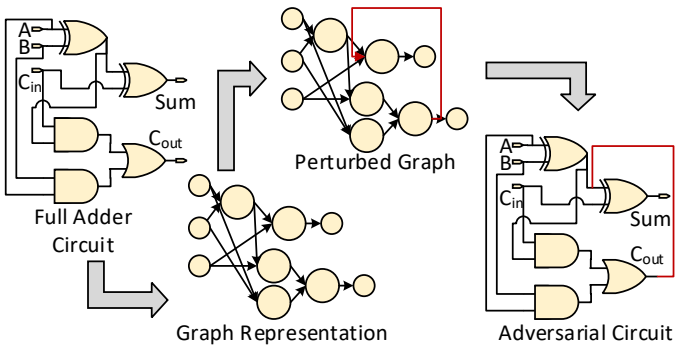

Figure 2: Illustration of why existing adversarial example generation techniques are inappropriate for our case.

4.1 Limitations of Existing Adversarial Example Generation Techniques

Adversarial examples in the context of GNNs refer to inputs that are purposefully crafted to deceive the GNN's predictions. Typically, adversarial examples in GNNs are generated by introducing perturbations to the input graph data. These perturbations are carefully designed to exploit vulnerabilities or limitations in the GNN model, causing it to make incorrect predictions. Researchers have developed a variety of perturbation techniques. These perturbation techniques use one or more of the following four approaches: adding edges, deleting edges, injecting nodes, and modifying features. However, such perturbations cannot be used for hardware security problems that operate on Boolean circuits because (i) these perturbations affect the functionality of the circuit, (ii) they may also lead to violations of circuit design rules, and/or (iii) they violate our threat model.

Example. Figure 2 uses a full adder circuit, its graph representation, an example perturbation, and the corresponding adversarial circuit to demonstrate why such perturbations cannot be used to generate adversarial examples for Boolean circuits. The perturbation adds an edge (shown in red) to the graph. However, doing so (i) changes the functionality of the circuit and (ii) has two drivers for a gate input, which violates circuit design rules. Similarly, the perturbation techniques that delete edges or inject nodes cannot be directly applied to GNNs used in hardware security. Moreover, modifying features is not applicable because although this perturbation technique would neither change the functionality of the circuit nor result in design rule violations, our threat model (Sec. 3) prevents us from controlling the node features directly.

Since these widely used perturbation techniques against GNNs are not applicable to our case, we devise a new way to generate adversarial examples that satisfy the constraints of not altering the circuit's functionality, not violating design rule constraints, and not violating our threat model. Our perturbation involves a series of modifications to the gates and wires of the circuit, but for each modification, we ensure that the circuit's functionality remains unchanged and the design rule constraints are not violated. Hence, after applying this series of functionally equivalent modifications, we obtain the final perturbed circuit that is functionally equivalent to the original circuit but can still result in misclassification by the target GNN.

4.2 Preliminary Formulation

As explained above, we must devise a series of perturbations that do not change the circuit's functionality but still result in misclassification. To achieve these functionality-preserving perturbations, we rely on primitive circuit transformations applied on circuits during the synthesis process, i.e., when a Verilog (or even a circuit) circuit description is translated (or re-translated) into a circuit. Here, since we use the open-source synthesis tool ABC [6],[2] we use its primitive circuit transformations, such as `refactor`, `refactor -z`, `resub`, `balance`, etc., to cause functionality-preserving perturbations. When applied to a circuit, these transformations change the circuit's structure but not the function. However, the order of application of these transformations affects the perturbed circuit and, hence, the success of the perturbation. Moreover, different circuits have different structures and thus require different transformations in different orders. So, to find the optimal sequence of transformations for a given circuit that results in misclassification by GNN4IP, we design an RL agent that finds the optimal policy for (i.e., solves) the MDP, denoted as a tuple $(\mathcal{S}, \mathcal{A}, P(s_{t+1}|a_t, s_t), R(s_t, a_t), \gamma)$, defined as follows:

- **States** $\mathcal{S}$ is the set of all possible values of the state vector. The state vector, s_t, that characterizes the circuit at time t, is defined as a list of pre-determined features in that circuit: s_t = [# inputs, # outputs, # gates, # wires, # AND gates, # OR gates, # NAND gates, # NOR gates, # INV gates, # BUF gates, # XOR gates, # XNOR gates, # other gates], where "other gates" refers to all gate types not explicitly listed in the array, e.g., flip-flops. We select these features since the resulting state vector captures information about the structure of the circuit, and it is closely related to the node features used in GNN4IP [89].

- **Actions** $\mathcal{A}$ is the set of the following functionality-preserving transformations in ABC: {`refactor`, `rewrite`, `resub`, `balance`, `refactor -z`, `rewrite -z`, `resub -z`}. We choose these transformations since they can produce different resynthesized circuits while preserving functionality [6]. We also add the `no-op` (short for "no operation") action to this set to denote no action. Doing so allows the agent to not perturb more if the current perturbed circuit is sufficient to evade GNN4IP. An individual action, a_t, is the transformation chosen by the agent at time t.

[2] ABC is a widely-used open-source synthesis tool developed at UC Berkeley.

- **State transition** $P(s_{t+1}|a_t, s_t)$ is the probability that action a_t in state s_t leads to the state s_{t+1}. In our case, the chosen transformation (i.e., the action a_t) is provided to ABC, which applies the transformation to the current circuit (represented by state s_t), and results in the resynthesized circuit (represented by state s_{t+1}). Note that since this transformation is deterministic, the state transition is also deterministic:

$$P(s_{t+1}|a_t, s_t) = \begin{cases} 1, & \text{if } \text{ABC}(s_t, a_t) = s_{t+1} \\ 0, & \text{otherwise} \end{cases}$$

- **Reward function** $R(s_t, a_t) = r_t$ is equal to α (> 0) if the next state is misclassified by GNN4IP as not pirated; it is 0 otherwise.

$$R(s_t, a_t) = r_t = \begin{cases} \alpha, & \text{if } \text{GNN4IP}(s_1, s_{t+1}) = \text{ not pirated} \\ 0, & \text{otherwise} \end{cases} \quad (1)$$

  Here, s_1 is the initial state, i.e., the original circuit we wish to pirate, and $\text{GNN4IP}(N_A, N_B)$ is the trained GNN-based IP-piracy detector function that takes as input two circuits, N_A and N_B, and returns "pirated" if it determines that circuit N_A is pirated from N_B or vice versa (since the function is symmetric) and returns "not pirated" otherwise. The reward is designed so that the agent tries to successfully evade detection by GNN4IP with the smallest number of perturbations.

- **Discount factor** γ $(0 \leq \gamma \leq 1)$ indicates the importance of future rewards relative to the current reward.

The initial state s_1 is a randomly picked (from the set of all circuits GNN4IP is trained with) original circuit that we wish to pirate and fool GNN4IP with. At each step, t, the agent in state s_t chooses an action a_t, arrives in the next state s_{t+1} according to the state transition rules, and receives a reward r_t. This cycle of state, action, reward, and next state is repeated T (a pre-determined finite number) times, constituting one *episode*. At the end of each episode, the agent's state reflects the final perturbed circuit. We train our agent using the Proximal Policy Optimization algorithm with default parameters unless specified otherwise [71].

Our experiments indicate that this preliminary agent performs well for some circuits but not for most of the circuits on which GNN4IP is trained. We analyzed the agent in greater detail and discovered some challenges faced by this preliminary formulation, which are explained and addressed next.

4.3 Effective and Generalizable Actions

Challenge: Ineffective and Specific Actions. The preliminary formulation relies only on the transformations available in the ABC synthesis tool to perturb the circuit. Those transformations (i.e., the actions defined above) have two issues.

Table 2: New actions based on allowed/prohibited standard cells. ANDx indicates an x-input AND gate. ● indicates allowed standard cells, and ○ indicates standard cells that are prohibited for that action.

Action	AND2, OR2	NAND2, NOR2	ANDx, ORx ($x \geq 3$)	NANDx, NORx ($x \geq 3$)	XOR, XNOR	INV, BUF
a^1	●	●	○	○	●	●
a^2	●	●	●	●	●	●
a^3	○	●	○	○	○	●
a^4	○	●	○	●	○	●
a^5	○	●	○	○	●	●
a^6	○	●	○	●	●	●
a^7	●	○	○	○	●	●
a^8	●	○	●	○	●	●
a^9	●	○	○	○	○	●
a^{10}	●	○	●	○	○	●

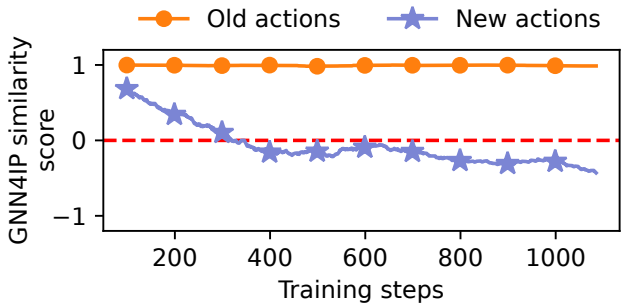

Figure 3: Comparison of the evolution of GNN4IP similarity scores with old and new actions as training progresses.

(i) They do not change the state significantly for several of the circuits. Thus, GNN4IP easily detects the structural similarity between the original and the pirated circuits. (ii) They are specific to the ABC synthesis tool, resulting in virtually zero compatibility with other open-source as well as industrial standard commercial synthesis tools such as Synopsys Design Compiler [75] and Cadence Genus [15].

Solution ❶: To address this challenge, we devise novel, more effective (albeit still functionality-preserving) actions for the agent that are extremely likely to change the state, i.e., the node features of the pirated circuit. These novel actions are the 10 different gate type (also called "standard cell") selection strategies shown in Table 2. For instance, if action a^1 is chosen, the synthesis tool (i.e., ABC, Synopsys Design Compiler, or Cadence Genus) is allowed to use the 2-input AND (AND2 in the table), OR, NAND, and NOR standard cells (i.e., gates), and XOR, XNOR, INV, and BUF standard cells, but not allowed to use 3 or higher input AND, OR, NAND, and NOR standard cells. So, if, in state s_t, action a^1 is chosen, s_{t+1} will not contain 3-input AND, OR, NAND, and NOR standard cells. Another advantage of these new actions based on standard cell selection strategies is that they are agnostic to the synthesis tool. All widely used synthesis tools, both open-source and commercial, are compatible with these

new actions, unlike the actions defined in the preliminary formulation. This synthesis-tool-agnostic nature of the actions is essential for generating adversarial examples against some of the GNNs in hardware security, as explained later in Sec. 5.

Simply adding these 10 new actions to the previously mentioned 8 actions (`refactor`, `rewrite`, ..., etc.) would result in an extremely large action space ($(10 \times 8)^T$, where T is the number of steps in an episode) for the agent. Hence, to reduce the action space, for each of the T steps in an episode, we only let the agent choose one of the 10 standard cell strategies and apply three fixed transformations (if using ABC): `rewrite`, `balance`, `refactor` (in that order). In other words, at each step, the action space of the agent is the set of 10 functionality-preserving transformations shown in Table 2 (and the `no-op` action for no change to the state; this allows the agent not to perturb more when the current perturbed circuit is sufficient to evade GNN4IP), and for each individual action from those, we apply the fixed transformations (if using ABC) `rewrite`, `balance`, and `refactor` in that order.

Figure 3 compares the GNN4IP similarity scores as a function of first $\approx 1K$ training steps for 10 `c432` benchmarks from the GNN4IP repository [4]. Lower similarity score indicates successful attack. The dashed red line is GNN4IP's threshold for classifying a circuit as pirated. The superiority of the agent's learning and performance is clearly visible: with the new actions, the agent quickly learns to generate adversarial circuits that fool GNN4IP (leading it to classify pirated circuits as not pirated), whereas with the old actions, the agent is unable to generate successful adversarial examples.

4.4 Sparse Rewards for Faster Training

Challenge: Unnecessary Reward Computations Another challenge faced by the preliminary formulation is that it involves reward computation at each step. Reward computation requires querying the trained GNN4IP model with the updated state, s_{t+1}, to determine if it is classified as pirated or not. Since this involves loading the trained model, parsing the original and current circuits, and performing a forward pass of the GNN, it consumes at least a few seconds. Since RL agents typically need several thousands, if not tens of thousands of steps, to learn, this time-intensive reward computation slows the RL training process dramatically.

Solution ❷: To reduce training time, we employ the strategy of computing rewards only at the end of the episode instead of at each step of the episode. Doing so reduces the frequency of reward computation, leading to less time per episode during training. Note that computing rewards at the end of the episode instead of at each step can affect the performance of the agent, i.e., it may lead to sub-optimal convergence. However, our results show that our agent still converges to an effective policy, i.e., it learns to generate successful adversarial examples. Table 3 shows the two ways to provide rewards (at each step and at the end of each episode) and their impacts on the training rates and the percentage of successful episodes against GNN4IP. It is evident that the sparse reward computation increases the rate dramatically while actually improving the percentage of successful episodes. Hence, we use sparse rewards (i.e., at the end of each episode) to train our RL agent.

Table 3: Comparison of training rates for the reward methods: at each step vs. at end of episode.

Method	% of successful episodes	Rate	
		(steps/min)	(eps./min)
Reward at each step	77	18.13	3.46
Reward at end of episode	89	67.73	13.33
Improvement	1.15×	3.73×	3.85×

4.5 Multi-Task Learning

Challenge: MDP Specific to one GNN. So far, we formulated an MDP, that when solved by an RL agent, yields adversarial examples against GNN4IP. However, this MDP is specific to GNN4IP. If we wish to target other GNN techniques, we would need to devise separate MDPs, each with their separate RL agents. In other words, we would have different RL agents to learn different tasks, i.e, generate adversarial examples against different GNNs. However, training separate RL agents for different tasks is not ideal because each RL agent would be independent and would require training from scratch instead of learning knowledge common among different tasks. This would result in a large runtime to generate adversarial examples against all the GNNs, limiting the scalability of our technique. To overcome this challenge, we need to devise a single RL agent that learns different tasks, i.e., generates successful adversarial examples against all GNNs.

Solution ❸: We devise a contextual Markov decision process (CMDP) formulation that can enable multi-task learning by a single RL agent. A CMDP is denoted as a tuple $(\mathcal{C}, \mathcal{S}, \mathcal{A}, \mathcal{M}(c))$, where $\mathcal{C}$ is called the context space, $\mathcal{S}$ is the state space, $\mathcal{A}$ is the action space, and $\mathcal{M}$ is a function mapping any context $c \in \mathcal{C}$ to an MDP $\mathcal{M}(c) = (\mathcal{S}, \mathcal{A}, P^c(s_{t+1}|a_t, s_t), R^c(s_t, a_t), \gamma^c)$. In other words, given a context $c \in \mathcal{C}$, the CMDP reduces to a regular MDP specific to that context. A key feature required to formulate a CMDP is that the state and action spaces of all the constituent MDPs need to be the same. Since our state and action formulations from Sec. 4.3 are agnostic to the underlying GNN, we can formulate the CMDP against all GNNs by designing different appropriate reward functions for the different GNNs. In other words, we can construct a CMDP that encompasses MDPs against all GNNs and then train a single RL agent that finds the optimal policy for the CMDP, and hence for all its constituent MDPs. Next, we formulate this CMDP.

- **The context space** $\mathcal{C}$ is the set of one-hot encoded binary strings, one for each GNN we target. Since we tar-

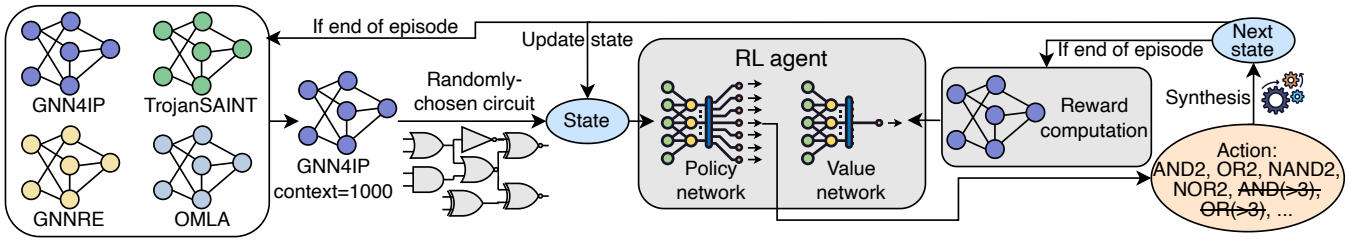

Figure 4: Final *AttackGNN* architecture.

get four GNNs (GNN4IP, TrojanSAINT, GNN-RE, and OMLA), $\mathcal{C} = \{1000, 0100, 0010, 0001\}$, with 1000 reducing the CMDP to the MDP for GNN4IP, and so on.

- **States** $\mathcal{S}$ of the CMDP are as defined in Sec. 4.2.
- **Actions** $\mathcal{A}$ of the CMDP are as defined in Table 2.
- **State transitions** $P^c(s_{t+1}|a_t, s_t)$ of the CMDP are the as defined in Sec. 4.2 for all $c \in \mathcal{C}$.
- **Reward functions** $R^c(s_t, a_t)$ for the constituent MDPs of the CMDP are defined separately as follows:

  TrojanSAINT is a GNN-based hardware Trojan (HT) localization technique. Given a set of nodes (i.e., gates in a circuit), it classifies each node as HT-free or HT-infested, which helps determine the location of an HT in the circuit. To generate adversarial examples against TrojanSAINT, we design the end-of-episode reward function (hence subscript T) as:

$$R(s_T, a_T) = r_T = 1 - \alpha_{TS}(s_{T+1}) \tag{2}$$

  Here, $\alpha_{TS}(N)$ is the performance of TrojanSAINT on the input HT-infested circuit, N, measured according to [52] as the average of true positive and true negative rates.

  GNN-RE classifies gates in a circuit into different modules (adders, subtractors, comparators, multipliers, and control logic). To generate adversarial examples against GNN-RE, we design the reward function as:

$$R(s_T, a_T) = r_T = 1 - \alpha_{RE}(s_{T+1}) \tag{3}$$

  Here, $\alpha_{RE}(N)$ is the accuracy of the trained GNN-RE classifier that takes as input a circuit, N, and returns the labels ("adder", "subtractor", "comparator", "multiplier", or "control logic") for the nodes in N.

  Since **OMLA** uses GNNs to predict the key bits used to obfuscate the circuit, the adversarial examples are designed to result in poor classification accuracy. To this end, we design the reward function as:

$$R(s_T, a_T) = r_T = e^{-5|0.5 - \alpha_{OMLA}(s_{T+1})|} \tag{4}$$

  Here, $\alpha_{OMLA}(N)$ is the key prediction accuracy of the trained OMLA GNN that takes as input an obfuscated circuit, N, and returns the predicted key bits (0 or 1 for the key gates (i.e., the obfuscation gates that take key bits as inputs) in N. The reward is designed to provide marginally increasing returns as OMLA's accuracy drops closer to 0.5, i.e., it performs no better than a random guess.

  In summary, the reward functions for MDPs are designed to generate adversarial examples so that the corresponding GNN yields low accuracy or a high misclassification rate. Finally, the reward function for the CMDP is a congregation of the individual MDPs' rewards:

$$R^c(s_t, a_t) = \begin{cases} Eq.(1), & \text{if c=1000} \\ Eq.(2), & \text{if c=0100} \\ Eq.(3), & \text{if c=0010} \\ Eq.(4), & \text{if c=0001} \end{cases}$$

- **Discount factors** γ^c for the CMDP are as defined in Sec. 4.2 for all $c \in \mathcal{C}$.

We solve this CMDP using a single RL agent, thus performing multi-task learning. Next, we unify all three solutions we developed and describe the final RL formulation that generates adversarial examples using ❶ effective and generalizable actions, ❷ sparse rewards for achieving faster training, and ❸ CMDP for multi-task learning.

4.6 Final Formulation

Figure 4 illustrates the final architecture of our RL agent against GNNs in hardware security. For each episode, the agent starts with a randomly picked circuit for a randomly picked target GNN (GNN4IP in the figure) and takes an action according to the policy parameterized by a neural network.[3] Based on the action, a synthesis recipe is created, which is compiled using the appropriate synthesis tool (ABC/Synopsys Design Compiler/Cadence Genus) to generate the next state of the agent. More specifically, we use the open-source ABC tool [6] when working with GNN4IP and OMLA and the industry-standard Synopsys Design Compiler [75] when working with TrojanSAINT and GNN-RE since the latter GNNs require gate names to be preserved after synthesis for correct labeling, which is not supported

[3] In addition to the policy neural network, the agent also contains a value neural network that predicts the expected reward for a given state-action pair, which is used to train the RL agent.

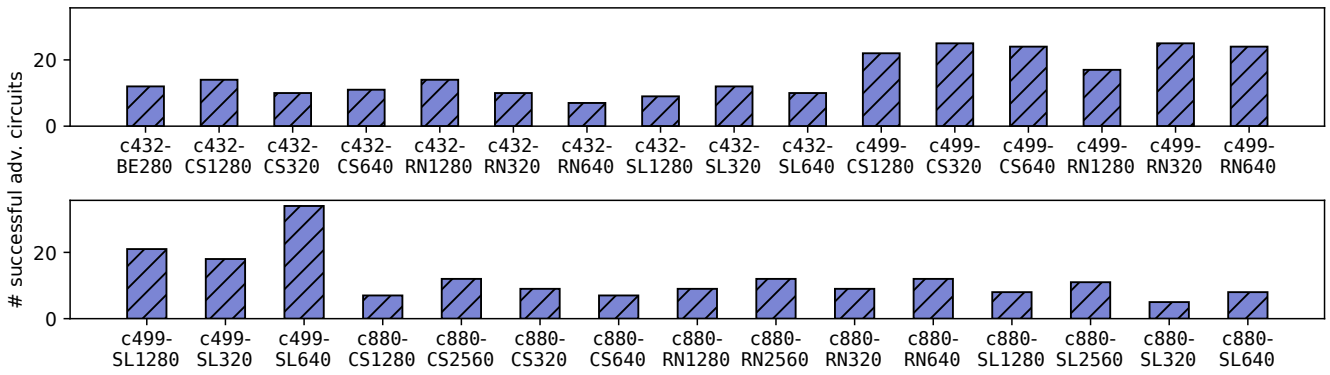

Figure 5: Number of successful *AttackGNN*-generated adversarial circuits against GNN4IP (higher values: better attack).

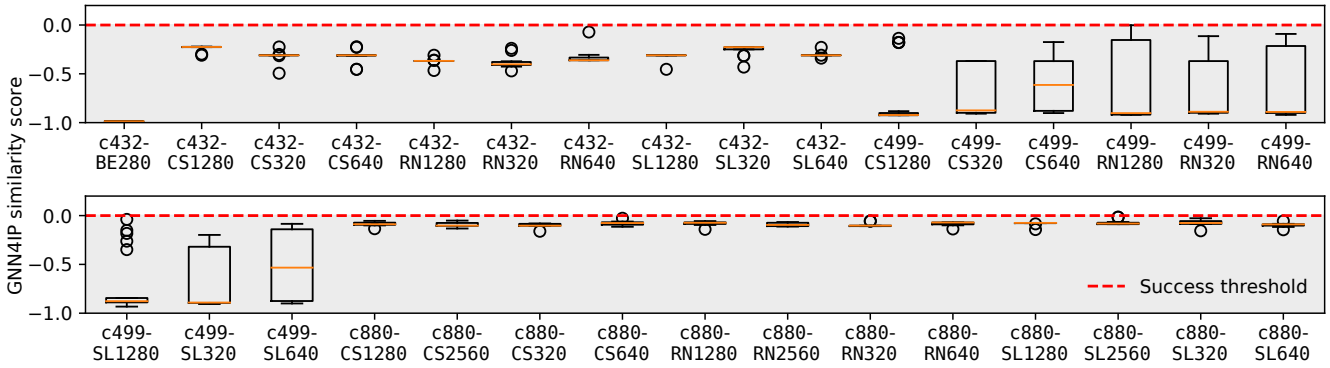

Figure 6: Distribution of GNN4IP similarity scores for *AttackGNN*-generated adversarial circuits (lower values: better attack).

in ABC.[4] Then, the agent chooses another action, and so on. This cycle is repeated T times, which constitutes an episode. At the end of the episode, the final state is evaluated using the chosen GNN for that episode to produce a reward for the agent. After a fixed-size batch of episodes, the Proximal Policy Optimization (PPO) algorithm translates the rewards into losses, which are used by the Adam optimizer [51] to update the parameters of the neural networks that make up the agent. After several such batches of updates to the parameters, the rewards saturate, and the neural networks converge, resulting in the agent learning an optimal or a near-optimal policy to generate successful adversarial examples against all target GNNs. Next, we demonstrate the efficacy of this multi-task RL agent in generating adversarial examples.

5 Results

5.1 Experimental Setup

We implemented *AttackGNN* using *PyTorch 1.12* and *stable-baselines3* and trained it using 16 cores in a Linux machine with a *Dual AMD EPYC 7443* processor with a 256GB RAM. We implemented custom parsers and glue scripts in *Python3*. We used the Proximal Policy Optimization algorithm [71] for training the RL agent. We used a two-layered, 64×64 fully-connected neural network with Tanh activation function for our policy and value networks. We selected the reward parameter, α for GNN4IP in Eq. (1), as 1 to have it on the same scale as the other rewards (Eqs. (2), (3), and (4)). Our MDP formulation for identifying perturbations follows the state (s) $\rightarrow$ action (a) $\rightarrow$ next state $\rightarrow$ reward (r) flow. For GNN4IP and OMLA, we set T, the episode length, as 5, so there is a five-step evolution of state: $s_0 \rightarrow a_0 \rightarrow s_1 \ldots \rightarrow s_5 \rightarrow r$. Whereas for TrojanSAINT and GNN-RE, we set T as 1, so there is a one-step evolution of state: $s_0 \rightarrow a_0 \rightarrow s_1 \rightarrow r$, meaning that there are two states in the flow. This is not supervised learning because T must be 0 for supervised learning, i.e., no state evolution. Moreover, we observed that setting T as 1 for TrojanSAINT and GNN-RE reduced the runtime and was still sufficient to generate successful adversarial examples using Synopsys Design Compiler.

5.2 Success Against GNN4IP [89]

We obtained the GNN4IP code and a dataset of 31 different circuits from the GNN4IP repository [4]. Using our RL agent, we generated adversarial examples for each of these 31 circuits. Since GNN4IP detects IP piracy between two circuits, a successful adversarial example should fool GNN4IP into classifying a pirated circuit as not pirated, i.e., assign it a sim-

[4] Note that *AttackGNN* is compatible with all synthesis tools.

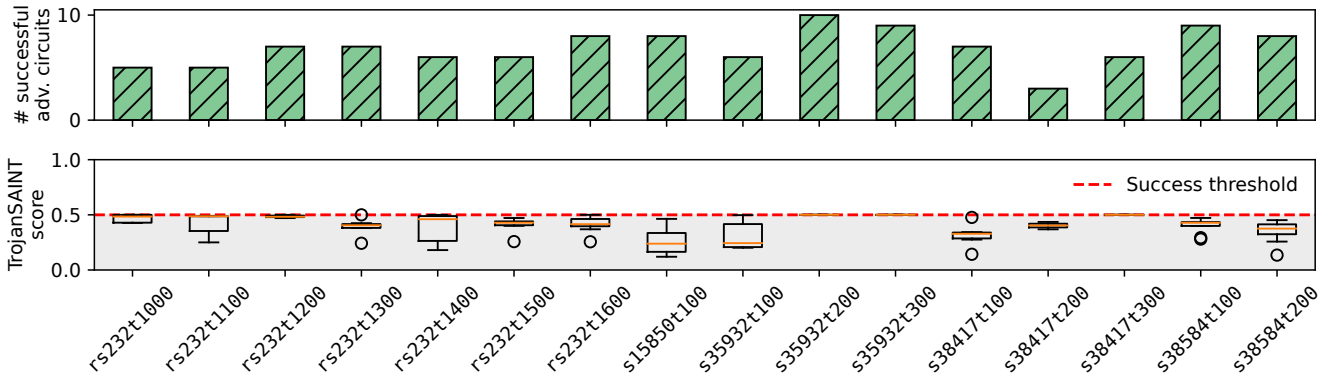

Figure 7: Top: Number of successful *AttackGNN*-generated adversarial circuits against TrojanSAINT (higher values: better attack). Bottom: Distribution of TrojanSAINT's scores for those adversarial circuits (lower values: better attack).

ilarity score < 0. Another important thing to note is that we generate adversarial examples by perturbing circuits from the training set itself, i.e., circuits that GNN4IP has seen during training. This is a more difficult setting for our attack than the typical setting where one perturbs a circuit from the testing set, i.e., circuits that GNN4IP has not seen before. We follow this difficult setting to showcase the exceptional capability of *AttackGNN* in generating successful adversarial examples.

Figure 5 shows the number of successful adversarial circuits found by our RL agent for each of the 31 circuits from GNN4IP's training set. As the results show, ***AttackGNN* easily generates many successful adversarial circuits against GNN4IP**. Figure 6 presents further analysis of our adversarial circuits vis-a-vis the distribution of the GNN4IP similarity scores for those circuits. The figure demonstrates that for most successful adversarial circuits, GNN4IP's similarity score is significantly less than 0 even though all those adversarial circuits are actually pirated from the original circuits.

5.3 Success Against TrojanSAINT [52]

We obtained the TrojanSAINT code from the TrojanSAINT repository [77]. Moreover, following TrojanSAINT [52], we used 16 HT-infested circuits from the TrustHub suite [78]. The TrustHub suite is a repository of many real-world circuits with various HTs that cause denial-of-service, degradation in performance, leak secret keys, etc. For each of the 16 circuits, we train a separate GNN as is done in TrojanSAINT [52]. Then, we use the single *AttackGNN* agent to generate adversarial circuits against all 17 trained GNNs. Since TrojanSAINT performs binary classification, we define an adversarial circuit, i.e., a perturbed HT-infested circuit, as successful if TrojanSAINT's score (average of true positive rate and true negative rate) is below 0.5, i.e., 50%.

Figure 7 shows the number of successful *AttackGNN*-generated adversarial circuits (top) and the TrojanSAINT score distribution (bottom) for them. We observe that even though *AttackGNN* is not trained separately for each of the 17 different TrojanSAINT GNNs, it easily generates plenty of successful adversarial circuits against TrojanSAINT. Moreover, like GNN4IP, **all successful adversarial circuits result in poor TrojanSAINT performance**.

5.4 Success Against GNN-RE [11]

We tested *AttackGNN* against GNN-RE using a dataset of 37 circuits containing combinations of adders, subtractors, comparators, multipliers, and control logic with bit widths from $\{4, 8, 16, 32\}$ [32]. In total, the dataset contains 24 circuits. We follow the training procedure described in [11] to train GNN-RE. Given a circuit, GNN-RE classifies the gates in the circuit into one of the five classes (adders, subtractors, comparators, multipliers, and control logic). Hence, our *AttackGNN* tool generates adversarial circuits by perturbing the given circuit with the objective of decreasing the classification accuracy of GNN-RE in a black-box setting. We define an adversarial circuit as successful if it results in GNN-RE's classification accuracy of $\leq 25\%$. An important note here is that we consider the more stringent scenario where we generate adversarial examples for the circuits that GNN-RE has seen during training, as opposed to generating adversarial examples for circuits not seen by GNN-RE.

Figure 8 shows the number of successful adversarial examples generated by *AttackGNN* against GNN-RE (top) and GNN-RE's accuracy distribution for those adversarial circuits (bottom). The nomenclature for the circuit labels is explained in Table 4. Even though a single *AttackGNN* RL agent perturbs the circuits seen by GNN-RE during training, it **successfully fools GNN-RE and results in GNN-RE's accuracy to drop to < 0.25, i.e., $< 25\%$.**

5.5 Success Against OMLA [9]

To assess *AttackGNN* against OMLA, we use the the publicly available circuits from the OMLA repository [64]. This dataset comprises a sum of 3996 distinct obfuscated circuits distributed across four specific circuit sets (`c1355`, `c1908`, `c2670`, and `c3540`) derived from the ISCAS benchmark suite.

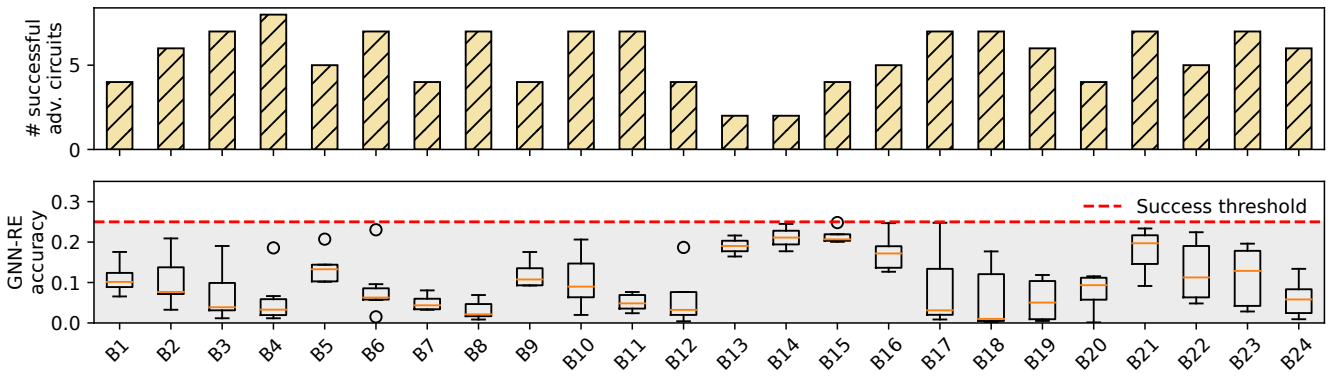

Figure 8: Top: Number of *AttackGNN*-generated successful adversarial circuits against GNN-RE (higher values: better attack) Bottom: Distribution of GNN-RE's accuracy for those adversarial circuits (lower values: better attack).

Table 4: Name encoding for the circuits in GNN-RE repository [32]. ● and ○ indicate the presence and absence of that substring in the name of the circuit benchmark, respectively. For instance, `B7` corresponds to the "add_mul_combine_16_bit.v" circuit from the GNN-RE repository [32].

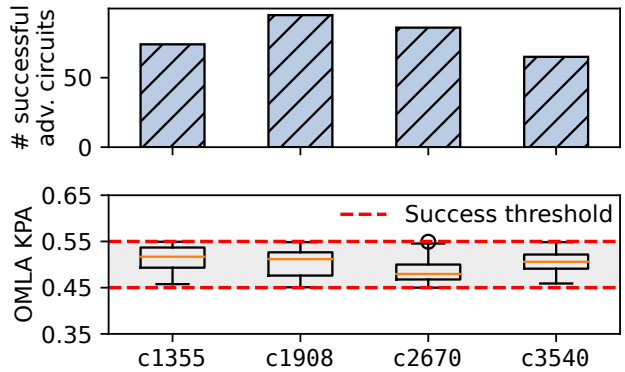

Figure 9: Top: Number of successful adversarial circuits against OMLA (higher values: better attack). Bottom: OMLA's accuracy for them (values near 0.5: better attack).

We selected these circuits due to OMLA's notable high key prediction accuracy (as high as 95%). Similar to TrojanSAINT, OMLA also trains separate GNNs for each of the four circuits, so we follow the same training process [9]. Then, we use a single *AttackGNN* agent to generate adversarial circuits against all four GNNs from OMLA. Since OMLA predicts the values of the key bits to unobfuscate the circuit, we use the key prediction accuracy (KPA) to measure the success of OMLA. A KPA of 100% means OMLA has recovered all key bits correctly, and a KPA of 50% means OMLA is no better than a random guess. So, we define an adversarial circuit as successful if OMLA's KPA is between 50% and 55%.

Figure 9 shows the number of our successful adversarial circuits against OMLA for all four circuit sets, `c1355`, `c1908`, `c2670`, `c3540`, (top) and distribution of OMLA's KPA for those adversarial circuits (bottom). Both figures clearly illustrate the **success of *AttackGNN* in perturbing obfuscated circuits that render OMLA no better than a random guess**.

5.6 Success Against GNN4TJ [88]

Here, we analyze the efficacy of GNN4TJ, a GNN-based HT detection technique. Given a circuit, GNN4TJ classifies whether that circuit contains an HT or not. To ensure proper evaluation in our experiments, we used the pre-trained GNN4TJ model as well as the benchmark circuits released by the authors at [4]. Additionally, we also included five other HT-free circuits from the OpenCores [66] in the evaluation process. Testing a total of 15 HT-free and 19 HT-infested circuits, GNN4TJ reported an accuracy of 55.88%. However, a closer look at the confusion matrix in Figure 10 reveals an interesting insight. The false positive rate of GNN4TJ is $\frac{15}{15+0} = 100\%$. In other words, GNN4TJ classifies all circuits as HT-infested. Note that of the 15 circuits that GNN4TJ incorrectly classifies as HT-infested, 9 are circuits that GNN4TJ has seen during training. This indicates that GNN4TJ has a high bias towards classifying any circuit as HT-infested, mak-

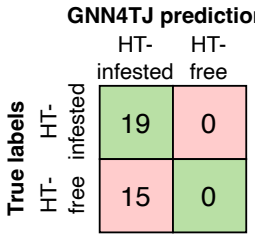

Figure 10: Confusion matrix for GNN4TJ predictions.

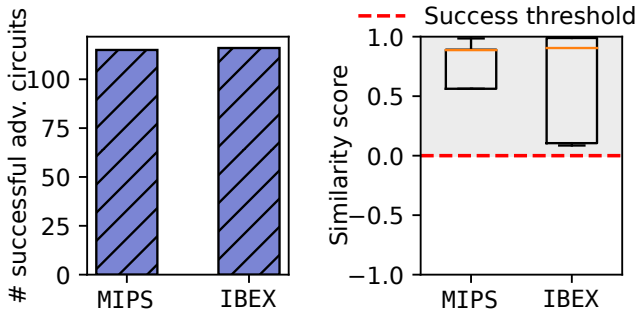

Figure 11: Left: Number of successful adversarial circuits (higher values: better attack). Right: Distribution of GNN4IP similarity scores for `MIPS` adversarial circuits with `IBEX` and vice-versa (higher values: better attack).

ing the technique impractical as a HT-detection tool. Since GNN4TJ is highly biased, we do not evaluate it using adversarial examples because no matter what adversarial example (i.e., an HT-infested circuit designed to fool GNN4TJ) is generated, the adversarial example will likely never be classified as HT-free by GNN4TJ making the evaluation moot.

5.7 Ramifications of Adversarial Examples in Hardware Security

IP Piracy. So far, we evaluated the efficacy of *AttackGNN* against GNNs mainly on the benchmarks released for the respective GNNs. Next, we demonstrate the practicality of *AttackGNN* by showcasing a case study on two large-scale circuits, the Stanford `MIPS` [65] and the Google `IBEX` [45] processors.[5] In particular, we demonstrate the ability of our technique to fool GNN4IP for these large-scale circuits. To that end, we (i) use *AttackGNN* to generate a variety of perturbed circuits for the `MIPS` processor and then query GNN4IP to detect piracy between those perturbed circuits and the `IBEX` processor; and (ii) we generate a variety of perturbed circuits for the `IBEX` processor and then query GNN4IP to detect piracy between those perturbed circuits and the `MIPS` processor. We perform this cross-evaluation to determine the false positive rates of GNN4IP on real-world circuits. Figure 11 shows that *AttackGNN* generates > 100 successful adversarial circuits for both the cases in just one hour of training. Even though `MIPS` and `IBEX` are completely different circuits, *AttackGNN* easily fools GNN4IP into classifying them as pirated. Moreover, the distribution of the similarity scores given by GNN4IP to our adversarial circuits of these vastly different processors is also shown in Figure 11.[6] It is evident that not only is GNN4IP susceptible to false positives, the magnitude of incorrect classification (as measured by the incorrect high similarity scores) is alarming. This case-study demonstrates the importance of adversarial evaluation in hardware security. Failing to do so can result in a classifier that is highly inaccurate and can lead to circuits being incorrectly flagged as pirated with high confidence.

HT Localization. Next, we demonstrate the ramifications of adversarial examples for the case of HT localization by showcasing an attack on an `AES` encryption circuit. `AES` is a widely-used encryption algorithm (i.e., cipher) and is the first and only publicly accessible cipher approved by the U.S. National Security Agency NSA for top secret information [22]. For this case study, we design and insert an HT that leaks the secret key when 2^{128} encryptions are done. Then, we use *AttackGNN* to generate adversarial examples for this HT-infested `AES` and evaluate TrojanSAINT's efficacy in locating the HT. *AttackGNN* successfully generates 10 unique adversarial circuits, each of which results in a 50% or lower score from TrojanSAINT.[7] Again, this case study reinforces the need for a thorough evaluation of GNN-based techniques in hardware security, as failing to do so can have disastrous consequences.

Results Summary. All our results validate the efficacy and generality of our technique. A single *AttackGNN* RL agent successfully generates adversarial examples against all considered GNNs in just 12 hours of training.

6 Related Work and Discussion

In this section, we first discuss other works that generate adversarial examples or use reinforcement learning (RL) for security problems and how *AttackGNN* is different from them. Then, we provide a detailed description of another related work that targets the GNNs in hardware security and outline the key points that differentiate our work from it. Finally, we discuss potential countermeasures against *AttackGNN*.

6.1 Adversarial Examples and RL in Security

There has been a plethora of work on attacking systems by generating adversarial examples [3, 18–20, 24, 27, 28, 39, 40,

[5] To ensure compatibility with GNN4IP, we assume full-scan access for these processors.

[6] Note that, unlike Figure 6 in Sec. 5.2, since the objective of this experiment is to determine the false positive rate of GNN4IP, a successful adversarial circuit is one that fools GNN4IP to classify as pirated, i.e., its similarity score should be higher than 0.

[7] "Score" here refers to the average of true positive and true negative rates, i.e., the metric used in TrojanSAINT [52].

44, 48, 53–55, 57, 58, 62, 68, 82, 86, 90, 92, 93]. Just over the past couple of years, researchers have designed adversarial attacks against perceptual hashing [68], automatic speech recognition systems [18, 19, 27, 40, 82, 90], speaker identification [3], malware detection [39, 44, 53–55], image captioning systems [20, 86, 92], image detection [48, 57], and even an automatic reviewer assignment system used in a top security conference [28]. All these attacks perturb certain features in the input space to fool a detection/recognition/classification system into producing incorrect outputs. Researchers have also proposed adversarial attacks against GNNs in general [24, 62], albeit not in hardware security. Since these techniques do not target hardware circuits, they employ existing graph perturbation techniques and work with graphs with a couple thousand nodes. In contrast, our work (i) designs new kinds of perturbations suitable for hardware circuits, (ii) works with circuits that contain up to $258K$ gates (i.e., nodes), and (iii) to the best of our knowledge, is the first work that generates successful adversarial examples against GNN-based classification systems used in hardware security.

In another direction, researchers have also used RL to devise new attacks and defenses in hardware security [21, 23, 26, 33–36, 41, 42, 59, 67, 70]. However, these works are orthogonal to ours: they target specific problems in hardware security (e.g., HTs, fault injection, cache-timing attacks), whereas our work generates adversarial examples against GNNs used in hardware security. Researchers have also explored the potential of using generative adversarial networks (GANs) to generate adversarial examples [5, 83]. However, such works attack traditional deep neural networks, so the potential of GANs for generating adversarial examples against GNNs, and specifically GNNs for hardware security, is yet to be explored.

6.2 Attacking GNNs in Hardware Security

Different from this work, `PoisonedGNN`, which targets some of the GNNs in hardware security, assumes a threat model of a backdoor attack, where the attacker has access to the training data, the training process, and the trained model's parameters [8]. This enables it to insert backdoors into the target model, reducing its accuracy during inference.

Unlike `PoisonedGNN`, *AttackGNN* is an adversarial example-based attack technique that (i) does not require access to the training procedure, (ii) works under the constraints of not being allowed to change the model parameters or structure, (iii) works with black-box access to the model under attack, and (iv) does not devise specific techniques (i.e., backdoors) dependent on the target GNNs; rather, *AttackGNN* generates adversarial examples in an agnostic manner, using only black-box access to the target GNNs, resulting in thwarting GNNs used in four different hardware security problems.

6.3 Potential Countermeasures

There are several options to protect GNNs against adversarial attacks. (i) Adversarial training involves injecting adversarial examples into the training set such that the trained model can correctly classify the future adversarial examples [37]. However, research has also shown its limitations in general machine learning settings [17] as well as for GNNs [31, 38]. (ii) Researchers have also devised adversarial perturbation detection techniques as a countermeasure against adversarial attacks [47, 85]. However, these techniques are not applicable to *AttackGNN* since our work does not use the typical node/edge perturbation techniques. (iii) Different from the previous heuristic-based approaches, certifiable robustness techniques provide guaranteed defense against adversarial attacks under some assumptions [13]. However, such techniques focus on typical node/edge perturbations, different from our perturbations that potentially change the entire graph. More future work is needed to devise such certifiable robustness techniques for our case.

7 Conclusion

Graph neural networks (GNNs) have shown great have shown great potential in addressing several critical hardware security problems. However, we observe that these state-of-the-art GNN-based techniques have lacked thorough evaluation, particularly against the threat of adversarial examples.

Using reinforcement learning (RL), we devised a first-of-its-kind automated technique, *AttackGNN*, that generates adversarial examples against GNNs used in hardware security. To do so, we couldn't rely on existing perturbation-based adversarial example generation methods since working with hardware circuits poses unique constraints (maintaining circuit functionality and obeying circuit design rules) and challenges (scaling to large circuits). We overcame these constraints by developing circuit functionality-preserving perturbations. Moreover, we developed custom optimizations improving the effectiveness and efficiency of our RL agent, allowing it to scale to practical circuits. We also devised a contextual Markov decision process formulation enabling a single RL agent to generate successful adversarial examples against GNNs for four classes of hardware security problems. *AttackGNN* is agnostic to the target GNN architecture and only requires black-box access to the GNNs.

Experimental results confirm that *AttackGNN*-generated adversarial examples fool all GNNs considered in this work. We also showcase the power of *AttackGNN* in (i) fooling an IP piracy detector for the `MIPS` and `IBEX` processors and (ii) creating a circuit compromised with an HT that can leak an `AES` secret key while evading an HT localization technique.

Acknowledgments

This work was partially supported by the National Science Foundation (NSF CNS–1822848 and NSF DGE–2039610). We thank Dr. Lilas Alrahis from New York University, Abu Dhabi, for helping us set up the OMLA and TrojanSAINT GNNs. We also thank our anonymous shepherd for their help in improving the manuscript.

8 Appendix

8.1 Pseudocode

Algorithm 1 details the pseudocode for *AttackGNN*, which runs an iterative process until convergence. In each iteration, (i) the while loop in line 4 rolls out and collects trajectories in $\mathcal{T}$ according to the current policy, π_θ, and (ii) the PPO algorithm updates the current policy using the collected trajectories $\mathcal{T}$ (line 13). During the rollout phase, at the beginning of each episode, a random GNN is selected (which also determines the length of that episode, T). Then, a random circuit (from the target circuits) is selected for that GNN, which, along with the context of the target GNN, c_{GNN}, constitutes the initial state, s_0. Then, the episode is run following the current policy's actions, and the generated trajectory is stored in $\mathcal{T}$, which is then used by the PPO algorithm to update the current policy until convergence. Note that assessing *AttackGNN*'s theoretical computational complexity is non-trivial because it involves RL training and closed-source circuit synthesis algorithms, whose complexities are unknown and difficult to derive. However, the practical runtime required for

Algorithm 1: *AttackGNN* pseudocode

Input: List of GNNs and their corresponding circuits
Parameter: Number of steps in rollout, $J = 32$
Output: Trained *AttackGNN* policy π_θ

while not converged **do**
  $j \leftarrow 0$ // rollout step counter
  $\mathcal{T} \leftarrow \phi$ // for storing rollout trajectories
  while $j < J$ **do** // J-step rollout
    GNN, $T \leftarrow$ Pick a random target GNN
    $s_0 \leftarrow c_{\text{GNN}}|$random circuit for GNN
    for $t = 0, 1, 2, \ldots, T-1$ **do**
      $a_t \leftarrow \pi_\theta(s_t)$
      $s_{t+1} \leftarrow P^c(s_t, a_t)$
      $r_t \leftarrow R(s_t, a_t)$
      Store trajectories in $\mathcal{T}$
      $j \leftarrow j+1$
  $\pi_\theta \leftarrow \text{PPO}(\mathcal{T})$ // update policy using PPO

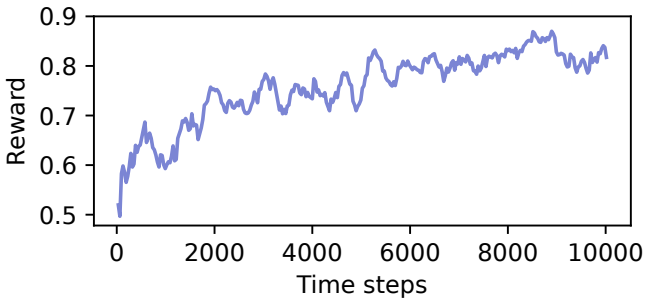

Figure 12: *AttackGNN*'s training reward curve

generating successful adversarial examples against all circuits for all GNNs is less than 12 hours, making *AttackGNN* extremely efficient.

Also note that *AttackGNN* generates successful adversarial examples during the training process itself. This follows the assumptions for adversarial attacks where, for instance, an adversary attempting IP piracy has access to the circuit they wish to pirate as well as to the target GNN they wish to fool so they can query the GNN with the desired circuit as we do during RL training. Moreover, this approach of generating new attacks/defenses during the training process has also been used in recent related works on RL for hardware security, such as [33, 59].

8.2 Convergence and Performance

Here, we provide results demonstrating the convergence and the performance of *AttackGNN*. Figure 12 shows the training reward curve: it is evident that the agent converges to a high reward within 10000 time steps. Figure 13 illustrates *AttackGNN*'s performance in terms of the number of

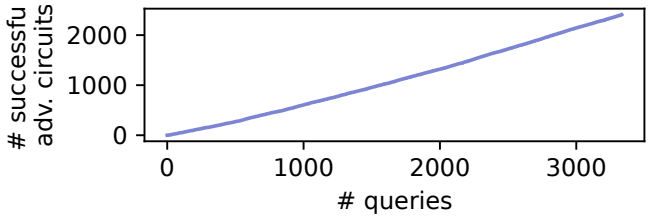

Figure 13: *AttackGNN*'s performance with increasing number of black-box queries

(non-unique) successful adversarial circuits as a function of the number of black-box queries. As expected, *AttackGNN*'s performance increases with an increasing number of queries.

Note. This work does not intend to highlight the limitations of any specific technique(s). Instead, it is a reflective endeavor to illustrate how the application of machine learning advancements to address hardware security challenges can potentially introduce new vulnerabilities. Moreover, it emphasizes the importance of comprehensive evaluation and how, as a community, we can approach to mitigate these vulnerabilities.

INSIGHT: Attacking Industry-Adopted Learning Resilient Logic Locking Techniques Using Explainable Graph Neural Network

Abstract

Logic locking is a hardware-based solution that protects against hardware intellectual property (IP) piracy. With the advent of powerful machine learning (ML)-based attacks, in the last 5 years, researchers have developed several learning resilient locking techniques claiming superior security guarantees. However, these security guarantees are the result of evaluation against existing ML-based attacks having critical limitations, including (i) black-box operation, *i.e.,* does not provide any explanations, (ii) are not practical, *i.e.,* non-consideration of approaches followed by the semiconductor industry, and (iii) are not broadly applicable, *i.e.,* evaluate the security of a specific logic locking technique.

In this work, we question the security provided by learning resilient locking techniques by developing an attack (INSIGHT) using an explainable graph neural network (GNN). INSIGHT recovers the secret key without requiring scan-access, *i.e.,* in an oracle-less setting for 7 unbroken learning resilient locking techniques, including **2 industry-adopted logic locking techniques**. INSIGHT achieves an average key-prediction accuracy (KPA) of 2.87×, 1.75×, and 1.67× higher than existing ML-based attacks. We demonstrate the efficacy of INSIGHT by evaluating locked designs ranging from widely used academic suites (ISCAS-85, ITC-99) to larger designs, such as `MIPS`, Google `IBEX`, and `mor1kx` processors. We perform 2 practical case studies: (i) recovering secret keys of locking techniques used in a widely used commercial EDA tool (`Synopsys TestMAX`) and (ii) showcasing the ramifications of leaking the secret key for an image processing application. We will open-source our artifacts to foster research on developing learning resilient locking techniques.

1 Introduction

1.1 Security Threats in IC Supply Chain

Integrated circuits (ICs) serve as the workhorse of all electronic systems, from smartphones to artificial intelligence systems. The demand for high-performing systems has catalyzed technological scaling, making transistors miniaturized. As a result, manufacturing costs for ICs have increased substantially. For instance, the manufacturing costs for TSMC (a leading contract IC manufacturer) have surged 10×, jumping from four billion dollars (22nm node) [1] to 40 billion dollars (2nm node) [2]. Escalating manufacturing costs have forced leading chip (semiconductor) design companies (*e.g.,* Apple, NVIDIA) to transition to a globalized IC supply chain model. While chips are designed in-house, the fabrication, testing, and packaging of ICs are outsourced to off-shore and geographically disparate foundries, which could be (i) potentially untrustworthy and (ii) prone to geopolitical conflicts [3].

A U.S. government report revealed that the U.S. relies heavily on East Asia, which handles 75% of the world's IC production [4]. Meanwhile, the U.S. *only* manufactures 10% of the ICs, indicating a significant security threat. Several security concerns emanate due to the globalized landscape of manufacturing chips, such as hardware intellectual property (IP) piracy [5–10], reverse engineering [11, 12], IC counterfeiting [13, 14], and insertion of hardware Trojans [15–17]. In this work, we focus on the problem of hardware IP piracy.

1.2 Hardware IP Piracy

Hardware IP piracy poses a financial burden for IC design companies, causing losses of billions of dollars. A U.S. Department of Justice report indicates that one IC design company lost around $8.75 billion due to IP theft [18]. Furthermore, IP theft by nation-state adversaries has significant ramifications on national security. For example, in 2009, attackers gained unauthorized access to sensitive information on the F-35 fighter jet, compromising its advanced capabilities and highlighting the risks of hardware IP piracy [19].

Researchers have proposed countermeasures against hardware IP piracy—three prominent examples are logic locking [20], IC camouflaging [11], and split manufacturing [21]. Logic locking protects the hardware IP from all the untrustworthy entities in the IC supply chain [22], *i.e.,* foundry, test-

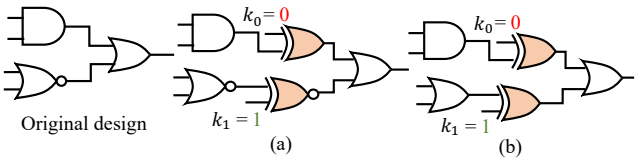

Figure 1: (a) Logic locking and (b) TRLL-locked design [24].

ing, and end-user, unlike IC camouflaging and split manufacturing. Logic locking has attracted attention from academia, government, and commercial entities. For instance, the Defense Advanced Research Projects Agency (DARPA) is investing in several initiatives [23] to thwart hardware IP piracy.

1.3 Logic Locking for Hardware IP Protection

Logic locking modifies the original design by inserting additional logic, *i.e., key-gates* controlled by a secret key (Figure 1(a)). The secret key is stored in a tamper-proof memory and programmed by a trusted facility (*e.g.,* an IC design house) *after* the fabrication and testing of ICs. Inserting key-gates results in additional inputs, *i.e., key-inputs*. The locked design functions correctly after applying the correct key, while an incorrect key produces corrupted outputs. *Logic locking is analogous to a password protection mechanism protecting the hardware IP using a password, i.e., a secret key.*

DARPA is proactively funding the research and development of secure logic locking techniques through programs such as the Automatic Implementation of Secure Silicon (AISS) [23], Structured Array Hardware for Automatically Realized Applications (SAHARA) [25], and Efficient Cross-Layered IP Protection Scheme (ECLIPSE) [26]. Besides, leading electronic design automation companies such as Synopsys and Mentor Graphics have integrated logic locking in their tools, *i.e.,* TestMAX [27] and TrustChain platform [28].

Although there have been 300+ papers in logic locking [22,29], over the last 5 years, researchers have focused on developing locking techniques resilient to machine learning (ML)-based attacks, *which is also the scope of our work.*

1.4 ML-based Attacks on Logic Locking

ML-based attacks identify and exploit the structural and functional hints in the hardware implementation of locked designs to recover the secret key [30–34]. These attacks use different approaches, such as unsupervised learning [32], graph neural networks (GNNs) [31,33], and random forest [30].

Limitations of Existing Attacks. Existing ML-based attacks: (i) operate as a black-box, *i.e.,* do not provide any explanations regarding the failure of attacks, (ii) do not consider industry-adopted locking techniques, and (iii) are not broadly applicable, *i.e.,* evaluate the security (predict the secret key) of a given locking technique and do not apply to different locking techniques. These limitations also compromise the evaluation methodology and heuristics to develop and benchmark learning resilient locking techniques. In our work, we question the security of learning resilient locking techniques by overcoming the aforementioned limitations.

1.5 Our Goals and Contributions

We assume the role of a practical attacker and aim to recover the secret key from several unbroken and industrially adopted locking techniques. These techniques involve various algorithms, such as (i) XOR/XNOR-based locking [24,35], (ii) adversarial learning [36], (iii) multiplexer (MUX)-based locking [37], and (iv) adversarial sample generation [38]. Hence, there is a need to develop an attack that is broadly applicable and recovers the secret key by evaluating the hardware implementation of learning resilient locking techniques.

However, numerous obstacles exist to developing an attack that has broad applicability. **First**, as an attacker, we only have access to the underlying locked design with Boolean logic gates and wires; it is computationally challenging to examine each substructure in the locked design and ascertain the role played by the substructure in recovering the secret key. **Second**, the locking techniques considered in this work follow different algorithms to thwart learning-based attacks; developing a broadly applicable attack encompassing several techniques is challenging. **Finally**, it is challenging to obtain suitable/relevant explanations and use them to enhance the efficacy of the attack in recovering the secret key.

We address the abovementioned obstacles and develop a practical attack, INSIGHT, using explainable ML. Researchers have used explainable ML for malware detection [39–41], ML security [42], and network security [43], and explainability has provided insights into the decision-making process of ML models, making their outputs understandable to humans. Furthermore, GNNs are suitable for Boolean logic designs since circuits are best represented as graphs [44,45]. Therefore, we utilize GNNs for our work and improve our attack significantly by using explainable GNNs (or explainers).

However, utilizing explainers to develop an attack is not straightforward, and several challenges exist in developing a practical attack: ① selecting a suitable explainer, *i.e.,* choosing an appropriate explainer for recovering the secret key of locked designs, ② identifying vulnerabilities, *i.e.,* finding exploitable hints (structural/functional), ③ attacking practical designs, *i.e.,* evaluating the security of logic-synthesized designs, ④ tackling unique graph representations, *i.e.,* recovering secret from non-XOR/XNOR/MUX key-gates, and ⑤ insufficient training datasets, *i.e.,* attacking locked designs having limited (or no) training samples.

We overcome challenge ① of selecting a suitable explainer by evaluating state-of-the-art explainers (§4.3). We overcome challenge ② of identifying structural vulnerabilities (hints) in locked designs by analyzing GNN explanations and modifying our problem modeling (§4.4). For challenge ③ of attack-

ing practical locked designs, we use the explanations from the explainer and improve the architecture of the GNN by incorporating attention (§4.5). To enable the attack for ④ unique graph representations, *i.e.,* different key-gates, we perform local and global graph transformations and modify the attack pipeline to account for other key-gates (§4.5). Finally, we perform data augmentation and follow semi-supervised learning to attack locked designs with ⑤ insufficient training datasets (§4.6). Our primary **contributions** are as follows.

- We develop an explainability-guided GNN-based attack (INSIGHT) that recovers secret keys from the hardware implementation of 7 unbroken locking techniques. To the best of our knowledge, our work is the **first** to use explainable GNN to develop a successful attack in semiconductor supply chain security (§4).
- We showcase the efficacy and applicability of INSIGHT on 7 unbroken locking techniques. These techniques are published at premier EDA and security venues and are yet unbroken. In fact, **2 of the locking techniques are integrated into `Synopsys TestMAX`**, a widely used EDA tool in the semiconductor industry. INSIGHT achieves an improved accuracy of 1.75×, 2.87×, and 1.67× compared to existing open-source attacks OMLA, SCOPE, and MuxLink (§5).
- We experiment with designs from the widely used ISCAS-85, ITC-99, and EPFL academic suites to open-source designs such as the Stanford `MIPS` processor [46] (≈23k gates), Google `IBEX` processor [47] (≈18k gates), DARPA Common Evaluation Platform `GPS` [48] (≈193k gates), and `mor1kx` processor [49] (≈158k gates). We experiment with different key-sizes and synthesis settings, demonstrating scalability and broad applicability (§5).
- We perform 2 practical case studies. We showcase the efficacy of INSIGHT on designs locked using `Synopsys TestMAX` [50] (§5.5) and illustrate the ramifications of secret key leakage for an image processing application (§5.6).
- We mention the findings provided by INSIGHT (§5.4) and discuss potential countermeasures that IC designers can utilize to strengthen the locking techniques (§6.3).

2 Background and Preliminaries

We initially describe machine learning (ML)-attack resilient logic locking techniques (§2.1). Next, we discuss existing ML-based attacks on logic locking (§2.2) and their limitations (§2.3). Finally, we briefly discuss graph neural networks (GNNs), explainable GNNs, and key definitions (§2.4).

2.1 ML-attack Resilient Logic Locking

Researchers proposed various locking techniques in response to ML-based attacks (§1.4). These techniques: (i) eliminate the correlation between key-value and key-gate, (ii) do not depend on logic synthesis-based transformations, and (iii) replace inverters in the design with key-gates (XOR/XNOR/-MUX). For our work, we chose 7 unbroken locking techniques, including **2 industry-adopted techniques.**

UNSAIL [38] inserts key-gates to mitigate ML-based attacks that exploit hints from the design structure to resolve structural transformations caused by logic synthesis [30]. **TRLL** [24] inserts XOR/XNOR-based key-gates randomly, ensuring no correlation between the type of key-gate and the key-bit (Figure 1(b)). **TRLL+** [35] improves `TRLL` for designs with limited inverters and minimizes the number of correct keys. **TroMUX** [37] randomly inserts MUX key-gates to thwart ML-based attacks [32, 33]. **RGLock** [51] replaces XOR/XNOR gates with modified XOR/XNOR gates. **ALMOST** [36] uses adversarial learning, and **SimLL** [52] inserts MUX key-gates between logic gates, showcasing functional similarity to thwart ML-based attacks.

Apart from being unbroken, the above-mentioned locking techniques claim at least one of the following properties: (i) <=50% key-prediction accuracy (equivalent to random guess) against ML-based attacks, (ii) do not depend on logic synthesis-based transformations to improve security, and (iii) do not reveal the secret key through the presence of structural and functional hints.

Researchers evaluate the security of the aforementioned locking techniques using **key-prediction accuracy (KPA)**. KPA is defined as the percentage of correctly recovered key-bits, *i.e.,* $KPA = |Kc|/|K| * 100$, where $|Kc|$ is the number of correct key-bits and $|K|$ is the key-size. We use the **KPA metric** to evaluate the efficacy of INSIGHT (§5.2 and §5.3).

2.2 Existing ML Attacks on Logic Locking

SAIL [30] is an ML-based attack on X(N)OR-based locking. It converts the locked design to a vector format consisting of the structural information (connectivity between logic gates) and gate-types of the logic gates around the key-gate. SAIL uses a neural network to predict if the key-gates have undergone changes due to logic synthesis and restores any changes that might have occurred. Finally, SAIL predicts the secret key-value upon reverting the post-synthesis modification. **OMLA** [31] leverages GNN-based subgraph classification to recover the secret key-value in X(N)OR-based locking. It converts the locked design to a graph and extracts subgraphs around the key-gate. Next, OMLA uses GNN to exploit the structural and functional hints from the extracted subgraphs to predict the secret key. **SnapShot** [34] uses a convolutional neural network (CNN) to recover the secret key in X(N)OR-based locking. It converts the locked design to a vector format and extracts structural features (*e.g.,* path depth, fan-out) from the locality around key-gates. Based on the extracted features and locality, CNN predicts the secret key. **SCOPE** [32] uses unsupervised learning and exploits hints (*e.g.,* area) to recover the secret key in multiplexer (MUX)-based locking. It exploits the changes in the locked design when a single key-bit value is hard-coded and predicts each key-input (one at a time) based

Table 1: Distinctions and advantages of INSIGHT compared to existing ML/GNN-based attacks.

Attack	Task	Attacks industry-adopted locking techniques	Key-gate types	Explainer insights	Adaptability to new techniques	Applicable to logic-synthesized designs
SAIL [30] (2021)	Neural network-based classification	✗	X(N)OR/MUX	✗	✗	✓
SnapShot [34] (2021)	CNN-based classification	✗	X(N)OR	✗	✗	✓
OMLA [31] (2021)	GNN-based subgraph classification	✗	X(N)OR	✗	✗	✓
SCOPE [32] (2021)	Unsupervised learning	✗	MUX	✗	✗	✓
MuxLink [33] (2022)	GNN-based link prediction	✗	MUX	✗	✗	✗
INSIGHT (This Work)	Explainability-guided GNN-based node classification	✓	X(N)OR/MUX/ (N)AND/(N)OR	✓	✓	✓

on the difference of synthesis-based hints when the key is 0 and 1. **MuxLink** [33] leverages GNN-based link prediction to recover the secret key in MUX-based locking. It extracts the subgraph (neighborhood) around the input nets of MUX key-gates, considering the correct (incorrect) connection as a positive (negative) link. It extracts structural and functional hints from the subgraph and uses GNN to perform binary classification on the extracted subgraph to predict the correct connections (or secret key).

2.3 Limitations of Existing Attacks

Existing ML-based attacks lack in the following aspects. **Firstly,** the aforementioned attacks operate as a black-box, *i.e.,* provide only KPA as a result and do not provide explanations regarding the success/failure of the attack. As a result, these attacks cannot be strategically improved to evaluate the security of new/unbroken locking techniques. For instance, OMLA obtains a KPA of 49.97% for the unbroken locking techniques. In contrast, INSIGHT utilizes explainable GNN to improve the attack strategically achieving a KPA of 87.30% for the aforementioned locking techniques.

Secondly, existing ML-based attacks do not evaluate industry-adopted locking techniques (`TRLL` [24] and `TRLL+` [35]). These techniques are integrated into an industry-adopted and widely used semiconductor EDA tool, `Synopsys TestMAX`. In contrast, INSIGHT achieves a KPA of 88.76% on `TRLL` [24] and `TRLL+` [35] locking techniques.

Finally, existing ML-based attacks are not broadly applicable to different locking techniques. The attacks are proposed to (i) evaluate the security of either 1 or 2 locking techniques and (ii) apply to either X(N)OR-based locking or MUX-based locking techniques. Unlike existing attacks, INSIGHT recovers secret keys in 7 unbroken logic locking techniques consisting of 7 different types of key-gates, *i.e.,* X(N)OR/(N)AND/(N)OR and MUX (Table 1). Moreover, INSIGHT evaluates the locking techniques that utilize different key-gate insertion algorithms such as (i) random XOR/XNOR locking [24, 35], (ii) adversarial learning [36], (iii) random MUX-based locking [37], (iv) adversarial sample generation [38] and (v) functionality similar locking [52].

2.4 (Explainable) Graph Neural Networks

GNNs perform inference (predictions) on graph-structured data and demonstrate significant performance in applications such as learning patterns in protein interactions [53], recommender systems [54, 55], and computer security [56, 57]. GNNs can (i) handle irregular and structured data and (ii) incorporate topological information from the graph into the learning process. GNNs are used for (i) node classification, (ii) link prediction, and (iii) graph classification. **Explainable GNNs** make predictions of the model transparent and interpretable by providing human-understandable explanations. They explain predictions through the importance of features, nodes, and edges in the graph. Explanations can help to build trust in the model and facilitate the adoption of GNNs in real-world applications. Next, we provide some definitions.

Substructures (or subgraphs) are the local neighborhood around to-be-classified nodes. **Subgraph extraction** extracts the local neighborhood of unlabeled to-be-classified nodes. **Node classification** classifies the unknown nodes based on the features of the nodes in their local neighborhood. **Neighborhood-based node classification** uses subgraphs around to-be-classified nodes for classification instead of individual nodes. It captures structural information from the local neighborhood of the unlabeled node to predict node labels.

3 Threat Model

Our work considers an oracle-less threat model widely used in the logic locking literature [5–10, 22]. Next, we discuss the notations and outline the attacker's location, resources available to the attacker, and the attacker's goal.

Notations. A combinational design $\mathcal{D}_{orig}$ is represented as a directed acyclic graph with x primary inputs (PI) and y primary outputs (PO), where $PI = \{0,1\}^x$ and $PO = \{0,1\}^y$. $\mathcal{D}_{orig}$ implements the Boolean function $F_{orig} : PI \rightarrow PO$. $\mathcal{D}_{orig}$ is locked using a locking technique $\mathcal{L}$ with a secret key $\mathtt{K}$, resulting in a locked design $\mathcal{D}_{lock}$ consisting of additional key-inputs $KI = \{KI_0, KI_1, ..., KI_{|K|-1}\}$, where $KI = \{0,1\}^{|K|}$ and $|K|$ is the cardinality of KI, *i.e.,* key-size. The locked design $\mathcal{D}_{lock}$ implements the Boolean function $F_{lock} : PI \times KI \rightarrow O$.

Note that $\mathcal{D}_{lock}$ is functionally equivalent to $\mathcal{D}_{orig}$ only upon loading the correct secret key (K), *i.e.,* $F_{orig}(j) = F_{lock}(j, \mathtt{K})$, $\forall j \in PI$. $\mathcal{D}_{lock}$ is converted to a Graphics Database System II (GDSII)* represented as $\mathcal{D}_{lock}^{GDS}$ and sent to a potentially untrustworthy foundry for fabrication. The foundry converts $\mathcal{D}_{lock}^{GDS}$ to a chip $\mathbb{D}_{lock}$. $\mathbb{D}_{lock}$ is tested, packaged, and sent to a trustworthy facility (*e.g.,* design house), which loads the correct key in the tamper-proof memory and obtains an activated chip $\mathbb{D}_{orc}$. The activated chip is also known as an oracle in the logic-locking community. Additionally, $\mathcal{A}^{\mathbb{T}}$ represents an attacker $\mathcal{A}$ using technique $\mathbb{T}$ to recover the secret key (K).

Attacker location. We assume that the attacker $\mathcal{A}$ is located in an untrustworthy foundry. A foundry could be potentially untrustworthy since (i) most chip design companies (*e.g.,* Apple, NVIDIA) outsource the fabrication of chips to off-shore foundries [58], and (ii) the U.S. relies heavily on overseas foundries for its manufacturing needs [4, 59] representing a pernicious security threat (§1.1,§1.2).

Attacker resources. The resources available are as follows.

- Attacker $\mathcal{A}$ has access to reverse-engineering tools [60] and can reverse-engineer GDSII of a locked design ($\mathcal{D}_{lock}^{GDS}$) to extract the reverse-engineered gate-level netlist ($\mathcal{D}_{lock}$).
- We consider an oracle-less threat model, *i.e.,* the attacker has no access to the functionally activated chip/oracle ($\mathbb{D}_{orc}$) for the following reasons.
  - Firstly, having simultaneous access to GDSII ($\mathcal{D}_{lock}^{GDS}$) and the activated chip/oracle ($\mathbb{D}_{orc}$) may not be practical. This limitation arises because an attacker is located in an untrustworthy foundry, but $\mathbb{D}_{orc}$ is available only after the fabrication, testing, and activation of the chip (performed by loading the correct key onto the memory).
  - Secondly, we assume scan-chain† protection techniques in $\mathcal{D}_{lock}$; these techniques (*e.g.,* DisORC [24], scan-chain locking [61]) either disable or protect the scan-chain access. For example, DisORC [24] corrupts the outputs of an oracle ($\mathbb{D}_{orc}$) whenever a potential attack utilizing a scan chain is detected. Since the outputs of $\mathbb{D}_{orc}$ are corrupted, the attacker can no longer rely on an oracle to obtain correct input/output pairs, thus preventing (restricting) the oracle-guided attacks. Scan-chain locking techniques [61] lock selected flip-flops to restrict the controllability and observability of the scan-chain. Restricting the controllability and observability of the scan-chain hinders an attacker's ability to access and control the internal states of the scan flip-flops. Consequently, scan-chain locking restricts oracle-guided attacks.
  - Thirdly, the oracle-guided threat model is less challenging than the oracle-less threat model, especially since there is no access to $\mathbb{D}_{orc}$. If chips are manufactured for military purposes [62], it is unlikely that an attacker in the foundry can access an activated chip/oracle ($\mathbb{D}_{orc}$).
  - Finally, we consider the same threat model (oracle-less) as the targeted locking techniques (TRLL [24], TRLL+ [35], UNSAIL [38], RGLock [51], TroMUX [37], ALMOST [36] and SimLL [52]). These techniques mitigate attacks that do not have access to an oracle.
- Attacker $\mathcal{A}$ knows the locking technique implemented in the locked design. In addition, $\mathcal{A}$ can (i) identify key-inputs (*KIs*) and (ii) detect key-gates in the reverse-engineered locked design $\mathcal{D}_{lock}$. To identify *KIs*, $\mathcal{A}$ can trace the connections from the tamper-proof memory (TPM) to the chip, as the secret key is stored in the TPM. Furthermore, $\mathcal{A}$ can detect the key-gates by identifying the logic gates connected to key-inputs. These assumptions are consistent with *Kerckhoff's* principle, which asserts that the security of a system should rely exclusively on the secrecy of the secret key, K, and not on the secrecy of other system aspects [63].

Attacker goal. The goal of attacker $\mathcal{A}$ is to recover the secret key K from the GDSII of a locked design, obtaining the recovered design $\mathcal{D}_{rec}$ and enabling IP piracy [5–10, 22].

4 INSIGHT

We explain why we use explainable machine learning (ML) to develop an attack (§4.1), followed by the problem modeling (§4.2). However, using explainers is not straightforward, and we face various challenges. We elaborate on these challenges and outline our solutions to overcome them (§4.3–§4.6). Finally, we discuss the overall architecture of INSIGHT (§4.7).

4.1 Why Explainable ML/GNN?

Recovering the secret key from unbroken locking techniques entails identifying structural and functional hints from the locked design. To develop a practical attack, an attacker requires feedback. Existing attacks utilize ML (GNN) models as a black-box and (i) perform feature engineering, (ii) tune the model parameters, and (iii) improve the model architecture based on human interpretation. However, a systematic approach requires understanding the inner workings of the trained ML model and making informed decisions. To that end, using explainable ML in the attack pipeline could aid an attacker in improving the attack systematically. INSIGHT uses explainable GNN to understand the reasons behind the incorrect predictions of the attack on targeted locking techniques. Explainable GNN provides explanations of the important nodes and features influencing the predictions of GNN-based node classification. Using the explanations obtained by explainable GNN, we determine the important nodes/features that help improve our attack. Without an explainable GNN, it would be difficult to ascertain the factors (important features and nodes in the graph) that lead to incorrect predictions of the attack (as it requires an exhaustive search among features and nodes around the key-gate).

*A database file used to represent IC layout information.

†Scan-chain access converts flip-flops into pseudo-primary inputs and outputs, enabling the attacker to access and control the internal states. Assuming scan chain access represents the best-case scenario for an attacker.

4.2 Problem Modeling

Problem Definition. Given a locked design D_{lock} having key-size $|K|$, INSIGHT aims to recover the secret key K of targeted locking techniques using explainable GNN.

Preliminary Problem Modeling. We map the problem of key prediction to GNN-based node classification. Node classification aims to classify the *key-gates* or *key-inputs* (KI_i) to either a key-value of {0} or {1}. Recall that GNN-based node classification classifies unknown nodes based on the features of the nodes in their local neighborhood; therefore, we perform neighborhood-based node classification (§2.4). Next, we discuss the 4 steps in detail.

(1) Convert to Graph. The locked design D_{lock} is converted to a graph $G = (V, E)$ with nodes V and edges E, where nodes (edges) represent the Boolean logic gates (wires). $G = (V, E)$ is provided as an input to subgraph extraction.

(2) Subgraph Extraction. Subgraphs are extracted around all the key-gates with key-inputs $\{KI_0, KI_1, .., KI_{|K|-1}\}$ for r hop-size, where r is user-defined and design specific. Consider an example of extracting the subgraph around key-gate KI_i in graph G with nodes $\{u_0, u_1, ...u_N\}$, where N is the number of nodes in G. The subgraph extraction step returns a subgraph $G'(V', E')$ where any node $v \in V'$ is at a hop-size of r (or less). After extracting their features, the subgraphs around key-gates are provided to GNN for node classification.

(3) Feature Extraction. We extract the following features for the nodes in subgraphs: (i) gate type, (ii) input degree (inp), (iii) distance of the node from the key-gate (DE), (iv) a (+/-) sign indicating if a node is located in the fan-in/fan-out of the key-gate (sign), (v) subgraph size (SS), (vi) output degree (out), and (vii) truth table of logic gates (TT). Feature (i) and (vii) captures the functionality of the node, while (ii), (iii), (iv), (v), and (vi) capture the structure of the nodes in the subgraph. The feature for subgraph G' is given as X', where x'_v corresponds to the feature of node $v \in V'$.

(4) Node classification aims to predict the key-value for all the key-inputs (key-gates), similar to OMLA. GNN classifies the subgraphs extracted around key-gates. For predicting the key-value for G', *i.e.,* the subgraph extracted around KI_i, the GNN returns p_i, *i.e.,* its corresponding class as: $p_i = g(G', X, '\sigma)$ where $p_i \in \{0, 1\}$, X' is the feature vector of G', g corresponds to GNN, and σ are trainable parameters of GNN (weights and bias). The key-value of KI_i is equal to p_i.

GNN. We leverage state-of-the-art GNN, *i.e.,* graph isomorphism network (GIN) [64], which is widely used and performs best for graph classification. Here, GNN performs neighborhood-based node classification for subgraphs extracted around the key-gates.

The preliminary problem modeling does not provide explanations that aid in (i) finding structural hints and (ii) improving the attack for targeted (unbroken) locking techniques.

Challenges. The challenges toward developing an explainability-guided GNN-based attack are (i) selecting a suitable explainer and (ii) inferring the explainer results to identify structural hints for targeted locking techniques. Next, we explain the challenges and our solutions in detail.

4.3 Selecting A Suitable Explainer

Since our attack aims to recover the secret key from the targeted locking techniques, it is necessary to understand the reasons behind the failure of existing ML-based attacks to identify the structural hints that aid in improving the attack.

Challenge (1). An explainable GNN must (i) be computationally efficient, *i.e.,* runtime should not be prohibitively large, and (ii) provide relevant explanations. Selecting a suitable explainer with these characteristics poses a key challenge.

Solution (1). To address challenge (1), we consider explainers that have demonstrated effectiveness in node classification tasks. We evaluate 4 state-of-the-art explainable GNNs—GNNExplainer [65], SubgraphX [66], ZORRO [67], and PGExplainer [68] renowned for their effectiveness in node classification tasks [69]. GNNExplainer and ZORRO provide explanations for **features and nodes** in the neighborhood of a given node, whereas PGExplainer provides explanations for **only nodes** in the neighborhood of a given node. SubgraphX provides information regarding the important subgraph, *i.e.,* the neighborhood of a given node. We provide the preliminary problem modeling (trained on TRLL-locked designs) as input to the explainers. We evaluate the relevancy of important features obtained from the explanations by temporarily removing the top feature (important nodes) from the dataset to observe the change in the model predictions. A significant change in predictions indicates the high importance of features (nodes).

Runtime. GNNExplainer and PGExplainer exhibit better computational efficiency than others. For example, the runtime of SubgraphX ($\approx$ 60 min) is 600$\times$ higher than GNNExplainer (6 s) and 1200$\times$ higher than PGExplainer when generating explanations for subgraphs with an average of 35 nodes. ZORRO has an acceptable runtime, *i.e.,* 58 s. Hence, we do not consider SubgraphX due to its large runtime.

Relevant feature explanations. Only GNNExplainer and ZORRO provide explanations for features. These explainers provide the importance scores for the features of preliminary problem modeling. The top feature returned by GNNExplainer is gate-type, and ZORRO is DE. Removing the gate-type feature reduces the key-prediction accuracy (KPA) of the preliminary model from 50.78% to 46.09%. Removing the DE feature reduces the KPA to 50.78%. These results indicate that removing the gate-type feature affects KPA more than removing DE, indicating higher importance for the gate-type feature. Hence, we do not consider ZORRO due to its non-relevant feature explanations.

Relevant node explanations. We evaluate the relevancy of nodes for GNNExplainer and PGExplainer. They both provide the importance scores of nodes in the subgraph around the key-gate. We consider the nodes with higher importance scores as

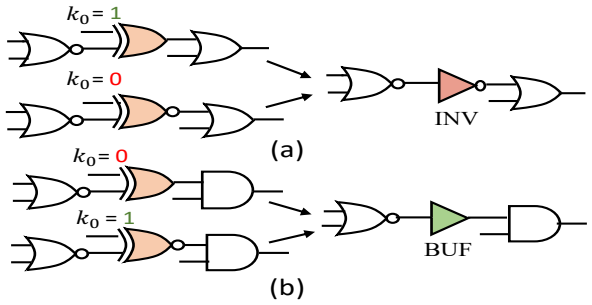

Figure 2: Mapping key-prediction problem to (a) inverter (INV) and (b) buffer (BUF) prediction problem.

important nodes. The KPA of preliminary problem modeling decreases from 54.68% to 46.87% for GNNExplainer and to 51.56% for PGExplainer by removing the important nodes returned by the corresponding explainers. Results indicate that removing important nodes returned by GNNExplainer affects KPA more than the important nodes returned by PGExplainer. Hence, the important node explanations returned by GNNExplainer are more relevant.

In conclusion, GNNExplainer is a more suitable explainer for INSIGHT due to its (i) computational efficiency and (ii) ability to provide relevant explanations. Consequently, we utilize GNNExplainer in our work.[‡]

4.4 Identifying Structural Hints

Challenge ②. GNNExplainer provides explanations for extracted subgraphs of the targeted locking techniques (§4.3). The preliminary problem modeling obtains a KPA of 50.52%. The next challenge is identifying the reasons behind the failure of the preliminary problem modeling (§4.2). Understanding the reasons can help in improving the performance (KPA) of the attack. Next, we analyze the explainer results.

Failure of Preliminary Problem Modeling. We analyze the explainer results and observe that the preliminary problem modeling (§4.2) trains the same substructure (neighborhood around key-gate) for two key-values (classes) (Figure 2).

Example 1. Consider Figure 2(a); even though the logic gates in the neighborhood of the key-gates are identical, the key-input values are different. Such training samples create ambiguity for the ML model, resulting in lower KPA.

Identification of Common Structural Hints. Example 2. Consider Figure 2(a) for the TRLL-locked design; even though the key-input values for both substructures are different, both key-gates transform into an inverter upon applying the correct key, *i.e.,* XOR key-gate with key-input of "1" and XNOR key-gate with key-input of "0." Thus, if a GNN model were to train both designs with the same neighborhood, *i.e.,* substructure around the key-gate for inverter prediction instead of key-values, the ambiguity of the GNN model would be discarded.

[‡]Please refer to Appendix A.1 for further details on GNNExplainer.

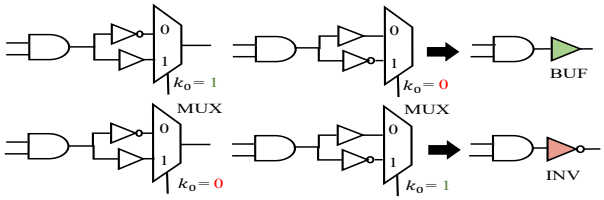

Figure 3: Example of transforming key-prediction for TroMUX [37] to inverter/buffer prediction problem.

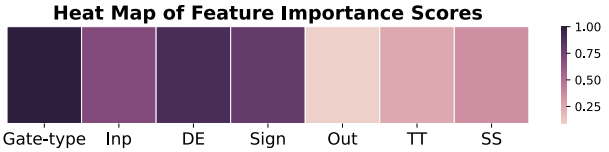

Figure 4: Heat map of importance scores of features of INSIGHT, *i.e.,* gate-type, inp, sign, out, TT, and SS.

The same is true for Figure 2(b), where both the substructures can be trained for buffer prediction.

In TRLL [24], TRLL+ [35], UNSAIL [38], and ALMOST [36], the key-gates map to either a buffer (inverter) based on key-input and key-gates (XOR/XNOR). In TroMUX [37], an inverted and non-inverted logic of the locked wire is fed to the MUX-based key-gate. This construction can also be converted to an inverter/buffer prediction problem (Figure 3). The same is also true for RGLock [51]. Thus, recovering the key in the aforementioned locking techniques can be mapped to an inverter/buffer prediction problem.

Solution ②. To address challenge ②, we propose advanced problem modeling that classifies the *key-gates* in the locked design as an inverter (INV) or buffer (BUF). We map the inverter/buffer prediction to the GNN-based node classification problem as follows. The first two steps, *i.e.,* (1) conversion of locked design to graph and (2) extraction of the subgraph, remain the same (§4.2); however, the feature extraction and modified node classification are explained next.

Feature Extraction. In advanced problem modeling, we refine the feature selection by conducting an explainer analysis on 7 features (§4.2). We observe that the features (i) gate-type, (ii) inp, (iii) DE, and (iv) sign have higher importance compared to the remaining features (Figure 4). Hence, we utilize these 4 features in advanced problem modeling.

Modified Node Classification aims to predict whether the *key-gate* maps to INV/BUF. The GNN classifies the subgraphs extracted around key-gates as: $p_i = g(G', X', \sigma)$ where, $p_i \in \{0, 1\}$. The output class returned by GNN maps to an INV/BUF, *i.e.,* $p_i = 0$ for an INV and $p_i = 1$ for a BUF.

Post-processing. We recover the key-values by utilizing the (i) predictions of GNN-based node classification and (ii) type of the key-gate, *i.e.,* (X(N)OR/MUX/(N)AND/(N)OR) (Table 2). For example, if the key-gate is XOR, and GNN predicts INV (BUF), the key-value is inferred as 1 (0) (Figure 5 (a)).

Table 2: Mapping of key-gate to INV, BUF, constant–0 (const–0), and constant–1 (const–1) based on key-value.

Key-value	XOR	XNOR	AND	NAND	NOR	OR
0	BUF	INV	const–0	const–1	INV	BUF
1	INV	BUF	BUF	INV	const–0	const–1

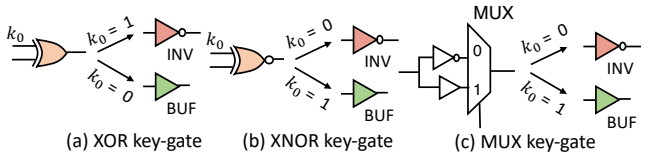

Figure 5: Mapping between key-gate, key-value, and GNN prediction (INV/BUF) for X(N)OR and MUX key-gates.

Similarly, if the key-gate is XNOR, and GNN predicts INV (BUF), the key-value is inferred as 0 (1) (Figure 5 (b)). If the key-gate is MUX, the key-value is inferred based on the connections of INV and BUF to the MUX. If GNN predicts INV, and INV is connected to the first (second) input of MUX, the key-value is inferred as 0 (1) (Figure 5 (c)).

In conclusion, the advanced problem modeling successfully predicts the secret key (KPA of **99.52**%) for designs locked with TRLL (Table 3).

4.5 Attacking Logic Synthesized Designs

Challenge ③. The semiconductor industry performs logic synthesis[§] to reduce the area, power, and delay of circuits. The advanced problem modeling (§4.4) reduces KPA (70%) for synthesized TRLL-locked designs. The KPA for non-synthesized designs from the same benchmark suite is 99.52% (Table 3). Modifying the attack to improve KPA for synthesized locked designs is challenging due to the different graph representations in logic-synthesized designs.

Solution ③. Using our advanced problem modeling, we input the trained model on synthesized TRLL-locked designs to GNNExplainer. We observe that the nodes in the subgraph, *i.e.,* the logic gates in the neighborhood of the key-gate contribute with different importance to the prediction. As manually inferring the explainer results and providing the important nodes to the attack is time-consuming, we improve the architecture of GNN by incorporating an attention layer. The attention layer assigns varying degrees of importance to the nodes in the subgraph using learnable weights [70]. The attention weight $\alpha_{vu}^{(t)}$ measures the strength of connectivity between the node $v \in V'$ and u in a graph G' for the t^{th} layer of GNN as follows.

$$\alpha_{vu}^{t} = \text{softmax}\left(f(a^{\top}[W^{(t)}h_v^{(t-1)}||W^{(t)}h_u^{(t-1)}])\right) \quad (1)$$

where $f(\cdot)$ is a LeakyReLU activation function, $h^{(t-1)}$ is output of $(t-1)^{th}$ GNN layer with $h_v^{(0)} = x'_v$, where $x'_v \in X'$, $W^{(t)}$ is a learnable weight matrix, and a is vector of learnable parameters. Thus, the modified GNN with an attention layer (i) captures relevant information (important nodes) from the local neighborhood of the key-gate without the need for GNNExplainer, and (ii) reduces the manual effort of identifying important nodes using GNNExplainer. Incorporating attention increases KPA by 10% for synthesized designs (Figure 6).

[§]A process transforming a behavioral chip description to an optimized hardware implementation, *i.e.,* a netlist consisting of Boolean logic gates.

Table 3: Key-prediction accuracy (KPA) for TRLL-locked designs ($|K| = 128$) using advanced problem modeling.

Design	b14_C	b15_C	b17_C	b20_C	b21_C	b22_C
Solution ②	99.78	99.68	99.06	99.53	99.53	99.53

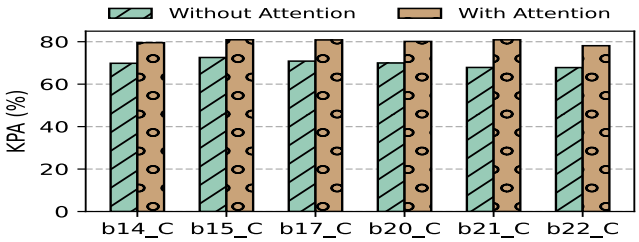

Figure 6: Improvement in key-prediction accuracy (KPA) for TRLL-locked designs for $|K| = 128$ with and without attention.

Challenge ④. Depending on optimization techniques (*e.g.,* minimizing area, power), logic synthesis tools may generate designs consisting of non-XOR/XNOR/MUX-based key-gates. We observe the KPA for our advanced problem modeling being limited for such designs. Thus, INSIGHT needs to be extended to tackle non-XOR/XNOR/MUX-based key-gates.

Solution ④. To address challenge ④, we first perform graph transformations to maximize the number of XOR/XNOR-based key-gates. We use a commercial logic synthesis tool (*e.g.,* Synopsys Design Compiler) with different optimization commands to generate structurally disparate (and functionally equivalent) locked designs. Doing so increases the number of XOR/XNOR-based key-gates in the locked design. However, even after these graph-based transformations, we observe non-XOR/XNOR-based key-gates. To that end, we extend the GNN prediction classes for other type of key-gates (Table 2). Considering key-values '1' and '0', the key-gates (AND/NAND/NOR/OR) either map to INV, BUF, constant–1, or constant–0. Thus, we introduce two additional classes to the prediction tasks, *i.e.,* constant–1 and constant–0. Incorporating the above-mentioned steps improves KPA by 1.53× (on average) for synthesized ALMOST designs (Table 4).

4.6 Lack (or Scarcity) of Training Data

Challenge ⑤. To facilitate (i) reduction in time-to-market, (ii) lower economic costs, and (iii) easier integration of chips, the semiconductor industry follows the concept of design-reuse [71]. Thus, an attacker is assumed to have access to

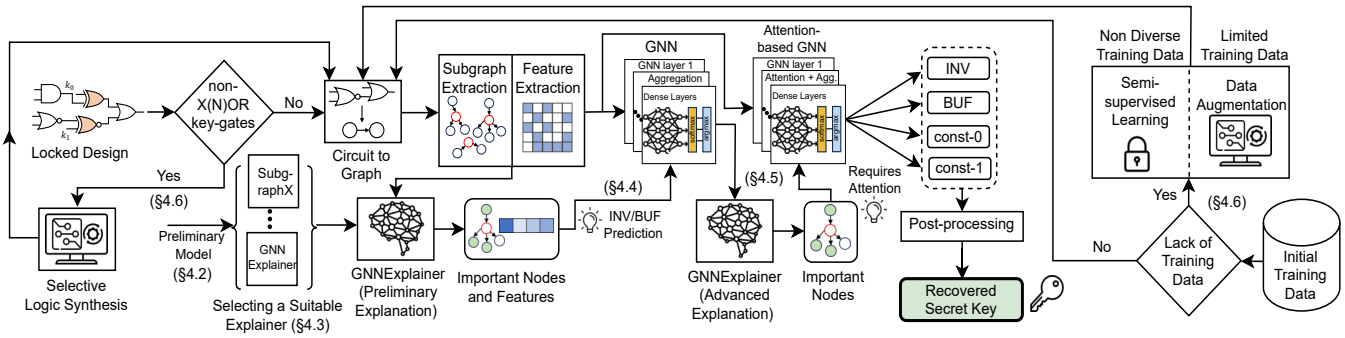

Figure 7: Architecture of INSIGHT.

Solution ⑤	76.56	82.79	71.87	72.56	74.83
Improvement (×)	1.11×	1.15×	1.08×	1.09×	1.10×

datasets consisting of diverse examples to effectively capture the underlying patterns and relationships in the (graph) data. This is analogous to a library of publicly available designs having similar graph structures compared to the locked design under attack. However, an attacker faces considerable challenges when they have limited access to training data owing to a (i) closed-source (proprietary) locking technique and (ii) limited diversity of subgraphs in the training dataset. Thus, we utilize two techniques, *i.e.,* data augmentation and semi-supervised learning, to increase the training samples.

Solution ⑤. To address challenge ⑤, we propose data augmentation and semi-supervised learning. **Data Augmentation** augments training samples by graph transformations, *i.e.,* logic synthesis using logic optimization procedures (known as synthesis recipes). This step increases the overall training samples, which vary in structure, *i.e.,* graph-based representation. For instance, the GNN model trained using the circuit library approach showed lower KPA for synthesized RGLock designs. Data augmentation increases the KPA by 1.11× (Table 5). **Semi-supervised Learning** can be used by an attacker having access *only* to the locked design and *no/limited access to a circuit library*. This corresponds to cases when attacking a newly developed/unknown hardware IP. An attacker adopts semi-supervised learning and locks other (unprotected) logic gates in the design to generate training samples. Semi-supervised learning increases the KPA by 1.29× (from 67.14% to 86.94%) for the TroMUX-locked design, AES, compared to training on a circuit library, *i.e.,* designs from the ITC-99 benchmark suite.

4.7 Final Architecture (Putting it all Together)

We illustrate and describe the final architecture of INSIGHT in Figure 7 and Algorithm 1. Given a locked design D_{lock} with $|K|$ *key-gates*, INSIGHT recovers the secret key using explainable GNN. We use GNNExplainer to improve our attack

since it provides relevant explanations and is computationally efficient (§4.3). Next, as per the explanations from GNNExplainer, we map the key-prediction problem to INV/BUF prediction (§4.4). To attack logic-synthesized designs, we utilize another insight from GNNExplainer, highlighting the varied importance of nodes (in the neighborhood of *key-gates*) toward predictions. Consequently, we improve the attack by incorporating attention (§4.5). If the locked design consists of non-X(N)OR-based key-gates, we perform graph transformations, *i.e.,* logic synthesis, to increase the number of X(N)OR key-gates (lines 8–9 in Algorithm 1) and extend the GNN prediction classes for different types of key-gates (Table 2).

If an attacker has access to a circuit library ($\mathbb{C}_{lib}$), they generate the training dataset using a circuit library (lines 10–11).[¶] If there is no access to a circuit library, we lock the unprotected logic gates in the locked design to generate training samples, *i.e.,* semi-supervised learning (lines 12–13) (§4.6). If a limited training dataset exists, we perform graph transformations to increase the number of training samples, *i.e.,* data augmentation (lines 14–15) (§4.6). Next, we convert the designs to graphs (line 16) and extract the (i) subgraph (neighborhood of *key-gates*) and (ii) features of the training and testing samples (line 17) (§4.2). We then train the modified GNN with the training subgraphs and obtain a trained GNN model (T_{GNN}) (line 18). Upon obtaining the trained GNN model, we test the GNN for testing subgraphs ($Test_{subgraphs}$) and obtain GNN predictions (y_{test}), *i.e.,* INV/BUF prediction (line 19). The inference algorithm of attention-based GNN is mentioned in lines 1–7. Upon obtaining the GNN predictions, (i) we pass the predictions (y_{test}), subgraphs of testing data ($Test_{subgraphs}$), and trained GNN model (T_{GNN}) through GNNExplainer to obtain corresponding explanations in terms of importance scores for features and nodes in the subgraph (line 20) and (ii) perform post-processing on the predictions (y_{test}) to obtain the secret key (K_{pred}) using the mapping between INV/BUF prediction and key-gate types (line 21).[‖] The computational complexity of INSIGHT depends on all the aforementioned steps. It is non-trivial to derive the time complexity of INSIGHT due to the closed-source commercial logic synthesis algorithms utilized for graph transformations.[**]

5 Results

We outline our experimental setup (§5.1) and evaluate INSIGHT on 7 unbroken locking techniques (§5.2, §5.3). We perform experiments on designs from the ISCAS-85 and ITC-99 academic suites to open-source designs such as the Stanford `MIPS` processor [46], Google `IBEX` processor [47], DARPA Common Evaluation Platform (CEP) `GPS` [48], and `mor1kx` processor [49]. Finally, we perform 2 practical case studies: (i) recovering the secret key from designs locked using `Synopsys TestMAX`, a commercial, widely used EDA tool (§5.5), and (ii) showcasing the ramifications of leaking the secret key using an image processing application (§5.6).

5.1 Experimental Setup

Implementation Setup. We implement INSIGHT using *Python 3.7* (converting locked designs to graphs and post-processing of graph neural network (GNN) predictions), *PyTorch 1.12* (GNN-based node classification), and deep graph library (GNNExplainer). We perform experiments on a single compute node of AMD *EPYC Rome* CPU with 128 cores operating at 2.25GHz with 512GB RAM each. We use a graph isomorphism network as the baseline GNN architecture. It consists of 2 multilayer perceptron layers and 4 to 6 GNN layers (based on the dataset). Moreover, we implement a multi-head attention layer in GNN where the number of heads varies between 1 and 4 (based on the dataset). We set the batch size and hidden dimension to 128 and use a LeakyRelu activation function. We set the number of epochs to 100 and use the Adam optimizer with a learning rate 0.001.
Locking Techniques. We implement `TroMUX` and `RGLock` in *Python 3.7*, as the source codes are not publicly available. We received the binaries of `TRLL` and `TRLL+` from the authors. We received locked benchmarks from the authors of `ALMOST` [36] and `SimLL` [52]. Also, we obtain open-source benchmarks for `TroMUX` [72] and `UNSAIL` [73]. For experiments with `Synopsys TestMAX`, we use version `T-2022.03-SP5-4`.
Designs. We demonstrate the efficacy of INSIGHT on designs from ISCAS-85 [74], ITC-99 [75], and EPFL [76] benchmark suites widely used in the hardware design/security community. We conduct experiments on open-source designs such as the Stanford `MIPS` processor [46] (≈23k gates), Google `IBEX` processor [47] (≈18k gates), DARPA CEP `GPS` [48] (≈193k gates), `mor1kx` processor [49] (≈158k gates), crypto cores [77], `openMSP430` microcontroller [78], arithmetic designs, and an image-processing application [79]. These designs encompass a diverse range of IPs comprising processors, arithmetic designs, controllers, microcontrollers, crypto cores, a GPS core, and an image processing application (Gaussian blurring), widely used in hardware designs.

5.2 Evaluation of Locking Techniques

We evaluate the efficacy of INSIGHT using key-prediction accuracy (KPA) (§2.1). We compare the KPA with existing and open-source ML-based attacks [31, 32] for non-synthesized (Table 6) and synthesized (Table 7) locked designs.
Non-Synthesized Designs. Table 6 depicts the performance of INSIGHT with existing ML-based attacks for `TRLL`, `TRLL+`, `TroMUX`, and `RGLock`. INSIGHT achieves a significantly higher KPA than existing ML-based attacks, *i.e.,* our attack improves KPA by **2.96**×, **1.64**×, and **1.86**× than SCOPE, MuxLink, and OMLA. Notably, INSIGHT achieves a KPA of ≈ 100

[¶] The to-be-attacked locked design is not a part of the circuit library.
[‖] Refer to Appendix A.2 for integrating INSIGHT with LL techniques.
[**] Refer to Appendix A.3 for details on computational complexity.

Table 6: Efficacy (measured in KPA) of INSIGHT compared to existing ML-based attacks for **non-synthesized** designs. "–" indicates designs do not support locking for key-size ($|K|$) = 256. All numbers are in percentage and averaged across ten trials.

for TRLL. On average, INSIGHT achieves a KPA of 99.60%, 96.53%, 88.30%, and 79.48% for TRLL, TRLL+, TroMUX, and RGLock, respectively. In contrast, the KPA of OMLA is ≈ 50%, equivalent to a random guess. *Our results highlight that* INSIGHT *successfully recovers the secret keys for non-synthesized locked designs, indicating that the aforementioned techniques leak exploitable structural information.*

Synthesized Designs. Recall that the semiconductor industry performs logic synthesis to reduce the area/power/delay of circuits (§4.5). Hence, we perform security analysis on synthesized locked designs. Table 7 depicts the performance of INSIGHT on synthesized locked designs. INSIGHT improves KPA by **2.8**× and **1.56**× than SCOPE and OMLA. On average, INSIGHT achieves a KPA of 79.64%, 75.14%, 83.12%, and 74.78% for TRLL, TRLL+, TroMUX, and RGLock, respectively. Our results highlight that INSIGHT recovers the secret key for synthesized locked designs, whereas other ML-based attacks [31, 32] are severely limited. *In addition, our results indicate that the aforementioned techniques rely on synthesis-induced transformations to enhance security.*

Other Locking Techniques. We evaluate the security of ALMOST [36],UNSAIL [38], and SimLL [52]—these techniques claim security against ML-based attacks (§2.1). On average, INSIGHT achieves a KPA of 77.4% for ALMOST, 78.56% for UNSAIL, and 99.51% for SimLL (Table 8), indicating broad applicability across learning resilient locking techniques.

5.3 Analysis of INSIGHT

Effect of Graph Transformations. The underlying structure of the graph, *i.e.,* locked design changes with synthesis recipes.[††] Thus, we analyze the impact of synthesis recipes on the efficacy of INSIGHT. We fix the synthesis tool (widely used commercial EDA tool—Synopsys Design Compiler), locking technique as TRLL, and technology library as Nangate 45nm. Our results indicate that the differ-

[††] Sequence of optimization commands to minimize area/power/delay.

Table 8: Efficacy (KPA (%)) of INSIGHT on open-sourced ALMOST [36], UNSAIL [38], and SimLL [52] designs. "–" indicates designs are not open-sourced and publicly available.

ence between the average KPA for both synthesis recipes is negligible (refer to Table 13 in Appendix A.4 for results).

Scalability and Runtime. We analyze the impact of (i) key-size and (ii) design size on the attack runtime of INSIGHT (refer to Figure 9 in Appendix A.4 for results). The attack runtime increases with a negligible difference with an increase in key-size (64 to 256). In addition, INSIGHT is scalable to larger designs such as IBEX, mor1kx processor, and GPS; *i.e.,* the attack runtime on these designs (with an average of 123k gates) is 597.31 seconds. Note that INSIGHT performs inference on the subgraphs extracted around the key-gate. Thus, the runtime depends on the subgraph size rather than the design size. The training time for INSIGHT is: (i) 6 hours for circuit library-based training, (ii) 36 hours for samples generated using data augmentation, and (iii) 8 hours for semi-supervised learning. These numbers (training and attack runtime) show that an attacker in the foundry can perform this attack, given that the time allotted to foundries for fabrication is 3 months [16].

5.4 Findings of INSIGHT

- Recall that we embed structural and functional features to the datasets (§4.2) and convert the key-prediction problem to inverter/buffer prediction (§4.4). We note that the explainer attributes higher importance to structural features than functional features when the key-gate maps to a buffer. Conversely, higher importance is attributed to functionality, *i.e.,* gate-type, when the key-gate maps to an inverter.
- In the considered TRLL-locked designs, if the key-gate has inputs of primary input and *key-input*, the key-gate maps to an inverter irrespective of the logic gates in the neighborhood. Similarly, if the output of the key-gate is connected to a primary output, the key-gate maps to a buffer.
- Logic synthesis is a *double-edged sword* for the security of learning resilient locking techniques. While ALMOST uses adversarial learning to generate synthesis recipes for locked designs (§2.1), our experiments demonstrate that an attacker can use logic synthesis to reduce the security guarantees through tailored graph transformations (Table 4).

Table 9: Efficacy (KPA (%)) of INSIGHT on practical designs locked using Synopsys TestMAX ($|K|=128$).

5.5 Security Evaluation on Practical Designs

We evaluate the security of practical designs locked using TroMUX [37] and Synopsys TestMAX. For TroMUX, we launch attacks on 7 locked crypto cores and microcontroller [72] for varying key-sizes. On average, we achieve a KPA of 89.13% (Table 10). TRLL and TRLL+ are integrated into an industry-adopted and widely used semiconductor EDA tool, Synopsys TestMAX. We evaluate the security of processors and GPS locked using TRLL and TRLL+ (Table 9). On average, INSIGHT achieves a KPA of **98.82**% and **98.63**%, highlighting that it (i) can successfully recover the secret keys from practical designs locked using industry-adopted locking techniques and (ii) is scalable w.r.t. design size and key-sizes.

5.6 Ramifications of Leaking Secret Key

We showcase the ramifications of leaking the secret key using an image processing application (hardware implementation of Gaussian blurring [79]) as follows. We lock the 16-bit adders in the hardware implementation with $|K|=16$ using TRLL [24]. Subsequently, we launch INSIGHT and OMLA [31] to recover the secret key of the locked adders. INSIGHT recovers 93.75% of the secret key, while OMLA recovers only 50% of the secret key. Next, we evaluated the functionality of the recovered design by simulating the image processing module with adders recovered by INSIGHT and OMLA. For example, consider the image in Figure 8 (a) as input. The output of the design recovered by INSIGHT (Figure 8 (c)) is similar to the original output (Figure 8 (b)). However, the output of the design recovered by OMLA (Figure 8 (d)) is completely different from the original output (Figure 8 (b)). This case study shows that by using INSIGHT, an attacker can cause a

practical attack by recovering the secret key.

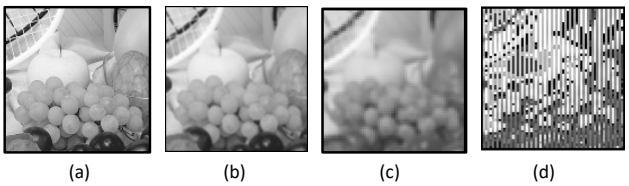

Figure 8: Gaussian blurring example. (a) input image, (b) output (golden) image, (c) output image recovered by INSIGHT, and (d) output image recovered by OMLA [31].

6 Related Work and Discussion

To the best of our knowledge, INSIGHT is the first to use explainable machine learning (ML) to develop a successful attack in semiconductor supply chain security. Here, we discuss (i) different hardware IP protections and attacks, (ii) the actionability of INSIGHT, and (iii) potential countermeasures.

6.1 Hardware IP Protections and Attacks

FuncTeller [80] proposed an oracle-guided attack on embedded field programmable gate array (eFPGA)-based hardware redaction and recovered the approximate functionality of eFPGA-redacted components using logic synthesis principles and querying input/output pairs from an oracle. **Chhotaray *et al.*** [10] introduced a formal syntax for design-hiding schemes to protect design IPs against reverse-engineering attacks. **Han *et al.*** [9] proposed an oracle-guided attack recovering the secret key in selected corrupt-and-correct-based locking techniques. It leverages logic synthesis principles utilized in IC design tools to recover the secret key. **Yasin *et al.*** [8] proposed the first-of-its-kind provably-secure logic locking technique, providing quantifiable resilience against oracle-guided attacks and removal attacks. The security guarantees of [8] were broken by Han *et al.* [9]. **Massad *et al.*** [12] proposed an oracle-guided attack on IC camouflaging. The attack employed an SAT solver to compute discriminating set of input patterns to recover the Boolean functionality of the camouflaged logic gates. **Rajendran *et al.*** [11] proposed an IC camouflaging-based defense technique considering an oracle-guided threat model. It strategically selects logic gates (to be camouflaged) by leveraging VLSI/IC testing principles to thwart reverse-engineering. This technique was broken by Massad *et al.* [12]. **Imeson *et al.*** [7] proposed a split manufacturing-based defense technique that thwarts oracle-less attacks from untrusted foundry and leveraged 3D IC technology to obfuscate security-critical wires in designs.

In contrast, INSIGHT: (i) is an explainability-guided attack that employs explainable GNN, (ii) attacks learning resilient logic locking techniques, (iii) provides explanations, and (iv) is an oracle-less attack.

6.2 Actionability from INSIGHT

INSIGHT provides explanations in terms of importance scores for the (i) nodes in the neighborhood of key-gate and (ii) features responsible for predictions (§4.4). Hardware designers can understand these explanations as they are just numbers (Appendix A.1). However, the actionability of explanations from INSIGHT varies with the level of expertise (beginner, intermediate, and advanced) in ML/GNNs. Next, we describe the actionability of the explanations in enhancing the attack and locking technique w.r.t. expertise in ML/GNNs.

Hardware designers with a **beginner's** knowledge of ML/GNN can interpret the important nodes or features in the subgraph extracted around key-gates based on importance scores. Through this information, a designer can protect the important nodes and features, as showcased in §6.3. Hardware designers with an **intermediate** knowledge of ML/GNN can modify the problem modeling of INSIGHT by analyzing the importance scores of nodes/features across different data samples, *i.e.,* subgraphs extracted around different key-gates. For instance, we modified the problem modeling by analyzing the explanations from INSIGHT (§4.4). Similarly, a designer can modify the locking technique by obtaining the global reason behind the success of the attack by analyzing explanations. Hardware designers with **advanced** knowledge of ML/GNN can map explanations provided by INSIGHT to the working of the GNN model. For instance, we modified the architecture of GNN by analyzing explanations (§4.5). Moreover, with advanced knowledge in ML/GNN, a designer can enhance a locking technique by performing and analyzing graph perturbations, *i.e.,* analyzing how changes such as locking important nodes or graph transformations impact the GNN predictions and performance of INSIGHT.

6.3 Limitations and Countermeasures

Limitations. INSIGHT could not recover (i) the entire secret key for many designs, *i.e.,* there remains scope for improvement, and (ii) the key-value in densely locked regions, *i.e.,* key-gates surrounded by a majority of locked gates.

Potential countermeasures. INSIGHT uses explainability-guided GNN-based node classification and recovers a significant portion (**87.30**%) of the secret key of 7 unbroken locking techniques. Existing ML-based attacks provide KPA as a result. Although designers can identify which key-gates are incorrectly predicted using KPA, the metric does not provide the reasons behind the predictions. Understanding the reasons behind the predictions will aid designers in strategically developing countermeasures against ML-based attacks. INSIGHT provides explanations regarding (i) important nodes in the neighborhood of key-gate and (ii) important features responsible for predictions (§4.4). Using these explanations, we propose 2 potential countermeasures against INSIGHT.

The **first** direction (**CM#1**) is a consequence of **important**

Table 11: Efficacy (KPA (%)) of INSIGHT compared to existing ML-based attacks (OMLA [31] and SCOPE [32]) for potential countermeasures (CM#1 and CM#2) for $|K| = 128$.

Design	OMLA [31]		SCOPE [32]		INSIGHT (This Work)	
	CM#1	**CM#2**	**CM#1**	**CM#2**	**CM#1**	**CM#2**
b14_C	51.51	42.31	32.26	26.98	70.31	68.75
b15_C	51.28	46.46	25.71	26.12	64.84	63.28
b17_C	47.50	49.55	34.09	35.18	67.96	64.84
b20_C	46.15	50.00	35.00	37.09	66.40	63.28
b21_C	55.17	49.32	20.69	28.69	65.62	70.31
b22_C	48.79	50.00	31.17	27.66	65.62	62.50
Average	**50.06**	**47.94**	**29.82**	**30.29**	**66.79**	**65.49**

node explanations provided by explainable GNN. We observe that the nodes in the neighborhood of the key-gate contribute with different importance to the prediction. We lock the important nodes in the neighborhood of the key-gate to thwart INSIGHT from exploiting hints. To evaluate the efficacy of CM#1, we launch existing ML-based attacks (OMLA and SCOPE) and INSIGHT on selected ITC-99 designs (locked using CM#1) for $|K| = 128$. INSIGHT obtained a KPA of **66.79**%, whereas existing attacks (SCOPE and OMLA) obtained a KPA of 29.82% and 50.06% (Table 11).[‡‡]

Design tradeoffs. We observe that the number of key-gates in designs locked using CM#1 increases with the number of important nodes, leading to higher area and power overheads (Table 12). One potential way to reduce the overheads is to lock the important nodes in an iterative approach (in the descending order of importance scores). In this approach, important nodes are locked until the attack (INSIGHT) is thwarted.

The **second** direction (**CM#2**) is a consequence of **important feature** explanations returned by explainable GNN. Recall that the gate-type feature has higher importance compared to other features (§4.5). To thwart INSIGHT from exploiting the gate-type features from the neighborhood of the key-gate, we perform custom graph transformations in the neighborhood of the key-gates. For example, if the "XNOR" gate-type feature is of higher importance, we transform the neighborhood of the key-gate so that it does not utilize the"XNOR" gate. INSIGHT obtained a KPA of 63.83%, whereas existing attacks OMLA [31] and SCOPE [32] obtained a KPA of 47.94% and 30.29%, as shown in Table 11. **In conclusion**, CM#1 and CM#2 decrease the KPA of INSIGHT by 1.32× and 1.36× compared to targeted locking techniques.

Design tradeoffs. The custom graph transformations result in higher area and power overheads (Table 12). One potential way to reduce the overheads is to search for an important feature (gate-type) iteratively and eliminate the gate-type that results in higher overheads for custom graph transformations.

[‡‡]Providing theoretical analysis supporting the robustness (security) of proposed countermeasures involves delving into the mathematical underpinnings of ML/GNN models, an ongoing research in the ML community. Consequently, providing theoretical evidence against ML/GNN-based attacks is non-trivial and beyond the scope of the current work.

Table 12: Area, power, and delay overheads (in %) for potential countermeasures (CM#1 and CM#2).

7 Conclusion and Ramifications

By harnessing the potential of an explainable graph neural network (GNN), we developed INSIGHT, which recovers the secret key (without requiring scan access) of **7** unbroken learning resilient locking techniques, including **2 industry-adopted techniques**. We overcame 5 critical challenges: (i) selecting a suitable explainer, (ii) identifying exploitable structural hints, (iii) attacking logic-synthesized designs, (iv) tackling unique graph representations, and (v) tackling insufficient training datasets. We showcased the efficacy of INSIGHT on designs ranging from widely-used academic benchmarks to processors. INSIGHT achieves an improved key-prediction accuracy of **2.87**×, **1.75**×, and **1.67**× compared to existing ML-based attacks. Finally, we perform 2 practical case studies showcasing the promise of INSIGHT on designs locked using `Synopsys TestMAX` and illustrating the ramifications of leaking the secret key. Our work highlights the potential of using explainable GNN, and our developed solutions can be used for other hardware security problems.

Ramifications. INSIGHT questions the security of learning resilient locking techniques (including industry-adopted techniques). INSIGHT: (i) acts as a litmus test showcasing the real efficacy of learning resilient locking techniques, (ii) cautions developers of locking techniques to remain cognizant of the fact that attackers can improve attacks by using explanations from ML/GNN explainers, and (iii) provides explanations, thereby aiding designers in developing countermeasures.

Ethical Considerations. We highlight that while INSIGHT can be potentially harmful at the hands of a malicious attacker whose goal is to break a logic locking defense, it is important to note that logic locking is not yet widely utilized by IC design companies for hardware IP protection. Our research, therefore, presents a timely opportunity to evaluate and enhance these techniques, paving the way for a solid and stable solution before widespread adoption. INSIGHT sheds light on vulnerabilities in learning resilient locking techniques, thus encouraging the research on effective countermeasures against ML/GNN-based attacks. Through this work, we invite logic-locking developers to work collaboratively with us on developing learning resilient locking techniques.

A Appendix

A.1 GNNExplainer

High-level overview. GNNExplainer is a model-agnostic explainable GNN that provides explanations for predictions made by a GNN model on graph-based machine learning tasks (*e.g.,* node classification, link prediction). GNNExplainer takes the following inputs: (i) graph, (ii) features of the graph, (iii) prediction of the graph, and (iv) trained GNN model. In the context of INSIGHT, the (i) input graph refers to an extracted subgraph, *i.e.,* logic gates in the neighborhood of

key-gates, (ii) features correspond to functionality/structure-based features extracted for the logic gates in the subgraph, (iii) prediction of the graph is an INV/BUF prediction, and (iv) trained GNN model refers to attention-based GNN trained on the training dataset (§4.4 and §4.5).

GNNExplainer provides explanations in terms of importance scores for nodes and features for a given graph. Consider an input (sub)graph G', its corresponding features X', a trained GNN model T_{GNN}, and the prediction $y = T_{GNN}(G')$. GNNExplainer generates an explanation (G'_S, X'^F_S), where $G'_S \subseteq G'$ is the (important) neighborhood in the input graph G'. X'_S represents the features of G'_S, whereas X'^F_S represents the set of features masked by the mask F, *i.e.,* $X'^F_S = \{x'^F_i \mid v_i \in G'_S\}$. The importance scores of nodes and features are real numbers in the range of $(0,1)$, with higher scores indicating greater importance of the respective node or feature.

Methodology of GNNExplainer. The importance scores are calculated using mutual information (MI), and GNNExplainer is formalized as an optimization framework, where H refers to entropy and Y refers to predicted label distribution:

$$\max_{G'_S} \mathrm{MI}(Y, (G'_S, X'_S)) = H(Y) - H(Y \mid G' = G'_S, X' = X'_S). \quad (1)$$

For a given (sub)graph G', MI measures how much the probability of predicting y changes when the (sub)graph is restricted to G'_S and its features are restricted to X'_S. For example, if removing v_i from G' decreases the probability of prediction y with a large value, the node v_i is a good explanation, *i.e.,* an important node in (sub)graph G'. The entropy $H(Y)$ in Equation 1 is constant as T_{GNN} is fixed for a given trained GNN. Thus, maximizing mutual information between the predicted label distribution Y and explanation (G'_S, X'_S) is similar to minimizing conditional entropy $H(Y \mid G' = G'_S, X' = X'_S)$, which can be expressed as follows:

$$H(Y \mid G' = G'_S, X' = X'_S) = -\mathbb{E}_{Y \mid G'_S, X'_S}[\log P_{T_{GNN}}(Y \mid G' = G'_S, X' = X'_S)]. \quad (2)$$

where $\mathbb{E}$ is the expected value and $P_{T_{GNN}}$ represents the probability of the trained GNN model T_{GNN} in predicting Y, given that G' is restricted to G'_S and X' is restricted to X'_S.

Thus, the explanation for prediction y is a subgraph G'_S that minimizes the uncertainty of T_{GNN} when the GNN inference/-computation is limited to G'_S. In simpler terms, the subgraph G'_S is selected to optimize the understanding of how the GNN arrives at its prediction when focusing only on a subset of (sub)graph G', *i.e.,* G'_S and the subset of features (X'_S).

Training process. GNNExplainer has no training process. It provides explanations for the predictions made by GNNs.

Nature of outputs. The explanations are real numbers in the range of $(0,1)$.

A.2 Integration of INSIGHT

INSIGHT can be integrated with existing X(N)OR/MUX-based logic locking techniques, including the 7 learning resilient locking techniques targeted in our work. Next, we discuss the feasibility of integrating INSIGHT with existing locking techniques, focusing on the (i) format of the locked designs compatible with INSIGHT, (ii) additional steps required to be performed on the locked designs, and (iii) software requirements for installing INSIGHT.

Compatible locking techniques. INSIGHT is compatible with X(N)OR/MUX-based locking techniques. For instance, in our work, we showcased the compatibility of INSIGHT with existing X(N)OR-based and MUX-based locking techniques.

Format of locked designs. INSIGHT is compatible with gate-level designs in the Verilog format, mapped to a technology library. Such a format (technology-mapped Verilog designs) is widely adopted in academic research and semiconductor industries for hardware design.

Additional steps. INSIGHT requires no additional steps for locked designs in Verilog format. INSIGHT converts the Verilog designs to graph format and performs explainability-guided GNN-based node classification and post-processing to recover the secret key (§4.7). However, users must manually analyze the explanations provided by INSIGHT to enhance the attack or improve the logic locking technique.

Software requirements. INSIGHT is tested on 2 Linux operating systems (Ubuntu and RedHat). The software requirements are minimal, and INSIGHT requires Python 3.7, Pytorch 1.7.0, and installation of standard Python packages (*e.g.,* networkx, gensim, scikit-learn, and numpy).

Example of integration of INSIGHT with existing locking technique. Consider an example of attacking designs locked using the SimLL technique [52]. SimLL-locked designs, open-sourced by the authors, are provided in BENCH format [52]. To ensure compatibility with INSIGHT, we convert the SimLL-locked designs from BENCH format to technology-mapped gate-level designs in Verilog format. Such a conversion is performed using a custom Python script. Next, we perform graph transformations, *i.e.,* logic synthesis on the locked designs to transform the MUX-based key-gates into Boolean logic gates. Finally, we provide the synthesized locked designs to INSIGHT to obtain predictions and explanations.

A.3 Computational complexity of INSIGHT

The computational complexity of the final architecture of INSIGHT (§4.7) depends on the time complexity of the subgraph extraction, feature extraction, commercial logic synthesis tools utilized for graph transformations, attention-based GNN inference, and GNNExplainer. The subgraph extraction step obtains the subgraph $G'(V', E')$ comprising the neighbors of the target node, *i.e.,* key-gate for a hop-size of r from graph $G(V,E)$. The time complexity of extracting neighbors is $O(|V| + |E|)$, where $|V|$ ($|E|$) is the number of nodes (edges) in the graph $G(V,E)$. The feature extraction step includes extraction of (i) gate-type, (ii) input degree of the nodes in the subgraph, (iii) distance of the nodes in the subgraph from

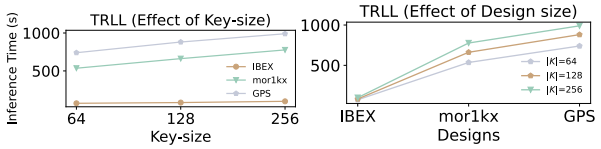

Table 13: Efficacy (KPA (%)) of INSIGHT on TRLL-locked designs synthesized with two different synthesis recipes.

Design	Setting_A	Setting_B
b14_C	79.64	79.54
b15_C	78.90	80.91
b17_C	81.98	80.83
b20_C	80.10	80.12
b21_C	81.45	80.88
b22_C	77.51	78.11
Average	**79.93**	**80.05**

the key-gate (DE), and (iv) a (+/-) sign indicating if the node is in fan-in/fan-out of the key-gate. The time complexity of extracting (i) gate-type is $O(1)$, (ii) input degree is $O(|E'|)$, (iii) DE is $O(1)$, and (iv) sign is $O(1)$. The time complexity of the attention-based GNN is $O(|E'|)$ [81] for a sparse subgraph and $O(|V'|^2)$ for a dense subgraph, where $|V'|$ ($|E'|$) denotes the number of nodes (edges) in the subgraph $G'(V', E')$. The time complexity of GNNExplainer is $O(|E'|)$ [68].

Deriving the time complexity of graph transformations is non-trivial due to the closed-source commercial logic synthesis algorithms, whose complexities are unknown. However, the practical runtime required for the graph transformations is an average of 30 minutes, making the graph transformation step extremely efficient.

A.4 INSIGHT: Additional Results

(a) (b)

Figure 9: Impact of (a) key-size and (b) design size on INSIGHT runtime for IBEX, mor1kx, and GPS designs.

Effect of architecture. The learning resilient locking techniques offer protection against hardware IP piracy for various design types, including arithmetic designs and controllers. Next, we analyze the security of two widely-used classes of designs, *i.e.,* arithmetic designs and controllers.

Arithmetic designs. We choose different architectures of widely-used and prevalent arithmetic designs (multipliers, log2, square-root, square, and adders) and lock them using TRLL. We adopt the standard *leave-one-out* training approach, *i.e.,* when attacking a locked multiplier (adder), we train the GNN using the remaining locked multipliers (adders).

Multipliers. We choose three multiplier architectures (Wallace-tree, Booth, and array) used in digital signal processing applications [82]. The architectures have average KPA of 82.42%, 96.48%, and 99.22%, respectively (Table 14).

Adders. We choose three adder architectures (ripple carry, carry-skip, and kogge-stone). The architectures have an average KPA of 97.26%, 99.22%, and 96.48% (Table 14).

Table 14: Efficacy (KPA (%)) of INSIGHT on architectures of adders and multipliers locked using TRLL [24] for $|K| = 128$.

Adder	Bit-width	KPA (%)
Kogge-stone	64	95.31
	128	99.22
Carry-skip	64	99.22
	128	99.22
Ripple carry	64	99.22
	128	93.75
Average	–	**97.92**
	–	**97.39**

Multiplier	Bit-width	KPA (%)
Booth	64	75.00
	128	89.84
Wallace-tree	64	99.22
	128	93.75
Array	64	99.22
	128	99.22
Average	–	**91.15**
	–	**94.27**

Log2. We choose two log2 architectures (binary search and Newton-Raphson). We observe both architectures having a comparable KPA, *i.e.,* 99.22% for binary search architecture and 98.44% for Newton-Raphson architecture (Table 15).

Square-root. We choose two square-root architectures (non-restoring and Newton-Raphson). We observe both architectures having a comparable KPA, *i.e.,* 96.09% for non-restoring architecture and 99.22% for Newton-Raphson architecture (Table 15).

Square. We choose three architectures (Wallace-tree, Booth, and array). We observe that Booth multiplier-based square design has a comparatively lower KPA (90.62%) than other designs, *i.e.,* 99.22% for array-based square design and 98.44% for Wallace-tree-based square design (Table 15).

Controllers. We choose four controllers from the EPFL benchmark suite [76] (Table 16). We observe an average KPA of 99.02%, indicating that INSIGHT exploits the structural hints in the hardware implementation of the aforementioned controllers when locked using TRLL.

Table 15: Efficacy (KPA (%)) of INSIGHT on log2, square-root, and square locked using TRLL [24] for $|K| = 128$.

Design	Architecture	KPA (%)
Log2	Binary search	99.22
	Newton-Raphson	98.44
Square-root	Non-restoring	96.09
	Newton-Raphson	99.22
Square	Array	99.22
	Booth	90.62
	Wallace-tree	98.44

Abstract

In this paper, we present ESauron — the first proof-of-concept system that can detect diverse forms of spy cameras (i.e., wireless, wired and offline devices) and quickly pinpoint their locations. The key observation is that, for all spy cameras, the captured raw images must be first digested (e.g., encoding and compression) in the video-capture devices before transferring to target receiver or storage medium. This digestion process takes place in an inbuilt read-write memory whose operations cause electromagnetic radiation (EMR). Specifically, the memory clock drives a variable number of switching voltage regulator activities depending on the workloads, causing fluctuating currents injected into memory units, thus emitting EMR signals at the clock frequency. Whenever the visual scene changes, bursts of video data processing (e.g., video encoding) suddenly aggravate the memory workload, bringing responsive EMR patterns. ESauron can detect spy cameras by intentionally stimulating scene changes and then sensing the surge of EMRs even from a considerable distance. We implemented a proof-of-concept prototype of the ESauron by carefully designing techniques to sense and differentiate memory EMRs, assert the existence of spy cameras, and pinpoint their locations. Experiments with 50 camera products show that ESauron can detect all spy cameras with an accuracy of 100% after only 4 stimuli, the detection range can exceed 20 meters even in the presence of blockages, and all spy cameras can be accurately located.

1 Introduction

Hidden spy cameras placed in sensitive locations such as hotels and dressing rooms are increasingly a threat to individual privacy [1, 2, 3]. A recent survey of travelers in the US revealed major concerns about hidden spy cameras, and an alarming percentage (11%) of Airbnb users have found a hidden camera in their short-term rental [4]. Modern spy cameras are highly miniaturized and can be easily installed anywhere in a private space or implanted into daily objects, such as smoke detectors, bathroom light fixtures, USB chargers, or power outlets (examples shown in Figure 1). Worse still, recent research [5] reported that a significant number of private devices, e.g., home security and surveillance cameras, are at risk of being manipulated by hackers, thus becoming spy cameras [6, 7, 8].

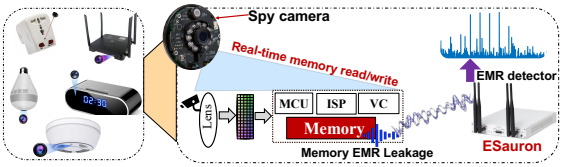

Figure 1: Examples of commodity hidden spy cameras and the principle of employing ESauron to detect them.

Unfortunately, it is difficult to detect such spy cameras due to their small form factors and/or stealthy working mode. Depending on the transferring methods of real-time video captures, a spy camera can be wired/wireless to a remote receiver or onboard storage. Recent research proposed to detect hidden cameras by searching for the tell-tale signs of tiny reflections from camera lens [9], or analyzing the traffic patterns of RF signals emitted from their radio interfaces [10, 11, 12, 13, 14]. However, these techniques still bear a few major limitations. First, the light-reflecting-based methods assume users are aware of the approximate location of the cameras, which is not always the case. A user usually has to carry a detecting device and scrutinize the entire private space, which requires a slow and meticulous sweep while exhibiting high false positives due to ambient reflections. Second, RF scanning-based methods are only applicable to hidden cameras that wirelessly stream their recorded videos, whereas a substantial portion of spy cameras rely on wired transmission or local storage, meaning that they do not initiate any wireless connections. All of the above evidence

*Corresponding Author.

suggests that there is still a lack of effective method to detect diverse forms of spy cameras.

This paper aims to reliably detect diverse forms of spy cameras (i.e., wireless, wired and offline devices) and quickly pinpoint their locations despite of these challenges. Our key insight is that despite diversified models and forms, all cameras for video recording will inevitably digest the captured raw images in real-time before transferring to target receiver or storage medium. The digestion process takes place in an inbuilt read-write memory (as illustrated in Figure 1) whose operations cause electromagnetic radiation (EMR). Therefore, we may be able to detect a functioning hidden spy camera if we can receive and identify its unique EMR traces over the air. Despite recent studies, e.g., EarFisher [15], Memscope [16], DeHiREC [17] and CamRadar [18], on EMR-based hidden device detection, however, due to ignorance of the critical dynamic traits (frequency drift) of memory EMRs in camera devices, they are ineffective in distinguishing and continuously tracking the time-varying EMRs from even a single device, not to mention common scenarios deployed with multiple cameras probably of the same model. Moreover, due to the weak of ADC EMRs produced by simple switched-capacitor circuits, DeHiREC and CamRadar's detection range is limited within dozens of centimeters, bringing insurmountable hurdle for device identification and localization when spy cameras are deployed high up in a room. Due to lack of thorough characterizing on memory EMR from camera devices, the inability to continuously differentiate and track camera devices of the same model, and lack of EMR-based positioning capability, existing works are still far from effective hidden camera detection in real scenarios. To address these problems and achieve the goal of ESauron, we need to answer the following research questions.

- **RQ 1:** What are the characteristics of the EMR traces leaked from a spy camera?
- **RQ 2:** How to effectively identify the extremely weak EMR leakage from a spy camera especially when it is at a distance and interfered by other devices also producing EMRs in similar spectrum?
- **RQ 3:** Given the EMR traces of an identified spy camera, can the weak and memory workload-relevant EMR signals be used for pinpointing its location under the multipath and shadowing effects?

We begin by conducting an analytical model and extensive measurements to address **RQ 1**. This involves analyzing memory EMRs resulting from image data processing, which emits EMR signals at the memory clock frequency. Our spectrum analysis identifies harmonic components around the memory clock. To address **RQ 2** and overcome the challenge of detecting weak EMR signals, we utilize the unique EMR spectrum characteristics. Our enhanced signal processing algorithm aggregates energy from multiple harmonic components, significantly improving the signal-to-noise ratio. This enhancement enables the accurate detection of weak EMR emissions even from considerable distances, even in the presence of obstacles. In the presence of interference from non-camera devices emitting EMRs in a similar spectrum, we establish a causal relationship between camera scene changes and responsive EMR patterns. This analysis eliminates the impact of interference, ensuring accurate spy camera detection. To distinguish mixed EMRs from multiple spy cameras, we conduct extensive measurements on 50 camera products. These measurements reveal unique memory clock fingerprints in the EMR spectrum, both static and dynamic. These fingerprints are then used to separate and track each spy camera's memory EMRs. Addressing **RQ 3**, we employ a received signal strength (RSS)-based iterative-approximation search algorithm to guide the receiver toward the spy camera's location. EMRs, operating at relatively low frequencies, are less susceptible to multipath and shadowing effects. This approach enables the accurate pinpointing of spy camera locations by following the RSS gradient.

We built a prototype platform of ESauron, with a laptop PC equipped with a plug-in miniature strobe light and a USRP B210 with a log-periodic antenna. Note that we are working on hosting our system on Raspberry Pi to miniaturize the platform equipment of ESauron.

Summary of contribution. Our contributions are summarized below:

- We propose ESauron, a first generalized system to detect and pinpoint all kinds of hidden spy cameras, including wireless/wire-connected and storage-based offline devices.
- By digging out the underlying cause of memory EMRs leaked by spy cameras and characterizing a series of unique properties, we design techniques to sense and differentiate memory EMRs, and assert the existence of spy cameras.
- We present a searching algorithm to heuristically search the appropriate direction to move forward to approach the spy camera. In this way, ESauron can quickly guide the user to the spy camera's location.
- We design a proof-of-concept system of ESauron with USRP B210 with a log-periodic antenna. We demonstrated the effectiveness of the proposed system design through a full-fledged testbed implementation and comprehensive experiments in real environments.

2 Background and Motivation

In this section, we first introduce the hardware architecture and processing logic of consumer-grade cameras. Then, we investigate the memory models used in spy cameras and explain the source of memory EMR.

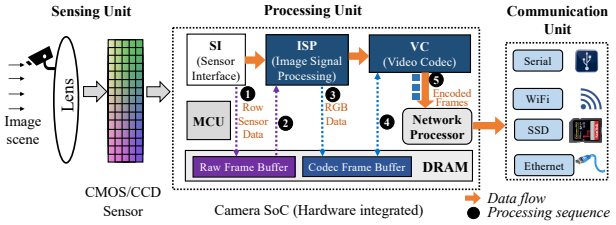

Figure 2: Hardware modules inside a customer-grade camera. A scene image through a lens is first digitized by a CMOS/CCD sensor. A dedicated video SoC chip is used for multimedia preprocessing, i.e., image signal processing (ISP), codec and transmission (networking processor)

2.1 Basic Operation of Video Cameras

Hardware architecture. Figure 2 depicts the hardware architecture of general consumer-grade cameras, comprising a sensing unit, processing unit, and communication unit. The sensing unit, typically a CMOS/CCD image sensor, captures and digitizes the target scenes to generate raw image data, and then passes them to the processing unit that is located on the camera system on chip (SoC). The processing unit contains: (1) an image signal processor (ISP) module that performs operations such as demosaicing, noise reduction, auto exposure, autofocus, auto white balance, and image sharpening designed to convert raw images into high-quality video frames; (2) a video codec (VC) module that compresses the video frames following standard protocols such as H.264/H.265. After that, the communication unit transfers the encoded frames to a target receiver or storage medium through wireless or wired paths, e.g., Ethernet, WiFi, or serial bus.

Table 1: Memory models used by different camera products.

Brand	Model	SOC chip	Memory frequency	Transfer Mode
Google Nest	Cam Indoor	Ambarella S2LM	DDR3-1600	Wireless\Storage
Logitech	Circle 2	Ambarella S2LM	DDR3-1600	Wireless
Arlo	Pro 3	OV 00798	DDR2-667	Wireless
Amcrest	IP2M-841W	Ambarella S2LM	DDR3-1600	Wireless\Storage
Hikvision	DS-IA	HK-2019	DDR3-1700	Wired
Hikvision	EzvizC2C	Hisilicon 3518	DDR3-1700	Wireless
Xiaoyi	Y1	QG2101A	DDR3-1033	Wired\Wireless
Dahua	LC-TC7	Hisilicon 3518	DDR3-1700	Wireless\Storage
Xiaomi	SXJ01ZM	Grain 8136	DDR2-1600	Wireless
Skyworth	c10	Hisilicon 3518	DDR3-1700	Wireless\Storage

Essential memory operation. From the perspective of the data flow, as illustrated in Figure 2, the raw images need to be first transferred and cached to the SoC memory. Then, the ISP module reads out the SoC memory and, together with a microprocessor (MCU), executes the image processing operations. The resulting RGB data (i.e., pixels) are further stored in the frame buffer within the SoC memory. On this basis, the VC module loads the pixel data from the memory and performs encoding, which involves scene analysis, motion estimation, macroblock classification, intra/inter-frame encoding, deblocking filter, etc. Almost every encoding step will exchange a mass of intermediate data with the SoC memory, among which motion estimation is most overwhelming. In other words, a dynamic change of the scene can drive a new round of motion estimation, which brings a notable increase in data exchange between the VC and the SoC memory, namely memory workload.

Note that existing consumer-grade cameras, no matter spy cameras, surveillance or ordinary camera, are with similar hardware architecture and processing logic.

2.2 Memory Models on Spy Cameras

Does any camera-device have an inbuilt read-write memory? For a camera device, despite diversified models and forms, the captured raw images must be first digested (e.g., encoding and compression) before transferring to target receiver or storage medium. Such encoding/compression processes have to exchange (read and write back) a mass of intermediate data with a specified memory. Thus a read-write memory is indispensable to any form of camera-devices, even the miniaturized spy cameras (as shown in Figure 16 below).

DRAM used in modern camera devices. DRAM has been widely adopted by consumer electronics due to its low cost, low power consumption, and high efficiency. Generally, DRAM can be divided into SDRAM (Synchronous Dynamic Random-Access Memory) and DDR SDRAM (Double Data Rate SDRAM, denote as DDR memory). Owing to its much higher data transfer efficiency, DDR memory has dominated the memory market [19]. Specific to the camera memory models, our survey in Table 1 reveals the same trend. We have purchased and examined 50 camera products from a major e-commerce portal. Our survey covers a variety of camera types, including miniature spy cameras, webcams, surveillance cameras, and home security cameras; and a variety of brands, such as Hikvision, Logitech, Arlo, Dahua, and some unknown models. We found all the cameras, without exception, are equipped with DDR memory (e.g., DDR2-667/1600, DDR3-1033/1600/ 1700) in their SoC.

2.3 Memory EMR Leakage

We now demystify the DDR memory EMR (referred to as memory EMR in the rest) and present the analytical model on the spectrum patterns of memory EMR.

Generation of memory EMR. DDR memory is composed of a large number of basic memory units, each consisting of a transistor and a capacitor. The charging state of

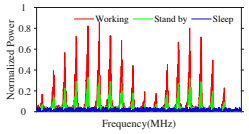

Figure 3: The spectrum mode of the memory EMR under different working conditions of the spy camera.

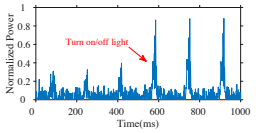

Figure 4: Distance-relevant RSS preservation.

the capacitor determines the memory unit's logic state, i.e., 1/0. When the DDR memory is read/ written, the memory clock immediately drives a large amount of switching voltage regulators' activities, by which the selected capacitors are charged/discharged by the transfer of electrons. Following the Faraday law of electromagnetic induction [20], the corresponding acceleration/deceleration of electrons produces EMR which resonates at the memory clock frequency [21].

If a certain read/write operation involves more memory units, the memory clock will drive more switching activities in proportion to the number of capacitors, resulting in stronger emanations at the memory clock frequency, and vice versa [21]. Therefore, the EMR amplitude is highly dependent on the memory workload.

Memory EMR analysis. The simplest form of a memory clock is a sine wave [15]. However, such a single-carrier clock can lead to excessive EMR intensity that may violate the regulatory requirement for electromagnetic compatibility. Modern clock generators instead adopt spread spectrum clock (SSC) techniques [22, 23], which distributes the EMR energy as $V_{ssc}(t) = A\cos 2\pi f_0 t + \frac{\Delta f}{f_m}\sin(2\pi f_m t)$, where f_0 is the center frequency of the memory clock, f_m and Δf are the modulation frequency and peak frequency offset, respectively. The descriptions of used symbols are listed in Appendix A. Due to stability requirements, the clock signal $V_{ssc}(t)$ has to go through a band-pass filter for harmonic components suppression. Then the energy of the memory EMR is non-zero only at frequencies f_{nz}, where the frequency of the i-th non-zero memory EMR can be expressed as

$$f_{nz}(i) = f_0 - if_m. \quad (1)$$

Consequently, the memory EMR is composed of a series of *harmonic* components, where the frequency interval between consecutive harmonic components is f_m, and the first harmonic component is at f_0. Note that f_m is a constant and only depends on the memory hardware model. The theoretical analysis on memory EMR has been well explained in previous literature [24, 15].

Although existing techniques and regulations on electromagnetic interference and electromagnetic compatibility have made much effort to reduce the unintentional EMR leaked from DDR memory. However, it is still inevitable that DDR memory will produce EMR at the clock frequency when there are fluctuating currents.

2.4 Measurement of EMR Spectrum Patterns

We conduct empirical studies to verify the spectrum patterns of memory EMR. Our measurements are conducted with representative memory models, DDR2-800/ 1600, DDR3-1700/1866, and DDR4-2133/2400, which are widely equipped with spy cameras. We employ a USRP B210 with a log-periodic antenna to capture the EMR leakage. We configure the carrier frequency to be the memory center frequency f_0, set the sample rate to 2 Mhz, and take an FFT over 1s window of the captured signal to convert it into individual spectral components. Meanwhile, we create different workloads, i.e., write the memory intensively, put it in standby state with only periodical refresh operation, and put it to sleep state. We derive four observations from the measurement study.

First, from the analysis of spectrum patterns as illustrated in Figure 3, we observe that in both the working state and standby state, DDR memory operations do produce (leak) EMR signals, of which **the frequency spectrum features a series of energy peaks distributed over around 1 MHz near the memory clock frequency f_0 (e.g., 850MHz)**.

Second, an auto-correlation of the peak frequencies confirms that **the frequency interval (i.e., f_m) between consecutive peaks is constant**, agreeing well with the above analysis. For instance, f_m =31.25 kHz and 31.16 KHz, for DDR3-1700 and the DDR2-1600, respectively.

Third, the results also demonstrate that **the amplitude of memory EMR varies with the memory workload**. With the presence of intensive workload, the amplitudes of all energy peaks escalate significantly compared with the standby state. Yet the workload does not affect the locations of the frequency peaks, which corroborates the analysis in Eqn. (1).

Fourth, we further measure the correlation between scene change and the memory EMR. We find a **strong causal relationship between the stimulus of camera scene changes and the responsive EMR pattern**. By intentionally stimulating scene changes with turning on/off light, the spy camera immediately produces responsive EMR patterns as shown in Figure 4.

3 Threat Model

The attacker's goal is to surreptitiously record the video of privacy-sensitive environments with pre-deployed hidden spy cameras described in Figure 1. As a detector, ESauron tries to detect and quickly pinpoint the above hidden spy cameras.

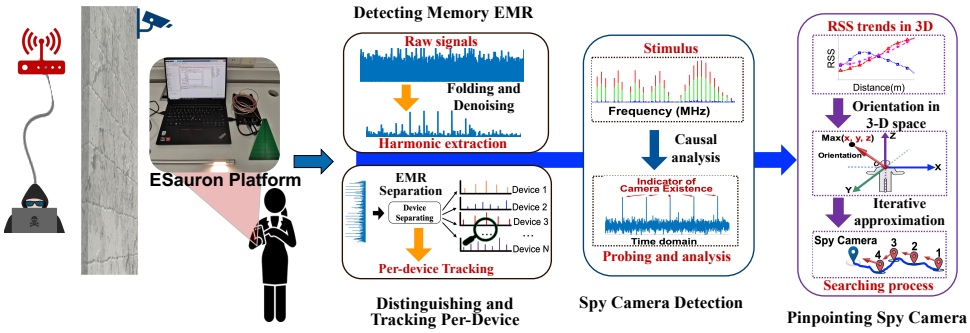

Figure 5: The architecture of ESauron, consisting of four major modules: Sensing of memory EMR, Separating and tracking per-device's EMRs, Stimulus-based spy camera detection, and Pinpointing of spy cameras.

3.1 Attack Model

We make the following assumptions about the attackers.

Concealment and deployment of the cameras. The attackers are able to hide the camera anywhere in the private space. For the sake of coverage, the attacker can install any number of spy cameras of the same or different brands.

Type of spy camera. The attackers can use different forms of spy cameras. Depending on the transferring methods of real-time video captures, the spy camera can be wired/ wireless to a remote receiver or stored in offline on-board memory. Moreover, we have no restrictions on the appearance and the manufacturer of the spy camera. In addition, the attacker may hack an innocuous camera (e.g., webcam or home security camera) used by the victim, and convert it into a spy cam.

Limited manipulation of camera hardware. We assume the attackers use consumer-grade cameras. They can change the camera configurations but are unable to modify the bottom memory system.

3.2 Capability of the Detection System

Equipment composition. The RF capturing device can capture the signal whose frequency band matches with that of the EMR signal of the spy cameras. A typical detection system of ESauron shall consist of the following devices: 1) broadband antenna that can capture the EMR signal, 2) software defined radio (SDR) that can down-convert and digitize the signal, 3) a plug-in miniature strobe light to bring continuous stimulus to trigger traceable and stable memory EMRs, and 4) PCs that can analyze the characteristics of EMR spectrum and run detection and localization algorithms.

Usage pattern of ESauron. The ESauron system can be carried by a user anywhere in a given privacy-sensitive room. To achieve a better detection performance, a user can request the other people at the scene to keep still or leave temporarily.

Environment. In a scene of privacy-sensitive environments, such as hotel, office and conference room, there will inevitably be various other electronic devices, especially some legal or authorized camera devices, which will also generate EMR and interfere with the detection. However, as a detector, the system should know the characteristics of the above-mentioned devices' EMRs to mitigate such interference and boost detection efficiency.

Detection range limitation. ESauron's detection capability is highly dependent to the strength of emitted EMR signals. A memory can be wrapped by a perfect electromagnetic shielding cage to prevent EMR leakage. ESauron's detection range depends on how well-established the electromagnetism shielding device (see Sec. 5.3.2).

4 ESauron Design

In this section, we presents the detail design of ESauron.

4.1 ESauron Overview

As depicted in Figure 5, ESauron consists of four major modules within its workflow: *(i) Detecting memory EMR:* ESauron employs a folding algorithm that leverages the unique spectrum characteristics of memory EMR to accurately capture EMR signals with high sensitivity; *(ii) Distinguishing and tracking per-device's EMRs:* ESauron then separates the memory EMRs of different devices, and tracks the EMR pattern of each potential spy camera based on their memory clock fingerprints; *(iii) Stimulus-based spy camera detection:* By intentionally inducing scene changes, ESauron excavates the causal relationship between the stimulation and responsive EMR pattern to assert the existence of a spy camera; *(iv) Pinpointing of spy cameras:* ESauron leverages both the sensitivity to scene changes and distance-relevant properties of memory EMR to quickly pinpoint the spy cameras' locations.

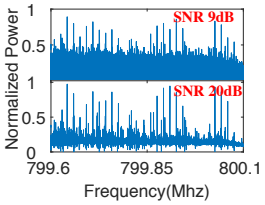

Figure 6: The spectrogram of original and denoised harmonic components.

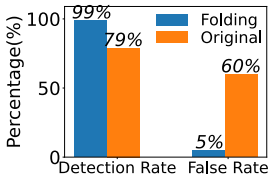

Figure 7: Folding-based memory EMRs extraction.

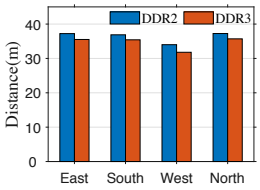

Figure 8: Folding-based memory EMRs detection range.

4.2 Detecting Memory EMR

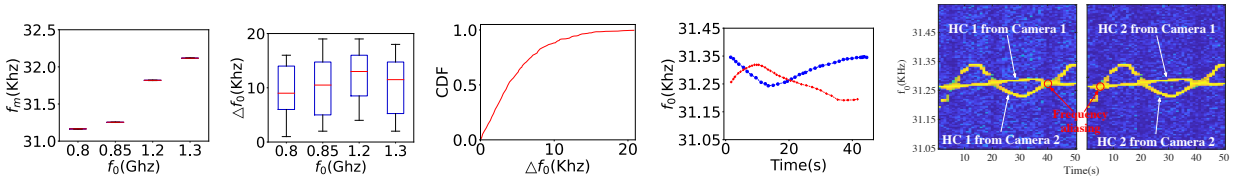
We first present ESauron's EMR sensing module, which consists of folding-based memory EMR extraction and wavelet-based denoising.

4.2.1 Augmenting the strength of weak EMR signals

Recall that the memory EMR spectrum consists of a series of evenly separated harmonic components, of which the i-th harmonic component is located at the frequency of $f_0 - i \cdot f_m$. Based on this observation, we utilize the folding algorithm (see details in Appendix B), which is generally used for amplifying periodic astronomical signals, to search for possible peak frequency offset f_m to extract the harmonic components, and put all extracted EMR harmonic components with the same f_m into the same group.

To make the process computationally efficient, instead of performing a full spectrum scan, we investigated the typical center clock frequency ($f_0 \in G_{f_0}$) among the available DDR memory products in the market, and identify and checked the intervals between each visible harmonic components f_0 in the spectrum as the possible, referred to as $G_{f_0}^{f_m}$. In execution phase, ESauron iteratively selects a specific f_0 from G_{f_0}, and then scans the frequencies around f_0. Suppose $\mathcal{R}$ represents the series of N frequency samples in the memory EMR spectrum, and $\mathcal{R}[i][(\in [0,N])]$ is the amplitude of the i-th sample. The employing of folding is to search for and aggregate the energy from the EMR signals emitted from the same device, i.e., signals consisting of harmonic components separated by the same frequency samples offset, i.e., a possible candidate of $G_{f_0}^{f_m}$, denoted as f_m^c. To search for potential EMR harmonic components, the spectrum is first divided into small windows of samples with size f_m^c and then added in a window-wise fashion [25]

$$P_{f_m^c}[i] = \sum_{j=0}^{\lceil N/f_m^c \rceil - 1} \mathcal{R}[i + j \cdot f_m^c], \quad 0 \leqslant i < f_m^c. \tag{2}$$



Through this folding mechanism, the energies of those harmonic components separated by f_m^c can be accumulated while the fused noise is likely smaller due to their non-periodicity in the frequency domain. The position of the folding peak, i.e., the i that maximizes $\|P_T[i]\|$, depends on the offset of memory's center clock frequency, i.e., Δf_0. For the application scenarios of ESauron, the actual f_m^c of potential spy cameras is unknown. So ESauron folds every possible f_m^c in $G_{f_0}^{f_m}$ to search for each harmonic component in the memory EMR spectrum. Even if some harmonic components may be completely overwhelmed by noise, ESauron still deduces the potential location of the harmonic component by Eqn. (1). In this way, ESauron can accurately extract all potential harmonic components sourcing from memory EMRs for follow-up processing. Those harmonic components with the same f_m are grouped into a set G_{f_m}. Note that these harmonic components could still originate from different devices with the same memory model. We will explain how to separate them in Sec. 4.3.

4.2.2 Wavelet based denoising

Even after the folding process, residual noise exists within the extracted harmonic components in G_{f_m}. The noise could come from various sources such as nearby electric devices and the camera's intrinsic noise. To eliminate such noise, we employ wavelet denoising [26] to eliminate the residual noise from the extracted harmonic components in G_{f_m}. The signal can be decomposed into detail coefficients (α_k) reflecting high-frequency information and approximate coefficients (β_k) reflecting low-frequency information through multi-layer wavelets. Through this multi-resolution decomposition, the peak frequency of memory EMRs and noise usually have different expressions at different layers of α_k and β_k. Finally, a level-dependent reconstruction is employed using all the coefficients as:

$$x_n = \sum_{k \in Z} \alpha_k^{(J)} \bar{g}_{n-2^J k}^{(J)} + \sum_{l=1}^{J} \sum_{k \in Z} \beta_k^{(l)} \bar{h}_{n-2^l k}^{(l)}$$

where $\bar{g}$ and $\bar{h}$ are rescaled discrete orthogonal functions. The spectrogram of a typical EMR harmonic component before and after the processing stage is shown in Figure 6, where the SNR is improved substantially, from 9 dB to 20 dB. The wavelet-based noise reduction is actually achieved by additional processing like thresholding or filtering the wavelet coefficients decomposition. By setting coefficients below certain amplitude thresholds to zero under the assumption

(a) Invariant f_m (b) Δf_0 (c) CDF of Δf_0 (d) Clock drift (e) Fluctuation trend of HCs

Figure 9: The device-specific static and dynamic traits. (a) f_m is only significant across different devices; (b) f_0 differs even across the identical devices; (c) f_0 is randomly distributed between 0 and 30 kHz; (d) Each camera device has a unique clock drift pattern; and (e) Fluctuation of harmonic components' (HC) drift pattern among two spy cameras (SP).

they manifest noise, crucial denoising is realized. Appropriate threshold selection is key to balancing signal distortion against noise removal.

To validate the effectiveness, we deploy different kinds of devices configured with a known DDR memory and then use both the folding algorithm and wavelet processing to extract the affiliated EMR harmonic components. As shown in Figure 7, compared with the energy threshold-based detection method, the folding algorithm can improve the detection rate from 79% to 99%, which means ESauron almost never misses any harmonic components. On the other hand, the false detection rate (i.e., mistaking other harmonic components for the target memory EMR) is decreased from 60% to around 5%. The residual error can be further reduced using the static/dynamic traits unique to each device (Sec. 4.3). Besides, the harmonic component energy after denoising can also significantly increase the SNR of received EMR and improve sensing distance. As illustrated in Figure 8, for both the DDR2-1600 and DDR3-1700, which are the most widely used memory models by spy cameras according to our investigation, the detection range can be up to 30 meters.

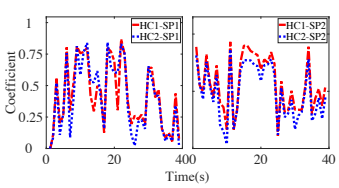


Figure 10: Fluctuation of the correlation coefficient of each harmonic component.

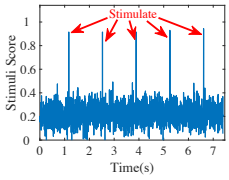

Figure 11: Causality analysis on stimulus-triggered EMRs patterns changes with t-test.

4.3 Distinguishing Per-Device's EMRs

ESauron further leverages both static and dynamic device-specific traits to differentiate different devices' EMRs in each group of EMR harmonic components (i.e., G_{f_m}).

4.3.1 Device-specific EMR traits

Static traits: center clock frequency offset. For the static traits, the offset of f_m is invariable for the same devices, whereas sufficiently diverse across different devices as shown in Figure 9(a), which should be attributed to the different modulation frequencies of their clock generators. In comparison, due to the imperfect manufacturing process, there exists an intrinsic center clock frequency offset $\triangle f_0$ between DDR memory products even with the same model as shown in Figure 9(b).

To examine whether the static $\triangle f_0$ is sufficiently diverse, we select an arbitrary pair of identical DDR memory products, denoted as D_i and D_j. Due to the similar f_m, the separability of their EMR features depends only on $\triangle f_0$. If the $\triangle f_0$ is too small, the two devices' harmonic components will overlap in frequency. We observe that the bandwidth of all harmonic components is within 300 Hz, which is consistent with previous research [15] and significantly smaller than $\triangle f_0$, that randomly distributes between 0 and 20 kHz as shown in Figure 9(c), in other words, implying that the static traits of the memory EMR spectrum are device specific and can be exploited to identify and distinguish different devices. However, due to the randomness of the memory's center frequency f_0, when $\triangle f_0$ is no larger than the bandwidth of harmonic components, the static traits alone can not effectively separate the coexisting devices.

Dynamic traits: time-varying clock drift patterns. For the dynamic traits, due to the uncontrollable heating effect inside memory caused by read/write operation [27, 28], the memory clock f_0 experiences continuous change in amplitude and phase in the time domain as illustrated in Figure 9(d), leading to time-varying f_0 for a specific device. Due to the spread spectrum clocking, all affiliated harmonic components $V_{ssc}(t)$ on a device originating from the same clock source $V_{clk}(t)$, hence producing the same fluctuation trend for f_0. Figure 9(e) plots the traces of frequency drift of two devices with the same DDR memory. We observe completely different fluctuations, implying that even when two devices have identical static traits, namely (f_0, f_m, $\triangle f_0$), their EMR harmonic components can still be effectively separated by exploiting the dynamic traits. The highly diverse EMR patterns present device-specific traits for discriminating multiple potential spy cameras.

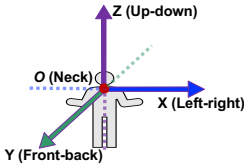

Figure 13: User-centered 3-dimensional reference system.

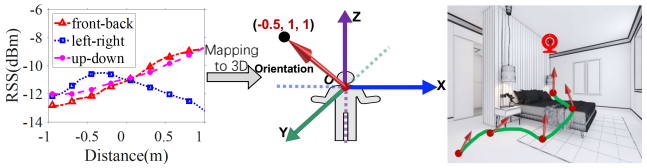

Figure 14: Example on the principle of mapping EMR RSS trend in three dimensions (left part) to an orientation vector in user-centered 3-D reference system (middle part); Iterative process (right part)

4.3.2 Distinguishing memory EMRs

We design an iterative process to leverage the above device-specific static and dynamic traits, to separate devices whose EMR harmonic components are clustered in the same group G_{f_m}. We first sort all harmonic components in G_{f_m} by center frequencies, i.e., $G_{f_m} = \{sc^0_{f_m}, sc^1_{f_m}, \cdots, sc^n_{f_m}\}$, where $sc^i_{f_m}$ denotes the i-th harmonic component in the group. We select a harmonic component with the highest peak (caused by a device that has the strongest memory EMR) in G_{f_m}, and also select all the affiliated harmonic components with the frequency offset $i \cdot f_m$, where i is an integer. Then we remove all the affiliated harmonic components from G_{f_m} and move to a temporary subgroup $\overline{G_{f_m}}$. Due to the spread spectrum clocking, the frequency drift of the same device's harmonic components must be with the same fluctuation trends. If these harmonic components in $\overline{G_{f_m}}$ are produced by the same devices, they can experience consistent fluctuations in time domain, such as the *harmonic component 1* and *harmonic component 2* of device 1 in Figure 9(e).

Thus, to quantify the consistency of all harmonic components in $\overline{G_{f_m}}$, we further calculate the correlation coefficient R_c of the consecutive samples of each harmonic component in the time domain. Although auto-correlations can effectively quantify the instantaneous match across harmonics at any given time, it is important to highlight that they are unable to measure the similarities in the long-term frequency drifting behavior of these harmonic bands. Thus we then employ Dynamic Time Warping (DTW) [29] to measure the similarity between the trends of R_c between different harmonic components in $\overline{G_{f_m}}$. Those harmonic components having similar trends in the time domain, as illustrated in Figure 10, can be exactly identified as the affiliated harmonic components belonging to the same device. If so, ESauron names the device as *Bob* and moves all the affiliated harmonic components in $\overline{G_{f_m}}$ to a device group $G_{f_m}(Bob)$. The above procedure is executed in a loop until the highest folding peak meets a predefined threshold. In this way, ESauron can separate all devices that are equipped with a DDR memory, which may include potential spy cameras.

In practice, due to the dynamic traits, the static traits (f_0, f_m, $\triangle f_0$) will be shifted over time. Hence, ESauron has to monitor the separated devices in real-time and leverages the limited frequency drift in a short period to keep track of each device's harmonic components in the time domain. It is worth noting that although the dynamic traits can also bring about the harmonic components' frequency aliasing of different devices, as illustrated in Figure 9(e), possibly mistaking the device track, it would not affect the follow-up spy camera detection and pinpointing as long as they can be separated.

4.4 Stimulus-based Spy Camera Detection

Note that the sudden change of light intensity can lead to significant scene change for a working camera, which in turn triggers a surge in camera memory access and processing to encode new visuals. In contrast, the activity of non-camera devices is independent of the change of light intensity. By intentionally inducing scene changes via turning on/off light, ESauron can excavate the causal relationship between the stimulation and responsive EMR pattern to assert the existence of spy cameras. Once the affiliated EMR harmonic components of device D are identified, we adopt a stimulation method to assert whether D is a spy camera.

Stimulation strategy. In the stimulation stage, we intentionally turn the room light on and off to create global scene changes, which can suddenly aggravate memory workload and hence trigger responsive EMR patterns from the cameras. Then, ESauron senses and extracts the affiliated EMR harmonic components of device D, and tracks the EMR pattern changes in response to the stimulus.

ESauron uses a method of t-test [30] to analyze the causal relationship between the intentional stimulus and responsive memory EMR pattern. Specifically, ESauron first samples the EMRs and calculates the variance of memory EMR pattern over a time window to determine whether it is in steady state. If so, ESauron instructs the user to start the lights on/off stimulation. Then, ESauron adopts t-test to perform causality analysis between the pre- and post-stimulus EMR patterns. A t-test takes the mean μ, variance σ, and the number of samples N of the two compared sets (i.e., the sets of samples captured in during pre- and post-stimulus), and then computes a t-score. Here the t-score represents the degree of difference between the two sets of samples. A large positive t-score is an evidence that the mean of samples in post-stimulus is significantly larger than that in pre-stimulus.

Existence assertion. Once the t-score is calculated, coupled with the sample size, the degree of the difference (referred to as "Stimulation score") is normalized and determined by referring to the t-test distribution table [30]. Figure 11 shows the traces of intentional stimulus and stimulation score when probing the EMR signal of a spy camera. Even though normal video processing brings misleading stimulation scores, they are much lower compared with the case of intentional stimulation.

4.5 Pinpointing Spy Camera's Location

After determining the existence of a spy camera D, we further leverage both the sensitivity to scene changes and distance-relevant properties of the memory EMR to quickly pinpoint the spy camera's location.

Unearthing distance-relevant information. ESauron leverages the relative change of RSS along the receiver's trajectory to guide it approximately towards the EMR source, i.e., the camera. To this end, ESauron equips a plug-in miniature strobe light [31] on the receiver, to produce continuous stimulus and trigger traceable EMRs. Although the RSS of EMR from cameras situated indoors does not strictly adhere to the Friis free space path loss model given the rich multipath propagation, the general trend of RSS decrease over distance is invariant. So ESauron employs a simple Kalman filter to average out the multipath effect. We move the ESauron in the opposite direction of the spy camera. From Figure 12, we observe that although there are several solid or weak points in the middle, the RSS preservation after filtering continues to decline.

Orientation in 3-D space. We introduce a simple process to track the EMR RSS tendency along different directions, and then determine the orientation of spy camera relative to the ESauron receiver/user. Specifically, for each orientation, we construct a 3-D reference coordinate with the center of the user's neck as the origin, as illustrated in Figure 13. The horizontally extended left and right arms are respectively marked as the negative and positive x-axis; and accordingly the y and z axes can be defined.

Then, the user needs to move the receiver along each axis. ESauron can analyze the EMR RSS tendency accordingly, as illustrated in the left part of Figure 14, where we normalize the RSS and the distance changes in one arm length. ESauron then selects the maximum RSS values along each direction, denoted as $(RSS^x_{max}, RSS^y_{max}, RSS^z_{max})$. ESauron leverages the EMR RSS tendency in different directions to generate an overall direction of spy camera in 3-D coordinate system relative to the ESauron user, as illustrated in the middle part of Figure 14.

Iterative-approximation process. The user iterates the above process of moving towards the RSS-maximizing direction, until the RSS reaches its maximum value, i.e., the user is closest to the camera. It is worth noting that this iterative-approximation process has great tolerance against the deviation from the optimal searching path, because the deviation does not accumulate over search steps, and the trend of RSS drop over distance remains unchanged. By holding ESauron in an apartment room where a spy camera was installed in a corner of the roof, ESauron can identify the RSS-maximizing direction at any location of the room. The right side of Figure 14 shows the iterative process to move towards the spy camera.

5 Evaluation Results

5.1 Experimental Setup

Figure 15 shows the prototype platform of ESauron, composed of a laptop PC equipped with a plug-in miniature strobe light and a USRP B210 with a log-periodic antenna LP0965 (850 MHz-6.5 GHz, 5-6dBi, Size: 15*14cm). The USRP B210 is controlled by using Matlab in the laptop PC, which implements the signal processing mechanisms that constitute ESauron.

Testing cameras. We evaluated ESauron on 50 cameras of 10 typical brands on the market of both the US and China, as shown in Figure 16 and Table 1. All the cameras use H.264/H.265 codecs which are the most popular codecs used by spy cameras. Those cameras can be divided into 4 categories, including 13 miniature spy cameras, 10 surveillance cameras, 17 IP webcam in laptop/smartphone, and 10 home security cameras.

Testing scenarios. We experiment with ESauron in 4 typical privacy-sensitive environments (Hotel, Bathroom, Office

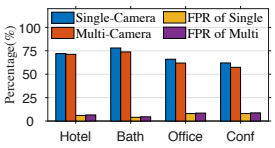

Figure 19: The detection rate and FNR of ESauron in a single stimulus round.

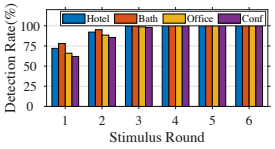

Figure 20: The single-camera detection rate of ESauron in the multiple stimulus rounds.

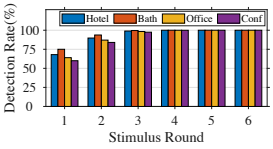

Figure 21: The multi-camera detection rate of ESauron in the multiple stimulus rounds.

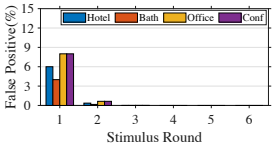

Figure 22: The false positive rate of ESauron in the multiple stimulus rounds.

and Conference room) as illustrated in Figure 17. The dimensions of the rooms are: Hotel ($5\times6m^2$), Bathroom ($2\times3m^2$), Office ($3\times4m^2$), and Conference room ($10\times12m^2$). For each environment, we hide the cameras inside furniture or appliances (e.g., a wardrobe or a bedside table) to imitate practical attack scenarios. In addition, we set up 4 extreme scenarios (Computer room with severe memory EMR interference, spying outside the window, spying with one-way mirror, and camera SoC behind concrete wall by camera re-factoring) that could possibly happen, as illustrated in Figure 18 .

Note that in all these experiment scenarios, spy cameras may coexist with other electronic devices, such as voice assistants, smart projectors, desktop computers, etc., that can produce memory EMRs to interfere with the ESauron detector. Also, we know the models of legal or authorized camera equipment in the environment. To ensure the objectivity, we conduct double-blind experimental procedure, which involves an attacker team for hiding spy cameras and an isolated defender team (the co-authors of this paper) for detecting the hidden cameras. Specifically, the defender team operated the ESauron prototype system from an isolated room with no information on the number, models or locations of the hidden cameras.

Comparing ESauron with Existing Work. We consider EarFisher [15] and CamRadar [18] to compare our work in terms of robustness: EarFisher relies on the network to actively import data volumes to stimulate devices to generate electromagnetic leakage. CamRadar detects spy cameras through electromagnetic leakage from ADCs.

Performance metrics. To evaluate the performance of ESauron, we use the following metrics:

- Detection rate. The ratio of the number of detected spy cameras to the total number of actually deployed spy cameras.
- False positive rate (FPR). The ratio of the number of devices that ESauron falsely regarded as spy cameras to the total number of devices that were detected as spy cameras.
- False negative rate (FNR). The ratio of the number of actual spy cameras failed to detect the presence to the total number of actually deployed spy cameras.
- Positioning distance efficiency (PDE). The ratio of the Euclidean distance between the initial location of ESauron and spy camera to the total length of walking route for finding out spy camera.

5.2 Spy Camera Detection Performance

We first deploy a single camera at eight fixed corners respectively at the room's top and middle wall, and calculate the average detection rate for all deployment locations. Figure 19 shows that, with a single stimulus (i.e., turn on and off the light once), the detection rate ranges from 62% to 78% across different room types. The detection rate tends to be higher in darker scenes. This is mainly because the stimulus significantly changes the scene, and accordingly the spy cam memory switches from the standby state to the high-load state, making the EMR signals more prominent.

Figure 20 further shows the detection rate of ESauron after the multiple stimuli. The interval between each stimulation is not less than 1 second. We observe that the detection rate improves quickly with the number of stimuli, e.g., from 78% to over 99.7% after 3 successive stimuli in the bathroom. Although the detection rate in the conference room is the worst, it increases rapidly to 97.7% after 3 stimuli.

Since there may be other electronic equipment in the environment, the FPR performance is also essential. Figure 22 shows that the FPR for all room types. The offices and conference rooms have the highest FPR because of the most number of electronic devices nearby. After the second round of stimulation, the FPR quickly dropped below 0.6% for all room types. After 3 rounds of stimulation, the FPR dropped to 0.

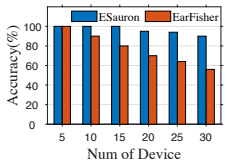

Figure 23: The upper limit of the number of ESauron separation devices.

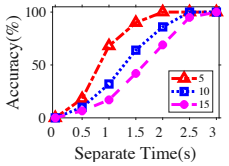

Figure 24: The time cost of the ESauron in separating the cameras.

5.3 Robustness Analysis

5.3.1 Multi-camera detection accuracy

We also conduct quantitative study to evaluate the maximum number of spy cameras that ESauron can successfully detect. Note that the detection of spy cameras consists of two steps, i.e., separating and classifying the harmonic components of different devices and then asserting whether they are spy cameras, and the former is decisive to the detection. Thus we first emulate a scenario where there are multiple devices equipped with the same DDR memory in a computer room with 30 personal computers (PCs). By starting different number of PCs, we evaluate how many devices can be successfully identified by separating and classifying their EMR harmonic components. Figure 23 shows that, when the number of devices increases to 30, the separation accuracy of ESauron remains at 90%, while the separation accuracy of EarFisher is only 56%. Because EarFisher does not consider the aliasing of harmonic components from different devices at all, the separation capability of EarFisher is limited to around 15. It is worth noting in practical applications, the number of devices that ESauron can accurately separate is much larger than 15, because of most devices in a deployment location usually use different DDR memory products, producing EMRs with different center frequency, such as DDR2-1600's 800 MHz and DDR3-1700's 850 MHz. ESauron can easily separate these devices by channel hopping.

Since the time cost for successfully separating multiple devices is also critical to ESauron's performance on spy camera detection. We define the time from the collecting of the first EMR signals to successfully separate all devices' harmonic components as "Separating time". Figure 24 shows when there are no more than 15 devices, ESauron can successfully separate 99% harmonic components within 3 second.

On that basis, we set 15 cameras at the same time to different locations in each of the deployment locations, and evaluate the average detection rate. Figure 19 shows that the multi-camera detection rate is similar to that of single-camera detection under a single stimulus. Figure 21 shows after only 4 stimuli in all deployment locations, all the deployed spy cameras (100%) can be successfully detected.

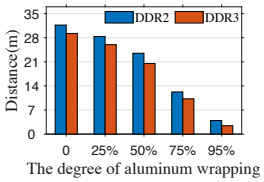

Figure 25: Impact of aluminum sheet's coverage on detection distance.

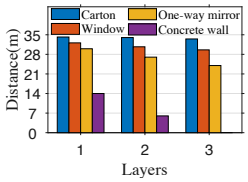

Figure 26: Influence of varying hiding conditions on detection distance.

5.3.2 Detection distance

We define the detection distance as the maximum distance at which ESauron can detect the camera over several rounds of stimulation. Considering the many methods an adversary may employ to prevent spy cameras from being spotted, we evaluate the EMR detection distance in several extreme situations. First, we emulate an scenario where the adversary packages the camera body to prevent EMR leakage. We cover the spy camera housing with an aluminum sheet, and gradually increase the coverage by changing the size of the sheet. The aluminum sheet in our experiments comes from the casing of a Coke can. Figure 25 shows the effect on the EMR detection distance. We observe that when the coverage is less than 50%, the detection distance decreases, and the variance increase. This is because the aluminum sheet reduces electromagnetic radiation in some directions while strengthening radiation in other directions. When the coverage is increased to 95%, the detection distance decreases significantly but remains above 2 meters. Note that 100% metal coverage is impossible since the lens area has to be exposed.

The spy camera can also be hidden and retrofitted in a variety of ways. For example, it can be hidden in a carton box. Spy cameras can also be deployed outside windows to monitor rooms. The processing unit can be decoupled from the lens unit (linked by a cable), and hidden inside a concrete wall to shield the EMR signals. In a bathroom, the camera can even be deployed behind a one-way mirror.

We evaluate the effects of cartons, outside windows, one-way mirrors, and concrete walls on the detection distance, respectively. Figure 26 shows that the carton (around 5 mm thick) does not affect the detection distance. As the number of layers of the windows (5 mm thick each) and the one-way mirror (12 mm thick each) increases, the detection distance decreases slightly. A concrete wall (25 cm thick) has the most significant impact on the detection distance, and can reduce the detection distance to 14 m. A double-layer concrete wall further reduces the distance to 6 m. Three layers of concrete walls can effectively mask the EMR signals.

Table 2: Detection distance (m).

Shell Type	ESauron	CamRadar
Plastic	30.6	0.7
Metal	11.2	0.2

Comparison with CamRadar. We have also conducted an evaluation of the detection distance for both ESauron and CamRadar using the same experimental setup. The detection distances for ESauron and CamRadar are listed in Table 2. Specifically, we consider two scenarios where the opponent encapsulates the camera body to prevent electromagnetic radiation (EMR) leakage, using either a plastic case or a metal

case. In the case of a plastic housing, ESauron achieves a detection distance of 30.6m, while CamRadar only achieves a detection distance of 0.7m. When the housing is made of metal, ESauron has a detection distance of 11.2m, whereas CamRadar only reaches 0.2m.

It is important to note that CamRadar relies on detecting electromagnetic interference from analog-to-digital converters (ADCs) in cameras to identify hidden cameras. This limitation restricts CamRadar's detection range to less than 1 meter, as ADC emissions tend to be relatively weak. In contrast, our proposed solution focuses on capturing memory EMR from real-time encoding workloads, which exhibit significantly stronger emissions. This enables ESauron to achieve detection ranges beyond 10 meters in most cases.

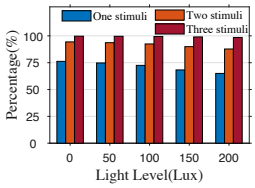

Figure 27: Detection performance under different light levels.

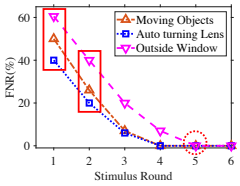

Figure 28: False negative rate in different conditions.

5.3.3 Impact of lighting conditions

We test ESauron at different times of the day with different ambient light intensities which are measured using a smartphone light sensor. Figure 27 shows the detection performance of ESauron at 5 ambient light levels. As the intensity of ambient light increases, the detection rate of ESauron decreases from 76% to 65% under a single stimulus. This is because strong ambient light can weaken the spy camera's sensitivity to the intentional stimulus by turning on/off room light. Even though, the increase of stimulus rounds can compensate for the impact of lighting conditions. Results show even with a light intensity of 200 Lux, the detection rate can be up to 98% after three rounds of stimulation.

5.3.4 False negative rate

When an intentional stimulus can not trigger an obvious responsive memory EMR pattern, it possibly causes the false negative rate (FNR). In our experiments, we observe three extreme situations can bring false negative detection: (1) Existing moving objects within spy camera's monitoring view; (2) Refactoring an automatic fine tuning mode for the camera lens by the adversary; and (3) Spy camera deployed outside a glass window that can be affected by the outdoor situation. Under these extreme situations, the spy camera's memory activities can possibly and coincidentally occur at the same time of EMR sensing, bringing non-causal EMRs pattern and leading to false negative results. By emulating the three scenarios, we repeat ESauron's spy camera detection mechanism more than 100 times under each scenario. Figure 28 shows the FNR of ESauron after different round of stimulus. All three extreme situations have high FNR (more than 40%) because of the non-causal EMRs pattern caused by other irrelevant activities. Even though, due to the picture estimation of advanced coding techniques, ESauron remains robust to these extreme situations after multiple stimulus rounds. As shown, after only 5 rounds of stimulus, the FNR is close to 0. The results demonstrate that ESauron has good robustness even in extreme situations. With the increase of stimulus round, ESauron can reliably detect spy cameras.

5.4 Camera Location Inference Accuracy

We conducted localization experiments in the above 4 representative environments. In the hotel room, spy cameras are placed in five fixed locations: the upper left/corners of the wall, the headboard, the bedside table, and the opposite side of the bed. In the office and conference room, spy cameras are installed in the following locations: two sockets, on top of curtains, in the upper left/right corners of walls. In the bathroom, the cameras are hidden in the lampshades and the upper left/right corners of the walls. We tested 13 spy cameras in 10 trials for each situation. Positioning is determined to be successful when there is a spy camera within 0.5 meters of ESauron's final estimated location. For each trial, we calculate the localization time and the positioning distance efficiency for different rooms.

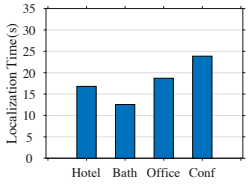

Figure 29: Localization time in different environments.

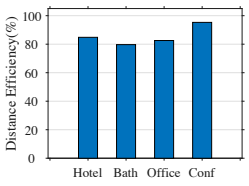

Figure 30: Positioning distance efficiency.

We successfully positioned the spy camera in all trials. From the results in Figure 29, we found that the bathroom has the short localization time, and the positioning task can be completed in as fast as 4.1 seconds. But due to multipath, it takes 16.7 seconds in the slowest bathroom case. In the conference room (the largest), ESauron still completes the task in 32.3 seconds. From Figure 30, we observe that the distance efficiency of the conference room is as high as 95.3%. In larger room types, ESauron is more efficient. In all room types, the efficiency of ESauron exceeds 79.7%.

6 Related Work

Detecting cameras by identifying light reflection and EMI. Prior research has shown that, by illuminating a suspicious place with laser or flashlight, hidden cameras can be pinpointed based on the tiny glint of the lens [32]. Similarly, a ToF sensor can reveal the location of lens [33], since the lens causes a sharp increase ToF along the depth direction. These approaches assume that the users are aware of the approximate location of the cameras and can shed light towards the lens, which may not be easily satisfied in practice. Besides, these methods are cumbersome to use and require significant user involvement. Alternatively, [34] employs a smartphone's magnetometer to sense the changes in electromotive force, and then infer the existence of spy cameras. However, all electronic devices can cause the change in electromotive force. Thus to search out a spy camera, the user must scrutinize the entire private space, which requires a meticulous scanning process while no guarantee that the detected electronic device is a spy camera.

Traffic analysis for wireless-connected cameras. Information leakage from wireless cameras has been investigated in prior research [35, 36, 13, 37, 14]. It is well established that scene variations (e.g., sharp change in lighting conditions) may modulate the video codec workload and hence the data traffic from a wireless camera. Exploiting such phenomenon, [12] further pinpoints the camera location. While these techniques are promising, they only work for wireless cameras, whereas a significant number of hidden cameras are either wired or store data to a local memory card. The key difference is that ESauron can accurately detect both wireless and wired spy cameras by leveraging the leakage of memory EMR signals and can quickly pinpoint cameras' locations.

EM side-channels. Recent research also leveraged the EM side channels of ADC, CPU and memory for attestation [38, 18], memory profiling [39, 15], and malware detection [40, 41, 42, 17]. Among them, EarFisher [15], Memscope [16], DeHiREC [17] and CamRadar [18] are the most relevant to ESauron. EarFisher and Memscope explored the possibility of exploiting memory EMR to detect wireless eavesdroppers, opening up new possibility of detecting stealthy electronic device with leaked EMR signals. Based on EarFisher, DeHiREC and CamRadar respectively leveraged the EMRs sourcing from the ADC to detect voice recorder and spy camera.

Although Memscope observed the negative impact of dynamic traits (frequency drift) of memory EMRs, rather than harnessing this feature to enhancing continuous tracking, it bypasses the dynamic traits by only leveraging stable harmonic peak interval to identify memory devices. Due to the ignorance of the critical dynamic traits of memory EMRs in camera devices, existing works are ineffective in distinguishing and continuously tracking the time-varying EMRs from even a single device, not to mention common scenarios deployed with multiple cameras probably of the same model. Moreover, due to the power of the ADC is much lower than the power of the memory, CamRadar and DeHiREC's detection range is limited within 1 meter, thus a user has to carry CamRadar and scrutinize the entire private space, requiring a slow and laborious sweep, bringing insurmountable hurdle for device identification and localization when spy devices are deployed in high places. Due to lack of thorough characterizing on memory EMR from camera devices, the inability to continuously differentiate devices of the same model, and lack of EMR-based positioning capability, existing works are still far from effective hidden camera detection in real scenarios.

Unlike these methods, ESauron features a new paradigm that actively stimulates the memory EMR of hidden cameras and pinpoint their locations. Moreover, based on the memory clock spectrum, ESauron innovates a signal processing chain to not only extract weak memory EMRs under poor signal conditions, but also distinguish and track individual memory EMRs when multiple devices coexist in a crowded environment.

Device Localization. Wireless indoor localization has been well explored in the past decade. Early work used signal strength fingerprinting or model-driven methods [43, 44, 45]. Angle of Arrival (AoA)[46, 47] or Time of Flight (ToF) [48] can further improve the spatial resolution. They require sophisticated receiver hardware or explicit synchronization with the transmitter. In comparison, ESauron adopts a received signal strength (RSS) based iterative-approximation search algorithm to heuristically direct the receiver towards the spy camera. Due to their relatively low frequency, the EMRs are less vulnerable to multipath and shadowing effects. On this basis, ESauron can continuously trigger the stimulus while the receiver moves towards the locations with an increasing RSS, until it approach the spy camera.

7 Discussions

ESauron's detection range is up to 20 meters, which applies to the majority of scenarios and outperforms the COTS camera detection methods, such as LAPD [33] 0.45-1.5m, E-Eye [37] 0.2m, and CamRadar [18] 1m. This significant advantage is mainly attributed to ESauron's unique techniques tailored for camera memory EMR, including the harmonic folding algorithm to extract weak EMR signals and the device fingerprinting to separate mixed EMRs. These innovations address the limitations of previous works that fail to consider memory EMR's critical traits.

Limitations. ESauron still has certain limitations: i) Stim-

ulus restriction. ESauron relies on active stimulation which may not always be feasible, especially when the user has no control over the target environment. ii) Inapplicable to detect emissions from cameras in some smartphones. The latest smartphones employ low-power DDR techniques [49][50] and integrate Faraday cages internally to mitigate electromagnetic radiation (EMR) leakage [51]. The combination of the two measures significantly increase difficulty to detect smartphone cameras' memory EMRs using the current ESauron prototype. Based on ESauron, we will further study the characteristics of smartphone camera and try to detect its activities in the future. iii) Detection object limitation. Many low-power IoT devices do not use DRAM, hence the detection of such-kind IoT devices is beyond the capability of ESauron. iv) Deficiency in portability. As a prototype system, ESauron requires dedicated sensing hardware and is not easy to carry. The miniaturization of ESauron such as hosting our system on Raspberry Pi (PiSDR) to replace laptop and miniaturize ESauron system, and using a customized low-cost USRP (RTLSDR) to replace B210 for cost reduction, remains a work in progress. v) Antenna Limitations. The log-periodic antenna have some directionality, which could cause false negatives when the radiation direction is not aligned with the antenna orientation. By using ESaron to detect spy cameras, we can mitigate such errors by turning the antenna to change its direction to cover 360-degree. Furthermore, cameras emit EMR in complex electromagnetic patterns, not just in a single direction. Therefore, even if the main lobe is misaligned, other side lobes can still be captured.

Addressing these limitations would further enhance ESauron's applicability. On the whole, ESauron represents an important step towards protecting personal privacy against hidden spy cameras. The proposed techniques open up new capabilities to detect cameras in a generalized manner. The results clearly demonstrate the feasibility of exploiting inevitable memory EMR leakage for spy camera detection, which was not shown before.

Noting that compared with log-periodic antenna, Yagi antenna is with smaller size. Based on our study on the spectral characteristics of camera's memory EMRs in this work, we plan to work on miniaturize ESauron system in future work. We are likely to use a customized Yagi antenna in the miniaturized system to replace the log-periodic antenna.

Potential problem of ESauron. While our system, ESauron, aims to empower users to detect hidden recording devices, we acknowledge that its detection capabilities could inadvertently result in privacy violations if misused. In fact, ESauron could potentially introduce a new privacy attack vector, as hackers could exploit it to infer users' activity routines within private locations.

8 Conclusion

Privacy protection in indoor environment has been an important but unsolved problem. In this paper we propose ESauron, which uses the leaked memory EMRs to detect spy cameras and pinpoint their location. We implemented and evaluated ESauron under various representative indoor scenarios, which demonstrates ESauron's effectiveness and robustness. We consider ESauron as a first exploration to detect and pinpoint all kinds of hidden spy cameras, including wireless/wire-connected and storage-based off-line devices.

A Frequently Used Symbols

Table 3 lists the frequently used symbols and the corresponding descriptions in this paper.

Algorithm 1: ESauron's folding scheme.

Input : $\mathcal{R}$, G_{f_0}, $G_{f_0}^{f_m}$
Output: G_{f_m}

for *each* $f_0 \in G_{f_0}$ **do**
  Initialize $P_{f_m^c}[i]$;
  for *each* $f_m^c \in G_{f_0}^{f_m}$ **do**
    $P_{f_m^c}[i] = \sum_{j=0}^{\lceil N/f_m^c \rceil - 1} \mathcal{R}[i + j \cdot f_m^c]$;
  end
  Find the max in $P_{f_m^c}[i]$, denote it as f_m;
  Put f_m inte set G_{f_m};
end
return G_{f_m};

Table 3: Symbol Description.

Symbols	Description
$V_{clk}(t)$	The EMR energy.
$V_{ssc}(t)$	The EMR energy after spread spectrum clock (SSC) techniques.
f_0	The center frequency of clock.
f_m	The modulation frequency of clock.
Δf	The peak frequency offset of clock.
f_{nz}	The frequency of the i-th non-zero memory EMR.
G_{f_0}	The set of potential memory center frequency f_0.
G_{f_m}	The set of harmonic components with the feasible f_m.
$\mathcal{R}$	The series of N frequency samples.
f_m^c	The harmonic components separated by the same frequency samples offset.
$\|\|P_T[i]\|\|$	The position of the folding peak.
α_k	The detail coefficients.
β_k	The approximate coefficients.
$sc_{f_m}^i$	The i-th harmonic component in the group G_{f_m}.
μ	The mean of the two compared sets.
σ	The variance of the two compared sets.
RSS	The received signal strength.

B The Folding Algorithm

Algorithm 1 outlines the folding algorithm used to extract harmonic components from the electromagnetic radiation (EMR) spectrum. The algorithm takes three inputs: the series of frequency samples from the captured EMR signal ($\mathcal{R}$), the set of potential memory center clock frequencies (G_{f_0}), and the set of feasible modulation interval values ($G^{f_m} f_0$) derived from Gf_0. It produces the set of detected modulation intervals (G_{f_m}) that identify distinct memory emanation sources.

The algorithm proceeds by iterating through each candidate center frequency f_0 from the set G_{f_0} (Line 1). For each assumed f_0, it attempts to fold the EMR spectrum $\mathcal{R}$ using different modulation interval values f_m^c from the associated set $G^{f_m} f_0$ (Lines 3). The folding operation involves summing the amplitude samples within windows of width f_m^c (Lines 4), thereby aggregating harmonic components separated by that interval. The modulation interval f_m resulting in the maximum folded amplitude peak is selected as the preferred value for a detected device (Line 6). Subsequently, f_m is added to the output set Gf_m for further analysis (Line 7). Once all potential f_0 values have been scanned, the algorithm returns the final set G_{f_m} containing the extracted modulation intervals (Line 9).

Through iterative folding of the EMR spectrum using feasible intervals based on memory clock models, the algorithm proves efficient in extracting harmonic patterns from multiple devices even at low signal-to-noise ratios. The resulting set G_{f_m} forms the basis for distinguishing and tracking individual memory EMR sources.

Improving the Ability of Thermal Radiation Based Hardware Trojan Detection

Ting Su, Yaohua Wang*, Shi Xu, Lusi Zhang, Simin Feng, Jialong Song, Yiming Liu, Yongkang Tang, Yang Zhang, Shaoqing Li, Yang Guo, Hengzhu Liu

National University of Defense Technology

Abstract

Hardware Trojans (HTs) pose a significant and growing threat to the field of hardware security. Several side-channel techniques, including power and electromagnetic radiation (EMR), have been proposed for HT detection, constrained by reliance on the golden chip or test vectors. In response, researchers advocate for the use of thermal radiation (TR) to identify HTs. However, existing TR-based methods are designed for the ideal HT that can fully occupy at least one pixel on the thermal radiation map (TRM). In reality, HTs may occupy multiple pixels, substantially diminishing occupancy in each pixel, thereby reducing the accuracy of existing detection methods. This challenge is exacerbated by the noise caused by the thermal camera. To this end, this paper introduces a countermeasure named noise based pixel occupation enhancement (NICE), aiming to improve the ability of TR-based HT detection. The key insight of NICE is that noise can vary the pixel occupation of HTs while disrupting HT detection. Consequently, the noise can be exploited to statistically find out the largest pixel occupation among the variations, thereby enhancing HT detection accuracy. Experimental results on a 0.13 μm Digital Signal Processing (DSP) show that the detection rate of NICE exceeds the existing TR-based method by more than 47%, reaching 91.81%, while maintaining a false alarm rate of less than 9%. Both metrics of NICE are comparable to the existing power-based and EMR-based methods, eliminating the need for the golden chip and test vectors.

1 Introduction

Hardware Trojans (HTs) are stealthy modifications to a circuit that can allow unauthorized access to and control over the content and communication of an integrated circuit (IC) [7, 14, 24, 28]. This emerging threat is compounded by the outsourcing of IC fabrication to third-party foundries due to economic and market forces. The attack poses a particularly powerful and stealthy risk because the unused spaces within the IC layout can be exploited by untrusted foundries to insert additional malicious circuits [49]. Addressing the fabrication stage attack is thus a crucial and urgent priority.

To mitigate this threat, side-channel techniques [2, 3, 4, 10, 19, 20, 22, 31, 39, 41] are studied due to their fast and cost-effective characteristics compared with destructive detection methods [27, 28]. Side-channel techniques rely on extracting the information of ICs through their power, electromagnetic radiation (EMR), and thermal radiation (TR). Dakshi et al. [2] initially proposed a countermeasure using power analysis. Subsequently, researchers have expanded upon similar concepts by utilizing EMR to enhance side-channel analysis [3, 10, 19, 20]. He et al. [19, 20] suggested that EMR traces can be used to detect HT with a considerable performance, identifying different types of HTs with an average accuracy rate of 89.2%. However, these methods rely on the IC fingerprinting from fabricated golden chips or test vectors to trigger the HT, both of which are challenging to obtain.

In 2014, Intel introduced a method that leveraged transient power consumption and TR, capable of detecting HTs with power consumption as low as $0.05\mu W/m^2$ [31]. Inspired by this method, TR-based methods were proposed to 1) identify regions with HT via statistical analysis [38, 44], and 2) detect HTs with power proportion as small as 0.14% in AES circuits through spatial projection transformation [42, 43]. The major limitation of these TR-based methods is that they still rely on the golden chip. In response to this limitation, Tang et al. [41] proposed a method to compare the Active Areas (AA) restored from Thermal Radiation Maps (TRM) with that of the IC design, so that HTs inserted during fabrication can be detected. Figure 1 presents the core processing flow of TRMs. Following the de-noising stage, incremental TRMs are utilized to distinguish between logic and vacant regions through statistical analysis, generating the actual AA shape of the fabricated IC. By comparing this AA shape with the design data, extra AA regions (i.e., possible HTs) can be successfully detected. Evaluations in [41] indicate that as long as the HT is larger than one pixel ($15\mu m * 15\mu m$) of the thermal camera, successful detection can be achieved.

(b) Mechanical vibration causes the image dithering. Dark and light colors represent scenes at different times.

Figure 2: Sub-pixel HTs and the mechanical vibration

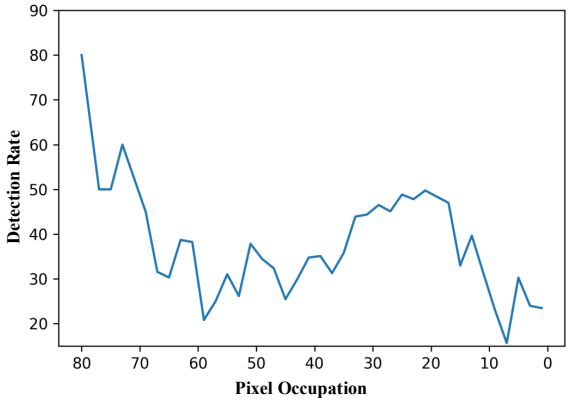

Figure 3: Performance deteriorates for the existing method

Despite the confirmed potential, existing TR-based methods are designed for the ideal HT that can fully occupy at least one pixel on the TRM. Such ideal HTs are not realistic due to the fact that HTs often extend across multiple pixels (shown in Figure 2(a)), occupying only sub-pixels in TRMs. Consequently, there is a significant reduction in occupancy within each pixel, leading to the ambiguous distinction of the TR for each sub-occupied pixel between logic or vacant areas, thereby rendering the current TR-based method impracticable. As illustrated in Figure 3, the performance of current methods deteriorates with decreasing pixel occupation. Notably, the detection rate drops below 50% when the HT occupies less than 70% of a pixel. Moreover, the noise resulting from the mechanical vibration of thermal cameras exacerbates the complexity of the issue. This disturbance induces image dithering in the TRMs sampled at different times (shown in Figure 2(b)), markedly diminishing the detection accuracy of sub-pixel HTs.

In order to improve the ability of TR-based methods, we propose a noise based pixel occupation enhancement (NICE) mechanism for HT detection. The primary observation of NICE is that noise can vary the pixel occupation of HTs while disrupting HT detection. As shown in Figure 4, a given HT position can result in different pixel occupation scenarios due to varying vibration directions. This observation motivates us to explore the optimal vibration direction, aiming to find out the largest pixel occupation scenario among the variations, which can prove instrumental in distinguishing HT pixels from vacant pixels, thereby significantly enhancing the accuracy of HT detection.

We implement NICE through a statistical manner, where TRMs are categorized into multiple sets based on the convergence of pixels dithering and the law of large numbers. This categorization is facilitated by estimating the dithering direction for each pixel, derived from the relationship between pixel occupation and TR increment. Subsequently, TRMs at each direction are processed independently for HT detection using Kolmogorov-Smirnov (K-S) statistic and the Pauta criterion. Finally, the detection results are statistically aggregated to derive the final conclusion. We carry out evaluations on a $0.13\mu m$ Digital Signal Processing (DSP) chip using a $15\mu m$ thermal camera to validate the efficacy of our approach.

The major contributions of this paper are:

1. We observe the impracticality inherent in the current TR-based method, designed for the ideal HT that fully occupies at least one pixel on the TRM. In real-world applications, where the HT typically occupies only a portion of one pixel, we demonstrate that the average detection rate of the current method falls below 45%.
2. We propose NICE, a noise based pixel occupation enhancement mechanism, aiming to improve the ability of TR-based methods. The key idea of NICE is to statistically find out the largest pixel occupations of the sub-pixel HT among variations caused by noise.

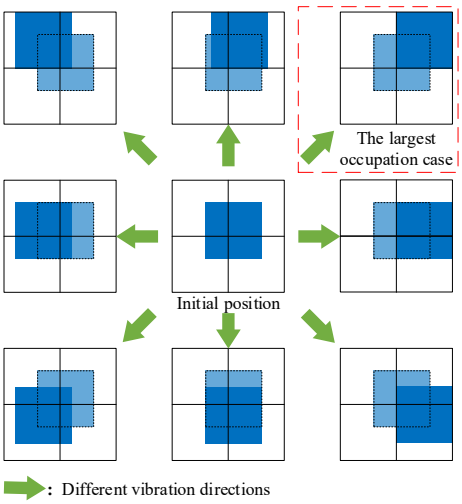

Figure 4: Different changes of pixel occupation caused by vibration directions

3. We demonstrate that NICE can improve the detection rate of sub-pixel HTs that exceeds the current TR-based method by more than 47%, reaching 91.81%, while maintaining a false alarm rate of less than 9%. Both metrics of NICE are comparable to the existing power-based and EMR-based methods, eliminating the need for the golden chip and test vectors.

2 Background

This section aims to provide a comprehensive understanding of the detection mechanism used in existing TR-based methods, along with an overview of the existing methods.

2.1 Threat Model

Adversaries inside the foundry possess complete access to the IC design layout, enabling them to carry out an HT attack during the IC fabrication. Various fabrication-time HTs have been studied recently, demonstrating the potential threat of this type of attack [26, 32, 33, 49]. These fabrication-time HTs can be divided into two categories: 1) additive HTs which implement HTs through insertion of additional logic cells to the original circuits; 2) modification HTs which modify the original logic cells to serve as HTs. Yang et al. [49] inserted analog HT for the attack, referred to as A2. Lin et al. [26] inserted Trojan side-channels (TSCs) which used side-channel leakage for HT implementations to leak exploitable information. Perez et al. [32, 33] demonstrated that attackers can insert a side-channel HT (SCT) into a finalized layout requiring minimal knowledge about the chip. There are also instances of modification HTs [5, 15]. However, such type of HTs remains largely unexplored [46] due to its tremendous effort [12], a-priori knowledge, and skill-dependent nature [48].

In our threat model, 1) we focus primarily on the additive HT, realized through the addition of transistors or gates [45, 46, 47], a more commonly employed approach in existing research [46]. This choice is practical as additive HTs are characterized by effective concealment and low implantation complexity. They minimally affect the original IC design, leveraging ample unused space within the IC for inserting additional gates and transistors [18, 41, 46, 48]. 2) We assume the victim cannot obtain a golden chip for HT detection [48], which is a reasonable assumption given the expensive and time-consuming nature of the reverse engineering process it entails. 3) We also assume the victim may lack test vectors capable of activating the HT. Detecting HTs poses inherent challenges due to the unknown function, structure, and location, leading to a lack of a-priori knowledge about their activation mechanism in real-world scenarios [17].

2.2 Physical Mechanism

The fundamental component of the IC is the metal-oxide-semiconductor (MOS) transistor. In its quiescent state, the MOS transistor's parasitic capacitance and intrinsic resistance convert electric energy into heat (Q), as elucidated by the specific heat capacity theory.

$$\Delta T = \frac{Q}{Cm}$$
$$Q = P_{leak} = i_{leak} V_{dd}$$

Where, i_{leak} is the leakage current, V_{dd} is the voltage, and C represents specific heat capacity. The temperature variation ΔT in each area of IC should be determined by the power consumption (P_{leak}) in that.

TR is a fundamental physical phenomenon exhibited by all objects at temperatures above absolute zero ($-273.15^{o}C$). Consequently, the incremental intensity of TR ($\Delta I(v, i_{leak})$) generated by the quiescent work of MOS transistors can be described by Planck law [6].

$$\Delta I(v, i_{leak}) = \frac{2hv^3}{c^2} \frac{1}{e^{hv/kT} - 1}$$
$$= \frac{2hv^3}{c^2} \frac{1}{e^{hvCm/Ki_{leak}V_{dd}} - 1}$$

Where, v represents the frequency of TR, and h denotes the Planck constant.

The essence of TR-based detection lies in the impact of HTs on the TR within the infected region. When the HT is inserted into the vacant regions of the IC through additional circuits, it results in additional power consumption in the corresponding area. Consequently, by observing the power changes reflected in the TR signal, we can effectively identify these alterations in the TRMs of the IC and detect HTs.

More specifically, the $\Delta I(v, i_{leak})$ of the additional circuits will no longer be zero due to the presence of leakage current.

The detection and localization of inserted HTs can be achieved by verifying the incremental TR in the vacant regions of the target chip. Therefore, the larger the size of the HT, the more pronounced the change, facilitating easier detection.

Relevant studies [31, 41] have demonstrated numerous advantages of TR-based detection over traditional methods. The TR-based method offers non-contact detection with high resolution, making it faster and more cost-effective than destructive techniques [27, 28]. Additionally, TR-based methods exhibit relatively lower susceptibility to process variation [21, 29, 35], which is an inevitable deviation arising from the fabrication process of ICs. This is attributed to the fact that the $\Delta I(v, i_{leak})$ of the logic region is sufficiently large, rendering it hardly affected by the small variations in the manufacturing process.

$$\begin{aligned}\Delta I(v,R) &= \frac{2hv^3}{c^2}\frac{1}{e^{hvCm/Ki_{leak}^2 R(1-\Delta R)}-1} \\ &= \frac{2hv^3}{c^2}\frac{1}{(e^{\frac{1}{1-\Delta R}})^{hvCm/Ki_{leak}^2 R}-1}\end{aligned}$$

Where, R is the typical resistor under a certain process, ΔR is the deviation of R.

Obviously, $e^{\frac{1}{1-\Delta R}} \to \infty$ is a necessary condition for $\Delta I(v,R) \to 0$, because $2hv^3/c$ and $hvCmR/Ki_{leak}^2$ are larger than 0. In other words, the TR change caused by HTs cannot be merged by the process variation noises, only if the deviation of R approaches to 100%.

2.3 Existing Methods

In 2014, Intel [31] proposed that transient power consumption and TR can be utilized to detect HT. According to their research, the detection probability is greater than 50% when the power consumption of HTs is lower than $0.05\mu W/m^2$ with effective process variation mitigation. While showing promise, this method relies on stronger simulation tools, currently limiting its practical implementation to theoretical considerations.

To enhance detection performance, Chen et al. [9] proposed a method that focuses on enhancing the spatial detail of TRMs to effectively eliminate noise. This was achieved by combining adaptive filtering in the time domain and guided filtering in the space domain, resulting in the improvement of 6.14dB in the signal-to-noise ratio of TRMs. Additionally, drawing inspiration from the concept of spatial projection transformation, principal component analysis (PCA) was employed to identify the key factors within the TR information. This enabled the detection of HTs comprising fewer than 20 gates [43] or with power proportions as low as 0.14% in AES circuits [42]. However, it is important to note that these TR-based methods encounter significant limitation. They heavily rely on the availability of the golden-chip, which is challenging to obtain in practice. As a result, the deployment and practical implementation of these methods is hindered.

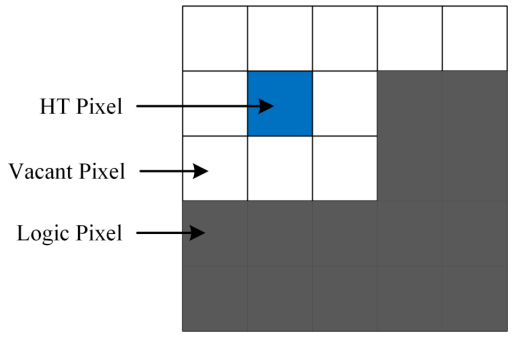

Figure 5: The HT fully occupies one pixel

In order to tackle the challenge posed by the requirement for a golden-chip, researchers have been exploring golden-chip-free methods for HT detection. Su et al. [40] proposed a method involving the pre-placement of Ring Oscillators (ROs) with different stages in the vulnerable areas of ICs. These ROs are designed to emit special TR signals. Consequently, these areas exhibit significant changes in the corresponding TRMs when an HT is inserted. However, a persistent challenge remains in that vulnerable areas within the IC are often difficult to fully occupy, rendering the practical application of this approach challenging, particularly in the context of ASICs.

Tang et al. [41] proposed another solution utilizing AA shapes obtained from the GDS II file as a reliable reference for golden-chip-free HT detection. In their suggested detection scenario, the pixels in TRMs are categorized into two groups: vacant pixels and fully occupied pixels, as illustrated in Figure 5. The fundamental concept of this method is that the additional HT pixel can be considered as the normal logic pixel in TRMs, with the distinction that its TR information differs from that of the vacant pixel. They employed statistical methods to generate the actual AA shape through the differentiation of logic and vacant regions, as illustrated in Figure 1. The procedure involves verifying the normal distribution of the TR of the logic region through a K-S test. Subsequently, the Pauta criterion is applied to identify significant differences between the TR of the vacant region and this established normal distribution. Their experiments demonstrated the effectiveness of this method in detecting HTs that occupy larger than one pixel ($15\mu m * 15\mu m$) on a $130nm$ DSP. However, despite the confirmed potential, current methods assume ideal HTs that fully occupy a pixel, making them far from practical use. Therefore, further exploration and development of TR-based countermeasures are still required.

3 Motivation

In this section, we explore the potential of utilizing mechanical vibrations to enhance sub-pixel HT detection, preceded by a detailed overview of the impact of sub-pixel HTs and mechanical vibrations on TR-based detection.

3.1 Sub-Pixel HTs Analysis

In this paper, our focus is on sub-pixel HTs distributed across multiple pixels, as depicted in Figure 2(a). This situation arises from the transparent nature of HTs when inserted into a chip, posing challenges in ensuring precise alignment of the HT boundaries with the pixels. In such cases, each infected pixel could be easily blurred as either a logic or vacant area.

This issue can be analyzed by considering the detection mechanism discussed in § 2.2. When the IC is operating statically, the incremental TR intensity $\Delta I(v, i_{leak})$ is correlated with the number of MOS transistors in the corresponding region. In other words, the TR distinction between sub-occupied and vacant pixels depends on the pixel occupation.

Figure 6 illustrates possible scenarios where a sub-occupied pixel might be misidentified as a vacant area. The TR distinction between fully occupied pixels and vacant ones is significant, as indicated by solid lines in the figure. However, some low-occupied pixels (represented by dashed lines) tend to closely resemble the vacant pixel (shown by the blue line). This indicates that certain sub-pixel HTs may evade detection using existing methods, as the occupancy in each pixel is significantly reduced. Moreover, the pink interval in the figure represents an area where HT may be missed, a concern that could be exacerbated by white noise. In this study, our aim is to investigate approaches to enhance the detection performance of sub-pixel HTs.

3.2 Noise Caused by Mechanical Vibration

The performance of sub-pixel HT detection is also influenced by the noise resulting from mechanical vibration. In many high-end thermal cameras, such as modern "Focal Plane Array" (FPA) cameras with cooled detectors, the cooling of the detector is achieved using a Stirling cooler [11]. The Stirling cooler consists of a compressor and an expander, where the gas is compressed to a high pressure in the compressor and then undergoes a pressure drop in the expander to generate

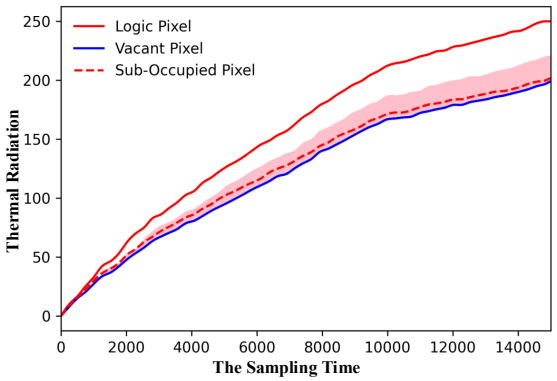

Figure 6: The TR distinction among fully occupied, sub-occupied and vacant pixels

refrigeration. The Stirling cooler is essential for maintaining a constant operating temperature of the detector, thereby improving the quality of TRMs. However, due to the nature of refrigeration, mechanical vibration becomes inevitable, and the noise level of the cooler may slightly increase over time. While the camera is in operation, the noise caused by the cooler can be both visually and audibly perceptible.

Mechanical vibration refers to the oscillatory motion of a particle or a body around its equilibrium position [50]. Simple harmonic motion is an example of mechanical vibration that exhibits certain key characteristics such as frequency (ω) and amplitude (A). Simple harmonic motion is mathematically represented by the following formula:

$$x(t) = A\cos\omega t$$

In TR-based HT detection, the mechanical vibration of the thermal camera can introduce image dithering in the TRMs. Figure 7 illustrates how mechanical vibration can alter the TR distinction between sub-occupied and vacant pixels. The pink area in the figure indicates that vibrations in certain directions may enhance this TR distinction, while in other directions, the opposite effect occurs. However, the stack of different vibration directions complicates the differentiation between sub-occupied and vacant pixels, thereby posing challenges for accurately detecting sub-pixel HTs with existing methods.

Overall, it is crucial to investigate mechanisms for mitigating this noise in TR-based methods. Typically, noise reduction techniques can be implemented through hardware or software approaches. However, the vibration is coming from the internal detector, which is not tightly coupled to the lens or casing. This precludes possible hardware approaches to measure or approximate the vibration data, due to its attenuation and delay. A possible way to address the vibration is through image dithering elimination, such as the method involving the extraction and alignment of prominent features of the TRMs. However, it is widely recognized that noise can be suppressed to a certain extent but not entirely eliminated. Consequently, existing software methods may not effectively handle imperceptible dithering within the pixels, as depicted in Figure 2(b). This motivates us to take advantage of the vibration.

3.3 Exploiting the Potential of Noise

In our investigation, we made an intriguing observation regarding the influence of mechanical vibration on the position of HTs within TRMs. Mechanical vibration induces shifts in HT positions, broadening the range of potential position cases. As depicted by the dashed line in Figure 7, this heightened variability can enable HTs to reach the largest pixel occupation in specific directions, thereby augmenting the TR distinction with vacant areas compared to the vibration-free case (represented by purple lines). This motivates us to find out the vibration direction that can enhance this distinction, thereby improving the accuracy of sub-pixel HT detection.

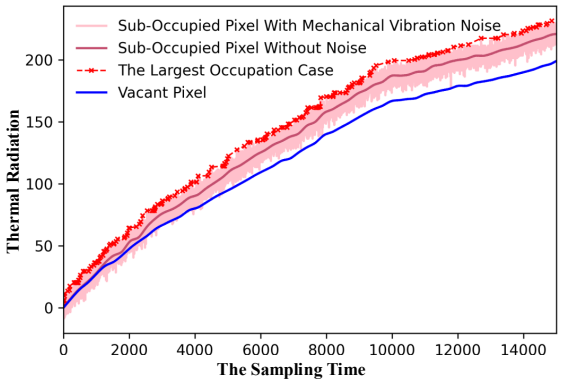

Figure 7: The effect of mechanical vibration on TR distinction

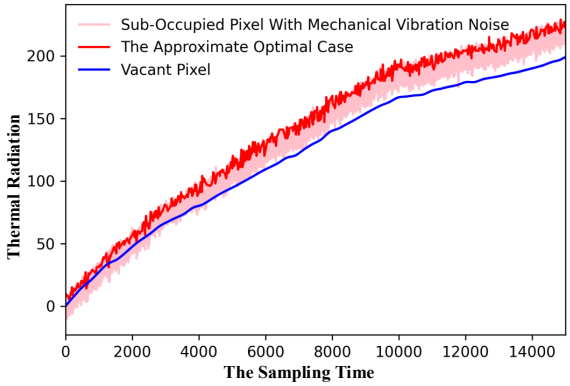

Figure 8: The TR distinction between sub-occupied and vacant pixels in the approximate optimal case after direction-based TRMs classification

However, this is a non-trivial task for a given HT, due to the presence of diverse biases in vibration directions among different HTs. Figure 9 shows that HTs with different initial positions may undergo entirely opposite changes in occupancy, even when subjected to the same vibration direction. Consequently, identifying a direction that uniformly optimizes detection across all HTs within the IC is impractical.

An alternative approach involves the application of a divide-and-conquer strategy, transforming the problem into a direction classification task for the TRMs dataset. The key insight of this approach lies in the imperative to identify any HT with corresponding bias in each direction, due to the transparency of HTs' distribution to the tester. More specifically, this strategy encompasses two considerations: 1) Direction-based detection involves identifying each HT at every individual direction, ensuring the inclusion of the approximate largest pixel occupation. 2) Furthermore, by aggregating the detection results from other directions characterized by a high pixel occupation, as illustrated in "The high pixel occupation case" within Figure 9, detection accuracy can be further enhanced. Clearly, direction-based detection also serves to alleviate the impact of noise caused by mechanical vibrations, reducing the difficulty of differentiation.

According to this strategy, the procedure entails identifying the dithering direction within the pixel at each sampling time, subsequently classifying TRMs based on the direction. Despite the challenges in precisely measuring shifts within pixels, hindering the accurate determination of their direction and magnitude, the observed correlation between variations in pixel occupation and incremental TR changes suggests an approximate method to identify the possible dithering directions of pixels. As illustrated in Figure 10, through the analysis of incremental TR for each pixel, we can determine whether the pixel occupation is exhibiting an increase (depicted in red) or a decrease (depicted in blue) relative to the previous sampling time, consequently revealing the corresponding dithering direction. By considering the possible directions of the majority of pixels within the TRM, we can determine the most likely dithering tendency (P_{trend}) of the entire image using statistical analysis methods, as depicted in the following formula.

$$p_{di} = \sum_{k=1}^{N} p_{di}^{k}$$

$$P_{trend} = \max_{1 \le i \le n} \{p_{di}\}$$

Where, the probability p_{di} of different dithering directions (di) can be calculated as the sum of p_{di}^{k} for each pixel k. n and N respectively represent the number of vibration directions and pixels within the TRM.

In Figure 10, all four pixels have the possibility to move up. According to the law of large numbers, as the number of pixel samples increases, the determination of the dithering tendency approaches its true situation.

$$\lim_{N \to \infty} P\{|\frac{\mu_N}{N} - P_{trend}| \ge \varepsilon\} = 0$$

After classifying TRMs at each sampling time, we can approximate the largest occupation case for sub-pixel HTs with corresponding biases from the direction-classified TRMs, as shown in Figure 8. The accuracy of this approximation is determined by the number of directions and the associated step size, as depicted in the following formula.

$$\{TRMs_{opt}\} \subseteq \lim_{n \to \infty} (\{TRMs_{d1}\}, \{TRMs_{d2}\}, \ldots, \{TRMs_{dn}\})$$

Where, the $\{TRMs_{opt}\}$ represents the TRMs set with the largest occupation case for sub-pixel HTs and the $\{TRMs_{dn}\}$ represents the TRMs set at the dithering directions dn.

4 Noise Based Pixel Occupation Enhancement for HT Detection

In this section, we introduce the NICE mechanism to enhance the accuracy for sub-pixel HT detection, including the detection framework and core detection algorithms.

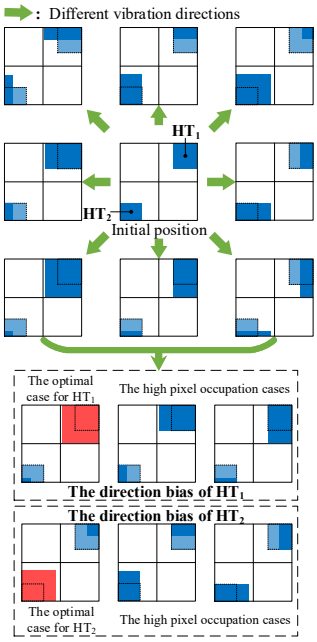

Figure 9: The biases of HTs towards the direction of vibration

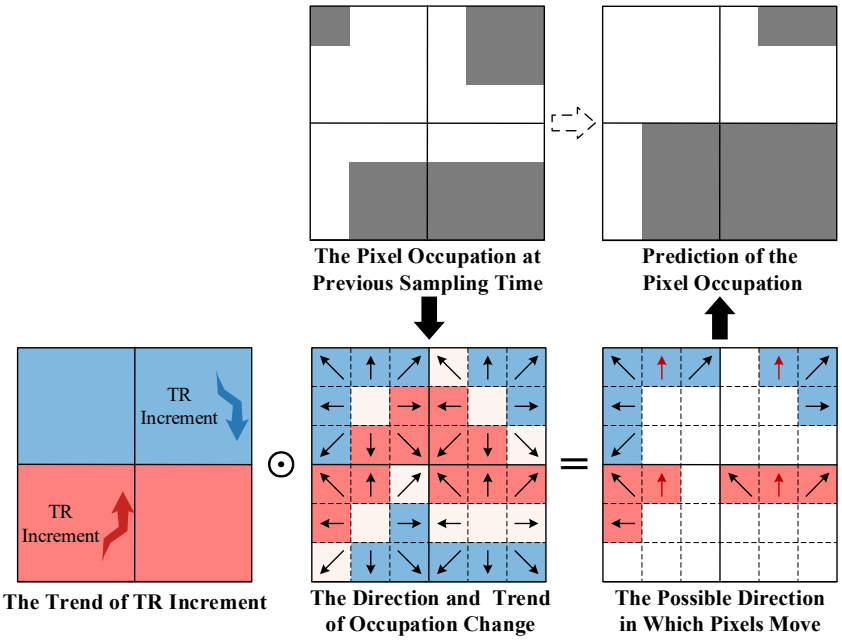

Figure 10: The tendency determination of image dithering

4.1 Detection Framework

Inspired by the analysis presented in § 3.3, we propose a novel HT detection framework called NICE. The primary objective of NICE is to approximate the HT's largest pixel occupations among the variations caused by noise, achieved through the application of direction-based classification. Figure 12 shows the detection framework employed by NICE, which comprises two major components: TRMs classification and detection result aggregation.

Specifically, TRMs are categorized into several sets based on the direction of image dithering, and corresponding golden references are extracted from the design data of the target IC. Subsequently, each set of TRMs is processed independently for HT detection using the K-S statistic and the Pauta criterion. By comparing with golden references in the corresponding direction, multiple results indicating possible HT pixels are obtained. Finally, the detection results are statistically aggregated to produce the final result, thereby significantly enhancing the detection accuracy of sub-pixel HTs.

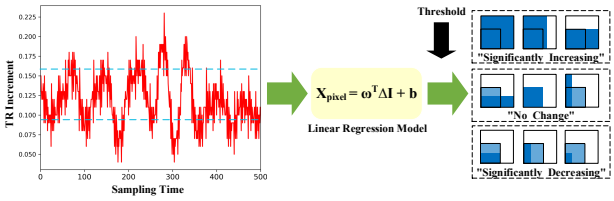

Figure 11: The trend determination based on TR increment

4.2 Direction-based TRMs Classification

The primary principle behind TRMs classification involves the convergence of pixel dithering, where the dithering trend of each pixel can be estimated by the variation in TR increment. A detailed implementation of the algorithm is provided in Appendix A.1.

1) Estimating possible dithering directions for each pixel. For a single pixel, its TR increment fluctuates over time. The magnitude of change in the TR increment depends on whether the pixel occupation increases or decreases. To ascertain the trend of pixel occupation, we have formulated a backward linear regression model to delineate the relationship between pixel occupation and TR increment, as shown in the following equation.

$$\mathbf{X_{pixel}} = \omega^T \Delta \mathbf{I} + b$$

Where, $\Delta \mathbf{I}$ is TR increment, $\mathbf{X_{pixel}}$ is pixel occupation.

Determining trends of pixel occupation over time. The TR increment data of all pixels is employed to facilitate the fitting of model parameters, with the TR increment of each pixel evenly corresponding to approximate occupation values based on the occupation variation interval specific to each pixel. This interval is calculated from the golden references containing occupation information for each pixel. Subsequently, the model utilizes the TR increment of each pixel to reevaluate its occupation at every sampling time, enabling the determination of whether the pixel exhibits an increase or decrease in occupied regions compared to previous time.

Estimating possible dithering directions. Pixel dithering

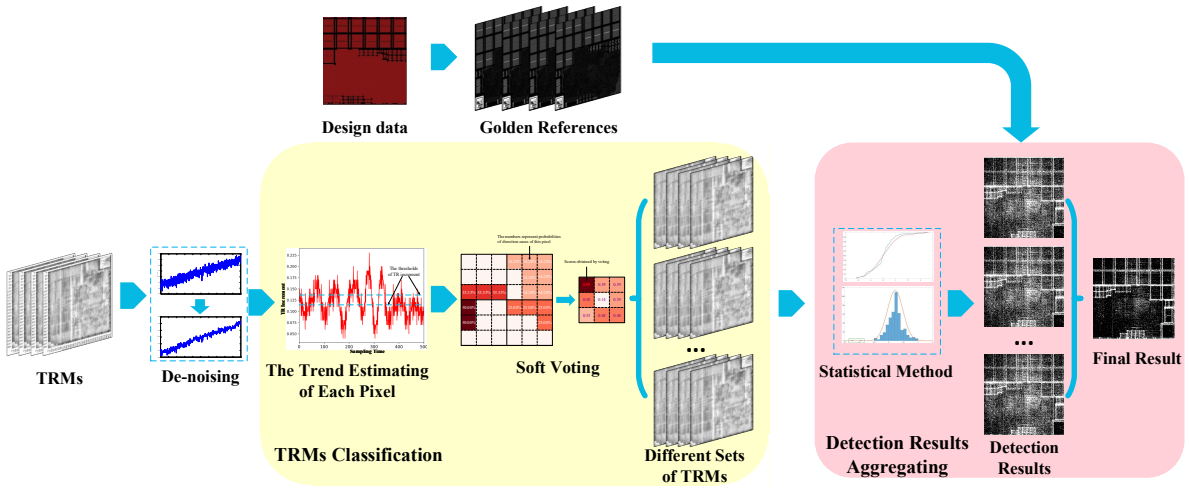

Figure 12: The detection framework for NICE

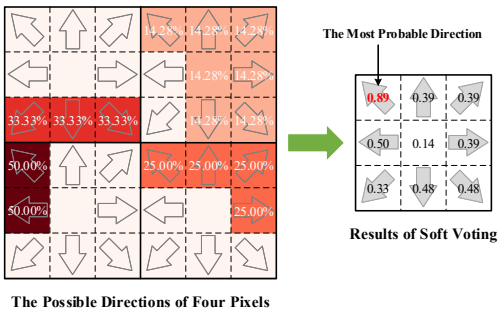

Figure 13: TRMs classification based on soft voting. The percentages represent probabilities of the pixel dithering in different directions.

is estimated through approximate matching, given the challenge of accurately determining the dithering direction and position based on occupation changes, as depicted in Figure 11. The occupation change is classified into three categories using a threshold: "significantly increasing", "significantly decreasing", or "no change". These categories correspond to different dithering direction sets, typically covering nine fundamental directions. In this way, multiple possible dithering directions for the pixel at each time are identified, enhancing the error tolerance of the classification. Moreover, we set the threshold on the occupation change instead of the TR increment, enabling its application to the detection of various ICs.

2) Classifying TRMs into different direction sets. The dithering directions of the entire TRM can be ascertained by the convergence of all pixels at the same sampling time. It is well known that image dithering affects every pixel equally, so the correct dithering direction can be obtained by the statistical analysis of classification results of all pixels according to the law of large numbers. Figure 13 shows the Soft Voting method employed for the global statistical analysis of pixels exhibiting multiple potential dithering directions. We assign equal weights to all possible directions of the pixel, and calculate the probabilities of various pixel directions, facilitating the determination of the most probable dithering trend through a weighted average. The equation for Soft Voting is provided in Appendix A.1. As a result, the TRM at each sampling time can be classified into different direction sets, matching the corresponding golden reference.

4.3 HT Detecting and Results Aggregating

Conducting HT detection by traversing all directions. The TRMs set in each direction is processed independently to distinguish between logic and vacant regions through statistical analysis. Specifically, the statistical parameters of logic regions are extracted from the TR increment data, after verifying whether this data follows a normal distribution using the K-S statistic. The *mean* and *standard deviation* of the distribution are used to identify the vacant regions in the TRMs. According to the Pauta criterion, when the TR increment of a certain pixel deviates from the *mean* of logic regions by more than three *standard deviations*, it can be considered a vacant pixel with significant probability. By comparing these results with the golden references, several possible sets of HT pixels can be identified.

Aggregating results for possible HT pixels. Multiple results are obtained after traversing detection in all directions, facilitating the accurate detection of possible HT pixels. The target HT is hard to be detected in every direction, as sub-occupied pixels can be easily misclassified as either logic or vacant areas. Typically, sub-pixel HTs are detected in only a few results, especially in cases with the largest pixel occupation. In such scenarios, suspicious pixels are considered as potentially indicating the presence of an HT inserted during fabrication, if an extra AA is detected.

However, TRMs classification is challenging to ensure complete accuracy. A few TRMs may be misclassified due to white noise or unreasonable classification thresholds, which may result in a false alarm. To mitigate this, the information from suspicious pixels in other directions can be utilized to further determine whether the result should be corrected. Specifically, if an extra AA is detected in a certain direction while the suspicious pixel corresponds to a logic region in most other references, the result should be corrected, thereby reducing the false alarm. More details on the HT detection are presented in Appendix A.2.

4.4 NICE System Implementation

To implement the proposed method, we construct the corresponding software and hardware systems. Figure 14 shows our hardware acquisition system which consists of three major parts: a thermal camera, a support and isolation platform, and a low-noise module. The thermal camera works continuously during the data acquisition stage to capture high-quality TRMs, while the support platform ensures that the target IC can be positioned on the focal plane of the thermal camera, and is insulated from external vibrations using an air floating system. The heat conduction and environment noises can be mitigated during the acquisition through our low noise module. The heat dissipation equipment can form a low temperature environment in the chamber specially designed for shading, which can spray the low temperature nitrogen into the chamber from a dewar bottle. Then, the TRMs processing is completed by the computer equipped with an Intel(R) Core(TM) i7-9700 CPU, operating Python-based software.

This modular design of NICE system facilitates integration into real-world post-silicon HT detection scenarios and enables adaptability for detecting various ICs. The isolation platform and the low-noise module effectively mitigate the environmental interference, making NICE suitable for deployment across various environments. The support platform allows for adjustments to accommodate different thermal cameras through simple replacement of connection flanges, ensuring compatibility with different chip technologies. Moreover, the NICE system is not affected by larger ICs, as TRMs can be acquired and processed region-by-region for a larger IC using the X-Y Horizontal platform. While this may increase processing time, parallel computation offers a viable solution.

5 Experiment and Evaluation

In this section, we conduct experiments to evaluate the performance of NICE and further investigate the impacting factors for the effectiveness of NICE. The performance evaluation covers the following five vectors:

- **Evaluation for sub-pixel HT detection** (§ 5.2). We evaluate the performance of NICE in comparison with existing methods for sub-pixel HTs detection.
- **Performance analysis across different HTs** (§ 5.3). We analyze the detailed detection performance for various HT samples with different sizes.
- **Sensitivity to the number of TRMs samples** (§ 5.4). We assess the effectiveness of NICE based on several groups of TRMs with different sample sizes.
- **Sensitivity to classification thresholds** (§ 5.5). We explore six classification thresholds to guide the selection of a classification threshold.
- **Sensitivity to the white noise** (§ 5.6). We analyze the impact of different white noise levels on the detection performance of NICE.

5.1 Experiment Scheme

In this experiment, the target IC is a high-end universal DSP under the $0.13\mu m$ process, which is depackaged before the test. The TRMs acquisition system is equipped with a thermal camera with a spatial resolution of $15\mu m * 15\mu m$ and Noise Equivalent Temperature Difference (NETD) of $30mK$.

Figure 15 presents our experiment scheme, designed to assess the constraints of the previous method and the effectiveness of the NICE mechanism. The proposed scheme consists of three major components: an equivalently approach to implement "HT", generating actual AA shapes, and statistical analysis.

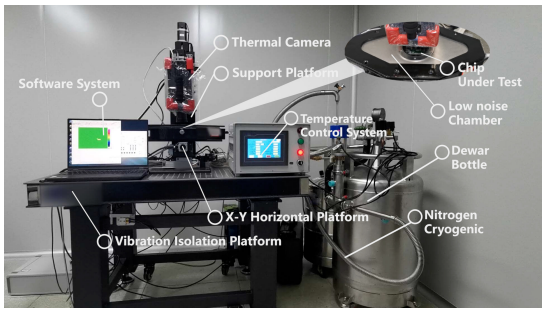

Figure 14: The platform of NICE

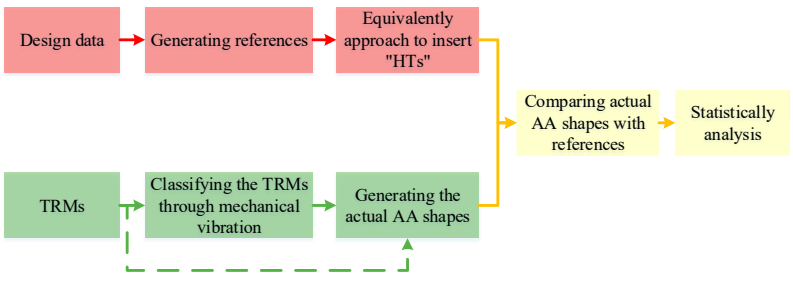

Figure 15: Experiment scheme in this paper

1) "HT" insertion: The equivalently approach is employed to implement "HT" which is challenging to implement in large numbers within the real IC. This method is similar with [41] and [34], and extend both HT size and insertion scopes. Upon extracting the golden reference from the IC design, we randomly remove certain logic regions of the IC layout. These regions appear as vacant in the golden references but remain logic in the actual IC. In our experiment, all logic pixels can be regarded as "HT", and each pixel should be iteratively detected. This process provides sufficient "HT" samples, exhibiting varying sizes and arbitrary locations within the IC.

2) Actual AA shapes generation: In this experiment, 15000 consecutive sample time TRMs are selected to generate AA shapes, after suppressing the white noise with high frequency through an eight-level wavelet filtering with the "Sym6" base. Following our NICE mechanism, TRMs are categorized into nine direction sets, as illustrated in Figure 22. Consequently, nine different AA shapes will be obtained by the K-S statistic and the Pauta criterion, then results are aggregated to form the final result. However, the classification process is omitted for the previous method, which directly generates the AA shape through the subsequent processing of unclassified TRMs affected by mechanical vibrations.

3) Performance evaluation and sensitivity analysis: The statistical method is utilized to analyze detection results, encompassing performance evaluation and sensitivity analysis. The performance of the previous method and NICE is compared by the detection rate and the false alarm rate for detecting all "HT" samples, which respectively represent the recall rate of extra AA pixels and the error rate in the vacant region of golden reference. Additionally, the robustness of NICE is assessed through the adjustment of the number of TRMs, the classification threshold, and the level of white noise.

5.2 Evaluation for Sub-pixel HT Detection

Overall performance. Our results reveal a significant enhancement in performance compared to previous methods. We successfully reproduce the results of [41], using the same process IC and a similar thermal camera with the same resolution. The experimental result shows that the detection rate of this method can reach up to 99% for the "HT" that fully occupies one pixel. However, there is a substantial decrease in accuracy when this method is applied to detect sub-pixel "HTs". In contrast, as presented in Table 1, NICE can detect sub-pixel "HT" samples with a detection rate of up to 91.82% and a false alarm rate below 9%, representing a performance improvement of more than 47% over the previous method.

We can visually compare the performance between them in Figure 16, where the logic and vacant regions are respectively depicted by black and white pixels. Evidently, NICE exhibits superior capability in recovering the AA shape of the IC.

Detailed analysis. Figure 17 provides a detailed illustration of the performance improvement achieved by NICE, presenting the detection results for different pixel occupation cases. It can be observed that when the "HT" occupies more than 70% of a pixel, NICE can achieve great detection accuracy with a detection rate reaching up to 97.5%. This can be attributed to the NICE can capture samples near the detection threshold when they are slightly affected by vibrations. Moreover, NICE also demonstrates the substantial enhancement when "HTs" occupy less than 10% of a pixel, despite they may be notably challenging to detect. This can be attributed to the ability to approximate the largest pixel occupation case among the variations, even when "HT" is minute in the current scenario.

The case of the occupation within the range of 10%~60% of a pixel presents the most complex scenario, imposing limitations on the overall performance of NICE. However, NICE improves the detection rate of these samples by over 40%.

Impact of the variability of pixel occupation. To delve deeper into the mechanics of NICE, the statistical data for the occupation change of all "HT" samples can be leveraged to illustrate the functioning of NICE. We counted the proportion of all pixels that changed by more than 10% and analyzed the detection results. Figure 18 depicts the statistical results of the occupation change aligned with the observed trend of NICE performance enhancement.

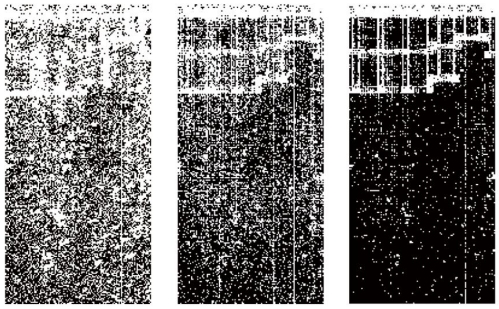

Figure 16: The AA shapes restored from parts of the IC

Table 1: Detection results of NICE and the previous method

	Previous method	NICE (single set)	NICE (final result)					
Thresholds:			1%	2.5%	5%	10%	15%	20%
Detection rate	44.36%	67.48%	45.26%	87.77%	91.81%	90.53%	83.20%	84.30%
False alarm rate	15.90%	13.42%	12.56%	16.18%	8.44%	9.85%	13.13%	10.09%

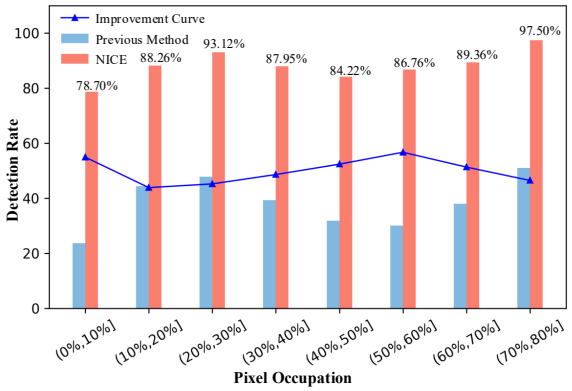

Figure 17: The detection rate of NICE and the previous method

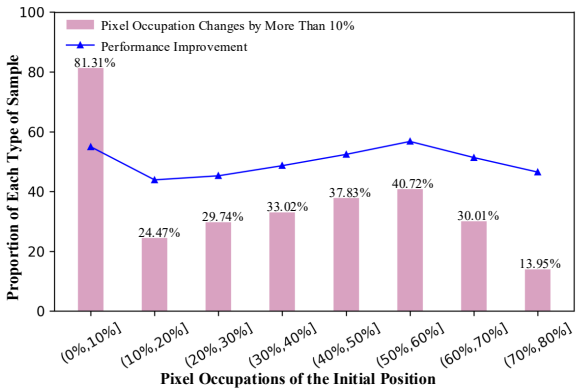

Figure 18: The statistics of the occupation change for "HTs"

The statistical result for "$\leqslant 10\%$" samples with significant occupation changes is 81.31%, closely matching the detection rate of the corresponding samples in Figure 17 (78.70%). This observation underscores the fundamental efficacy of NICE in detecting a sub-pixel HT that spreads across multiple pixels.

The improved performance for "10%~60%" samples can be attributed to the effectiveness of TRMs classification. This approach not only enhances the detection performance of a single set of TRMs but also consolidates multiple detection results from the same sample. As outlined in Table 1, the results of detecting a single set of TRMs indicate a maximum performance increase of up to 23.12%.

The detection rate of the "more than 60%" samples is the highest (more than 93%), while their pixel occupations change little. The reason is that the stable TR change makes detection easier for NICE, when HT is large enough.

5.3 Performance Across Different HTs

Overview. Unlike other side-channel detection methods sensitive to HT types, TR-based methods are mainly influenced by HT size, as it affects the TR distinction between sub-occupied and vacant pixels. Therefore, we conduct experiments with a range of HT sizes to evaluate the detection capabilities of NICE, including HTs that occupy multiple pixels and those smaller than a single pixel. Figure 19 provides detection results for HTs with different sizes. We can observe that NICE can effectively identify HTs occupying more than 70% of a pixel with a 98% detection rate, whereas the previous method only performs well when HTs are more than two pixels.

Detailed analysis. It can also be observed that as HT size increases, the detection rate of NICE converges rapidly. This is because larger HTs are more likely to achieve higher occupation within certain pixels through the vibration, making them easier to identify. In contrast, the previous method exhibits limited improvement in detection rates even when the HT size exceeds a pixel. This limitation arises because HTs typically partially occupy multiple pixels. Overall, the result indicates that NICE can push the detection boundary of TR-based methods from more than two pixels to only 0.7 pixels.

5.4 Sensitivity to the Number of TRMs

Overview. In a practical detection scenario, the smaller TRM samples may be acquired for HT detection to further control the cost and overhead. Therefore, we try to analyze the impact of the number of TRMs on NICE. Figure 20 presents the performance trend for detecting HT with decreasing TRM samples. We can observe that NICE achieves steady performance, with a detection rate of more than 91% even when the number of samples is decreased to 50% (7500) of TRM samples in § 5.2. However, the performance will deteriorate when the sample size is reduced to a third (5000).

Detailed analysis. This result demonstrates that the NICE is effective in the smaller-samples scenario with a high detection rate, which indicates its robustness. However, NICE is implemented based on statistical methods, which can be completely effective when the TR growth of the IC is sufficient. Therefore, its performance inevitably deteriorates with decreasing the number of TRMs, when parts of the TR information are lost. To address this, we further conduct experiments based on the interval sampling method to simulate the reduction of sampling frequency, which shows a more stable performance in the red curves in Figure 20.

False alarm. We can also observe that the false alarm rate is more affected by the sample reduction than the detection rate. Fortunately, interval sampling is also effective in reducing false alarms. Therefore, sufficient TRM samples are recommended for NICE. Even in certain cases where the sample size must be reduced, it is more reasonable to reduce the sampling frequency or interval sampling in sufficient TRMs.

5.5 Sensitivity to Classification Thresholds

Overview. The sensitivity of NICE to different classification thresholds is explored to guide the selection of optimal

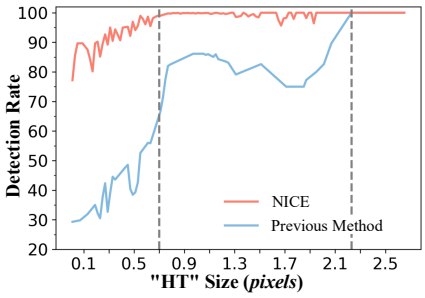

Figure 19: Detection results for HTs with different sizes

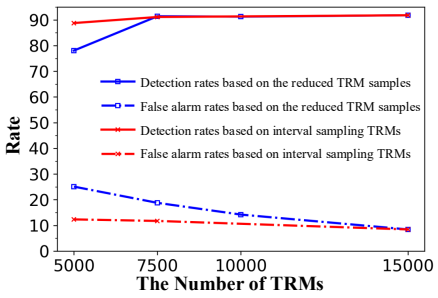

Figure 20: Detection performance based on different TRM samples

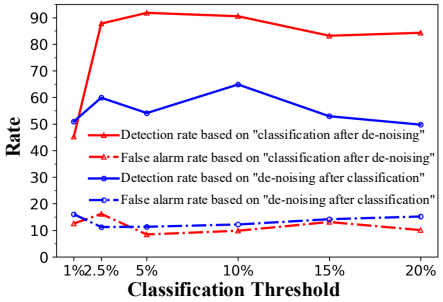

Figure 21: The detection performance for sensitivity analysis of classification thresholds and white noise

Table 2: Performance based on different noise levels

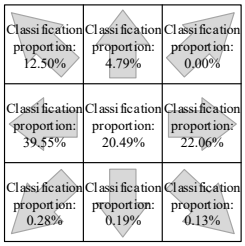
Noise leve (dB)	7.80	-5.57	-12.85	-20.33
Detection rate	91.81%	91.07%	87.18%	64.86%
False alarm rate	8.44%	9.31%	10.09%	12.20%

thresholds. We classify TRMs based on occupation change thresholds of more than 1%, 2.5%, 5%, 10%, 15% and 20%. The detection results in Table 1 indicate that a threshold of 5% provides the best performance, as also illustrated by the curves in Figure 21. Figure 22(a) presents the classification results of TRMs based on the 5% threshold, indicating the direction determination of image dithering within the pixel. It can be observed that the dithering tends to be more pronounced in the horizontal direction, which aligns with the structural characteristics of our system.

Detailed analysis. The reasonable threshold can be further verified by the results shown in Figures 22(b) and 24. As illustrated in Figure 22(b), classification with thresholds of 1% and 2.5% results in fewer categories compared to other thresholds, because the tiny occupation changes can not be recognized by the thermal camera. Furthermore, Figure 24 shows the dithering over time in the horizontal direction, demonstrating that the frequency of image dithering is faster with the decrease of threshold. The result indicates that if the threshold is too large, the occupation changes caused by different dithering directions would be confused, which reduces the precision of classification.

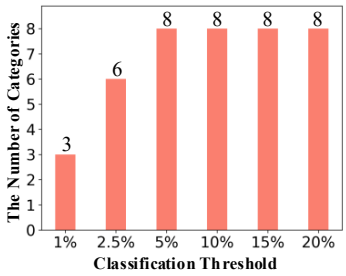
False alarm. We can observe in Figure 21 that the false alarm rate can be affected by the unreasonable threshold. Comparing among the cases with thresholds of 2.5%, 5%, and 10%, where their detection rates are close, the unreasonable threshold (2.5%) results in a significant increase in the false alarm rate. Fortunately, the law of large numbers ensures the accuracy of our method, as long as the threshold value is not excessively large or small, such as from 5% to 10% in this experiment, which is robust enough for different thresholds.

5.6 Sensitivity to White Noise



Overview. To investigate the potential impact of white noise on the accuracy of dithering trend determination, we conduct an experiment comparing two different TRMs processing flows: "classification after de-noising" and "de-noising after classification". As shown in Figure 23, the presence of white noise may limit the classification of TRMs to three dithering directions, even resulting in inconsistencies (as depicted in Figure 23(a)) with the correct dithering trend. Figure 21 illustrates that the combined effect of white noise and threshold settings can significantly reduce the detection performance of NICE. Nevertheless, with a well-selected threshold of 10%, NICE also outperforms previous methods, achieving a detection rate of 64.86% and a false alarm rate of 12.20%.

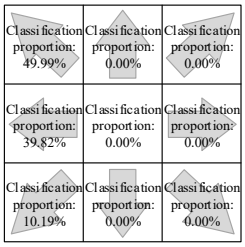
Detailed analysis. To evaluate the impact of different noise levels on detection performance, we gradually reduce the noise levels in the initial data, estimating these levels using the Signal-to-Noise Ratio calculation in Python combined with the Kaiser window. As shown in Table 2, while white noise can affect the performance of NICE, its impact is manageable. For example, utilizing the simple four-layer wavelet filtering, the detection rate can reach 87%, and with wavelet filtering of more than six layers, the detection rate can increase to over 91%. This suggests that NICE demonstrates a certain robustness against white noise.



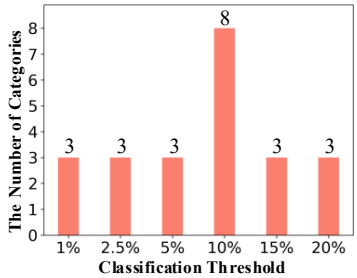
False alarm. The experimental results indicate that white noise can lead to TRM classification errors, resulting in the increased false alarm rate. One effective solution is to eliminate white noise before TRM classification. Moreover, according to our experiments, as the effects of classification thresholds and white noise are combined, a well-selected threshold can suppress the false alarms caused by white noise.

6 Discussion

Investigating the potential of thermal cameras across chip technologies. As semiconductor technology continues to scale down, the detection of sub-pixel HTs becomes increas-



(a) The result of TRM classification with thresholds of 5%



(b) The number of classification categories with different thresholds

Figure 22: TRMs classification results with various thresholds

(a) The result of TRM classification with thresholds of 20%

(b) The number of classification categories with different thresholds

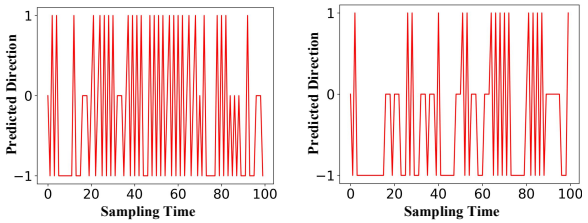


Figure 23: TRMs classification results without noise reduction

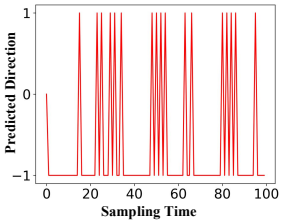
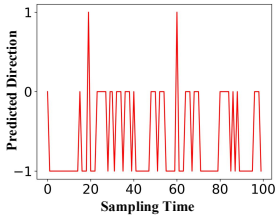
ingly challenging. A potential strategy to address this issue is to employ thermal cameras with ultra-high resolution. However, while more advanced cameras offer higher capabilities, there are technical limitations that restrict the continuous improvement of resolution. Moreover, using the high-resolution camera for HT detection in relatively large technology nodes incurs increased economic costs and computational overhead. NICE focuses on enhancing the capabilities of given thermal cameras, pushing the detection boundary from more than two pixels to only 0.7 pixels, as shown in Table 3.

Taking the proposed hardware system as an example, NICE can detect HTs with 40 gates, compared to the original 110 gates, under a 130nm process using a 15μm thermal camera. As shown in Table 4, most of HTs in Trust-Hub are smaller than 100 gates. Moreover, the A2 HT implemented under the 130nm process consists of around 170 standard MOS transistors, which corresponds to approximately 43 gates, based on the circuit structure in [13]. In these scenarios, existing TR-based methods require a 12μm thermal camera to achieve detection under 130nm process, while NICE can cover these HTs with a 15μm thermal camera. Overall, NICE enables a more flexible and cost-effective selection of thermal cameras.



Comparing detection performance of NICE with other techniques. Table 5 summarizes the detection performance and characteristics of NICE alongside other side-channel techniques, which indicates that the performance of NICE reaches the average level of other side-channel methods, and even shows slight improvement as the IC size increases. Although some methods claim to achieve extremely high detection rates, they are often constrained by stringent conditions, requiring either a golden chip or specific testing vectors to trigger the HT. In contrast, NICE stands closer to practical use due to its high performance and reasonable detection conditions.

Limitation and evasion techniques. There are still some limitations in the current implementation of NICE: *1) Smaller HTs.* Adversaries can potentially evade our detection by designing increasingly smaller HTs. In fact, smaller HTs present significant challenges to all existing detection methods. We anticipate that using the most advanced thermal camera (1.5μm),



(a) The threshold is 5%

(b) The threshold is 10%

(c) The threshold is 15%

(d) The threshold is 20%

Figure 24: The direction determination of the first 100 sampling times in the horizontal direction

NICE can extend the detection capabilities to identify HTs consisting of approximately 26 gates and 35 gates under 7nm and 5nm chip technologies, respectively [1]. A review of recent HT designs [8, 13, 14, 23, 25, 26, 46] and those documented in Trust-Hub (as illustrated in Table 4) reveals that existing HTs exceed 35 gates, typically around 100 gates. This trend likely stems from the consideration that extremely small HTs may restrict their malicious functionality and compromise their stealth [46].

2) Modification HTs. As described in our threat model, NICE currently does not support the detection of modification HTs. These HTs can be created by making slight alterations to the dopant [5] or parameters [15] of transistors without introducing additional logic. However, this type of HT remains largely unexplored [46] due to the significant effort [12], prior knowledge, and specialized skills required for its design [48]. Currently, one feasible detection technique for these HTs is

reverse engineering, which can achieve accurate detection but at the cost of significant economic and time resources.

3) HTs inserted in filler areas. There are alternative methods for implementing additive HTs, such as replacing filler cells with logic cells through the Engineering Change Order (ECO) flow [32, 33]. Filler cells can be divided into two types: (a) traditional fillers with no transistors, which resemble vacant areas on TRMs, and (b) active fillers in advanced technologies containing transistors. HTs implanted in active fillers may evade existing TR-based detection techniques. However, our preliminary exploration suggests there are some distinguishable features between logic areas and these fillers in the TRM. We believe that NICE can be enhanced by incorporating extension algorithms to further distinguish between active fillers and logic areas, which remains part of our future work.

Overall, the attacker and defender are engaged in an ongoing game of strategy and evolution. Despite the possibility of existing TR-based detection being evaded, we believe that enhancing sub-pixel HT detection by exploiting the potential of noise can provide valuable insights into post-silicon HT detection. Besides, recent studies have developed Reinforcement Learning (RL)-based HT insertion methods [16, 36, 37], which increase the difficulty of HT activation and show great potential to evade detection techniques that require HT activation. Given the activation-free characteristic, NICE is complementary to these activation-based detection methods and can be combined to enhance the overall HT detection capability.

7 Conclusion

In this paper, we observed that the noise caused by mechanical vibration can vary the pixel occupation of the HT, which can help us address the challenge for sub-pixel HT detection. To this end, we proposed NICE, a noise based pixel occupation enhancement mechanism. The experimental results demonstrate that NICE can greatly improve the performance for detecting the sub-pixel HTs compared with existing TR-based methods. Our results provide a direction for noise mitigation but also suggest how to use noise for performance improvement of TR-based methods.

Acknowledgments

We thank our anonymous reviewers and shepherd for their insightful feedback. A Algorithm Details

We introduce more implementation details of NICE.

A.1 TRMs Classification

As mentioned in § 4.2, the direction-based TRMs classification is the primary algorithm of NICE mechanism, involving a linear model and a soft voting method to classify all TRMs into different direction sets. The processing flow of our implementation consists of four stages, as shown in Algorithm 1.

Algorithm 1 Direction-based TRMs Classification

Input: TRM, REF, DIR, $threshold$
Output: Classified TRM

// Preprocessing of TRM Sequences and Golden References
1: $TRM \leftarrow$ WAVELET(TRM)
2: **for** $trm_t \in TRM$ **do**
3: $\Delta trm_t \leftarrow trm_{t+1} - trm_t$ // Calculating TR increment
4: **end for**
// Calculating occupation change for each pixel
5: **for** $REF\_pixel_{ij} \in REF$ **do**
6: $occups\_range_{ij} \leftarrow$ MAX(REF_pixel_{ij}) − MIN(REF_pixel_{ij})
7: $DIFF \leftarrow$ DIFFER(REF_pixel_{ij}, DIR)
8: **for** $diff_n \in DIFF$ **do**
9: **if** $|diff_n.value| < threshold$ **then**
10: $nochange\_set^n_{ij} \leftarrow diff_n.pair$
11: **else if** $diff_n.value \geq threshold$ **then**
12: $increase\_set^n_{ij} \leftarrow diff_n.pair$
13: **else**
14: $decrease\_set^n_{ij} \leftarrow diff_n.pair$
15: **end if**
16: **end for**
17: **end for**
// Fitting the linear model
18: **for** $tr\_pixel_{ij} \in \Delta trm$ **do**
19: $occup_{ij} \leftarrow$ APPROX($tr\_pixel_{ij}, occup\_range_{ij}$)
20: LINEARMODEL $\leftarrow$ FITMODEL($tr\_pixel_{ij}, occup_{ij}$)
21: **end for**
// Determining trends of pixel occupation over time
22: **for** $TR\_pixel_{ij} \in \Delta TRM$ **do**
23: $PRED\_occup_{ij} \leftarrow$ LINEARMODEL(TR_pixel_{ij})
// Estimating possible dithering directions
24: **for** $pred\_occup_t \in PRED\_occup_{ij}$ **do**
25: $\Delta occup_t \leftarrow pred\_occup_{t+1} - pred\_occup_t$
26: **if** $|\Delta occup_t| < threshold$ **then**
27: $pred\_dir^t_{ij} \leftarrow$ MATCH($nochange\_set_{ij}$)
28: **else if** $\Delta occup_t \geq threshold$ **then**
29: $pred\_dir^t_{ij} \leftarrow$ MATCH($increase\_set_{ij}$)
30: **else**
31: $pred\_dir^t_{ij} \leftarrow$ MATCH($decrease\_set_{ij}$)
32: **end if**
33: **end for**
34: **end for**
// Classifying TRMs into different direction sets
35: **for** $trm_t \in TRM$ **do**
36: $most\_dir_t \leftarrow$ SOFTVOTING($pred\_dir_t$)
37: Classified $TRM \leftarrow$ CLASSIFY($trm_t, most\_dir_t$)
38: **end for**

1) Preprocessing of TRM sequences and golden references (Line 1-17). The preprocessing of TRM sequences (TRM) involves wavelet filtering and the difference method to calculate

the TR increment (Line 1-4). In this paper, WAVELET represents an eight-level wavelet filtering with the "Sym6" base. Golden references (REF) are used to calculate the occupation variation interval ($occups\_range$) specific to each pixel, generated from the IC design based on preset dithering directions. In the subsequent stage, differential pixel occupations ($DIFF$) between references in various directions (DIR) are calculated using the difference method (DIFFER) (Line 5-7). Directions pairs ($diff.pair$) are then classified into three categories by comparing the difference value ($diff.value$) with the threshold: "significantly increasing" ($increase\_set$), "significantly decreasing" ($decrease\_set$), or "no change" ($nochange\_set$) (Line 8-17).

2) Determining trends of pixel occupation over time (Line 18-23). After the TR increment of each pixel evenly corresponds to approximate occupation values ($occup_{ij}$) based on the occupation variation interval ($occups\_range$), the TR increment data of all pixels is used to fit the linear model (LINEARMODEL), which can estimate the occupation of each pixel at every sampling time ($PRED\_occup_{ij}$).

3) Estimating possible dithering directions (Line 24-34). Based on outputs of the linear model, the occupation change of each pixel ($\Delta occup_t$) is calculated using the difference method, and evaluated for significance based on the threshold. Possible dithering directions ($pred\_dir$) are approximated by matching (MATCH) results to the corresponding category.

4) TRMs classification (Line 35-38). For the entire TRM at each sampling time (trm_t), the most likely direction ($most\_dir_t$) is determined using the soft voting method (SOFTVOTING), as depicted in the following equation, enabling the classification of all TRMs into the corresponding direction sets (Classified TRM).

$$Prob_{max} = \max_{1 \le k \le n} \{ \sum_{i=1}^{M} \sum_{j=1}^{N} p_{ij}^{dk} \}$$

$$p_{ij}^{dk} = \begin{cases} 0 & ,dk \in possible\ directions \\ \frac{1}{number\ of\ possible\ directions} & ,dk \notin possible\ directions \end{cases}$$

Where, the probability of entire TRM dithering in every direction is determined by the sum of probabilities (p_{ij}^{dk}) of pixels dithering in that direction (dk). The maximum of results ($Prob_{max}$) indicates the most probable dithering of TRMs.

A.2 HT Detection

As mentioned in § 4.3, each direction set of TRMs (TRM_{dir}) is subjected to HT detection. Algorithm 2 shows the processing flow of our implementation.

Reference [41] has discussed the principle of the AA shape generation in detail. This stage involves selecting some pixel samples ($pixel\_sample$) from the entire TRM until their TR increment data conforms to a normal distribution, as verified by the K-S statistic (Line 1-18). In this paper, SELECT is implemented by traversing all rows and columns of the TRM. Then, according to the Pauta criterion, vacant pixels can be distinguished from logic pixels based on the mean ($mean$) and standard deviation (std) extracted from the TR increment data of logic pixel. To prevent random errors, a pixel must be considered a vacant pixel at most sampling times, which is determined by P_vacant (Line 19-26).

After comparing the result ($type_{ij}$) with the golden reference at corresponding direction (ref_pixel_{ij}), several suspicious pixels (SUS) can be identified (Line 27-30). To reduce the possibility of false alarms, further analysis is conducted to determine whether the pixel is the logic region in most references at other directions when the suspicious pixel is detected in only one direction (Line 31-41). Beyond that, other suspicious pixels should be regarded as potential HT pixels.

Algorithm 2 HT Detecting and results aggregating

Input: TRM, REF, DIR
Output: $result$
// HT detection for each direction set
1: **for** $dir_n \in DIR$ **do**
2: $TRM_{dir} \leftarrow TRM[dir_n]$, $ref_{dir} \leftarrow REF[dir_n]$
3: **for** $trm_t \in TRM_{dir}$ **do**
4: $\Delta trm_t \leftarrow trm_{t+1} - trm_t$
// K-S statistic
5: **repeat**
6: $pixel\_sample \leftarrow$ SELECT(Δtrm_t)
7: **if** K-S($pixel\_sample$) is True **then**
8: $mean \leftarrow$ MEAN($pixel\_sample$)
9: $std \leftarrow$ STANDARD($pixel\_sample$)
10: **end if**
11: **until** K-S($pixel\_sample$) is True
// Pauta criterion
12: Initialize a 2D matrix: $P\_vacant = 0$
13: **for** $tr\_pixel_{ij} \in \Delta trm_t$ **do**
14: **if** $mean - tr\_pixel_{ij} \ge 3 \times std$ **then**
15: $P\_vacant[ij] += 1$
16: **end if**
17: **end for**
18: **end for**
19: Get the number of TRMs in each direction set: N
20: **for** $p\_vacant_{ij} \in P\_vacant$ **do**
21: $ref\_pixel_{ij} \leftarrow ref_{dir}[ij]$
22: **if** $p\_vacant_{ij} > N/2$ **then**
23: $type_{ij}$ is Vacant Pixel
24: **else**
25: $type_{ij}$ is Logic Pixel
26: **end if**
// Identifying suspicious pixels
27: $sus\_pixel_{ij}^{n} \leftarrow$ COMPARISON($type_{ij}, ref\_pixel_{ij}$)
28: **end for**
29: $SUS[dir_n] \leftarrow sus\_pixel^{n}$
30: **end for**
// Result aggregating
31: **for** $SUS\_pixel_{ij} \in SUS$ **do**
32: **if** SUS_pixel_{ij} is the Suspicious Pixel at only one direction **then**
33: **if** REF_pixel_{ij} is the Logic Pixel at most of directions **then**
34: $result_{ij} \leftarrow$ is not HT Pixel
35: **else**
36: $result_{ij} \leftarrow$ is HT Pixel
37: **end if**
38: **else**
39: $result_{ij} \leftarrow$ is HT Pixel
40: **end if**
41: **end for**

Endokernel: A Thread Safe Monitor for Lightweight Subprocess Isolation

Abstract

Compartmentalization decomposes applications into isolated components, effectively confining the scope of potential security breaches. Recent approaches nest the protection monitor within processes for efficient memory isolation at the cost of security. However, these systems lack solutions for efficient multithreaded safety and neglect kernel semantics that can be abused to bypass the monitor.

The Endokernel is an intra-process security monitor that isolates memory at subprocess granularity. It ensures backwards-compatible and secure emulation of system interfaces, a task uniquely challenging due to the need to analyze OS and hardware semantics beyond mere interface usability. We introduce an inside-out methodology where we identify core OS primitives that allow bypass and map that back to the interfaces that depend on them. This approach led to the identification of several missing policies as well as aided in developing a fine-grained locking approach to deal with complex thread safety when inserting a monitor between the OS and the application. Results indicate that we can achieve fast isolation while greatly enhancing security and maintaining backwards-compatibility, and also showing a new method for systematically finding gaps in policies.

1 Introduction

In modern operating systems, processes serve as the fundamental unit of isolation and sharing between applications. As a result, an application has access to all the resources of this *virtual* runtime environment, including memory, file systems, networks, and code, among others. Unfortunately, this monolithic environment poses a significant security threat. Without isolation, any local problem becomes global – a buffer overflow could lead to arbitrary reads and writes, or even take full control and escalate privileges within the system [9, 10, 12, 20]. For example, the Heartbleed vulnerability, caused by an incorrect bounds check in OpenSSL, allowed attackers to overread server memory and expose sensitive information. [24]. Using a safe language appears to be a good solution, but even these are not immune (e.g., CrateDepression in Rust [29]), as they incorporate libraries of unknown origin leading to large-scale exploits [11, 25, 33, 65, 72].

Privilege separation [51] decomposes applications into compartments that are isolated by a runtime monitor. Early work successfully separated and isolated OpenSSL using process isolation [4, 30], and modern browsers employ process isolation for vulnerable components. However, process isolation incurs prohibitive overheads for components that frequently interact [60]. Thus, it can only be applied at a coarse granularity, leaving many attack surfaces exposed. For example, an integer overflow in the NGINX HTTP parser [18] could overflow the stack and allow control flow hijacking, which cannot be efficiently isolated with processes.

Recent work nests the monitor within the process using more efficient single-address space mechanisms (*e.g.,* Memory Protection Keys) that isolate at page granularity [32, 54, 60, 61]. However, their defenses are incomplete; for instance, both ERIM and Hodor [32, 60] neglect to prevent bypass through system call interfaces such as reading from the pseudo file system [15]. Donky [55] prevents these but neglects other system interfaces, and Cerberus [61] ignores multithreaded synchronization for signals [54]. Jenny [54] provides comprehensive policies, as discussed in this paper, it lacks a practical multithreaded isolation model and fails to protect against nested signals, creating inconsistencies between the monitor and the kernel that can be exploited. μSWITCH [50], through kernel modifications, avoids synchronization challenges and also delivers signals on an untrusted stack which is corruptible by untrusted attackers. Notably, all efforts evaluated security at the system call boundary and neglected to systematically assess kernel semantics that influence memory isolation (*e.g.,* `sendmsg` and the pseudo file system), while also including glibc or larger runtimes (*e.g.,* Go) in the TCB.

Our aim is to enhance nested monitor design, with secure and compatible emulation of system interfaces, while retain-

[1] Authored before joining Amazon.com

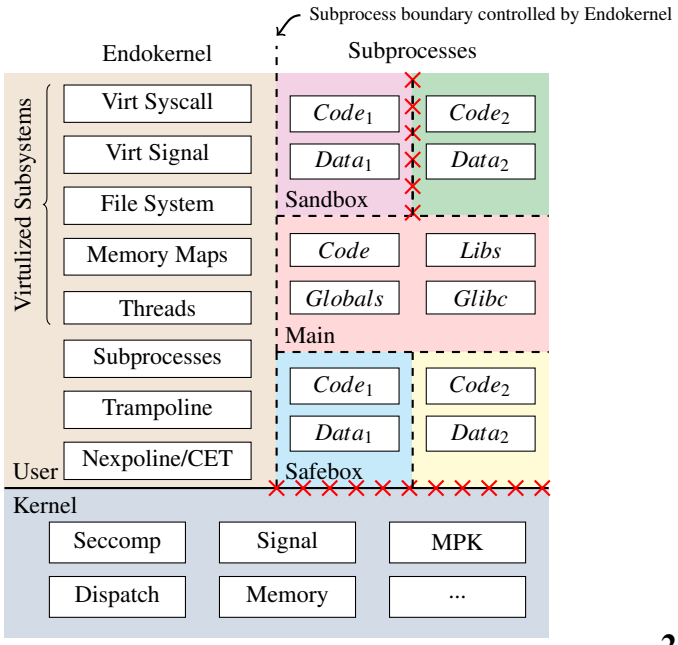

Figure 1: System Diagram for Endokernel

ing efficiency and avoiding the complexity of operating system changes. We first summarize how the Linux kernel affects the integrity of intra-process isolation by reviewing past attacks and analyzing the Linux implementation. Building on this, we derive invariants that monitors need to adhere to in order to mitigate these attacks at the system interface level. This leads to the development of novel policies, especially for multithreaded monitors. Additionally, we enhance compatibility through the virtualization of signals. We embody these invariants in the design and implementation of the Endokernel architecture that creates two privilege levels within the single-address-space using Intel® Memory Protection Keys.

We present a prototype Endokernel, including a new simple-to-use subprocess abstraction that provides process-level isolation for modules within a process, and apply it to isolate components in the NGINX server, including the HTTP parser and the OpenSSL library to demonstrate the effectiveness of the Endokernel. Figure 1 offers a detailed view of the Endokernel architecture, highlighting the Endokernel the organization of subprocesses. The monitor shows near-native performance for network benchmarks ($1.5\% - 5\%$ overhead) and cpu-intensive tasks ($< 4\%$ overhead), whereas file-based benchmarks observe overheads between $4 - 55\%$ (zip and sqlite3). The Endokernel passes 95.95% of the Linux Test Project regression tests, ensuring a high degree of compatibility with Linux. Our primary contributions include:

- A Methodology for systematically examining monitor safety based on critical internal kernel interfaces instead of the system call interface led to the identification of design flaws in synchronization between monitor and kernel states as well as unique signal management and control-flow integrity vulnerabilities (§3). We evaluate both prior work and our own against these threats (§6.1).
- The exploration of the design and implementation of the first thread-safe monitor using fine-grained locking revealed subtle inconsistencies. These occur when a thread is interrupted between verifying a condition and issuing a system call, leading to Time-of-Check to Time-of-Use (TOCTOU) violations (§3.3)."
- An embodiment of the methodology, new attack vectors, and thread safety is presented in a set of invariants that are specified and enforced in the Endokernel design (§4) and implementation (§5). A unique aspect of the prototype is backwards-compatible emulation (§6.3) while ensuring security (§6.1) and low performance degradation (§6.2) for essential system interfaces. We demonstrate the value by compartmentalizing NGINX and sudo (§7).

2 Background

We aim to produce a new in-process protection monitor that identifies invariants to ensure thread safety of the monitor and backwards-compatible system emulation while retaining security and performance. Table 1 presents an overview of the key dimensions of key related work that are described in part in this section, with novel observations and methods presented in the following section.

2.1 Memory Protection Keys

Memory Protection Key (MPK) enhances page memory protection by allowing each page to be tagged with a pkey, which serves as a privilege marker ranging from 0 to 15. The CPU features a 32-bit `PKRU` register, where every two bits correspond to a pkey's access denial (AD) and write denial (WD). The CPU performs additional checks beyond standard page protection by using the `PKRU` register to determine if reading (AD) or writing (WD) to this page is restricted. The user-accessible PKRU register can be modified using the `wrpkru` instruction, enabling lightweight memory isolation [60]. However, since MPK operates in user space, it is susceptible to threats from the operating system, such as the manipulation of `/proc/self/mem` to circumvent MPK protections [15]. Or, an attacker can abuse the `wrpkru` instruction to modify the `PKRU` register. Thus, effective isolation and monitoring are essential to maintaining MPK's integrity and supporting robust intra-process isolation policies.

2.2 Intra-process Isolation and Monitor

Intra-process isolation is a strategy that compartmentalizes different components of an application within a single process.

It ensures that a compromise in one part of the application does not threaten the security of the remaining parts. MPK aids in achieving efficient intra-process isolation. Nonetheless, due to MPK's vulnerabilities, it is crucial to use an intra-process monitor alongside it, to reduce threats from the operating system and keep the isolation effective. Specifically, the operating system could circumvent MPK or compromise the integrity of the intra-process monitor in the following ways.

System Calls Bypassing MPK Protection Most system calls adhere to MPK protection. However, several system calls that enable users to manipulate the page table have already been highlighted in previous work [54, 61]. Obvious examples include `mprotect` and `mmap`, which all monitors need to restrict. The kernel also provides additional system calls to change page attributes, such as `vmsplice` and `splice` that can move physical pages and thereby bypass MPK. Furthermore, the `userfaultfd` mechanism allows handling page faults in user space, enabling users to map physical pages to virtual addresses during a page fault, thereby changing their contents. `arch_prctl` can be used to change the base address of the monitor's thread local storage and must be restricted. System calls, including `personality`, `set_thread_area`, `seccomp`, `ptrace`, `execve`, coredump and others [54, 61] that functionally affect the monitor's system calls, need to be prohibited or emulated.

System Calls Impacting Control Flow and Context Signals are necessary for compatibility and are widely used for Inter-Process Communication and process state control, such as NGINX using signals to implement timers and reload configuration files. When delivering a signal, the kernel interrupts the current process, resets `PKRU`, and jumps to the start of the signal handler. Similarly, the `sigreturn` system call interprets the data on the stack as a sigframe and uses its contents to restore the PKRU register and control flow. The problem is that altering the control flow will leak privilege and context information to untrusted domains. However, the kernel's implementation of signals does not take into account the presence of different domains within a process, making it insecure. Moreover, `sigreturn` can be abused because the kernel does not track whether a signal genuinely exists. `rseq` can also be used to alter control flow and therefore needs to be restricted.

Instructions Bypassing MPK and Altering Monitor State The following instructions can compromise the state of MPK or an intra-process monitor: `XRSTOR`, `WRPKRU`, `swapgs`, and TSX instructions. ERIM mitigates these instructions through binary scanning. That means we must ensure that all pages mapped as executable by `mmap` and `mprotect` adhere to a Write-XOR-Execute policy after being inspected by the monitor, and prevent methods such as shared memory from changing executable pages without the monitor's knowledge.

2.3 Threat Model

We assume that implementations are complete and bug-free, with a focus on attacks that exploit system interfaces. We assume that user domains may have vulnerabilities, thereby providing attackers with opportunities to undermine the monitor's integrity. We assume an attacker is present in one of the isolated user domains, with full control over that domain. Under the constraints of both the domain and the monitor, the attacker can execute arbitrary code, perform jumps, and read/write memory in an attempt to escape. We assume that the monitor is loaded and executed prior to any user code execution, thereby enabling it to run before any user code is

executed. We consider Denial-of-Service (DoS) attacks and side-channel attacks to be outside the scope of our work.

3 Motivation

Despite previous efforts to identify vulnerabilities in MPK and intra-process monitors, we found that their approaches to inspecting system calls, managing multithreading, and handling signals were flawed, leading to security risks and performance issues. This is because the nested nature of intra-process monitors presents unique challenges in achieving security and effectiveness while ensuring backward compatibility. In this section, we will outline the challenges faced by intra-process monitors and our proposed solutions to tackle these issues.

3.1 Inside-out System Calls Analysis

The kernel always has the privilege to bypass MPK. It is up to the monitor's policy to ensure that the kernel does not abuse this privilege. Apart from system calls used to manipulate page protections, the kernel can also create temporary mappings to access physical pages, which is referred to as highmem, bypassing MPK protection. The kernel temporarily maps pages into the highmem area to access the virtual memory of a remote process in these system calls. The new mappings do not include MPK information, thereby bypassing MPK protection. Typical examples include `/proc/PID/mem`, `process_vm_readv` and coredump. However, previous work has only deduced potentially threatening interfaces from the functionality of system calls. Instead, we identified that all such accesses originate from the same set of kernel APIs `kmap_*`. Therefore, we retrieved all the code in the kernel that uses this API, traced back the system calls that utilize them, and prohibited the use of these calls. Most of the usage, such as in `user_events_data`, appears in filesystem-related code or drivers triggered through `ioctl`, but we have discovered some rather special uses that cannot be directly traced back to system calls. Therefore, we conducted some manual analysis. For example, `sendmsg` with `MSG_ZEROCOPY`. Among them, the exploitation of `sendmsg` is very subtle because during the system call the kernel correctly checks the privileges of the virtual memory. After passing the check, the driver can directly access the physical pages of this virtual memory to achieve zero-copy at any moment after the system call returns. This leaves us with an exploitation opportunity. Since `mmap` and `mprotect_pkey` are two separate syscalls, we can exploit the window between these calls to bypass the kernel's checks. Consequently, when the network driver sends data, it accesses the data that has been protected by MPK. By identifying the common kernel APIs that enable these bypasses, we can formulate more targeted security policies to prevent such escapes and respond immediately as new functionalities are provided in the kernel.

3.2 Secure Signal Design

The signal provided by the kernel is not secure for the monitors. Previous monitors attempted to patch and reuse the kernel's signal infrastructure. However, all patches are limited by the semantics of system calls provided by the kernel, making security hard to achieve. For example, most monitors need to maintain the current context's information and switch the `PKRU` register upon exiting the monitor at the same time. Yet, sigreturn can only switch CPU registers without changing the monitor's context information, leaving space for attackers. Both Jenny [54] and μSWITCH [50] attempted to fix the kernel's interface but failed. This is due to their inability to effectively manage state synchronization and data security during signal delivery and sigreturn processing As an intermediary layer between the kernel and user programs, intra-process monitors require their own mechanism to maintain and deliver signals without relying on the kernel. This allows the delivery of signals and the state of sigreturn to be entirely under the monitor's control. Moreover, by avoiding additional kernel context switches, the performance of signal delivery with a monitor is also improved.

3.3 Thread-safe Monitor

Threads enable multiple execution flows within a single process using the shared memory space. Even servers with single-threaded event loops, such as NGINX, use threads to offload tasks like disk I/O. Multithreading introduces more attack vectors and synchronization challenges for the security of intra-process monitors. Consequently, some works do not support multithreading, while others overlook the security issues introduced by multithreading. Monitors track the ownership of objects such as memory pages and file descriptors, using this information to ensure the validity of system calls from users. However, this information is not always consistent, creating a gap between the kernel and userspace monitor. Figure 2 illustrates this dilemma, where a critical race exists between system calls and state updates, leading to a loss of synchronization between the kernel and the monitor. Specifically, within the monitor, we need to check the user's parameters and fulfill the application's request through one or more system calls. The kernel's state is updated during the execution of these system calls, and the kernel uses locks to ensure its consistency. However, the state in the monitor does not automatically update after the system calls finish. Attackers can disrupt the operation of the monitor within the current thread by sending signals or exploit these unsynchronized states through TOCTOU attacks, causing the monitor in other threads to use incorrect states for checks. Also, attackers can exploit the state that fails to update promptly after the system call returns. For instance, attackers can first open a legitimate file and read it. After passing the policy inspection, we can close it in another thread, and race against another

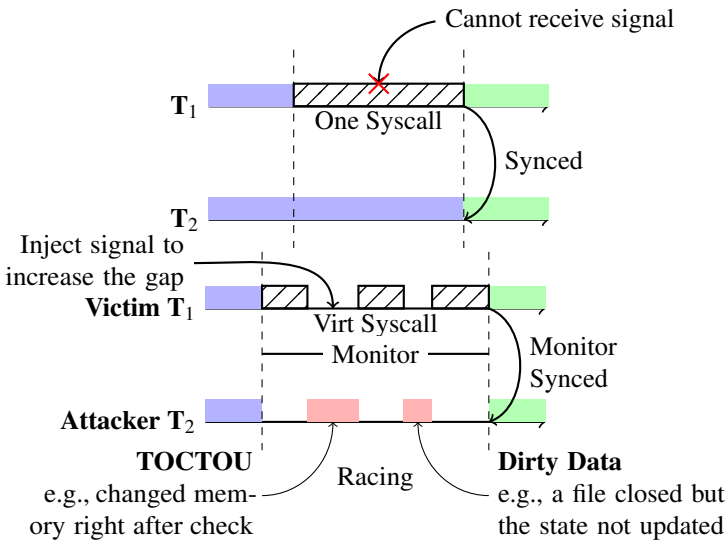

Figure 2: General Pattern of a Monitor Synchronization Problem caused by the gap between the system calls and the monitor; ▨ = Synchronized blocks (e.g., locked). ■ = State before syscall; ■ = State after syscall; ■ = Racing Area (data mismatches between kernel and monitor expose vulnerabilities);

domain to open its private file using the same file descriptor ID. Unless locks cover the entire system call, leading to issues with availability, this desynchronization is unavoidable. We developed principles for updating states that can handle desynchronization effectively. This is to ensure that the object will always use the least privileged level among the states before and after a system call. By doing so, we guarantee that the monitor always assumes the worst-case scenario, regardless of the order in which threads execute.

4 Endokernel

In this section, we define the intra-process protection model provided by Endokernel and the resources and policies it involves. This model outlines the identification of each isolated entity within the process, their methods of interaction, and the rules for allocation, sharing and destruction of resources they hold. Through this model, we define the internal boundaries of isolation within the process, identifying the objects and policies that the intra-process monitor must protect. By integrating it with security analysis, we have summarized and identified all invariants that the intra-process monitor needs to maintain during emulation or system calls. Thus we ensure the integrity of the monitor and isolation domains when handling system calls or introducing new functionalities, by using these invariants as a checklist.

4.1 Privilege Model

We define the following protection model, where a subprocess representing different privilege entities can run concurrently within a process space, orthogonal to threads. All privilege definitions are with respect to this subprocess and are divided into two parts: resources and policies. A subprocess can uniquely control certain resources: **memory**, **system objects**, and **entry points**. **System objects** include resources acquired during the subprocess's execution. **Memory** and **entry points** are established when creating a subprocess, such as isolating a segment of the program's code and data to secure it within a subprocess. This subprocess can also dynamically obtain additional memory via system calls.

Entry points are set during the initialization phase of subprocess. They are the functions through which access to the subprocess is permitted. Other subprocesses can switch to this subprocess only through these designated functions. Each subprocess implements three types of policies: **System Limitation**, **Call Permission**, and **Memory Sharing**. The **System Limitation** policy restricts access to certain system interfaces within the subprocess, such as specifying which files can be accessed, or entirely blocking system calls. The **Call Permission** policy governs whether a subprocess can call into another subprocess. And, the **Memory Sharing** policy determines the conditions for one subprocess to access the memory of another. Together, these policies outline the permissible interactions and resource access between subprocesses.

Our nested intra-process monitor, Endokernel, provides the above isolation guarantees for user programs. It ensures the integrity of its own policies and those of its subprocesses across system interfaces, system call emulation, virtualization, and multithreaded environments.

4.2 Invariants

Endokernel must ensure that the following invariants are maintained at any point during user-space execution. These invariants serve as the fundamental security guarantees provided by our monitor, and they act as the foundation for building policies for other subprocesses. We will demonstrate how we maintain these invariants within a complex process space when introducing the implementation of Endokernel in § 5.By upholding these guarantees, we can effectively identify operations that require the attention of the monitor when dealing with complex interfaces and kernel behaviors.

Synchronization guarantee

Invariant 1 (Weak Metadata Synchronization) : The memory metadata refers to the corresponding virtual memory's read, write, and execute permissions, as well as the subprocess ownership. Although the kernel can ensure synchronization between the operating system's data structures and process page tables before and after system calls, the monitor still

needs to maintain the subprocess ownership of addresses and ensure that this ownership information is correctly mapped onto the operating system's memory protection keys. Achieving synchronization in some situations can be challenging. To address this, we define the **weak synchronization** requirement, which ensures that metadata permissions are always **less than or equal to the actual permissions**. This requirement ensures that permissions used by the monitor remain appropriately constrained, preventing synchronization-related security issues. An illustrative example of a security violation resulting from failed synchronization is the bug in Jenny, detailed in §6.1.

Memory-related guarantees

Invariant 2 (Memory Policy Integrity) : All memory reads and writes occurring during the execution of any subprocess must adhere to their memory access policies or the memory policies set when sharing the memory. This includes memory reads and writes resulting from system calls and operations performed by the process in-process monitor *on behalf of* the current subprocess.

Invariant 3 (Page Integrity) : The mapping of virtual addresses to physical addresses and permission settings for memory associated with a subprocess can only be changed by the subprocess that owns the virtual address. Sharing of a page is only allowed if all subprocesses with a shared mapping to the page grant permission for sharing.

Control Flow-Related Guarantees

Invariant 4 (System Callgate and Path Integrity) : Every system call must have a path start with the Endokernel, indicating that a specific entry point for the in-process monitor needs to be active in the current context when the `syscall` instruction is executed. This invariant allows us to guarantee that checks for system calls are consistently performed, ensuring security and integrity without compromise.

Invariant 5 (endocall Integrity) : Any switch between subprocesses must either begin execution through a function call from one of the specified entry points (endocall), or, after the Subprocess has finished executing, return to the calling Subprocess and return address. Furthermore, any cross-Subprocess call must satisfy the *Call permission* defined in the privilege model.

Invariant 6 (Subprocess Atomicity) : After an endocall or invocation of the monitor, the target's execution process is invisible to the caller. This does not imply thread safety for the target; rather, under the guarantee of **I5**, the caller is blocked and only returns after the execution has completed, without being able to interfere with the target's execution state during the process. Please note that only the basic CPU state, such as registers, is protected here, without considering other shared global data or the influence of other threads.

Instruction-Related Guarantees

Invariant 7 (Instruction Blacklist) : Some instructions are considered privileged and are therefore prohibited from being used during the execution of a subprocess. For example, `WRPKRU`, `syscall`, and other instructions. Since the monitor and other subprocesses share the same process space, we require that even when jumping to a blacklisted instruction legitimately created by the monitor during execution, their execution will not have any actual effect.

Complete Mediation

Invariant 8 (Complete mediation) All system resources, during their creation, operation, loading, access, callbacks, duplication, and destruction, are intercepted and subject to inspection by the Endokernel for filtering or virtualization. This includes the restrictions on file systems, virtualization of signals, threads and analysis of the functionality and parameters of known system calls.

5 Endokernel Prototype

To meet all the requirements of the Endokernel, we have designed a basic framework for an intra-process monitor running on Linux, as shown in Figure 1. On the left side are the system components of the Endokernel, and on the right side is a simplified subprocess provided by these components for user privilege definition. In typical applications, developers can compartmentalize program modules based on their origin, importance, and trustworthiness. Modules are assigned to different subprocesses– safebox, main, and sandbox– each with a specific security level and default privileges, facilitating seamless integration. For instance, an isolated parser module can ensure that it cannot access any other modules by default. This also means a limitation on the isolated parser module's access to system calls and other subprocesses. For web engines like NGINX, protecting OpenSSL can prevent other modules from accessing its critical keys. Applications can have multiple safebox subprocesses, and access between them will also be restricted. Furthermore, developers have the ability to define custom isolation methods with specific access policies based on their application requirements, such as achieving further separation of glibc.

In a nutshell, Endokernel is built upon intercepting and securely isolating user system calls, offering fundamental protection to operating system interfaces through system call virtualization, such as filtering dangerous system calls. When encountering operations that require updating the state within Endokernel, such as threads, signals, memory, and file systems, the virtualized syscall dispatches the operation to the respective module for processing and returns the results to the user. The core objectives of the components provided by Endokernel are to: 1) Filter and inspect all system calls we have identified, ensuring the security of Endokernel and sub-

process; 2) Update and maintain Endokernel's internal state in a multithreaded environment, ensuring that decisions in (1) are based on correct information; 3) Preserve the integrity of Endokernel and subprocess's internal state and control flow, with the kernel signal delivery; 4) Offer the same interfaces and behaviors as Linux under secure conditions, maximizing system compatibility. On top of this, we have focused on examining the inevitable gap between such an intra-process monitor and the kernel, as well as the resulting security risks and mitigation methods.

Virtualization of System Calls Endokernel can virtualize system calls, which allows us to ensure **I8** by providing more complex virtualization for those system calls that cannot be simply allowed or denied across subprocesses. We classify them into four categories: those that need to be fully virtualized, partially virtualized, passed through, and prohibited. Full virtualization means that we will implement function code in the Endokernel similar to the same functionality in the kernel, somewhat like Usermode Linux, meaning that the actual providers of these features will be Endokernel. In other cases, we will pass the system call to the kernel for execution, but we will check the parameters and return values to ensure that the system call is executed safely. Alternatively, we will simply pass through the system call to the kernel if it is harmless (e.g., `getppid`). Finally, for system calls like `rseq`, we simply prohibit them. This enables us to:

1. Prohibiting specific system calls (privileged, Codemodify_ldt, `io_uring`, etc.)
2. Allowing memory map to track memory used by subprocess, ensuring proper isolation and management.
3. Enabling file system protection and restrict access to files or other system objects, enforcing access policies.
4. Supporting virtual signal and thread with Linux-compatible interfaces, ensuring compatibility with existing applications.
5. Restricting the set of allowed instructions (**I7**) that can be loaded as executable, preventing the execution of potentially harmful instructions. We implemented the instruction blacklist using ERIM's binary scanning.
6. Virtualizing `exec` to ensure that Endokernel is loaded first in new processes, maintaining the integrity of the security mechanisms.

Secure System Call Isolation We adopted nexpoline [70] and Control Flow Enforcement Technology (CET) to secure the system call interface in the userspace. Nexpoline is a secure and lightweight system call interception mechanism. We use nexpoline to partition user space into trusted and untrusted portions while ensuring **I4** of the Endokernel. With nexpoline, only the trusted portion can make system calls. Nexpoline leverages seccomp or SUD to control the privilege of syscalls, along with MPK, to transform system calls in user space into permissions determined by MPK. Nexpoline consists of a trampoline responsible for context switching, default policies necessary to protect the trusted portion, and signal redelivery. In this work, we utilize nexpoline's trampoline and extend the implemented policies and virtualization on the system interface like signal to support subprocess isolation. In addition to that, we also attempt to achieve **I4** through a global control flow integrity policy. By enabling CET, we only need to confine the range of the syscall instruction within the monitor's code segment. And, by generating the endbr64 instruction only at the only entry point of the monitor, and using seccomp or SUD to limit the caller's IP address of the syscalls.

Virtualization of Signal The Virtualized Signal is responsible for ensuring **I5** and **I6**. Due to the complexity of signals and the limitations of system calls, merely filtering parameters cannot safely permit the use of signals. Any such implementation would either be insecure, incomplete, or both. The registration, delivery, mask and return of signals must be fully emulated by Endokernel to ensure that these invariants are not violated by signals. All signals are registered with an entry-point to the Endokernel's signal handler. The `sigprocmask` is used to prevent the signal handler from being re-entered and it gets unset only when returning from the Endokernel's signal handler, ensuring **I1**. The monitor controls the delivery of signals and ensures **I5** and **I6**. When a signal occurs while the program is executing in the monitor, our signal virtualization pushes it in the pending queue in the monitor, and uses `sigreturn` immediately to continue the execution of the monitor. When a program is executing in a subprocess, the monitor attempts to deliver signals immediately if they are not masked. If a signal cannot be delivered at that moment, it is also queued. Upon returning from the subprocess or the monitor, the program checks the queue for any signals that can now be delivered. If there are deliverable signals in the queue, we create a signal context using the state of the subprocess to which it will return and delivers the signals to that subprocess. This ensures that signals do not cross subprocess boundaries, as they are only generated and handled within the context of their respective subprocesses. In order to secure the signal stacks, we utilize `sigaltstack` to provide a signal stack for signal delivery, thereby preventing threads running in the same process from tampering with the stack. To be noted here, the kernel has a flaw when delivering signals to the user when MPK is enabled and can cause kernel panic. In our design, we fixed this bug with a kernel patch, but not changing any other behaviors.

Filesystem Multiplexing The file system contributes partially to **I3** , considering the access to /proc/self/mem pointed out in Pitfall [15]. In addition, the file system implements extra access restrictions for system objects in the privilege

model, including forbidding accesses to specific files and accessing file descriptors belonging to other subprocesses. The maintenance of this information also needs to adhere to the **I1**, which we will detail in the following paragraph about memory management. It is worth noting that the file descriptors themselves are still the same within the process space, but their accesses are restricted, which is more convenient for sharing between different modules.

Importantly, considering the unique form of io_uring bypassing system calls for access, we cannot allow user programs to directly use such shared queues.

Memory Management Memory Maps provides the necessary information for the monitor to define and enforce **I2**. To achieve this, the monitor tracks or virtualizes a series of system calls that modify the memory metadata. For example, we record the ownership and access permissions of memory during `mmap`, ensuring that this ownership is not violated in subsequent accesses. The main challenge of this component is the inevitable synchronization issue. We still rely on the operating system to allocate, release, and protect memory. Simultaneously, the information also needs to be maintained within Endokernel. During the gaps between system calls, there will inevitably be moments when the access permissions recognized by the operating system and hardware are inconsistent with those maintained in Endokernel's data structures, leaving potential opportunities for attacks.

In our implementation, we adhere to the concept of **I1** by conservatively handling the information in Endokernel. The principle involves maintaining permissions at the minimum necessary level during system calls, with a priority on lowering permissions and deferring any elevation. For example, before executing the mprotect system call, we first lock the data structure within the monitor that maintains page permissions. We check the current subprocess's access permissions, then update the record to the lesser privilege before and after the mprotect call. Afterward, we unlock it and proceed with the system call. Once the call is completed, we lock and update the monitor's records to the actual permissions. This approach ensures that in all critical states, attackers will not gain more privileges than they should actually have. By doing so, we effectively maintain the integrity of memory policies and minimize potential security risks.

Multithreading The creation of a thread implies that a new subprocess will inherit the current running state and start executing. During this process, Endokernel must create the relevant thread local storage to track the new context's state based on the old state, such as the currently executing subprocess and nexpoline. This ensures that **I5** will not be forgotten or affected by the creation of new threads. Also, the synchronization and racing of the system objects and monitor's data structures among threads have profound effects on the correct virtualization of system calls and **I1**.

Trampoline and Context Switching Endokernel needs to maintain information across all subprocesses, including resources, privileges, restrictions, and entry points, while also ensuring a secure trampoline for switching between them. This serves as the source of information for the privilege model and **I5**. Here, since this information and trampoline code reside in user space and are always executable, similar to nexpoline, we also need to prevent attackers from bypassing trampoline checks or exploiting instructions such as `WRPKRU` or others through arbitrary jumps.

Additionally, we cannot prevent the kernel from delivering signals during the execution of the trampoline. Therefore, we also need to rely on signal virtualization to avoid signal delivery when the context is in a critical state. When the trampoline finishes and returns, we will perform signal delivery checks for the subprocess about to resume, thereby delaying signals that occurred during the call. From the caller's perspective, the signals appear to occur at the moment the trampoline returns. This is similar to the situation in Linux where signals are delivered during a system call, thus ensuring the implementation of **I6**.

Adapting Existing Applications To integrate Endokernel into an application, developers need to inform Endokernel about the data, program addresses, entry points, and required access permissions of the subprocess to be protected through special system calls. Due to MPK limitations, these addresses must occupy separate pages to avoid affecting other subprocesses. To simplify this process, as illustrated in Figure 3, we designed a series of header files that streamline these steps. By defining the relevant information of the subprocess to be isolated and annotating the target code using the provided macros, our header files automatically add the corresponding attributes, ensure the memory layout complies with Endokernel requirements, and generate the necessary initialization calls based on the desired isolation type. Subsequently, the function calling the subprocess can be invoked using the `xcall` macro. Furthermore, our approach supports the isolation of shared libraries. By providing Endokernel with the addresses of these libraries through system calls, Endokernel automatically scans their linkmaps, protects the relevant memory, and redirects library function calls through `xcall` using PLT hooks. Additionally, we provide a header-only allocation library that allows subprocesses to obtain protected heap memory.

6 Evaluating Endokernel Runtime

In this section, we evaluate the security, performance, and compatibility of Endokernel virtualization, *i.e.,* the Endokernel transparently executing the main application while isolating itself. We introduce a few novel attacks exposed through our exploration.

Table 2: Quantitative security analysis based on Pitfalls [15] and original attacks. ○ = vulnerable ● = prevented.

6.1 Security Evaluation

As summarized in Table 2, Endokernel is able to monitor those known attack methods [15] at the system call level and define specified policies to mitigate them. In addition to that, 5 more classes of attack have been identified by this work. We explored a combination of multiple attack dimensions, including privilege escalation via unattended syscalls, signals, multi-threading, multi-domain, other CPU features like TSX instructions, and more race conditions that create inconsistency between the monitor and the OS.

Incorrect Signal Return Handling The signal stack must use a PKEY different from the user's to prevent tampering attacks [15]. But, the kernel only uses the default PKRU when delivering signals. Jenny [54] modified the kernel to alter the PKRU during signal delivery and revert it upon sigreturn. This necessitates the kernel to track whether it is awaiting a sigreturn. Jenny's method not only disrupts the kernel's ABI guarantees and restricts the use of nested signals but also imposes extra synchronization requirements during sigreturn. Jenny failed to correctly implement synchronization of signal states between the kernel and the monitor, allowing attackers to deceive the kernel into using an incorrect PKRU for sigreturn. This ultimately enables attackers to access privileged PKRU values that should only be allowed to the monitor. While we also modified the kernel to ensure signals will not cause a kernel panic, no changes have been made to its behavior. By simulating the kernel's signal behavior within Endokernel, we completely avoid the attack surface associated with signal delivery and sigreturn.

Forged Signal Delivery At the signal handler's entry point, we use `WRPKRU` to switch to the monitor. However, attackers can jump to this location and forge signals, claiming to have received them from the kernel. Thus, we are left unable to regain the PKRU state prior to the `WRPKRU` switch, complicating the monitor's ability to distinguish genuine signals from counterfeit ones. To mitigate this attack, nexpoline [70] utilizes the fact that the default PKRU from the kernel can write to the monitor's thread local storage. Before the `WRPKRU` switch, we write a flag to the for subsequent validation and clear it after the signal context switch. Because attackers lacking a privileged PKRU cannot forge this flag, they are also prevented from forging signals.

Fork and Retry Attack The fork system call allows an attacker to duplicate the current process, providing two main advantages. First, it grants the attacker in the parent process privileged access and control over the child processes. Second, and more significantly, it enables the attacker to attempt multiple retries of an attack that may not succeed in a single attempt, important for race-based attacks with narrow timing windows. By spawning a large number of child processes, the attacker can repeatedly attempt the attack without affecting the parent process complicating detection. To counter this, we propose limiting the parent process's debugging privileges over its child processes and restricting the maximum number of child processes.

Syscall TOCTOU Attack TOCTOU is a problem that must be addressed for secure multithreading monitoring. An attacker can change the pointer parameters involved in the system call in another thread. For example, use `open("/good")` for the system call and replace it with `"/secret"` after it has passed our filter. We avoid this type of attack by ensuring that all pointers in system calls are copied to Endokernel if we need to examine them.

Page Table Syscall Abuse The most straightforward system call of this type is the series of system calls represented by `mprotect`. However, there are other system calls that operate on page properties that are ignored. In addition to `userfaultfd` [54], we also find `vmsplice` that moves the underlying page directly without copying it. Therefore, the properties of the virtual memory addresses it accesses also need to be examined.

High Memory Access Syscall Abuse The `/proc/PID/mem` file, `process_vm_readv` and `process_vm_writev` system calls allow a process to read and write the memory of another process. As described in Section 3, other system calls that result in accessing high memory may also lead to similar issues and need to be prohibited or have their functionalities limited. Otherwise they can be used to bypass MPK's protection. For example, `/sys/kernel/tracing/user_events_data` can allow the attacker to write 1 or 0 to the memory of the monitor when used with the `ioctl` system call. We limit the access of these system calls using our monitor.

TSX Instruction Probing The TSX [36] instructions are designed to allow the CPU to execute a series of instructions in a transactional manner. If the transaction fails, the CPU will roll back to the restore code with an error code. This allows the attacker to probe the content of an execute-only memory created by MPK and leak information about the instructions executed. Considering that Intel® has removed TSX support in newer processors, we recommend turning off TSX.

`rseq` Control Flow Attack `rseq` allows the developer to configure a critical region where the control flow is transferred to an abort address if the process gets scheduled to another CPU. This allows the attacker to hijack the execution of other subprocesses, even the monitor, to the location specified by the attacker, while the PKRU does not change after the transfer. Although this address needs to start with a specific sequence of bytes, it is not difficult to generate such a gadget via mprotect. And the address range where `rseq` takes effect can be changed at any time by modifying only one structure in user space. Therefore, this system call needs to be blocked to prevent such an attack.

Inconsistency of Monitor and Kernel Status via Syscall Intra-process monitors inevitably need locks for synchronization. Otherwise, maintaining the correct state of system resources and domains within the monitor to decide on policies would be impossible, leading to the races and attack surfaces illustrated in Figure 2. However, we cannot simply put a lock on access to all emulated system calls because this would mean only one thread could make a system call through the monitor at any one time. For instance, when handling long-running IO system calls, we must unlock because the execution of system calls is beyond the control of user space. Synchronization issues like this are unavoidable unless we modify the kernel, similar to μSWITCH, to let the monitor and kernel use the same data structures. This would require extensive modifications to the kernel. Our solution is that each time we unlock and invoke real system calls, we require that the permissions for every resource and domain recorded inside Endokernel are less than or equal to their actual access permissions. Thus, even in cases of inconsistency, Endokernel will not make decisions that are considered incorrect in terms of security. Even if the monitor denies access, such denial is inherently a possible result of multithreaded competition, and therefore, it does not exceed the application's expectations.

6.2 Performance Evaluation

We conducted all experiments on an Intel 11th generation CPU (i7-1165G7) with 4 cores at 2.8GHz, with both Turboboost and hyper-threading disabled. The test system had 16GB of memory, ran Ubuntu 20.10, and used a kernel version 5.9.8 with both CET and SUD backported. Since CET has not yet been integrated into the kernel, we used Intel's CET patches. SUD is already available in the latest kernel. Besides that, our kernel modifications involved a net change of +82 -45 LoC to address a kernel panic bug during signal delivery with sigaltstack. For our micro and application benchmarks, we averaged results over 100 repetitions and examined various Endokernel configurations. Endokernel utilizes nexpoline [70], which allows for different configurations based on mechanisms like seccomp or syscall user dispatch, represented as nex-sec or nex-sud, respectively. nex-sec relies

solely on seccomp for enhanced compatibility, whereas nex-sud requires a more recent kernel version or the backporting of the SUD patch. We also integrated CET with seccomp and SUD to secure the system call interface, indicated as cet-sec and cet-sud. Since nexpoline already meets all the security requirements of Endokernel, and CET serves more as a reference for the performance impact under Control Flow Integrity (CFI), which represents a stronger constraint. We aimed to include a comparison with the ptrace and seccomp based MBOX [37] in our evaluation, but it failed to complete some benchmarks. Observations showed that strace performed better than MBOX by a margin of 2.7%, leading us to use strace for comparison instead. This setup provided a comprehensive framework for evaluating the performance and security enhancements offered by Endokernel in various configurations.

6.2.1 Microbenchmarks

System call overhead: We evaluated Endokernel's overhead on system calls and signal delivery in comparison to native and the ptrace-based techniques. Figure 4 depicts the latency of LMBench v2.5 [45] for common system calls. Each Endokernel configuration and the ptrace-based techniques intercepted system calls and provided a virtualized environment to LMBench. Overall, nex-sud and nex-sec that were based on nexpoline had better performance than CET-based configurations. Endokernel added a fixed cost of $0.5-2\mu$sec per system call for nexpoline based isolation. Endokernel had high overhead for protecting fast system calls, like `read` or `write` 1 byte (126%-900%, approx. 284% for nexpoline only), whereas long-lasting system calls like `open` or `mmap` only observed 29%-150% overhead. We demonstrated the difference by performing a throughput file IO experiment. Figure 5 showed high overheads for reading small buffer sizes, which amortize with larger buffer sizes. Since the overhead induced by Endokernel is per `syscall`, reading a file with larger buffers has much less overhead.

Thread scalability: Endokernel employs the weak synchronization principle to prevent races and TOCTOU attacks. The scalability of Endokernel is showcased in Figure 6 using sysbench [39], which performs concurrent reads of a 1 GB file across a varying number of threads. Due to the locks implemented in Endokernel, the number of `futex` system calls increases with the thread count, reaching optimal performance at 4 threads. The overhead associated with each configuration mirrors that observed in the microbenchmarks. cet-sec and cet-sud decrease by up to 60% because the syscall overheads of CET-based configurations are the highest.

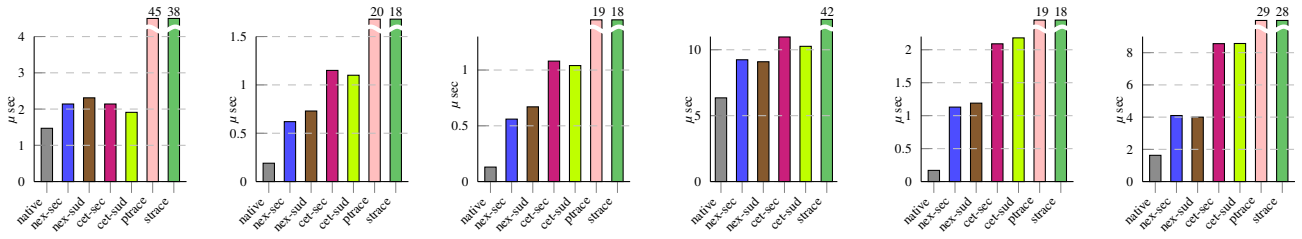
6.2.2 Overhead on Applications

Along with the microbenchmarks, we analyze the performance of common applications such as lighttpd [41], Nginx [46], curl [17], SQLite database [56], and zip [35] protected by Endokernel. Figure 7 shows the overall overhead of each application compared to the native execution. All network traffic is handled locally to avoid any network skew or extra latency, and the client and server are assigned to separate cores to minimize interference.

`curl` [17] downloads a 1 GB file from a local web server. It is a particularly challenging workload for Endokernel, since `curl` makes a system call for every 8 KB and frequently installs signal handlers. In total it calls more than 130,000 `write` system calls and more than 30,000 `rt_sigaction()` system calls to download a 1 GB file. However, libcurl supports an option not to use signals, which reduces the overhead by about 10% on average for Endokernel, but strace gets worse by about 140%.

Lighttpd [41] and Nginx [46] serve a 64 KB file requested 1,000 times by an Apachebench tool [1] client on the same machine. All configurations perform within 94% of native. nex-sud outperforms all other configurations and highlights Endokernel's ability to protect applications at near-zero cost with a throughput degradation of 1%. In contrast, strace has about 30% overhead.

SQLite [56] runs its speedtest benchmark [56] and performs `read()` and `write()` system calls with very small buffer sizes to serve individual SQL requests. Contrary to the microbenchmarks, the difference between configurations is larger. Configurations using syscall user dispatch (nex-sud) observe about 30% less overhead when compared to their Seccomp alternatives. Strace performs poorly with more than 500% overhead.



zip [35] compresses the full Linux kernel 5.9.8 source tree which opens all files in the source tree, reads their contents, compresses them, and archives them into a zip file. The observed performance degradation is similar to microbenchmarks for `openat()`, `read()`, and `write()` system calls.

Summary Network-based applications like lighttpd and Nginx perform close to native whereas file-based applications observe overheads between 4 and 55%, and small file access is the worst as in SQLite.

6.2.3 Overhead on SPEC2017

Setup We evaluated the overhead of virtualization brought by Endokernel under compute-intensive workloads on SPEC2017 intrate and intspeed version 1.1.9. All evaluations were conducted with boost and ASLR disabled, intrate running on a single core, and intspeed using 4 threads.

Result As shown in Figure 8, for most tasks, the overhead introduced by Endokernel is within 2%. This minimal overhead is primarily because the tasks in SPEC use fewer system calls. Some tasks show a negative overhead, which is due to the overhead being smaller than the variation between tests. CET configurations introduces additional performance overhead. We employ IBT solely to ensure callgate integrity, while the shadow stack is mandated for global use. Additionally, the CPU must access the legacy map to verify the indirect jumps

(a) `open()` (b) `read()` (c) `write()` (d) `mmap()` (e) `install signal` (f) `catch signal`

Figure 4: System call latency of the LMBench benchmark. Std. dev. below 5.7%.

within user applications, further contributing to the overhead.

6.3 Compatibility Evaluation

We use the Linux Test Project (version 20200515) to evaluate the compatibility of Endokernel. LTP is a regression test kernel conformance test of the user's runtime environment. It evaluates whether the Linux kernel and the user runtime behave as expected. Endokernel being an intermediate level that runs in the user and crucially provides kernel functionality to the rest of the user programs, using this test project helps us ensure that the part of the kernel functionality we are emulating is correct and consistent in the boundary condition.

Baseline LTP runs 2136 test cases. The original kernel 5.9.8 reports 188 test cases skipped and 22 test cases failed. We excluded these tests going forward, since Endokernel relies on the kernel for functionality, leaving 1926 test cases in total.

Result After testing, Endokernel only failed 78 out of 1926 or 95.95% of LTP. We categorize the failed tests.

Security Implication (19 / 78): These tests fail because Endokernel protects subprocesses. Endokernel, *e.g.*,, prevents

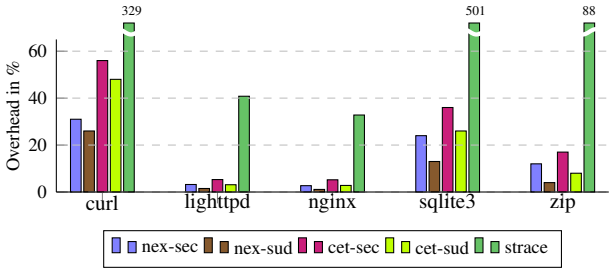

Figure 7: Normalized overhead of diff. Linux applications. Std. dev. below 2.4%.

access to core dumps, ptrace, or changes to seccomp.

Lack of Kernel Functionality (33 / 78): The kernel does not support modifying the PKEY of a shared memory segment. Endokernel cannot overcome this limitation of Intel® MPK.

Inconsistency of Kernel Functionality (11 / 78): Some tests try to probe the functionality of the kernel under certain edge cases. They depend on their own environment resulting in inconsistent or unstable results when the Endokernel is also running. E.g., in the OOM test case, sometimes the kernel not only kills the Endokernel, but also the parent process running it. We consider these tests to have failed for reasons of rigor, although they do sometimes pass.

Secondary Loader (5 / 78): For security purposes, Endokernel must be loaded as the first process. This requirement affects the `O_EXEC` flag on files, which cannot be modified in user space. Some tests use sudo, leading to issues for the kernel to properly set the user ID or require the process name to be different.

Issues Caused by Endokernel (5 / 78): In edge cases Endokernel fails which do not cause disruptions for usual applications. For example, Endokernel has to limit the arguments to an `exec`'d program to forward information to the Endokernel in the other process leading to tests with enormous argument length to fail. Cpuhotplug03 fails to find processes by name due to uniform naming under Endokernel, and mmapstress08 conflicts due to Endokernel's memory allocation strategy.

Unsupported system calls (2 / 78): Linux frequently introduces new system calls and our system successfully blocks unknown `syscalls`.

Racing causes by the kernel (1 / 78): This issue occurs in

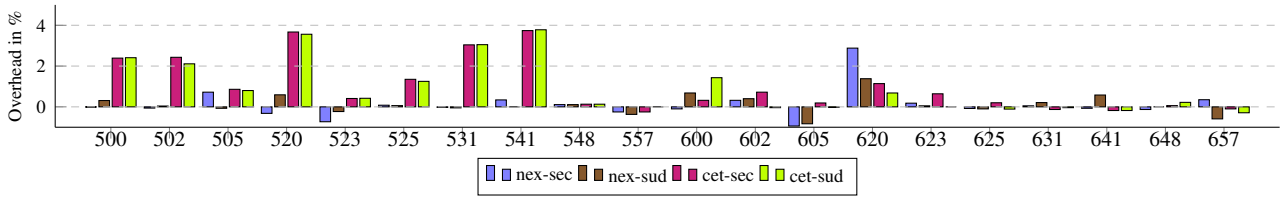

Figure 8: SPEC2017 normalized overhead for different configurations.

hugemmap06 due to the kernel's inability to perform `mmap` and `mprotect` atomically. A brief gap between these operations can lead to failures in concurrent threads. This situation is uncommon because other threads usually do not have knowledge of the addresses involved in these allocations and resembles an attack.

7 Using and Evaluating Subprocess

We demonstrate the extensibility of the Endokernel by using the subprocess virtual privilege rings to 1) eliminate the recent `sudo` vulnerability [19] and 2) implement a significant refactoring of NGINX: memory and system isolation of buggy parsers and restricting sensitive crypto access to OpenSSL while the main portion of the application maintains partial system object access.

Eliminating `sudo` Privilege Escalation. Recently, a bug was found in the `sudo` argument parser allowing an attacker to corrupt a function pointer to gain control with root access [19]. We compartmentalized `sudo` so that the parser code, in file `parse_args.c`, is isolated, and restricted to only the command line arguments and an output buffer. With these changes, the worst possible attack is to overflow the parser's internal buffer causing a segfault, but nothing harmful. In summary, by changing approximately 200 lines of code, importing our libsep in `sudo` and using Endokernel, we confined the argument parser and successfully prevented the root exploit. This applies more generally. Commonly parsers execute with too many privileges and could benefit from similar changes.

Towards a Least-Privilege NGINX We present a novel compartmentalization of NGINX, which allows us to measure the effort and performance costs of improving the security of a complex system while using the Endokernel and subprocess. Our goal is to isolate the NGINX parser and secure the OpenSSL library. By isolating the parser code in NGINX, we address the frequent vulnerabilities and excessive privileges of string handling operations which often require limited functionality. This strategy is commonly used in the work of syscall filtering [3, 22, 26, 47, 63], but often applied at the process-level. We also protected the OpenSSL library using the automatic shared libraries isolation provided by the Endokernel. By isolating OpenSSL, which handles private keys, we prevent potential key leakage. The value of isolation lies in its ability to protect against common exploits (e.g., CVE-2009-2629, CVE-2013-2028, and CVE-2013-2070) utilized

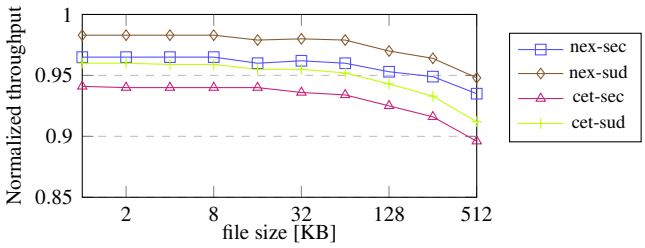

Figure 9: Normalized throughput of privilege separated NGINX using TLS v1.2 with `ECDHE-RSA-AES128-GCM-SHA256, 2048, 128`. Std. dev. below 1.5%.

by attackers to hijack control flows and to leak or compromise sensitive information (e.g., cookies, private responses data, passwords, or keys). The essence of this protection is to prevent the majority of the application from accessing key information, thereby reducing the TCB and safeguarding critical data such as session and private keys.

Performance. We evaluate the least-privilege Nginx shielding OpenSSL and isolating the HTTP parser. We measure the throughput downloading files with varying sizes and normalize to the native performance using ab (see Figure 9). All tests are performed locally with a pinned CPU core. Strace suffers from its interception costs and falls below 50% for large files. The results indicate less than 10% overhead for the different nexpoline techniques and the lowest for nex-sud at 3-5%. The number of system calls increases with file size, leading to decreased performance of Endokernel.

During the initialization of NGINX, 89 `xcalls` are made to initialize OpenSSL, and an additional 16 `xcalls` are needed to start each new HTTPS session. Furthermore, the number of `xcalls` for each connection escalates with file size, ranging from 129 for $1k$ to 312 for $1024k$.

8 Related Work

Compartmentalization enhances software security by isolating components to limit damage from breaches. Various approaches, including software-based, operating system-based, and hardware-assisted methods, offer security benefits but compromise on efficiency or complexity. This section reviews these techniques, highlighting their strengths and limitations in comparison to our intra-process security monitor, which aims for efficient and secure system interface emulation with-

out compromising backward compatibility.

Software-based techniques. Software Fault Isolation (SFI) [62] started a research field to inline security checks within application code. The goal is to translate an application via a compilation pass to enforce security properties such as Control-Flow Integrity (CFI) [2], Code-Pointer Integrity [40], or intra-process isolation [38, 52]. Similar needs arise in web applications, where protections against native code [71] vulnerabilities have spurred the development of WebAssembly [52]. However, they suffer with large performance overheads from inlined security checks and also lack safeguards against operating system-level attack vectors.

OS-based techniques. To address the limitations of traditional process-based isolation, various kernel abstractions have been developed that employ existing mechanisms such as page tables to facilitate intra-process solation. Light-weight contexts (lwC) [42], secure memory views (SMV) [34] and nested kernel [21] introduce a lighter form of isolation. These approaches enable the association of multiple virtual address spaces with a single process, allowing for quicker context switches. Shreds [13] combines OS-based and software-based techniques to enhance performance, while Wedge [8] incorporates runtime checks to strengthen security. However, the performance of these methods is still constrained by the overhead of context switching, an issue that Endokernel addresses through more efficient intra-process isolation techniques using hardware designed specifically for this purpose. SEIMI [64, 68] uses Supervisor Memory Access Prevention designed for ring 0 to restrict access to user memory, offering efficient privilege switching even compared to MPK and MPX. However, it only allows the user space to be divided into two domains and requires a complex hypervisor mechanism to run both user applications and the kernel in supervisor mode. Moreover, these OS-based techniques require the use of customized operating systems, which poses challenges for system maintenance.

Hardware-based techniques. CPU vendors have proposed methods to avoid context switches, for example, by switching address spaces with `VMFUNC`, altering memory access permissions based on domain using `WRPKRU`, specialized instructions like `WRSS`, or pointer capabilities with MTE [5] or CHERI [14, 66]. Each technique introduces its own set of limitations, performance characteristics, and security implications. Dune [7] utilizes Intel VT-x to allow a process to operate in both privileged and unprivileged CPU modes. Secage [43] achieves a similar separation by utilizing Intel®'s `VMFUNC` to switch address spaces in user space. Koning *et al.* [38] develop a compiler that isolates components with varying techniques and demonstrate the performance differences. ERIM, HODOR, Donky, Jenny, and others [32, 48, 49, 54, 55, 57, 60] enable the secure use of MPK for intra-process isolation and demonstrate efficient isolation techniques. Furthermore, EPK [28] expands the maximum number of domains by combining MPK and VMFUNC. Techniques based on MPK require coordination between user programs and the OS to ensure these mechanisms are not bypassed, making them vulnerable to OS-level attacks [15, 61]. CETIS [69] leverages Intel® CET's shadow stack for secure memory, which restricts write operations to these areas using the newly added `WRSS` instruction, avoiding context switches. Nevertheless, it only supports secure and non-secure memory domains and depends on CFI to ensure the security of these instructions. Capacity [23] uses ARM's MTE for intra-process isolation, allowing only authorized pointers to access tagged memory region. While this approach offers more flexible isolation and sharing compared to MPK, it poses challenges in the security model as it relies on the confidentiality of the pointer.

System call and signal virtualization. PKU-Pitfall [15] demonstrated how the operating system interfaces can be used to bypass intra-process isolation and motivated the need for system call virtualization. Linux security module (LSM) [67] intercepts system calls in the kernel and can be used to implement a system call filter as suggested by SELinux [44], AppArmor [6], Tomoyo [31] and Smack [53]. However, LSM as well as large kernel subsystems like the filesystem, would have to be extended to recognize different domains in userspace and its interface does not support modifying arguments making virtualization impossible. Alternatively, Seccomp [16] offers the userspace a programmable system call filter using BPF programs and can be used to limit the OS interface [71]. However, BPF can only access limited system call information, making it incapable of implementing flexible filtering or virtualization. In some configurations, Endokernel relies on Seccomp to prevent system calls outside the trusted monitor.

9 Conclusion

We propose Endokernel and its implementation, a continuation of the minimalist philosophy of microkernel that provides user space isolation. In this process, we addressed synchronization and signal issues that are inevitable for multithreaded intra-process monitors. We proposed an inside-out approach to identify more system call pathways that could lead to MPK bypass, thereby enhancing the reliability, compatibility, and efficiency of intra-process monitors. We evaluated the performance overhead of Endokernel across different use cases and conducted a comprehensive analysis and comparison of its security. We implemented subprocess isolation within Endokernel and isolated OpenSSL and the parser in NGINX to demonstrate Endokernel's practical use case.

Abstract

eBPF has become a critical component in Linux. To ensure kernel security, BPF programs are statically verified before being loaded and executed in the kernel. However, the state-of-the-art eBPF verifier has both security and complexity issues. To this end, we choose to look at BPF programs from a new perspective and regard them as a new type of kernel-mode application, thus an isolation-based rather than a verification-based approach is needed. In this paper, we propose HIVE, an isolation execution environment for BPF programs on AArch64. To provide the equivalent security guarantees, we systematize the security aims of the eBPF verifier and categorize two types of pointers in eBPF: the *inclusive type* pointer that points to BPF objects and the *exclusive type* pointer that points to kernel objects. For the former, HIVE compartmentalizes all BPF memory from the kernel and *de-privileges* the memory accesses in the BPF programs by leveraging the *load/store unprivileged* instructions; for the latter, HIVE utilizes the *pointer authentication* feature to enforce access controls of kernel objects. Evaluation results show that HIVE is not only efficient but also supports complex BPF programs.

1 Introduction

Linux eBPF allows users to load programs into the kernel and customize its behavior without modifying the kernel code [11]. eBPF provides an instruction set and execution environment in the kernel. At load time, the BPF program undergoes a static verification to ensure kernel security. Then, it is compiled and mounted at a specified kernel location. BPF programs are allowed to call helper functions, which are offered by the kernel to enable interaction with the system.

While eBPF has been used in various scenarios [2, 4, 9, 13, 15, 15, 32, 34, 37], it presents two issues in use. The first is the *complexity issue*, where legal programs may fail in the verification due to the verifier's limited capabilities [2, 13, 15, 37]. Researchers have resorted to "verifier-oriented programming" to circumvent this issue, such as masking memory accesses to reduce the complexity of verification [37]. Even so, it remains a persistent issue highlighted by many literature [13, 15, 37]; The second is the *security issue*, where malicious programs may pass the verification due to vulnerabilities [3, 14, 18, 31]. According to statistics, over half (36/60) of eBPF's CVEs come from the verifier since 2014 [31].

Through systematic analysis, we found that the above issues primarily come from the *full path analysis* stage of the verification (§3). It executes symbolically the program at the entry and explores all possible execution paths to check whether the state is illegal or not. However, it encounters the well-known *state explosion* problem, which significantly limits the accuracy of such analysis. Therefore, the verification-based method has become the bottleneck of eBPF.

In this work, we aim to address the above challenges in eBPF, to enable its broader practical application. Specifically, current BPF programs are considered part of the (untrusted) kernel code, so eBPF uses the verification-based method to "review" the code to identify all abnormal behaviors. But we choose another perspective — *BPF programs are no longer part of the kernel code, but a new type of kernel-mode application that interacts with the kernel through helper function calls rather than system calls, so kernel security should be achieved by isolating BPF programs, not by verification.*

As such, we propose to build an isolated execution environment for eBPF, dubbed HIVE[1], and enforce runtime isolation for BPF programs, thus eliminating the need for full-path analysis in the verification. Our design is based on AArch64, which is particularly motivated by the growing popularity of Arm-based processors in the mobile, PC, and server market, but should be also applicable to other ISAs, such as x86 (§9).

Our first step is to understand the security goals of the verifier in its full-path analysis. To this end, we conducted a comprehensive analysis of the verifier (§3) and concluded three security goals: 1) *memory safety* that ensures BPF pro-

†This work was done while he was a visiting student in ICT.
*Zhe Wang is the corresponding author. wangzhe12@ict.ac.cn.

[1]We call it HIVE to refer to a beehive for the bees in the eBPF logo.

grams cannot arbitrarily access kernel memory; 2) *leakage prevention* that prevents BPF programs from leaking kernel information; and 3) *DoS prevention* that ensures BPF programs cannot cause crashes or excessively consume CPU time.

The core approach taken by HIVE is to *de-privilege the BPF program*: the memory of the BPF program is mapped to an independent address space (called BPF space) and set to be un-privileged pages; the BPF program still runs at the privileged level, but is compiled to use the load/store un-privileged (LSU) instructions. The verifier, even without full-path analysis, can prevent illegal instructions and illegal control flows at load time. This simple setup naturally achieves the above goals: *Firstly*, as the kernel memory is set to be privileged pages, the BPF program cannot access them, thus ensuring memory safety. *Secondly*, the layout in the BPF space cannot be used to infer the kernel address space layout, thus preventing information leakage. *Thirdly*, HIVE captures exceptions and monitors the BPF program's execution time, rolls back the execution state, and uninstalls the BPF program once an exception or timeout is detected, thus preventing DoS.

However, it is difficult for BPF programs to be completely *decoupled* from the kernel, thus such a strict isolation execution environment is not practical. The *first challenge* is that there is a large amount of data in BPF objects that are inaccessible to BPF programs, such as metadata in maps. Simply mapping all memory into BPF space will face the problem of sub-page attacks; the *second challenge* is that legal access to kernel objects by de-referencing kernel pointers is also prohibited due to all instructions being emitted as LSU instructions; the *third challenge* is that it is difficult to prevent kernel pointers from being leaked without the ability to accurately identify them. We analyze all eBPF pointers, classify them into two categories, and process them separately in HIVE.

The *inclusive type pointers* can be de-referenced by the same memory access instruction, they point to BPF data objects and share the same logic of security checks that the pointer can only access the raw data inside its corresponding object, and it cannot be leaked. To ensure their security, HIVE compartmentalizes all BPF memory (e.g., stack and maps) and isolates all BPF-accessible memory regions to the BPF space. The pointers can be leaked safely due to the design of independent/decoupled address space.

The *exclusive type pointers* point to kernel objects, and a memory access instruction can only be used to de-reference a pointer of the same kernel object type. However, the de-referenced points are unknown without the full-path analysis. To address this, HIVE proposes the *exception-based point-of-use probing* method to dynamically identify the de-referenced points, perform security checks, and patch the code to use the regular load/store instruction to access the kernel object. To enforce memory access controls, HIVE utilizes the pointer authentication (PA) feature to ensure pointer integrity and type safety. Furthermore, HIVE also proposes *a descriptor-based method* to hide the real pointers.

We implemented and evaluated HIVE on Apple mini with M1 chips. The core of HIVE is a kernel module that manages the BPF space and monitors the exception. It also modifies the eBPF subsystem, such as removing the full-path analysis. We use two web servers (i.e., Nginx and Apache) and two databases (i.e., Memcached and Redis) to evaluate the performance of HIVE when running 161 BPF programs from BCC [35] and Tracee [4]. The experimental results show that HIVE is efficient compared with the vanilla eBPF. To evaluate the complexity promotion effectiveness, we successfully replaced 10 in-tree kernel modules with HIVE-equipped eBPF and applied HIVE to accelerate system calls.

To summarize, the contributions are as follows:

- **A comprehensive study on eBPF's verifier.** We conduct a comprehensive study on the verifier for the first time, resulting in a summary of its security properties and a discussion of its issues in complexity and security.
- **A novel isolated execution environment for BPF programs.** We propose a new isolated execution environment on AArch64, HIVE, to isolate the BPF programs by combining a set of hardware features, which could provide the same level of security guarantees as static verification.
- **New insights from implementation and evaluation**. We implement and evaluate a prototype of HIVE. The results show that the dynamic isolation for BPF programs can be practical, and it could replace the verification.

2 Background

2.1 Extended Berkeley Packet Filter (eBPF)

At load time, the eBPF verifier performs static analysis to ensure the kernel's security. Once the verification is passed, the program will be compiled into the native code and mounted to the specified kernel location. eBPF provides a RISC instruction set and an execution environment inside the kernel which offers the following supports.

- **Registers**. There are 11 registers (`r0-r10`) and will be mapped into physical registers after JIT compilation.
- **Maps.** Users can statically apply for custom-sized data areas through *maps*, which are key-value stores. Maps can be accessed by both user processes (via syscall) and BPF programs, enabling the data exchange between them.
- **Stack.** The BPF function's frame is stored on the BPF stack, which uses the kernel stack. BPF and kernel stack frames are arranged in the order of function calls.
- **Context.** When the kernel calls the BPF program, it passes a *context* structure, which is a program-type related kernel object, through the function parameter.
- **Helper functions.** Programs are allowed to call *helper functions*, which are dedicated functions offered by the kernel to enable interaction with the system.

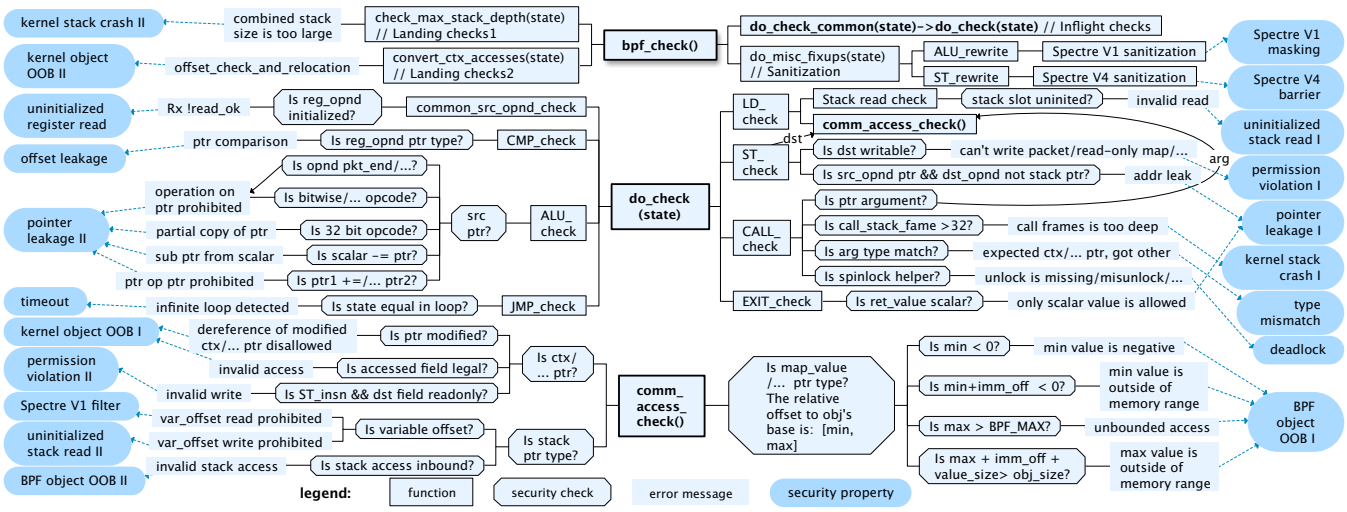

Fig. 1: The security checks and corresponding security properties of the verifier in the full-path analysis.

2.2 Hardware Features on AArch64

Unprivileged load/store. The access right of a memory access instruction is determined by the current exception level (EL) and the target memory's permission. The code runs at EL0 (i.e., the user mode) can access the unprivileged pages (abbreviated to *U-page*) in user space but cannot access the privileged page (abbreviated to *P-page*) in kernel space, and we call that *EL-based memory isolation*. But the *load/store unprivileged (LSU) instructions*, i.e., `ldtr` and `sttr`, is an exception. No matter which EL they are executed at, they are treated as if at EL0, and thus cannot access P-pages.

E0PD. E0PD [6] is introduced in ARMv8.5-A as hardware mitigation to prevent the fault timing attacks launched by malicious users against the kernel. It prevents the unprivileged memory accesses to the (lower or upper or both) halves of the address space and generates the translation fault in constant time when accessing. There are two bits `E0PD0` and `E0PD1` of the `TCR_EL1` register which controls whether unprivileged memory accesses to the lower-half (user) or the upper-half (kernel) of the address space is disabled, respectively.

Pointer Authentication. Pointer Authentication (PA) [6] is a hardware feature in ARMv8.3-A that employs the cryptographic authentication code to protect the pointer's integrity. It attaches a PA Code (PAC) to a pointer in the unused bits of a 64-bit address. PA introduces `pac*` and `aut*` instruction families to *sign* and *authenticate* a pointer with a 64-bit *modifier* using the *key* indicated by the instruction name. [2]. The `pac*` instructions calculate the PAC and attach it to the pointer. The `aut*` instructions authenticate a pointer and clear the PAC in the pointer, making the pointer usable. If the authentication fails, the pointer will be modified to an invalid pointer.

[2]For example, the `pacda` specifies signing data pointers using the `A` key.

3 Understanding the eBPF Verifier

3.1 The Workflow of the Verifier

The workflow of the verifier consists of three consecutive stages, with the later stages becoming more complex. The *pre-process* stage scans the BPF program linearly to find relocation items and check if there are any unallowed opcodes, e.g., indirect calls; The *CFG check* stage searches the control flow graph and forbids any out-of-bounds jumps or unreachable codes; The last stage creates a state machine that records the type and range of all registers and stack slots during the path exploration. Meanwhile, it verifies that all states conform to a set of security properties that do not threaten the kernel. Since it traverses all possible paths, we call it *full-path analysis* in this paper. The full-path analysis performs most of the analysis and integrates the majority of security checks, focusing on it allows for a comprehensive understanding of the verifier's capabilities and limitations.

3.2 The Internals of Full-path Analysis

3.2.1 The Methodology of Study

Due to the lack of comprehensive documentation explicitly about the verifier, we had to understand its design manually. To this end, we dedicated 80 person-days to meticulously review and understand the verifier's source code. We undertook a top-down analysis from the verifier's entry to all exits. We collected all checks and scrutinized the triggering conditions, the check's content, its dependencies, and restrictions.

All checks share a distinguishing feature, which is a conditional judgment statement with an error message output (e.g., `verbose()`). Among these checks, some of them are not related to the full-path analysis. For example, the division-

Table 1: Summarized security goals and their corresponding security properties in full-path analysis.

Security Goal	Description	Against Attacks	Corresponding Security Properties in Fig. 1
SG-1: Memory Safety	① Programs can only access BPF memory, and specific kernel objects such as context.	OOB Access	BPF object OOB I/II, kernel object OOB I/II, permission violation I/II, *type mismatch*
SG-2: Information Leakage Prevention	① Programs cannot write pointers into maps, and calculation among pointers is not allowed.	Layout Leakage	pointer leakage I/II, offset leakage, *type mismatch*
	② Programs cannot read uninitialized information.	Uninitialized Rd	uninitialized register read, uninitialized stack read I/II
	③ Programs cannot speculatively access areas outside the BPF program's memory.	Spectre	Spectre V1 filter/masking, Spectre V4 barrier
SG-3: DoS Prevention	① Programs cannot crash while executing.	Crash Kernel	kernel stack crash I, kernel stack crash II
	② Programs cannot execute for too long.	Denial-of-Service	timeout, deadlock

by-zero check checks if the `imm` operand in the instruction is 0. Filtering such checks is simple by inspecting whether the condition contains the `env` or not. This is due to the program state used in the state machine being recorded in the verifier's environment structure (`struct bpf_verifier_env *env`).

Among all the checks, some are complexity or functionality checks, such as the combined branch state cannot exceed `8,192` to prevent state explosion. We filter these checks by understanding their semantics, supplemented by the error message. For example, these checks usually contained phrases like "`too many`" or "`too complex`". Conversely, the security checks typically contained words like "`prohibited`" or "`invalid`". By understanding the filtered security checks and their semantics, we obtain all the security properties that the verifier wants to ensure in the full-path analysis.

3.2.2 The Security Properties in Full-path Analysis

Fig. 1 gives a panoramic view of how the verifier performs the security checks in the full-path analysis. `bpf_check()` is the entry point of the verifier, and the `do_check()` it calls contains most of the security checks in the full path analysis. Since they are performed during the path traversal along with the state tracking, we call them *inflight checks*. Whenever an instruction is encountered, it will perform security checks based on the semantics of the instruction and all operands' states (i.e., the type and the value range). After the path traversal, the `check_max_stack_depth()` and `convert_ctx_accesses()` are called in sequence to perform some global security checks, which we call the *landing checks*. For instance, it checks the combined BPF stack frames' size does not exceed the upper limit to prevent kernel stack crashes. Finally, `do_misc_fixups()` is called to instrument some sanitization code to prevent Spectre attacks.

The verifier contains hundreds of security checks, we have merged and simplified similar security checks in Fig. 1 for ease of introduction. The left and right sides give the summarized 20 security properties of these security checks. For example, underflow and overflow are both disallowed when accessing BPF objects, which corresponds to *BPF object OOB I*. As for kernel object access instructions, the immediate offset is checked based on a whitelist to ensure the BPF program only accesses legal fields, which ensures *kernel object OOB I*.

While some security checks have explicit security properties that can be summarized based on judgment conditions and error messages, some properties need to be inferred. Take *uninitialized stack read II* as an example, BPF programs are not allowed to write to the stack using variable offsets due to the state maintenance of stack slots. When a variable offset is involved and a stack slot is uninitialized, the verifier cannot determine if this write would initialize this slot, potentially leading to an uninitialized stack read. The detailed descriptions of all security properties are listed in Appendix A.

The summarized security goals. Security properties are the security that the verifier must ensure at the implementation level. Based on them, we also summarize the security goals at the design level, as shown in Table 1. All security goals were emailed to the eBPF developers and got confirmation. For **SG-1**, BPF programs can only access their own memory. The permission violation and type mismatch between pointers could lead to illegal memory access, thus they are also memory safety related; For **SG-2**, the information leakage should be prevented, including kernel layout, uninitialized information, and kernel memory accessed speculatively. Besides, the type mismatch between scalars and pointers could also leak kernel layout; For **SG-3**, DoS attacks should be prevented due to the preempt being disabled when the BPF program is running, and the exception handling is not supported in eBPF.

3.3 The Dilemma of Full-path Analysis

Although eBPF developers have been dedicated to improving the verifier, it still faces the following dilemmas.

The capability dilemma. To avoid the *state explosion* and ensure the analysis can finish in a constant time, several restrictions are imposed on the program, including limiting the number of loops and branches. Kernel developers have recognized this challenge and tried to address it over the years. For example, eBPF supports the intra-procedure analysis instead of the whole program in 2017. However, it can lead to state overestimation and even exacerbate complexity problems.

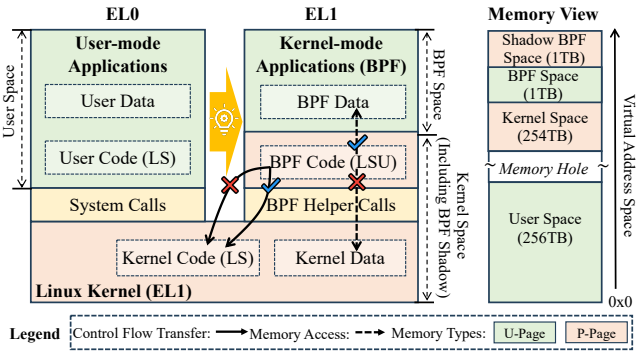

Fig. 2: The high-level design of HIVE.

Constant loops were supported in 2019 after extensive design and attempts. Helper functions such as `bpf_loop()` were introduced in 2021 to handle a special kind of loops. However, while these functions seemingly address the loop problem, they impose limitations on passing state between loop iterations, along with the loop body and condition, deviating from commonly used loop patterns (detailed in Appendix B). Up to now, complex BPF programs still cannot pass the verification.

The correctness dilemma. The code size and complexity of the full-path analysis have significantly increased over the years, making formal verification challenging and leading to design and implementation bugs. The full-path analysis has been responsible for over 90% of CVEs in the eBPF verifier in the past decade. Despite its potential, unprivileged eBPF programs have been dismissed as unsafe by the Linux community. As the core of the verifier, the intricate implementation of the full-path analysis contributes to these security issues.

4 Overview

4.1 Threat Model

The goal of HIVE is to provide an isolated execution environment for BPF programs to replace the full-path analysis in the verifier. We assume the pruned verifier and other components of the eBPF subsystem are secure and trustworthy. The goal of the adversary is to compromise the security goals listed in Table 1 through adversary-controlled BPF programs. BPF programs may execute arbitrary legal instructions, access arbitrary memory, and call arbitrary helpers. Note that the pruned verifier still guarantees the control flow safety.

4.2 High-level Design

Our key insight is that BPF programs can be executed as kernel-mode applications. An analogy can be drawn from the isolation of user applications: User applications running at EL0 cannot access kernel memory because the kernel memory pages are set up as privileged pages; each user application runs in its own independent and continuous address space; crash isolation can be achieved via monitoring exceptions. If an isolated execution environment can be created for BPF programs, some of the heavy-lifting tasks performed by static verification can be replaced by hardware-assisted dynamic isolation. This is the key idea behind HIVE.

As shown in Fig. 2, HIVE creates such an isolated execution environment as follows: *Firstly*, HIVE creates an independent address space for each BPF program, dubbed *BPF space*. BPF space holds all BPF data and is set as U-Pages. Note that the BPF code is kept in the kernel space, which is set to be P-Pages, as is done in a vanilla OS. In this way, users cannot infer the kernel layout from the BPF space. *Secondly*, HIVE emits all BPF memory access instructions as LSU instructions, which can access the BPF data on the U-Pages, but cannot access the kernel memory on the P-Pages. Because of Privileged Access Never (PAN) [6], helper functions are forbidden from accessing the BPF data. Therefore, HIVE creates a separate space that maps the BPF data as P-Pages for them, hence creating a *shadow BPF space*. Both shadow BPF spaces and BPF spaces are 1TB in size and are placed at the highest address. *Thirdly*, HIVE captures all exceptions and times the execution of BPF programs. Once an exception or a timeout is caught, HIVE will roll back the state to the entry of the target BPF program and unload it.

4.3 Challenges

Since BPF programs are highly coupled to the kernel, isolating them from the kernel still faces the following challenges:

C-1: BPF data requires object-granular isolation. The full-path analysis tracks the type of each pointer and the range of the pointed object, ensuring that it can only access the *accessible region* inside the BPF data object. This is because BPF data objects are non-contiguous and interleaved with other inaccessible objects. For example, eBPF embeds object management structures (including function pointers, lock pointers, etc) into these objects, which also need protection. However, the EL-based memory isolation used in HIVE cannot provide such finer-grained (or sub-page) protection.

C-2: Kernel objects need to be accessed securely. eBPF allows BPF programs to directly access specific fields of kernel objects. However, such fine-grained kernel object access control is difficult for two reasons: 1) The LSU instructions cannot access the kernel space; 2) HIVE cannot distinguish which instruction accesses the kernel object. Simply setting the page where the kernel object is located to be U-Page will be vulnerable to sub-page attacks; Copying all accessible fields of kernel objects into the BPF space each time the BPF program is executed will bring high performance overhead.

C-3: The pointers of kernel objects cannot be leaked. Since maps can be accessed by users through system calls, the full-path analysis prevents all pointers from being written to maps,

Table 2: Differences between different eBPF pointer types.

Types	Point to	*Modifiable*	*Instr. De-reference* Access Form	Pinned	*OOB Check Method*
Inclusive[1]	BPF obj	✔	arbitrary form	✘	bound-check
Exclusive[2]	Kernel obj	✘	constant offset[3]	✔	whitelist

[1] Including 10 types: *ptr_to_stack*, *ptr_to_buf*, *ptr_to_mem*, *ptr_to_tp_buffer*, *ptr_to_map_key*, *ptr_to_map_value*, *ptr_to_packet*, *ptr_to_packet_meta*, *ptr_to_packet_end*, and *ptr_to_flow_keys*.
[2] Including 8 types: *ptr_to_tcp_sock*, *ptr_to_socket*, *ptr_to_sock_common*, *ptr_to_xdp_sock*, *ptr_to_ctx*, *ptr_to_btf_id*, *ptr_to_map*, and *ptr_to_func*.
[3] Except for *ptr_to_map* and *ptr_to_func*, other types of pointers are allowed to be de-referenced directly via memory access instructions.

preventing the leakage of pointers. HIVE places BPF's data into a fixed BPF space to eliminate security problems caused by the leakage of BPF object pointers. But, the pointers that point to allowed kernel objects must be prevented from being leaked. Without pointer/type tracking, HIVE cannot recognize these pointers and prevent them from being leaked.

5 Detailed Design

The above challenges are due to the lack of pointer/type tracking capabilities in HIVE. In this section, we analyzed the pointer type features of eBPF in §5.1, and introduce how HIVE integrates its design in §5.2, §5.3, and §5.4. Importantly, the design of HIVE is compatible with the eBPF standard, allowing seamless execution of any BPF program.

5.1 eBPF Pointer Types

There are 18 types of pointers in eBPF and we classified them into two types based on their usage and constraints: the *inclusive type* and the *exclusive type*. The *inclusive type* pointer points to the BPF data object, and the latter points to the kernel object. Pointers of the same type share the same functional constraints but differ between different types.

In eBPF, the *exclusive type* is performed with more strict constraints. This is due to the support of direct memory access to specific fields of kernel objects [1]. eBPF introduces a virtual data structure for each BPF-accessible kernel object during programming. Each virtual structure solely encompasses BPF-accessible fields of its corresponding kernel object. At load time, eBPF will relocate all accesses to the fields of virtual structures to the actual fields of kernel objects. However, the precise relocation requires three constraints (shown in Table 2): 1) *their value cannot be modified*, allowing for accurate pointers tracking; 2) *they can be only de-referenced through the memory access instruction in the form of pointer plus offset*, allowing for the relocation by rewriting the immediate operand of the instruction; 3) *memory access instructions that access a kernel object are not allowed to be used to access BPF objects or even other types of kernel objects*, allowing for enforcing the memory access control.

Except for the *OOB*-related security properties, all properties are the same for these two pointer types. The difference in OOB security properties is just in how they are ensured: *the OOB check for the inclusive type is a range check, but for the exclusive type, it is a whitelist based on the kernel object.*

5.2 Handling Inclusive Pointer Types

In eBPF, all the inclusive type pointers have the same security checks, thus they have a unified parent type `mem_type`. However, security checks are only performed by using the more exact inclusive types due to only raw data in BPF objects can be accessed and stored in fragments. This fragmented accessible memory poses challenges to the EL-based memory isolation. A feasible approach is to organize accessible segments into a contiguous BPF memory space.

5.2.1 BPF Memory Compartmentalization

In this section, we introduce how HIVE compartmentalizes all BPF objects into the BPF space.

Stack separation. BPF programs use a stack, which is on top of the kernel stack. The stack frames of BPF functions are only accessed through the BPF stack frame pointer register, which is mapped to a physical general-purpose register (the `%x25` on AArch64), and its derived pointers. The JIT compiler will also instrument code to store/restore (using the `%sp` register) return addresses and callee-saved registers during the BPF function call/return. In HIVE, the BPF stack frames are separated from the kernel stack by isolating them to a new stack. At load time, HIVE allocates a dedicated memory region as the BPF stack (for each CPU core) in the BPF space, and adjusts the `%x25` to point to it. As such, helper functions can be called freely without stack switching and still use the kernel stack. To prevent attackers from causing the kernel stack to overflow through continuous function calls, HIVE also places an unmapped guard page at the lowest position of each kernel stack. HIVE also instruments instructions to manage BPF stack frames (detailed in §C.1).

Maps separation. Maps are composed of metadata and values that are stored next to each other. The metadata usually contains the type, data pointers, and function pointers, which must be separated from values. To do this, HIVE slightly adjusts the structure of the map, separates all the values from the maps, maps them into the BPF space with the allowed permission (e.g., the read-only), and leaves a pointer pointing to them (detailed in §C.2). This change is transparent to the BPF program because it only uses the address of the value, and the parsing on the maps is done by helper functions.

Packets separation. Packets, which are buffers pointed to by the `data` field in the context, are allocated when network packets arrive. Simply mapping them into the BPF space could bring high-performance overhead due to the packet

freeing will cause the mapping canceling, which incurs the high-cost TLB shootdown. To this end, HIVE allocates the packet from a dedicated memory pool, which is implemented as a `kmem_cache` in the slab. It will be double-mapped into the BPF space with allowed access permissions based on the BPF program's type, such as read-only and writable. This eliminates the need for high-cost page table manipulation.

Since a BPF program processes all packets sequentially (either individually or in groups), it is secure allowing access to all packets at the same time. Furthermore, for parallel packet processing, HIVE prevents potential concurrent attacks by isolating different queues. Specifically, BPF programs can utilize multi-queue network interfaces for parallel execution, these interfaces have multiple independent receive/send queues, and each queue will be handled in parallel on a different CPU core. HIVE associates each queue with specific `kmem_cache` and maps them into different BPF spaces of a BPF program respectively. When the BPF program processes the packets in a queue, HIVE will set the corresponding BPF space for the BPF program, so that the BPF program can only see all the packets in one queue at the same time.

5.2.2 BPF Memory Isolation (SG-1)

Isolation of direct memory accesses. HIVE separates all accessible BPF objects and maps them in the BPF space. Therefore, containing type pointers no longer requires object-level range checking, they only need to check whether the access target is in BPF space through the EL-based memory isolation mechanism. However, this method leads to a new problem: user programs and BPF programs can access each other's memory. To address this problem, HIVE leverages `E0PD` to enable/disable unprivileged access to user space and BPF space. Specifically, when the kernel calls a BPF program, HIVE will clear `E0PD1` to enable the access to the BPF space, and set `E0PD0` to disable the access to user space; when the kernel returns to the user program, HIVE checks if any BPF program has executed, if it has, HIVE reverse the `E0PD` settings. This design can avoid unnecessary `E0PD` settings.

Sanitization of helper's parameters. The inclusive type pointers can be passed to helpers through parameters. The full-path analysis performs the range/type checking for the parameters that HIVE should do the same. Besides, as mentioned in §4.2, the inclusive type pointers also need to be converted to point to the shadow BPF space when passed to helpers. Benefiting from the design of BPF space memory layout/alignment, the range/type checking, and the pointer conversion can be performed through one logical operation instruction. HIVE instruments an `orr xn, 0xffffff0000000000` instruction for each function parameter of the inclusive type pointer before calling helpers. In this way, the kernel can access the BPF space in a disguised way while the pointer is also checked. Note that an attacker may set a pointer point to the boundary of the BPF space to induce helpers to access memory outside the BPF shadow space. But it is safe that the helper will overflow access to BPF space and trigger permission fault.

5.2.3 Information Leakage Prevention (SG-2)

Independent address space (SG-2.1). HIVE creates an independent address space for each BPF program and ensures separated BPF objects are randomly mapped into it. All the inclusive type pointers are relocated to point to this space. Thus, attackers cannot infer any kernel layout information from the inclusive type pointers that can be safely leaked.

Use after initialization (SG-2.2). HIVE initializes all memory allocated in the BPF space at load time. Each time the BPF program is executed, the BPF stack of the current core will be reused without re-initialization. If an uninitialized read of the BPF stack occurs, it will still access the content of the last execution and will not cause memory leaks in the kernel.

Convert Spectre to Meltdown (SG-2.3). The key to Spectre v1 and v4 attacks [21] is to transiently access the sensitive data and use its value to encode and access a legal memory address that could cause the change of the cache state. As mentioned in §4.2, BPF programs use LSU instructions in HIVE, thus accessing the kernel space (speculatively) will cause the permission fault. A hardware patch named CSV3 [5] is added to mitigate the Meltdown attack [27], which *forbids the data loaded under speculation with a permission fault to be used to form an address to be used by other instructions in the speculative sequence*. Therefore, thanks to the transformation of LSU instructions and the CSV3 patch, Spectre attacks can be blocked from the hardware level without any software effort.

5.3 Handling Exclusive Pointer Types

Since the exclusive type pointers cannot be modified and their de-referenced points are exclusive, we propose to *utilize the `PA` to ensure the pointers' integrity, and the regular `LS` (load/store) instruction to provide the ability to access kernel objects*. However, the `PA+LS` method still faces three challenges: 1) how to design a secure modifier to prevent pointer substitution attacks; 2) how to ensure the *authentication* operations are done at all points of use; 3) how to address the problem of information leakage. In the following subsections, we will introduce how HIVE addresses the above challenges.

5.3.1 The Design of Modifier and the Sign

PA suffers from pointer substitution attacks — pointers signed with the same modifier can be replaced with each other and pass the authentication [24, 25]. To avoid pointers being replaced by other type pointers, pointers from other BPFs, or pointers from historical executions, we must ensure that the modifier is *different for each exclusive type and historically*

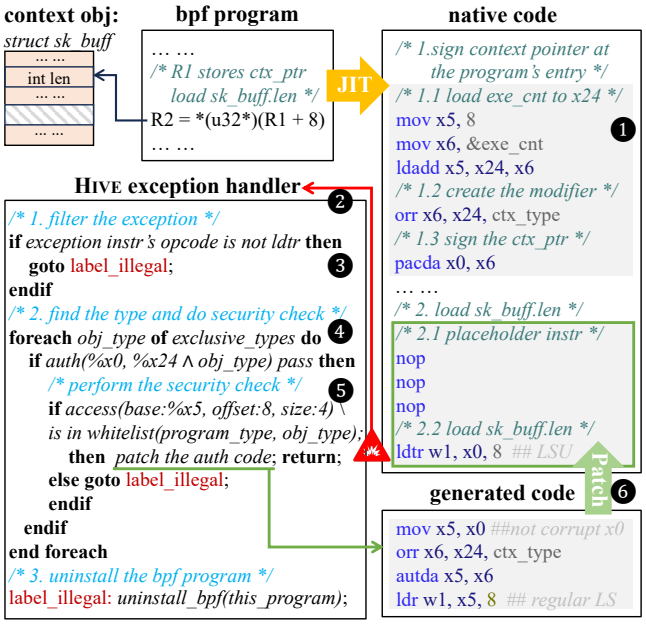

Fig. 3: An example of the exclusive pointer type solution.

unique to each BPF program. Pointers of the same type generated during BPF program execution are safe to replace each other because the security checks are only type-related.

In HIVE, the modifier is designed to be the following form: `EXE_CNT ∨ PTR_TYPE`, where `EXE_CNT` is a 64-bit execution counter for all BPF programs. The counter only uses the upper 61 bits, which starts from 0 and increases by 8 each time, ensuring that the lowest 3 bits are 0. `PTR_TYPE` is a 3-bit constant value that represents the exact type (8 types in all). Since `EXE_CNT` is determined each time the BPF program is executed, HIVE uses the unused `%x24` register in eBPF to store its value at the program's entry. When signing or authenticating an exclusive type pointer, the OR result of the `%x24` and the type is calculated as the modifier (❶ in Fig. 3). Two unused registers `%x5` and `%x6` in eBPF are used as the temporal registers for HIVE to conduct such calculation.

For most cases, the `pacda` instruction is instrumented after the pointer generation point, such as relocation at load time, helper returns, and program's arguments. For the dynamically loaded pointers from kernel objects, HIVE instruments the `pacda` instruction right after the load operation at runtime because it can only be identified at runtime (detailed in §5.3.2).

5.3.2 The Authentication and Security Checks (SG-1)

The exclusive type pointers can be de-referenced directly and passed into helper functions. For each helper call, HIVE instruments an `autda` instruction to authenticate the parameter which is the exclusive type pointer. If authentication passes, it means the pointer has not been modified and matches the parameter type. However, it is difficult for direct memory

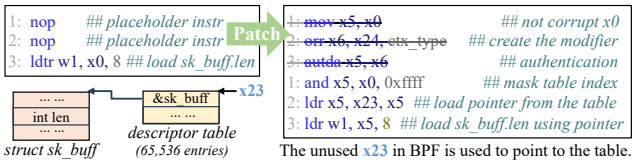

Fig. 4: The code de-referencing the exclusive type pointers.

accesses because HIVE does not know where to instrument.

Exception-based point-of-use probing. To address this, we observed that de-referencing a signed exclusive type pointer via the LSU instruction will trigger the hardware exceptions in HIVE (will be discussed later), so we can know the use points of the exclusive type pointers lazily by catching and filtering such exceptions (❷❸ in Fig. 3). It is feasible that once an instruction accesses one type of kernel object, it can no longer access other types of objects. Note that since the PAC is stored in the highest 16 bits of a pointer, and the highest 16 bits of the effective addresses in the kernel and BPF spaces are both 1, the sign operation will not change the pointer, that points to the kernel object originally, to point to the BPF space. The signed pointer may point to the user/kernel space or the memory holes, accessing them by using the LSU instructions will trigger the permission fault or the translation fault.

The authentication code generation. A BPF program usually has different exclusive types of pointers, and HIVE needs to know which type of de-referenced pointer triggers the exception. To this end, HIVE tries to use all types to authenticate the pointer when handling the exception (❹). Only when the types match can it pass the authentication. If no type is matched, it means that the pointer may be corrupted and HIVE will uninstall the BPF program. If a type is matched, HIVE will check the whitelist based on the range of access (from the instruction operand), the program type, and the exclusive type (❺). If the check passes, HIVE will generate a regular LS instruction along with the authentication code and patch the original code (❻). Note that the patched code cannot corrupt the signed pointer due to it may be used to probe subsequent use points. To achieve in-place patching, HIVE inserts `nop` instructions during the code jitting before memory access instructions with the constant offset that is in the whitelist.

5.3.3 The Design of Type Descriptor Table (SG-2)

All kernel objects accessed in BPF programs are initialized by the kernel (that ensures **SG-2.2**). But, the `PA+LS` method cannot ensure the confidentiality of pointers (**SG-2.1**), and the PA feature is vulnerable to Spectre attacks [33] (**SG-2.3**). Therefore, we need another method that is compatible with the `PA+LS` method to solve these problems. Inspired by the *file descriptor* mechanism, we propose a *type descriptor based* method to hide the real pointers and enforce their usage.

Specifically, HIVE transforms the pointer to a descriptor

which indexes a descriptor table that stores the actual pointers in it. HIVE sets up a table with `65,536` (2^{16}) entries for each exclusive type. The base address of each table will be stored in an unused register in eBPF. Pointers to different objects of the same type are stored in different entries, and unused entries are filled with invalid addresses. Fig. 4 shows the patched code based on the descriptor table, which is used to replace the patched code based on authentication (❻ in Fig. 3). It performs a mask operation on the descriptor to ensure that the access to the descriptor table will not go out of bounds (line 1), then uses the descriptor to index the table of the corresponding type to obtain the actual pointer (line 2), and finally uses the regular `LS` instruction to access the kernel object (line 3). For helper calls, HIVE inserts the same instructions at lines 1-2 to recover the pointer for each exclusive type pointer parameter and store the original value in the kernel stack; when the helper returns, HIVE restores the original value of the parameter to prevent the pointer leakage. The design of the descriptor table ensures pointers' confidentiality (**SG-2.1**) and the mask operation prevents Spectre attacks (**SG-2.3**).

The authentication-based point-of-use probing method remains the same, we only replace the authentication-based patched code with the table look-up code. The newly patched code could also provide the same security guarantees on **SG-1** — *it forces the use of the table corresponding to the target type to ensure type matching and the addresses of target objects obtained from the table are either legal or invalid.*

5.4 Secure and Passive DoS Prevention (SG-3)

BPF program may bring two types of DoS: trigger an exception, and execute without terminating. For the former case, HIVE passively captures all triggered exceptions, rolls back the state to the entry point of the program, and unloads it; For the latter case, HIVE checks the BPF execution time each time there is an interrupt coming and rolls back the state when the executed instructions reach a certain threshold.

Exceptions capturing. The BPF program changes the memory state in three folds: BPF data in the BPF space, BPF management structures in the kernel, and some kernel objects. Changes to the first two types of data do not affect the state of the kernel. The fields modified by the third type of kernel object are just raw data for the kernel and do not affect the execution of the kernel. Therefore, they can be cleared by uninstalling the BPF program simply. HIVE only needs to store all BPF-accessible registers at the entry of the BPF program and restore them during the roll-back.

Execution timing. HIVE maintains a timetable for each executing BPF program to track their execution time. When an interrupt occurs, HIVE checks the duration of the currently executing BPF program and either uninstalls it if it exceeds the configured time limit or updates the timetable if it is within the limit. The advantage of this method is that it accurately accounts for the execution time of the BPF program, including the helper functions, which could avoid DoS problems caused by underestimating execution time in the verification [18].

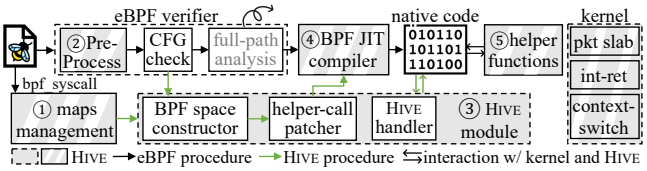

Fig. 5: The workflow of HIVE.

6 System Implementation

The prototype of HIVE (shown in Fig. 5) is implemented on Linux-v6.6.1/AArch64. The core of HIVE is a kernel module (③) to manage the BPF space, handle helper calls, and manage exceptions. HIVE modifies the eBPF subsystem and the core kernel. For the eBPF subsystem, HIVE modifies the map management (①) to achieve maps separation, the verifier (②) to skip the full-path analysis, the JIT compiler (④) to perform the code instrumentation and transformation, and rewrites 11 helper functions (⑤); for the core kernel, HIVE only modifies 43 LoC, including creating the packet slab, configuring the `EOPD`, and timing the execution of BPF programs.

Patch detail. During page fault handling, the patching handler is invoked with the fault type and address. To avoid concurrent execution, the handler's execution is protected by a *mutex* lock. Upon acquiring the lock, it verifies the LSU form of the patch point. If passed, an IPI is sent to halt other cores' execution, forcing them to execute a waiting function, which disables interrupts and repeatedly checks a patching flag. Subsequently, the handler performs the code patching by changing the code page to writable, carrying out the instruction rewriting, flushing the instruction cache, and changing the permission back. Finally, the handler sets the patching flag to resume execution on other cores and returns to re-execute at the fault location.

Prevent reading of uninitialized registers. For the 11 registers used for eBPF, the full-path analysis forbids the BPF program to read them before they are initialized. To this end, HIVE clears all possible uninitialized registers when the BPF program interacts with the kernel. Specifically, HIVE zeros all context-irrelevant registers at the program entry, and clears all caller-saved registers during the helper function returns.

Register uses of HIVE. On AArch64, 12 registers are unused in eBPF (`%x5-6`, `%x8`, `%x13-18`, `%x23-24`, `%x28`) and can be used in HIVE. HIVE uses 2 registers (`%x5-6`) as temporary registers, 6 registers (`%x13-18`) that store the base of descriptor tables (for a BPF program type, up to 6 exclusive types can be used simultaneously), 2 registers that store the frequently used pointers (`%x23` for the context, `%x24` for the `EXE_CNT`). When calling helper functions, HIVE does not need to store

Table 3: Security equivalence analysis between HIVE and the verifier in the full-path analysis.

Line	Security properties	How HIVE ensures the corresponding security property	Equal
1	BPF object OOB I/II	HIVE compartmentalizes all accessible areas of BPF objects into the BPF space, thus the object-granular OOB is relaxed to space-granular OOB securely. The use of EL-based memory isolation prevents BPF programs from the BPF space OOB.	✔
2	kernel object OOB I/II	Accesses to kernel objects are converted to use the descriptor table, which only contains accessible kernel objects. Besides, whether the accessed fields of accessible objects are legal is verified during the probe process.	✔
3	permission violation I	The compartmentalized maps' values and the packet slabs are mapped with the allowed permission into the BPF space.	✔
4	permission violation II	The first access to a kernel object field will be captured and checked for access permission in the probe process.	✔
5	pointer leakage I/II, offset leakage	The independent BPF space eliminates the kernel layout information in inclusive type pointers that can be safely leaked. For exclusive type pointers, the type descriptors hide the real pointers and only indicate the use order of kernel objects.	✔
6	type mismatch	HIVE matches the pointer type parameters at helpers call. For inclusive pointer types, HIVE uses the `OR` operation to ensure the pointer points to the BPF space to achieve type matching. This is because HIVE compartmentalizes all BPF objects into BPF space, thus these types can be safely cast to their unified parent type `mem_type`, which is equivalent to the BPF space; For exclusive pointer types, HIVE enforces to use of the corresponding type descriptor table during the helper call to ensure type matching; For scalar type, HIVE performs nothing because casting to a scalar from a pointer is safe since pointers have no kernel layout information anymore. Note the parameter type matching when calling between BPF functions is unneeded because it serves the state tracking in the intra-procedure analysis of the verifier and is not required by HIVE.	✔
7	uninitialized reg read	The verifier checks the registers are initialized before use to prevent kernel registers leakage. HIVE provides same guarantee by clearing all BPF-used registers at the program's entry and all non-caller-saved registers during the helper return.	✔
8	uninitialized stk rd I/II	BPF stack is decoupled with kernel stack and is initialized at program loading time.	✔
9	Spectre V1 filtering, Spectre V1 masking, Spectre V4	The LSU instructions cannot be utilized to access the kernel speculatively due to the CSV3 patch. The LS instructions used in HIVE are prevented from speculatively accessing kernel memory outside type descriptor tables and allowable kernel objects by using dedicated registers (to store the table base address) and masking the descriptor (to avoid the table OOB).	✔
10	kernel stack crash I	BPF program may crash the kernel stack by nesting function calls, HIVE maps an unmapped guard page at the lowest position of kernel stack to avoid overflow via continuously pushing registers and return addresses on the kernel stack.	✔
11	kernel stack crash II	BPF program may crash the kernel stack by allocating a huge frame. Since HIVE separates the BPF stack from the kernel stack, the frame size has no impact on the kernel stack—the size of the content HIVE pushes on the kernel stack is fixed.	✔
12	timeout, deadlock	HIVE times the execution of each BPF program, and it uninstalls the program if its execution exceeds the configured time.	✔

`%x23` and `%x24` due to they are callee-saved registers, `%x13-18` will be protected by storing them in the kernel stack.

Inter-BPF isolation. Similar to the user space, the BPF space only holds one BPF program's data. HIVE switches BPF space by switching the kernel page table (setting `TTBR1_EL1`) for different BPF programs. In detail, HIVE allocates an ASID and creates a kernel page table for each BPF program which shares kernel space but has independent (shadow) BPF space. To avoid unnecessary switching, HIVE merges BPF programs with the same type and capability from the same user into one BPF space and only switches page tables when different BPF programs switch executions.

Additional helper functions handling. The verifier maintains a list, which is reused by HIVE, to ensure the BPF program can only call the allowable helper functions based on the program type. Among all 209 helper functions in Linux-v6.6.1, 198 helpers can be handled by the aforementioned methods to ensure argument safety. 11 helpers are discussed separately because the full-path analysis performs additional functional checks, and removing such analysis in HIVE could affect the functionality. Take the `bpf_spin_lock()` as the example, the full-path analysis needs to ensure there is no spinlock acquired in the current program state. HIVE rewrite such helpers by adding additional record-and-check logic in them (detailed in Appendix D).

Security property customization. BPF programs are specified with capabilities, and the verifier only ensures part of the security properties based on the specified capabilities. There are 4 types of capabilities in eBPF, i.e., `CAP_BPF`, `CAP_NET_ADMIN`, `CAP_PERFMON`, and `CAP_SYS_ADMIN`. For example, the verifier ensures all security properties for programs with only `CAP_BPF`, while do not consider the pointer leakage and Spectre for the BPF programs with `CAP_PERFMON` or `CAP_SYS_ADMIN`. Similarly, the security properties guaranteed by HIVE can also be customized. For example, HIVE can use the *authentication-based* method instead of the *descriptor table* method (§5.3.3) on the patched code for that capability combination. Now, HIVE supports all security properties by default, we leave the customization as future work.

7 Security Evaluation

In this section, we not only analyze the security of HIVE but also use real attacks to evaluate its security effectiveness.

7.1 Security Analysis of HIVE

HIVE brings two types of attacks: attacks on the security goals of the full-path analysis, and attacks on HIVE framework.

Security equivalence analysis. In §5, we introduced how HIVE achieves the security goals. Here we analyze how HIVE ensures the security properties of the full-path analysis at the implementation level. Table 3 shows the point-to-point analysis, and the results illustrate that HIVE can achieve equivalent security. In sum, HIVE compartmentalizes and maps BPF objects with allowed permission into the isolated and

Table 4: Real attacks against the security properties.

CVE ID	Root Cause	Target Property	Status[1]
2020-27194	Incorrect bound of OR insn.	dead loop	●
2021-3490	Incorrect 32-bit bound of bitwise.	BPF obj OOB	●
2021-31440	Incorrect bounds of 32-64 convert.	pointer leakage	●
2022-23222	Mischeck of *_OR_NULL Pointer.	kernel obj OOB	●
2020-8835	Incorrect 32-bit Bound.	kernel stack crash	●
2021-4204	Improper input validation.	offset leakage	●
2023-2163	Incorrect branch pruning.	type mismatch	●
2021-34866	Lack map pointer validation.	permission violation	●
2021-33624	Mispredicted branch speculation.	Spectre V1	❍

[1] ●: the attack is mitigated by HIVE, ❍: CVE is confirmed but lacks exploit.

address-independent BPF space to ensure BPF object (pointers) related properties (lines 1/3/5/6/9/10); HIVE proposes the exception-based probing and the type-based descriptor table mechanisms to ensure kernel object (pointers) related properties (lines 2/4/5/6/9); HIVE initializes the BPF memory and clears the BPF-used registers during the helper function calls to ensure uninitialized read related properties (lines 7/8); HIVE captures all exceptions and timing the execution time to ensure the DoS-related properties (lines 11/12).

Particular attacks against HIVE. We then discuss the possible attacks on HIVE architecture as follows:

- *Probe abusing attacks*: The probing mechanism allows kernel object access by transforming the LSU to the LS dynamically. Attackers may abuse it to access arbitrary kernel memory or trigger DoS. However, such an attack cannot be conducted: 1) HIVE verifies the legality of kernel objects at the first access time. The patched code forces access to legal objects and fields; 2) Although the probe triggers an exception, consuming more CPU time, the kernel will not be DoSed because HIVE also times the execution of the program, which will be uninstalled once timeout. Based on our experiments on a large number of BPF programs (§8), the kernel object access is concentrated (the probe count is in single digits), and legitimate BPF programs will not be unloaded due to the probe.
- *Descriptor replacement attack*: In HIVE, the authentication is only performed on the first access of the descriptor, which may allow attackers to corrupt the descriptor at subsequent accesses. However, HIVE ensures that each descriptor access point will only use a fixed and same type of descriptor table and the descriptor will be masked to ensure that it does not overflow the table. Therefore, even if the descriptor is modified, the attacker cannot access the kernel object (field) that is not allowed.
- *Attacks on PA*: Attackers may substitute exclusive type pointers that are signed with the same modifier [24, 25]. Due to the historical unique modifier design in HIVE, such an attack can only be conducted by massively executing BPF programs to overflow the 61-bit EXE_CNT. However, even the simplest BPF program with only prolog/epilog costs 129 cycles at least, 2^{61} executions would cost almost 3,000 years ($129 * 2^{61}/3.2Ghz/3600/24/365 = 2,947.56$), making this attack infeasible.
- *Hardware configuration tampering*: Attackers may directly disable LSU or E0PD through hardware configurations. For example, one may disable LSU by enabling the UAO bit in the PSTATE register or disable E0PD by setting the TCR_EL1 register. However, both registers can only be modified via privileged instructions, which cannot be generated by the eBPF JIT compiler. Since the jitted code is protected by the DEP mechanism, the BPF program cannot inject such instructions via code self-modification.

```
1: /* precondition, R: R1 = 1, V: R1 lower
2:    32-bit = 1,  upper 32-bit unknown */
3: R2 &= R1 // trigger bug, R: R1=1, V: R1=0
4: R2 = <OOB off> // R: R2 = off, V: R2 = off
5: R2 *= R1 // R: R2 = off, V: R2 = 0
6: ptr += R2
7: *ptr = 0xbad // OOB access
```

1: /* precondition, R1 stores ctx_ptr */
2: // R0: ctx_ptr, ctx_id in Hive
3: R0 = R1
4: if (R1->len > 4)
5:    // R0: sock_ptr, sock_id in Hive
6:    R0 = bpf_sk_fullsock(...)
7: R2 = *(u32*)(R0 + 0x4) // id replace
```

(b) Descriptor id replacement attack

Fig. 6: Code snippet of the different attacks. For (a), **R** denotes runtime value. **V** denotes verifier-deduced values.

7.2 Real Attacks against HIVE

To evaluate the security of HIVE, we investigated 9 CVEs (shown in Table 4) in the verifier and conducted attacks against specific security properties. To better explain how HIVE mitigates these CVEs, we elaborate on the exploit paths for CVE-2021-3490, which is a vulnerability due to the incorrect 32-bit boundary deduction for bitwise operations. As shown in Fig. 6 (a), it first constructs a register with the lower 32-bit value is 1 and the upper bit 32-bit value unknown, while the runtime value is 1. Then it uses an AND operation to trigger the bug, making the verifier mistakenly think R1 is 0 while the runtime value is 1 (line 3). After the multiple and plus operation, the ptr is OOB, while the verifier still thinks it points to the beginning. The confused value allows it to bypass the verification for an illegal store (line 7). After HIVE transformed the memory access instruction into LSU, the store triggered a permission fault. Then, HIVE caught the fault and tried to authenticate the pointer. Since the pointer was forged, it failed authentication, leading to program uninstallation.

As for the Spectre attack of CVE-2021-33624, the verifier's Spectre mitigation can be bypassed because the verifier mispredicts the impossible branch. While its PoC was implemented on an x86_64 machine, we were unable to perform it on the AArch64 architecture. For other attacks, experiments showed that HIVE can successfully mitigate them.

To evaluate attacks against the HIVE framework, we wrote a BPF program to conduct a *descriptor replacement attack* (as mentioned before). Fig. 6 (b) gives the PoC that sets R0 as different exclusive type pointers on different paths, which is illegal. Suppose on the first execution the R0 is *ctx_ptr*,

Slowdown(%)	23.2	20.9	14.5	5.9	12.4	11.2	3.7	3.8

after the probe, the jitted code for line 7 is authenticated and rewritten into context-type-related descriptor code, which loads the context pointer from its corresponding table and performs the load operation. For the subsequent execution, no matter which path it takes, it always performed the context load operation, making the replacement attack ineffective.

8 Evaluation

Experiments setup. This section focuses on performance and complexity evaluation. The experiments are conducted on Linux v6.6.1, which runs on a Mac mini with an 8-core M1 CPU with PA support and 16 GB RAM. The processor is equipped with 4 efficiency cores and 4 performance cores, and all experiments were conducted on performance cores.

8.1 Performance Evaluation

8.1.1 Micro-benchmark

HIVE makes four sets of transformations on a program: **S1**: handling of inclusive pointer types; **S2**: handling of exclusive pointer types; **S3**: handling of helper function parameters; **S4**: preparing the environment at the program's entry. Therefore, we evaluated their latency separately (shown in Table 5).

For **S1**, we measured the latency of LSU instructions and found they are as fast as regular instructions (shown in column *1st Set*), which implies a high isolation efficiency.

For **S2**, we measured the instructions that related to the sign and the authentication operations in PA and found they are relatively efficient (shown in column *2nd Set*). We also evaluated the latency of one point-of-use probing and found that the overhead of probing a single kernel object access point is extremely high. But this is not a problem, because the subsequent experiments show that all probings can be completed in the first few executions of the BPF program.

For **S3**, we measured the instructions that handle helper parameters. We use an empty helper with different parameters (column *3rd Set*) to calculate the latency difference of a call with and w/o HIVE. The `1-in/ex` represents one parameter of inclusive/exclusive pointer type. The latency is relatively small and does not depend much on the number of parameters. The reason is that the handling between parameters has no data dependence, thus processors can process it in parallel.

For **S4**, we measured the latency of switching `E0PD` (setting `TCR_EL1`), switching page table (setting `TTBR1_EL1`), and dedicated registers initialization. As a comparison, we also evaluated the `SVC` instruction for syscall, whose latency is 145.37 cycles. We can see that these three operations are relatively efficient. Since the domain-switching affects the whole system state, we also evaluated its impact on the kernel operations. We loaded an empty BPF program to hook all syscalls and ran the lmbench [30]. The results (in Table 6) show HIVE incurs significant overhead on *null call* and *null I/O*, which only involve very little kernel operation. As a result, syscalls with simpler operations tend to have higher overheads.

8.1.2 Real-world Applications

To evaluate the overhead on real-world applications, we chose to load the BPF program in advance and then ran the applications to trigger the execution of the BPF program.

Workload. We chose two databases (Redis-7.2.4 and Memcached-1.6.21) and two web servers (Nginx-1.24.0 and Apache-2.4.59) as user applications. The experiments were conducted in the *local environment* to eliminate the network latency and evaluated with three configurations: without running BPF programs, running BPF programs with vanilla eBPF, and running BPF programs with HIVE-equipped eBPF. Web servers are evaluated with *ApacheBench* which sent a total of 100K requests with different request file sizes varied from 32KB to 256KB. Databases are evaluated with the *memtier* which sent 100K requests with different key sizes varied from 32B to 256B.

BPF program selection. The BCC project [35] provides a collection of BPF programs for profiling, performance analysis, network analysis, and security. We chose 32 programs and loaded them into the kernel by running their corresponding scripts at the same time. The Tracee [4] application contains 129 BPF programs for syscall tracing, which are loaded together by running the Tracee executable file. These BPF programs cover the majority of contemporary BPF ecosystem usage scenarios and are also used by other related works [28,29].

Performance results. We measured the throughput of the applications to evaluate the performance overhead brought by BPF programs. Table 7 gives the experimental results. The *baseline* column shows the throughput without BPF programs. The *eBPF-Tracee/BCC* and HIVE-*Tracee/BCC* columns show the throughput under vanilla eBPF and HIVE, respectively. The high overheads indicate that BPF programs are triggered

Table 7: The experimental results of real-world applications when running BPF programs with and w/o HIVE.

[1] The application's throughput (thousands of requests per second). [2] The CPU utilization (%). [3] The overhead (%) of vanilla eBPF and HIVE compared to baseline which does not load BPF programs.
[4] The overhead (%) of HIVE compared to the vanilla eBPF, which is calculated using the throughput directly. [5] The average number of times BPF programs are executed per request.

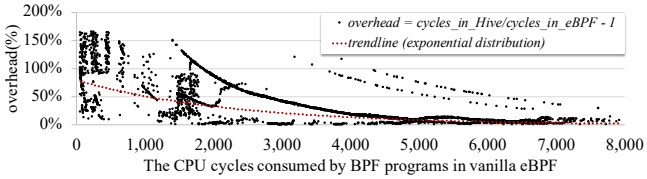

Fig. 7: HIVE's overhead on the CPU time for BPF programs.

extensively. The HIVE/*eBPF-OH* column shows the overhead of HIVE compared with vanilla eBPF. On average, HIVE decreases the throughput by up to 4.18% and 2.00% when running Tracee and BCC compared to vanilla eBPF, respectively. It shows that HIVE is very efficient in practical applications even for such an extreme scenario of eBPF (i.e., running a huge number of BPF programs simultaneously).

To demonstrate that HIVE is fully evaluated, we also count CPU utilization and BPF program execution frequency. The results show that the CPU is saturated and the execution of the BPF program has little impact on the CPU utilization, except for Redis when running BCC. This is because Redis is a single-thread server and each BCC program has its independent process, causing process switching frequently. On average, each request triggered 695.1 to 13115.8 executions of BPF programs, showing that BPF programs were executed on the critical kernel path during the experiment.

Statistic of probing times. Since each probing will trigger an exception that consumes more CPU time, we performed statistics on point-of-use probes. The results show that a single probe consumes about 60k CPU time, and the number of probes of each BPF program is **less than 3 times**, which shows that the access to kernel objects is very concentrated.

Statistic the CPU time consumed by BPF programs. We counted the execution time of the same execution of BPF programs with or w/o HIVE. The determination method for the same execution under different configurations is the same BPF program, program parameters, and helper calling sequence at the same time. As Fig. 7 shows, when the BPF program's execution time is relatively short (e.g., consuming less than 2,000 CPU cycles in vanilla eBPF), HIVE can bring up to 165% overhead. With the BPF program executing longer, the overhead decreased (e.g., less than 5% when vanilla eBPF consumes over 6,000 CPU cycles). This is because most of the overhead comes from the entry and exit code (e.g., domain-switching), while the overhead from instrumentation in the program's body (e.g., register masking) is negligible.

8.2 Complexity Evaluation

As kernel developers claimed, the ultimate goal of eBPF is to "replace *kernel modules* as the de-facto means of extending the kernel". Therefore, we used real-world kernel modules to evaluate the complexity promotion of HIVE. We also used a system call speed-up scenario to show the potential of HIVE.

8.2.1 Supporting Real-world Kernel Modules

We compiled 10 in-tree kernel modules, i.e., `polynomial`, `crc-ccitt`, `libarc4`, `prime_numbers`, `ghash`, `sha3`, `xxhash`, `libchacha`, `libsha256`, and `des`, from crypto utilities and general libraries into BPF programs. And we loaded them with the vanilla or HIVE-equipped eBPF. The vanilla eBPF rejected all of them due to non-constant loops (7), too many branches (1), or the computation of inclusive type pointers (2). Since loops and branches are no longer limited, and the calculation of inclusive type pointers is allowed w/o leaking the kernel layout, HIVE can successfully load and run these BPF programs. We obtained their output by using a user program to read the maps, compared them with that of the kernel modules, and confirmed the correctness.

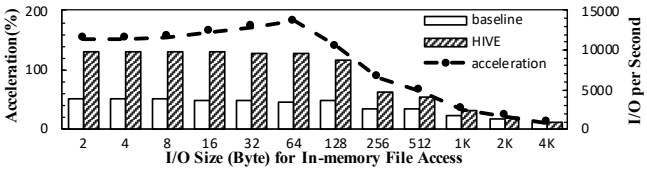

Fig. 8: IOPS (I/O per second) of `pread()` (baseline) and BPF program run in HIVE against different buffer sizes. The percentage number is the acceleration ratio of HIVE.

8.2.2 Eliminating Context Switches in System Calls

User-kernel context switching often causes prominent overhead. Existing literature eliminated such overhead by running the syscall-intensive component in the kernel [22, 39]. The eBPF was not adopted because complex code could not pass the verification. However, this is no longer a problem in HIVE.

We followed the experiment used in UB [39] that accelerates the file I/O requests. The original program iteratively reads a file to a userspace buffer via `pread()` syscall. We compiled the syscall-intensive code into a BPF program and loaded it into the kernel. The syscall invoking was transformed into helper calling. The BPF program and the user program communicated through maps and a dedicated syscall. The vanilla eBPF rejected the BPF program due to the non-constant loop whose iterations number is passed from the user program, while HIVE can run it successfully. We gradually increased the buffer size for each read and evaluated the acceleration ratios. As Fig. 8 shows, HIVE accelerated syscall-based I/O up to 181% when the I/O size is small. For larger I/O sizes, IOPS acceleration drops due to the file accessing time becoming the dominant factor rather than context-switching.

9 Discussion

BPF-infrastructure abusing attacks on HIVE. While our threat model assumes a secure kernel, it is important to consider the implications if the kernel has vulnerabilities. As a representative work that abuses BPF infrastructure, EPF [19] uses the BPF interpreter and JIT compiler for privilege escalation attacks. In eBPF which is equipped with HIVE, EPF can still conduct such attacks by modifying the interpreter and the JIT compiler to inject gadgets. The defenses proposed by EPF and HIVE provide complementary approaches to isolate the kernel and BPF bidirectionally.

The Spectre V2 attack can exploit unprivileged eBPF to inject gadgets into the kernel to access the kernel memory speculatively [8]. HIVE transforms most of the memory access instructions into LSU form which cannot be used to leak the kernel data speculatively, but a very few regular memory access instructions are still used to access the kernel objects which could be abused by attackers: *they could control the table base register (%x23 in Fig. 4) to point to an arbitrary location speculatively*. However, it could be mitigated by transforming the code to use the PC-relative addressing form to enforce accessing the descriptor table.

Since the kernel has arbitrary access to the shadow BPF space, this makes "return-to-bpf" attacks possible: *the kernel can de-reference a corrupted data pointer to access the payload stored in the shadow BPF space*. This attack is similar to the classic return-to-user attack [20]. The difference is that the payload of the latter is stored in user space, so we could reuse the existing PAN-based protection mechanism against return-to-user attacks in Linux. Specifically, HIVE disables the shadow BPF space. Since the BPF space is set to be the U-pages, the kernel code cannot access it due to the PAN mechanism. Legal access of helpers can be through using the LSU instructions or disabling PAN temporarily.

Applied to the X86 platform. Since X86 does not have LSU-like instructions, we cannot de-privilege BPF memory accesses. The domain-based isolation hardware PKS [16] can be used to isolate the BPF program and the kernel in different domains and switch domains when accessing kernel objects or calling helper functions. PA technology can be implemented in software at low cost because HIVE only performs the *sign* and *auth* operations when the exclusive type pointers are generated and used for the first time. Since X86 has a smaller number of general-purpose registers (only 2 unused), while HIVE needs to use up to 10 registers, we can use floating point registers as "swap" registers.

10 Related Work

Enhancing eBPF security. Many works noticed the security issue and tried to harden the execution environment of BPF programs by using the Intel PKS [28] or SFI methods [26]. These works only considered memory safety and failed to harden all security properties which also exposed vulnerabilities. Even for memory safety, their security is weak due to the lack of complete BPF memory compartmentalization and object-granular protection of kernel objects. For example, they don't separate the metadata in maps, and the memory pages where the kernel objects are located are accessible.

Use of load/store unprivileged instructions. The LSU instructions have already been used for security [7, 10, 23, 38]. However, these works differ from HIVE in both scenario and design. To protect the system on ARM Cortex-M processors, Silhouette [38] and uXOM [23] transform regular load/store instructions to LSU instructions to protect the shadow stack and the code, respectively. uSFI [7] enforces the trusted code to use LSU instructions to access all memory. To protect the system on ARM Cortex-A processors (especially on AArch64), ILDI [10] and PANIC [36] protect the sensitive data in the kernel or user process by using PAN+LSU — the data are placed into U-Pages, and regular load/store instructions at EL1 cannot access them due to the PAN feature. They

can only be accessed legally by using LSU instructions. Different from ILDI and PANIC, HIVE proposes to use LSU instructions to de-privilege the memory accesses of malicious BPF programs, thus protecting the trusted kernel. Especially, HIVE uses the EL-based memory isolation not the PAN.

Use of pointer authentication. PA has been used to protect the pointers in vulnerable software. PACStack [24] and PACTight [17] ensured the integrity of code pointers against the control flow hijacking attacks. PARTS [25] protected all code and data pointers. PTAuth [12] used PA to attach some information to data pointers to ensure the temporal memory safety of the heap. Differing from these works, HIVE uses PA to protect the pointers against malicious BPF programs. The biggest difference is that during the compilation phase, HIVE does not know at which points to authenticate.

11 Conclusion

The use of a static verification method in eBPF limits the complexity of BPF programs and brings security vulnerabilities. This paper presents a security-equivalent isolated execution environment on AArch64 for running BPF programs, which ensures kernel security at runtime and allows complex BPF programs to be loaded with low runtime overhead.

A The Description of Security Properties

We summarized the descriptions of the security properties in Table 8. The verifier tracks all the BPF objects' sizes and permissions, and the pointers' bounds point to them, thus whenever a BPF object is accessed, it forbids underflow/overflow and permission mismatch (lines 1/2/5). For BPF-accessible kernel objects, the verifier uses its whitelist, which records all readable/writable fields of each type of kernel object, ensuring legal fields with correct memory access width (lines 3/4/6).

When calling a helper function, it ensures each parameter matches the formal arguments in the signature (line 7). It maintains the status of each stack slot, thus pointers can be spilled into the stack and restored to the register. However, the BPF program cannot store pointers in other memory, because their later usage is not tracked, thus unable to prevent pointer leakage (line 8). Any operation that may leak the pointers indirectly (e.g., bitwise, compare) is not allowed (lines 9/10).

The stack memory and BPF registers may contain residual kernel information (e.g., pointers), it forbids operation that may lead to uninitialized access (lines 11/12/13).

It only considers Spectre V1 and V4 attacks, which are mitigated via different solutions. For example, Spectre V1 attack is mitigated by the *alu_sanitizer*, which adds mask instructions to prevent possible OOB speculative access. It also restricts stack access to simplify the Spectre V1 analysis

Table 8: Security properties related to the full-path analysis.

	Security property	Description
1	BPF object OOB I	Accessing BPF objects disallow underflow or overflow.
2	BPF object OOB II	BPF stack access is checked to prevent exceeding 512B.
3	kernel object OOB I	Computation of pointers to kernel objects (e.g., context objects) is disallowed, and the immediate offset in memory access instruction is checked based on a white-list to ensure the BPF program accesses legal fields.
4	kernel object OOB II	The whitelist is used to rewrite kernel object access based on the immediate offset in the instruction to ensure the BPF program accesses legal fields.
5	permission violation I	Read-only maps cannot be written to, and the same applies to packets for specific BPF program types.
6	permission violation II	Specific fields of kernel objects are read-only, ensured by the whitelist check.
7	type mismatch	Argument pointers must be matched to prevent BPF programs from using helper functions to arbitrarily access kernel objects. Pointers cannot be passed as scalars to prevent pointer leakage.
8	pointer leakage I	Pointers are disallowed as BPF function return value or for writing into memory, except for pointer spill due to maintained stack slot states.
9	pointer leakage II	Pointers are disallowed from performing certain calculations like bitwise or inter-pointer calculations.
10	offset leakage	Pointers cannot be compared with other pointers or non-zero scalars to prevent offset leakage.
11	uninit reg read	Registers must be initialized before use.
12	uninit stack read I	The BPF stack must be initialized before use.
13	uninit stack read II	BPF programs cannot write to the stack with variable offsets, as the full-path analysis needs to maintain the state of each stack slot. If the variable offset relates to an uninitialized slot, it cannot decide whether this write will initialize it or not.
14	Spectre V1 filter	BPF programs cannot read from the stack with variable offsets to simplify the Spectre V1 analysis.
15	Spectre V1 masking	Pointer arithmetic instructions with possible Spectre V1 attack is masked with the max range deducted by the full-path analysis.
16	Spectre V4 barrier	Store with possible Spectre V4 attacks are identified and instrumented with barrier instruction.
17	kernel stack crash I	The max depth of BPF call frame cannot exceed 32 to avoid kernel stack crash.
18	kernel stack crash II	The size of the combined BPF stack for each BPF function cannot exceed the upper limit (512B).
19	timeout	BPF program cannot contain dead loops.
20	deadlock	BPF program cannot cause deadlock.

(lines 14/15). The barrier instruction mitigates Spectre V4 if a possible speculative store is detected (line 16).

The call frame of the BPF program cannot be too deep (e.g., less than 32) because it may crash the kernel stack (line 17). Similarly, the size of the combined BPF program stack of the deepest call frame cannot be too large (line 18).

The kernel disables the preemption when the BPF program executes, thus the BPF program cannot stuck (e.g., dead loop, deadlock) to keep the kernel functional (lines 19/20).

B Complexity Issue Intensify with bpf_loop

Fig. 9 gives an example for the `bpf_loop()` helper, the original loop uses the `i < len` statement as the loop condition. Since the `len` variable may be unknown at the loading time, the full-path analysis has to speculate its range as large as possible (e.g., u32_max), thus failing to enumerate all program

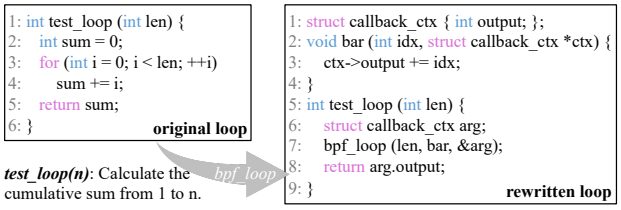

Fig. 9: The code example of `bpf_loop()`.

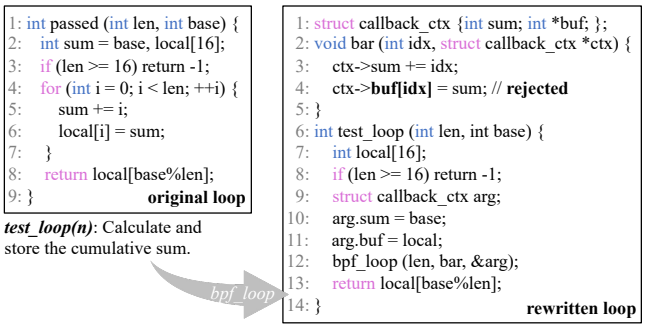

Fig. 10: The negative example of `bpf_loop()`.

states, leading to program rejection. The bpf_loop() helper tries to solve this problem by encapsulating the loop body into a new function (`bar()` in the example), callback it using bpf_loop() with `len` as its call count and `arg` as its argument. The bpf_loop() will call the `bar()` for `len` times and pass the `index` from `0`. Inside the `bar()`, it stores the computed result and returns `0`, which means continue for the loop, while returning `1` means break the loop.

While this helper aims to address the complexity issue, it could worsen the problem. As the Fig. 10 shows, the original function can pass the verification but fails after being rewritten by the `bpf_loop()`. This is due to the inability to pass states between the loop body and condition. For example, in the original function, the `i` variable is always less than `len` (which is less than 16), thus the memory access instruction in line 6 is safe. After the loop body becomes an independent function, which is verified independently, the full-path analysis cannot ensure the range of `idx`, thus rejecting the BPF program for possible OOB access. Besides, this callback style function restricts pointer passing between function calls, thus the loop body cannot use any self-defined pointers (`buf` in line 4), which is another limitation.

C The Details of Compartmentalization

C.1 The BPF Stack Handling

The BPF stack is on top of the current kernel stack. Besides, the return address and callee-saved registers (*metadata*) are also stored in the kernel stack and are only accessed by `%sp`.

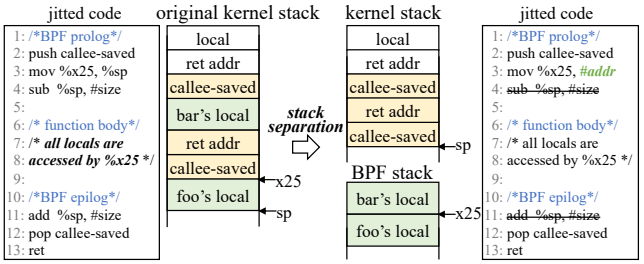

Fig. 11: The stack separation process. The kernel calls the `bar()` in BPF, and the `bar()` calls the `foo()` in BPF.

As shown in Fig. 11, HIVE moves the local variables into BPF space by replacing the initialization of `%x25` in the prologue (`mov %x25, %sp`) with another instruction (`mov %x25, #addr`), and leaving the *metadata* on the kernel stack. The stack adjustment instructions (lines 4/11) are optimized away. HIVE instruments instructions to adjust the `%x25` to manage the BPF stack when entering the BPF program and calling BPF functions. Without full-path analysis, HIVE does not know the size of each stack frame, so it uses the upper limit (512B) allowed in eBPF as the fixed size of each frame. The size of the BPF stack is set to be 8MB by default, HIVE only allocates the bottom two pages at load time, and the remaining pages are allocated lazily via the page fault exception.

Since the control flow safety is guaranteed (forward control flow is ensured by the first two stages of the verifier, and backward control flow is ensured by return address isolation), instructions that operate `%sp` are emitted/instrumented by the JIT compiler and cannot be abused by attackers. The advantage of this design is that there is no need to switch the physical stack pointer `%sp` when the kernel function and the BPF function call each other. During the BPF program's execution, the interrupt handlers and the helpers can be called directly as they both use the kernel stack.

C.2 The Maps Separation

There are 33 distinct types of maps in the current eBPF with mainly two types of implementations: array maps and hash maps. The shadowing process is straightforward for array maps since they are stored continuously and of a fixed size. eBPF provides map properties to page-align the values, which helps HIVE to only shadow the data area of the maps.

However, the hash maps are stored non-contiguously, preventing HIVE from shadowing the hash maps directly into the BPF space. To this end, we slightly adjust the structure of the maps, separating all values from the maps and leaving a pointer to point to the new location of the values. Fig. 12 gives the separation of the hash_map structure, all values are separated and stored in the BPF space, while the metadata remains in the kernel space. The change in the map structure does not affect the normal functionality of BPF programs.

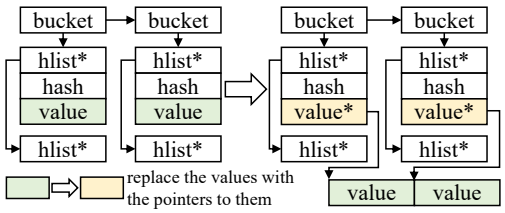

Fig. 12: The hash map separation.

D Miscellaneous Helpers Rewriting

The 11 helpers that need rewriting are introduced as follows:

- *bpf_spin_[lock|unlock].* The full-path analysis needs to ensure no spinlock is acquired in the current program state when calling the `bpf_spin_lock()`, and the lock must be released before the BPF program exits. To this end, HIVE handles these helpers by adding additional record-and-check logic in them. For example, HIVE maintains a per-program spinlock table for the `bpf_spin_lock()`, each time this helper is called, HIVE checks if the current BPF program has acquired a spinlock already, if true, the BPF program will be uninstalled. Otherwise, HIVE updates the spinlock table. This table also ensures the BPF program will release the spinlock through the `bpf_spin_unlock()` helper before the BPF program exits.
- *bpf_timer_[init|set_callback|start|cancel].* eBPF provides callback timer functions via these 4 functions, and the full-path analysis ensures all the timers are initialized by use, as well as their integrity. Since these functions all require the state of the timers, HIVE maintains a timer table for them, and updates the table based on their functionalities (e.g., insert an entry in the table when the texttbpf_time_init is called). Once a timer is corrupted by the BPF program, HIVE can detect that in the helper by the timer table.
- *bpf_dynptr_[from_mem|read|write|data].* A dynptr is a pointer that stores metadata alongside the address. The full-path analysis ensures it is read-only to the BPF program and can only be used through helpers. To this end, HIVE maintains a dynptr table for them. Each time a dynptr is generated, it will be recorded into the table, and HIVE checks the table when the dynptr is used. Different from the full-path analysis, the BPF program can corrupt the dynptr, but it will be identified once the dynptr is used.
- *bpf_kptr_xchg.* Unlike other PTR_TO_BTF_ID helpers, the btf_id in this helper is determined dynamically by the full-path analysis, which ensures the corresponding argument has BTF information in the maps when calling this helper. Since HIVE cannot determine which path contains which map with BTF information, it needs to dynamically find the map by the pointer value and ensure the corresponding map contains the BTF information.

BUDAlloc: Defeating Use-After-Free Bugs by Decoupling Virtual Address Management from Kernel

Junho Ahn, Jaehyeon Lee, Kanghyuk Lee, Wooseok Gwak, Minseong Hwang, Youngjin Kwon

School of Computing, KAIST

Abstract

Use-after-free bugs are an important class of vulnerabilities that often pose serious security threats. To prevent or detect use-after-free bugs, one-time allocators have recently gained attention for their better performance scalability and immediate detection of use-after-free bugs compared to garbage collection approaches. This paper introduces BUDAlloc, a one-time-allocator for detecting and protecting use-after-free bugs in unmodified binaries. The core idea is co-designing a user-level allocator and kernel by separating virtual and physical address management. The user-level allocator manages virtual address layout, eliminating the need for system calls when creating virtual alias, which is essential for reducing internal fragmentation caused by the one-time-allocator. BUDAlloc customizes the kernel page fault handler with eBPF for batching unmap requests when freeing objects. In SPEC CPU 2017, BUDAlloc achieves a 15% performance improvement over DangZero and reduces memory overhead by 61% compared to FFmalloc.

1 Introduction

Memory bugs persist as enduring security vulnerabilities in software systems. Arising from developers' oversights and the use of memory-unsafe languages, these bugs are prime targets for exploitation by attackers. Among the myriad of memory bugs, use-after-free (UAF) vulnerabilities stand out as particularly notorious. Recent research evaluates its significance, ranking UAF bugs seventh among the top 25 most prevalent and impactful vulnerabilities in CWE [25].

Numerous strategies have been proposed to prevent or detect use-after-free (UAF) bugs, including explicit labeling [16, 31, 33, 38], reference counting [29, 39], pointer nullification [28, 43, 46], garbage collection (GC) [17, 24], and one-time-allocator (OTA) [25, 42, 44, 45]. The explicit labeling method involves tagging memory chunks as used or freed, with runtime checks verifying the tags on each access. However, this incurs significant performance overhead. Pointer nullification nullifies the freed objects and their associated virtual addresses. However, tracking dangling pointers also incurs performance overhead. Reference counting, while effective in some cases, is not universally applicable to all C/C++ applications and also suffers from high performance overhead due to runtime checks. GC-based approaches have gained popularity due to their modest performance and memory overhead. Nevertheless, they also come with several limitations.

Firstly, GC-based approaches suffer from poor scalability in multi-threaded applications. For example, MarkUs [17] necessitates concurrent threads to scan the application's memory while causing pauses in the application threads. Although Minesweeper [17] attempts to optimize this issue with linear memory scans, they still encounter stop-the-world delays in concurrent applications. Secondly, applying GC-based approaches to applications using obfuscated pointers, such as pointers with flags or reference counters, is challenging and often results in excessive memory overhead due to false positive detections [17]. Thirdly, the intricate design of GC-based approaches frequently involves severe security flaws, either by design or implementation [44]. Lastly, most garbage collection-based methods quarantine freed pointers and repurpose them once dangling pointers are eliminated. However, this approach is not suitable for accurate detection.

Recently, researchers have gained interest in rethinking the OTA approach to overcome the limitations of the GC-based approach. The fundamental concept behind the one-time-allocator (OTA) is never reusing allocated virtual addresses for subsequent allocations, ensuring each allocation request receives a distinct memory chunk. While OTA doesn't eliminate UAF bugs, it makes them unexploitable. In a basic OTA implementation, each object is allocated on a separate page, which is unmapped when the object is freed. However, this object-per-page allocation leads to significant memory bloat due to internal fragmentation. To address this, OTA incorporates the notion of virtual aliasing [23], where multiple aliases of objects are mapped to a single page [42]. However, the aliased-based OTA introduces a notable performance overhead due to frequent system calls (one syscall for each allocation or free). Recognizing these limitations, recent efforts have revisited OTA to overcome the performance challenges posed by the original approach.

FFmalloc [44] abandons virtual aliasing and uses a group-based memory allocator to aggregate objects of similar sizes and deploy batching when freeing objects. While FFmalloc provides good performance across various workloads, it faces

significant memory bloat, up to 800%, at the cost of forgoing virtual aliasing. Additionally, FFmalloc sacrifices the detectability of UAF bugs, a key advantage of OTA over garbage-collection (GC) based approaches. DangZero [25] revives virtual aliasing to enable precise UAF bug detection. To mitigate system call overhead, DangZero utilizes library OS (LibOS) where the library kernel and an application run in the same protection domain. For protection, the LibOS instances execute within a virtualization. While DangZero shows low memory overhead, it has several drawbacks. Virtualization inherently incurs significant IO overhead due to a complex IO stack. Moreover, DangZero requires substantial engineering effort as it must reimplement kernel features such as demand paging, copy-on-write, and NUMA migration. Notably, the current DangZero prototype lacks support for copy-on-write on fork, necessitating the copying of all allocated memory during fork operations.

This paper introduces BUDAlloc, presenting a new design approach for the practical implementation of OTA. BUDAlloc aims to strike a balance between performance and memory overhead while providing strong UAF bug detectability. BUDAlloc does not compromise compatibility, allowing unmodified binaries to use BUDAlloc by simply replacing the default allocator using `LD_PRELOAD`.

The core idea of BUDAlloc consists of two parts: separating virtual address from in-kernel memory management, and co-designing a one-time-allocator and virtual address management at the user-level. This co-design provides several performance benefits for implementing virtual aliasing. Firstly, creating alias pages in BUDAlloc does not necessitate system calls, as the user-level OTA manages the virtual address layout. Second, BUDAlloc provides good scalability in multi-threaded applications. The Linux kernel employs coarse-grained locks (`mmap_sem`) to protect virtual and physical memory operations, exhibiting scalability bottlenecks when memory system calls are frequently invoked, as is the case in OTA. In BUDAlloc, virtual address operation is independently managed at the user-level, thereby significantly reducing lock-holding times during memory system calls.

The mechanism enabling the collaborative design of user and kernel levels is eBPF. When allocating an object, the user-level OTA generates alias information (policy) as user-level metadata and shares it with the kernel. Using eBPF, BUDAlloc customizes the in-kernel page fault handler to perform virtual to physical mapping (mechanism) according to the shared alias information. This design minimizes the interference with existing kernel implementation, allowing BUDAlloc to reuse the existing kernel implementations such as demand-paging, copy-on-write, and NUMA migration.

Furthermore, BUDAlloc offers an option for selecting protection and precise detection. When freeing an object, BUDAlloc defers unmapping a page containing the object and batches unmapping operations when handling the next page fault. While this introduces a potential window for a dangling reference, our observations indicate that this window is sufficiently small to detect most UAF bugs in practice (Table 3). However, for precise detection, BUDAlloc provides a method to immediately unmap a page upon releasing an object, albeit incurring a performance penalty.

We implement BUDAlloc in both the Linux kernel and a user-level memory allocator from scratch, with 2,870 and 8,259 lines of code respectively. At first, we evaluate the performance and memory overhead of BUDAlloc compared to recent OTAs, FFmalloc [44], and DangZero [25], as well as GC-based MarkUs [17]. In SPEC CPU 2006, compared to DangZero, BUDAlloc demonstrates faster performance than DangZero by 5% even in the full detection mode and 15% in the prevention mode. BUDAlloc shows acceptable memory overhead (30%) and significantly better bug detectability, while providing 13% lower performance. We evaluate the scalability using multithreaded PARSEC 3.0 and show the most scalable performance improvement, even faster performance when using more than 8 threads compared to FFmalloc. We then conduct real-world performance tests using Nginx [11] and Apache [8], demonstrating similar performance and memory overhead to GLIBC without scalability issues, unlike other work.

Finally, we test BUDAlloc's resilience against use-after-free vulnerabilities using six CVEs commonly found in state-of-the-art OTA researches. Even in prevention mode, BUDAlloc instantly detected five out of six UAF bugs due to its high bug-detection precision. Additionally, we employ the Fuzzer and unit tests to assess the robustness of BUDAlloc, discovering no reports exceeding 24 hours in HardsHeap [47] and passing all suites in NIST Juliet tests [12].

This paper makes the following contributions.

- We propose a new design idea to implement OTA by co-designing user and kernel level, reducing system call overheads.
- We present a practical approach to detect many UAF bugs without compromising performance.
- We showcase that the co-design strikes the balance among performance, scalability, memory use, and bug detectability in real workloads.

2 Use-After-Free Bug

Memory-unsafe languages, such as C and C++, are extensively used in the development of software systems, including Redis, operating systems, and web or mobile applications. However, they are easily affected by a series of memory safety issues, such as use-after-free, double-free, and invalid-free errors. Among these, the use-after-free (UAF) bug stands out as one of the most frequently reported and exploited security vulnerabilities. UAF occurs when a program attempts to access a dangling pointer that points to a previously freed object. In severe cases, attackers can hijack the freed object, altering its content with malicious data.

Various research efforts have proposed methods to detect or mitigate use-after-free bugs. One approach involves labeling each memory block to track its allocation and deallocation, and checking the metadata when the pointer is dereferenced [22,31,33,38,46]. However, dynamically checking the pointer references introduces significant overhead. Another strategy is to actively invalidate or block dangling pointers when an object is freed, utilizing garbage collection or dynamic tracking [17,24,28,43]. However, these methods suffer from high CPU utilization and performance degradation, low scalabilities, and occasionally stop the entire program from sweeping the memory space. Finally, approaches using randomized patterns for allocation [34] offer probabilistic detection only.

Detection and protection. Defending against UAF bugs involves both immediately detecting the bugs and protecting against their malicious behavior. Detecting encompasses protection and can be applied for online [9] and offline sanitizer [16], and bug triaging. Usually, protection can operate much faster than detection. Detecting UAF bugs at runtime or through program analysis poses challenges due to the temporal nature of these bugs (i.e. the part where the bug occurs is different from where it actually happens). As a result, existing UAF detection work exhibits unacceptable performance and resource overheads. To the best of our knowledge, no OTA system has simultaneously achieved high bug detectability, good performance, and minimal memory overhead. To address this, we introduce an efficient UAF detection mechanism by co-designing the secure allocator with the kernel using eBPF.

One Time Allocator. One-time-allocator (OTA) [23] has regained popularity, particularly with the extensive address space offered by modern 64-bit architectures. OTA ensures that allocated virtual addresses are never reused, preventing attackers from dereferencing and manipulating a freed object with a dangling pointer. OTA has to allocate a distinct virtual address at every memory allocation and remove accesses to deallocated memory.

Figure 1 shows an overview of the virtual aliasing of OTA. OTA divides the virtual address space into two sections; canonical and alias. OTA uses the canonical address internally, while the application uses the alias address. OTA first allocates a canonical address using the internal memory allocator when the user application requests memory. Subsequently, OTA assigns one or more alias addresses and maps the alias addresses (*VA2, VA3, and VA4* in Figure 1) to the canonical address (*VA1*). Each alias address has a different offset within the same canonical page. OTA can detect UAF bugs immediately after unmapping the alias page from the page table since alias pages are not duplicated or reused. On allocation, OTA returns the alias address to the user application. Upon free, OTA reverses these steps by unmapping the alias address from the page table and freeing the canonical address using the original free operation in the internal memory allocator (e.g., `free`).

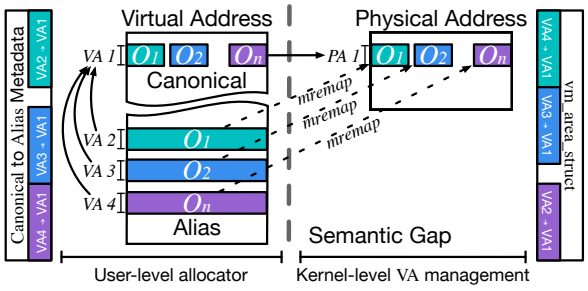

Figure 1: Overview of virtual aliasing.

3 OTA Design Problem

This section analyzes challenges when implementing OTA (§3.1) and discusses the limitations of the current OTA designs: trade-offs in performance, memory footprint, and bug-detect precision (§ 3.2) as well as compatibility problems (§ 3.3). These limitations motivate us to safely co-design the memory allocator with a custom page fault handler.

3.1 Challenge: Semantic Gap

To implement OTA, the widely adopted approach is virtual aliasing [23]. As illustrated in Figure 1, each object has its own virtual alias, with at most one virtual alias accommodated in a virtual page. The *alias-per-page* allocation makes it easy to prevent use-after-free bugs. When an object is freed, OTA disconnects the mapping of the virtual page containing the freed alias object, preventing access to the freed object. However, the alias-per-page allocators suffer from high internal memory fragmentation. Therefore, virtual aliasing makes multiple aliases to be mapped to the same physical page.

OTA records the mappings of alias to canonical page in user-level metadata. According to the alias to canonical mapping, kernel maps alias to physical pages on the page fault. However, this information is not visible to the kernel. We call this problem *semantic gap* in OTA. How to address the semantic gap significantly affects the performance, the size of memory footprint, and bug-detect precision of OTA.

Trade-off 1: Performance and memory footprint. To synchronize the user-level information to the kernel, OTA allocators have to perform system calls (e.g., `mremap` and `unmap`) to bridge the semantic gap. However, frequent system calls cause significant performance overhead. Previous work addressed this problem by deferring `unmap` system calls and batching them, yet they faced notable memory overhead stemming from memory fragmentation [44].

Trade-off 2: Performance and bug-detect precision. Accurate detection of use-after-free bugs closely related with how to handle the `free` operation in OTA. When freeing an object, to detect the reuse of an alias address precisely, OTA has to instantly unmap the alias address from the page table. Unfortunately, this operation requires at least one system call per `free` operations, which incurs significant overhead. Therefore, previous use-after-free works typically favored the prevention

over detection for the performance, despite the feasibility of the detection [17, 24, 44].

3.2 Limitations of Previous OTAs

In this section, we show how the previous OTAs address the trade-off caused by the semantic gap and discuss their limitations. Table 1 summarizes the discussion.

3.2.1 No alias mapping

The most straightforward approach is abandoning alias to canonical mapping, so the semantic gap does not exist. All objects are allocated in canonical address space (i.e., virtual address) directly without having aliases and a canonical page is mapped to a physical page. Therefore, this approach does not need to remap multiple alias addresses to a single canonical page, showing less performance overhead. To prevent use-after-free bugs, this approach must not reuse the allocated canonical address and free a physical page when all objects in a canonical page are freed. Consequently, this approach suffers from high internal fragmentation in physical pages because it cannot reuse empty space in a canonical page (and a physical page). Only when all objects in a canonical page are freed, this OTA frees (unmaps) the physical page mapped to the canonical page, bloating memory footprint significantly when the lifetime of objects varies.

FFmalloc [44] is an example of this approach. It achieves performance close to native memory allocators but introduces significant memory overheads up to 800% in real-world applications [45]. Also, before a physical page is unmapped, FFmalloc cannot detect the use-after-free bug, having the lowest detecting precision.

3.2.2 Syscall-based approach

This approach uses system calls to synchronize the mapping with the kernel, addressing the semantic gap. For allocating an object, syscall-based OTA uses `mremap` to establish alias mapping, and for freeing an object, it issues `mprotect` or `munmap`.

However, while this approach is convenient to implement, syscall-based approach suffers from several limitations. Firstly, this approach incurs high performance overhead due to frequent system calls as `malloc` and `free` require a system call for each. Secondly, even with attempts to serialize and remove locks from the user-level allocator, the frequent mapping and unmapping through the system call leads to high serialization overheads to global kernel locks (e.g., `mmap_sem`) [42, 44]. Thirdly, it results in virtual address fragmentation caused by frequent `mmap` and `munmap`, which in turn fragments the kernel's memory data structure, taking a longer time to find empty address space. We observe that this approach often crashes a process by hitting the Linux kernel's limit of the address fragments (65536) [42].

The state-of-the-art syscall-based OTA is Oscar [42]. To mitigate the overhead of frequent system calls, Oscar speculatively combines freeing and mapping of same-sized objects in one single `mremap` based on the observation that recently freed objects have a high chance of being reused after freeing. Despite that, Oscar suffers from the highest overhead compared to other approaches because it still necessitates at least one system call per `malloc` or `free` operations.

System call batching. Tuning the kernel to support batching system calls could mitigate system call overheads [27, 41]. However, solely batching system calls is not the definitive solution. Firstly, complex system calls like `mmap` or `mremap` typically consume a significant portion of execution time for the kernel software, not the context change. Secondly, the complexity of in-kernel memory metadata also incurs a `vm_area_struct` fragmentation on the OTA. Lastly, even with system call batching, it is inevitable to encounter overheads from the synchronization of kernel metadata such as `mmap_sem` lock. Oscar tried to batch system calls using custom `IOCTL`, but they could not optimize it successfully. They eventually abandoned this approach as, in certain benchmarks, batching system calls led to a slowdown. Oscar analyzes the failure to the challenge of accurately predicting which canonical address will be needed in the future and the side effect of disrupting the favorable memory access patterns of `malloc` by reusing recently freed slots in the canonical address.

3.2.3 LibOS-based approach

Using Library OS, this approach accesses the page table directly while virtualization ensures the protection. The library kernel and OTA run at the same privilege level. OTA controls the virtual to physical mappings without using system calls, thus eliminating the semantic gap problem.

DangZero [25] implements OTA using a Library OS. It manages aliases by directly updating page table mappings and precisely detects any occurrences of use-after-free bugs. However, to safely grant access to page tables, it relies on mechanisms such as Dune [20] or Kernel-Mode-Linux (KML) [30], which introduce fundamental overheads for running on a virtual machine. For instance, Dune shows approximately a 40% performance degradation due to an increased system call overhead [25]. Furthermore, virtualization incurs significant overhead when it comes to performing IO through virtualized storage and network stack [3, 36] as well as address translation overhead due to nested page table translation. The address translation cost is exacerbated by the higher TLB miss rate in OTA where each alias occupies one TLB entry. Another drawback is compatibility because this approach completely bypasses the kernel. Therefore, to be compatible with existing POSIX semantics and APIs, DangZero has to implement complex in-kernel features like fork, demand paging, and copy-on-write for the alias pages, which requires significant efforts to work them completely. Unfortunately, DangZero does not support copy-on-write on fork, exhibiting significant overhead when creating a process. We discuss details in the next section (§3.3).

	Memory Bloat	Syscall Overhead	Scalability	Bug-detect Precision	Compatibility
No alias mapping [44]	Very High	Low	Very High	Very Low	Fully Compatible
Syscall-based [42]	Moderate	Very High	Low	Detector	No COW
LibOS-based [25]	Low	VM overhead	Single thread only	Detector	No COW, proc fs, etc
BUDAlloc-detection	Low	Low	Very High	Detector	Fully Compatible
BUDAlloc-prevention	Low	Very Low	Very High	High	Fully Compatible

Table 1: Comparisons of previous OTAs.

3.3 Compatibility Problem

Fork compatibility. Syscall-based and LibOS-based approaches cannot use copy-on-write. Syscall-based approach necessitates using `MAP_SHARED` for canonical allocations, which changes the semantics of memory to be shared in case of the `fork`. LibOS-based approaches bypass the kernel when creating alias mappings, thereby the kernel is not aware of these pages during `fork`. To ensure `fork` compatibility they have to copy the entire parent address before `fork` without copy-on-write, which increases the latency of `fork` sensitive workloads [35]. In 1GB workloads, the LibOS-based approach takes 1,724ms whereas both our system and a normal Linux process take only 520ms. Fork is not only used for process spawning but also for large databases for consistency snapshot [14], fuzzers, and lambda functions for avoiding initialization overheads [7, 48]. Ensuring scalable performance of `fork()` is crucial for supporting such applications.

Other issues. The LibOS approaches also necessitate the application developers to build their physical address management policies and mechanisms such as `proc fs`, resident set accounting, NUMA-aware placement, or swapping, as the kernel is not aware of allocated alias pages in the page table. For instance, to measure the maximum resident set size of the benchmarks, we have to use the internal accounting mechanisms of DangZero, despite other allocators can conveniently use utility `time` which uses the `proc` filesystem of the kernel.

3.4 Threat Model

We assume a program contains one or more use-after-free bugs, and the attacker can use at least one use-after-free bug, for information leaks, privilege escalation, corrupting data, etc. However, we do not assume that the attacker has the ability to corrupt the OTA allocator. Preventing other classes of memory bugs, such as out-of-bound access or side-channel attacks, are beyond the scope of this work. In prevention mode, we allow crashing at UAF or accessing the old data. In detection mode, we only allow crashing at UAF, rejecting any other class of bugs from UAF. These threat models are compatible with the previous OTA approaches that aim to detect or prevent use-after-free bugs [17, 25, 42, 44].

4 BUDAlloc

BUDAlloc seeks to strike the balance between performance, scalability, memory bloat, and bug-detection precision while providing full compatibility with existing API semantics.

4.1 BUDAlloc Design Overview

Separating address management. At the core design of BUDAlloc lies separating the address management of the kernel into virtual address management and physical address management. The user-level part of BUDAlloc has full control over managing the virtual address space while the kernel controls the physical address management such as page fault handling and the actual page mapping of the designated virtual address. This design allows full compatibility because BUDAlloc reuses well-designed kernel implementation to support existing compatible functions, such as copy-on-write on fork or on-demand paging. Additionally, developers can use the existing interfaces, such as the Linux `proc` file system, to manage applications.

Co-design user-level allocator and kernel. With the separation of address management, BUDAlloc co-designs the user-level allocator and kernel, which removes the duplicated metadata management for the semantic gap. The user-level OTA manages the virtual address, customizing the in-kernel page fault handler safely using BUDAlloc. The custom page fault handler and user-level OTA share the alias to canonical mapping metadata, addressing the semantic gap in OTA. The user-level OTA specifies alias to canonical mapping at the user-level, without the need for expensive exceptions like system calls (policy). Kernel establishes page table mapping according to the metadata while handling page faults (mechanism).

Fine-grained locking. To enhance scalability, BUDAlloc reduces lock contention for managing virtual and physical addresses, which are protected by global locks in the kernel, by shifting virtual address management to the user-level. In addition, BUDAlloc uses fine-grained locking to protect the shared metadata. These design choices are critical for OTA, which incurs intensive lock contentions due to frequent system calls.

4.2 User-level Components of BUDAlloc

As the outcome of co-designing user and kernel space, BUDAlloc consists of user and kernel components. This section introduces the design and optimization of user-level components of BUDAlloc. Figure 2 shows the overall design of BUDAlloc. The user-level allocator incorporates two functions: user-level OTA and virtual address manager (`LibMM`). As an OTA, BUDAlloc uses virtual aliasing. After creating an alias page, BUDAlloc inserts the alias to canonical mapping to the metadata, implemented by trie. The metadata is shared with

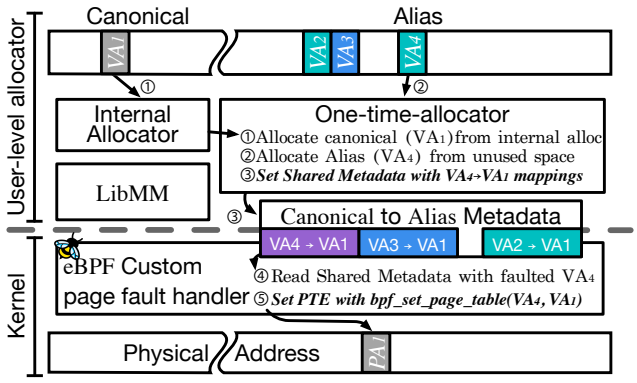

Figure 2: Overview of the BUDAlloc one-time-allocator.

kernel components (§4.2.1). The in-kernel custom page fault handler examines the metadata to establish a mapping from an alias page to a physical page (§4.3). As a virtual address manager, `LibMM` manages canonical address and the virtual address layout of the internal allocator. (§4.2.2).

4.2.1 One Time Allocator

BUDAlloc replaces the existing memory allocators. When a user application requests allocation, BUDAlloc transparently intercepts memory APIs using `LD_PRELOAD`, and relays memory requests to the internal memory allocator.

Allocating an object. The internal memory allocator allocates a new canonical address, which is not exposed to the application. Then, the user-level OTA creates a new virtual alias page for the object. As an OTA, BUDAlloc avoids reusing the alias page in subsequent allocations. Notably, unlike the syscall-based approaches, this step does not require the `mremap` system call because BUDAlloc manages the virtual address space directly in user-level. BUDAlloc inserts the alias-to-canonical mapping into the trie metadata and returns the alias address to the application. Unlike the Linux kernel, which uses a linked list for metadata, the trie metadata does not incur virtual address fragmentation. Upon an alias page fault, BUDAlloc custom page fault handler searches the trie metadata for the canonical address associated with the faulted alias address. If the entry exists and is valid, the custom page fault handler maps the alias page with the same physical address as the canonical address.

Freeing an object. When a program releases the alias object, BUDAlloc scans the trie metadata to find the corresponding canonical address and notifies the internal memory allocator to reuse the canonical. This design is crucial to mitigate internal fragmentation. FFmalloc cannot reuse it because it forgoes virtual aliasing for performance.

As discussed, the degree of bug-detection precision is closely related to how to design freeing objects. To immediately detect UAF bugs, OTA should instantly remove the mapping of freed alias pages. Unfortunately, this requires at least one system call to execute an `unmap` operation. Therefore, BUDAlloc supports two modes for immediate detection and prevention of UAF bugs.

Deferred alias free. BUDAlloc offers a prevention mode, allowing users to defer the freeing operation at the expense of relaxing UAF detection. In this mode, BUDAlloc postpones the unmapping of alias pages from the page table until the occurrence of the next page fault. More precisely, BUDAlloc inserts freed alias addresses into a per-thread ring buffer. When a newly allocated alias address is accessed, a page fault occurs, and the BUDAlloc custom page fault handler unmaps all addresses stored in the ring buffer while handling the page fault. To ensure correctness in deferred freeing, the internal allocator must reuse freed slots of the canonical address after the associated alias pages are removed from the page table. BUDAlloc tracks the states per-thread ring buffer and ensures that there exists no alias to canonical mappings to the freed canonical address before the canonical address is reused by the internal memory allocator.

Due to the deferring, the prevention mode allows a potential window for a dangling reference. However, unlike the previous work [17, 24, 44], the time window is small, which is *min*(time taken to the next page fault, batching delay). We set the batching delay to 10 ms, and dynamically adjust the ring buffer length based on the deallocation rate (e.g., `free`). Given that UAF bugs tend to manifest after a long-term period rather than a short-term [28], BUDAlloc detects almost all UAF bugs in prevention mode as demonstrated in various CVEs (§5.1).

Detecting memory bugs. At the time of freeing an alias address, if the trie entry corresponding to the alias address in the user-level allocator is empty, BUDAlloc regards this as an invalid free or a double free. If successful, the alias-to-canonical mapping is removed from the trie, and during the next page fault, if the custom page fault handler finds no corresponding canonical address in the trie, BUDAlloc reports a use-after-free bug to the user.

4.2.2 Virtual address manager (`LibMM`)

We use `mimalloc` [10] as the internal allocator. The internal allocator uses system calls (e.g., `mmap`, `munmap`, and `madvise`) to allocate and reclaim virtual addresses from the operating systems. BUDAlloc intercepts the memory system calls from the internal allocator and forwards them to `LibMM`. `LibMM` is a compatible layer for managing the internal allocator as the canonical allocator. The canonical allocator remains unaffected by virtual address fragmentation. Thus we manage the `LibMM` using a linked list like the Linux kernel. Upon a page fault, the custom page fault handler determines whether the faulted address is canonical or alias. If it is a canonical page, it maps a physical address to the faulted address. If it is an alias fault, it searches the shared metadata to handle the page fault by policies of the BUDAlloc.

4.2.3 Optimizations

Prefaulting alias pages. OTA allocates the objects to distinct alias pages. Thus, in theory, there should be at least one page

fault per object if batching is not used. However, using BUDAlloc user-defined page fault handler, BUDAlloc can prefault alias pages anticipating upcoming memory access patterns based on the semantics of alias pages. We store the object size along with a canonical address in the shared metadata (trie). For prefaulting, BUDAlloc uses two algorithms based on the object size in the trie entry.

For objects smaller than the page size, BUDAlloc prefaults consecutive alias pages. BUDAlloc manages a reservation pool that stores alias pages of the same size and inserts these alias pages into the trie entries. Upon a page fault, BUDAlloc prefaults the next consecutive alias pages until it reaches the maximum limit (128 in our implementation).

For objects greater than a page size, BUDAlloc takes a heuristic based on the window-based algorithm. The window size determines the prefaulting size of the faulted address. Initially, the window size is a page size, and BUDAlloc adaptively increases the prefaulting window by a factor of two. This reduces the overall page fault rates on a logarithmic scale for the newly allocated objects.

4.3 Kernel Components of BUDAlloc

BUDAlloc extends the kernel to collaborate with the user-level OTA and `LibMM` using eBPF. The design goal is as follows: Firstly, BUDAlloc must be secure and isolated from both the kernel and the other user processes. Secondly, BUDAlloc ensures seamless compatibility with various kernel features, such as fork, clone, on-demand paging, swapping, or NUMA. Thirdly, BUDAlloc facilitates fine-grained locking for scalability.

4.3.1 Decoupling address space

BUDAlloc allows the user-level OTA to establish virtual-to-physical mapping for virtual aliasing. However, directly exposing the layout of physical addresses to users bleaches the security guarantees of the kernel. Instead, BUDAlloc constructs pseudo-physical address, and allows the user-level OTA to use it. The user-level OTA provides a virtual address and pseudo-physical address for aliasing, and the kernel translates the pseudo-physical address to the physical address and finally establishes the mapping between the virtual address and physical address. BUDAlloc reuses the process's page table to convert a pseudo-physical address into a physical address. Pseudo-physical address restricts BUDAlloc to managing only the virtual addresses of the owner process. Therefore, even if the owner process is compromised, it cannot access or modify other processes' memory.

This level of indirection allows decoupling address space between what user-level OTA uses and what kernel manages. Decoupling address space hides the physical address information such as address space layout or page table policies from BUDAlloc. The amount of information accessible to BUDAlloc is identical to what is shown in the Linux kernel (i.e. `/proc/pid/maps`). In addition, by decoupling, the kernel has complete control over the physical address. It transparently applies kernel-specific tasks hidden from the user-level OTA, such as resident-set-size counting or NUMA migration policies. Note that, as BUDAlloc reuses the process's page table, there is no additional space overhead when mapping from pseudo-physical to physical addresses.

Type	API
Page Table	bpf_set_page_table(void *vaddr, size_t len, void *pindx, u64 vm_flags, u64 prot)
	bpf_unset_page_table(void *vaddr, size_t len)
Shared Memory	bpf_uaddr_to_kaddr(void *uaddr, size_t len)

Table 2: A summary of BUDAlloc helper functions used for page table modification and shared memory.

4.3.2 User-Defined Page Fault Handler

As previously explained, the user-level OTA involves sharing alias-to-canonical mapping metadata with the kernel (policy). The customized page fault handler then updates page tables based on this metadata (mechanism), bridging the semantic gap. At its essence, we expand the Linux kernel page fault handler using extended Berkeley Packet Filter (eBPF). eBPF enables users to execute a simple program in the Linux kernel without modifying the source code [6].

Reasons for using eBPF. There are several reasons for our choice of using eBPF for the custom page fault handler. Firstly, eBPF ensures the safety of the eBPF program by rejecting invalid API usages, removing denial-of-service attacks, and ensuring memory and control-flow safety [5]. Secondly, eBPF is efficient, as it statically checks the eBPF program and compiles it into native code using a Just-In-Time Compiler (JIT). Thirdly, eBPF can load custom kernel logic without requiring privileged permission (e.g., `sudo`). Linux offers `CAP_BPF` capability, allowing eBPF programs to be loaded with normal user privilege [1]. Lastly, eBPF supports various toolchains, including C, Python, or even Rust, utilizing the LLVM compiler backend [5, 6].

Custom page fault handler. We implement two helper functions to control the page table and one helper function to share the memory between the kernel and the user. Also, we extended POSIX `mmap` system call to register a virtual address range used for `LibMM` and OTA. Table 2 shows the summary of BUDAlloc helper functions. The user-level OTA can specify the mapping of virtual pages with size `len` to a physical page for aliasing using `bpf_set_page_table`. The specified physical address, `pindx`, serves as a pseudo-physical address. If `pindx` is unused, BUDAlloc maps it to a new zeroed physical page and associates the virtual address with the pseudo-physical address. Upon invoking a custom page fault handler, it populates the faulted address by referencing the shared metadata associated with the handler. Upon completion of the page fault handling, the customized page fault handler returns 0 for success or 1 for failure. In case of failure, the kernel page fault handler sends a `SIGSEGV` to the process.

eBPF programming restrictions. Although eBPF ensures safety through static verification, eBPF restricts the maximum number of instructions (1M for `CAP_BPF`) for ensuring termination of an eBPF program. Despite that, we are able to implement the required functionalities within the restrictions. For looping, we leverage the recent eBPF features, `bpf_loop` [2] to implement iterations with unknown count or complex branches. However, we need to address two implementation challenges. Firstly, eBPF lacks features for flexible shared mapping between the user and the kernel. To overcome this limitation, we introduce new helper functions (Table 2). Specifically, `bpf_uaddr_to_addr` is utilized to create a shared map between the kernel and the user, ensuring the validity of the resulting kernel address. Shared memory between the user and the kernel shares the same physical address but has different virtual addresses to maintain separation between the kernel and the user. BUDAlloc transparently ensures the safety and validity of the shared mappings in case of `fork` or `unmap`. BUDAlloc utilizes the helper function for sharing the metadata between the custom page fault handler and the user-level allocator. Secondly, eBPF supports only atomic operations for the synchronization. Therefore, we co-design the custom page fault handler to control the synchronization only using atomic operations (§4.4).

4.3.3 Confining logic errors

BUDAlloc ensures the ordering and atomicity of the helper functions to protect race conditions on the page table modifications by a reader-writer lock. While BUDAlloc cannot prevent logic errors in eBPF, such as specifying an incorrect page when creating an alias, or denial of service attack by refusing to handle page fault, these errors are isolated from other processes by the safety guarantee of eBPF. In BUDAlloc, an eBPF program cannot modify page tables of other processes because BUDAlloc helper functions verify the current pseudo-physical address belongs to the process. Also, we ensure the Translation Lookaside Buffer (TLB) are flushed before and after page table modifications in an eBPF program. When a helper function carries out page table modifications kernel flushes the TLB without requiring explicit TLB flush operations from an eBPF program. While this may be a conservative approach that rules out optimizations of coalescing TLB flushes, we prioritize the correctness and safety of page table updates by leveraging well-debugged kernel code.

4.4 Scalability

The BUDAlloc user-level allocator is optimized for multi-threading scalability, using fine-grained locking and lock-free data structure. This is particularly important in the OTA, as it frequently incurs metadata update operations, stressing the scalability bottleneck due to coarse-grained kernel locks (e.g., the `mmap_sem` in the Linux `mm_struct`) [4].

Opportunity. By decoupling virtual address and physical memory management, BUDAlloc reduces the contention window of coarse-grained kernel locks because virtual address operations such as finding empty virtual address and returning freed virtual address range are moved to the user-level, reducing lock contentions. Furthermore, BUDAlloc allows the user to implement fine-grained locking using the semantics of the user-level allocator. This user-centric approach allows for greater flexibility in deploying user-provided data structures instead of using the existing kernel ones, enabling optimized co-designing locks to safeguard critical sections.

Shared trie metadata. We optimize the shared trie data structure between the in-kernel custom page fault handler and the user-level OTA. Given that both frequently access this metadata, ensuring scalability is essential. The trie entry comprises four levels, each using 48 bits of virtual addresses as an index. We experiment both using global locks and reference-counting-based lockless mechanisms for the trie, and discover that combining the two mechanisms yield the best performance due to the locality of the alias addresses. We assign the last level of the trie to each thread to hold per thread pool of consecutive alias addresses, typically accessed by the same thread due to the spatial locality. Unlike the last-level entry, which stores the canonical address, upper-level entries store the next-level entry, which remains unmodified during operations. Consequently, we adopt different locking mechanisms based on the level of the trie entry.

The shared trie dynamically allocates and reclaims each level, maintaining consistency through reference counting for upper-level nodes (L1-L3) and spinlock for leaf nodes (L4). A thread increases the reference count (using atomic operations) for upper-level nodes before accessing them and decreases the count upon completing trie access. BUDAlloc frees a node if its reference count reaches zero, ensuring that a thread doesn't access a dangling (freed) node. Since leaf nodes' contents can be modified, BUDAlloc uses spinlocks to serialize accesses to a leaf node. These spinlocks are shared among user threads and eBPF code.

However, the BUDAlloc custom page fault handler cannot acquire spinlock, since eBPF does not allow unbounded spinning. Therefore, we use `trylock` inside the BUDAlloc custom page fault handler and reattempt the page fault after a failed lock acquisition.

Deferred free list. In prevention mode, for scalability, BUDAlloc uses a per-thread ring buffer to list deferred alias pages, protected by per-thread spinlock. The ring buffer is shared with the kernel. To ensure the safety of deferred freeing, when a thread frees an alias and reuses the associated canonical address, the page fault handler must unmap the freed alias page before the thread uses the new object using the reused canonical address. To do this, BUDAlloc marks the trie entry of the new alias with the thread index of the per-thread ring buffer. In the rare scenario where a BUDAlloc custom page fault handler cannot acquire the lock using `trylock` and trie entry is marked, it retries the page fault to guarantee the previous

mapping is invalidated. If it is not marked, it skips the deferred free and proceeds with processing the page fault. In detection mode, this logic is not required because detection mode does not defer freeing an alias page.

Supporting fork. When a thread initiates a fork system call, other threads may interact concurrently with the user-level OTA. Therefore, it may end up with inconsistent lock states before and after the fork. Therefore, we implement a global read-write lock to protect against invalid fork states. Before fork operation, the user-level OTA releases all holding spin locks and awaits the completion of the fork using the read-write lock. Similar mechanisms are commonly used by other allocators to support fork operations safely [19].

4.5 Compatibility

While BUDAlloc moves virtual address management to the user-level, BUDAlloc maintains compatibility of existing kernel features such as copy-on-write, demand paging, and the `proc` file system. Therefore, BUDAlloc runs unmodified binaries by replacing its default memory allocator using `LD_PRELOAD`. Nevertheless, some parts of the Linux kernel are closely integrated with both physical and virtual management. We outline two specific cases of such scenarios and describe how to tackle these challenges.

VA-Chain reverse map. The operating system traditionally maintains a reverse mapping that locates a virtual address (address of a PTE) of a physical page, crucial for physical address management tasks like swapping, migration, compaction, and copy-on-write. Linux uses an object-based reverse map, tightly coupled with the metadata for virtual address management, `vm_area_struct`. However, BUDAlloc does not use the metadata because it bypasses the virtual address management in kernel. To address this, we revise a VA-chain-based reverse map, utilizing the unused fields in Linux's `struct page`. Unlike Linux's PTE-chain, which stores references to PTEs in the page table from a page, the VA-chain stores virtual addresses of a page using double-linked lists. The reverse mapping information is directly stored in the struct page, offering a more flexible solution for BUDAlloc. It consumes 16 bytes per mapping. If virtual addresses are allocated contiguously, the memory overhead for the reverse map is only 16 bytes. In our evaluation, the VA-based reverse map shows acceptable memory overhead in real workloads (§5.3).

PTE reference count. If the last entries in the page table are released, the kernel deallocates the upper level of the page table entry to remove unused page table entries. The Linux kernel achieves this by utilizing the `vm_area_struct` to selectively clear the last-level page table entries using the virtual address allocation information. To clear these last-level entries without explicit knowledge of `vm_area_struct`, we employ reference counting. BUDAlloc reuses the `struct page` field to keep track of the references of the PTE entries. BUDAlloc helper function increases the reference count (using atomic operations) upon setting a PTE entry and decreases the count upon unsetting a PTE entry. When the reference count reaches zero, BUDAlloc clears the upper-level page table entry. By leveraging the reference count, BUDAlloc effectively manages the page table, ensuring efficient memory usage.

4.5.1 Compatibility Study

On demand paging. By the design of decoupled address space (§ 4.3.1), BUDAlloc easily supports demand paging. The user-level OTA specifies alias and canonical mapping in the pseudo-physical address, so it does not give any restrictions for physical memory management. Therefore, BUDAlloc populates the page table entry at the page fault.

Copy on write. Both syscall-based and LibOS-based approaches face challenges when it comes to supporting copy-on-write, as discussed in §3.3. Therefore, they copy the entire address space during a fork, which causes significant overhead in an application with a large memory footprints. In contrast, BUDAlloc doesn't encounter these issues. Like the demand paging, decoupled address management allows transparent kernel physical management during fork operations. Note that, users can implement their fork logic using eBPF. By default, BUDAlloc allows the users to reuse the existing copy-on-write implementation in the kernel.

Proc file system. BUDAlloc supports `proc` file system to monitor memory states. In contrast, DangZero requires implementing supplemental mechanisms for replacing `proc` system. For instance, while DangZero necessitates custom logic to monitor memory usage, BUDAlloc transparently supports utility `time`, which internally use `proc` file system.

4.6 Discussion

BUDAlloc shares the fundamental limitation of OTA, increased Translation Lookaside Buffer (TLB) pressure and cache line misses. Unlike non-OTA, which reuses freed objects in subsequent allocations, BUDAlloc necessitates the allocation of new alias pages for each allocation, resulting in reduced cache line hits and increased TLB pressure. Furthermore, since it refrains from recycling freed virtual addresses, BUDAlloc may eventually exhaust virtual addresses. FFmalloc also suffers from the same problem. DangZero uses garbage collection for reusing alias addresses with significant performance overhead. BUDAlloc can incorporate and optimize the same mechanism. We leave this as future work.

4.7 Security Analysis

Attackers who compromise processes using BUDAlloc cannot attack other processes or kernel. Firstly, BUDAlloc isolates pseudo-physical addresses between processes. This ensures that BUDAlloc can manage the virtual address of the owner process only. Even if the owner process is compromised, it cannot access or modify virtual addresses of other processes or kernel space. Additionally, a pseudo-physical address hides the secure information of the physical address, revealing only

what the Linux kernel exposes to the user space. This ensures that no kernel address layout information or sensitive policies, such as Kernel Address Space Layout Randomization (KASLR), are exposed to user space program.

Secondly, BUDAlloc uses eBPF [5] for isolating custom page fault handler from the kernel or other user processes. BUDAlloc requires `CAP_BPF` capability as a normal user, which prevents access to arbitrary kernel memory and leakage of kernel pointers to users, and allows isolation of user space processes [1]. eBPF ensures the safety of BUDAlloc through static analysis using a static verifier. We disable the eBPF *bypass_spec_v1* feature, which incorrectly rejects BUDAlloc due to false positives during verification. Recent CPU mitigates speculative side-channel attacks [26], and fixing these false positives in the verifier is beyond the scope of this paper. However, bugs in the eBPF verifier or helper functions, including additional helper functions in Table 2, could undermine isolation. BUDAlloc trusts the eBPF verifier and helper functions, and these bugs are not part of the BUDAlloc threat model.

5 Evaluation

We evaluate BUDAlloc in terms of security and performance. For security evaluation, we perform CVE analysis, NIST Juliet test suite [12] and HardsHeap [47]. For performance evaluation, we evaluate BUDAlloc with SPEC CPU 2006, SPEC CPU 2017, PARSEC 3.0, Apache, and Nginx Webserver. We implement BUDAlloc on Linux 6.4.0 by 2870 lines of code, and testing with Intel(R) Xeon(R) Gold 5220R CPU at 2.2GHz with 24 cores, 172GB DRAM - 2666 MHZ, 512 GB SSD, and 10-Gigabit Network Connection. In all the experiments, we disable hyper-threading, CPU power-saving states, and frequency scaling to reduce the variance. We use Non-Uniform Memory Access (NUMA) in the PARSEC 3.0 benchmarks (§ 5.5) to fully utilize all 48 cores in the motherboard. We use `time` to get the resident set size (RSS) and total execution time except DangZero. We set the default configuration for the other memory allocators for all evaluations. We use a KVM virtual machine to evaluate test cases on DangZero [25], as it is the default option for running Kernel-Mode-Linux in DangZero.

5.1 Security Evaluation

CVE Analysis. To evaluate the robustness of BUDAlloc compared to other OTA systems, we evaluate a set of Common Vulnerabilities and Exposures (CVEs) commonly referenced in the recent OTA papers [25, 44, 45]. These CVEs address real-world applications' use-after-free bugs in PHP, Python, mruby, and libmimedir. Additionally, we expand our test sets to include the latest real-world exploits of PHP, Python, mruby, our own UAF real-world corpus, and UAFBench [15]. Table 3 shows our protection results: BUDAlloc successfully defends against all attempted attacks.

As predicted, in the case of FFmalloc, it is successful in preventing use-after-free (UAF) bugs, but fails to detect most of the UAF bugs, since FFmalloc delays the unmapping of canonical pages until consecutive pages are freed. However, in contrast, BUDAlloc, even with deferred free enabled (BUDAlloc-p for prevention), successfully detected all UAF bugs in 29 out of 30 separate tests. This capability comes from the detection time interval being short enough to identify the bugs. Furthermore, a user can easily switch to full detection by deactivating deferred free. In this configuration, BUDAlloc successfully detects attempted attacks (BUDAlloc-d for detection). In contrast to other OTA research [25, 44], BUDAlloc achieves near-complete detection even in prevention mode.

Table 3: Summary for BUDAlloc-d (detection), BUDAlloc-p (prevention), DangZero, and FFmalloc. We use default settings for the previous works. Benchmarks with a star(*) involve a precondition leading to a UAF bug, which is detected and aborted in FFmalloc and BUDAlloc during arbitrary or double `free()`.

NIST Juliet Test Suite. We evaluate the robustness of BUDAlloc using the NIST Juliet Test Suite v1.3 [12]. This test suite comprises over one hundred unit tests for use-after-free (CWE 416) and double-free (CWE 415) bugs, including cases classified as false positives and false negatives. BUDAlloc successfully detects all bugs in detection mode and prevents all bugs without encountering any false positives.

HardsHeap. HardsHeap [47] is an automated tool designed for fuzzing secure allocators. We apply HardsHeap to check the resilience of BUDAlloc against UAF bugs. After running for more than 168 hours, HardsHeap detected no issues or errors. This empirical experiment shows the hardness of the BUDAlloc one-time-allocator.

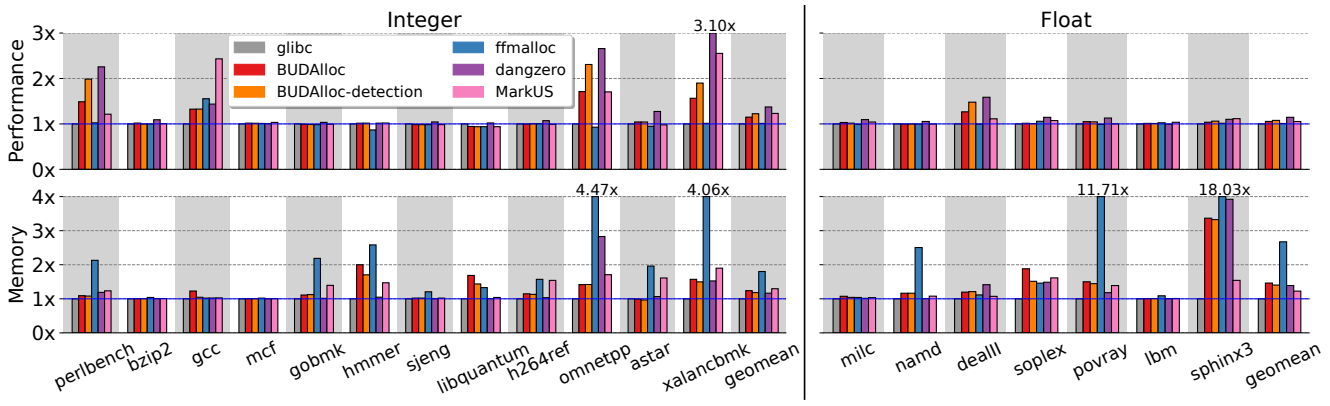

Figure 3: Overhead of SPEC CPU2006 compared with the GLIBC memory allocator. 1x means no overhead. Lower is better.

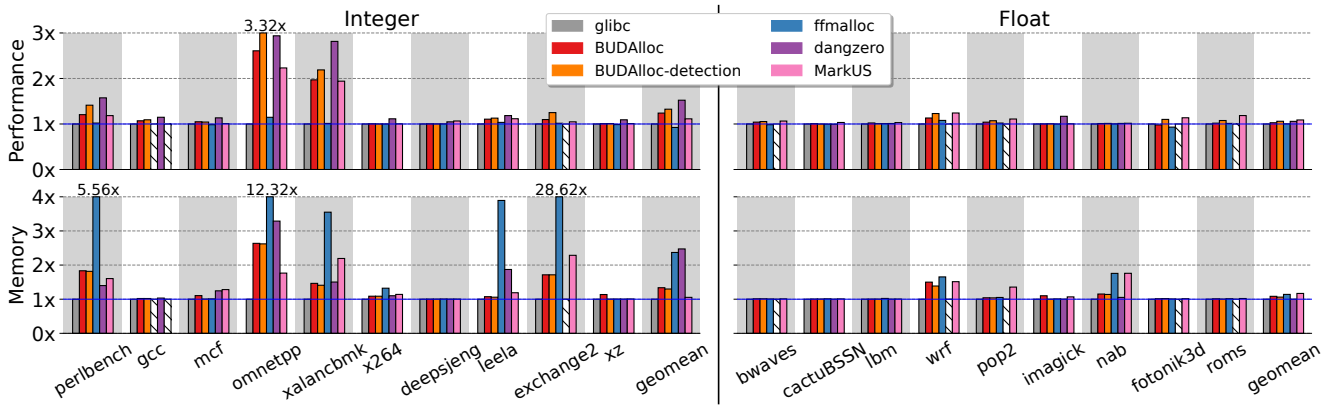

Figure 4: Overhead of SPEC CPU2017 compared with the GLIBC memory allocator. 1x means no overhead. A white bar indicates that a specific allocator did not run. Lower is better.

5.2 Performance Evaluation

We evaluate BUDAlloc using widely adopted benchmarks in OTA research and real-world programs to analyze and compare BUDAlloc performance overheads. We select four sets of benchmarks; SPEC CPU 2006 and SPEC CPU 2017 for single-threaded applications (§5.3), PARSEC 3.0 for multi-threaded applications (§5.4), Apache and Nginx Web server for real-world applications (§5.5). We compare the overhead of BUDAlloc on SPEC CPU 2006 and SPEC CPU 2017 with MarkUs [17], DangZero [25], and FFmalloc [44]. To achieve optimal performance in DangZero, we choose to disable an alias reclaim for a fair comparison. SPEC CPU 2017 contains workloads using a Fortran library, which requires multi-threading. Unfortunately, DangZero lacks multithreading support, causing crashes in several SPEC CPU 2017 benchmarks, specifically `bwaves`, `wrf`, `pop2`, `exchange2`, `fotonik3d`, and `roms`. Also, FFmalloc and MarkUs failed to execute `gcc`.

5.3 Single-threaded Benchmarks

Table 4 summarizes the average performance and memory overhead for five iterations of the commonly executable SPEC CPU benchmarks. We use `glibc` as a performance baseline.

5.3.1 SPEC CPU 2006

System	SPEC CPU 2006		SPEC CPU 2017	
	Perf.	Mem	Perf.	Mem
BUDAlloc-p	1.11×	1.31×	1.18×	1.24×
BUDAlloc-d	1.16×	1.25×	1.23×	1.20×
DangZero	1.28×	1.24×	1.31×	1.27×
FFmalloc	1.01×	2.08×	1.01×	1.90×
MarkUs	1.16×	1.27×	1.17×	1.28×

Table 4: Normalized execution time (perf) and memory usage (mem) in SPEC CPU 2006 and 2017 except `gcc` and benchmarks using Fortran library. Lower is better.

Performance overhead. BUDAlloc shows a moderate performance overhead compared to other systems, with a geometric mean of 1.11× for BUDAlloc in prevention mode, 1.16× for BUDAlloc in detection mode, 1.28× for DangZero, 1.01× for FFmalloc, and 1.16× for MarkUs in SPEC CPU 2006. DangZero reports a higher geometric mean overhead compared to BUDAlloc. This is because, unlike BUDAlloc, DangZero requires virtualization for direct page table access, introducing consistent virtualization overhead across all workloads. Importantly, the performance overhead of DangZero is slower than BUDAlloc in the detection mode (BUDAlloc-d) which detects

every UAF bug like DangZero. While FFmalloc reports almost no overhead in SPEC CPU 2006, it exhibits significantly high memory overhead, as mentioned later. Fundamentally, FFmalloc offers faster performance than detectors like BUDAlloc. FFmalloc does not manage alias-to-canonical mappings, groups small-sized objects into pages to reduce TLB misses, and does not unset a page table after freeing. However, this strategy in FFmalloc leads to delayed detection of UAF bugs and higher memory overheads compared to BUDAlloc. Notably, BUDAlloc is faster than FFmalloc in the `gcc` workload, which has the highest memory operations per second, causing frequent system calls in FFmalloc. Unlike FFmalloc, BUDAlloc manages system calls in the user space, resulting in almost zero system call overhead during high-frequency allocation. It shows comparable results to DangZero's direct page table modification with virtualization. Also, when we compare BUDAlloc with the syscall-based approach Oscar [42], which reports a geometric mean of 1.4× overhead, BUDAlloc demonstrates faster performance.

Memory overhead. Figure 3 shows the memory overhead with default configurations in previous works. BUDAlloc demonstrates an acceptable overhead of geometric mean 1.31× in prevention mode and 1.25× in detection mode. In contrast, FFmalloc exhibits approximately 2.08× memory overhead in SPEC CPU 2006. Notably, FFmalloc experiences significant peaks in malloc-intensive benchmarks such as `omnetpp`, `xalacbmk`, `povray`, and `sphinx3`. This is attributed to high memory fragmentation. To mitigate system call overhead, FFmalloc allocates memory in chunks and delays memory release until at least 8 consecutive chunks can be freed. MarkUs and DangZero exhibit similar memory overhead to BUDAlloc. We find that `sphinx3` incurs the highest memory overhead among all workloads due to its highly fragmented alias address spaces from frequently allocated small chunks with mostly unused pages. However, among the three OTA-based approaches, BUDAlloc demonstrates the smallest memory overhead in `sphinx3`.

Performance breakdown. In Figure 5, we breakdown the performance overhead of SPEC CPU 2006 to discover the impact of BUDAlloc on both user and kernel stack. Notably, allocating aliases incurs less overhead than freeing them, thanks to the user and kernel co-design that avoids system calls for alias allocation. The performance of user-level parts is sensitive to the application memory allocation patterns. For example, in the `gcc` benchmark, the application frequently allocates objects, which puts pressure on the internal memory allocator when allocating canonical address. However, due to the semantic-aware prefaulting, overall kernel time is relatively small in the `gcc`. In the kernel, we observed that the most overhead comes from modifying page table entries. Flushing the TLB incurs a small geomean overhead of 0.09%, less than 2.7% in our implementation for the challenging `omnetpp` workload. This workload puts high TLB pressure on the OTA

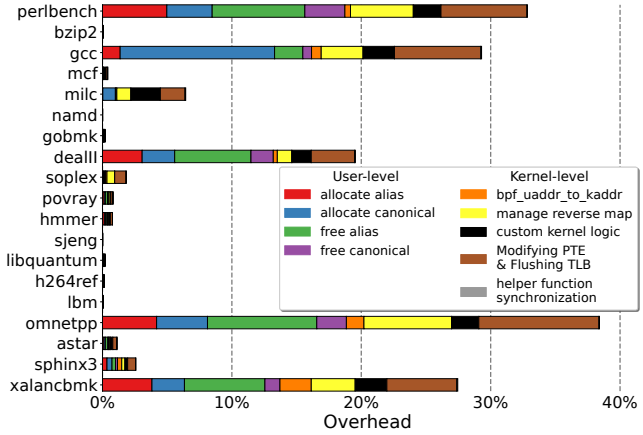

Figure 5: SPEC CPU 2006 performance breakdown.

due to its memory usage pattern. To modify a page table entry, BUDAlloc helper functions traverse the page table iteratively, requiring one iteration per object. Reverse mapping incurs the second-largest overhead, taking up to 6.7% in `omnetpp` and 0.11% on average, mainly due to traversing list entries.

5.3.2 SPEC CPU 2017

BUDAlloc exhibits a moderate performance overhead and efficient memory use compared to previous approaches in SPEC CPU 2017, which aligns with the result from SPEC CPU 2006. The performance overhead of SPEC CPU 2017 is 1.18× for BUDAlloc in prevention mode and 1.23× for BUDAlloc in detection mode while DangZero and MarkUs suffer from 1.31 × and 1.17× slowdown respectively. In terms of memory overhead, BUDAlloc prevention incurs 1.24×, BUDAlloc detection 1.20×, DangZero 1.27×, FFmalloc 1.90×, and MarkUs 1.28×. In the `gcc` benchmark, BUDAlloc shows faster performance (1.07× in prevention and 1.09× in detection) compared to DangZero (1.14×). For benchmarks that use the multithreading Fortran library, the performance overhead is as follows: BUDAlloc in prevention mode is 1.05×, BUDAlloc in detection mode 1.10×, FFmalloc 1.0×, and MarkUs 1.11×. The memory overhead is as follows: BUDAlloc in prevention mode 1.16×, BUDAlloc in detection mode 1.14×, FFmalloc 1.75×, and MarkUs 1.51×. We assume that in the multithreading Fortran library, MarkUs shows the worst performance overhead due to garbage collection. In `omnetpp_s`, BUDAlloc experiences higher performance overhead (2.61×) compared to SPEC CPU 2006, mainly due to the frequent deallocation of small objects in `omnetpp_s`. This increases TLB pressure and unmapping page table overhead, which is fundamentally unavoidable in OTA. In such workloads, BUDAlloc shows distinct trade-offs in the performance and memory overhead; FFmalloc shows a smaller overhead than BUDAlloc in performance, but memory use is 12.32× while BUDAlloc shows 2.8×. Compared to MarkUs, BUDAlloc has a more aggressive memory deallocation policy for small memory objects than MarkUs, resulting in lower performance but less

memory overhead in SPEC CPU 2017.

5.4 Multi-threaded Benchmarks

The PARSEC workload contains a suite of parallel programs for evaluating the performance of multiprocessor systems. Despite its widespread use in literature, the PARSEC 3.0 benchmarks are no longer actively maintained. Consequently, we had to exclude several workloads from PARSEC 3.0 due to issues such as compiled binaries hanging on our system when using GLIBC, as reported in previous studies [44]. Our experiments involved running 15 benchmarks across six different core counts: 1, 2, 4, 8, 16, 32. We evaluate the performance using BUDAlloc, GLIBC, FFmalloc, and MarkUs. We are unable to include DangZero in our evaluations because it lacks support for multithreading applications. Additionally, we omit any failed executions and represent them as white bars in the results. For `canneal`, to ensure an accurate comparison of scalability, we adjust the region of interest (ROI) to exclude the single-threaded parts, which accounted for nearly 85% of the execution time in GLIBC with 32 threads.

To analyze the data, we partition the workloads into CPU-intensive and memory-intensive workloads based on the number of allocation frequency. The highest allocation rate in CPU-intensive workloads is `facesim`, 4,619 per second, while the lowest rate in Allocator intensive workloads is `vips`, 23,343 per second, about 5× higher than `facesim`.

CPU Intensive workloads. In the `blacksholes`, `bodytrack`, `facesim`, `ferret`, `fluidanimate`, `freqmine`, `netferret`, `netstreamcluster`, `streamcluster`, and `x264` workloads, BUDAlloc, FFmalloc, and MarkUs show similar results since these workloads do not heavily utilize memory allocators.

Allocator Intensive workloads. In allocator-intensive workloads, such as `canneal`, `dedup`, `netdedup`, `swaptions`, and `vips`, BUDAlloc shows scalable results, even outperforming FFmalloc in some workloads. Figure 7 illustrates the overall geometric mean of performance improvement normalized by the glibc single thread. FFmalloc exhibits optimal performance with fewer than 4 threads, but BUDAlloc surpasses FFmalloc with more than 8 threads. We observe that FFmalloc eventually encounters bottlenecks due to frequent kernel system calls, which causes the in-kernel global lock contention in the multi-threaded workload. As shown in Figure 6, with more than 32 threads, FFmalloc experiences a significant performance drop in `dedup`, `netdedup`, and `vips`. These benchmarks heavily stress the memory allocator and invoke FFmalloc frequently call `mmap` and `munmap`, which hold a global lock in the kernel.

MarkUs shows the worst performance in these workloads despite similar performance overhead in single-threaded benchmarks with BUDAlloc. These outcomes are unsurprising, as GC-based systems like MarkUs typically involve synchronization between the GC thread and the main thread, which can be severed when there is no dedicated core for offloading. However, BUDAlloc bridges the semantics of user space to manage the metadata lock, enhancing OTA performance in multithreading applications despite the increased bug-detection precision which results in higher page table modification rates.

In `swaptions`, despite the scalability advantages of the BUDAlloc design, BUDAlloc shows worse performance than FFmalloc. This is due to `swaptions` frequently allocating and freeing large objects, placing significant stress on the alias to canonical mapping in OTA. In BUDAlloc, this results in page faults whenever a memory object is accessed and frees the previous alias page for precise bug detection. FFmalloc mitigates these overheads by using large chunks of memory, at the cost of losing bug-detect precision. However, this approach could be configured differently. We conduct tests on `swaptions` using the same logic as FFmalloc for handling large objects. With this configuration, BUDAlloc demonstrates improved performance by approximately 38%, surpassing FFmalloc's performance by about 13% while maintaining a similar memory overhead as BUDAlloc. However, adopting this configuration may lead to significant memory overhead in other applications, similar to FFmalloc. Consequently, we adhere to our original BUDAlloc model for managing large objects.

5.5 Apache and Nginx

We evaluate the performance and memory overhead using the real-world workload of the Apache Web Browser (version 2.4.58) [8] and Nginx [11]. Apache and Nginx Web servers are widely adopted for serving HTTP servers. We connected two Linux machines via an internal 10G network, directly linked by the network interface cards. For the evaluation, we use 16 maximum processes with a 64 Kbytes test set for the server. We tested the benchmark on the GLIBC, BUDAlloc, FFmalloc, MarkUs, and DangZero. Apache adopts a thread-centric approach for the concurrent connections, whereas Nginx adopts an event-driven model using a process. We check the scalability of BUDAlloc in Apache, and memory overhead in Nginx. Unfortunately, we failed to execute DangZero under vhost-net due to kernel panic. We assume that the old kernel version Linux 4.0.0 has some issues with vhost-net which is used by DangZero. Additionally, we encountered null pointer dereference bugs that prevented the execution of Apache, even when using the `pre-fork` mode. As a result, we opted to exclude DangZero from the Apache evaluation.

Apache. As shown in Figure 8, BUDAlloc demonstrates comparable performance, latency, and memory overhead compared to GLIBC. However, FFmalloc shows approximately 8× higher memory usage because Apache frequently allocates and deallocates small objects to handle incoming packets, leading internal allocator fragmentation. MarkUs experiences a significant performance drop under heavy loads after 200 concurrent client connections, as Apache stresses worker threads to serve concurrent client connections, resulting in contention between mark-and-sweep threads and application threads.

Nginx. Unlike Apache, Nginx uses a worker process model

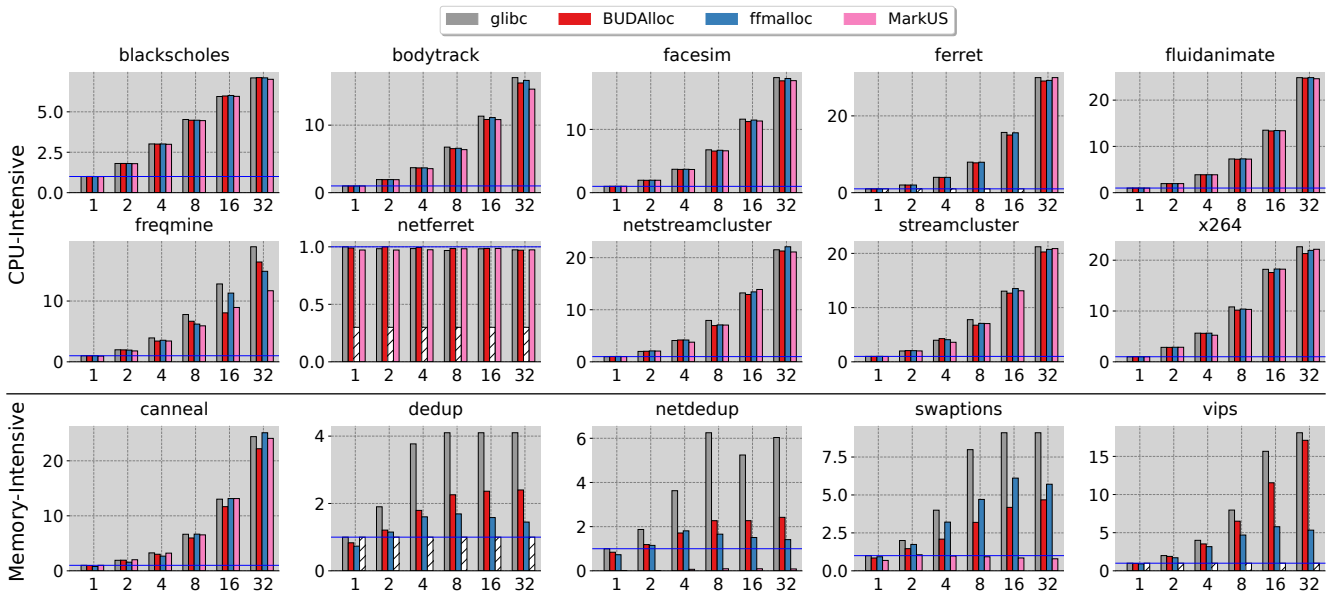

Figure 6: Speedups of PARSEC 3.0 based on the number of threads (higher is better). Performance is normalized to the GLIBC single thread. A white bar indicates that a specific allocator did not run.

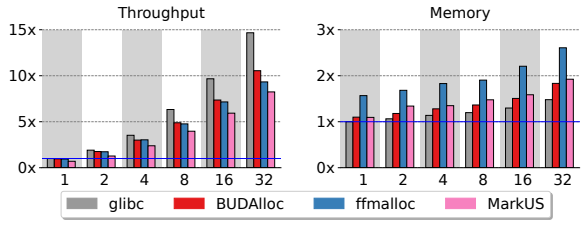

Figure 7: Normalized overall geometric mean for all executable workloads in PARSEC 3.0 with GLIBC single thread. BUDAlloc shows the least memory overhead, and highest scalability, overtaking FFmalloc in more than 8 threads. We replace crashed workload performance with the one of GLIBC to compute the overall geometric mean.

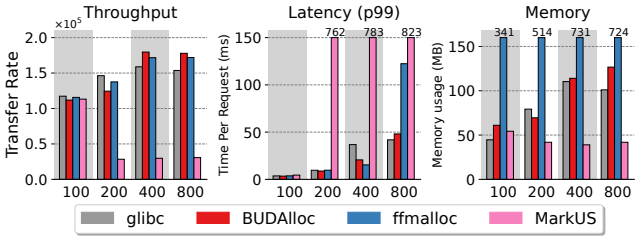

Figure 8: Apache throughput (Requests/sec) and average latency (p99) with varying concurrent connections.

by spawning processes. For Nginx benchmarks, we employed default settings with 400 concurrent connections. BUDAlloc, MarkUs, and FFmalloc exhibited comparable results with GLIBC at 0.98×, 1.04×, and 0.95×, respectively, without significant contention in MarkUs. However, we observed high memory overhead in FFmalloc (7×) and MarkUs (154×), unlike BUDAlloc (1.1×). Unsurprisingly, FFmalloc showed high memory overhead in the malloc-stress settings. Interestingly, MarkUs exhibited the highest peak in memory usage on the Nginx web server. Upon investigation, we believe this may be attributed to memory leaks resulting from false positive detection in MarkUs. This finding aligns with the prior research [25, 45]. DangZero shows around 8.9× performance overhead compared with GLIBC, due to virtualization over the network I/O stack using `virtio` [37].

In summary, only BUDAlloc demonstrates similar performance, memory consumption, and scalability compared to the baselines GLIBC, even with high bug-detecting precision.

6 Related work

Secure heap allocator. Existing work on creating secure heap allocators, such as OpenBSD [13], Cling [18], and DieHarder [34], typically focuses on protecting the metadata of heap allocators by maintaining a bitmap to store allocation states called BIBOP allocator (Big Bag of Pages) [40]. However, BIBOP allocators introduce significant performance overheads from bitmap tracking and synchronization overheads for multithreading applications. FreeGuard [40] solves the performance problem of the BIBOP allocator using a novel combination of both free list (sequential) allocator and BIBOP allocator. However, it fails to protect against use-after-free bugs and still incurs unacceptable memory overhead in certain applications. In contrast to bitmap-based allocators, BUDAlloc maintains free lists for better performance while effectively preventing metadata corruption, by deferring canonical frees until the next page fault handler.

Use-after-free prevention. There are trains of work for preventing use-after-free bugs. These works cannot guarantee detection, but prevent the bugs from malicious attacks. DangNull [28], FreeSentry [46], DangSan [43] and pSweeper [29]

track pointers to all allocated objects and explicitly nullify pointers when the referenced objects are freed. MarkUs [17], and Minesweeper [24] attempt to eliminate UAF bugs using a garbage collector, quarantining freed objects until all references to them vanish from the applications heap, stack, or registers. However, they encounter significant CPU and memory overhead due to traversing dangling pointers.

Use-after-free detection. Compared with the prevention, detecting UAF bugs is more challenging due to the complexity of the mechanisms. Approaches like CETS [32] and Undangle [21] utilize dynamic runtime for detecting UAF bugs. However, they have to inject guards on every memory access or employ heavy runtime taint analysis, resulting in significant performance and memory overhead.

In contrast, tools like Valgrind [16] and AddressSanitizer [38] focus on detecting use-after-free bugs for debugging purposes rather than security. Unfortunately, their mechanisms can be easily detoured by attackers using simple exploitable programs that trigger use-after-free bugs [28].

7 Conclusion

This paper presents a practical OTA designed by separating virtual and physical address management and by co-designing one-time-allocator and virtual address management at the user-level. BUDAlloc showcases well-rounded results in terms of performance, memory use, scalability, and bug detectability compared to FFmalloc, DangZero, and MarkUs.

Abstract

This paper presents a novel attack technique called page-oriented programming, which reuses existing code gadgets by remapping physical pages to the virtual address space of a program at runtime. The page remapping vulnerabilities may lead to data breaches or may damage kernel integrity. Therefore, manufacturers have recently released products equipped with hardware-assisted guest kernel integrity enforcement. This paper extends the notion of the page remapping attack to another type of code-reuse attack, which can not only be used for altering or sniffing kernel data but also for building and executing malicious code at runtime. We demonstrate the effectiveness of this attack on state-of-the-art hardware and software, where control-flow integrity policies are enforced, thus highlighting its capability to render most legacy systems vulnerable.

1 Introduction

Code-reuse attack (CRA) is a category of modern exploit techniques where attackers hijack control flows of legitimate software and transfer the control to existing code snippets, known as gadgets, to utilize them for malicious purposes. Techniques such as return-into-libc [60], return-oriented programming (ROP) [8, 19], and jump-oriented programming (JOP) [3, 15] fall into this category.

A notable series of studies have been conducted on control-flow integrity (CFI) enforcement to prevent control-flow hijacking attacks. The possible execution flow of a program can be approximated using its source or binary code prior to execution. The result can be represented as a control-flow graph (CFG), where a block of code corresponds to a node, and a flow path between nodes is represented as an edge. At runtime, the CFG is used to constrain the flow of control along predetermined forward and backward edges throughout the nodes. By invalidating arbitrary changes in control transfers, CRAs that are enabled by corrupting indirect branch targets of indirect calls, jumps, and returns can be eliminated. A significant number of studies have followed the seminal work [1, 2] on CFI enforcement, and some of them have been adopted to the toolsets used in actual practice [17, 27, 28, 50, 71]. The downside of the CFI policy enforcement is that its performance overhead increases as the number of indirect branches increases.

On the one hand, certain studies [14, 63, 78, 79] have proposed relaxed CFI enforcement policies to improve performance or compatibility. However, these policies have faced vulnerabilities that bypass their lenient enforcement [10, 21, 30, 31]. On the other hand, another group of studies has aimed to improve the precision of CFI enforcement. This has been achieved through techniques such as combining CFG generation with a compilation toolchain [18, 29, 61, 72] or supplementing dynamic data obtained at runtime [22, 35, 43, 44, 62, 73]. Their efforts narrowed down the size of a possible target set of an indirect branch (referred to as an equivalence class) [1, 2].

The CFI enforcement techniques currently in use, such as Microsoft Control Flow Guard (CFG) [50], PaX Reuse Attack Protector (RAP) [71], GNU Compiler Collection (GCC) CFI [28], Clang/LLVM CFI [17], and fine-grain CFI enforcement with indirect branch tracking (FineIBT) [27], employ static analysis during the compilation process to produce CFI policy-enforced binaries. These techniques incorporate the aforementioned studies with an emphasis on practicality and deployability. Some of them have even adopted hardware-based control-flow enforcement mechanisms [4, 38].

A critical requirement shared by most CFI enforcement research is *non-writable code*, which implies that code memory should be immutable at runtime. When CFI is enforced at the user level, the immutability can be maintained as long as a program itself does not modify access rights to its code memory, and the kernel sets the page table attributes to read-only. Unfortunately, this implies that CFI at the kernel level is neutralized with page table modification if a vulnerability in the kernel allows an attacker to read and write arbitrary data to memory [23, 45]. To ensure code immutability, hypervisor-level authority can be utilized [33, 66, 68], and the practicality of this approach has been showcased by Microsoft

Windows [52].

In this paper, we present a novel form of data-only attack (DOA) called page-oriented programming (POP). POP enables an attacker to create an arbitrary control flow by executing a page-level CRA. It leverages direct branches in non-writable code memory and remaps desired gadgets in pages to the branch targets by modifying page tables. The state-of-the-art CFI enforcement focuses solely on ensuring the safe transfer of control through indirect branches. Meanwhile, in cases where hypervisor-based write protection is in place, an additional address translation layer is introduced by the hypervisor. This layer maps the OS's physical addresses (i.e., guest physical addresses) to their corresponding physical addresses (i.e., host physical addresses) with read-write-execute permissions. However, this mechanism does not delve into mappings of logical addresses to guest physical addresses within the OS. POP exploits these blind spots by remapping the virtual address of the direct branch target to the physical address of the gadget within the kernel. Consequently, POP circumvents current CFI implementations in a novel way.

Our POP involves three steps: page carving, page stitching, and page flushing. First, an attacker creates a list of gadgets and system calls that are carved out of the kernel binary. Second, the attacker creates a new control flow to a security-sensitive function by chaining these gadgets together. The physical pages containing the gadgets are then stitched together, along with the created control flow, after modifying the page tables. Finally, the attacker may need to flush stale information from the translation lookaside buffer (TLB) of the CPU after altering the page tables to ensure that the new mappings between the virtual and physical addresses are functional.

We explain the concept of POP and illustrate its three steps. We first transpose a real-world vulnerability into an up-to-date system that offers hypervisor-based kernel integrity protection, featuring both hardware and software-based CFI mechanisms. Subsequently, we present a proof-of-concept exploit that allows a user-level application to establish a new control flow leading to a security-sensitive function, ultimately achieving privilege escalation despite state-of-the-art CFI protections. This demonstration highlights the feasibility and effectiveness of the POP scheme.

2 Background

Numerous studies have been conducted on CFI thus far, resulting in a diverse range of research outcomes. These outcomes can be broadly categorized into academic achievements and practical applications.

2.1 Control-Flow Integrity

Academic Achievements. CFI studies aim to obtain more detailed information by implementing it within compiler

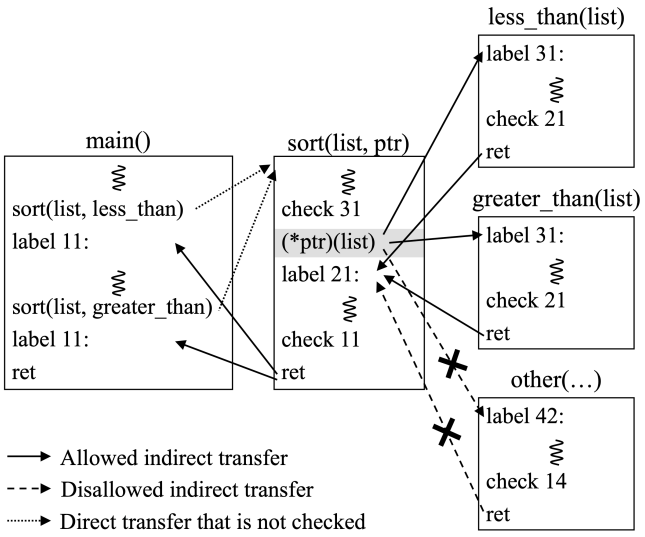

Figure 1: Example of a control-flow graph and control-flow integrity

toolchains and creating a more precise CFG. Modular CFI (MCFI) [61] utilizes a function label per unique function signature to restrict indirect branches and support module linking. Kernel CFI (kCFI) [29] enhances CFG precision by incorporating jump tables and restricted pointer indexing. PittyPat [22] and μCFI [35] use dynamic instrumentation using Intel Processor Trace (PT) [38] to obtain more precise indirect branch targets. CFI with look back (CFI-LB) [44] and origin-sensitive CFI (OS-CFI) [43] add call-site information of indirect branches. Notably, OS-CFI utilizes additional data on function pointer origin, resulting in the reduced size of the equivalence class.

This series of trials exhibited two limitations. One limitation was the performance overhead. At runtime, CFI introduces the additional burden of testing whether each indirect branch is directed toward a predetermined set of nodes (Figure 1). While Abadi et al. [1, 2] excluded direct branches from consideration, assuming that the destinations of direct branches (the dotted arrow in Figure 1) are not easily replaceable, their work still resulted in an execution overhead of up to 45%. Recent research [43] has made progress in reducing the overhead, but it is still over 14% at the NGINX benchmark. The other limitation is the incompatibility with legacy systems. The aforementioned CFI studies require source code for precise CFG generation during the pre-analysis process. Some of them [22, 35] even rely on traces of dynamic instrumentation obtained from the CPU at runtime. However, legacy commercial-off-the-shelf (COTS) binaries and CPUs are unable to meet the requirements of these studies.

CFI for binary executables (Bin-CFI) [79] and compact CFI and randomization (CCFIR) [78] enforce CFI on COTS binaries by analyzing binary executables instead of relying on

CFI Implementation	Commodity OS	Forward Edge Policy	Backward Edge Policy
Microsoft CFG [50] with CET [4, 38]	Windows	Bitmap-based verification	Hardware-based shadow stack
PaX RAP [71] (open-source version)	Linux	Type-based verification	Type-based verification
GCC CFI [28] (only CET)	Linux	Hardware-based indirect branch tracking	Hardware-based shadow stack
Clang/LLVM CFI [17] with CET	Linux, Windows	Type-based verification with hardware-based indirect branch tracking	Hardware-based shadow stack or shadow call stack (only for AArch64)[1]
FineIBT [27] (embedded with CET)	Linux	Type-based verification[2] with hardware-based indirect branch tracking	Hardware-based shadow stack or shadow call stack (only for AArch64)

Table 1: Control-flow integrity implementations currently in use and their policies for commodity OSes

source code. These approaches enforce relatively relaxed policies, resulting in lower overhead as compared to the CFI techniques based on the precise CFG. Conversely, the kBouncer [63] and ROPecker [14] techniques aimed to detect ROP patterns at runtime by leveraging a hardware-provided feature, that is the Last Branch Record (LBR) of Intel, which stores recently executed branch history. These approaches loosen the restrictions in policy enforcement to improve performance; however, this trade-off can result in attacks that bypass their CFI policies [9, 10, 21, 30, 31].

Practical Applications. Among the various CFI implementations, the most notable ones have already been adopted into the two major commodity OSes: Microsoft Windows and Linux. Table 1 summarizes the CFI implementations that are currently used.

In Microsoft Windows, a software-based forward-edge protection called CFG is developed, which can be optionally equipped with Windows 10 and 11 series. Moreover, a hardware-based backward-edge protection mechanism called shadow stack is employed. This mechanism is built on Control-flow Enforcement Technology (CET) that has been commercialized by Intel.

In Linux, several major compilers support CFI protections. First, RAP provides type-based indirect branch protection. Additional backward-edge protection can be achieved through return address duplication and encryption. Second, GCC supports the indirect branch tracking and shadow stack features of CET for CFI protection. Third, Clang/LLVM offers its own type-based forward-edge protection and software-based shadow call stack for backward-edge protection. Recently Clang/LLVM has also adopted CET. Starting from November 2022, the Linux kernel has enabled a hybrid CFI protection scheme, called FineIBT, which ensures the accuracy of the forward indirect branch by validating the hashes of functions and using CET. In the case of FineIBT, the hash validation is performed by callees, whereas in other schemes, it is performed by the callers. Notably, the hardware-based backward-edge protection, shadow stack, is only applicable to the userspace in Linux, while the other CFI implementations can be applied to both user applications and the kernel.

[1] AArch64 of ARM only supports the feature. It was integrated for the x86_64 system but later removed owing to performance overhead and race condition problems [48].

[2] PaX RAP and Clang/LLVM CFI employ a caller-side verification policy, whereas FineIBT employs a callee-side verification policy.

2.2 Code Immutability and Protection Mechanisms

Code region must be preserved as non-writable at runtime since CFI policies cannot be enforced on dynamically generated or self-modified code [1, 2]. The responsibility for ensuring the immutability of user- and kernel-level code memory has been given to the kernel.

Data-Only Attack. It is an attack technique that manipulates non-control data [34, 36, 39, 70] without violating CFI policies. Data-only attacks (DOAs) are effective when the kernel or drivers have memory access vulnerabilities [55, 56]. These vulnerabilities would allow an attacker to break the kernel address space layout randomization (KASLR) and gain escalated privileges by modifying credentials. Moreover, if the vulnerability enables reading and writing arbitrary memory [53, 54], the attacker could manipulate both user- and kernel-level code. This manipulation can occur even when CFI enforcement is in place by altering page tables that are supposed to be protected by the kernel [20, 23, 45].

Hypervisor-Based Kernel Integrity Protection. Recent hardware-based virtualization processes support hypervisors in enforcing strong security policies. Running at a higher privilege than the kernel, the hypervisor utilizes second-level address translation (SLAT), which allows the hypervisor to set page permissions separately from the kernel. Moreover, Mode-Based Execution Control (MBEC) from Intel [38] and Guest Mode Execute Trap (GMET) commercialized by AMD [4] impose further restrictions on code page execution, which is determined by the execution modes designated as either user-mode or supervisor-mode. These features cooperate with the SLAT and enable sophisticated page permissions. Consequently, modern operating systems employ the hypervisor as

a monitoring and controlling entity with elevated privileges. While the 12th generation CPU products from Intel provide Hypervisor-managed Linear Address Translation (HLAT) to ensure page table integrity for the kernel, SLAT with MBEC or GMET is a widely adopted feature in modern CPUs. Further discussion on this topic is presented in Section 7.

Secvisor [68] and NICKLE [66] can maintain kernel code integrity with hypervisor-level authority, and their implementations in Linux have been demonstrated. The current Microsoft Windows series include a feature called Hypervisor-Protected Code Integrity [52], which provides virtualization-based memory integrity for kernel code. These hypervisor-based mechanisms utilize SLAT to translate the physical addresses used in the guest OS to the physical addresses in the host OS. During this second-level translation process, the CPU ensures that the access to physical pages adheres to the defined page attributes. For instance, if a process in the guest OS attempts to write to an address on a page that is marked as executable only and not writable, an exception occurs during the SLAT process. The hypervisor can interpret this as a code modification attack. Similarly, if an exception occurs when data is written to read-only credentials, the hypervisor may consider it as a credential modification attack. Furthermore, if an exception is raised while executing code in kernel mode and the code is located in a code page that lacks the supervisor-execute permission of MBEC and GMET, the hypervisor may identify it as a control-flow hijack or an unauthorized kernel code injection. For the purpose of data protection, Credential Guard [51] from Microsoft utilizes a virtualized enclave to store security-sensitive data such as credentials. A framework called PrivWatcher [41] was also proposed, which includes a hypervisor-based read-only safe area where credentials can be securely stored, and its prototype was implemented in Linux.

The CFI enforcements in commodity OSes have evolved to incorporate stronger countermeasures against traditional CRAs and page table attacks by leveraging hardware assists and the notion of hypervisors [17, 27, 50, 52, 66, 68].

3 Assumption and Threat Model

We assume our target system is fortified with cutting-edge CFI protection mechanisms. Namely, hardware-assisted CFI policies and hypervisor-based kernel integrity protection prevent control-flow hijacking techniques like ROP and JOP. Additionally, the page-level write protection [33, 52, 66, 68] and read-only safe area scheme [41, 51] of the protection mechanisms thwart unauthorized code alterations, code injection, and unauthorized modifications to kernel credentials. Thus, an attacker has to invoke legitimate kernel functions to perform malicious behaviors such as privilege escalation and spawning a root shell.

We have the same set of assumptions regarding system vulnerabilities and the capabilities of potential attackers as in prior studies [6, 20, 65, 68, 71]. Specifically, the system has an arbitrary kernel memory read and write vulnerability. By exploiting it, an attacker can manipulate page tables, disable KASLR, and manipulate the kernel of the system. The attacker, possessing local user privileges as in previous studies [20, 23, 45], can also execute system calls and programs, thereby collecting system information such as the kernel binary, the size of system memory, and the list of kernel symbol names. Leveraging these capabilities, the attacker may attempt typical control-flow hijacking techniques and kernel modification. However, these trials must be hindered by the presence of CFI policies and the hypervisor running on the system.

4 Motivation

Contemporary CFI approaches are fortified by the kernel CFI policies, which control indirect branches, and by the hypervisor, which ensures the sanity of the kernel during the second-level address translation process. In other words, direct branches and page-mapping information inside the OS have been out of the spotlight. Our study revisits DOAs against page tables, shedding light on the blind spots.

Kernel Control-Flow Integrity Policies. Most of the CFI-related studies, including hardware-assisted kernel CFI, have primarily concentrated on validating indirect branches, overlooking the direct branch targets. This oversight is attributed to the assumption that the targets reside in read-only code memory. However, if the immutability of code memory cannot be guaranteed, the effectiveness of most CFI implementations must be reassessed.

Non-Writable Code Mechanism. As shown in Figure 2a, the kernel code is protected by SLAT. A normal function, kern_normal(), resides at the guest logical address (GLA) `0xffff1100`, while a security-sensitive function, kern_sensitive(), is located at GLA `0xffff2100`. Based on the page table, their corresponding guest physical addresses (GPAs) are translated as `0xff001000` and `0xff002000`, respectively. These GPAs are then translated again by the hypervisor via SLAT, resulting in the host physical addresses (HPAs) of `0x00001000` and `0x00002000`, respectively.

Let us consider a scenario where an attacker attempts to modify the code of kern_normal() and successfully manipulates an attribute of the page in the page table, as shown in the upper-left corner of Figure 2b. However, because the corresponding page in the SLAT table still does not grant write permission, an exception occurs, leading to termination. In the case of page injection, as depicted in the lower-left corner of Figure 2b, an arbitrarily injected page cannot have a corresponding page in the SLAT table or be granted execute permission without authorization from the hypervisor. Consequently, this situation triggers an exception.

The "RWX" access control during SLAT can offer write-protection for code pages; however, it is unable to ensure the integrity of the kernel code. Figure 2c illustrates a sce-

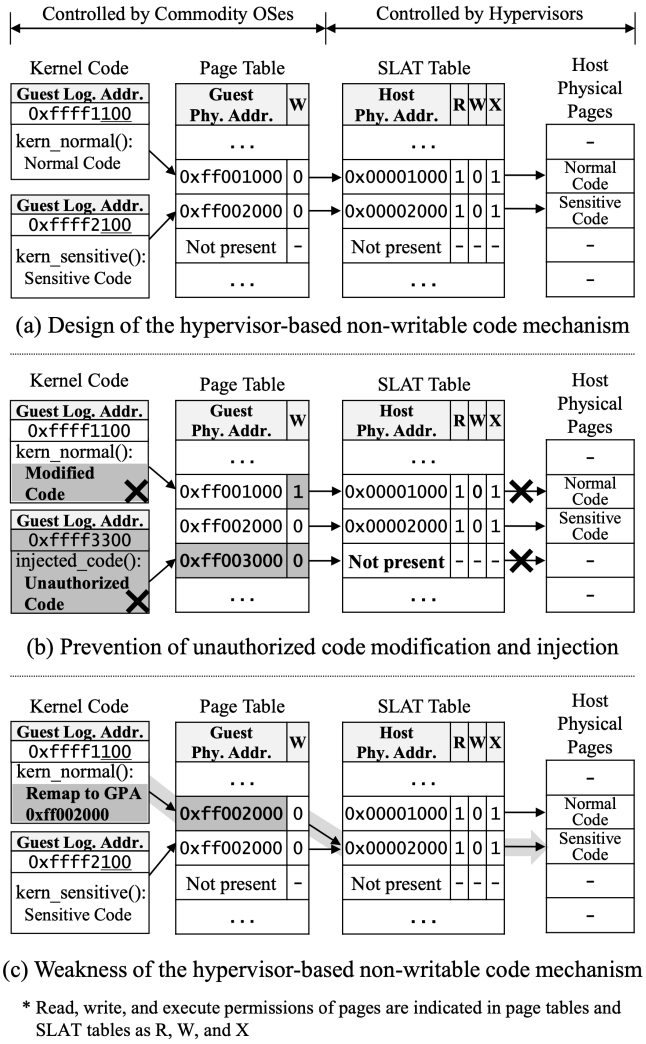

Figure 2: Effectiveness and weakness of the hypervisor-based non-writable code mechanism

nario where the physical page mapped to kern_sensitive() is remapped to kern_normal(). This remapping can be achieved by modifying the page tables, particularly when the two functions share the same page offset, such as `0x100`. If the GPA of kern_normal() (`0xff001000`) is changed to match the GPA of kern_sensitive() (`0xff002000`), SLAT will translate it to the corresponding HPA (`0x00002000`) when the attacker invokes kern_normal(). Consequently, the code of kern_sensitive() will be executed, and the attacker can even pass arbitrary arguments to the function. This scenario hints at the possibility of a page-level CRA.

Revisiting DOAs against Page Tables. Traditional page table attacks focused on enabling write permission for immutable pages. Some attacks corrupted code or read-only function pointers [20,23,45,75], while others duplicated pages to evade hardware-based external monitors [40]. By utilizing arbitrary kernel memory read and write vulnerabilities, the traditional attacks were achieved by (i) changing the permissions of page tables directly, (ii) duplicating and inserting physical pages with new page table entries, or (iii) remapping page table entries to existing physical pages. Although the attack techniques led to identical results for the attacker, we discovered a new capability of page remapping, especially remapping arbitrary virtual addresses to existing code pages. In other words, if we identify page-level gadgets, we can reuse them to perform ROP-like attacks. The page-level CRA technique is the core part of exploiting two blind spots we found.

We discover a new pathway leading to the same goal of traditional CRAs by remapping arbitrary virtual addresses to existing code pages. We identify page-level gadgets and link the gadgets to direct branch targets. That results in creating an arbitrary control flow circumventing CFI policies and hypervisor-based protection in Section 5.

5 Page-Oriented Programming

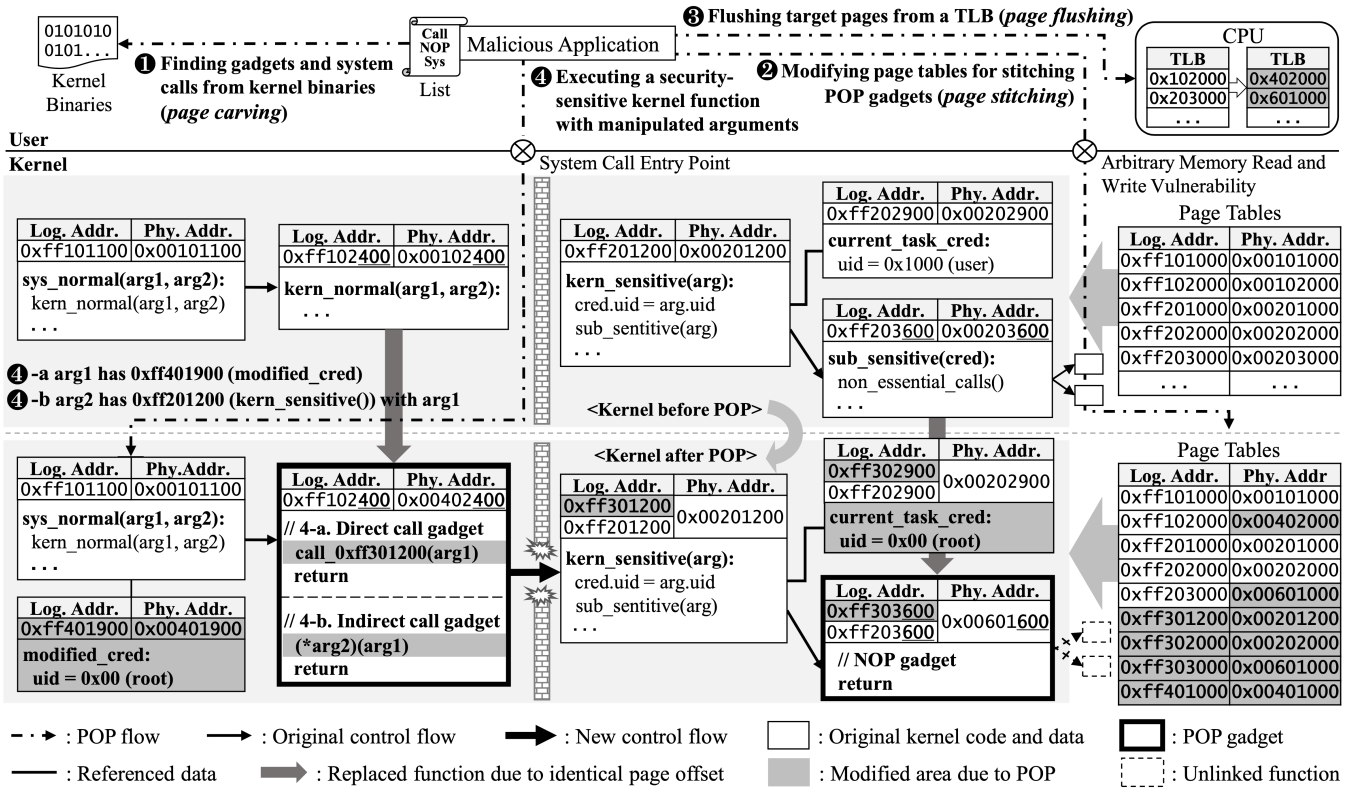
5.1 Overview

POP is a new type of CRA that can circumvent robust security enforcement, including kernel CFI and hypervisor-based kernel integrity protection. It primarily focuses on the direct branches and performs a page-level CRA by remapping the physical addresses of the gadgets to the branches and chaining them together. It sets up new control flows from system call functions to security-sensitive functions within the kernel.

Characteristics of POP. Our POP attack can occur even on state-of-the-art CFI protection schemes, in contrast to typical ROP attacks [8, 15, 19, 60], which manipulate stack or heap memory, and page table attacks [20,23,45,75], which modify kernel code. Additionally, as depicted in Figure 3, the POP technique offers a notable merit of intuitively passing arguments by invoking a system call and chaining a few gadgets. Consequently, it does not require any complicated argument passing or stack pivoting. POP consists of three steps: (i) page carving, (ii) page stitching, and (iii) page flushing.

Page Carving. Before reaching the security-sensitive function, kern_sensitive(), gadgets and system call candidates must be identified from kernel binaries (❶). These gadgets are of two types: *call gadgets* for function chaining and *no-operation (NOP) gadgets* that serve to prevent the remapping explosion, which is presented in Section 5.3. Gadgets can be identified by analyzing a kernel binary file or an extracted binary image from the kernel memory.

Page Stitching. The system call candidates and gadgets are combined through page stitching, which creates new control flows by remapping physical pages to logical addresses (❷). In the page stitching step, an attacker frequently exploits an arbitrary kernel memory read and write vulnerability to manipulate page tables, as discussed in Section 3. Let us assume that the logical and physical addresses of kern_normal() are



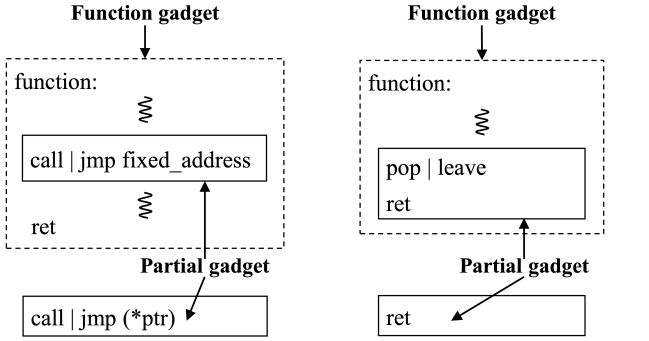


Figure 3: Page-oriented programming (POP) overview

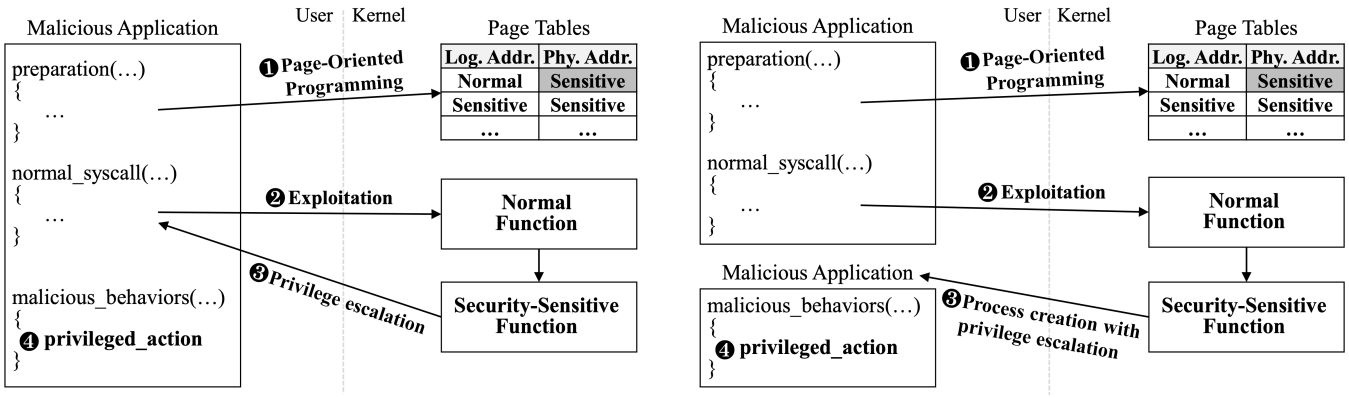
`0xff102400` and `0x00102400`, respectively, and their page offset is `0x400`. This implies that any gadget with the same page offset can replace the function. Consequently, the attacker can create a new control flow by replacing the page with a call gadget located at the physical address `0x00402400`, as shown in the lower-left part of Figure 3.

The call gadgets that were previously gathered are divided into two types: *direct* and *indirect call gadgets*. In particular, when using *direct call gadgets*, additional page remappings are required according to the target logical address. As illustrated in the lower-left part of Figure 3, let us assume that a new control flow has been created over `0xff301200` using the direct call gadget; then, the sensitive function and related data, kern_sensitive() and curret_task_cred, respectively, must be remapped to `0xff301200` and `0xff302900`, respectively. In the case of *indirect call gadgets*, these page remappings are not necessary. If a target function is non-essential, such as sub_sensitive(), it can be replaced with a NOP gadget whose physical page is `0x00601600` and is unlinked with the fall-through. Furthermore, as shown in the lower-left corner of Figure 3, if arbitrary data, such as modified_cred, are required, the attacker can forcibly inject it into the page table for subsequent exploitation. The attacker can then pass the data to the target system call as an argument.

Page Flushing. POP specifically focuses on remapping page



(a) Call gadgets (b) No-operation (NOP) gadgets

Figure 4: POP gadget types

tables in the kernel and does not modify the TLB cache entries that are accessed when invoking a system call. If the original and remapped pages are mixed in the TLB, the exploitation may fail. To this end, POP must be able to flush the TLB entries by executing or accessing kernel pages that trigger the flushing algorithm of the TLB (❸).

At the end of POP, as shown in the upper-middle part of Figure 3, the attacker finally proceeds to invoke a system

(a) Round-trip type exploitation

(b) One-way type exploitation

Figure 5: Two types of exploitation strategies of POP

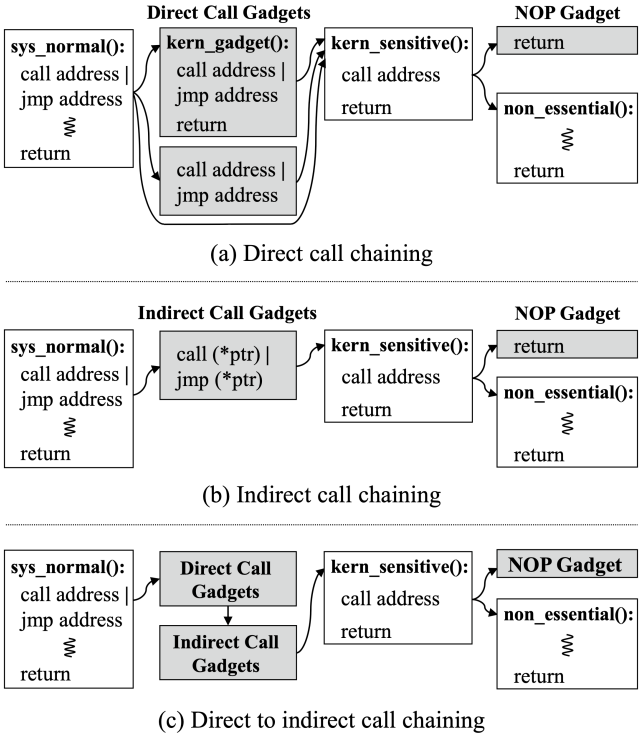
call with arbitrary arguments that will eventually be chained to the target function, that is, kern_sensitive(), in the kernel (❹). Using the direct call gadget, the attacker passes the first argument, `arg1`, which specifies the address of modified_cred (`0xff401900`) holding root credentials via sys_normal() (❹-a). Otherwise, for the indirect call gadget, the attacker should pass the argument containing the address of kern_sensitive() (`0xff201200`) along with `arg1` through sys_normal() (❹-b). Consequently, current_task_cred, shown in the lower-right of the figure, is updated, and the attacker gains the administrator privilege, known as root.

Next, we describe the details of our three-staged POP technique, which aims to subvert state-of-the-art CFI protection mechanisms.

5.2 Page Carving

Gadgets for POP are categorized into two types based on their purpose: *call gadgets* (Figure 4a), which chain the system call candidates to the security-sensitive functions, and *NOP gadgets* (Figure 4b), which unlink non-essential functions if required. Moreover, based on their forms, these gadgets can be classified into *function gadgets*, which utilize the entire functions, and ROP-like *partial gadgets*, which only leverage specific code pieces as required. Note that call gadgets with indirect branches are considered partial gadgets because the CFI policy enforces indirect branches within functions.

The page carving step is a process that extracts the candidates for call gadgets, NOP gadgets, and system calls from kernel binaries and creates a list. The kernel binaries are disassembled and converted into assembly code. Function gadgets are then extracted from this result, encompassing all functions within the kernel. Partial gadgets are obtained by examining each page offset, disassembling the code pages of the kernel binary from page offset 0 to 4095, and converting them into assembly code. Owing to disassembling of arbitrary instruction sequences, some of the partial gadgets have invalid instructions. Therefore, they are removed from the list. System call candidates are also identified from the assembly code by utilizing system call-related information, such as the system call table and symbol names. They are included in the list as well. System call candidates can also be considered part of the gadget if they contain direct branches.



When identifying gadgets and system call candidates, we considered the two strategies for exploitation flows, as illustrated in Figure 5: (i) *round trip*, where the control flow executes a security-sensitive function and then returns to the caller, and (ii) *one way*, where the control flow executes the security-sensitive function without the need to return.

In the *round-trip* strategy (Figure 5a), an attacker regains control after exploiting the system via POP. In this case, the attacker can gain escalated privilege and perform additional procedures, such as modifying system files and gaining a root shell within the malicious application, by returning to the exploitation point. In the round-trip strategy, the pair of call and return instructions are required when chaining gadgets.

In the *one-way* strategy (Figure 5b), the attacker performs similar operations as in the round-trip approach, except that the security-sensitive function must execute attacker-targeted applications, including the malicious application with escalated privilege. Unlike the former, the control flow does not return to the exploitation point. Therefore, the pair of call and return instructions need not be considered.

5.3 Page Stitching

The page stitching step, a core component of POP, chains the previously collected gadgets and system call candidates. This step identifies new control flows capable of reaching a security-sensitive function and employs arbitrary memory read and write vulnerabilities to remap the page tables. The step consists of the following four phases: chaining gadgets,

(a) Direct call chaining

(b) Indirect call chaining

(c) Direct to indirect call chaining

Figure 6: Different methods of chaining gadgets. POP gadgets are shown in gray boxes.

avoiding the remapping explosion, modifying page tables, and allocating free physical pages.

Phase 1 - Chaining Gadgets. This phase involves chaining gadgets that link the system call candidate to the security-sensitive function along with arguments. As shown in Figure 6, we define three types of gadget chains: (i) direct, (ii) indirect, and (iii) direct to indirect calls. These gadget chains cater to both round-trip and one-way exploitation strategies, as discussed in Section 5.2.

(i) Direct call chaining (Figure 6a) consists of call and jump instructions. The gadget can be directly chained to a security-sensitive function if the page offset of the direct branch in it matches the page offset of the sensitive function. Otherwise, the gadgets need to be chained by combining other call gadgets until the chain reaches the sensitive function. Ideally, the system call candidate can also reach the sensitive function if their page offsets are identical, resulting in the shortest gadget chain in POP.

(ii) Indirect call chaining (Figure 6b) typically links only with an indirect branch. POP creates a new control flow by chaining a single indirect call gadget, as it can invoke an arbitrary function allowed by the CFI policy.

(iii) Direct to indirect call chaining (Figure 6c) combines both direct and indirect call chains. It is used if the aforementioned chains are not affordable, although it is a longer path to the sensitive function.

Direct call chaining requires the remapping of additional pages. When the logical address of the security-sensitive function is modified, the physical pages containing subfunctions and data within the sensitive function must be remapped accordingly. If the gadgets used for page stitching involve subfunctions and data, they must also be remapped correspondingly. The remapping process varies depending on the addressing mode employed. For example, we need to identify the base address of the segment or address of the instruction to calculate the exact value when segment- or instruction pointer-based addressing mode is used, respectively. The addressing modes are detailed in Section 6.1.

When exploiting the security-sensitive function with data arguments, the size of a logical address has to be considered along with the gadget chain and system call candidate. Let us assume that the system call candidate is invoked with a 4-byte argument, which contains the logical address of the malicious credentials to be passed to the sensitive function. In this case, the upper 4 bytes of the argument will be trimmed, and only the lower 4 bytes will be delivered to the sensitive function, even though an 8-byte argument is passed through the system call. Consequently, the physical page of the malicious credentials needs to be remapped to an address within the 4 GB address space, and the 4-byte argument is passed to the sensitive function.

Phase 2 - Avoiding the Remapping Explosion. For reliable exploitation, page remappings should be minimized, which causes code changes in the logical address space. This can be achieved by prioritizing the selection of gadgets with indirect calls and shorter lengths, without subfunctions and data references, and those on a single physical page. However, if an exploitation method other than direct call chaining is not applicable, hundreds of physical pages may need to be remapped depending on the structure of a security-sensitive function. The importance of subfunctions and data must be determined to prevent this *remapping explosion*, and non-essential ones must be remapped using NOP gadgets to unlink function calls, as shown in Figure 6. Data also need to be remapped to dummy physical pages. Note that employing the unlinking technique, which replaces the fall-through with the NOP gadget, can be used to weaken the security features of the sensitive function.

Phase 3 - Modifying Page Tables. The vulnerability of arbitrary memory read and write is leveraged to remap page tables with the chained gadgets and data. As described in Section 3, we assumed that an attacker can exploit kernel vulnerabilities to obtain useful symbol information from the kernel. Consequently, the attacker can traverse the process list, obtain the page tables of the malicious application, and modify them according to the gadget chain.

If the attacker forcibly modifies the page tables of the kernel code area, it may cause side effects on other processes that

share the same kernel code. To resolve this issue, we utilize private page tables to prevent the propagation of changes to all processes. Whenever we need to modify the original page tables, we allocate private page tables using the following free page allocation methods of POP. The pages are initialized by copying data from the original page tables, and the copied pages replace them. For instance, in the x86_64 Linux system, the top-level private page table is set to the CR3 register of the CPU by modifying the target process context within the kernel, such as the task_struct and mm data structures. Lower-level private tables replace the original ones by modifying related entries in higher-level page tables [40]. Additionally, commodity OSes typically employ large pages, such as 2 MB and 1 GB pages, for the linear address space. In that case, private page tables have to be allocated by extending the large page to 4 KB pages.

Phase 4 - Allocating Free Physical Pages. New physical pages have to be allocated to create private page tables. They are also required even when passing data as arguments to the system call candidate during the exploitation process. Securing these new physical pages can be achieved by (i) allocating pages from the free physical page pool in the kernel or (ii) obtaining them from the process heap area.

The kernel manages a pool of free physical pages to handle system memory efficiently and sequentially allocates pages when necessary. Allocating pages from the kernel exploits this characteristic. When free pages are needed, the method arbitrarily obtains them from the end of the pool to the beginning with a simple counter. It is a straightforward process and does not need memory allocation functions of the kernel. However, when the system memory is exhausted, the kernel will overwrite the allocated pages.

On the other hand, the heap is an isolated area for each process. Therefore, obtaining free pages from the heap can result in individual availability of free pages. However, the method requires traversing the page tables of the process to determine their physical pages.

5.4 Page Flushing

The remapped addresses resulting from the page stitching step may interfere with previously cached addresses in a TLB. Therefore, it is crucial to flush the TLB prior to exploitation. In commodity OSes, the TLB entries are frequently flushed as their memories are exhausted by applications, system services, and interrupts. This implies that TLB entries associated with the pages that were forcibly remapped are flushed out in adequate time after page stitching. Unfortunately, in x86_64 systems, the page table has a global bit that delays the flushing. This global bit is used for kernel code pages that are used in process-wide sharing. As such, to accelerate TLB flushing, the page flushing step unsets the global bits of the entries that are remapped through the page stitching step. Moreover, it leverages the CPU affinity to perform exploitation and page flushing on the same core because of the independent TLB for each CPU core.

6 Evaluation

POP is not only a practical but also an effective CRA under state-of-the-art CFI enforcement. To demonstrate its effectiveness, we revisited a real-world page-remapping vulnerability, CVE-2013-2595 [53], along with its exploit code [64] on a Linux system. The vulnerability allows arbitrary remapping of physical pages to the userspace. Consequently, an attacker can read and write arbitrary kernel memory and conduct typical page modification attacks, such as altering kernel code or credentials. However, hypervisor-based kernel integrity protection can prevent these typical page modifications, as discussed in Section 3. To show the page-level CRA still functions under the CFI enforcement, we rewrote the exploit code only with the arbitrary memory read and write capability and POP technique. Additionally, we assessed the distribution of system call candidates and gadgets across various kernel versions and configurations to demonstrate the feasibility of POP.

The evaluation was conducted on an HP Victus 16 laptop, which features an Intel i7-12700H processor and 16 GB of memory. To enable Clang/LLVM CFI with CET and FineIBT, we employed Linux kernel versions 6.1.12 and 6.2.8, respectively, and compiled these kernels using LLVM 6.0.0 on Ubuntu 22.04.2. To leverage the SLAT and MBEC features, we extended an open-source lightweight hypervisor [33] and integrated hypervisor-based kernel integrity protection. We ported CVE-2013-2595 to our vulnerable kernel driver and executed it for evaluation. The code and data we used are accessible via our GitHub repository [32].

At the time of writing, a shadow stack feature was incorporated in the Linux kernel. Therefore, we did not utilize this feature in our evaluation. However, the evaluation results were not affected by it because POP does not rely on stack corruption techniques.

6.1 Proof-of-Concept Exploitation

We constructed a PoC exploit for the Linux kernel version 6.2.8 with FineIBT. Another exploit for Clang/LLVM CFI with CET is not significantly different, except for the address values. As several CRA studies [3, 8, 15, 19] have shown the effectiveness of indirect call gadgets, we developed a round-trip type exploitation scenario to demonstrate the distinctive differences and characteristics of POP. One of the strengths of POP is the ability to provide attackers with the flexibility to select arbitrary entry points with arguments. To emphasize this advantage, we intentionally chose a system call candidate whose direct branch aligns with the page offset of the security-sensitive function and whose argument has a length of 64

Symbol Name	Offset Value	Usage
sys_call_table	0x1400400	Breaking KASLR

bits. This enabled us to create a new control flow using the minimum number of gadgets.

Preparation of Attack Primitives and Page Carving. To perform POP, an attacker must acquire symbol information and data structures from the kernel. In Section 3, we assumed that the attacker could run arbitrary programs locally and exploit a kernel memory read and write vulnerability. As a result, we obtained the kernel binary from the boot directory of the system and disassembled it using the objdump tool. Within the kernel binary, we located the kallsyms_offsets table to access symbol information. The table contains the offset of each kernel symbol and is composed of hundreds of 4-byte values in a continuously growing format. We identified the table by searching for its distinctive feature within the kernel binary. To complement symbol names to the table, we extracted them from the /proc/kallsyms file because its symbol list originates from the table [42]. We then added symbol information to the kernel assembly code. Finally, we collected system call candidates and gadgets through static analysis of the assembly code we generated, as discussed in Section 5.2. We employed the Python scripting language for it and compiled a list for page stitching.

To access the kernel area from the user level and break KASLR, we first read the /proc/meminfo file to obtain the system memory size. Then, we exploited CVE-2013-2595 to map all physical memory to the user area and searched the start address of the kernel code by matching its signature in every 4 KB page. Once we found the start address of the kernel, we could read and write arbitrary kernel memory using this address along with symbol information. KASLR loads the kernel into a random location each time the system boots. To defeat it, we needed to obtain the address of an arbitrary kernel function. The kernel stores the addresses of system call functions in the sys_call_table array, and the first system call is sys_read(). Therefore, the first value in sys_call_table contains the address of __x64_sys_read() (`0xffffffffbbe6fda0`). By subtracting the offset value of __x64_sys_read() (`0x46fda0`) within the kallsyms_offsets table from it, we obtained the base address of the kernel code (`0xffffffffbba00000`) and broke KASLR. Using the base address, we consequently mapped kernel virtual addresses to userspace virtual addresses. Hereafter, we refer to kernel addresses calculated based on the default kernel address (`0xffffffff81000000`).

We identified kernel structures by analyzing the kernel assembly code with the symbols to trace runtime kernel data. For example, we obtained each offset of the field in the task_struct and cred data structures by analyzing clear_tasks_mm_cpumask(), prepare_kernel_cred(), and __set_task_comm() that modify the fields. We also reconstructed the mm_struct data structure from pgd_alloc() to manipulate page tables. Using the data structures, symbol information, and the base address of the kernel, we traversed the init_task variable (`0xffffffff8301bb00`) with the well-known technique that traces linked lists [25] to obtain the task_struct data for the malicious application. We also accessed the top-level page table information for page stitching with the pgd field of the mm_struct data structure within the task_struct data. Furthermore, by reading the page_offset_base variable (`0xffffffff829d7008`), we obtained the direct mapping area (`0xffff888000000000`) where system memory is mapped one-to-one, then used it to allocate free physical pages. The __per_cpu_offset table (`0xffffffff829dd9e0`) was also identified to access the per-CPU data of CPU 0 (`0xffff88846f600000`). The symbol information we utilized for POP is summarized in Table 2.

Page Stitching. The control and data flows of the security-sensitive function, commit_creds, are shown in Figure 7. To clarify, we merge duplicated data references and function calls into a single entity. In line 3, the function starts with the `endbr64` instruction that allows indirect branches to execute it. This implies indirect call gadgets can reach it even under CET enforcement. In line 8, the `rbx` register stores the sum of the base address of the `gs` segment, the value of the `rip` register, and `0x7ef0c776` to access the task_struct data of the currently running process, that is, current_task. The instruction employs a combination of the segment- and instruction pointer-based addressing modes. The value of the `rip` is `0xffffffff811253ca`. When it is added to `0x7ef0c776`, the result represents an offset of `0x31b40` (percpu_hot) from the base address of the `gs` segment. The base address of CPU 0 in __per_cpu_offset variable is `0xffff88846f600000`. Consequently, by adding the offset and the base address, we can obtain the final address of the current_task, `0xffff88846f631b40`. In line 13, the suid_dumpable variable is also accessed via the `rip` register, and the address of the value is `0xffffffff846178a8`.

The most important part of commit_cred() is in line 26, where credentials are updated. Other functions are not essential and can be remapped or replaced with NOP gadgets. A straightforward approach is to replace these

```

Figure 7: Control and data flows in commit_creds(). Duplicated function calls and data references are merged.

non-essential functions with NOP gadgets, which helps us avoid the potential explosion caused by remapping. However, when it comes to page remapping, it is important to note that if a function shares the same page as commit_creds() or if two or more functions are located on the same page, those functions cannot be replaced with NOP gadgets. While developing the PoC exploit, we identified four functions: inc_rlimit_ucounts(), dec_rlimit_ucounts(), key_fsuid_changed(), and key_fsgid_changed(), which could not be replaced with NOP gadgets. The first two functions had no subfunctions, while the latter two had multiple ones. Upon further analysis, we discovered that their subfunctions were not called when the thread_keyring field of the cred data structure was zero. With this information, we remapped these functions and modified the thread_keyring field accordingly.

Finding gadgets with specific direct branches is a straightforward process, and we manually searched gadgets from the gadget list using a simple text search tool, the grep

Target Name (Origin)	Page Stitching	
	Remapping to Logical Address (Origin +0x38a000)	Replaced by NOP Gadget
commit_creds()	0xffffffff814af3b0	-

Table 3: Page stitching table for commit_creds(). Physical pages of functions and data are remapped to new logical addresses. Physical pages of NOP gadgets replace non-essential functions to avoid the remapping explosion.

tool. To perform page stitching with minimal gadgets, we chose __64_sys_removexattr(), which included a direct branch at `0xffffffff814af3b0`. The page offset of the system call matched the page offset of commit_creds() at `0xffffffff811253b0` with a displacement of `0x38a000`. We also chose the functions and data listed in Table 3. They were either remapped for the system call or replaced by NOP gadgets, as discussed in Section 5.3.

Free physical pages were allocated in reverse order, beginning from `0xffff8880003ff000`, which is 16 GB away from the value of page_offset_base. One free page was allocated for the malicious credentials, which were copied from the credentials of init_task. The thread_keyring field of the malicious credentials was set to zero to skip the subfunctions. Additionally, ten free pages were utilized to maintain private page tables.

Page Flushing and Exploitation. Before page flushing, we attached the malicious application to CPU 0 with the taskset tool and cleared all global bits of the remapped pages from the page tables. Subsequently, we waited until the remapped pages were flushed from the TLB. Through our experiments, 60 seconds were sufficient to wait in our evaluation environment. Finally, the application successfully obtained root privilege by passing the malicious credentials (`0xffff8880003ff000`) as an argument to the __x64_sys_removexattr system call.

6.2 Branch and Gadget Distributions

The Linux kernel consists of a static-linked vmlinux file and kernel modules. Kernel modules have a significant amount of code base but are selectively loaded only when necessary. Therefore, they are not always available for exploitation. Commodity OSes typically tailor their kernels based on the default configuration of the Linux kernel. Consequently, we focused

Kernel Version	Configuration	System Call	
		Total	Candidate
6.1.12 (Clang/LLVM CFI with CET)	Commodity	992	252
	Kernel Default	992	220
6.2.8 (FineIBT)	Commodity	992	257
	Kernel Default	992	229

Table 4: Number of system calls and system call candidates in Linux kernels. It includes 64-bit and 32-bit system calls.

on the .text section of the vmlinux file and compared kernels built with commodity and kernel default configurations to show the feasibility of POP.

Distribution of System Call Candidates. POP can utilize both 64-bit and 32-bit system calls, and we identified all system call candidates with prefixes such as __x64 and __ia32 across kernel versions. While extracting system call candidates using the common rules described in Section 5.2, we applied additional strict rules. (i) The first direct branch of the system call has to be explicitly reached without any control-flow diversions and exceptions. System calls were excluded if they contained conditional branches, floating-point instructions, or undefined instructions before the first call or jump instruction. (ii) At least, the first argument (`rdi`) has to remain controlled before the first call or jump instruction. We also applied these rules to function and partial gadgets. Table 4 lists the total number of system calls and the number of system call candidates that were identified. Even with the strict rules, we could identify more than 220 system call candidates out of 992 system calls. Kernels built with default configurations had fewer system call candidates than commodity configurations. The default configuration did not retain frame pointers for functions, resulting in shorter system call functions. Consequently, some system call candidates were excluded because their branch targets pointed to the pages where their branches are located.

While analyzing system call candidates, we discovered that page offsets of direct branch targets were aligned to a 16-byte boundary. The alignment characteristic was observed in both Clang/LLVM CFI and FineIBT. Thus, the first gadget following after a system call candidate must be 16-byte aligned. However, this does not limit the capability of POP because function gadgets are also aligned to it. Hereafter, we refer to 16-byte aligned as aligned and 16-byte unaligned as unaligned.

Distribution of Function and Partial Gadgets. We applied three rules while identifying all functions and partial gadgets. First, we searched all functions in the kernel for function gadgets, selecting only complete function forms. Tail-call functions that call other functions with jump instructions were excluded because they require additional gadgets. Although system call candidates could also be used as function gadgets, we did not include them in our evaluation. Second, we disassembled code units of every 32 bytes across all page offsets to identify partial gadgets. The size of the partial gadgets was determined based on two reasons: (i) the branch targets of system call candidates are aligned by 16 bytes. A 32-byte size allows for address overlapping and is adequate for collecting gadgets. (ii) We aimed to keep the gadget size and search space small for simplicity. After identifying the function and partial gadgets, we selected call gadgets from them if the target of the first branch was reachable and valid. Specifically, we considered six arguments: `rdi`, `rsi`, `rdx`, `rcx`, `r8`, and `r9`, which could be passed to the system call candidates for indirect call gadgets. Finally, we extracted NOP gadgets in which no call and jump instructions go outside of the gadgets. All gadgets were considered for both the round-trip and one-way exploitation strategies.

The results of analyzing the gadgets for each kernel version are listed in Table 5. The code size represents the size of the .text section extracted with the objdump tool from the vmlinux file. The numbers at the top are the count of aligned gadgets, while the bold numbers in parentheses indicate the sum of aligned and unaligned gadgets. Kernels with commodity configurations had more gadgets than default configurations, except for call gadgets that use jump instructions. The reason was that the default configuration frequently utilized tail calls with jump instructions. The table reveals that the numbers of aligned direct call and NOP gadgets are sufficient for performing POP. However, the number of aligned indirect call gadgets is noticeably smaller compared to the others.

To find a way to reach unaligned indirect call gadgets, we analyzed the distribution of branch targets in aligned direct call gadgets. Table 6 lists the number of aligned direct call gadgets whose branch targets can jump to unaligned addresses. The table reveals that at least over 8.7% of total gadgets have unaligned branch targets. Figure 8 illustrates the distribution of page offsets for these unaligned branch targets. Each dot on the map represents gadgets within a 16x16 address range, indicating the presence of multiple gadgets in this range. Kernels built with Clang/LLVM CFI, as shown in Figures 8a and 8b, exhibit a large number of unaligned branches within the ranges of `0xea1` to `0xeaf` and `0x5c1` to `0x5cf`, respectively, resulting in horizontal lines. Conversely, kernels built with FineIBT, shown in Figures 8c and 8d, do not display such patterns. Furthermore, all kernel versions display concentrated areas at the upper-left and lower-right corners. Although gadgets are gathered in specific offsets, unaligned branch targets are evidently distributed across various page offsets. In conclusion, unaligned indirect call gadgets can be reached utilizing unaligned target branches, as shown in Table 5.

7 Discussion and Mitigation

Although POP has the capability to generate new control flows through the DOA technique even in the presence of strong

Version	Configuration	Code Size (KB)	Function Gadgets			Partial Gadgets				
			Direct Call		NOP	Direct Call		Indirect Call		NOP
			Call	Jump		Call	Jump	Call	Jump

Kernel Version	Configuration	Aligned Direct Call Gadgets	
		Total	Unaligned Branch Target
6.1.12 (Clang/LLVM CFI with CET)	Commodity	78,231	8,889
	Kernel Default	74,385	8,540
6.2.8 (FineIBT)	Commodity	80,845	7,018
	Kernel Default	74,282	6,430

Table 6: Number of aligned direct call gadgets and unaligned branch targets in them

CFI policies, it also has certain limitations stemming from its dependence on page table modifications. These limitations can be leveraged as mitigations to effectively prevent the success of POP attacks.

Limitations of Page-Oriented Programming. The remapping of functions and gadgets has the potential to disrupt the exploitation flow. For instance, if memory copy functions such as strcpy() and memcpy() are replaced with gadgets, recursive calls may occur and lead to failure when the security-sensitive function executes these functions. Furthermore, if the subfunctions of the sensitive function are spread over multiple physical pages and remapped, they may unintentionally modify the execution flow of other kernel functions, resulting in their failures. However, these limitations can be alleviated by (i) substituting unused functions in the exploitation flow with gadgets, (ii) unlinking non-essential subfunctions instead of remapping them, and (iii) recovering all remapped pages to the original pages after exploitation.

Page table modification requires multiple read-and-write operations, exploiting an arbitrary memory access vulnerability in the kernel. These attempts may lead to system crashes during context switches or be affected by other CPU events, depending on the characteristics of the vulnerability. Even when leveraging CVE-2013-2595, the system can still crash because page table modification is not an atomic operation. Nonetheless, the risk can be reduced by setting the top-level table of private page tables to the pgd field of the mm_struct data structure after thoroughly preparing the private page tables, as described in Section 5.3. This approach can mitigate

the side effects of partially-linked private tables and allow for atomic-like modification.

Mitigations. Several mechanisms, including Secvisor [68], HyperSafe [76], TrustZone-based Real-time Kernel Protection (TZ-RKP) [6], Secure Kernel-level Execution Environment (SKEE) [7], kCoFI [18], and the work of Song et al. [69], have been proposed to protect page tables by escorting page updates. These methods are effective in detecting and preventing unauthorized modifications of them. However, frequent page updates can lead to notable performance overhead. Data-flow integrity (DFI) [11] and software fault isolation (SFI) [12, 74] can prevent POP by limiting arbitrary memory read and write vulnerabilities. They impede paths to the kernel DOAs, but runtime overhead is not negligible. In contrast, PT-Rand [20] and Microsoft Windows employ a strategy of randomizing page tables, thus aiming to hide their locations. Randomizing page tables incurs lower performance overhead; however, completely concealing them from all execution paths within the kernel is challenging [67].

Recent studies on kernel compartmentalization and domain isolation [47, 49, 65] leverage special hardware features such as pointer authentication code with memory tagging extension and SLAT table switching called Extended Page Table pointer (EPTP) switching of the hardware-based virtualization technology. Although these mechanisms require kernel changes in commodity OSes to collaborate, they provide robust compartment or domain isolation through hardware and access policies. Therefore, they can prevent page remappings with lower overhead by isolating page tables from unauthorized accesses.

The 12th generation processors from Intel have recently introduced a specialized extension called HLAT as part of the Virtualization Technology-Redirect Protection (VT-rp). This enhancement aims to mitigate page remapping attacks. At the time of writing, Microsoft Windows 11 ensures support for the HLAT extension [37], while Linux does not. With HLAT, the guest OS is required to invoke hypercalls before and after safely updating the page table information. However, this may potentially hinder performance and cause synchronization issues in multicore environments. Furthermore, HLAT is only available on Intel CPUs starting from the 12th generation, and it is uncertain whether all CPU vendors will support this feature. As demonstrated, POP remains a viable and effective attack technique for most current systems, and legacy systems still need other mitigations we discussed.

8 Related Work

Control-Flow Integrity. Heuristic-based CFI research, such as ROPGuard [26], kBouncer [63], and ROPecker [14], have focused on analyzing return traces to determine the characteristics of ROP attacks with reasonable performance overhead. Other studies, such as Bin-CFI [79], CCFIR [78], opaque CFI (O-CFI) [57], kCoFI [18], kCFI [29], MCFI [61], and indirect function-call checks (IFCC) [72], employed static analysis on source code or binaries to investigate control flow deviations using CFGs generated from the analysis.

In contrast, πCFI [62], PathArmor [73], PittyPat [22], μCFI [35], CFI-LB [44], and OS-CFI [43] aimed to generate precise CFGs by combining dynamic information such as execution flow, execution path, and pointer origin information, to enforce stringent CFI policies. Additionally, hardware-based techniques for preventing deviations in indirect branches were explored, including hardware-enforced CFI (HCFI) [16], Transactional Synchronization Extensions-based CFI (TSX-CFI) [59], and PAL [77]. These techniques leveraged customized or commodity hardware such as Intel Transactional Synchronization Extensions (TSX) [38] and ARM Pointer Authentication (PA) [5].

Previous CFI research has made substantial contributions to enforcing CFI policies by reducing the target set of the indirect branch and leveraging hardware support. However, a limitation of these approaches is that they primarily concentrate on enforcing policies over indirect branches. Although kCoFI and kCFI considered page table protection, it is still uncertain whether they can effectively prevent POP in commodity OSes with negligible performance overhead.

Bypassing Control-Flow Integrity. Several research groups, including Carlini and Wagner [10], Davi et al. [21], Göktaş et al. [30, 31], Evans et al. [24], and Carlini et al. [9] have investigated the weaknesses of CFI policies. They demonstrated that several CFI studies based on heuristics and static CFGs are still bypassed using techniques such as flushing return traces and exploiting target sets of indirect branches.

Instead of exploiting the weaknesses, other studies by Chen et al. [13], Morton et al. [58], and Hu et al. [34] proposed DOAs that rely only on data to escalate privileges without deviating from the CFG. Data-oriented programming (DOP) [36] and block-oriented programming (BOP) [39] proposed CRA techniques along valid execution paths. Additionally, several studies have targeted the kernel [23, 45, 46] and demonstrated code modification and privilege escalation by modifying non-control data, such as page tables and credentials. They exemplified that DOAs are applicable even beyond the user level.

POP can be compared to DOP and BOP in the sense that it achieves the CRA without modifying any code. However, POP is not quite restricted by CFI policies because it exploits direct branches. Consequently, POP does not require complex computations, making it a more straightforward and intuitive technique.

Kernel Integrity Protection. In x86_64 environments, previous research on kernel integrity protection with hardware has employed the virtualization technology (VT) of the CPU. Diverse approaches, including Secvisor [68], NICKLE [66], and Shadow-box [33], have utilized the SLAT of VT to ensure that kernel code remains non-writable. Secvisor, in particular, proposed a page update mechanism using the hypervisor, but

its performance overhead was more than double because all page faults were handled by it. In contrast, PrivWatcher [41] focused on a lightweight protection mechanism for credentials. It leveraged SLAT to establish a safe region inside the kernel to prevent unauthorized modification of credentials.

SeCage [47] and xMP [65] utilized the SLAT-related feature, EPTP switching, and supported memory isolation with access policies. Their isolation mechanisms could isolate page tables from unauthorized accesses with kernel changes. Recently, a new hardware feature, HLAT, has been introduced by Intel to hinder page remapping attacks. Although the latest CPUs may mitigate performance overhead and prevent POP through it, protecting legacy systems with older CPUs or without support for the feature is an open problem.

9 Conclusion

We introduced a novel CRA technique called POP and demonstrated its PoC on an up-to-date system. This attack is practical and capable of creating arbitrary control flows, effectively bypassing the current CFI implementations by undermining their critical assumption of code memory immutability. While the attack can be mitigated on cutting-edge hardware products, other existing systems still remain susceptible to this attack at present.

Abstract

Despite decades of mitigation efforts, SYN flooding attacks continue to increase in frequency and scale, and adaptive adversaries continue to evolve. Meanwhile, volumes of benign traffic in modern networks are also growing rampantly. As a result, network providers, which run thousands of servers and process 100s of Gbps of traffic, find themselves urgently requiring defenses that are secure against adaptive adversaries, scalable against large volumes of traffic, *and* highly performant for benign applications. Unfortunately, existing defenses local to a single device (e.g., purely software-based or hardware-based) are failing to keep up with growing attacks and struggle to provide performance, security, or both. In this paper, we present SmartCookie, the first system to run cryptographically secure SYN cookie checks on high-speed programmable switches, for both *security* and *performance*. Our novel split-proxy defense leverages emerging programmable switches to block 100% of SYN floods in the switch data plane and also uses state-of-the-art kernel technologies such as eBPF to enable *scalability* for serving benign traffic. SmartCookie defends against adaptive adversaries at two orders of magnitude greater attack traffic than traditional CPU-based software defenses, blocking attacks of 136.9 Mpps *without packet loss*. We also achieve 2x-6.5x lower end-to-end latency for benign traffic compared to existing switch-based hardware defenses.

1 Introduction

Distributed Denial-of-Service (DDoS) attacks have been studied for decades, but despite this rich history, volumetric attacks are still an important and unsolved problem today. In 2023, attacks increased by over 300% [5, 44], with downtime costing companies an average of $20,000-$40,000 hourly [25, 32]. One driving factor behind this growth is the widespread availability of DDoS-for-hire services, costing as little as $10 hourly and making it increasingly easy to launch attacks [34]. In recent years, DDoS attacks have also shaped political landscapes and played major roles in cyber warfare [23, 24, 29, 39].

One of the most common DDoS attacks, namely *SYN floods*, consume server memory until the server is forced to drop benign traffic [37, 38, 58]. SYN floods constituted up to 94.7% of all DDoS attacks in 2020 [49] and continue to remain a critical threat today [50]. Additionally, benign traffic volumes also continue to grow exponentially, reaching staggering loads of up to hundreds of Gbps in cloud-provider networks [63].

To respond to growing threats and traffic volumes, network providers (e.g., cloud providers, enterprise networks, ISPs) urgently require *scalable* defenses that block volumetric attacks *without compromising security* against adaptive adversaries or *degrading application performance* [21, 40, 58]. In other words, they need defenses with three key requirements: **security** (blocking attacks from adaptive adversaries), **scalability** (handling large amounts of benign and attack traffic), and **performance** (low latency for benign clients).

While state-of-the-art SYN-flooding defenses using *SYN cookies* have been proposed and standardized for many years, existing solutions have failed to simultaneously provide security, scalability, *and* performance [2, 3, 51, 67, 72]. Designing and practically implementing modern SYN-flooding defenses that meet each of these requirements is particularly challenging. Compared to defenses against many other volumetric attacks (e.g., ACK floods, RST floods, UDP amplification), SYN-flooding defenses cannot simply drop, rate-limit, or ignore unsolicited traffic. Doing so might cause denial of benign client requests, particularly since adversaries often spoof attack packets using legitimate addresses. Instead, defenses must identify and block large-scale attacks (requiring costly compute) while keeping per-flow state to track large numbers of verified connections (requiring large chunks of memory).

Server-Based Solutions. Server-based SYN cookie defenses are the time-honored way to provide security and can scalably handle *benign traffic* by default [2, 3, 67]. However, under large-scale attacks, software-based packet-processing and cryptographic cookie computation incur high overheads and lead to CPU exhaustion (§8). Ultimately, once the server's limited CPU capacity is overwhelmed by *volumetric attacks*, these defenses collapse and again result in DoS.

Switch-Based Solutions. High-speed programmable hardware switches present a unique opportunity to overcome this additional attack vector on end host CPU consumption. Switches provide packet-processing at orders of magnitude faster rates, and thus have the potential to execute the required cryptography more performantly than end hosts. However, purely switch-based solutions [51, 72] must operate under strict hardware constraints, including limited compute and limited memory. First, cryptographic primitives are not natively supported in switches and are computationally expensive. As a result, existing switch-based defenses use the insecure CRC32 to compute SYN cookies [51, 72], *abandoning security* and defeating the purpose of the SYN cookie check (§2.4). Additionally, because switches have only tens of MBs of memory [48], memory-intensive SYN-flooding defenses which track per-connection state *struggle to scale* [72] or *degrade application performance* [51] (§2.5).

Division of Labor to the Rescue. To overcome the limitations of existing solutions, we propose **SmartCookie**: a novel *split-proxy* defense that leverages collaborative programmable data planes on hardware and software targets. Our design *intelligently* partitions the defense workload to maximize the benefits of both switch-based and server-based defenses, while minimizing the limitations of each approach.

Key Insight. Our key insight for motivating SmartCookie's novel division of labor is two-fold. Switches are highly performant and have potential to quickly and *securely* block volumetric attacks, but they are memory-limited and scale poorly at keeping exact state for verified flows. This makes switches excellent as a first line of defense, but they should not be required to keep per-flow state. Meanwhile, servers enjoy superior memory resources, but are prohibitively slow at packet processing. This makes them ideal for exactly tracking *benign flows*, without the burden of blocking *attacks*.

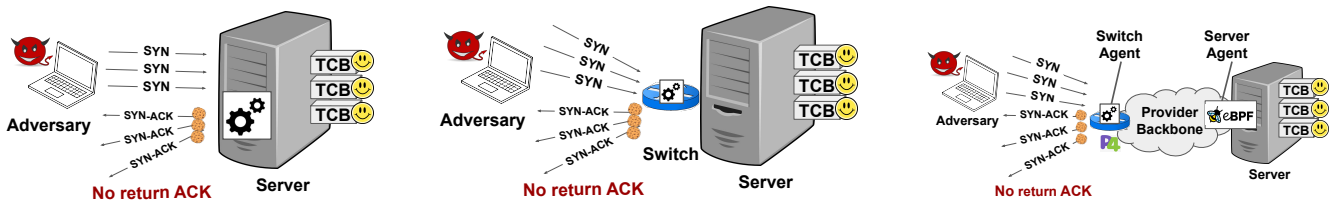
At a high level, SmartCookie takes traditional SYN cookie defense elements, refactors them, splits them between a co-designed *switch agent* (running on the switch data plane) and *server agent* (running on the Linux kernel data plane), and stitches switch agent and server agent together with a collaborative protocol. We identify three key elements of existing defenses: **F1) SYN cookie checks**, **F2) TCP sequence number translations**, and **F3) keeping state for verified connections**. Following our key insight, we refactor and map defense elements **F1-F3** to switch and server as follows: SmartCookie switch agent *securely* performs cookie checks to quickly stop bad traffic (**F1**) and *approximately* tracks verified connections (**F3.A**) instead of keeping exact state, while SmartCookie server agent handles sequence number translations (**F2**) and *exactly* tracks verified connections (**F3.B**).

SmartCookie switch agent maintains approximate state using compact data structures with well-defined accuracy guarantees (§6.3). Note that in contrast to prior work, our defense does not require exact state at the switch, but *still achieves overall exact defense results*, due to its split design.

Contributions and Roadmap. This work makes the following contributions:

- The first system to run cryptographically secure SYN cookies on programmable switches, using robust hashes instead of the insecure CRC32 used in prior works (§5).
- The first split-proxy SYN-flooding defense for modern programmable data planes, using in-switch compact data structures for memory scalability and server-side eBPF for immediate deployability (§6).
- An end-to-end SmartCookie prototype with a *switch agent* implemented in P4 on Tofino switches and a *server agent* written in eBPF on Linux servers, which is resilient against attack rates of 136.9 Mpps (about 92Gbps) *without any packet loss*, with potential for easily reaching even higher rates (§8).
- 19x-105x throughput improvement over *software* solutions resulting from offloading of cookie computation and verification to high-speed switch hardware (§8.2) and 48-84% latency improvement with our novel split design over existing *hardware-only* designs (§8.3).

We present limitations of existing defenses in §2 and describe the threat model, problem setting, and architecture of SmartCookie in §3 and §4. We include a security analysis in §7, discuss additional features and future directions in §9, present related work in §10, and conclude in §11.



Ethics Statement. This work raises no ethical issues.

2 Limitations of Existing Defenses

2.1 Limitations of Server-based Defenses

Traditional server-based SYN-flooding defenses use *SYN cookies* to protect server memory, encoding state normally saved to server-side Transmission Control Blocks (TCB) during connection setup in a cryptographically computed cookie instead [2] (Figure 1a). The server uses the SYN cookie as the initial sequence number (ISN) that is placed in the sequence number field (`seq_no`) of the SYN-ACK packet sent to the client. Clients automatically return the cookie in the acknowledgment number of the final ACK of the TCP handshake, as $\texttt{ack\_no} = \texttt{seq\_no} + 1$. This returned cookie is then verified by the server.

In server-based defenses, the server cryptographically computes and verifies cookies and performs packet processing for every potential connection, introducing an added attack vector on server compute resources. Because these defenses run on general-purpose CPUs, they can easily be overwhelmed under heavy attack loads, due not only to cookie computation but also to software-based packet-processing overheads (§8, Table 1). Thus, server-based defenses struggle to scalably stop volumetric attacks, degrading application performance and again resulting in denial-of-service for benign clients.

(a) Server-based defense. (b) Switch-based defense. (c) SMARTCOOKIE: a split defense.

Figure 1: SMARTCOOKIE versus server-based and switch-based defenses.

2.2 Limitations of SYN Cookie Proxies

To protect the server from CPU exhaustion, the SYN cookie mechanism can run in a proxy placed in the NIC of the server or in a switch near the server (Figure 1b). Proxies perform cookie computation and verification in place of the server, only establishing a connection with the server for verified clients and thus defending against attacks that cause excessive consumption of server CPU cycles [33, 60]. Defense proxies also monitor previously verified connections to determine which packets require cookie checks.

However, this approach has fundamental drawbacks as well. First, proxies incur overheads related to connection setup. Specifically, after a proxy verifies a client, it must perform a second, separate proxy-to-server setup handshake to establish the connection from the server's point-of-view. This increases latency since the proxy must buffer any packets received from the client while it establishes the server-side connection. Additionally, proxies need to translate TCP sequence numbers between client and server, because there is a mismatch between the ISN chosen by the proxy as the SYN cookie value and the ISN chosen randomly by the server [60]. This forces the proxy to keep exact per-flow state to track verified connections (in addition to the per-flow state kept by the server), and the proxy must perform costly sequence number translations on every packet throughout the remainder of the connection. We note the SYN proxy design also relies on assumptions of symmetric routing, since all packets must pass through the proxy in both directions for sequence number translations.

2.3 Opportunities of Programmable Switches

Programmable switches are similar in price to fixed-function enterprise-grade switches. They are an attractive option for high-speed, flexible, and cost-efficient defenses against large-scale attacks [18, 19, 51, 72, 73]. While it is clear that switches have significantly more potential than servers for a performant and robust defense, we argue that programmable switches also showcase concrete benefits over SmartNICs as well.

Target Choice. Although some state-of-the-art SoC-based SmartNICs offer larger memory banks and cryptographic accelerators for specific primitives (e.g., MACsec/IPsec encryption) [55], switches have faster packet processing and offer better performance to cost/power ratios than alternative SmartNIC approaches [46, 51, 55]. For our target setting of large cloud enterprises, gateway switches can save bandwidth in the network core by blocking attacks directly at the network edge, before malicious traffic reaches the internal network and hosts' NICs. Still, SMARTCOOKIE could be deployed on SmartNICS, but given their lower capacity, these are better for smaller edge networks, and we choose to target switches.

2.4 Security Limitations of Switch Defenses

Prior works have leveraged high-speed switches as SYN cookie proxies in the network [51, 72]. Unfortunately, these systems have a crippling security flaw: they use the insecure CRC32 checksum as the "hash" for computing SYN cookies, abandoning security against adaptive adversaries.

The Need for a Secure Hash. SYN cookies are computed with a hash of the connection 4-tuple (source/destination IP addresses and port numbers), along with some secret key and a timestamp, so an adversary cannot perform a replay attack with the cookie at a later time. For security, this hash must be cryptographically robust, such that an adversary cannot easily craft a cookie that would pass as legitimate during a cookie check. Otherwise, the adversary could send many forged cookies to the victim, launching an attack more powerful than the original one: after verifying forged cookies, the victim must also prepare for new connections and allocate memory, wasting *both* compute and memory resources.

Insecurity of CRC. CRC is an error-detection checksum, not a cryptographic hash. When incorrectly used as a hash, it can be trivially cracked by an adaptive adversary performing key recovery and cookie forging attacks [70]. There are two broad attack vectors against CRC that can result in breaking the cookie defense: collision induction and nonce deduction.

Collision Induction. An adaptive adversary can exploit the fact that CRC is not collision-resistant to construct hash collisions. Without assuming security by obscurity, adversaries with knowledge of a CRC-based defense can simply send probe packets with different inputs to uncover a hash collision. Note the adversary has constant feedback on CRC outputs, as the defense must respond to all SYN packets.

	Secure Hash	High-Throughput	Non-Disruptive	Scales Beyond Switch Memory
Server-Based Cookies [2, 57, 60]	✓	✗	✓	–
Poseidon [72]	✗	✓	✓	✗
Jaqen [51]	✗	✓	✗	✓
SMARTCOOKIE	✓	✓	✓	✓

Table 1: Compared to existing defenses, SMARTCOOKIE is secure, high-throughput, non-disruptive, and scalable.

Nonce Deduction. Due to its linear nature, CRC is vulnerable to nonce deduction; an adaptive adversary can trivially crack CRC-based cookies in a few simple steps (we refer interested readers to §A for details). The simplicity and effectiveness of this attack leaves the door wide open for adaptive adversaries to completely break the CRC-based SYN cookie defenses of both [51] and [72]. In contrast, SMARTCOOKIE *securely* computes SYN cookies in the programmable data plane using a robust hash with strong security guarantees [8] (§5).

2.5 Performance Limitations of Switch Defenses

Existing switch-based defenses also struggle to provide memory scalability and good application performance [51, 72].

Poor Scalability. Poseidon [72] keeps per-flow state in the switch to perform sequence number translations for ongoing flows. Given limited switch memory, this simply cannot scale, as processing hundreds of thousands of flows at network speeds is a memory-intensive task (Table 1). In contrast, SMARTCOOKIE avoids keeping exact state in the switch by offloading it to the server, allowing the defense to scale (§6).

Disruptive Performance. Jaqen [51] also avoids keeping per-flow state on switches. However, it does so by disruptively forcing all benign clients to undergo a reset during connection setup, even after passing the SYN cookie check (Table 1). After this reset, clients eventually attempt a second handshake, which the Jaqen proxy allows through to the server, with some probability of false positive error. This enables server and client to directly choose sequence numbers without involving the Jaqen proxy. Unfortunately, Jaqen's design incurs extra latency (1-2 round-trip times) for benign connections, an especially undesirable performance penalty for clients across wide-area networks. In contrast, SMARTCOOKIE is transparent to clients, requiring a *single* handshake and maintaining good application-level performance (§8).

3 SMARTCOOKIE Problem Setting

The problems that state-of-the-art defenses experience against large-scale SYN floods are challenging to resolve, because they arise from the inherent hardware constraints of available targets and from the threat model experienced by network providers tasked with providing security, scalability, and performance. SMARTCOOKIE overcomes these challenges and presents a practical defense for large network operators, who control backbone switches and servers in their network. This setting opens unique opportunities for a division of labor that SMARTCOOKIE intelligently exploits (Figure 1c).

3.1 Threat Model

There are four key players in our threat model: clients, adversaries, switches, and servers. Switches and servers are controlled by the same network operator, which seeks to protect its servers from resource strain, while concurrently protecting network bandwidth. Under the same administrative authority, switches and servers can safely cooperate.

Clients. Client communications to any of the servers hosted by the provider backbone should be protected from SYN flooding disruption. Clients should also not experience degraded performance as a result of any deployed defense.

Adversaries. Our threat model focuses on *asymmetric* SYN-flooding attacks, where adversaries require orders of magnitude fewer resources than defenses. Asymmetric attacks are generally regarded as more challenging to defend against [17, 26], and their lower cost is likely what makes them so prevalent in the wild [50]. In our threat model, adversaries can spoof source IP addresses or utilize a limited number of compromised devices to send a flood of connection handshake requests that appear to be from unique clients and must be individually handled [7]. When spoofing, adversaries cannot gain feedback from the defense, as response packets to spoofed addresses never reach the adversary. Adversaries can also send some probe packets without spoofing to observe the resulting cookies and attempt to crack the cookie hash, as well as launch replay attacks using earlier cookies (§2.4). We assume the adversary can send attack traffic at up to Tbps rates. The adversary does not have physical access to the network switches or servers hosted by the provider backbone, and traffic from the adversary cannot reach the server without traversing a participating switch. In other words, the adversary cannot tamper with packets between the switches and servers internal to the provider backbone.

Switches. The switches are programmable, high-speed network hardware capable of Tbps processing rates. They are controlled by the same network provider and deployed at the network edge. Since the switches and servers are under the same *centralized* operator, we assume the communication channel between the switches and the servers is secure.

Servers. Physical servers, hereafter simply called servers, are owned, operated, and trusted by the network provider, and thus can be modified. Trusted defense modules run on the servers, but for immediate deployability, changes to the TCP/IP stack of the server's Linux kernel are not required. However, modest changes to the server TCP/IP stack can open further defense opportunities in the future (see §D). We

note that tenant VMs running on the physical servers are not trusted and thus are *unmodified* by the network provider. Also, in order to not affect the performance of applications running on the server, it is critical that any defense mechanism does not consume excessive CPU cycles.

3.2 Challenges

Modern programmable switches support flexible packet processing optimized for Tbps speeds [14,42,45]. They exert fine-grained control over packet forwarding in the data plane with line-rate throughput guarantees, but do so at the cost of strict constraints enforced by the underlying hardware [12, 13, 42]. Thus, there are fundamental challenges to overcome to realize the potential of a high-speed switch defense.

Challenge 1: Limited In-Switch Programming Model for Cryptographic Operations. Most programmable switches do not natively support any cryptographic primitives, and they can only process packets with a limited number of available operations (e.g., addition, subtraction, and XOR, but no multiplication or division). However, even more fundamentally, to guarantee high-throughput, switches use a pipeline model with only a limited number of stages for packet processing. Operations can also only be performed concurrently in a stage if there are no dependencies between operations. Finally, the output of one computation cannot be used until the following pipeline stage, making it difficult to fit all the necessary operations for cryptographic SYN cookie computation within the limited number of available stages. Thus, even if cryptographic accelerators were introduced on hardware switches, computing secure cookies within the computational constraints and limited stages is challenging, and could break the performance of the switch if done naively. We show how SMARTCOOKIE overcomes these challenges in §5.

Challenge 2: Limited In-Switch Memory for Per-Connection State. The amount of available data plane memory is limited, and it must be shared with other applications (e.g., routing tables) running on the switch. To perform sequence number translations and maintain the correctness of packet-processing, a naive defense would need to keep cumbersome per-flow state on the order of 6 bytes per connection (e.g., the 32-bit sequence number and hashed connection 5-tuple key). Unlike other data plane applications that require keeping significantly less state (e.g., a small 6-bit version number along with a hashed 5-tuple key) [52], the amount of state that must be kept by a defense cannot be further compressed with a hash digest, as this would cause information loss and break connections. Given available memory is on the order of tens of MBs, keeping this amount of state for every verified flow in a large network provider cannot scale to even hundreds of thousands of connections [51], and thus we simply cannot afford to allocate switch memory for each ongoing TCP flow. We show in §6 how SMARTCOOKIE intelligently partitions the defense to gracefully handle this challenge.

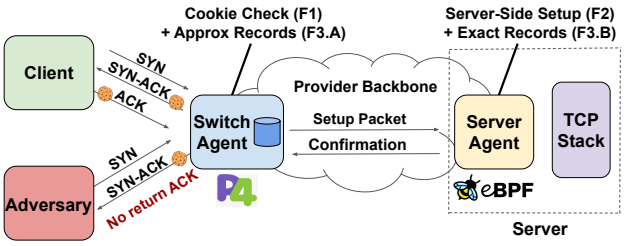


Figure 2: SMARTCOOKIE's split-proxy architecture.

4 SMARTCOOKIE Architecture

To overcome the challenges and existing limitations, SMARTCOOKIE proposes a novel split-proxy architecture (Figure 2).

Switch Agent. The SMARTCOOKIE switch agent performs cookie checks *securely* (F1) and tracks verified connections *approximately* (F3.A). This design is motivated by the underlying switch architecture, which is optimized for high-speed packet processing up to Tbps, an order of magnitude greater than the speeds of general-purpose CPUs. The switch agent is an ideal location for offloading of SYN cookie checks. It can securely and performantly block *100% of SYN floods*, without burdening the server (§5,§8). Recall that to achieve high throughput and low latency, however, the switch only has a limited amount of memory, and memory accesses are constrained. Thus, the switch agent should not be required to remember all the connections that have successfully passed the cookie check. In other words, *verified records* should be kept in an *approximate* data structure at the switch agent (§6.3).

Server Agent. Meanwhile, SMARTCOOKIE server agent is primarily responsible for handling benign connections, conducting sequence number translations (F2) and *exactly* tracking verified connections (F3.B). Servers offer greater compute flexibility and have fewer constraints on memory access and usage than switches. Thus, the server agent is ideal for maintaining exact information about verified connections and for performing sequence number translations on behalf of the switch agent. This offloading of unique per-connection sequence number translations is enabled by a special setup procedure, which the switch agent and server agent cooperatively perform using custom setup request and confirmation packets (§6). The server agent's sequence number translation mechanism ensures consistent sequence number progression, preserves the correctness of the TCP protocol, and is transparent to unmodified end hosts. We note that the greater compute flexibility at the server agent comes at the cost of lower packet-processing speeds as compared to hardware speeds, but this is a reasonable tradeoff since the amount of benign traffic the server agent must process is much smaller than the amount of attack traffic that the switch agent must identify and drop.

5 Secure SYN Cookies in the Data Plane

SMARTCOOKIE switch agent is responsible for performantly computing and verifying SYN cookies in the data plane, but for any defense to be worthwhile, this must be done securely.

Choice of Hash Function. There are several potential choices of data-plane hash functions. Recall that because of the computational constraints of the switch, it is extremely challenging to compute a cryptographically secure hash function in the data plane. Hence, several prior works [51, 72] opted to use the CRC32 checksum as a "hash" function to compute SYN cookies, resulting in significant vulnerability [70]. This is because an adaptive adversary can always send crafted SYN packets and observe the resulting cookies (i.e., a chosen-plaintext attack), efficiently solve and extract the key used in hashing, and then forge cookies for any 4-tuple, bypassing the defense entirely (§2.4).

SMARTCOOKIE securely computes and verifies cookies using *HalfSipHash-2-4* [8], which is from the SipHash family of hashes used by Linux for computing SYN cookies [2]. We also choose HalfSipHash-2-4 for performance reasons, as it is faster than SipHash-2-4, while still sharing the same construction. We believe HalfSipHash-2-4 *with key rotation* offers acceptable security against even well-provisioned adversaries (e.g., key brute-forcing adversaries), achieving good security along with lightweight performance. The hash is cryptographically robust and designed for speed on short inputs, making it ideal for computing cookies in the data plane, where the input to the hash is just a few bytes from the packet header.

Securely Computing Cookies. HalfSipHash is seeded by secret keys, used to initialize four internal variables *v0-v3* (Figure 3). The hash input gets mixed with these internal variables using arithmetic operations (Add, Shift, XOR) across several computational rounds. HalfSipHash-*c*-*d* performs *c* rounds of computation (compression rounds) for each *w* 32-bit word of the hash input. Once all input bytes have been processed by compression rounds, an additional *d* rounds of computation are performed, called finalization rounds. Finally, the four internal variables are XORed, giving the hash output.

Each round of computation requires 14 arithmetic operations, including six circular left shifts. Since most of the arithmetic operations directly use the output of the previous operation (Figure 3), they create a long dependency chain. Since the P4 language [36] does not natively support the circular shift operation, naively implementing a circular left shift of *n* bits requires three intermediate operations: a left shift of *n* bits, a right shift of 32 - *n* bits, and then a bitwise OR of these two intermediate results. Because of the dependency chain between the bitwise OR and the intermediate shifts, calculating a single circular shift will require two pipeline stages, which quickly becomes unreasonably costly given the limited number of available stages in the switch.

Instead of using a multi-operation, multi-stage approach to circular bit shifts, we optimize the computation by using a

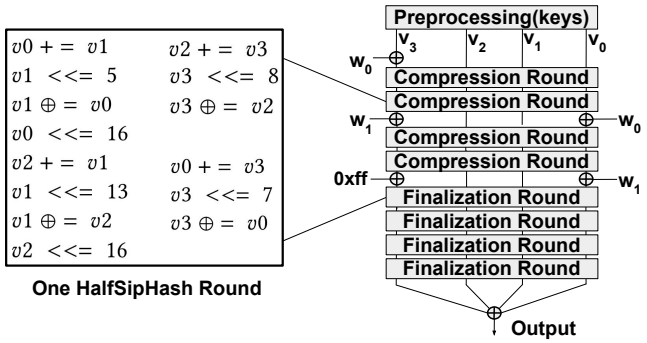

Figure 3: HalfSipHash-2-4 requires 2 compression rounds on each input word *w* and 4 finalization rounds at the end, with each round costing 14 operations.

built-in slicing primitive on the switch to slice out the desired upper and lower bits of the variable. We then use a supported concatenation primitive to stitch the newly relocated bits together in a new variable, fitting the full circular shift into one operation in a single pipeline stage. Additionally, we optimize the number of pipeline stages needed for the computation, by manually grouping the 14 arithmetic operations in a round into 4 stages based on their dependencies.

Recirculation. To calculate cookies, we need to operate HalfSipHash on a 16-byte ($w = 4$ word) input, requiring in total $2w+4 = 12$ compression and finalization rounds. Although we have optimized HalfSipHash for modern switch hardware, we still require several pipeline passes to perform all the rounds. Hardware switches support a packet recirculation feature that allows for computation across multiple pipeline passes. We note that naively using just the ingress pipeline of the switch for computing the hash would require $r = (2w+4)/2-1 = w+1 = 5$ recirculations. However, we integrate HalfSipHash with SMARTCOOKIE's switch agent logic to run in both the ingress and egress pipelines, reducing r to $(2w+4)/4-1 = w/2 = 2$ recirculations per hash.

In practice, network switches have dedicated recirculation ports, and additional ports can be reserved for recirculation. Dedicating additional ports for recirculation would reduce the bandwidth that could have been used for serving other traffic, but this is an acceptable performance tradeoff for the security gains of a robust hash. We show in §8 that even with recirculations, our HalfSipHash-based switch agent returns secure cookies 2.6x faster than the next fastest defense. Additionally, the recirculation limitations of our prototype result from the lack of cryptographic building blocks in the network hardware, which can be improved in the future.

Key Rotation. To defend against brute-force attacks, HalfSipHash keys are rotated periodically (e.g., every 5-30 seconds). This reflects our underestimation of the time needed to brute-force a key [8]. To ensure handshakes from clients are not accidentally blocked, cookies computed with an old key are still accepted for a short period after a key rotation.

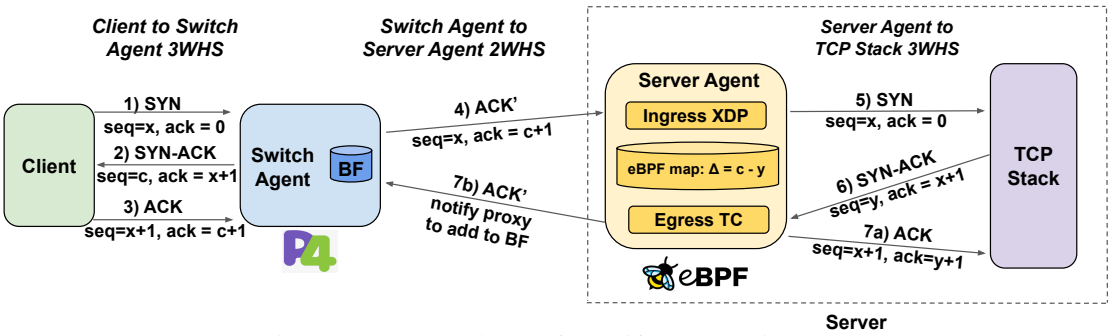

Figure 4: End-to-end setup for verified connections.

6 Split-Proxy Design

With our secure SYN cookie hash in the data plane, we can now safely offload cookie checks to a high-speed switch. However, we must still tackle the challenge of limited switch memory for handling benign flows. SmartCookie accomplishes this with a split-proxy design, where a switch agent and server agent cooperate to performantly stop attack traffic and correctly handle benign traffic. Our design avoids packet buffering during setup and bypasses sequence number translations at the switch agent, allowing it to *approximately* track verified connections and scale beyond available switch memory.

6.1 Switch to Server Two-Way Handshake

Figure 4 shows SmartCookie's complete setup procedure for verified connections. In `packets 1-3` SmartCookie switch agent verifies clients by performing a secure SYN cookie check as in the traditional defense. However, under the SmartCookie protocol, the switch agent does not buffer the final ACK of the TCP three-way handshake (3WHS) between the client and switch agent. Instead, the switch agent directly forwards this ACK packet to the SmartCookie server agent with an additional *setup tag*, notifying the server agent to bootstrap the connection setup (`packet 4`). The switch agent also uses this packet to instruct the server agent how to handle the difference in initial sequence numbers (ISNs) that were chosen by the switch agent and the server's network stack.

After receiving this tagged setup packet, the server agent sets up its side of the connection, shown with `packets 5-7a`. The server agent then sends a packet to the switch agent to confirm the connection establishment, completing the custom setup between switch agent and server agent as shown with `packet 7b`. Note that the server agent has been instructed by the switch agent how to handle sequence number deltas, so the client and server see their expected sequence numbers in both directions. This allows the switch agent to step into a passive forwarding role and avoid the expense of sequence number translations throughout the remainder of the connection.

SmartCookie converts the original 3WHS between switch and server into a custom two-way handshake (2WHS) between switch agent and server agent, notifying the server of the client connection, because at this point the server is still unaware of the client. We note that a 3WHS between switch agent and server agent is undesirable, causing overhead at the switch for buffering packets from the client while the second 3WHS is being conducted. Additionally, even after the end-to-end connection is established, per-packet processing at the switch for sequence number translations is undesirable. Instead, by explicitly informing the server agent of the connection and sending information for sequence number translations, the switch agent can safely forward packets from a verified connection without additional processing.

Handling Setup Latency and Packet Drops. SmartCookie reliably handles more complex scenarios introduced by connection setup latency, reordered packets, or packet drops. Consider the scenario where the 2WHS between the switch agent and server agent is not yet complete, either because it is still in progress or because the setup packet sent to the server agent has been lost. If the client sends additional data packets to the server during this state, the SmartCookie switch agent handles this gracefully by continuing to verify and tag these packets before forwarding them to the server agent (note that the switch agent never buffers client packets). Since the client has yet to receive any packets from the server, the server-side sequence numbers have not progressed and the client would still pass the cookie check at the switch agent. As long as the client's packets continue to pass the cookie check, the switch agent will tag and forward them to the server agent, and upon receipt of any tagged packet from the switch agent, the server agent will immediately set up the connection and send an explicit confirmation to the switch agent. Upon receiving this confirmation, the switch agent no longer tags any packets from the client and simply forwards packets in both directions.

6.2 Redesigned Server Setup

SmartCookie uses *eBPF* to facilitate division of labor between switch and server agents. Our design does not modify the network stack of end hosts, which is particularly beneficial for datacenter deployments where network operators may not control end host TCP behavior (e.g., tenant VMs).

eBPF Primer. eBPF (extended Berkeley Packet Filter) is a powerful and lightweight technology that allows for safe, fast, kernel-level execution of programs directly from user-space, without requiring programmers to rewrite kernel source code [10]. The Linux networking community has been taking advantage of eBPF for efficient packet filtering and safe kernel-level execution in many different security applications, including in the DDoS space [11, 57, 65].

Modified TCP Interface. With eBPF, we redesign the TCP interface between the network and the Linux kernel's network stack. This allows us to offload connection setup and sequence number translations to the server *without* modifying the kernel TCP stack, enabling immediate deployability. Our server agent deploys an eBPF ingress and egress program attached to different kernel hooks (XDP and TC, respectively), performing connection setup with the kernel network stack and sequence number translations on incoming and outgoing packets (see §B.2 for details). The eBPF programs act as a lightweight translation layer that converts custom packets received from the switch agent into proper TCP packets for regular TCP/IP processing by an unmodified kernel.

eBPF Map for Tracking State. eBPF maps can be used to communicate between user space and kernel space, and they are the only way to store and share state between eBPF programs. Maps are implemented as key-value stores, where values are defined by data type and size. The server agent uses an eBPF map to track the connection state of any given flow and to coordinate the behavior of the ingress and egress eBPF programs based on this state. The map key is the 4-tuple connection information (source and destination IP addresses and port numbers). The map value for each key stores the connection state of the connection and the sequence number delta to be applied for that connection. As shown in Figure 4, the sequence number delta for a given connection is determined to be $\Delta = c - y$, where c is the switch agent's original ISN (i.e., cookie value) and y is the ISN chosen by the kernel. At first, the server agent's ingress program extracts c from `packet 4` and stores it in the eBPF map temporarily. Later, the server agent's egress program extracts y from `packet 6` and then calculates and stores the true Δ in the eBPF map.

6.3 Compact Data Structure at Switch Agent

To determine which packets require cookie checks, the switch agent (like any standard defense) must maintain a record of verified connections. In prior designs, the proxy keeps a local record of *every* verified connection that has passed the cookie check, using this record to remember the sequence number deltas that must be applied to all packets in the flow. This is an unattractive solution because it requires per-flow state, and memory is a limited commodity in high-speed switches.

Bloom Filters for Approximate State. Since SmartCookie offloads sequence number translations to the server agent, the switch agent can avoid keeping exact state by using a resource-efficient compact data structure called a Bloom filter. The Bloom filter can *approximately* keep track of clients that have passed the cookie check and successfully established a connection with the server. Bloom filters are efficient and powerful approximate data structures, but they come at the expense of a small number of false positives. There are no false negatives in Bloom filters, which is an important feature that ensures benign traffic is never blocked. We note the purpose of the Bloom filter is *not* to stop an adversary's non-SYN packets from reaching the server, although this does happen as a bonus. Instead, the goal of this design feature is *to not keep per-flow state at the switch agent for verified flows*, reducing strain on the memory-constrained switch.

Implementing Bloom Filters in the Switch Agent. To approximately track the set of benign TCP connections, we use register memory arrays on the Tofino programmable switch to implement a Bloom filter. Since the switch's pipeline only allows accessing one index per array when processing a packet, we implement a Bloom filter variant called the Partitioned Bloom Filter (PBF) [6]. PBF splits its m-bit memory into k separate arrays $M_1[\cdot] \ldots, M_k[\cdot]$, each sized $\frac{m}{k}$, and uses k indexing hash functions $h_1, \ldots, h_k : \mathcal{F} \to [\frac{m}{k}]$ to map the input key $f \in \mathcal{F}$ (in our case, flow 4-tuple) into locations in the array. All arrays are initialized to zero. To insert a flow f, for each array i, we calculate the index $h_i(f)$ and mark 1 in the corresponding index, i.e., $M_i[h_i(f)] \leftarrow 1$. To query whether flow f has been added, we check the same indices and report positive if they are all 1, i.e., $M_i[h_i(f)] == 1, \forall i \in [k]$.

Automatically Cleaning the Bloom Filters. To prevent over-saturation and maintain the accuracy of the filters as time goes on, we can keep multiple Bloom filters at the switch agent in a rotating fashion, where at any given time window T_W, some filters are being written to, read from, or cleaned (i.e., emptied). A connection is considered active if any one of the Bloom filters reports a positive. For ongoing connections, we add to the most recent filter whenever we see the server sending a packet to the client; note that even for uni-directional upload traffic servers continuously send ACK packets to clients. Thus, when a filter is cleaned, ongoing connections automatically get carried over to the active filter.

We also note that T_W should be chosen such that we maintain a reasonable timeout window that reflects the characteristics of the majority of connections in the network [31]. A T_W value that is too small (e.g., a few seconds) will cause idling connections to be closed too early, while T_W values that are too large will require us to save too many active connections in the Bloom filter, causing increased memory usage and potentially higher false positive rates. Shorter T_W windows (also called "aggressive aging timeouts") are the security best practice for preserving stability and performance while under attack, and can be as short as 10 seconds [22, 68].

6.4 Handling False Positives at Server Agent

The server agent cooperates with the switch agent to perform a last-line-of-defense cookie check on the small fraction of packets that experience a false positive in the Bloom filter.

Identifying False Positives. The server agent knows to perform this cookie check on any packets that are not already part of an ongoing connection at the server and do not have a setup tag from the switch agent. We note that SYN packets are always stopped and handled at the switch agent, so the server agent only handles benign traffic and non-SYN packets (either adversarial or benign) that have triggered a false positive in the Bloom filter. If the false positive was the result of an adversary's non-SYN packet (e.g., if the adversary was attempting to perform an ACK flood), it would fail the cookie check at the server agent and get dropped (§7.2). However, if the false positive was triggered by a benign client (e.g., with the final ACK packet of the 3WHS between client and switch agent), then the packet would pass the cookie check at the server agent and the server agent would set up the connection with the kernel network stack.

Key Management. In existing SYN cookie defenses, only one party computes and verifies cookies. However, since both the switch and server agents verify cookies, they must share the same SYN cookie computation scheme so that cookies are consistent across the system. In other words, both switch and server agents must share the same hash functions and secret keys used to compute cookies; the network operator acts as the central controller for managing these keys across the system, installing the same initial key and performing periodic key rotation for both the switch and server agents. Furthermore, to ensure consistency when using timestamps to generate and verify cookies, SMARTCOOKIE relies on the network operator to synchronize clocks across the switch and server agents. We also note that on the server side, secret keys are only visible to the eBPF switch agent module and are not visible to applications or tenant VMs running on the server.

7 Security Analysis

We discuss possible attacks from adaptive adversaries against our system itself (above and beyond our initial SYN-flooding attack vector), and explain how we address them.

7.1 Attacks on the Cookie Check

Replay Attacks. When a cookie is first computed at the switch, it is computed with respect to the current epoch of time. When cookies are recomputed and verified, they are only accepted if they are from the current or immediately preceding epoch. While the Linux kernel uses 1 minute epochs [1], we choose 1 second epochs instead, to reflect round-trip times (RTTs) commonly seen on the modern Internet. This ensures that SMARTCOOKIE only accepts cookies returned within acceptable RTT delays, while defending against replay attacks with older cookies. For consistency, the cloud provider deploying SMARTCOOKIE should ensure that clocks are synced (e.g., NTP) between the switch agent and the server agent.

Cookie Forging and Key Recovery. An adversary can send probe packets to the switch agent and observe the returned cookies in order to crack the hashing mechanism and forge her own cookies; formally, this is performing a Chosen Plaintext Attack (CPA) against our hash function. The security of SMARTCOOKIE against cookie forging can be directly reduced to the security of the underlying HalfSipHash family of hash functions. Assuming the security properties of HalfSipHash, the adversary cannot recover the key without a brute-force search [8]. To make brute-forcing ineffective, SMARTCOOKIE rotate the key periodically (e.g., every 5-30 seconds). Thus, with the pseudorandom properties of HalfSipHash, the adversary's best attack strategy is reduced to simply guessing the cookie.

Lucky Cookies, and Saving TCP Options. The Linux kernel's default SYN cookie stores a quantized Maximum Segment Size (MSS) and discards all other TCP options. Our switch agent similarly encodes the MSS in cookies, for the server agent to later decode. This approach leaves 24 bits of entropy in the cookie, meaning that each adversary's attack packet has a negligible probability ($1/2^{24}$) of "luckily" guessing the right cookie by chance. If desired, it is possible to use 3-4 more bits of the cookie to save a few more TCP options, in exchange for slightly reduced entropy.

7.2 Attacks on the Bloom Filter

ACK Floods and TTL Expiry Attacks. The Bloom filter used by our switch agent to track verified connections has a small probability of reporting false positives; an adversary can send many ACK packets with randomized source IP addresses and port numbers, and a small fraction of these may trigger a false positive and be forwarded to the server. We refer to this as the ACK-flooding attack, and evaluate the performance of SMARTCOOKIE against such attacks in §8. We note that these false positive ACK packets will be silently dropped by the server agent after failing its last-line-of-defense cookie check (§6.4). We also filter TTLs of non-SYN packets that arrive at the switch agent, hiding from an adaptive adversary seeking to perform a TTL expiry attack whether her packets were dropped at the switch agent or at the server agent [62]. This prevents the adversary from getting feedback on which attack packets successfully triggered false positives. Thus, she cannot tailor attack packets for the Bloom filter's internal structure to achieve a higher false positive rate.

Opening Many "Legitimate" TCP Connections. The false positive rate of Bloom filters depends on the number of connections inserted. In our threat model (§3.1), adversaries have access to a moderate number of compromised devices to

launch *asymmetric* SYN-flooding attacks, but not enough to mount successful *symmetric* attacks, such as TCP connection floods. Connection-flooding adversaries would need to establish many "legitimate" TCP connections to raise the Bloom filter's false positive rate before launching a SYN-flooding or ACK-flooding attack, requiring significant resources (e.g., machines, memory, packet processing). Nevertheless, we note our filters are periodically cleaned and designed to achieve a reasonably low false positive rate under realistic traffic conditions (§6.3). Even with high rates of Bloom filter pollution, SMARTCOOKIE still blocks 100% of SYN floods in the switch and is highly resilient under ACK floods (§8.4).

8 Evaluation

We evaluate SMARTCOOKIE by running several experiments on a hardware testbed. We 1) demonstrate the performance of SMARTCOOKIE for securely computing SYN cookies with HalfSipHash in the switch data plane, compared to other approaches, and 2) show the overall performance of SMARTCOOKIE in comparison to Jaqen [51], the state-of-the-art switch-based SYN-flooding defense. We note that the authors own all testbed infrastructure, and attack traffic was only directed to dedicated testbed servers, raising no ethical issues.

8.1 Experiment Setup

Prototype Implementation. SMARTCOOKIE's switch agent is implemented in P4 targeted for an Intel Tofino Wedge100-32BF programmable switch, with approximately 1000 lines of code. The server agent is implemented with eBPF. For more details, we refer readers to Figure §4, §B.1, and §B.2. We have released our prototype source code on GitHub[1]. We also run prototypes of Jaqen SYN Cookie Proxy Mode 1 and Mode 2 [51], based on source code obtained from the authors.

Testbed. The testbed consists of four servers and an Intel Tofino Wedge32X-BF programmable switch. Two machines act as adversaries, each with a 20-core Intel Xeon Silver 4114 CPU and a Mellanox ConnectX-5 2x100Gbps NIC, generating attack traffic using DPDK 19.12.0 and pktgen-DPDK. Two other machines act as server and client, each with 8-core Intel Xeon D-1541 CPUs and Intel X552 2x10Gbps NICs. All machines run Ubuntu 21.10 with kernel v5.13.0, and the eBPF programs are built with BCC v0.24.0 and Clang v13.0.0-2. The server machines are all connected to the switch via Direct Attach Copper (DAC) cables, with under 0.1ms ping latency (round-trip time) between any pair of machines.

Setup: Realistic Traffic Load. To simulate a real-world setting with realistic benign traffic loads, we write customized client and server Go scripts to replay CAIDA anonymized Internet traffic trace 2018 [15]. We did not modify the Linux kernel's default TCP retransmission behavior.

[1] https://github.com/Princeton-Cabernet/p4-projects/tree/master/SmartCookie

Setup: Estimating the False Positive Rate. Our switch agent implementation uses Partitioned Bloom Filters with $k = 3$ arrays of 2^{20} bits each, with total memory size $m = 3 \times 2^{20}$ bits. For our experiments, we choose a connection timeout window T_W of 15 seconds for Bloom filter cleaning (§6.3), which reflects the default keepalive timeout of many applications [31]. We choose a 15-second trace window of benign traffic to match T_W, with $n = 579{,}600$ flows. Our trace represents heavier flow loads than the average from CAIDA trace statistics (386,000 flows over the same time window) [16]. Thus, we generously estimate our false positive rate as:

$$F_p(n,m,k) = \left(1 - \left(1 - \frac{k}{m}\right)^n\right)^k \approx 7.66\%. \qquad (1)$$

We replay each flow as an HTTP request in real time (approximately 38,500 requests per second), where the request starting time corresponds to the timestamp offset of the flow's first packet. We also measure the number of attack packets received at the server with this setup and verify that the measured false positive rate matches our expectations. Meanwhile, since Jaqen's prototype uses a smaller Bloom filter ($2^{16} \times 4$), we replay fewer flows ($48,800$) in Jaqen's experiments, such that the defense exhibits the same false positive rate of 7.66%. Since the number of connections in both experiments exceed the number of available ports, we add 65,536 IP addresses to both client and server; we use the connection 4-tuple as keys for Bloom filter lookups for both SMARTCOOKIE and Jaqen.

More generally, under different traffic conditions, time windows, and number of connections, we can use Equation §1 to estimate corresponding false positive rates. We also note that our current implementation did not exhaust the memory available on the Tofino 1 switch, and we can build larger Bloom filters to support more connections, trading off more memory for a reduction in the false positive rate. Other switch models (e.g., Tofino 2) also provide more onboard memory to further increase Bloom filter size and lower false positive rates.

Setup: DDoS Attacks. We run pktgen-DPDK on the adversary machines to generate SYN floods with randomized source IPs and ports. Due to false positives, Jaqen will allow 7.66% of SYN-flooding traffic to reach the server and trigger a *connection setup and kernel SYN cookie computation*. Meanwhile, since our switch agent handles 100% of SYN packets without passing any to the server, we run a separate experiment where we subject SMARTCOOKIE to ACK flood traffic (§7.2), 7.66% of which will reach the server and trigger *only eBPF SYN cookie verification* at the server agent.

8.2 Hashing Throughput

Under the experiment setup described above, we compare SMARTCOOKIE's performance against kernel-based SYN cookies and XDP-based cookies. Since prior work proposed running AES, a secure encryption algorithm, on Tofino

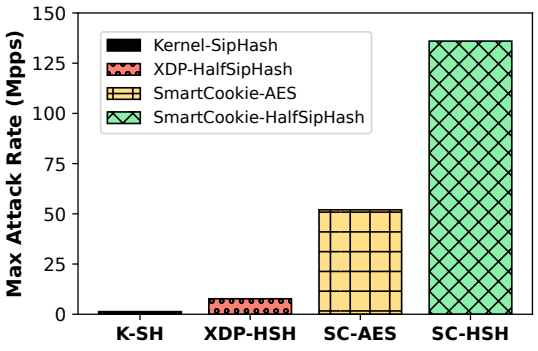

Figure 5: **Throughput.** SMARTCOOKIE-HalfSipHash defends against attacks *without packet loss* until a rate of 136.9Mpps, outperforming the next fastest defense by 2.6x.

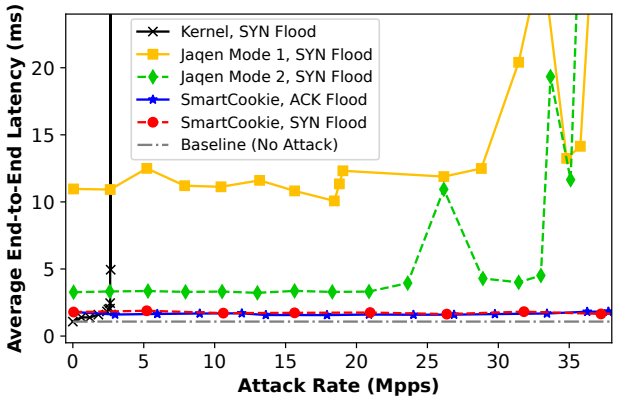

Figure 6: **Latency.** SMARTCOOKIE reduces latency by 48-84% compared to Jaqen, protecting client performance.

switches [20], we also implement and benchmark a variant of SMARTCOOKIE switch agent using AES to compute cookies.

Measuring Throughput. We measure the maximum attack rate in Mpps each defense can handle *before any packet loss*. Since our benchmark performs one hash calculation per SYN packet, we effectively measure maximum *hashing* throughput.

Results. As shown in Figure 5, SMARTCOOKIE-HalfSipHash significantly outperforms all other defenses, achieving a throughput of 136.9Mpps on high-speed switch hardware. This is *two orders of magnitude greater* than the throughput achieved by the software-based kernel defense, which uses SipHash and can only serve 1.3Mpps before the server's CPUs are exhausted. Using XDP to compute cookies can bypass the overhead of the kernel network stack and achieve 6x speedup (7.3Mpps), but this is still much slower than SMARTCOOKIE-HalfSipHash. Meanwhile, although SMARTCOOKIE-AES is faster than XDP, it requires more recirculations and only achieves 52 Mpps; SMARTCOOKIE-HalfSipHash outperforms it by 2.6x.

We note that Tofino switches have dedicated recirculation ports, *which operate without affecting capacity on other ports*. Our prototype switch agent achieves 136.9Mpps using a single Tofino 1 switch under its vanilla setup (pre-configured ports with 200Gbps recirculation throughput). To achieve even higher throughput, we can simply load balance between multiple switches to multiplex their throughput, or configure the switch to convert unused physical ports into extra recirculation bandwidth. For example, as a back-of-the-envelope calculation, using 20 recirculation ports, we could achieve 2Tbps recirculation throughput and serve roughly 1.4 billion requests per second. We also note that while repurposing additional ports for recirculation would reduce overall switch capacity, it will not affect latency. Finally, other switches exist (e.g., Tofino 2) with higher per-port throughput and more pipeline stages. Such switches, along with future hardware with native cryptographic support, can further reduce recirculation needs, additionally boosting throughput.

8.3 Latency

In this experiment, we launch both benign and attack traffic against a server as described in §8.1, and measure the end-to-end latency of benign application traffic while the server is under attacks of different magnitudes. We compare SMARTCOOKIE against the vanilla kernel-based SYN cookie defense and Jaqen's two SYN proxy modes. SMARTCOOKIE's design is transparent to clients and does not cause connection reset, leading to 48%-84% lower latency than Jaqen.

Measuring Latency. We measure the end-to-end application latency by initiating HTTP requests from the client to the server, with response size of 14.5KB (corresponding to the average flow size in the CAIDA 2018 trace). For each attack rate, we send 30 requests and calculate the average latency. Since Jaqen's Proxy Mode 2 triggers an application-layer reset, most applications (`curl`, `wget`, etc.) will wait for at least one second before retrying the connection. This timeout is an unreasonably large penalty for benign clients, and so we write a customized Go client script that immediately retries after a reset, waiting for only 1ms between connection attempts. This showcases the best possible performance of Jaqen, as it avoids the long default reset timeout, but we note that reconfiguring client applications is not always possible.

Results. As shown in Figure 6, SMARTCOOKIE has consistently low end-to-end latency (1.71ms), a 48%-84% reduction compared to Jaqen, even with the reconfigured fast retry client that bypasses Jaqen's default 1-second timeout. Jaqen Mode 1 incurs a reset and one additional round trip, with a minimum latency of 11.12ms. Jaqen Mode 2 incurs two additional round trips and an application-layer retry, requiring at least 3.31ms for end-to-end setup with our fast 1ms retry client and *over one second* for default TCP applications that have not been reconfigured. Meanwhile, SMARTCOOKIE's latency, which is only 1.71ms, is close to the baseline latency of the vanilla kernel without any attack (1.08ms).

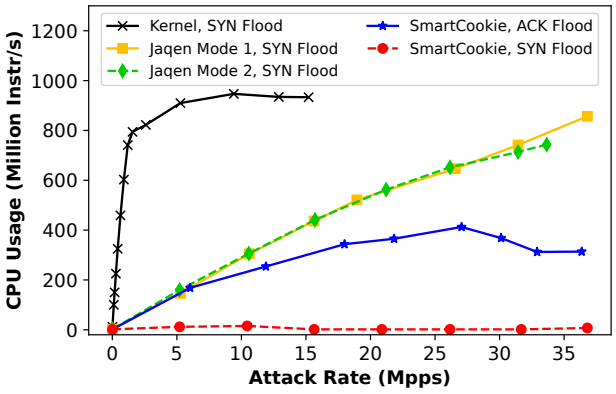

Figure 7: **CPU Usage.** SMARTCOOKIE has *no* server CPU overhead against SYN floods and reduces overhead against ACK floods by 33%-36% compared to Jaqen.

8.4 Server CPU Usage

Using the same setup from §8.1, we replay trace-based benign traffic while launching attack traffic at increasing rates. We measure the server's CPU overhead across various defenses. SMARTCOOKIE has *no overhead* for SYN floods and reduces overhead for ACK floods by 33-36% compared to Jaqen.

Measuring CPU. To measure CPU overhead, we use the `perf stat` command to read CPU performance counters and collect the number of instructions executed per second for each CPU core, taking the average across cores. We also repeat each measurement ten times and take this average. For more stable results, we turned off frequency scaling (Turbo Boost) and fixed all cores' frequency at 2.1GHz.

Results. Both modes of Jaqen exhibit similar server CPU overhead, as they both allow the same rate of false positive SYN packets to reach the server, where the defense degrades to SYN cookie computation on server software (Figure 7). We note that SMARTCOOKIE switch agent processes 100% of SYN packets directly on network hardware, completely protecting server CPUs from resource exhaustion for SYN cookie computation. With SMARTCOOKIE, servers experience *no CPU overhead during SYN floods*. Thus, in order to see the effect of false positives on CPU usage with SMARTCOOKIE, we also measure the overhead of the server agent handling map lookup and cookie verification for false positive ACK packets (§6.4): SMARTCOOKIE under an ACK flood exhibits approximately 33%-36% lower CPU overhead for the same attack rate and same false positive rate as Jaqen under a SYN flood. This is because Jaqen is a purely switch-based defense that degrades to the vanilla kernel's defense on false positives, which begins to suffer from attack rates as low as 1.3 Mpps. Meanwhile, SMARTCOOKIE is designed as a split-proxy system that cooperates with an XDP-based server agent for false positives (§B.2). XDP operates on raw packets early in the kernel stack before any socket buffer is allocated, lowering the overhead significantly compared to the kernel defense.

	SRAM	TCAM	HashUnit	Instr.
Jaqen Mode 1 (CRC)	4.6%	0.0%	19.4%	4.9%
Jaqen Mode 2 (CRC)	4.6%	0.0%	19.4%	6.3%
SMARTCOOKIE-AES	13.8%	0.1%	30.6%	9.4%
SMARTCOOKIE-HSH	6.8%	1.4%	56.9%	9.9%

Table 2: Resource usage on programmable switch.

	SRAM	TCAM	HashUnit	Instr.
tna_simple_switch.p4	6.3%	9.0%	0.0%	9.6%
+SMARTCOOKIE	12.6%	11.5%	54.2%	18.0%
switch.p4	33.6%	31.6%	19.4%	13.5%
+SMARTCOOKIE	40.1%	37.5%	73.6%	20.3%

Table 3: Adding SMARTCOOKIE to complex P4 programs.

8.5 Switch Resource Usage & Compatibility

In Table 2 we report SMARTCOOKIE's utilization of switch hardware resources with two variants of hashes (HalfSipHash and AES), as reported by Intel's P4i tool. SMARTCOOKIE has a trivial footprint for important shared resources (TCAM:1.4%, SRAM:6.8%). Notably, the HashUnit usage is highest (57%), but HashUnits are used less by other network functions. We also report resource utilization of Jaqen SYN Proxy (Modes 1 and 2), which use CRC as its cookie hash.

Furthermore, we successfully integrated SMARTCOOKIE-HalfSipHash into two feature-rich, complex P4 programs: `tna_simple_switch.p4` and `switch.p4`, demonstrating SMARTCOOKIE can co-exist with other sophisticated network functions. Table 3 presents resource utilization metrics for each base program and the variant with SMARTCOOKIE added, highlighting SMARTCOOKIE's efficient footprint and compatibility with other switch functions.

9 Discussion

Routing Considerations. We envision our defense deployed in a provider network with multiple edge switches, motivating the need to be robust to both asymmetric routing and potential routing changes. SMARTCOOKIE handles asymmetric routing by default with several clever design decisions, and it can handle routing changes using two high-level approaches, each with their own tradeoffs. Cooperating switch agents can maintain synchronized Bloom filters with state for all verified connections. Alternatively, Bloom filters across individual switch agents can dynamically adapt to routing changes using a packet sampling approach. Please see §C for more details.

Serving Tenants Transparently. SMARTCOOKIE does not modify the server's network stack, and can serve unmodified tenant VMs running on servers. From the tenant's point of view, the TCP protocol is unchanged. Today's high-performance VM hypervisors and container hosts often run specialized software switches (e.g., eBPF-based Cilium [4])

to handle tenant traffic, and SmartCookie 's server agent can be integrated into these software switches.

Handling Other DDoS Attacks. Although SmartCookie was explicitly designed for large-scale SYN-flooding attacks, by default it also handles other TCP-based volumetric attacks (e.g., ACK floods, SYN-ACK floods, RST/FIN floods), quickly dropping attack traffic on behalf of the server. We believe our design can also be generalized to UDP-based volumetric attacks, with mechanisms like those proposed in [69].

Transport Protocols. We note that SmartCookie makes assumptions about TCP and must be upgraded when clients use new features, like MPTCP. To avoid protocol ossification, SmartCookie should not be applied by default on all traffic. Instead, it should be an opt-in feature for tenants enabled only during attacks, like the Linux kernel's SYN cookie defense. Future servers and tenants using newer transport protocols would require updated designs; split-design defenses supporting newer protocols (e.g., MPTCP) and connection-oriented UDP traffic (e.g., QUIC) are interesting future works.

Further Improvements. Our eBPF server agent is independent of the kernel network stack, enabling direct deployability without kernel updates. In the future, the switch agent can synchronize ISNs with the kernel to entirely avoid sequence number translations and further boost performance (§D).

10 Related Work

SYN Cookie Defenses. State-of-the-art SYN cookie defenses, including standard practices such as DDoS scrubbing centers, struggle to capitalize on the unique capabilities of programmable switches. They either have the data plane do *too much* (e.g., performing the complete TCP handshake or keeping per-flow state) [51, 72] or *too little* (e.g., simply forwarding attack traffic to a server for software-based packet-processing) [27, 28]. These works miss opportunities to refactor the server, under-optimize switch resource usage, incur performance penalties on benign clients, and most importantly create vulnerabilities in the defense with insecure hashes.

The most closely related such work is Jaqen [51]. Unlike Jaqen, SmartCookie uses a cryptographically robust hash that provides strong security guarantees and does not sacrifice performance for scalability. [60] also proposed a SYN cookie proxy, but their proxy must similarly keep per-flow state and is implemented in software [9]. SmartCookie overcomes strict resource constraints to efficiently run SYN cookies directly on switch hardware.

Split Functionality. Poseidon [72] presents a two-part DDoS defense: a switch component on hardware and a server component running in software. However, Poseidon requires the majority of the defense to reside in software, which is orders of magnitude slower at packet-processing than switch hardware. More importantly, Poseidon's SYN cookie proxy uses an insecure hash, and it must also keep per-flow state. SmartCookie overcomes these limitations and presents a novel split proxy that preserves switch resources, optimizes performance, and computes cookies with a *secure* hash.

XDP. GateBot [11] is a DDoS defense system developed by Cloudflare that drops traffic based on iptable rules implemented with XDP. Recently, Google also used XDP to implement SYN cookies, taking advantage of XDP's early execution hook to bypass the kernel TCP stack [57]. SmartCookie provides an order of magnitude higher performance than XDP-based SYN cookies, stopping all SYN flood traffic in switches at the network edge and only relying on XDP-based cookies to handle a small number of false positives.

Cryptography in the Data Plane. Prior works have explored cryptographic functionality in the data plane, although some targeted software models instead of hardware environments. Scholz et al. [61] implemented prototypes of cryptographic hash functions, including SipHash, targeted for CPU backends, NICs, and FPGAs. [20] and [71] first implemented the AES cipher and HalfSipHash for Tofino switches. Our work leverages such cryptographic building blocks to design and implement a complete split defense system with end-to-end evaluation results. NeoBFT [66] further optimized HalfSipHash on switches by computing multiple message signatures in one batch. PINOT [69] implemented a lightweight 2-round Even-Mansour (2EM) cipher for switches for privacy-protecting IP address encryption; however, their implementation uses fixed permutations that cannot be quickly rotated, which introduces a potential risk for brute-force attacks.

General In-Network Defenses. Previous works used software-defined networking (SDN) to implement SYN-flooding defenses, outside of SYN cookies [28, 30, 52, 53, 59, 64]. Approaches include rate-limiting based on an upper-bound threshold of SYN packets [52], enforcing whitelists or blacklists based on completion of the TCP handshake [30, 53], and using switches to identify and steer suspicious traffic to software platforms for further handling [28]. More generally, other recent works proposed switch-based defenses against link-flooding attacks [73] and pulse-wave DDoS attacks [35]. Surveys of switch-based DDoS mitigations and other switch-based network security applications are presented in [18, 19].

11 Conclusion

SmartCookie is the first SYN-flooding defense to provide cryptographically secure SYN cookies on high-speed switches. With its novel split-proxy design leveraging programmable data planes, SmartCookie is robust against adaptive adversaries and scalably serves large loads of traffic while under attack, without disrupting benign flows or degrading performance. We show that, contrary to common belief, a hardware-software codesign performs better than a purely hardware design. With networks that are now end-to-end programmable, we believe many security applications would benefit from similar division-of-labor design principles.

Acknowledgments

We sincerely thank Alan Zaoxing Liu for his assistance in our evaluation. We are grateful to John Sonchack, Oliver Michel, Henry Birge-Lee, Hyojoon Kim, and Maria Apostolaki for their detailed and valuable feedback on earlier versions of our work, and we also thank the anonymous reviewers and shepherd for their insightful comments. Appendix

A Breaking CRC-Based Cookies

Given the connection 4-tuple m and the secret nonce n, the CRC-based cookie is typically generated using $\mathrm{CRC}(m\|n)$. We note CRC is linear and affine: for any A, B, and C we have

$$\mathrm{CRC}(A)\oplus\mathrm{CRC}(B)\oplus\mathrm{CRC}(C)=\mathrm{CRC}(A\oplus B\oplus C). \quad (2)$$

The adversary can send a SYN packet with known input m_0 and observe the output $\mathrm{CRC}(m_0\|n)$. Subsequently, the adversary can compute $\mathrm{CRC}(m_0\|0)$ herself, and derive

$$\mathrm{CRC}(0\|n)=\mathrm{CRC}(m_0\|0)\oplus\mathrm{CRC}(m_0\|n)\oplus\mathrm{CRC}(0). \quad (3)$$

Now that the adversary knows $\mathrm{CRC}(0\|n)$, she can compute new cookie value for any arbitrary 4-tuple m_x, as follows:

$$\mathrm{CRC}(m_x\|n)=\mathrm{CRC}(m_x\|0)\oplus\mathrm{CRC}(0\|n)\oplus\mathrm{CRC}(0). \quad (4)$$

We also note that the same attack can be applied even if the nonce is placed at different input locations.

B Additional Implementation Details

B.1 Switch Agent: Processing Details

The switch agent processes two classes of packets from the client and two classes of packets from the server agent:

- *SYN packets from the client*: the switch agent computes a SYN cookie and returns this to the client in the ISN of the SYN-ACK response packet.
- *Non-SYN packets from the client*: the switch agent checks its Bloom filter to determine validity. If the Bloom filter reports a positive, the packet is forwarded to the server. Otherwise, the switch agent performs a cookie check, forwarding the packet to the server agent with a setup tag if it passes the check and dropping the packet otherwise.

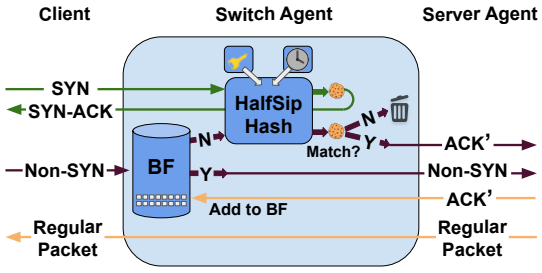

Figure 8: Switch agent logic flow.

- *Tagged confirmation packets from the server agent*: the switch agent adds the connection information to its Bloom filter. Note that instead of doing this directly after the cookie check, the switch agent waits for explicit confirmation from the second packet of the 2WHS, avoiding connection loss in scenarios where setup packets are lost between the switch agent and server agent (§6.1).
- *Regular packets from the server agent*: the switch agent passively forwards the packet to the client.

B.2 Server Agent: Linux eBPF Modules

The server agent is composed of eBPF modules that execute on the ingress and egress path of the kernel stack. Figure 9 demonstrates the tightly-knit functionality of the two modules, which can be understood as a progression of eBPF map `connection_states`. Entrance into these states is triggered by packets interpreted as *events*, and the associated *actions* for each state determine how packets are processed.

XDP Ingress Processing. eBPF programs can attach and execute at different kernel hooks, many of them occurring early on the path to the kernel network stack. eXpress Data Path (XDP) is a hook in the network driver that allows for execution of eBPF programs immediately after a packet is received off a network interface, before it even reaches the kernel TCP stack [41]. XDP operates on raw packet data before any socket buffer allocation. It offers the fastest in-kernel packet-processing without offloading to hardware [54].

The server agent's ingress program is attached at the XDP hook. As shown in in Figure 9, the ingress program initiates the 3WHS with the kernel network stack (**A1**) upon receipt of packets that are not already part of an ongoing connection and have a `setup` tag included (**E1**). The ingress program properly converts these setup packets into SYN packets and forwards them up the kernel stack. The sequence number delta for the connection is temporarily initialized and added to the map, and the `connection_state` stored in the map is set to `SYN_SENT` (**S1**). The ingress program also handles sequence number translations and checksum updates on all other incoming packets, before forwarding them up the network stack (**A4**). The module only processes TCP packets and simply passes non-TCP packets up the network stack.

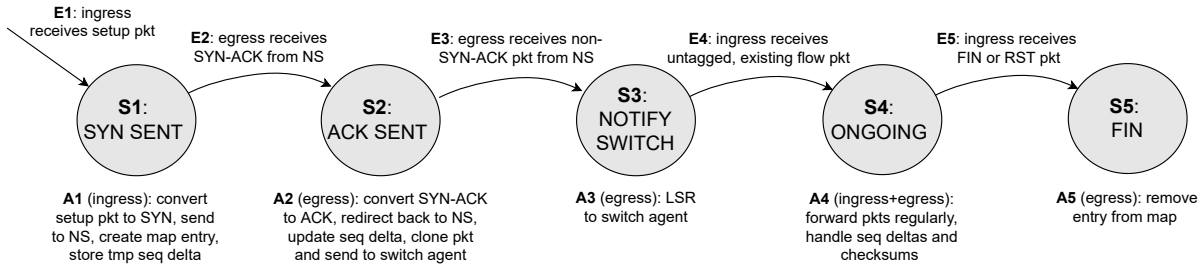

Figure 9: The server agent's eBPF map coordinates packet-processing between XDP ingress and TC egress modules.

TC Egress Processing. XDP is not yet supported on the kernel's egress traffic path, which is why we choose to implement egress processing at the traffic control (TC) hook, the next earliest hook in the stack. The TC hook offers access to the packet's socket buffer, providing greater processing flexibility at the cost of slightly lower processing speeds. If support for XDP on the egress path is added, SMARTCOOKIE's egress functionality can easily be ported from TC to XDP to further boost egress packet-processing performance.

SMARTCOOKIE's server agent uses a TC egress program to perform server-side setup and sequence number translations on outgoing packets. When the module receives an outgoing TCP packet from the network stack, it checks the stored `connection_state` and handles the packet accordingly (Figure 9). Generally, the server agent processes three types of packets from the switch agent:

- *Packets that are already part of an established connection*: the server agent performs sequence number and checksum updates and then passes the packet along to the kernel network stack for normal processing.
- *Packets with a setup tag that are not already part of an established connection*: the server agent knows the packet has successfully passed the SYN cookie check at the switch agent and bootstraps the connection establishment with the kernel network stack, saves the sequence number delta required for future packets, and sends the switch agent an explicit confirmation upon completion.
- *Packets that are not part of an established connection and also have no setup tag (false positives)*: the server agent performs a last-line-of-defense SYN cookie check on the packet, setting up the connection if it passes the check and dropping the packet otherwise.

C Routing Considerations

All traffic between clients and servers traverses a network switch (i.e., the edge switches are a 'cut' of the network between clients and servers). In a distributed defense with an upstream switch it is not guaranteed that all traffic will pass through the *same* switch in both directions (asymmetric routing) and traffic flowing in a single direction may also traverse different switches (routing changes). Asymmetric routing is very common due to hot-potato routing, a phenomenon where networks seek to pass traffic as quickly as possible out of their borders, resulting in traffic for one connection not taking the same path in both directions [56]. Routing changes, while less common at the connection level, can still occur and in particular affect longer-lived connections [56]. With an upstream defense, traffic from an ongoing flow could traverse a switch that did not perform the initial cookie check. This must be handled gracefully so the client can avoid additional verification or connection disruption.

C.1 Handling Asymmetric Routing

The SMARTCOOKIE protocol has removed the need for the switch agent to remain actively involved (i.e., with sequence number translations) in a connection once it has been established. This ensures that the switch agent need only *forward* return packets, especially since this traffic is coming from the servers and can be trusted without undergoing verification. Thus, once the setup phase has been completed, *any* switch in the provider backbone can safely forward the rest of the return traffic, supporting asymmetric routing and direct server return (DSR), regardless of the extent of asymmetry.

During connection setup, however, the switch agent must see the return traffic from the server to properly add the connection to its local record of verified connections. To accomplish this, the SMARTCOOKIE server agent ensures response traffic is routed through a single switch agent during setup by using loose source routing (LSR) to explicitly route response traffic from the server to the client through the *same* switch agent, until the switch agent has created a local record. In practice, when the switch agent sends a tagged packet to the server agent, it includes a switch agent identification (i.e., the IP address of the switch) that the server agent can use for routing relevant return packets. The server agent knows when the switch agent has updated its local record since the switch agent will stop tagging packets once the update is complete.

C.2 Handling Routing Changes

Routing changes are less common at the TCP connection level, especially when flow-aware load balancing (e.g., ECMP) is used instead of packet spraying [43]. Still, our switch agent must gracefully handle routing changes caused by configuration updates, equipment failures, or other unexpected reasons. We consider a scenario where a client has passed the cookie check at a given switch agent, `SwitchAgent_1`, and has been added as a verified connection to its local Bloom filter (BF), but has some packets routed to the server through a different switch agent, `SwitchAgent_2`, which does not have records of the connection. In this case, SMARTCOOKIE should ensure that a verified client would not get penalized by experiencing connection disruption (e.g., packet drops or connection reset) at the new switch agent.

BF Synchronization. For provider backbones that expect routing changes more regularly (e.g., with packet spraying), one solution could be to replicate BF state across the different switch agents, maintaining a copy of the set of all verified connections at each switch agent in a fault-tolerant manner [47]. However, if routing changes are expected infrequently (e.g., all connections are short-lived), synchronizing BF state could be avoided, as this would fill up the BFs unnecessarily and degrade the membership-reporting accuracy of the filters.

Packet Sampling. To avoid synchronizing state across BFs, the SMARTCOOKIE protocol could allow individual BFs to dynamically adapt to routing changes. To accomplish this, the switch agent could probabilistically allow a small sampling of non-SYN packets through to the server agent even if the packets are not in the BF and have not passed the SYN cookie check. By performing stateless rate limiting with probabilistic sampling, SMARTCOOKIE would trade off the risk of a routing change causing benign traffic to be dropped and the risk of allowing attack traffic through to the server agent.

More concretely, we consider a case where an adversary sends attack traffic with the same connection 4-tuple (spoofed from multiple vantage points) in order to cause traffic to enter the provider backbone through more than one switch agent. If the attack traffic consisted of SYN packets, each of the switch agents would initiate the SYN cookie check and the attack would be stopped at the network edge. For non-SYN packets, the switch agent would probabilistically let through a small number of unverified packets, placing a special tag on these packets before forwarding them to the server agent.

Upon receiving a packet with this special tag, the server agent would check to see if the packet was part of an active connection. If it was, the server agent would use LSR to respond to the specific proxy that sent the packet, signifying all is well and the switch agent can add the connection to its BF. However, if the packet was not part of an active connection at the server, the server agent would simply drop the packet and no further action would be taken. We note that this design requires minimal effort from the server agent, as it would simply perform connection lookups and would *not* perform any cookie checks for these special packets.

D Miscellaneous and Future Work

Header Field Compatibility and MTU. Setup tags added to packet headers are only visible within the cloud provider's internal network, between switch agent and server agent. Any such modifications are removed before unmodified packets are passed to the server's unmodified TCP stack. SMARTCOOKIE mostly tags handshake packets during connection setup, when packets are only 40 - 60 bytes. However, in special cases (setup packets dropped or routing changes) SMARTCOOKIE might tag a client's data packets, so the internal network's MTU should be roughly 10-20 bytes larger.

Integration with the Network Stack. The server agent interfaces with an unmodified TCP stack, which is useful in scenarios such as serving tenant VMs with customized kernels, or even VMs running a different guest operating system. However, the server agent needs to pay a small overhead for translating sequence numbers on every TCP packet. Without changing the trust model or requiring tenant VMs to have access to secret keys, a tighter integration with the Linux kernel of trusted physical servers can eliminate this performance penalty. Specifically, the server agent can explicitly instruct the kernel to choose the desired initial sequence number (ISN) and synchronize numbers between the switch and server.

Synchronize Initial Sequence Number. An unmodified Linux kernel chooses its ISN at random. By integrating the server agent 2WHS with the kernel's TCP connection setup, we could explicitly instruct the kernel to adopt the ISN chosen by the switch agent. This minor change in the kernel network stack would remove the need to perform sequence number translations in the server agent altogether, further improving its performance and automatically allowing the switch agent to avoid keeping per-flow state.

Avoid Duplicate Per-Flow State at Server Agent. We also note that currently the eBPF-based server agent maintains per-flow state for all TCP connections in an eBPF map, duplicating the kernel-maintained list of all TCP sockets. This leads to a small but non-negligible memory overhead. Future implementations of the server agent could query the connection state from the kernel's list of active TCP connections directly. This would allow the server agent to become stateless after connection setup, acting as an extremely lightweight module that only handles the 3WHS with the TCP stack and does not keep per-flow state.

Offloading the Server Agent. We can push the server agent to run directly on a NIC that supports eBPF hardware offloading, removing the overhead of running on the server's CPU. We can also run the server agent on a SmartNIC (e.g. NetFPGA), or even on a top-of-rack (ToR) switch in front of the server. These techniques would allow the server's CPU to be dedicated to only running application logic.

L↻↻py Hell(ow): Infinite Traffic Loops at the Application Layer

Abstract

Denial-of-Service (DoS) attacks have long been a persistent threat to network infrastructures. Existing attack primitives require attackers to *continuously* send traffic, such as in SYN floods, amplification attacks, or application-layer DoS. In contrast, we study the threat of application-layer traffic loops, which are an almost cost-free attack primitive alternative. Such loops exist, e.g., if two servers consider messages sent to each other as malformed and respond with errors that again trigger error messages. Attackers can send a *single* IP-spoofed loop trigger packet to initiate an *infinite* loop among two servers. But despite the severity of traffic loops, to the best of our knowledge, they have never been studied in greater detail.

In this paper, we thus investigate the threat of application-layer traffic loops. To this end, we propose a systematic approach to identify loops among real servers. Our core idea is to learn the response functions of all servers of a given application-layer protocol, encode this knowledge into a loop graph, and finally, traverse the graph to spot looping server pairs. Using the proposed method, we examined traffic loops among servers running both popular (DNS, NTP, and TFTP) and legacy (Daytime, Time, Active Users, Chargen, QOTD, and Echo) UDP protocols and confirmed the prevalence of traffic loops. In total, we identified approximately 296k servers in IPv4 vulnerable to traffic loops, providing attackers the opportunity to abuse billions of loop pairs.

1 Introduction

Traffic loops *at the network layer* are a widely-known occasional configuration issue that attackers can abuse to launch severe Denial-of-Service (DoS) attacks that overload networks and hosts. Such routing loops typically occur due to accidental router misconfigurations. Fortunately, the pioneers of the internet realized the problem of network loops early on and stopped it by design. When standardizing the Internet Protocol (IP), they included a dedicated IP header field to prevent packets from looping indefinitely. Any IP router decrements the value of this *Time-to-Live* (TTL) header field when it forwards a packet to the next hop. By discarding packets with TTL=0, routers enforce that IP packets do not spin infinite cycles — mitigating loops at the network layer.

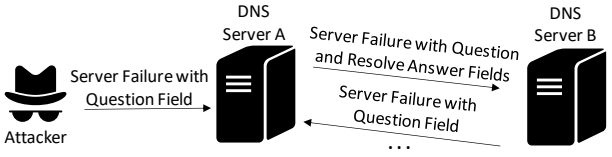

Figure 1: Example DNS traffic loop. The attacker (left) sends a single IP-spoofed, malformed DNS message to a server (middle), impersonating the IP address owner (right). This loop-trigger message combines a server failure with a valid question field, which server A resolves and replies to B. Server B then crafts a payload that preserves the server failure opcode and question field but strips the answer field. To this point, a packet loop is formed between the two servers.

In this paper, we show that traffic loops also exist *at the application layer*, irrespective of network-layer defenses. Surprisingly, app-layer loops have gained little attention except for an isolated past vulnerability in NTP in 2009 [38] or reports concerning only two legacy protocols [16]. Application-layer loops arise if two network services indefinitely respond to each other's application-layer messages. Such loops remain unnoticed by IP's TTL mechanism and are hence infinite. Without losing generality, imagine two DNS resolvers that respond with an error message when receiving an error message as input. If an error as input creates an error as output, and a second system behaves the same, these two systems will keep sending error messages back and forth — *indefinitely*. Attackers can invoke such endless loops by sending a single IP-spoofed packet. Worse, they can spawn loops in parallel. Figure 1 shows an example loop we identified among real DNS servers. In this example, an attacker can cause a loop among two faulty DNS servers by injecting a single DNS server failure message. Once injected, the servers send DNS

error messages back and forth — indefinitely.

Application-layer loops are an overwhelming attack primitive that can be abused for, e.g., launching link-flooding DoS attacks, overloading networks that host looping servers, exhausting computation resources of looping servers themselves, or economically damaging ASes due to increased upstream costs. Worse, attackers do not require large attack bandwidth to abuse loops. In fact, sending a *single* IP-spoofed packet creates an *infinite* loop among two servers. Moreover, attackers do not require any control of the looping servers or their configurations; all it requires is finding pairs of servers that loop. Application-layer loops thus provide the attackers with several benefits over existing DoS attack primitives, where attackers either have to *continuously* send traffic (e.g., SYN floods [17], amplification DDoS [8, 10, 14, 22, 24, 27]) and/or have to *control configurations* of the abused infrastructure (e.g., DNS-based attack chains that require partial control of the DNS zones [15, 36]). We thus believe that it is of utmost importance to systematically study the overall threat.

To this end, we devise a scalable methodology to identify application-layer loop internet infrastructures. We bootstrap our loop search with a list of known services of a given UDP-based application-layer protocol from past network scans. We then send a few hand-crafted discovery probes to these known services. These protocol-specific probes reflect protocol messages for which we do not expect answers, such as protocol-specific error messages or semantically invalid requests and responses. Seeing that many services unexpectedly *do* respond, we cluster their responses to abstract away syntactical differences while retaining semantic similarities. Next, we learn the *response function* per server, allowing us to reliably predict which response a server would send after receiving a given input. We then use these mappings to form a *loop graph* that encodes which response a server returns when receiving a given response as input. We traverse the loop graph to find potential loop pairs, i.e., two hosts that will send messages forth and back indefinitely. Finally, we randomly sample from the potential loop pairs and use a rate-limited proxy to verify their loop behavior in practice.

We apply this methodology to study loops in three popular UDP-based application-layer protocols (DNS, NTP, and TFTP) and six legacy protocols for which we suspect loop issues by design (Chargen, QOTD, Echo, Time, Daytime, and Active Users). We find that loops at the application layer are more common than intuitively expected. In fact, they seem to be a widespread problem of server implementations for all of the studied protocols. In DNS, NTP, and TFTP alone, we find 249K "loop hosts," i.e., hosts that attackers can abuse to construct a loop when being paired with other loop hosts. We empirically validate that this corresponds to over 5.3B potential "loop host pairs" of which we can probabilistically confirm 87.9%, affecting 7,318 ASes (9.7%) globally. In addition, we find 123.6k servers running legacy protocols, corresponding to 2.0B potential "loop host pairs," and we can probabilistically confirm that 78.1% of them can be abused. Unfortunately, we empirically validate that loops even exist *across protocols*, rendering them extremely hard to mitigate on a per-protocol basis alone.

To better understand mitigation options, we study the reasons for traffic loops. First and foremost, we find that responding to error messages or random data can quickly turn into looping behaviors. Second, some loops are protocol-specific, such as middlebox-induced loops in DNS, where servers react to well-formed DNS responses with another DNS response. Finally, legacy protocols such as Chargen and QOTD send responses irrespective of the payload they receive, entirely lacking a notion of requests and responses. This shows that standardization bodies and developers must be more careful about traffic loops. We were surprised to see that few standards explicitly mitigate traffic loops. Even *if* standards implicitly describe patterns of how to avoid loops (e.g., "do not reply to error messages when receiving an error message"), implementations either do not follow such optional advice, or the standard is not explicit enough (e.g., it does not specify how to react upon invalid messages such as random data). To increase awareness of this threat, we performed a large-scale disclosure operation, reaching out to the standardization experts and developers of the affected implementations.

2 Background and Related Work

Traffic Loops Traffic loops are a strong primitive for performing DoS attacks. Known classes of loops either operate at the network layer or are application-layer attacks that require (partial) control over service configurations.

Nosyk et al. found that *network-layer routing loops* can be used as mega amplifiers for DNS-based DoS attacks [37]. In such a routing loop, which is mostly caused by misconfigurations and inconsistent implementations of routing protocols, a packet circulates through a sequence of routers until its TTL decays. Given that a DNS censorship middlebox injects a DNS response upon observing a censored DNS query [39], a single DNS query can trigger repetitive answers from the middlebox if the middlebox is involved in routing loops. This way, an attacker can use routing loops to generate and send a huge amount of traffic to a target victim. Plenty of research [21, 30, 41] focuses on effectively identifying and eliminating routing loops.

However, there is little research on *application-layer loops*, and existing research is tailored to certain protocols and requires partial attacker control over configurations. For example, TsuNAME [36] is an app-layer loop attack against DNS servers. The attack exploits cyclic dependencies in DNS zone files. Two authoritative DNS resolvers with misconfigured zone files can refer to each other for resolving, and thus, a triggering query from the attacker can start a traffic loop between the two servers. Another application-layer loop attack abuses CNAME records [15]. By manipulating the CNAME records

on two authoritative name servers, an attacker can chain the CNAME records on two name servers to form an aliasing loop. However, to leverage these two attacks, attackers need to set up desired zone configurations or domain records on target servers. In [18], Chen et al. introduced a DoS attack against Content Delivery Networks (CDNs), where malicious customers can create forwarding loops among or inside CDNs by manipulating the forwarding process.

Existing traffic loops thus either rely on temporal network configuration errors or are tailored to certain application-layer protocols and require a high degree of attacker control. In contrast, the loops that we identify do not require any privileges or network errors and generalize to several application-layer protocols.

Related DoS Attack Primitives Once found, the traffic loops that we present in the paper can be abused as an almost infinitely-amplifying attack primitive (offering more severe amplification than previously known amplification attacks) and assist attackers in performing link-flooding attacks without requiring control over the endpoints involved in the attack. We discuss both primitives in the following.

Amplification attacks exploit network services that operate application-layer protocols with known amplification vectors [11, 33, 40]. For example, by spoofing the IP address of victim hosts and sending floods of query packets to DNS servers, an attacker can generate and direct significant attack traffic in the form of DNS responses to the victim. In amplification attacks, an attacker needs to continuously send floods of IP-spoofed packets to maintain the attack traffic — in contrast to needing only a single trigger message in traffic loops. Other than DNS [24], protocols such as NTP [27], SSDP [10], BitTorrent [8], and SNMP [22] can also be abused in such attacks. Knowing the threats of amplification attacks, the security community has also discussed mitigations. Source address validation (SAV) [28] is considered the best practice, as amplification attacks require an attacker to send IP-spoofed packets. However, a 2019 study [34] showed that over 21% of analyzed ASes do not deploy such outbound filtering.

Link-flooding attacks aim to overload entire network links, not just single hosts. The Coremelt attack [43] is an example in which thousands of attacker-controlled bots exchange low amounts of traffic to overload a network link they share. Similarly, the Crossfire attack commands bots to send traffic to public servers instead of forming pairs of bots [26]. But to coordinate either link-flooding attack, attackers require bots, i.e., compromised hosts. In contrast, loops abuse existing, non-compromised servers, which readily provide billions of loopable server pairs. An attacker can selectively pick loopable servers on victim links and trigger application-layer loops between them to launch a link-flooding attack. Such attacks can only be mitigated by SDN-based mitigations [25, 32, 44, 46].

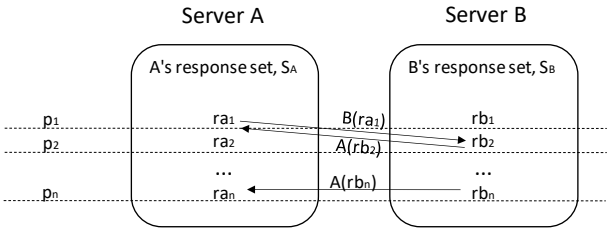

Figure 2: Example response functions of servers.

3 Methodology

Before discussing the details of our methodology, we first present the definition of a loop pair and formulate the research problem of finding loop pairs. Next, to show the underlying challenges, we discuss the limitations of a naïve straw-man approach. Finally, we introduce our methodology in detail.

3.1 Loop DoS Problem Formulation

Consider two UDP servers A and B. Upon receiving a packet p_i, A and B deterministically respond to a packet p_i using response functions $A(p_i) = ra_i$ and $B(p_i) = rb_i$, respectively. The response functions map a vector of incoming packets $P = p_1, p_2, \cdots, p_n$ to server-specific response sets, i.e., $S_A = \{(p_1, ra_1), (p_2, ra_2), \cdots, (p_n, ra_n)\}$ for server A and $S_B = \{(p_1, rb_1), (p_2, rb_2), \cdots, (p_n, rb_n)\}$ for B. Figure 2 illustrates this mapping. The mapping can now be used to find loops at the application layer. In the most simple case, when $A(rb_i) = ra_m$ and $B(ra_m) = rb_i$, we have $B(A(rb_i)) = rb_i$. That is, whenever A sends ra_m to B, B will respond with rb_i to A, which in turn sends ra_m, and so on — an endless loop. The attacker can trigger this loop by sending an IP-spoofed rb_i packet to A, forging the identity of B as the packet source (or alternatively: send rb_m to B in the name of A).

But loops may also exist in more complex settings that involve multiple response conversions. To generalize, when there are $B(\cdots A(B(A(rb_i)))) = rb_i$ (or $A(\cdots B(A(B(ra_i)))) = ra_i$), a loop between server A and B is possible and we call server A and server B a *loop pair*. This generalization allows us to find loop pairs for which $B(A(rb_i)) \neq rb_i$. For example, consider $A(rb_i) = ra_j$, $B(ra_j) = rb_k$, $A(rb_k) = ra_l$, and $B(ra_l) = rb_i$ — completing a loop after four response types.

In the following sections, we outline methodologies for how to identify possible loop pairs among servers. Basically, we need to learn the servers' response sets (e.g., S_A) or their response function (e.g., $A(p)$). The difficulty lies in the fact that the number of server pairs is quite large and the input space infinite — thus calling for scalable methods.

3.2 Straw-Man Approach for Finding Loops

Given two UDP servers, A and B, a naïve approach to identify possible loop pairs could operate as follows:

1. To learn the response sets (S_A and S_B) of servers A and B, we could generate random packets and collect A's and B's responses to these generated packets respectively.

2. We could then send all packets $ra_i \in S_A$ to server B and all packets $rb_m \in S_B$ to server A to learn the response function $A(p)$ where $p \in \{rb_1, rb_2, \cdots, rb_n\}$ and $B(p)$ where $p \in \{ra_1, ra_2, \cdots, ra_n\}$.

3. If we find $B(ra_i) = rb_m$ and $A(rb_m) = ra_i$, we could assume that servers A and B form a loop pair.

However, this straw-man solution suffers from three substantial issues that underline some of the core challenges of discovering loop pairs in a scalable and precise manner.

First, the methodology does not scale. Learning all possible packets in a real server's response set requires us to send a large number of random probes to real servers. Identifying loops among servers by sending all packets in each server's response set to all servers again (step (2)) induces an impractical number of probes when searching for loop pairs among millions of servers. With n servers and m probe packets, the straw-man approach may require us to send up to $n*m$ probes *to each server*, quickly demonstrating that this does not scale for n in the range of millions and large m due to the random nature of the naïve packet generation.

Second, the automated and random nature of the packet exploration phase (step (1)) — often the basis for software vulnerability search [9] — may trigger undesired bugs, crash, or otherwise interfere with the underlying server software. As we are neither interested in triggering such bugs nor find it ethical to explore them in live systems, we have to resort to less intrusive ways of exploring the response functions.

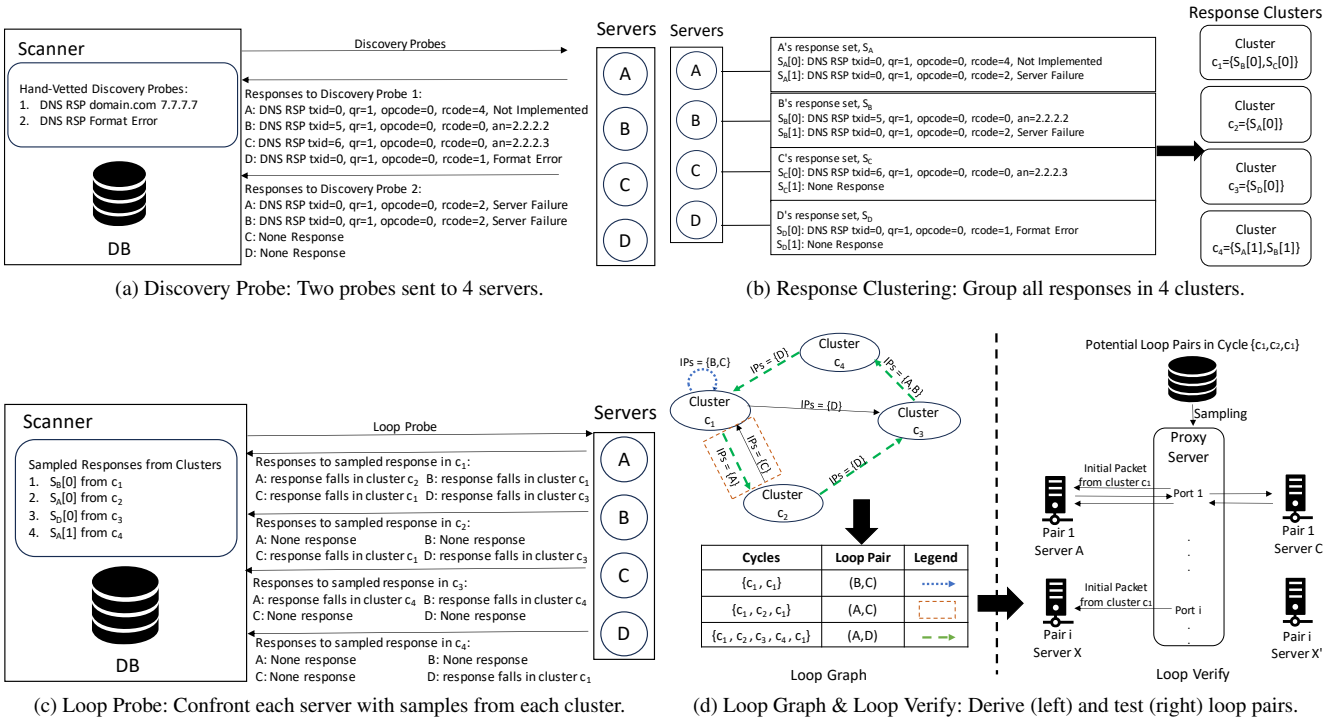
Third, the response matching phase (step (3)) may miss loops as it searches for exact payload matches only. However, in many network protocols, two non-identical packets may share their semantic meaning and thus what they trigger. For example, consider two DNS responses that contain different IP addresses in two otherwise-identical responses (e.g., due to load balancing). If the response behavior is not influenced by the concrete IP addresses in the input packet but rather based on the type of the DNS message and the number of DNS resource records, the naïve search would falsely neglect a loop. More formally, consider a case where $B(ra_i) = rb_m$ and $A(rb_m) = ra'_i$, where $ra_i \approx ra'_i$ but $ra_i \neq ra'_i$. If ra'_i is semantically equivalent to ra_i and thus triggers the same behavior at B, it is a viable loop trigger but would have been dismissed by the naïve search that searches for strict equality.

3.3 Methodology Sketch

Considering the constraints of the straw-man approach, we now provide a methodology to identify loop pairs that tackles the aforementioned challenges. For the sake of concreteness, without losing generality, we describe our methodology with the help of a running example of finding loops among DNS resolvers. But our chosen methodology generalizes also to other UDP-based application-layer protocols. Figure 3 illustrates our five-step methodology when applied to DNS. In general, given a list of IP addresses of a given UDP protocol, we conduct the following five steps to find loops:

1. Discovery Probes (Section 3.4): For a given UDP application-layer protocol, we send hand-crafted discovery probe packets to all servers to learn their responses. The collected responses represent potential entry gates to loops. With reference to our running example (Figure 3), we choose to send two discovery probes: a non-empty, valid DNS response with a type `A` record and a DNS format error response. They trigger six responses from servers *A*–*D*.

2. Response Clustering (Section 3.5): We then group the responses according to their semantics, abstracting away potential syntactical differences. Each cluster (ideally) represents an equivalence class of the semantics of the responses in the cluster. In our running example, the six syntactically different responses can be grouped into four semantic clusters.



3. Loop Probes (Section 3.6): Next, we sample loop probe packets from the identified clusters and send them to all servers. That is, we choose random representatives from each semantic equivalence class and learn how all servers react to them. The responses to these loop probes are clustered in the same way as in the previous step. In our running example, we randomly pick one probe from each cluster. We then send all these sampled probes to *A*–*D* and receive one to four responses from each server.

4. Loop Graph (Section 3.7): After learning the server response sets, we build a loop graph that shows which servers (edges) reply with which response when receiving an input (nodes). We then search for cycles in this loop graph, which hint at loop pairs. In our DNS example, we can immediately spot a trivial self-loop for cluster c_1 among hosts *B* and *C* (in blue, dotted). But the loop graph also reveals more complex cycles. For example, hosts *A* and *D* form a cycle using the response sequence $\{c_1, c_2, c_3, c_4, c_1\}$, i.e., $c_1 \rightarrow c_2 \rightarrow c_3 \rightarrow c_4 \rightarrow c_1$ (in green, dashed).

5. Loop Verification (Section 3.8): Finally, we verify loop pairs, e.g., (A,C), identified in the loop graph via a proxy server. In our DNS example, to verify loop pairs identified in the cycle $\{c_1, c_2, c_1\}$, the proxy stands as a person-in-the-middle between server *A* and server *C*. Then, the proxy uses its own IP to send a packet $S_B[0] \in c_1$ (see Figure 3 (c)) to host A and passively delegates further packets between the two hosts. If the proxy observes sufficient traffic between the two hosts, host A and host C are confirmed as a loop pair.

3.4 Discovery Probes

The first step in discovering loops is to learn the response set of real servers. To this end, we carefully craft hand-vetted discovery probes. In order to trigger diverse responses, we design

(a) Discovery Probe: Two probes sent to 4 servers.

(b) Response Clustering: Group all responses in 4 clusters.

(c) Loop Probe: Confront each server with samples from each cluster.

(d) Loop Graph & Loop Verify: Derive (left) and test (right) loop pairs.

Figure 3: Example of our 5-step methodology to identify loop pairs (here, e.g., (B,C)) among 4 DNS servers (A,B,C,D).

semantically different discovery probes according to various protocol aspects we find in their standards (e.g., RFCs). Figure 3 (a) provides a concrete example of discovery probes. For all four DNS servers, we send hand-vetted discovery probes, including DNS responses and DNS error messages. We will outline the concrete discovery probes in Section 4.1. After having crafted discovery probes for each of the analyzed application-layer protocols, we then use an off-the-shelf scanner to probe all servers of a given application-layer protocol. We save the responses for further clustering (Section 3.5).

The design choice to manually create discovery probes has pros and cons. Hand-vetted packets are inherently incomplete and cannot trigger all possible responses. This implies that we may underestimate the number of loop pairs we can find. We try to mitigate this challenge by creating probes with large semantic diversity, assisted by careful studies of the protocol specifications. Then again, in our eyes, hand-vetted probes are the most straightforward option to perform a large-scale experiment in an ethical manner. For each protocol, we only have around 30 hand-vetted discovery probes, which reduces the load to each probed system and limits the potential side effects on server stability during testing.

3.5 Response Clustering

In principle, each of the probed servers could respond to each discovery probe with a unique packet, resulting in millions of unique responses. As described in Section 3.2, to find potential loops, we need to send responses collected in Section 3.4 to all servers to learn servers' response functions. Sending this number of responses to each server is not scalable. We mitigate this scalability problem with an important observation. Namely, groups of the millions of unique responses are *semantically* the same; they are only *syntactically* different. For example, if two DNS responses only differ by the transaction ID header field, they should have the same effect. Grouping semantically-equivalent responses reduces the loop search to sending only a (few) representative(s) per group.

Thus, we cluster responses by abstracting away syntactic differences. For each UDP protocol, we identify important packet header fields and differentiate packets according to these critical fields. Each response falls exactly in one response cluster. Such a response cluster $c_i \in C$ is defined by several packet field values, where all packets in that response cluster exhibit the same values. The detailed clustering and critical field selection for each protocol is presented in Section 4. As shown in Figure 3 (b), when clustering DNS responses, we group packets according to the flags field and ignore syntactic differences such as TXID and IP addresses.

While clustering captures the behavior of most servers well, we also observe certain response behaviors that are not common among many probed hosts. As we are mainly interested in larger loops, we only consider response clusters with more than 10k unique hosts and ignore smaller ones.

3.6 Loop Probe

The clustered responses now help us to identify the servers' response functions. That is, for each server S, we would like to learn its mapping $S(c_i) = rs_i$ for all $c_i \in C$. Note that the response function operates on packets, and not on clusters. Then again, packets within a cluster share the same semantics. We thus sample five responses from each response cluster and use them as probes for all servers, which approximates the response function for *each cluster* instead of each packet.

We choose multiple instead of just one representative per cluster to verify the clustering step. In principle, samples from the same response cluster *shall* have the same effect. To verify this, we measure how many servers respond to how many probes of a given response cluster. If most servers respond to all five samples, it suggests the clustering performs well, and all samples indeed induce the same effect. Otherwise, we adjust the clustering discriminators (e.g., packet fields, see Section 3.5) and repeat the clustering and loop probing.

Note that the proposed approach only provides basic clustering validation. Real servers may generate semantically different responses to all five samples, which can thus undermine our validation. To improve the reliability of the verification approach, one can further check whether most servers generate semantically same responses for five samples.

At the end of the loop probe phase, we use the same response clustering methodology to group all responses to the sampled loop probes. By doing this, we can approximate each server's response function for the known response clusters.

In the example from Figure 3 (c), we use sampled responses from each response cluster to scan all servers again. After the clustering of the scan result, we learn that when receiving a packet from cluster c_1, DNS server A sends a packet in cluster c_2, i.e., server A has response function $A(c_1) = c_2$.

3.7 Loop Graph and Loop Search

Now, we have gathered all essential ingredients — the servers' response sets (Section 3.4) and response functions (Section 3.6) — to identify loop pairs among the probed servers. We encode this information in a directed graph where nodes are response clusters c_i and each edge $e_i = [c_i, c_m]$ is the set of server IPs with response function $F(c_i) = c_m$. Then, we conduct a depth-limited search to find possible cycles in the graph. Each cycle indicates possible loops among servers. Intuitively, cycles correspond to paths that span one or multiple response clusters between two alternating hosts.

Shorter cycles are easy to spot in the loop graph. When the cycle is of length one — i.e., a single response payload forms the loop — every IP involved in the edge can be paired with other IPs on the same edge to form a loop pair. Consider the example cycle $\{c_1, c_1\}$ shown in Figure 3 (d). Servers B and C on edge $[c_1, c_1]$ form a loop pair, and an attacker can trigger the loop by sending an IP-spoofed packet in cluster c_1 from server B to server C. For cycles of length two, each IP on one edge can form a loop pair with each IP on the other edge. Consider the example cycle $\{c_1, c_2, c_1\}$ in Figure 3 (d). By sending an IP-spoofed packet in cluster c_1 from server C to server A, an attacker can trigger a loop between server A and server C, where $A \in [c_1, c_2]$ and $C \in [c_2, c_1]$.

However, significantly longer cycles are also possible. We can generalize our cycle search to arbitrary cycle lengths. A cycle of length n from server A to B exists if there is a path of n edges alternating between A and B. We index edges involved in such a cycle as $e_1, e_2, \cdots, e_n$. Server A where $A \in e_1 \cap e_3 \cap \cdots \cap e_{n-1}$ ("odd edge indexes") and server B where $B \in e_2 \cap e_4 \cap \cdots \cap e_n$ ("even edge indexes") form a loop pair of cycle length n. Consider the example cycle $\{c_1, c_2, c_3, c_4, c_1\}$ with $n = 4$ in Figure 3 (d). Here, server A where $A \in [c_1, c_2] \cap [c_3, c_4]$ forms a loop pair with server D where $D \in [c_2, c_3] \cap [c_4, c_1]$. An attacker can trigger a loop by sending an IP-spoofed packet, e.g., of cluster c_1 or c_3 from server D to server A.

To find all potential loop pairs of a given protocol, we perform an exhaustive path search up to cycle length n over the protocol's loop graph. For the protocols we studied, loop graphs span 46–3,778 nodes. The complete search up to $n = 4$ terminates within 10 seconds (see Section 4). Our methodology is thus systematic, scalable, and still reasonably complete in identifying loop pairs for a given protocol.

3.8 Loop Verify

Finally, we verify the potential loop pairs to achieve two goals. First, the potential loop pairs identified in the loop graph are not necessarily vulnerable to abuse. For example, servers could aggressively limit the number of requests per IP address. In this case, a loop will stop automatically after reaching the rate limit. Such defenses cannot be identified by low-rate scans. Second, a final end-to-end attack verification tests if our methodology for identifying loops is reasonable.

We thus propose a proxy to verify loop pairs probabilistically. Figure 3 (d) illustrates the overall setup of the loop verify proxy. For each cycle in the loop graph, we sample a subset of loop pairs. The proxy serves as a person-in-the-middle between each sampled loop pair. This way, we can control the speed of the loop and stop it at any point, allowing for tests that do not overload real systems. Next, for loop pairs sampled from a certain cycle, e.g., $\{c1, c2, c1\}$, the proxy chooses a packet from cluster c_1 to initiate a loop. After the initial packet, the proxy server passively waits and delegates any packets between servers. Once the proxy observes sufficiently many packets exchanged between a sampled loop pair, we derive that the pair is actually vulnerable to a traffic loop attack. The percentage of sampled pairs that succeed in this final verification step helps approximate how many of the *potential* loops are *effective* loops that attackers can abuse.

4 Evaluation

In this section, we follow the five-step approach described in Section 3 to investigate loops in three protocols: DNS, NTP, and TFTP. The list of servers running DNS and NTP is provided by Shadowserver's daily report. Since Shadowserver only reports on IPv4 addresses, in this paper, we only find loop pairs from IPv4 servers. All of the experiments were performed from Jan 5 to Jan 10, 2024. In our evaluation, we observed ≈140k DNS servers, 86k NTP servers, and 22k TFTP servers that could potentially form loops.

Additionally, we investigated loops in six legacy protocols: Active Users, Daytime, Time, QOTD, Echo, and Chargen, observing 124k servers that could potentially form loops. Finally, we verify whether the IPs we found are actually vulnerable to the loop attack by using a UDP proxy to simulate the loop DoS attack. In the following, we present the loop identification and verification for each protocol in more detail.

4.1 Discovery Probes

The aim of the discovery probes is to trigger diverse responses from real servers. Ethically, we would like to design less offensive probes and minimize the number of probes. For each protocol, the discovery probes include both well-formed payloads and mutated payloads. In this section, we describe discovery probes designed for each protocol.

DNS DNS is used by various applications to, e.g., translate domain names to IP addresses. In short, controlled by a series of flags, DNS messages can be split into three major categories: query, response, and error. The DNS discovery probes cover different types of DNS messages. In total, we prepared 25 DNS discovery probes.

First, we constructed nine query-based payloads. When building query-based payloads, we first construct well-formed DNS queries using different rd (recursion desired) flags. When the rd flag is set, the server will attempt to resolve the query recursively, which may thus trigger different responses.

Next, we constructed semantically invalid queries by mutating well-formed DNS queries. For example, we constructed a DNS query payload where the question count field (qdcount) is 1, but the payload does not have an actual question field. We also constructed DNS query packets with mutated rcode fields. Normally, a DNS query should use rcode 0, which suggests no error. We instead replace the rcode with other known (e.g., 2, which indicates server failure error) or random values. We also mutate the opcode field of DNS query packets to other unused values while the packet still preserves a legit DNS query. In addition to building DNS packets with mutated header flags, we also built packets with mutated question fields. For example, we build DNS query packets asking for a DNS record of unknown qtype 280 and unknown qclass 280 instead of querying for a common 'A' record. Such mutated DNS queries can trigger server failures or format errors and thus enrich diversity.

Next, we constructed 11 response-based payloads. Similar to constructed DNS queries, the 11 DNS responses also include well-formed and semantics-violating response payloads. For example, in one of the responses, we set the question flag (qr) to zero, which indicates the payload is expected to be a DNS query, while the payload does include a well-formed answer record. Except for mutating header fields such as opcode, rcode, and ancount etc., we also built semantics-violating response payloads by adding random bytes to the payload, which can produce packets that cannot be successfully parsed.

Finally, we also include five well-formed error messages with different error type fields (rcode), including format error, server failure, not implemented, name error, and refused.

Note that the DNS discovery probes only cover basic DNS features. In particular, we did not prepare probes using extended DNS, e.g., DNS cookie and DNSSEC.

NTP NTP is a UDP-based protocol that provides clock synchronization between hosts in a network. NTP messages have eight different modes, controlled by the mode field, including reserved (mode 0), symmetric (mode 1, 2), client and server (mode 3, 4), broadcast (mode 5), NTP control message (mode 6), and private reserved (mode 7) [35]. NTP has a dedicated poll field that limits the interval between successive messages. It is thus less likely that standard NTP messages cause loops by successful requests. Consequently, when preparing the discovery probes for NTP, we mainly focused on unexpected NTP payloads that may trigger error messages from servers.

We constructed 30 such discovery probes, focusing on four different NTP modes: server (5x), broadcast/multicast (1x), NTP control messages (20x), and private reserved (4x). For server mode, we built several well-formed NTP packets with different stratum numbers (14-16) and KISS-O'-DEATH packets[1] with unregistered kiss codes. In principle, a server shall not respond to these constructed requests; they should only trigger responses from faulty implementations. In addition, we constructed one well-formed broadcast packet. Correctly implemented servers shall not respond to a broadcast message from clients; thus, the discovery probe will only trigger faulty servers. With respect to NTP control messages, we first built seven NTP error messages with defined error_code values (1 to 7) and also an NTP error message with an undefined error_code. Next, we constructed well-formed and mutated non-error NTP control messages, such as *write clock variables* and *trap response* messages. Finally, we constructed a few mutated NTP packets of private reserved mode by combining a well-formed NTP header with a dummy payload.

These four modes do not cover all NTP modes. In particular, we ignored client mode requests as they will mostly trigger

[1] KISS-O'-DEATH packets are used by NTP servers to rate-limit the NTP client's requests, which would only affect our scanner at most.

successful responses. We also did not construct any discovery probes of symmetric active or passive mode. In the symmetric mode, peers in both active and passive modes can synchronize the clock according to the received messages, which may interfere with the normal operations of servers.

TFTP TFTP is a UDP-based file transfer protocol that allows a client to read and write files on a remote host. TFTP offers five message types: read and write request, ACK, error, and data. According to RFC-1350 [42], upon receiving a request, a TFTP server chooses a transfer identifier (TID) from 0 to 65,535. In later communications, the server uses the TID as its source port. However, despite the RFC specification of using random source ports, some servers still use source port 69 to send a response. Because a TFTP server using random ports is less likely to be involved in a loop, we instead focus on those TFTP servers that use the fixed 69 port to send error messages. We designed 23 discovery probes covering all these message types except for write request.

We prepared nine query message probes. We first included well-formed read requests. Then, we also constructed read requests with mutated filename and mode fields, e.g., with a non-ASCII string mode field, which is non-compliant with the RFC. For data messages, we prepared three probes. In accordance with RFC-1350 [42], we built two well-formed data messages of sizes 512 and 0 bytes, indicating the intermediate transferring block and the last block, respectively. For the third message, we constructed a data message larger than 512 bytes, which is not allowed by the RFC. For ACK messages, we prepared two probes: one with a proper index field according to RFC-1350 [42] and one without. Finally, we constructed nine error probes: eight with standardized error codes and one with an unknown error code.

Note that TFTP requests may probe for specific files. If our requests happen to match an existing file, the server may start transferring the actual file content to us. To avoid such accidental leaks, we used a dummy filename `fJFJmcl.jieopg` in all query-based discovery probes. For a similar reason, we refrained from constructing discovery probes of write query type, as we may unintentionally create files on real servers.

Legacy Protocols We also include six legacy protocols in our analysis: QOTD (RFC 865 [6]), Chargen (RFC 864 [3]), Echo (RFC 862 [5]), Time (RFC 868) [7], Daytime (RFC 867) [4], and Active Users (RFC 866) [2]. Except for Time, which requires the client to send an empty UDP datagram, all other protocols define that servers should reply to arbitrarily-formatted requests. However, there is still a chance that Time servers do not follow RFC strictly and accept a non-empty UDP datagram. When receiving a UDP datagram, Chargen, QOTD, and Echo servers will send random data, a quote, or mirror the request, respectively. Time and Daytime servers respond with the current time (and day), and Active Users servers send a list of active system users. Thus, in principle, any two servers running these legacy protocols can form a loop pair. An attacker can initiate a loop by sending an arbitrary IP-spoofed UDP datagram to one of the servers. Thus, for all six legacy protocols, we use the same discovery probe: a UDP payload containing the single character 'a'. This way, we learn the accessible servers running each protocol.

Sending Discovery Probes After defining the discovery probes, we send them to servers of the respective protocols. We got the list of seed server IPs running the tested protocols from Shadowserver's daily report. The daily report includes 2,009,205 IPs for DNS and 1,712,434 IPs for NTP. As discussed previously, for TFTP, we only focused on TFTP servers that send error messages from port 69. Thus, instead of using Shadowserver's daily report, we performed a full IPv4 scan and found 148,676 IPs for TFTP. For the six legacy protocols, we performed a full IPv4 scan and found 3,238 Active Users servers, 13,983 Daytime servers, 13,195 Time servers, 52,707 Echo servers, 22,576 Chargen servers, and 17,927 QOTD servers. Since we use a non-empty UDP datagram as the discovery probe for Time servers, the discovered servers would accept a non-empty UDP datagram and are thus potentially vulnerable to the loop attack. For each protocol, we then use ZMap [48] to send the discovery probes to all seed servers of the given protocol. For each host, we wait for (at least) 10 seconds before proceeding with the next probe to avoid high query loads to real servers. We defer to Section 6 for a detailed discussion of our scanning setup.

We received at least one reply from 1,366,247 (68%) DNS servers, 1,626,754 (95%) NTP servers, and all 148,676 TFTP servers. For DNS, the response rates are significantly lower than for NTP. We speculate this is due to more aggressive IP address churn among DNS servers. Previous research also reported IP churn behavior for DNS servers, where the number of accessible IP addresses dropped to 60% percent after one day [29]. Similarly, Kührer et al. noted a significantly lower churn rate for NTP compared to DNS (Table 3 in [31]). To counter the IP address churn, we could perform full Internet scans ourselves — while causing higher loads to the Internet.

4.2 Response Clustering

We now describe how we cluster responses for each protocol.

DNS We collected 327,841 unique DNS responses via the discovery probes. We parsed each unique DNS payload according to the DNS packet structure. In the packet, we considered the opcode field and the 8-bit flag field (QR, AA, TC, RD, RA, Z) as important fields, and a payload is first categorized using these fields. Second, if the payload was a DNS response packet (QR flag is 1), we further categorized the payload according to its rcode (response code) field. Third, we categorized payloads according to the number of records

they contained, indicated by qdcount, ancount, nscount, and arcount fields. These field values can range from 0 to 65,535, so we created five categorization buckets of 0, 1, 2-256, 257-8,192, and 8,193-65,535. To our surprise, when inspecting collected responses, we found that some DNS servers sent a DNS response packet where the question field domain name did not match the domain name used in the discovery probes. Thus, we also categorized payloads based on whether the domain name in the QD or AN field matched the domain name we used in the discovery probes. We ignored the transaction ID and IPs during clustering, as they cannot change the semantics of a payload.

Among the collected responses, we also identified responses that cannot be parsed normally. However, such responses may still contain a complete or partial header. For these responses, we first categorized them as abnormal responses and then attempt to parse the DNS header byte-by-byte to the extent possible. The semi-parsed responses were then categorized using the extracted header information.

After clustering, we identified 90 clusters with more than 10k unique servers sending corresponding responses.

NTP We collected 8,459,730 unique NTP responses, all of which we attempted to parse. In the packet, we considered LI (leap indicator), VN (version number), stratum, poll, and mode as important fields. A payload would first be clustered according to these fields. Then, packets that were NTP control messages (mode 6) underwent further categorization. Unlike normal NTP headers, control message headers contain R, E, M flags, opcodes, and status fields — all of which we considered important categorization features. We ignored identifier, authenticator, and timestamps fields, as they should not affect the semantics of a packet.

Note that our NTP clustering approach only focused on NTP control messages. Other types of NTP messages can have more distinct fields. For example, NTP private reserved mode messages contain additional error and request code fields. By parsing NTP messages as common NTP headers and extracting stratum, leap fields, etc., we may omit or misinterpret some of such distinct fields.

Overall, we identified 55 NTP clusters with more than 10k unique servers sending corresponding responses.

TFTP We collected 533 unique responses from TFTP servers. The majority of responses were different types of error messages. Thus, our clustering for TFTP payloads mainly focused on the type of error. We first clustered the TFTP payloads according to their opcode, and if the TFTP payload is of error message type (opcode=0005), we further clustered them according to the errorcode field. As we inspected malformed error message responses from real servers, we categorized an error message according to syntactic correctness. For example, we clustered error messages by observing whether the error message correctly ends with a single NULL byte.

With this approach, we found six clusters with more than 10k unique servers sending corresponding responses.

Legacy Protocols Given that legacy protocols reply to arbitrary request payloads, we simply group all responses in a single catch-all cluster.

4.3 Loop Probe

As described in Section 3.6, for each non-legacy protocol, we sample five payloads per cluster and use ZMap to send them to all servers. For DNS, NTP, and TFTP, the number of sampled probes is 299, 248, and 18, respectively. This is less than five times the number of clusters because some clusters have fewer than five payloads. To further reduce the load of these additional probes, we increased the cooldown time between different probes per host to 15 seconds.

We then clustered the probed responses. To confirm the effectiveness of our clustering approach, as introduced in Section 3.6, we verified the number of IPs responding to different numbers of sampled probes in the same cluster.

For TFTP, the clustering performed well, as all six clusters had the majority of servers respond to all sampled payloads.

Regarding NTP, out of all 55 clusters, 44 clusters performed well. We treated the 11 problematic clusters as follows. Seven of them only received responses from less than a thousand servers; we dropped these clusters directly. For the other four, we also did not optimize the clustering as we found that these clusters are not involved in any potential cycles anyway.

For DNS, out of all 90 clusters, 88 clusters performed well, i.e., the majority of servers replied to all five sampled probes. The two bad clusters are DNS *response* packets containing a domain name that does not match the domain name we used in the discovery probe. In the two bad clusters, probe payloads containing `graph.facebook.com` trigger significantly more servers' responses than other sampled payloads. To understand why, we investigated the collected responses when using payloads containing `graph.facebook.com`. We believe the responses were generated by censorship DNS middleboxes, as in the answer field, the domain is resolved to a local IP `10.10.34.35`. A previous report recognized such responses as an attempt to block users' access by Iran [20]. As discussed in Section 3.6, we updated the clustering approach introduced in the previous section. We removed sampled payloads containing domain `graph.facebook.com` from the two bad clusters and manually added them to two new clusters.

We do not consider loop probes for legacy protocols as we expect identical behavior irrespective of the probes we send.

4.4 Loop Graph and Loop Search

So far, we gathered all the essential information to find potential loop pairs among real servers. Figure 4 shows the resulting loop graphs for DNS, NTP, and TFTP. Recall that

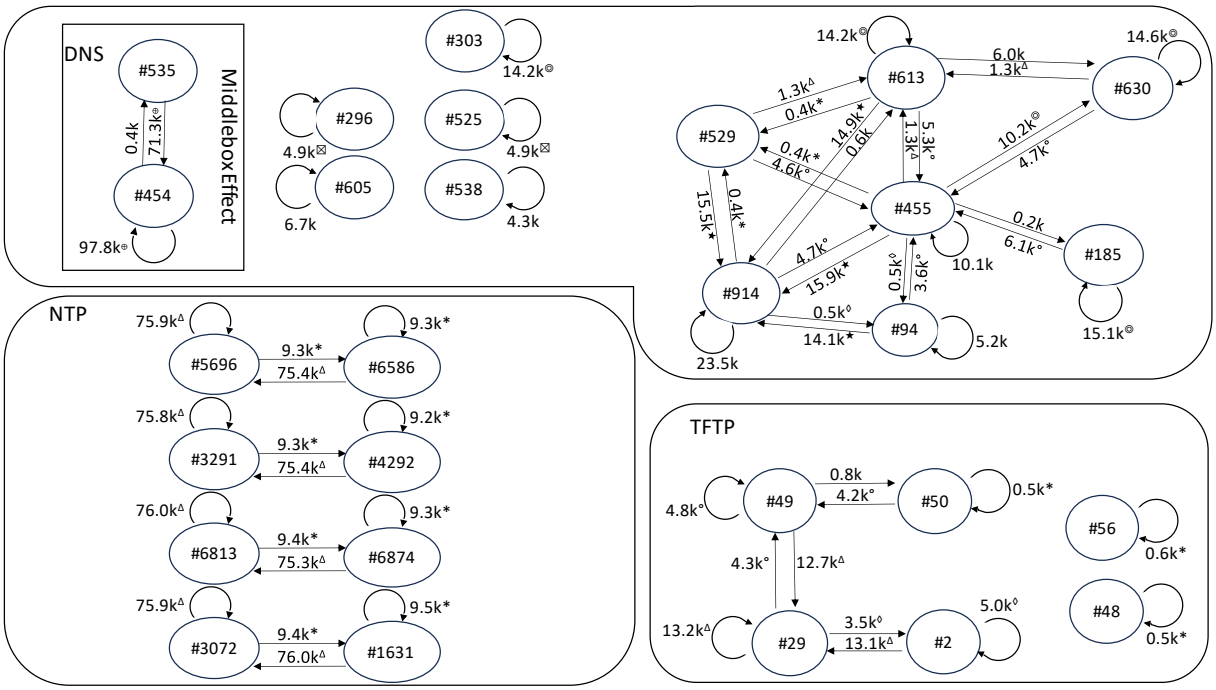


Figure 4: Loop Graph. Nodes in the graph represent payload clusters; Appendix B provides example payloads for several clusters. The edge from a node #A to another node #B indicates hosts that would send a #B response when receiving a #A payload, where the edge label is the number of servers with such behavior. For each protocol, edges labeled with the same symbols (*, ∘, ◎, △, ⊠, ★, ◊, ⨁) indicate that the majority of the server IPs ($> 70\%$) corresponding to these edges overlap.

nodes represent cluster IDs and edges from cluster c_i to cluster c_m are hosts with response function $F(c_i) = c_m$. To find all possible loop pairs per protocol, we searched for cycles up to length $n = 4$. When inspecting loops, we filtered out loops having edges corresponding to less than 100 IP addresses. In the following, we report on the loop pairs per protocol.

DNS For DNS, we identified 140,334 (10.2%) servers that can be involved in a loop. In this section, we focus on 24 identified major cycles. In DNS, the two largest cycles we identified, cycle {454, 535, 454} and cycle {454, 454}, affect 98,669 IPs. Recall from the previous section that the two largest cycles are caused by the newly identified middlebox-effect clusters (clusters 454 and 535).

In the two middlebox-related cycles, we found 89,040 (90.2%) affected IPs are from Iran, and 9,629 (9.8%) IPs are from other countries, e.g., China, Indonesia, Russia, etc. In particular, the number of affected Iranian IPs covers 93.1% of all known Iranian open resolvers from Shadowserver's daily report. Since clusters 454 and 535 are both DNS responses that DNS servers shall not react to, the high IP affect rate is a clear indicator that it is a nationwide reaction by Iran's middleboxes to inject DNS responses when observing clusters 454 and 535 packets. However, we did not observe the same behavior for affected IPs in other countries, though some countries, e.g., China [23], are known for having DNS censorship. In other words, affected IPs in other countries are not necessarily due to country-level middleboxes. Instead, vulnerable IPs outside of Iran are likely actual vulnerable DNS resolvers. In the end, even if some of the identified IPs are actual vulnerable DNS resolvers, they can still be paired with middlebox-effect IPs in Iran to form loop pairs.

For cycle {454, 535, 454}, upon receiving a response packet for a censored domain (e.g., graph.facebook.com) with many NS records (cluster 535), middleboxes or servers on edge [535, 454] inject a response packet containing only the answer for the censored domain (cluster 454). When other middleboxes or vulnerable servers (on edge [454, 535]) observe a response packet containing a censored domain, they instead inject a response containing multiple NS records. For cycle {454, 454}, it appears that a short response for a censored domain would again trigger middleboxes or vulnerable servers to inject responses for the censored domain. Previous research shed light on weaponizing HTTP middleboxes in DDoS attacks [14]. We show that the DNS middleboxes also have similar behavior that attackers can abuse for loop DoS attacks.

Note that our measurement for DNS middlebox-related loops has two limitations:

- Our scanner's location can impact the number of identified loop pairs. In the two middlebox-related loops, the majority of affected IPs are from Iran. These loops are caused by Iran middleboxes' reactions to DNS response

packets with a censored domain. According to previous research [12, 47], countries with DNS censorship tend to deploy middleboxes in border ASes. Since our scanner was located outside of Iran, when scanning open resolver IPs in Iran, the probe (e.g., of type 454) would go through border ASes and trigger middleboxes. However, when pairing two IPs in Iran, as the DNS packet is never routed to border ASes, the DNS middlebox would not inject forged responses to cause loops. As a result, we might overestimate the number of loop pairs for middlebox-related loops whenever we pair two IPs in Iran. Having said this, we can still pair vulnerable IPs in Iran with vulnerable IPs in other countries, which would cross the border ASes. When excluding Iranian-only pairs, we can still form 811.15M loop pairs.

- Given that we used a list of open resolvers provided by Shadowserver to perform the scan, we may also underestimate the number of affected IPs in middlebox-related loops. In principle, when pairing with vulnerable hosts in other countries, any Iranian IP can be used as a loop host, as the censorship middlebox on the path will be involved to inject responses. To show the potential underestimation, we perform a preliminary experiment. We picked three IPv4 blocks in Iran; each contains 65,536 IPs. Next, we send type 454 probes to all IPs in the three blocks. In total, we received type 454 responses from 193,239 (98.3%) IPs. However, Shadowserver's daily report only contains 10,946 (5.6%) open resolver IPs in the three IPv4 blocks.

Excluding the two middlebox-related loops, all other cycles affect 56,239 IPs in total. Among non-middlebox-related cycles, we observed server failure error message loops. When servers involved in these cycles received a DNS server failure response, they would reply with another DNS server failure response to form a loop. Cycles {630, 630}, {303, 303}, and {613, 613} are all loops caused by server failure error packets, affecting 14.6k, 14.2k, and 14.2k servers, respectively. Server failure responses in the three clusters (630, 303, 613) differ by whether the server supports recursion or not (flag ra is 0 or 1) and whether the server failure response includes an answer record. As shown in Figure 4, the majority of servers in these three cycles therefore overlap, which is a strong indicator that the problem is caused by shared faulty implementation that misinterprets a server failure message.

Interestingly, we also observed many loops triggered by DNS responses in cluster 455, i.e., common DNS responses to the domain controlled by us. Such loops can be classified into two categories. In the first category, a response to the domain controlled by us triggers an error message, and then the error message again results in a response to our controlled domain. Cycles {455, 630, 455} and {455, 613, 455} are this type of cycle, and they affect 15.0k and 6.6k IPs, respectively.

In the second category, a response to the domain controlled by us triggers a well-formed response with slight differences in flag fields, and the mutated response again triggers a response to our controlled domain. Cycles {455, 94, 455}, {455, 185, 455}, {455, 914, 455}, and {455, 529, 455} are all loops of this category. Compared to responses from cluster 455, payloads from clusters 94, 185, and 914 only differ from cluster 455 by *rd* (recursion desired), *ra* (recursion available), and *aa* (authoritative answer) flags, while payloads from cluster 529 contain additional resource records and NS records.

For all cycles in the two categories, each has an edge [X, 455], where X $\in$ {630, 613, 94, 185, 914, 529}. The majority of servers on edge [X,455] overlap, which indicates a faulty implementation used by servers that would accept and resolve an incoming response packet.

In addition to the clusters introduced previously, there are also several sets of IPs performing error message loops (e.g., {613, 630, 613}), legit response loops (e.g., {914, 94, 914}), and error message to legit response loops (e.g.,{613, 914, 613}).

Finally, we also identified several self loop cycles {296, 296}, {538, 538}, {605, 605}, and {525, 525}. Clusters 296 and 605 are both format error messages, where they differ by the *ra* (recursion available) flag. Clusters 538 and 525 are legit DNS responses to our domain, where they differ by the number of NS records in the DNS response.

NTP For NTP, we identified 12 cycles with 86,469 (5.3%) hosts potentially affected. As discussed in Section 4.1, for NTP, we expected to identify error message loops. As per our expectation, all NTP cycles are error message loops. Shown in Figure 4, NTP loops correspond to eight different clusters. The eight clusters are all NTP payloads of mode 7 (private reserved mode). Payloads of the eight clusters differ by the NTP version (v2 or v3) field and the implementation field (the poll field when parsed as an NTP header).

Shown in Figure 4, the same set of servers transform an NTPv3 error message (clusters 5696, 3291, 6813, 3072) to an NTPv2 error message (clusters 4292, 6874, 6586, 1631). Similarly, there is also a set of servers that transform an NTPv2 error message to an NTPv3 message. This suggests that there are sets of NTPv3 and NTPv2 servers running faulty software that would reply to an error message. Indeed, CVE-2009-3563 [38] describes an error message loop in ntpd [1], a popular NTP server implementation. The CVE shows that before ntpd v4.2.6, an attacker can cause an error message loop between ntpd servers using malformed mode 7 NTP packets. Thus, we believe that some of the loops we identified could be explained by outdated ntpd servers. The same set of faulty NTPv3 servers and NTPv2 servers can also form a loop when receiving an error message from a server running the same version, e.g., cycle {5696, 5696}.

TFTP For TFTP, we identified 9 cycles with 22,518 (15.1%) potentially affected hosts in total. These 9 cycles hint at faulty

servers that react to certain error messages and respond with another error message. Although the TFTP standard explicitly states that an error message "is not acknowledged," we still observed many TFTP servers diverging from this. In fact, *all* 9 TFTP cycles are error message loops.

As shown in plot Figure 4, TFTP loops are constructed from six clusters. Clusters 56, 49, and 29 are error messages of unknown transfer ID (error code 5), illegal TFTP operation (error code 4), and not defined (error code 0) types. Cluster 50 is slightly different from cluster 49. It is also error messages of illegal TFTP operation type; however, the messages feature an additional NULL byte at the end. Similarly, cluster 48 is also an illegal TFTP operation error message, but it does not end with a NULL byte. Different from other clusters, cluster 2 is a TFTP message with opcode 0. Opcode 0 is not specified in RFC [42]. However, as some TFTP payloads in cluster 2 contain an "invalid request" message, we believe these payloads are likewise error messages.

Legacy Protocols We omit the loop graphs and cycle search for the legacy protocols. We assume that each server of any legacy protocol can create a cycle with an arbitrary other server of the same (or even another) protocol.

4.5 Geo-Distribution

Before probabilistically verifying the potential loop pairs, we now provide a first analysis of ASes hosting potential looping servers. For all six non-legacy protocols, DNS, NTP, and TFTP, we found thousands of affected ASes overall. Figure 5 summarizes the geographical and topological breakdown of the affected servers for each non-legacy protocol.

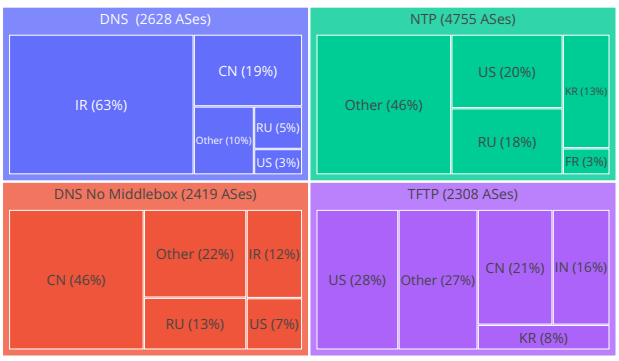

Figure 5: AS and geo-distribution of vulnerable servers.

For DNS, Iran and China have the most vulnerable DNS servers. The majority of affected IPs in Iran are involved in middlebox-related cycles discussed previously. In Figure 5, we also provide the analysis result when excluding the two middlebox-related cycles. When including or excluding middlebox-related cycles, AS `TCI` in Iran and AS `Chinanet-backbone` host the most vulnerable DNS servers, 72,026 and 7,191 IPs, respectively.

Regarding NTP, the US, Russia, and Korea host most vulnerable NTP servers. In particular, AS `Korea Telecom` alone hosts 5,018 affected NTP servers.

For TFTP, the US, China, and India are the top three sources of affected servers. Out of all ASes, the AS `Frontier-FRTR` hosts the most faulty TFTP servers (2,559).

4.6 End-to-End Loop Verification

In the loop graph, we identified *potential* cycles according to the response functions of each server. Next, we *verified* these loops in controlled end-to-end loop experiments following the approach proposed in Section 3.8.

In the experiment, we used the proxy to verify 100 sampled loop pairs from each cycle we identified. As one IP can be involved in several cycles, the same IP can show up in different sampled pairs. To avoid flooding real servers, we applied a rate limit per IP instead of per loop pair. The rate limit used by the proxy is 3 pps. To avoid sending too many packets to the sampled servers, the proxy would stop delegating packets once it found more than 25 packets sent between a loop pair. Finally, we checked the number of sampled loop pairs in each cycle that successfully reached a 25-packet loop.

Cycle	Loop IPs	Loop Pairs	Success Rate
{1631, 1631}	9.5 k	45.02 M	94%
{4292, 4292}	9.2 k	42.46 M	94%
{6874, 6874}	9.3 k	42.82 M	96%
{6586, 6586}	9.3 k	42.79 M	93%
{3291, 3291}	75.8 k	2872.10 M	93%
{6813, 6813}	76.0 k	2886.59 M	93%
{5696, 5696}	75.9 k	2878.17 M	98%
{3072, 3072}	75.9 k	2884.01 M	97%
{3291, 4292, 3291}	84.7 k	703.83 M	99%
{5696, 6586, 5696}	84.7 k	704.59 M	94%
{6874, 6813, 6874}	84.7 k	709.85 M	94%
{3072, 1631, 3072}	85.4 k	714.40 M	93%
Overall (estim.)	82.3 k	3.47 B	(avg) 95.2%

Table 1: NTP verification summary. For each cycle, we reported the number of potentially affected IPs, pairs, and the verification success rate. The last row (in bold) provides an estimation for the total number of *confirmed* IPs and pairs based on the weighted average of verification success rates.

In Table 1, Table 2, and Table 3, we provided the detailed verification results for each cycle we identified for NTP, DNS, and TFTP, respectively. For these three protocols, we performed the proxy verification within approximately three hours after the scanning. Overall, we found about 200k servers that can be abused in loops, giving attackers the opportunity to create billions of loop pairs.

For TFTP and NTP, the average verification rates were 84.5% and 95.2%, respectively. Combining the number of affected IPs from the loop graphs, we estimate that 82,318 (5.1%) IPs and 3.47B pairs for NTP and 19,027 (12.8%) IPs and 0.18B pairs for TFTP can be involved in a loop attack.

For DNS, we verified middlebox-related cycles[2] and non-middlebox-related cycles separately, and the verification success rates were 75.6% and 65.5% respectively. We observed that the verification success rates for some cycles, e.g., {538, 538}, {605, 605}, and {296, 296} are lower: 16%, 25%, and 24% respectively. In order to reason about this discrepancy, we observed the number of packets sent between each sampled loop pair. If we only observed zero or one packet among a loop pair, it mostly suggested at least one server in the loop pair was no longer accessible. Instead, if we observed more than two packets (while less than 25 packets) between a loop pair, the loop was mostly stopped because of the rate limit of at least one server in the loop pair. Out of the 100 sampled loop pairs, we found 83 failed pairs for cycle {538, 538}, 52 failed pairs for {605, 605}, and 42 failed pairs for {296, 296} with less than two packets sent. Thus, the low verification success rate for the three cycles was likely due to frequent IP address churn. Note that our proxy server only passively delegates packets while not verifying if the responses generated by servers are of the expected types, thus non-deterministic server behaviors can impact our verification. Indeed, a DNS server may behave differently against the same payload during the loop probe and the verification, e.g., due to caching. One can tackle such non-determinism by precaching the requested data or by performing the loop probe multiple times to filter out servers with non-deterministic behaviors. Overall, the verification success rate for DNS, including both non-middlebox-related cycles and middlebox-related cycles, was 70.1%. According to the number of affected IPs reported by the loop graph, we believe that 98,374 IPs (7.2%) and 1.01B pairs for DNS can be involved in a loop attack.

For legacy protocols, any of the discovered servers can be paired with others to form a loop pair. We thus sampled and verified 1000 random host pairs for each legacy protocol. For legacy protocols, the proxy verification is performed approximately 12 hours after the scanning. In Table 4 (see Appendix A), we summarized the verification success rate for the six legacy protocols: Active Users (67.5%), Daytime (79.6%), Time (78.8%), Echo (83.8%), Chargen (40.3%), and QOTD (87.8%). Of all legacy protocols, Chargen had the lowest verification success rate. Similar to DNS, we found that majority of failed pairs were caused by unreachable servers.

[2] As discussed in Section 4.4, when verifying middlebox-related cycles, we only pair IPs from Iran with IPs from other countries.

5 Discussion

We now discuss important aspects with respect to how attackers can accelerate loops or find cross-protocol loops, and describe mitigation strategies for the identified vulnerabilities.

5.1 Self-Amplifying Loops

In our experiment, we found some servers, e.g., Chargen (1.9k), sending more than one response upon receiving one probe. The majority of these servers sent two to nine responses upon receiving a probe, while there were some servers that sent dozens or even hundreds of responses. Such multi-response behaviors can be caused by network issues or faulty software. Either way, if such servers can be involved in a loop pair, the number of parallel loops could grow exponentially. Interestingly, 73.3% of these servers were concentrated in just three ASes, which further increases the threat of a loop-based DoS attack for the respective ASes.

5.2 Cross-Protocol Loops

The main focus of this work is on identifying loops among servers running the *same* UDP-based application-layer protocol. Unfortunately, though, attackers can also trigger loops *across* protocols. For example, DNS, NTP, TFTP, and other protocols implement format error messages. When a server receives a malformed request, it responds with a format error message to notify the client or help debugging. However, for two servers running different UDP protocols, they lack knowledge of the packet format of each other. Thus, such format error messages may enable cross-protocol loops.

We showcase such a cross-protocol loop as a concrete example with TFTP and DNS. Because unexpected packets from other protocols may crash server programs, we refrained from using the same methodology to discover cross-protocol loops among real servers. Instead, we emulated the cross-protocol loop in a local environment. We set up a local DNS server using bind9 [13] and a local TFTP server using erlang-tftp [19]. To set up the TFTP server, we used the example instruction in [19] to start a default TFTP server. For the DNS server, we used the default configuration of bind9. By sending a *TFTP not defined* error message to the DNS server, we successfully caused a loop between the two servers. bind9 interprets the TFTP message as a malformed DNS packet and replies with a *format error* message to the TFTP server. Upon receiving the format error response, the TFTP server finds the packet has an unknown error code and considers it as a malformed TFTP packet. Thus, the TFTP server sends a *not defined* error response to the DNS server and forms a loop. In Section 4.4, we showed that DNS and TFTP servers sending such messages are not uncommon, underlining that cross-protocol are not only a theoretical threat.

The six legacy protocols explored in the paper can also participate in cross-protocol loops. For example, a TFTP server and a Chargen server can form a loop pair easily. The Chargen server's dummy response would trigger the TFTP server's not defined error, and the error message would again trigger the Chargen server's response to sustain the loop. We confirmed such a loop is possible by using a local setup of erlang-tftp and xinetd's Chargen service [45], and we can form a loop by sending a dummy UDP payload to the Chargen server.

5.3 Automating Discovery Probe Generation

In this paper, we provide a methodology of identifying application-layer traffic loops. The discovery probe design requires manual efforts, which can limit the number of identified loops. In this section, we briefly discuss potential ways of automating the discovery probe generation. To automatically generate mutated payloads, fuzzing is a viable approach. Fuzzing would thus provide an even more systematic way to fully explore the threat landscape. However, fuzzing-generated discovery probes would require additional checks or strict restrictions to avoid crashing real servers. For example, when the length is not restricted, fuzzing can generate a long mutated payload, which is more likely to cause memory corruption. Next, fuzzing would also likely generate many semantically identical discovery probes. To reduce the number of probes, one could use our proposed clustering methodology to sample discovery probes from each cluster.

5.4 Loop Mitigation

We now discuss mitigation steps that developers and server operators can take to reduce the risk of loops.

Do not respond to errors Most loops are caused by servers reacting to error messages or responses from other servers. According to RFCs for all studied non-legacy protocols, a server should not reply to any error messages or responses generated by other servers. Enforcing this recommendation would mitigate the vast majority of loops. Recall that many loops we identified share the same set of faulty servers. Hopefully, we can eliminate a large number of loop pairs and vulnerable hosts by patching these vulnerable servers.

Suppress errors While error messages are useful for debugging and sometimes inherently important for protocols to function correctly, they do increase chances of loops. Recall the TFTP + DNS cross-protocol loop. When receiving a DNS error message packet, a TFTP server generates an error message in TFTP format, which is considered a malformed DNS packet when received by a DNS server. As servers do not know other protocols, cross-protocol loop attacks are rather hard to mitigate. One effective mitigation is to make servers stay silent when receiving "malformed" packets.

Rate limiting Servers can mitigate loops by applying rate limits. When the number of packets among two victim servers reaches the rate limit, the packet loop terminates. However, rate limits cannot mitigate the loop attack completely. For example, DNS resolutions can take a considerably long time, which can help an attacker to evade rate limits. Furthermore, rate limits may only degrade the packet loop but do not entirely stop it. In fact, the attacker can periodically send the loop-triggering payloads to victim servers to restart them.

Source port validation Loops always span two servers and their corresponding UDP server ports (e.g., 53 for DNS). Loops could be stopped if servers expect all benign requests to come from *different* ports, e.g., out of the ephemeral client UDP port range. This is an elegant and easy fix that likely works for most clients. The same logic can be applied for network-level filtering of attack traffic. That is, normally (at least) one of the two UDP ports in a given UDP stream come from the client-chosen ephemeral range. But note that this solution might break the compatibility of some software. For example, a popular NTP server software, ntpd [1], would, by default, use source port 123 to send symmetric mode messages to other NTP servers. Legacy DNS servers may also send requests from source port 53.

Quality of service To mitigate loops, network operators can give less preference to abused protocols to drop attack packets in case of network congestion. In particular, the UDP ports of the legacy protocols can be assigned low QoS priority. Non-legacy protocols (TFTP, DNS, NTP) instead require case-by-case decisions to minimize interference with normal services.

6 Disclosure and Ethics

We now discuss our disclosure process and revisit the ethical aspects of our methodology, experimental setup, and findings.

Disclosure We started the disclosure process of our work's findings in December 2023. Though we found loops in several protocols, there is no easy way to learn the vulnerable software and products that cause the loop behavior.

Fortunately, Shadowserver provided us with the fingerprints of vulnerable hosts. In parallel, we also disclosed the list of affected IPs to ASes. Some of the affected ASes provided us with information on affected products and software. The vulnerability is mostly caused by proprietary software used by vendors. As of Feb 2024, several vendors confirmed loop vulnerabilities: Broadcom (DNS), Honeywell (NTP), Mikrotik (TFTP), Brother (TFTP), and Microsoft (TFTP).

There are also end-of-life products from other vendors that are likely affected. For example, Cisco 2800/2970 routers can likely form an NTP loop, and Zyxel's old firewall products, e.g., ZyWall 2, is seemingly affected by a DNS loop.

Ethics We carefully designed our experiments according to ethical principles. For each protocol, we used hand-vetted discovery probes to minimize the probability of interfering with real servers. During the scanning, we followed general best practices [48] and also minimized the number of probes to servers via clustering and applied rate limits to avoid causing noticeable network or computational loads. Although we offered an opt-out option, we did not receive a single such request throughout our experiments, which underlines the low-rate and defensive nature of our scans.

7 Conclusion

We introduced a systematic approach for finding and verifying application-layer packet loops among real servers. Such loops can be abused in various attacks, e.g., link flooding and server resource exhaustion, and only require a limited attacker ability, i.e., to send IP-spoofed packets to initiate loops. These loops are prevalent among network infrastructures, with our work revealing billions of pairs that can be abused by attackers. Empirically, we also find packet loops among servers across protocols, which can affect even more real servers in practice. We hope this work can raise developers' and protocol designers' awareness of packet loops and help in patching vulnerable software and updating protocol standards.

Zero-setup Intermediate-rate Communication Guarantees in a Global Internet

Marc Wyss
ETH Zurich

Adrian Perrig
ETH Zurich

Abstract

Network-targeting volumetric DDoS attacks remain a major threat to Internet communication. Unfortunately, existing solutions fall short of providing forwarding guarantees to the important class of *short-lived intermediate-rate communication* such as web traffic in a secure, scalable, light-weight, low-cost, and incrementally deployable fashion. To overcome those limitations we design Z-Lane, a system achieving those objectives by ensuring bandwidth isolation among authenticated traffic from (groups of) autonomous systems, thus safeguarding intermediate-rate communication against even the largest volumetric DDoS attacks. Our evaluation on a global testbed and our high-speed implementation on commodity hardware demonstrate Z-Lane's effectiveness and scalability.

1 Introduction

Network-targeting distributed denial-of-service (DDoS) attacks flood routers and links with massive amounts of traffic, resulting in congestion and the subsequent dropping of legitimate packets along their communication path. Despite decades of research, volumetric DDoS attacks against network infrastructure remain a threat to the availability of Internet communication; both the number of attacks and their volume have been increasing over the past years with a large fraction of attacks relying on address spoofing [15, 52]. With botnets, in particular Mirai variants, and pulse-wave attacks on the rise, DDoS threats are becoming more pronounced [16]. Home connections with 10 Gbps speeds and botnets composed of powerful cloud VMs are simplifying the execution of volumetric DDoS attacks and render them increasingly potent [17].

In this work, we specifically focus on ensuring communication reliability for *short-lived intermediate-rate traffic*, including DNS communication, legitimate command and control systems, and access to websites. Those applications typically require rates ranging from individual packets to a few hundreds of kilobits per second, occasionally reaching up to several megabits per second at most, and often persist for the duration of a few seconds only. While short-lived traffic constitutes the majority of concurrent flows, it accounts for only little total traffic volume, i.e., less than 10% in terms of both packets and bytes per second [69]. Still, such communication is delay-critical, and therefore protection against volumetric DDoS should be *available immediately* and thus readily protect a flow's first packet(s), instead of being reactive.

As we elaborate in Section 8, existing solutions, both from industry and academia, have proven unsatisfactory in addressing this problem. Industry systems often grapple with scalability issues, substantial management overhead, and high cost, while research-based systems frequently resort to heuristics, work only reactively, cannot protect the whole forwarding path, cause latency inflation, or remain vulnerable to spoofed packet source addresses. Even next-generation bandwidth reservation systems designed to explicitly allocate bandwidth on specific inter-domain paths fall short of effectively addressing this challenge: the time required to establish a new reservation introduces substantial delays, which significantly outweigh the short-lived duration of the actual traffic transmission. Furthermore, the minimum validity period of a reservation typically spans over tens of seconds, resulting in wastage of reserved bandwidth for short-lived application traffic.

Apparently, protecting short-lived intermediate-rate communication in the global Internet is challenging and calls for novel, low-cost defense mechanisms that work proactively instead of reactively, provide communication guarantees rooted in solid theoretical foundations as opposed to heuristics, scale to large topologies, are fully resilient to source address spoofing, and do not introduce additional latency.

Our key insight lies in recognizing that (i) our target traffic class necessitates only a minimal amount of traffic, rendering a small pre-configured bandwidth allocation at routers sufficient to guarantee its forwarding, and (ii) effective enforcement of bandwidth isolation by a congested router requires the ability to ascertain the absence of spoofed source addresses.

Recent advancements in path-aware architectures have introduced mechanisms for authenticating traffic sources to ev-

ery on-path autonomous system (AS)[1] [42], with in-network filtering of spoofed traffic and thwarting reflection and amplification attacks as their primary objectives. However, we observe that these mechanisms possess untapped potential, as they can enable *meaningful* bandwidth allocations at routers, aligning with the requirements of our insight. Given that the security of these mechanisms is rooted in AS-level shared secret keys, our proposal centers on protecting short-lived intermediate-rate communication through *AS-level bandwidth isolation applied to source-authenticated traffic*, thus avoiding the need for the setup of measures such as bandwidth reservations prior to actual traffic transmission ("zero-setup").

Still, numerous challenges persist. These range from efficiently monitoring and scheduling traffic originating from tens of thousands of ASes without requiring excessive queues or memory at routers, to protecting against malicious end hosts that may drain their ASes' guaranteed rates. To address these scalability and security challenges, we adopt a hierarchical approach, wherein we organize ASes into groups that share a uniform trust environment. Consequently, traffic originating from within a router's designated group can be granted per-AS forwarding guarantees, while traffic from external sources can be scheduled at the AS group level. Furthermore, an AS can extend its guaranteed rates to its end hosts, thus ensuring DDoS protection for individual users.

The compilation of these ideas results in the design of Z-Lane, a system providing zero-setup communication guarantees for intermediate-rate Internet traffic. Z-Lane consists of (i) a gateway to be deployed at source ASes and (ii) an efficient scheduling mechanism to implement AS-level bandwidth isolation at border routers. Due to ubiquitous source authentication, Z-Lane can offer fundamental communication guarantees, avoiding the reliance on heuristic methods. If globally deployed, Z-Lane can defend the many end hosts in the Internet against even the largest DDoS attacks without introducing significant latency, thus extending its applicability beyond large-scale enterprises. Our main contributions are:

- The design of Z-Lane, a system providing zero-setup communication guarantees for intermediate-rate traffic.
- A formal analysis showing that Z-Lane can protect such traffic against volumetric DDoS attacks, emphasized through a comparative evaluation with related work.
- The deployment of Z-Lane on a global testbed to show its practical viability and incremental deployability.
- The implementation of a high-performance version of Z-Lane in DPDK that generates, validates, and schedules traffic at 160 Gbps line rate on commodity hardware.

[1] An AS is a network under a common administrative control such as an Internet service provider (ISP), a company, or a university.

2 Background

We build Z-Lane, our proposed system described in Section 4, on top of SCION [14], a path-aware Internet architecture, and use EPIC [42] to implement per-packet source authentication.

SCION. As in BGP, the building blocks of the SCION network architecture are autonomous systems (ASes). However, as a fundamental concept distinguishing SCION from BGP, ASes are grouped into *isolation domains (ISDs)*. An ISD is a set of ASes that span a uniform trust environment or a common jurisdiction. In practice, an ISD might comprise ASes of providers associated with the same country or organisations such as banks or health care services. A subset of ASes in an ISD are *core ASes*, which link to core ASes of other ISDs to enable global connectivity; all other ASes in an ISD are referred to as *non-core ASes*. An AS network typically consists of multiple routers, where some of them are internal routers and some of them are border routers. A SCION border router has one internal interface for connectivity (via internal routers) to AS-local infrastructure services, end hosts, and to other border routers of the same AS, and one or multiple external interfaces, which provide connectivity to other ASes. Switching from BGP to SCION requires replacing existing border routers; all internal routers can be reused.

Research on SCION is facilitated by its open-source implementation [60] and SCIONLab [2, 41], a global SCION research testbed; several proposed systems already made it from research into SCION protocol extensions. SCION is being deployed in the real world [4, 6, 32, 40, 65–67] and has reached a Technology Readiness Level (TRL) of 9 [12]. There is work in progress to standardize SCION at IETF [19].

Z-Lane relies on SCION due to its (i) availability properties and (ii) AS groupings. BGP has inherent limitations that can compromise availability, from expensive reconvergence processes to path hijacking vulnerabilities enabling traffic redirection and packet dropping. In contrast, SCION as a multipath architecture offers a more robust solution by allowing traffic sources to immediately switch to other paths in response to on-path router or link failures (without requiring reconvergece) and is resilient to hijacking attacks by design. Operating independently of BGP, SCION ensures that vulnerabilities or attacks in BGP do not affect its own security. Furthermore, to achieve scalability to tens of thousands of ASes, Z-Lane needs a way to group ASes based on mutual trust; such a grouping is already implemented through ISDs in SCION. The grouping must not be arbitrary but trust-based, as outside the group, Z-Lane-enabled routers only enforce bandwidth isolation for the whole group rather than for individual ASes, meaning that ASes inside the group share their fate regarding their guaranteed forwarding rates. As SCION packets always contain the source AS and ISD, Z-Lane routers can avoid keeping a map from IP prefixes to ASes and ISDs.

Table 1: Overview of Z-Lane and its key technologies.

Protocol	Description
SCION	Internet architecture that groups ASes into ISDs. It ensures rapid failover via multipathing and resilience against path hijacking through path authentication and authorization.
DRKey	Establishes symmetric keys between ASes and endpoints. Keys can be dynamically derived at routers.
EPIC	Prevents spoofing and reflection attacks by offering source authentication for both routers and destinations.
Z-Lane	Protects short-lived, intermediate-rate traffic from DDoS via configurable per-AS/per-ISD bandwidth isolation.

EPIC. EPIC ensures that every packet's length and origin, i.e., the source host's ISD, AS, and address, can be efficiently verified by all on-path border routers and the destination host. This enables EPIC to effectively counter attacks that exploit spoofed addresses for reflection and amplification early on the communication path. In EPIC, a source host proves its authenticity to on-path border routers by generating a per-packet hop validation field (HVF) for each AS along the selected path. These HVFs are then included in the SCION packet header, replacing the existing hop fields. A HVF serves as a message authentication code (MAC) and is computed using a host-level symmetric key shared between the source host and a specific on-path AS. These keys are established through the DRKey system [38, 57], enabling routers to efficiently derive the keys within tens of nanoseconds from a master key, avoiding to store per-host key tables. While DRKey creates AS-level keys as well, these are only accessible to AS infrastructure services and not to end hosts. Keys established with DRKey are valid for one day and can be renewed before their expiration; they are requested before any actual communication takes place and can be reused for all EPIC-authenticated flows. Through the deployment of a duplicate-suppression system, EPIC allows transit ASes to also filter replayed packets. Details on DRKey and EPIC can be found in Appendices A and B.

We rely on EPIC's efficient source authentication mechanism proven secure in a strong attacker model to prevent packet spoofing in Z-Lane. We use the EPIC system in particular due to (i) lack of alternatives and (ii) its integration into SCION. As we elaborate in Section 8, to the best of our knowledge EPIC is the only system that authenticates every packet's source (and its length) to every on-path AS, while operating at line rate and being stateless at routers, and thus scales at border routers to arbitrarily large topologies. EPIC's verification at all on-path routers contrasts other source authentication schemes where routers only probabilistically verify a subset of all received packets. Also, EPIC is specifically designed for path-aware networks like SCION. To authenticate its traffic, a source host in EPIC requires explicit knowledge regarding all on-path ASes. This requirement underscores the significance of SCION's path transparency, which is lacking in BGP.

Table 1 summarizes Z-Lane and its key technologies.

3 Requirements and Assumptions

In this section, we outline the problem we aim to solve, the requirements that any solution attempting to do so needs to satisfy, as well as our threat- and network models.

3.1 Problem Statement

Our objective is to provide communication guarantees to short-lived, intermediate-rate inter-domain traffic of protocols such as DNS, HTTP(S), or SSH despite volumetric DDoS attacks. Those protocols are characterized by their relatively low traffic volumes typically ranging from a single packet to a few megabits per second, and their short duration, from the time needed for a single round-trip to a few seconds. We focus on the availability of this type of communication across the Internet, i.e., on mitigating the impact of volumetric DDoS attacks on the forwarding behavior of legitimate traffic at routers. While EPIC mitigates attacks leveraging spoofed addresses for reflection and amplification, vulnerabilities persist in the face of attacks originating *from individual sources generating immense traffic volumes or from botnets where multiple distinct end hosts transmit traffic at lower rates* [36, 48, 64]. Such attacks can disrupt connectivity among target links and thus even disconnect whole regions and are often regarded as some of the most challenging threats to availability [70]. DDoS attacks targeted at end hosts or exploiting weaknesses in higher-layer protocols are not in the scope of this work.

3.2 Requirements

We require our system to:

R1 Guarantee forwarding of intermediate-rate inter-domain traffic despite arbitrarily large volumetric DDoS attacks.

R2 Provide guarantees also in Internet topologies comprising hundreds of thousands of ASes and billions of end hosts.

R3 Not require any setup process before end hosts can send actual traffic ("zero-setup"). This distinguishes our setting from inter-domain bandwidth reservation systems, which have an inherent reservation setup phase (Section 8).

R4 Avoid latency inflation, such as from added packet processing, queuing, or rerouting delays.

R5 Not incur substantial financial costs, including operational costs for providers and end domains.

Besides those main requirements, an ideal solution should attain high rates for traffic generation and forwarding while minimizing hardware demands, be incrementally deployable at border routers, and maintain a simple design relying on established primitives for effortless deployment and configuration. To the best of our knowledge, no currently existing system is able to satisfy all of those requirements (Section 8).

3.3 Assumptions

Adversary Model. For communication to be possible between some source and some destination host, there must exist at least one adversary-free path over the Internet (i.e., all on-path entities are benign), as attackers could trivially drop packets to prevent any communication. SCION usually provides dozens of paths to end hosts, allowing avoidance of paths where communication is not possible or has low QoS. In our model, on-path attackers can nevertheless observe, inject, and replay packets on inter-AS links.

Even when communication occurs on a path with benign entities only, off-path entities may attempt to hinder it, such as by creating congestion on forwarding devices along the route. Our adversary model allows off-path attackers to exhibit arbitrary behavior. In particular, off-path attackers can also control ASes, including compromised services, end hosts, and routers, where the attacker can also have access to AS key material. Those assumptions are in line with the attacker model of other work related to DDoS defense [31, 75].

Network Characteristics. We assume that adjacent ASes connect through direct links. If they instead connect through lower layer interconnects at an IXP, e.g., in a colocation facility, we expect the IXP to implement adequate isolation measures to protect each inter-AS peering against congestion in its network. Alternatively, an IXP may itself implement Z-Lane and explicitly participate in routing by registering as an AS. We further assume that every network link is connected to routers that are capable of handling traffic rates matching the link's capacity so that packets are never dropped at ingress.

4 Z-Lane System Description

This section describes Z-Lane, our proposed DDoS-defense system satisfying the requirements in Section 3.2.

4.1 Overview

With per-AS bandwidth isolation implemented through DDoS-resistant and adjustable *forwarding rate lower bounds for (groups of) ASes*, Z-Lane provides a novel perspective on how to achieve communication guarantees in a global Internet.

Guarantees for (Groups of) ASes. Z-Lane introduces the concept of bandwidth isolation at the level of (trust-based groups of) AS. At a border router, traffic originating from within its group gets per-AS forwarding guarantees, and traffic from outside is scheduled at the level of AS groups.

This design decision is motivated by (i) *scalability*, as AS-level traffic scheduling is challenging, whereas for groups of ASes it becomes feasible (analyzed in Section 4.5), (ii) *hierarchy*, as ASes can further pass on the AS-level lower bounded rates to their end hosts [75], (iii) *security*, because Sybil attacks, where an attacker creates many instances of a source in an attempt to get a higher share of a resource, are much harder when those sources are ASes [18], and (iv) *traffic stability*, i.e., aggregated traffic from one or multiple ASes naturally exhibits greater stability over time compared to flow or host-level traffic [55].

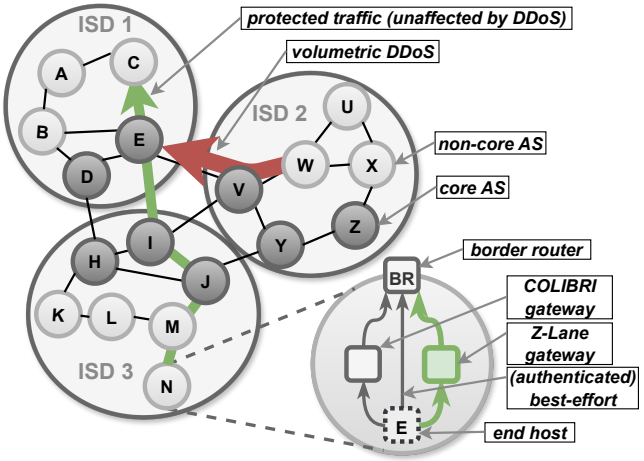

Figure 1: Overview. End hosts send short-lived traffic to the Z-Lane gateway, reservation traffic to the COLIBRI gateway, and all other traffic as authenticated best-effort directly to the border router. Z-Lane (and COLIBRI) traffic is protected at routers along the forwarding path from volumetric DDoS.

We instantiate the AS groupings with SCION isolation domains (ISDs). In the example in Figure 1, AS N of ISD 3 sends traffic to AS C of ISD 1, where its guaranteed rate at border routers protects this traffic against volumetric attacks from ISD-internal off-path attackers, e.g., AS L targeting the link between AS M and AS J, and ASes in off-path ISDs, e.g., AS W targeting the link between AS E and AS C.

Configurable Rates. Not all ASes generate identical traffic volumes, therefore Z-Lane allows a transit AS to configure different guaranteed rates for different ASes and ISDs. The configuration can for example be learned based on ASes' and ISDs' demands during normal operating conditions, such that the corresponding guaranteed rates can later automatically be enforced during periods of active attacks, enabling an AS to send traffic at the same rate as on previous days (Section 4.6).

If the guaranteed rate configured for a source AS is higher than its demand, its intermediate-rate traffic is completely unaffected by volumetric DDoS attacks. Z-Lane ensures that ASes and ISDs can send *at least* at their guaranteed rates, as it also forwards traffic exceeding their rate as best-effort. As long as there is remaining capacity, ASes and ISDs can thus overuse their guaranteed rates, so that no bandwidth is ever wasted. This implies that even if the allocated rate for a source AS is less than its demand, the AS can still communicate at its desired rate when there is no congestion. As we demonstrate in Section 5, the AS can also send data at the guaranteed rate during volumetric DDoS attacks, where communication would otherwise be impossible without the deployment of

Z-Lane. The decision how to configure the rates is ultimately up to the network operator and, importantly, does not require any inter-domain coordination. Due to the aggregation of ASes into ISDs, configurations remain manageable even if the Internet grows to hundreds of thousands of ASes.

End Host Guarantees. Z-Lane lets end hosts, more specifically their applications, define what traffic should be sent with forwarding guarantees, and what traffic should be forwarded over best-effort. Still, to protect against malicious end hosts, their AS has the ultimate authority in this matter and can reclassify traffic to be sent as best-effort only. This protection is implemented through a Z-Lane gateway, which schedules end host traffic and authenticates it towards on-path routers using a secret key not known to the end hosts. How traffic is scheduled is up to the AS operator; configurations can range from fair sharing to prioritizing certain traffic from critical AS services like routing or time synchronization. We emphasize that, to avoid any setup overhead (R3), neither ISDs, nor ASes or end hosts explicitly learn their configured rate; instead, end hosts implicitly discover their allowed rate through existing mechanisms like congestion control.

Compatibility with Other Systems. Bandwidth reservation systems cannot provide zero-setup communication guarantees and are therefore not suitable to protect short-lived intermediate-rate communication (Section 8). Still, we design Z-Lane to seamlessly coexist with them, as they complement our work by effectively protecting *non-setup-critical, high-volume communication* such as from video conferencing. We choose COLIBRI [27] as a reservation system instantiation, but other systems could be deployed as well. To prevent attacks targeting DRKey's AS-level key exchange, which is a fundamental requirement for EPIC, our design also ensures compatibility with the DoCile system [74], which leverages dedicated channels between neighboring ASes to successfully bootstrap the key exchange even under DDoS.

We therefore consider the following four types of inter-domain traffic: COLIBRI reservation traffic, DoCile's neighbor-based communication, authenticated traffic from EPIC, and unauthenticated SCION traffic.

4.2 Source Authentication

Z-Lane employs EPIC for authenticating traffic sources to border routers, allowing every border router to verify the authenticity of every received packet. An important insight in the design of Z-Lane is that efficient and reliable source authentication as provided by EPIC allows for *meaningful source-based traffic control at border routers*. The realization of this idea has not been possible so far because previous source authentication mechanisms would cause excessive communication or computation overhead and therefore impede deployment, or were based on heuristics or probabilities, and would thus fail to reliably distinguish between authentic and spoofed addresses (Appendix H). Z-Lane is the first system to explore the use of comprehensive source authentication to protect the availability of short-lived intermediate-rate Internet traffic – with *EPIC's security rooted in AS-level secret keys, it integrates seamlessly into Z-Lane*.

We want to highlight that EPIC together with a fairness mechanism provided by some congestion control algorithm, i.e., without any guaranteed rates, would not be enough in our threat model, as an attacker would just not respect the algorithm's feedback and instead keep sending traffic at high rates, or leverage a botnet to create many low-volume flows.

4.3 End Host Traffic Generation

End hosts, i.e., their applications, can choose among several mechanisms on how their traffic is forwarded (Figure 1). For long-term traffic they request a bandwidth reservation and use it by sending their COLIBRI traffic class packets through the COLIBRI gateway. While the overhead for requesting a reservation is significant, the result is a fixed amount of bandwidth that is exclusively reserved along the communication path. In a similar way, applications send short-lived intermediate-rate traffic using the EPIC traffic class over the Z-Lane gateway, where traffic is forwarded immediately without any delay (requirement R3), but without the applications knowing the concrete rates. In both cases traffic is protected against congestion on the communication path. The default option is for end hosts to send their traffic using the EPIC traffic class directly to a border router of their AS, where they are forwarded along the path using best-effort. This option is useful for non-latency-critical communication such as file downloads, or for long-term traffic for which no reservation is available, which can for example happen if the end host has already created a large number of reservations and gets denied from creating even more. Z-Lane envisages unauthenticated SCION traffic to be sent only in scenarios where it is not otherwise possible, e.g., if an AS needs to request shared keys using DRKey from another AS for the first time.

4.4 Z-Lane Gateway

ASes use the gateway to control the traffic volumes that their end hosts (incl. AS infrastructure services) are allowed to send using Z-Lane, which serves the primary purpose of protecting benign from malicious or compromised end hosts.

For end host traffic complying with the allowed rate, the gateway sets a QoS flag in the EPIC header, which indicates to on-path routers that the corresponding packets should be forwarded using the AS' guaranteed rate. If an end host's packet exceeds the allowed rate at the gateway, then either (i) the QoS flag is not set (or removed, if it was already set by the end host), meaning that those packets will be treated as best-effort, or (ii) the packets are dropped, depending on the AS' policy. In contrast to best-effort EPIC packets generated at

end hosts, which are authenticated using host-level keys, the Z-Lane gateway further authenticates packets from end hosts using AS-level keys, which are not available to the end hosts, preventing end hosts from setting the QoS flag themselves. Details of DRKey, EPIC, and the authorization procedure at the gateway, are described in Appendices A to C.

Attack Prevention. Compared to a design where end hosts can set and authenticate the QoS flag themselves, the Z-Lane gateway, which further rate-limits the traffic and authenticates it with the AS-level key, provides better protection against misbehaving end hosts. In particular, it prevents malicious, compromised, or misconfigured end hosts from executing volumetric DDoS attacks aimed at overusing its AS' guaranteed forwarding rate at on-path border routers, thus disrupting communication of legitimate end hosts in its own AS.

If the gateway would not authenticate traffic using the AS-level key, malicious end hosts could leak their host-level keys to other entities in the Internet to enable them to launch DDoS attacks using packets with a spoofed source. However, with our design, such leakage does not provide any benefits to such entities, as they would still need to either (i) obtain access to the end host AS' keys, or (ii) route traffic through the end host AS' gateway, both of which are inaccessible to them.

Incentivizing Compliance. In principle, end hosts can send arbitrary application traffic to the gateway, as the gateway does not inspect packet payloads. However, the gateway disincentivizes end hosts from using Z-Lane also for high-volume application traffic, which should instead be sent either as authenticated best-effort or over COLIBRI reservations: Because the gateway only adds the QoS flags to packets up to a certain rate, and because it cannot distinguish between low-volume short-term and high-volume long-term traffic, the QoS flag will be randomly set on a small fraction of both types of traffic, thereby foiling the forwarding guarantees of both short-term and long-term traffic.

4.5 Border Router Traffic Scheduling

An essential part of Z-Lane is the enforcement of the configured AS- and ISD-level traffic rates at border routers. The challenge is to find a solution that is based on simple and well-known mechanisms (to facilitate adoption), requires minimal state and queues (to allow deployment on different devices), can forward traffic at high rates (to keep up with traffic rates on inter-domain links), and scales to the size of the Internet (requirement R2). In the following, we present our solution to overcome those challenges; an overview is given in Figure 2.

Queues. We introduce the following five different per-router-interface egress queues. The *reservation* queue (R) contains COLIBRI packets belonging to a bandwidth reservation. The *neighbor* queue (N) is used for DoCile packets

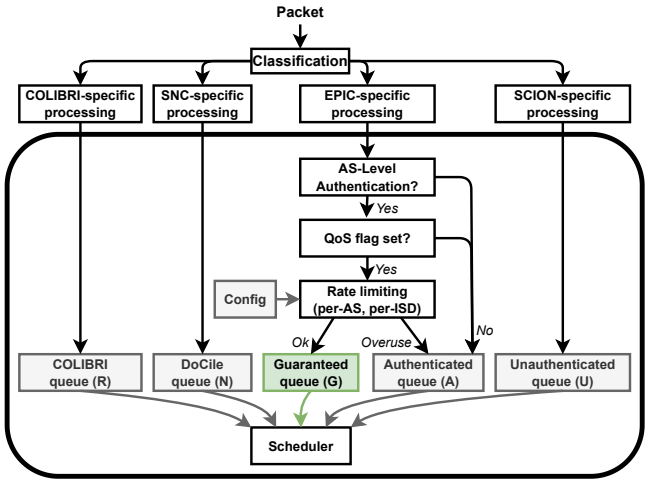

Figure 2: Z-Lane packet processing at the border router.

originating from or destined to a neighboring AS.[2] The *guaranteed* queue (G) is meant for AS-level authenticated EPIC traffic where the QoS flag is set. Host-level authenticated EPIC traffic or AS-level EPIC traffic where the QoS flag is not set goes to the *authenticated* queue (A). Lastly, the *unauthenticated* queue (U) contains standard, i.e., unauthenticated, SCION packets. Packets from the queues R, N, and G are forwarded preferentially, while A and U are best-effort queues.

Packet Processing. COLIBRI, DoCile, host-level authenticated EPIC, and unauthenticated SCION packets are processed by the border router according to their protocol, and in case they are not dropped during this step, they are directly put into their corresponding queue (R, N, A, or U). AS-level authenticated EPIC packets are, after protocol-specific processing, further classified before they are added to a specific queue. In particular, packets with the QoS flag set that originate from an AS inside the border router's ISD are per-source-AS rate-limited according to a previously defined configuration. Similarly, packets with the QoS flag set, which originate from an AS outside the border router's ISD are rate-limited on a per-source-ISD basis. When a packet causes a violation of this rate, it is enqueued at A. Otherwise, the packet is added to G. This ensures that traffic up to the configured rate is guaranteed to be forwarded, and everything above this rate is forwarded as best-effort. *Contrary to intuition, rate-limiting EPIC traffic does therefore not serve the purpose of upper bounding the egress rates of ASes and ISDs, but instead to provide them with a lower bound.* If a packet cannot be added to a queue because the queue is already full, then the packet is dropped.[3] This can only happen for the best-effort queues A, and U however. The per-AS and per-ISD rate limits at the router (and also the end host rate limits at the gateway) can be efficiently implemented using token buckets [49]. Appendices E and F explain why we neither use probabilistic

[2] DoCile is needed to bootstrap the keys used in EPIC under DDoS where the guaranteed Z-Lane rate for the neighboring AS cannot be used yet.
[3] Instead of tail drop, other disciplines such as RED [24] could be employed.

Table 2: Scheduling bounds for the different queues with example instantiations as percentages of the total egress capacity. Their sum must not exceed 100 %.

Queue	Lower/Upper Bound	Example
Reservation (R)	μ_R	50 %
Neighbor (N)	μ_N	10 %
Guaranteed (G)	μ_G	20 %
Queue	**Lower Bound**	**Example**
Authenticated (A)	μ_A	15 %
Unauthenticated (U)	μ_U	5 %

monitoring nor neighbor-based scheduling, even though those mechanisms could further reduce Z-Lane's memory footprint.

The border router not only forwards traffic, but also creates new packets. This happens for (i) bidirectional forwarding detection (BFD) [1], which is used to detect faults in the links between routers, and (ii) SCMP [68], where the router responds to, e.g., traceroute requests. BFD packets are added to N, while SCMP packets are enqueued at U.

Scheduling. A router egress scheduler determines which packets to forward on its link, which is only relevant when there is congestion, i.e., when traffic exceeds the interface's capacity. Without congestion, no packets are dropped.

There are two requirements that the scheduler must satisfy. First, it must provide a lower bound on the forwarding rate to A and U. If packets are added to one of those queues at a rate α, where the lower bound provided to this queue is μ, then traffic from this queue must be forwarded at a rate greater or equal to $\min(\alpha,\mu)$. This requirement ensures that best-effort traffic will not starve. Second, the forwarding rates for R, N, and G must both be lower- and upper bounded.If traffic arrives at such a queue at a rate α, where the bound provided to this queue is μ, then traffic from that queue must be forwarded at a rate of exactly $\min(\alpha,\mu)$. Both requirements together imply that in case R, N, or G are not fully utilized, the remaining egress capacity can be used for traffic from A and U. The queues and their bounds are summarized in Table 2. An efficient scheduler that satisfies those two requirements by enforcing the given bounds is the hierarchical token bucket (HTB) scheduler [11]. If the deployed COLIBRI protocol implementation already guarantees that its upper bound μ_R is never exceeded (for DoCile and Z-Lane this is always the case), then also schedulers such as the deficit round robin (DRR) scheduler [9], the weighted fair queueing (WFQ) scheduler [20, 53], or the enhanced transmission selection (ETS) scheduler [10] can be used. Whether μ_R is already enforced by COLIBRI depends on the concrete protocol implementation, e.g., reservation monitoring in COLIBRI could be performed deterministically or probabilistically, where only the former implementation guarantees this upper bound.

Design Rationale. Optimizing the number of queues and the state required for rate limiting is important to enable implementations on high-speed hardware [34]. Our presented design uses five static queues (R, N, G, A, and U) plus a variable

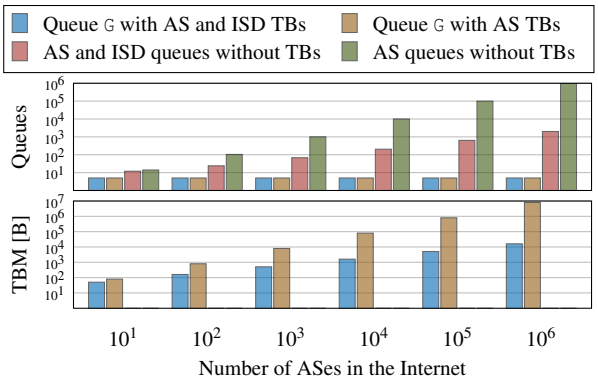

Figure 3: Nr. queues vs. token bucket memory (TBM) for different traffic control designs. Z-Lane implements a single queue G with per-AS and per-ISD token buckets (TBs).[4]

number of token buckets for per-AS and per-ISD rate limiting of guaranteed traffic at each interface, which constitutes a practically feasible, efficient, and simple-to-analyze solution to enforce Z-Lane's guarantees. However, other approaches satisfying Z-Lane's requirements are possible as well. Figure 3 compares (i) our proposal with designs based on (ii) a single queue G and per-AS token buckets, (iii) per-AS and per-ISD queues, and (iv) per-AS queues only, where the latter two do not require any token buckets. Monitoring 10^5 globally distributed ASes at a single egress interface for example requires (i) in Z-Lane only 5 static queues and 5.3 kB of memory, and otherwise (ii) 5 queues and 800 kB of memory, (iii) 638 queues, or (iv) 10^5 queues, respectively, which highlights the benefits of ISD-level traffic control. For (iii) and (iv), additional memory is needed for the queues and the scheduler, and the queues are also more difficult to add, modify, and remove at runtime. Still, approach (iii) has a manageable number of queues and could potentially be implemented with, e.g., SENIC [56], which keeps queues in memory and schedules—and thereby rate-limits—packets in the network interface card (NIC). The token bucket memory requirements are taken from Appendix D, where we describe an optimized rate limiter which reduces the memory overhead compared to current state-of-the-art implementations by 60-86%.

4.6 Configuration

The gateway configuration allows to set the rate up to which the QoS flag should be set of individual, or—based on IP prefixes—groups of end hosts and AS services. Similarly, the scheduling bounds μ for the different queues as well as the guaranteed forwarding rates for ASes and ISDs at border router interfaces can be configured by the router's network operator (Figure 2). The per-AS and per-ISD rates can either be absolute (e.g., 2 Gbps) or relative (e.g., 5 %) to the fraction μ_G of egress capacity dedicated to G. Thereby, the sum of the

[4]For simplicity, the analysis assumes that in a SCION Internet consisting of N ASes, an average ISD comprises approximately $\sqrt{N}$ ASes.

rates in relative terms must not exceed 100 %.

To simplify integration into an AS' network, Z-Lane has a default router configuration that ensures every AS and ISD receives an equal rate, thus minimizing initial management tasks. While this default configuration may not be optimal, as some ASes might get rates that are too low, it nevertheless enhances communication availability for all legitimate traffic sources compared to no communication during DDoS attacks. To accommodate shifts in traffic patterns at both AS and ISD levels, router configurations can be adjusted in real-time. As for other SCION router configurations, this happens via gRPC [28]. Distinct configurations can be implemented based on the prevailing traffic conditions. Configurations can be created according to an AS' policies, or be learned based on ASes' and ISDs' demands during normal traffic situations, such that the corresponding guaranteed rates can later automatically be enforced during periods of active attacks. The infrastructure for traffic data collection already exists in most ISP networks, and, under normal conditions, links tend to be underutilized, which is likely to be reflected in the traffic history [13]. Therefore, a good configuration can be achieved by allocating rates slightly above their historical values, thus accounting for estimation inaccuracies and traffic burstiness. In Z-Lane, rate estimation is further simplified as only the small fraction of short-term intermediate-rate traffic needs to be considered (the majority of Internet traffic is caused by video streaming [58]). Numerous methods exist for addressing the challenge of traffic forecasting [23], which is therefore not the focus of our work. Suitable methods may for example include prediction models utilizing simple moving averages or more sophisticated artificial neural networks. Traffic forecasting enables operators to tailor configurations to their networks' specific requirements, minimize management overhead, and allow for automatic configuration adjustments over time. Consequently, increased management overhead only arises if the network operator chooses to intervene manually.

Configuring bandwidth on a per-ISD basis not only reduces memory overhead for border routers but also simplifies their configuration, as there is a significantly lower number of sources to monitor. When ASes are added or removed within a router's ISD, the configuration needs to be updated to reflect those changes. An AS can achieve this by consulting its DRKey service about the ASes that have recently requested or renewed a shared symmetric key, as those keys are a prerequisite for any source to send traffic using Z-Lane. Topology changes in other ISDs do not necessitate the addition or removal of new configuration entries; only the ISD's guaranteed rate may require occasional updates.

5 Analysis

We assess and compare the protective capabilities of Z-Lane routers against volumetric DDoS attacks (requirement R1) and investigate the effects of partial deployment and misconfigured per-AS and per-ISD rates.

5.1 Definitions

In our analysis, we only consider queues `G` and `A`, i.e., assuming a worst-case scenario where all other queues are fully utilized. We define our system at the granularity of border router interfaces, where an interface Y of router R has egress capacity $c^{(R,Y)}$ (for traffic leaving the router). Traffic inside a router is described with variable f, where $f^{(R,X,Y)}_{(O,C)}$ refers to traffic of class C from origin O (an AS or an ISD) that arrives at interface X and is to be forwarded to interface Y of border router R. There are two traffic classes C can assume:

- α: Comprises AS-level authenticated traffic without QoS field set as well as host-level authenticated traffic.
- γ: AS-level authenticated traffic with the QoS field set.

A router always tries to enqueue packets of class α at queue `A`. A packet of class γ is added to queue `G` if the router has configured a guaranteed rate for the packet's origin AS or ISD and if the packet does not lead to an overuse of that rate; otherwise the router tries to enqueue the packet at `A` (Figure 2). To describe traffic aggregates, we use the "$\cdot$" notation. Traffic of class C arriving at router R that is to be forwarded to interface Y, for example, is written as $f^{(R,\cdot,Y)}_{(\cdot,C)}$, which is an aggregate over all traffic origins and all ingress interfaces of router R. Finally, $\mathcal{A}(R)$ is a function returning a router's AS, and $\mathcal{D}(S)$ returns an AS' ISD. In the context of Z-Lane, $r^{(R,\,Y)}_{(O)}$ is the egress bandwidth exclusively reserved to origin O at interface Y of border router R, i.e., R reserves a rate $r^{(R,\,Y)}_{(I)}$ to ISD I if $I \neq \mathcal{D}(\mathcal{A}(R))$, and a rate $r^{(R,\,Y)}_{(S)}$ if $\mathcal{D}(S) = \mathcal{D}(\mathcal{A}(R))$. If no rate is configured for some origin O, this is captured in our model by a value of zero for $r^{(R,\,Y)}_{(O)}$.

5.2 Rates: ISD-Internal and ISD-External

Traffic from a certain origin O of class γ that is guaranteed to be forwarded at queue `G` can be computed as follows:

$$g^{(R,\,Y)}_{(O)} := \min(f^{(R,\cdot,Y)}_{(O,\gamma)},\ r^{(R,\,Y)}_{(O)})$$

We refer to the guaranteed bandwidth for origin O that is potentially unused as follows:

$$u^{(R,\,Y)}_{(O)} := r^{(R,\,Y)}_{(O)} - g^{(R,\,Y)}_{(O)}$$

Also, $u^{(R,\,Y)}_{(\cdot)}$ is the sum of unused bandwidths over all possible AS- or ISD origins, respectively, or simply the unused bandwidth of $c^{(R,Y)} \times \mu_G$. We denote any communication that exceeds the corresponding rate limit as overuse traffic:

$$o^{(R,\,Y)}_{(O)} := \max\{f^{(R,\cdot,Y)}_{(O,\gamma)} - r^{(R,\,Y)}_{(O)},\ 0\}$$

Again, $o^{(R,\,Y)}_{(\cdot)}$ refers to the total overuse traffic of all origin ASes and ISDs. As we assume that the queues `R`, `N`, and `U` are

fully utilized, the leftover egress capacity $l^{(R,Y)}$, which can be used for overuse traffic from G and for traffic of class α, is the lower bound of A plus the underutilized capacities at G:

$$l^{(R,Y)} = (c^{(R,Y)} \times \mu_A) + u^{(R,Y)}_{(\cdot)}$$

In case there is no congestion, i.e., if $o^{(R,Y)} + f^{(R,\cdot,Y)}_{(\cdot,\alpha)} \leq l^{(R,Y)}$, the best-effort traffic $b^{(R,Y)}_{(O)}$ that origin O can send at queue A is equal to its overuse traffic $o^{(R,Y)}_{(O)}$ plus its traffic $f^{(R,\cdot,Y)}_{(O,\alpha)}$ of class α. In case of congestion, the leftover capacity $l^{(R,Y)}$ is shared with all other origin ISDs and ASes.

$$b^{(R,Y)}_{(O)} := \min\{\frac{l^{(R,Y)}}{o^{(R,Y)} + f^{(R,\cdot,Y)}_{(\cdot,\alpha)}},\ 1\} \times (o^{(R,Y)}_{(O)} + f^{(R,\cdot,Y)}_{(O,\alpha)})$$

We can now calculate the rate at which a router R forwards traffic originating from AS S at interface Y. This calculation depends on whether R is inside or outside the ISD of AS S.

ISD-Internal. If $\mathcal{D}(S) = \mathcal{D}(\mathcal{A}(R))$, the total throughput $t^{(R,Y)}_{(S)}$ of AS S can be computed as the sum of traffic forwarded at queue G and A together:

$$t^{(R,Y)}_{(S)} := g^{(R,Y)}_{(S)} + b^{(R,Y)}_{(S)} \tag{1}$$

ISD-External. If $\mathcal{D}(S) \neq \mathcal{D}(\mathcal{A}(R))$, with $I := \mathcal{D}(S)$, we can compute both the traffic volume $\widehat{g}^{(R,Y)}_{(S)}$ of AS S forwarded through queue G based on the guaranteed ISD rate, as well as the traffic volume $\widehat{b}^{(R,Y)}_{(S)}$ of AS S forwarded through queue A based on its ISD's best-effort share.

$$\widehat{g}^{(R,Y)}_{(S)} := g^{(R,Y)}_{(I)} \times \frac{f^{(R,\cdot,Y)}_{(S,\gamma)}}{f^{(R,\cdot,Y)}_{(I,\gamma)}},$$

$$\widehat{b}^{(R,Y)}_{(S)} := b^{(R,Y)}_{(I)} \times \left(\frac{(o^{(R,Y)}_{(I)} \times \frac{f^{(R,\cdot,Y)}_{(S,\gamma)}}{f^{(R,\cdot,Y)}_{(I,\gamma)}}) + f^{(R,\cdot,Y)}_{(S,\alpha)}}{o^{(R,Y)}_{(I)} + f^{(R,\cdot,Y)}_{(I,\alpha)}}\right)$$

The total throughput $t^{(R,Y)}_{(S)}$ of AS S can again be computed as the sum of traffic forwarded at queues G and A together:

$$t^{(R,Y)}_{(S)} := \widehat{g}^{(R,Y)}_{(S)} + \widehat{b}^{(R,Y)}_{(S)} \tag{2}$$

5.3 DDoS Attack Analysis

Based on the theory explored so far, we now analyze Z-Lane's resistance against volumetric DDoS attacks. For this, we consider a specific inter-domain path $p = [(R_1, X_1, Y_1), \ldots, (R_\ell, X_\ell, Y_\ell)]$, i.e., a list of border routers and their interfaces, over which an AS S sends traffic. To simplify our analysis, we assume that no other inter-domain path used by S intersects any egress interface of p:

$$\underset{1 \leq n \leq \ell}{\forall n:}\quad f^{(R_n,X_n,Y_n)}_{(S,\gamma)} = f^{(R_n,\cdot,Y_n)}_{(S,\gamma)}$$

In accordance with SCION's path segment combination mechanism, the first j on-path routers are inside the same ISD as S, while the last (ℓ-j) routers are in different ISDs (Figure 1):

$$\underset{1 \leq n \leq j}{\forall n:}\quad \mathcal{D}(S) = \mathcal{D}(\mathcal{A}(R_n)), \qquad \underset{j < n \leq \ell}{\forall n:}\quad \mathcal{D}(S) \neq \mathcal{D}(\mathcal{A}(R_n))$$

We further assume that for every on-path router the egress interface capacity is C, and that the total traffic from S' ISD, without the traffic from S itself, is T:

$$\underset{1 \leq n \leq \ell}{\forall n:}\quad c^{(R_n,Y_n)} = C, \qquad \underset{j < n \leq \ell}{\forall n:}\quad f^{(R_n,\cdot,Y_n)}_{(I,\gamma)} - f^{(R_n,\cdot,Y_n)}_{(S,\gamma)} = T$$

We use the example scheduling bounds from Table 2.

Z-Lane. We assume that all communication originating from S is sent over the Z-Lane gateway adding a QoS flag to every packet, and that on-path routers have the same guaranteed rates configured for S or $\mathcal{D}$(S), respectively:

$$\underset{1 \leq n \leq j}{\forall n:}\quad r^{(R_n,Y_n)}_{(S)} = r_{(S)}, \qquad \underset{j+1 \leq n \leq \ell}{\forall n:}\quad r^{(R_n,Y_n)}_{(I)} = r_{(I)}$$

We consider a scenario where at every on-path router the guaranteed rates of ASes and ISDs are always fully utilized, with the exception of the rates of S and $\mathcal{D}$(S), which depend on the throughput achieved at the previous entity:

$$f^{(R_1,\cdot,Y_1)}_{(S,\gamma)} = F, \qquad f^{(R_{n+1},\cdot,Y_{n+1})}_{(S,\gamma)} = t^{(R_n,Y_n)}_{(S)}$$

For the evaluation, we vary the transmission rate F of S and measure the achieved throughput $t^{(R_n,Y_n)}_{(S)}$ for each Y_n. We recall that the computation of $t^{(R_n,Y_n)}_{(S)}$ differs for routers inside and outside $\mathcal{D}$(S) (Equations (1) and (2)).

FIFO Router. As a first baseline, we compute the achieved throughput to routers with FIFO queuing only, meaning that all traffic goes into one single egress queue with capacity $c^{(R,Y)} \times (\mu_A + \mu_G)$. Therefore, in case of congestion, the throughput that AS S gets on some on-path router R_n decreases with the total traffic directed at interface Y_n:

$$t^{(R_n,Y_n)}_{(S)} = \min\{\frac{c^{(R_n,Y_n)} \times (\mu_A + \mu_G)}{f^{(R_n,\cdot,Y_n)}_{(\cdot,\cdot)}},\ 1\} \times f^{(R_n,\cdot,Y_n)}_{(S,\cdot)}$$

We work under the same assumptions as with Z-Lane, i.e., $(c^{(R,Y)} \times \mu_G) - r_{(S)}$ is fully used by other ASes or ISDs, and all their additional traffic is considered DDoS.

Per-flow Fairness. As a second baseline, we also evaluate a router enforcing per-flow fair rates. In this evaluation, the attacker is aware of this strategy and therefore creates twice the number of flows per traffic volume than the benign parties.

Local Isolation. Our third baseline provides bandwidth isolation exclusively based on AS-local information such as ingress-egress interfaces, representing mechanisms such as RCS [8] and PSP [13].

Results. We instantiate C, T, $r_{(S)}$, and $r_{(I)}$ with 40, 3, 1, and 4 Gbps, respectively. Figure 4 shows the source AS' throughput $t^{(R_n,Y_n)}_{(S)}$ at each on-path border router $n \in \{1, \ldots, 8\}$ when

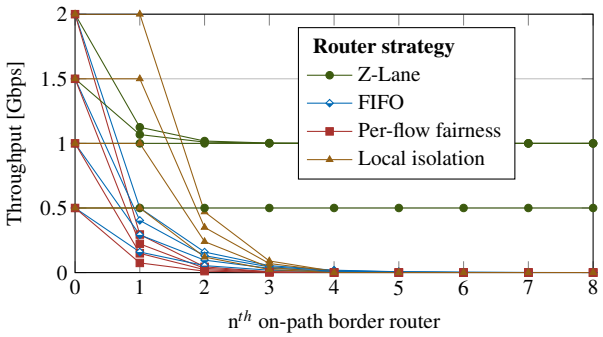

Figure 4: The source AS' achieved throughput at on-path routers, each under an attack twice as large as the egress capacity (traffic intensity X = 2), for different source transmission rates (F $\in \{\frac{1}{2}, 1, \frac{3}{2}, 2\}$ Gbps) and router implementations.

under a DDoS attack of D = 40 Gbps, i.e., with a traffic intensity of X = $\frac{C+D}{C}$ = 2.[5] For all values of the source AS' traffic rate F, the baseline results show an exponential decrease in throughput along the path. While local isolation can fully protect traffic at the first hop due to an interface-pair allocation unaffected by DDoS, it subsequently gets merged with attack flows, therefore sharing the same future allocations. With Z-Lane, for F > 1 Gbps, the throughput also decreases exponentially, but it never drops below 1 Gbps. Even for only three attacked border routers, Z-Lane provides up to 30 times higher throughput than the baseline. For F $\leq$ 1 Gbps there is no packet loss, the achieved throughput is always equal to F. Therefore, a misconfigured rate that has been set too high is ideal for the source AS as it protects all of its Z-Lane traffic, however, the unused guaranteed bandwidth could be of better use when assigned to a different AS or ISD. In contrast, a rate set too low means that the AS and its end hosts do not get all their desired traffic protected from DDoS attacks, meaning that the end hosts' applications must lower their rates until their sum is smaller than their AS' guaranteed rate.

The results of a partial Z-Lane deployment, where some on-path ASes either do not support Z-Lane or have not configured a rate for the source AS, can also be deduced from Figure 4. For F $\leq$ 1 Gbps, the outcomes align with the baseline experiments, where the x-axis signifies the number of ASes not providing guaranteed rates.

Congestion Control. We anticipate the FIFO results presented here to be even lower in reality. In the absence of attackers, when congestion occurs, end-to-end congestion control mechanisms, such as those employed by TCP, compel traffic sources to reduce their transmission rates to mitigate the situation. Under a large DDoS attack, however, attackers do not back off, resulting in invariably congested links. This in turn causes a vicious cycle of benign sources over and over reducing their transmission rate, i.e., actively lowering F. It has been shown that only very little congestion is enough for legitimate flows to reduce their rate [47, 51]. In Z-Lane, as soon as F $\leq$ 1 Gbps, this cycle is interrupted and communication is still possible at 1 Gbps.

[5] The average Internet path length is five AS-level hops [71], translating to five to eight on-path border routers, depending on the path crossing one or two border routers at each transit AS.

5.4 Security Analysis

Strategy. Unlike many other proposed solutions, Z-Lane does *not attempt to detect or actively mitigate* volumetric DDoS attacks, as this is impossible in our threat model, where attack traffic might be indistinguishable from benign communication. Instead, Z-Lane looks at the problem from a different angle, focusing on how to *protect benign communication* from getting dropped in transit. For an attacker-free forwarding path, Z-Lane's per-AS and per-ISD rates can effectively contribute to sustaining legitimate communication even in the face of the latest and most prevalent DDoS attacks, including botnet-size variants such as those seen in Mirai, or other elaborate techniques such as pulse-wave attacks.

Trust. In general, our threat model permits any combination of off-path ASes and ISDs (but not on-path ones) to be compromised. Due to the per-AS and per-ISD bandwidth isolation enforced by Z-Lane, the impact of a compromised off-path AS or ISD generating vast amounts of traffic is limited. Still, because of ISD-level (as opposed to AS-level) bandwidth isolation at routers outside an AS' ISD, the AS generally needs to trust other AS operators in its ISD. This trust is usually warranted due to ISDs being constructed based on a uniform trust environment or a common jurisdiction (Section 2). We highlight that such trust is not required regarding other ASes' end hosts. Even if a malicious AS would launch a flooding attack, other ASes inside its ISD, in particular also core ASes (which are at the boundary to other ISDs), can use Z-Lane's AS-level bandwidth isolation mechanism to prevent traffic floods from even reaching other ISDs.

Configuration. The configurable end host rates at the Z-Lane gateway protect benign end hosts from malicious end hosts in the same network trying to deplete their AS' guaranteed rates, and the configurable per-AS and per-ISD rates at border routers prevent Sybil attacks, where an attacker would create many ASes in an attempt to get a higher share of the routers' egress capacity. In today's Internet, large-scale volumetric DDoS attack have the potential to disrupt all communication over a certain link. With Z-Lane, even if rates were not optimally configured, every AS still strictly benefits compared to a situation without Z-Lane in place.

Spoofing. Successful spoofing of source addresses enables the exploitation of per-source rate limiting, potentially resulting in the disruption of traffic from a benign source. Therefore, in a Z-Lane router, if one AS can spoof traffic from another AS, it can exhaust its guaranteed rate. Similarly, at the Z-Lane gateway, if an end host can spoof traffic from another end host, it can deplete its allocated bandwidth. These observa-

tions motivate our reliance on EPIC's source authentication, which enables us to effectively mitigate such attacks.

6 Implementation and Evaluation

We demonstrate Z-Lane's integration into the SCION ecosystem, its incremental deployability, and its efficiency by implementing and evaluating it on a global testbed and as high-performance application.

6.1 SCIONLab Implementation

We implement a prototype version of Z-Lane's configurable scheduling mechanism in SCIONLab [2, 41], a global testbed that allows research and experimentation with SCION. The main purpose of this evaluation is to show that implementing and integrating Z-Lane in SCION is feasible, does not break other components, and can be performed incrementally.[6] As SCIONLab ASes are controlled by many different individuals and organizations and as we do not have access to their infrastructure, we add our own ASes to SCIONLab. To demonstrate fully protected forwarding, some of our ASes are directly connected to each other, and to demonstrate incremental deployment, others are connected to ASes of other entities around the globe. We obtained permission from the SCIONLab operators to conduct our measurements. During the three months for which our prototype was running, we have not observed any anomalous events. Moreover, we measured traffic statistics of a source AS for which we configured a rate of 10 Mbps at on-path routers that we congested with communication from other ASes, where the source AS always generated traffic below the configured rate. With normal SCION traffic we observed high latency and packet loss; with Z-Lane traffic on the other hand, all packets were successfully forwarded to the destination without significant change in latency. Unfortunately, this setup is not sufficient to demonstrate Z-Lane's defense against DDoS attacks exceeding a few hundred Mbps, as (i) our border router written in Go is not optimized for high performance and (ii) the majority of SCIONLab's inter-domain links are IP overlays, and might thus actually share the same underlying forwarding infrastructure. Also, the SCIONLab topology is not large enough to simulate Internet-scale behavior of Z-Lane. For this reason, we also implement and evaluate high-speed prototypes of Z-Lane's components.

6.2 High-Speed Implementation

We implement high-speed versions of the Z-Lane gateway and the Z-Laneborder router using Intel's Data Plane Development Kit (DPDK) [21].[7] We conduct performance measurements by executing both components one after the other (never at the same time) on a commodity machine with an Intel Xeon processor running at 2.1 GHz, while generating and monitoring traffic on a Spirent SPT-N4U. Four 40 Gbps bidirectional Ethernet links provide connectivity between the two machines. Both the gateway and the border router read packets from the corresponding ports, process them, and send them back to the Spirent machine. We implement the additional MAC computation introduced in Z-Lane (Appendix C) with AES in CBC mode, where we speed up the block cipher computation by taking advantage of Intel's AES-NI [30] hardware support. To avoid false sharing, we cache-align data structures like the token buckets.

Table 3: Mean gateway processing time for packets arriving from 32 000 different hosts. Highlighted tasks are only executed when the packet does not exceed a host's rate limit.

Task	Time [ns]
Parse and verify the received Z-Lane packet	62
Look up the token bucket (TB)for the source end host	42
Check whether the packet exceeds the TB rate	101
Subtotal	205
Set the QoS flag in the packet header	12
Look up the AS-level key	$38 \times \ell$
Compute the new/updated HVF	$61 \times \ell$
Overwrite the old with the new HVF	$9 \times \ell$
Total	$217 + 108 \times \ell$

Z-Lane Gateway. End host rate limiting at the gateway is implemented with a hash table mapping end host addresses to token buckets. We evaluate the gateway's throughput and per-packet processing time in an AS with 32 000 active end hosts. We distinguish between packets that are compliant with the corresponding end host's rate and packets that lead to an overuse of this rate. Overuse packets can be filtered early, i.e., without the gateway having to re-compute their HVFs.

A fine-grained analysis of the gateway's packet processing times is shown in Table 3. While filtering an overuse packet only takes 205 ns, packets that are rate-compliant pose an additional overhead of 13 ns to set the QoS flag plus 108 ns per on-path AS to update the corresponding HVF. Those numbers are negligible compared to end-to-end latencies that are typically on the order of milliseconds (requirement R4).

Figure 5 shows the gateway's forwarding performance for traffic sent over a path traversing five ASes.[8] Processing exclusively overuse packets compared to only processing rate compliant packets requires approximately four times less cores to achieve the same forwarding rate, which is consistent with the packet processing time results. At any point in time, the actual forwarding speed of the gateway is somewhere between the

[6] Z-Lane can be incrementally deployed where EPIC is implemented with separate MACs for path authorization and source authentication and where packets failing source authentication are forwarded with best effort.

[7] We chose DPDK because it (i) enables fast prototyping of data plane protocols, (ii) is supported on many devices [22], and (iii) is used by manufacturers of SCION border routers [5]. Still, any production-ready implementation of Z-Lane does not necessarily need to be based on DPDK.

[8] The average Internet path length is five AS-level hops [71].

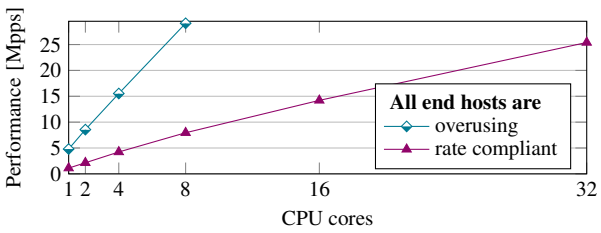

Figure 5: Gateway packet forwarding performance for different number of CPU cores and (i) overuse traffic only, compared to (ii) only traffic complying with the given rate.

evaluated overuse-only and the evaluated rate-compliant-only performance and depends on the end host traffic volumes and the configured rates. With a worst-case performance of 25.4 Mpps when using 32 cores,[9] we consider the gateway viable for real-world deployment scenarios. If more performance is needed, additional gateways can be added, where all traffic from a certain end host is forwarded to the same gateway instance to avoid synchronizing token bucket state.

Z-Lane Border Router. In the router, cores read and classify packets from their assigned ports and add them to queues, implemented by means of lock-free ring buffers, allocated for the corresponding egress port. A dedicated egress core reads the packets from its queues and schedules them according to the example capacity bounds in Table 2.For the queues `R` and `N`, we enforce their capacity upper bound through dedicated token buckets. Similarly, to implement the per-AS and per-ISD rate limiting, we use hash tables to map AS and ISD identifiers to token buckets enforcing those rates. For the evaluation of the border router, the Spirent machine generates up to 160 Gbps of traffic from a configurable mix of different traffic classes with an average payload size of ∼750 B, which is motivated by COLIBRI incentivizing the use long payloads to maximize the senders' goodput, while other traffic is expected to follow a packet size distribution with lower median [35]. Authenticated traffic with a QoS marker originates from 1000 ASes of the router's ISD and from 1000 other ISDs, which corresponds to an Internet topology of approximately 10^6 ASes. We evaluate the worst-case scenario, where all traffic is directed towards the same egress link.

To demonstrate the correct enforcement of the queues' lower and upper bounds, we generate up to 40 Gbps of different traffic mixes. The restriction to 40 Gbps in this evaluation ensures that packets are not dropped due to congestion, but from the enforcement of the upper bounds only. The results are shown in Figure 6. We observe that neither the 20 Gbps upper bound of `R` nor the 4 Gbps upper bound of `N` are exceeded at egress. Furthermore, traffic for `G`, `A`, and `U` are not upper bounded and can use any remaining capacity (traffic for `G` can overuse `G`'s upper bound because overuse packets are enqueued at `A`, which is not upper bounded).

To show the system's resistance against volumetric DDoS

[9] For 500 B packets this means ∼100 Gbps, for 800 B packets ∼160 Gbps.

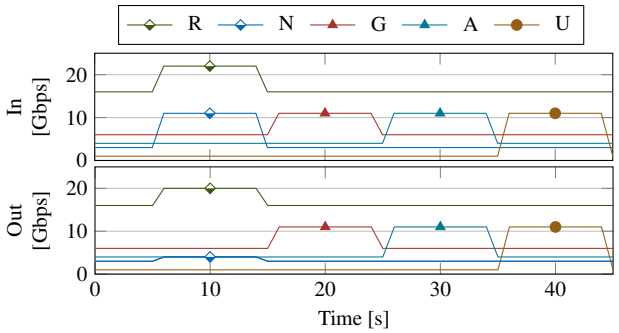

Figure 6: Router scheduling output in a congestion-free setting, i.e., the total ingress traffic rate never exceeds the egress capacity of 40 Gbps. The upper bounds of `R` (20 Gbps) and `N` (4 Gbps) are correctly enforced, and traffic to `G`, `A`, and `U` can use free capacity as desired.

Table 4: Border router DDoS resistance measurement results in Gbps. Traffic from AS X (part of `G`) is successfully forwarded at the configured rate of 928 Mbps.

	R	N	G	AS X	A	U	Total
In	64.0	12.0	37.0	0.928	30.0	17.0	160.0
Out	19.99	3.99	10.56	0.927	3.37	1.98	39.89

attacks, we track one particular AS X for which the border router is configured to allow a guaranteed throughput of 928 Mbps. We generate 159.072 Gbps of attack traffic from the different classes, where we overuse the upper bounds from `R`, `N`, and all the ISD and AS guarantees, with the exception of AS X. The results are shown in Table 4. We observe that the different traffic classes are correctly enforced. As all ASes apart from AS X are overusing their guarantees, where the overuse traffic goes to `A`, the throughput of authenticated traffic without the QoS marker set is relatively low, as it competes for bandwidth against this overuse traffic. As a desirable side effect, traffic sent over `G`, `R`, and `N` is forwarded with minimal latency and jitter, which results from their upper bounded capacity preventing those queues to grow.

The main challenge in terms of scalability is the concurrent access of different cores to the same lock-protected per-AS or per-ISD token bucket for packets destined to the same egress. This can potentially lead to increased lock contention for routers with a high number of ports. To solve this problem, the router can be replaced by multiple ones, each responsible for a subset of the original AS interfaces. Another solution is to reduce egress contention by performing additional rate limiting at ingress, where the ingress rate enforced for an AS or ISDs is the maximum of its rates configured at the egresses. This idea can be further extended to per-egress hierarchical rate limiting, where additional intermediate cores receive rate-limited packets destined to a specific egress from several other child cores, rate limit them again, and forward the rate-compliant packets to the next core in the hierarchy until they arrive at the top of the hierarchy. Alternatively, rate limiting

can also be performed in the NIC [56]. To provide better support for Z-Lane also on memory constrained devices, we describe in Appendix D an optimized rate limiter reducing the memory overhead compared to current state-of-the-art implementations by 60-86%. Z-Lane's deployment is further discussed in the following section.

7 Discussion

Lowering μ_U. An interesting configuration edge case is a value of zero for μ_U, i.e., for the router's lower scheduling bound for unauthenticated best-effort traffic (Table 2). This setting implies that in congestion-free periods unauthenticated traffic still gets through, but can starve completely during congestion. Even though the AS-level keys required for EPIC are initially requested based on unauthenticated best-effort, in case of congestion in `U` the keys can still be fetched using DoCile instead. Therefore, this setting does not introduce additional venues for DDoS. Instead, it provides benefits by (i) incentivizing the use of authenticated traffic and (ii) preventing the undesired situation where there is congestion in `A` but not in `U`, leading to an end host's authenticated best-effort traffic being dropped, while its unauthenticated best-effort traffic is still forwarded successfully. We emphasize that setting μ_U to zero is semantically not the same as removing the queue `U`.

Deployment Incentives and Future Work. Deploying Z-Lane is facilitated in several ways. The per-AS and per-ISD rates for example are defined independently by each AS without inter-domain coordination. Also, configuration complexity is low and Z-Lane can be incrementally deployed. For transit ASes, deploying Z-Lane means updating the software running on their SCION border routers, while source ASes have to run a Z-Lane gateway. As Z-Lane runs over existing public Internet infrastructure, it incurs low costs (requirement R5), while achieving availability guarantees similar to significantly more expensive leased lines or private backbones (Section 8). With Z-Lane, an ISP can maintain low-latency Internet connectivity despite DDoS attacks and thus offer better service and attract more customers, providing incentives for early adopters. Every source AS benefits from a transit AS allocating a guaranteed rate, even if that rate is lower than its demand. This contrasts complete communication outage due to current routers with mostly FIFO queuing and drop-tail mechanisms failing to protect against DDoS attacks (Section 5.3). Directions for future work include the implementation of Z-Lane on different hardware, the design of a protocol to automatically learn traffic profiles for router configurations, and a formal verification of Z-Lane's ecosystem, i.e., in combination with COLIBRI, DRKey, and DoCile.

8 Related Work

Table 5 shows that, compared to existing systems, Z-Lane excels in protecting short-lived intermediate-rate traffic.

One widely employed mechanism is network scrubbing, where traffic is redirected to a server cluster for filtering out malicious packets. The setup process is time-consuming, operationally complex, and may necessitate changes to the network architecture, and, once in place, it creates vendor dependency (vendor lock-in) and becomes a single point of failure, while introducing additional latency also for benign traffic. IP address spoofing can lead to traffic from benign sources being attributed as malicious, leading to collateral damage. Other solutions like CDNs reduce the attack surface by shortening communication paths to replicated services but can only protect certain path segments. While they can handle multiple terabits per second, they do not provide comprehensive DDoS defense against nation-state attackers and can be prohibitively expensive during attacks. Solutions like overprovisioning network capacities only shift the problem rather than addressing it fundamentally. Overprovisioning is financially expensive, and available capacity could be used more effectively. While leased lines and private backbones offer robust communication guarantees, they are not scalable for protecting billions of end hosts and come with significant financial costs.

Within academia, more economical solutions have been explored, primarily focusing on implementing DDoS defenses at routers. Unfortunately, the effectiveness of those solutions diminishes when faced with adversaries capable of spoofing IP packets, rendering them inadequate for offering fundamental protection against attacks. These proposed solutions encompass various approaches, ranging from history-based IP address filtering at edge routers [54] to fairness strategies for traffic flows [63, 76], as well as strategies for mitigating DDoS attack on programmable switches [45, 77]. An example is Pushback [46], which aims to identify flow aggregates responsible for congestion and subsequently imposes rate limits on these aggregates at upstream routers. However, it cannot provide instant protection for benign traffic against DDoS attacks nor defend against botnets. Even very recent proposals follow such a reactive pattern, i.e., they try to detect, classify, and then mitigate attacks [3]; in contrast, Z-Lane works proactively and can thus protect against threats instantaneously. To achieve flexibility regarding the deployment of congestion control algorithms (CCAs), RCS [8] enforces isolation at egress without necessitating inter-domain agreements. Nevertheless, its performance rates exhibit exponential decreases in path length when on-path routers are subjected to attacks. Similarly, PSP allocates bandwidth between interface-pairs based on historical traffic measurements [13]. Bandwidth reservation systems [7, 27, 73, 75] run an expensive setup process, which is necessary to make sure all on-path ASes agree on the allocated bandwidth and to fetch the necessary cryptographic tokens ("capabilities") required to send reservation traffic. Also, most such systems do not protect traffic on the return path. Appendix H elaborates on related work regarding source authentication systems, highlighting why only EPIC

can provide the necessary foundation for meaningful resource allocation at routers.

9 Conclusion

Protecting the availability of short-lived, intermediate-rate traffic of protocols like DNS, HTTP(S), or SSH is challenging. In-network volumetric DDoS defense solutions are often reactive, vulnerable to source address spoofing, fail to defend against legitimately looking attack traffic, cannot defend against attacks on longer paths, or significantly increase time to communication due to expensive defense setup procedures. We take a different look at the problem: letting every border router check the authenticity of every packet's source, Z-Lane can securely enforce AS-level bandwidth isolation at border routers, which is efficiently implemented through configurable forwarding lower bounds for (groups of) autonomous systems (ASes). Thus, every AS gets "zero-setup" forwarding guarantees that can be extended to its end hosts and that persist irrespective of off-path adversaries' attack patterns.

Z-Lane is both practical and cost-effective: traffic is sent over existing public Internet infrastructure, and deploying Z-Lane is simple and can be done incrementally, while it achieves properties similar to private or leased infrastructure. Z-Lane scales to Internet topologies consisting of hundreds of thousands of ASes, while only requiring five queues (two of them enable integration of related systems and are therefore optional) and a few kilobytes of memory per router interface.

Z-Lane provides a foundation for building exciting new systems on the public Internet, such as highly available industrial command-and-control or DNS systems, with strong communication guarantees despite volumetric DDoS attacks.

Acknowledgments

We extend our gratitude to Juan Angel García-Pardo, Francesco Da Dalt, and Marc Odermatt for their thorough review and constructive feedback on the manuscript, Fabio Streun for his assistance with the hardware setup, Giacomo Giuliari for his insightful feedback on the system, and Yih-Chun Hu for the enlightening discussions. We are also thankful to the anonymous reviewers for their valuable input and to our shepherd for guiding us through the final version of the paper. We gratefully acknowledge the support received from ETH Zurich, the Zurich Information Security and Privacy Center (ZISC), and armasuisse Science and Technology.

A DRKey

DRKey [38, 57] provides symmetric keys between ASes and endpoints and is a requirement both for COLIBRI and EPIC. Instead of simply storing exchanged keys at infrastructure components such as border routers, DRKey enables these components to rapidly compute the keys on the fly. To illustrate this mechanism, we consider some AS A, which maintains a secret key K_A that is known by its infrastructure components such as the control service and all border routers. When another AS B requests a key from AS A, the latter responds with an AS-level symmetric key $K_{A\to B}$ computed using a pseudorandom function (PRF):

$$K_{A\to B} := \mathrm{PRF}_{K_A}(B). \tag{3}$$

After receiving this AS-level key, AS B can use it to derive symmetric keys for its endpoints. It computes symmetric keys between endpoint H_B (in AS B) and AS A as follows:

$$K_{A\to H_B} := \mathrm{PRF}_{K_{A\to B}}(H_B), \tag{4}$$

Importantly, endpoint H_B cannot compute $K_{A\to H_B}$ itself, as it does not have access to $K_{A\to B}$. Instead, it fetches $K_{A\to H_B}$ from an infrastructure service in its AS. When traffic originating from endpoint H_B passes through a border router that belongs to AS A, the router can recompute $K_{A\to H_B}$ based only on its secret key K_A, the AS-identifier B, and the endpoint source address H_B, which are all part of the SCION packet header. By default, keys have a validity of one day.

B EPIC

EPIC [42] utilizes DRKey's efficient key derivation to enable per-packet source authentication in SCION. To authenticate itself to on-path border routers, an endpoint H_S in AS A_0 computes a per-packet hop validation field (HVF) for each AS A_i ($1 \leq i \leq n$) on the selected path. These HVFs are included in the SCION packet header.

$$K_i := K_{A_i \to H_S} \tag{5}$$

$$V_i := \mathrm{MAC}_{K_i}(\mathrm{tsPkt}, A_0, H_S, \sigma_i)\ [0{:}\ell_{\mathrm{val}}] \tag{6}$$

In this context, the function MAC_K generates a message authentication code using the key K, and tsPkt is a unique high-precision timestamp added to the packet header for every packet sent by the source end host. The last input to the MAC, σ_i, is an authenticator included by EPIC to achieve a property called *path authorization*, which protects the routing decision of ASes from malicious end hosts. The notation X[a:b] denotes the substring of X from byte a (inclusive) to byte b (exclusive), and the HVF is defined as the first ℓ_{val} bytes of the MAC output. To verify a packet's source, a border router recomputes the HVF of its AS and compares it to the HVF contained in the packet header. A duplicate-suppression system further allows ASes to filter replayed packets. EPIC also provides assurance to source hosts that their traffic indeed followed the selected path. Path validation is achieved by letting border routers replace the HVFs in the packet with the next ℓ_{val} bytes of the MAC output, i.e., $[\ell_{\mathrm{val}}{:}2\ell_{\mathrm{val}}]$. This serves as proof that the packet indeed traversed the ASes on the selected path. To communicate this information to H_S, the destination endpoint H_D returns a packet that contains the updated HVFs and tsPkt of the original packet.

C Z-Lane Gateway Authorization

Based on DRKey and EPIC, the Z-Lane gateway marks authorized packets such that other ASes' routers can later distinguish them from standard EPIC traffic that did not pass the gateway. This is achieved by replacing the packets HVFs with AS-level authenticated HVFs:

$$\widetilde{K_i} := K_{A_i \to A_0} \tag{7}$$

$$\widetilde{V_i} := \mathrm{MAC}_{K_i}(V_i) \tag{8}$$

Here, V_i is the arriving packet's HVF (Eq. 6).[10] Apart from the HVF (and the QoS flag), the gateway does not change any field in the packet header. Overwriting the HVF at the gateway does not break EPIC's path validation feature, because the border router later still updates the HVF to $V_i[\ell_{\mathrm{val}}{:}2\ell_{\mathrm{val}}]$, i.e., based on the original HVF computed by the end host; thus the destination will still see the original EPIC MACs. Computing $\widetilde{V_i}$ in addition to V_i increases the overhead at border routers. However, this increase is minimal, as only a single additional AES operation is needed; the key $\widetilde{K_i}$ is already derived and AES-expanded in the computation of K_i (Eq. 4). We choose this approach of computing $\widetilde{V_i}$ as a new MAC with input V_i instead of just recomputing V_i according to Equation (6) but with $K_{A \to B}$, as otherwise an end host would need to also communicate each σ_i to the gateway.

[10] We use an additional, not explicitly mentioned input to the MACs in Equations (4) and (8) to enforce domain separation.

D Memory-Efficient Rate Limiting

In standard literature, the token-bucket rate limiter is either implemented using a counter and a timer or using a counter and a timestamp [49] (plus the configured rate and burst size). The first approach does not scale because for every flow (or every source AS or ISD, in the case of Z-Lane) a separate timer is needed. Also, timers are often not suitable for high-performance applications. The second approach is computationally very efficient but typically not optimized for a low memory footprint: state-of-the-art implementations often require at least 20 B [26]—some even more than 60 B [29]—of memory per token bucket.[11] In this section, we present a data structure that requires only 8 B per token bucket, thus improving Z-Lane's memory-efficiency. Concretely, we do the following optimizations: (i) Configure the same burst size for every token bucket. This means that this value only needs to be stored once. (ii) Store the burst size in 2 B. This allows to define values up to 65 535 B. (iii) Reduce the size of the counter to 2 B. This is possible, because the counter cannot exceed the burst size, on which we put an upper bound in the previous step. (iv) Decrease the size of the rate field to 2 B. With a granularity of 100 kbps, this still allows to configure values up to 6.5 Gbps. (v) Only track short intervals. Instead of storing an 8 B Unix timestamp that measures the time elapsed since 1970, we use 4 B tracking an interval of only 1.3 s. The timestamp still stores time values at nanosecond precision. When monitoring α ASes and υ ISDs, this data structure thus requires only $2\,\mathrm{B} + (\alpha+\upsilon)\cdot 8\,\mathrm{B}$ instead of $(\alpha+\upsilon)\cdot 20\,\mathrm{B}$. In case the configured rates are the same for all monitored ASes and ISDs, they can be replaced by a single globally defined rate, thereby further reducing the per-token-bucket memory overhead by 2 B.

Monitoring Accuracy. Using timestamps to only track 1.3 s intervals can lead to false negatives, where the rate limiter wrongly considers a packet to cause an overuse of the configured rate. However, this situation can only arise if (i) a packet is sent a multiple of 1.3 s after the previous packet and (ii) the previous packet depleted the token bucket. More precisely, this is the case if a packet arrives at a time $t \in \left]\lambda\cdot 1.3\,\mathrm{s},\ \lambda\cdot 1.3\,\mathrm{s} + \frac{\ell}{\mathrm{rate}}\right]$ for $\lambda \in \mathbb{N}_{\geq 1}$, where ℓ denotes the packet's length. Therefore, if an AS stops sending any traffic for a random period of at least 1.3 s, then the probability of the next packet being illegitimately dropped is $\frac{\ell}{\mathrm{rate}\cdot 1.3\,\mathrm{s}}$. For

[11] Typical field sizes: 8 B for timestamp, 4 B for counter, burst, and rate.

$\ell \leq 1500\,\text{B}$ and rate $\geq 10\,\text{Mbps}$, this probability is at most 0.093%. If an AS does not stop sending traffic for at least 1.3 s, then packets are never illegitimately dropped.

E Probabilistic Monitoring

Probabilistic monitoring solutions try to reduce the memory overhead inherent to deterministic policing mechanisms (e.g., token buckets). Typically, those solutions first try to detect overuse flows using probabilistic data structures, and then further monitor suspicious flows deterministically, where the number of deterministic monitors is relatively low and upper bounded [59]. Often, overuse flows are then also added to a black list, causing all following traffic belonging to that flow to be dropped. Unfortunately, unlike in bandwidth reservation systems where the traffic sources know the exact traffic rate at which they are allowed to send, traffic sources in Z-Lane do not know the bandwidths configured at on-path ASes, which can lead to unintentional overuse. Also, blacklisting ASes or ISDs that are overusing their configured bandwidth contradicts Z-Lane's goal of achieving communication guarantees. Lastly, if there are more malicious ASes or ISDs than the number of available deterministic monitors, there will be false negatives, meaning that malicious ASes could actually overuse their configured bandwidth and disrupt the supposedly guaranteed communication of other ASes. For the use in Z-Lane, probabilistic systems are therefore not practical.

F Neighbor-Based Scheduling

Scheduling could be neighbor-based instead of source-based. While this would save memory at routers and might not even require source authentication, it is vulnerable to DDoS attacks, where an off-path attacker sends traffic over multiple paths entering different interfaces of the same router, but targeting the same egress. Legitimate traffic then still decreases exponentially with each attacked on-path router.

G Scalability in Large ISDs

To minimize router state in case of exceptionally large ISDs with tens of thousands of ASes, there are multiple options. For topology and routing policy reasons, not every AS can reach every router inside an ISD, therefore guaranteed rates at a router egress interface only need to be configured for ASes that can actually reach that interface. More pragmatically, a router could also simply monitor the ASes responsible for, e.g., 99.9 %, of the usually received traffic. Alternative solutions that do not explicitly lower the communication guarantees of smaller ASes include splitting the ISD into multiple smaller ISDs, or monitoring virtual ISDs, i.e., groups of intra-ISD ASes, e.g., based on AS identifier prefixes.

H Other Source Authentication Systems

Besides EPIC, there are other proposals that aim to achieve source authentication through cryptographic verification. OPT [38] and ICING [50] have significantly higher communication overhead than EPIC, and OPT further only achieves source authentication for routers in a weaker attacker model. PPV [72] only allows the destination host to validate the authenticity of packets, i.e., there is no mechanism in PPV for authenticating the source to on-path routers. Similarly, Hummingbird [33] authenticates a packet's source to the destination host; routers verify packets probabilistically using symmetric keys established with adjacent routers. In MASK [25], only a single on-path router can check the authenticity of the packet's origin. Other work focuses on the problem of authenticated broadcast [31, 61] or multicast [37], and also only authenticates packets to the receiver. Passport [44] leverages routing messages to exchange Diffie-Hellman keys and thus obtain shared secret keys between ASes than are then used for packet source authentication. However, routers in Passport need to cache the AS-level keys and cannot derive them on the fly. Non-cryptographic techniques such as hop count filtering [43] and even current best practices related to source address validation (SAV) [39] such as EFP-uRPF [62] are based on heuristics and therefore cannot provide strict security guarantees.

Towards an Effective Method of ReDoS Detection for Non-backtracking Engines

Abstract

Regular expressions (regexes) are a fundamental concept across the fields of computer science. However, they can also induce the Regular expression Denial of Service (ReDoS) attacks, which are a class of denial of service attacks, caused by super-linear worst-case matching time. Due to the severity and prevalence of ReDoS attacks, the detection of ReDoS-vulnerable regexes in software is thus vital. Although various ReDoS detection approaches have been proposed, these methods have focused mainly on backtracking regex engines, leaving the problem of ReDoS vulnerability detection on non-backtracking regex engines largely open.

To address the above challenges, in this paper, we first systematically analyze the major causes that could contribute to ReDoS vulnerabilities on non-backtracking regex engines. We then propose a novel type of ReDoS attack strings that builds on the concept of simple strings. Next we propose EvilStrGen, a tool for generating attack strings for ReDoS-vulnerable regexes on non-backtracking engines. It is based on a novel incremental determinisation algorithm with heuristic strategies to lazily find the k-simple strings without explicit construction of finite automata. We evaluate EvilStrGen against six state-of-the-art approaches on a broad range of publicly available datasets containing 736,535 unique regexes. The results illustrate the significant efficacy of our tool. We also apply our tool to 85 intensively-tested projects, and have identified 34 unrevealed ReDoS vulnerabilities.

1 Introduction

Regular expressions (regexes) are widely used in various fields of computer science such as software engineering, network security, string processing, and databases [9, 18, 21, 22, 45, 66], and are supported natively or via libraries in most modern programming languages [35]. Recent studies have reported [17, 21, 76] that 30-40% of Java, JavaScript, and Python projects use regexes. Despite the popularity of regexes, studies have shown that Regular expression Denial-of-Service (ReDoS) attacks are a widespread and serious security problem [10, 21, 45, 69], where attackers use malicious inputs (i.e., attack strings) to trigger super-linear worst-case matching time (e.g., quadratic or exponential time in the length of the input string) [21]. Further, the threat of ReDoS has a growing trend in recent years, as evidenced by multiple studies (e.g., [38, 67]).

Much research has been done on the detection of ReDoS vulnerable regexes. However, current methods have focused mainly on backtracking regex engines, leaving the problem of ReDoS vulnerability detection on non-backtracking regex engines largely open.

Basically, regex matching algorithms can be roughly categorized into two types—those based on backtracking search [68] and those based on finite automata (i.e., nondeterministic finite automaton (NFA) or deterministic finite automaton (DFA), or both). Backtracking approaches are usually simple to implement and easily extensible to support non-regular features. However, the downside is that the worst-case time complexity can be exponential in the length of the input caused by backtracking. Backtracking engines are used in, e.g., .NET, Python, Perl, PHP, Java, JavaScript, and Ruby.

On the other hand, non-backtracking automata-based approaches, which are based on the classical theory of automata, are usually faster, yet harder to implement. Due to their high performance capabilities, automata-based matchers are employed in many modern regex engines, e.g., RE2, and the engines in Go, Rust, grep, Hyperscan, and SRM.

Since non-backtracking matchers are widely used in modern regex engines, and performance-critical industrial applications such as Network Intrusion Detection Systems (NIDSes) [25] and Credential Scanning [58] use non-backtracking engines, it is important to systematically study the problem of ReDoS detection for non-backtracking engines.

Currently, there has only been one line of work, i.e. GadgetCA [74], in this direction, which focused on the *bounded* repetition (or bounded counting) operator of regexes. It ex-

[*]These authors contributed equally to this work.

perimentally showed that regexes using this operator have the potential to cause ReDoS attacks on non-backtracking matchers. However, the model used in GadgetCA is sound only on a limited subclass of regexes with counting. For example, $.^*(aa)^{\{100\}}$ and $.^*a^{\{0,100\}}a^{\{200\}}$[1] are not within this subclass [50]. For such regexes, GadgetCA may return wrong results. This suggests that the usability of the method proposed in [74] is quite limited. In other words, **the problem of ReDoS detection on non-backtracking engines caused by the full class of regexes with counting remains unsolved**. Example 1 shows a vulnerable regex from the intrusion detection system Snort [25], which specifies the correct string format of classids[2]. Since regexes with *nested* countings, e.g. $(\backslash x26\backslash x23\backslash d^{\{2,3\}}\backslash x3B)^{\{2\}}$, are forbidden from the subclass mentioned above, GadgetCA reports an internal error.

Example 1. $classid{=}\backslash s^*[\backslash x22\backslash x27]\backslash s^*[A{-}Za{-}z\backslash:\backslash\{{-}]^{\{0,42\}}((\backslash x26\backslash x23\backslash d^{\{2,3\}}\backslash x3B)^{\{2\}}[\hat{}\backslash x22\backslash x27]^{\{0,25\}})^{\{5\}}$

Besides, the use of *50MB* large-sized inputs as adapted in [74] to trigger ReDoS vulnerabilities in their experiments is impractical and less likely to be exploitable, as it is rare to encounter such a single large input in real-world scenarios. This reflects the relatively weak ability of the strings generated by their detector to trigger ReDoS vulnerabilities, as shown in our experiments, e.g., Table 5 and Table 7.

Moreover, there are **other potential factors** besides bounded repetition that could contribute to ReDoS attacks for non-backtracking engines, which, however, have not been considered in the existing literature. Consider the regex in Example 2, which is used in Regex101 [4] to match cardiac surgery terms. It is *bounded_counting-free*, i.e. does not have any bounded repetition operators, yet still has a descriptional complexity blow-up up to 1,087,951 DFA states in RE2.

Example 2. $.^*cc.^*(cor.^*ang.^*|heart.^*|icd.^*|pace.^*|cardi.^*|lhc.^*|aortic.^*|.rhc.^*|dual.^*lead.^*|cabg.^*|trans.^*).^*echo$

Yet GadgetCA fails to expose the vulnerability: The string generated by GadgetCA only forces RE2 to construct 1,027 DFA states and run for less than 0.17 seconds.

To address the aforementioned challenges, our research entails a systematic analysis of the diverse causes of ReDoS attacks produced by non-backtracking engines, and a search for effective techniques to analyze ReDoS attacks and generate attack strings for non-backtracking engines. Herein, we summarize the main findings of our research.

(1) **Causes.** By distinguishing whether a matcher generates the DFA in advance or not, non-backtracking matchers can be categorized into online and offline DFA matchers. Since constructing a DFA may explode doubly exponentially, the majority of non-backtracking matchers opt for online DFA matchers. We target this type of matchers and identify two classes of causes that could contribute to ReDoS vulnerabilities: (i) reaching the worst-case time complexity of NFA and online DFA matchers as well as various matching functions; and (ii) blow-up in DFA states, including determinisation blow-up, counting, and discrete character classes (§4). Considering the examples above, the ReDoS vulnerability of the regex in Example 1 is mainly resulted from the DFA state blow-up due to nested counting, while for Example 2, it is due to the use of discrete character classes.

(2) **Techniques.** At the heart of ReDoS detection are the attack strings—indeed, a regex is only considered vulnerable if such a string exists. Theoretically, finding an attack string is to find a string that triggers the worst-case complexity on regex engines. However, finding such a string is an arduous problem. Similar concerns are raised by Turoňová et. al [74]: "*Such a text is, however, also highly specific and the probability of generating it randomly is low.*" To effectively deduce attack strings for non-backtracking engines, our key idea is the use of the *simple strings* and solving the k-SIMPLE STRING problem for regexes (defined in §5). Intuitively, a simple string corresponds to an acyclic accepting path that is composed of distinct states and contains only one final state in the DFA. Thus using simple strings as attack strings will tend to force engines to construct more new DFA states to match them. We then model the attack string generation problem as the k-SIMPLE STRING problem, which finds a simple string of length at least k (i.e., a k-simple string), for a user-controlled parameter k. Due to the hardness of k-SIMPLE STRING (Theorem 1), to effectively accelerate the solving, we propose a novel incremental determinisation algorithm with heuristic strategies to lazily find the k-simple strings *without* explicit construction of finite automata.

Based on the ideas above, we propose EVILSTRGEN, a tool for generating attack strings for ReDoS vulnerable regexes targeting non-backtracking engines. EVILSTRGEN can effectively handle the full class of regexes used in non-backtracking engines and generate attack strings that cause severe ReDoS attacks on non-backtracking engines, while reducing the average length of attack strings used in GadgetCA by two orders of magnitude. Considering the Examples 1 and 2, EVILSTRGEN generates strings of length *100kB* that run in 1.61 seconds and 2.26 seconds respectively on RE2, thereby the vulnerabilities are successfully detected.

We assess EVILSTRGEN by comparing it to six state-of-the-art approaches on 16 regex engines (comprising 8 non-backtracking engines and 8 backtracking engines). Our analysis covers a broad range of publicly available datasets from different sources that contain 736,535 unique regexes. The results illustrate the significant efficacy of EVILSTRGEN.

The main contributions of this paper are listed as follows.

[1] Where $.^*$ accepts any string and the bounded repetition $E^{\{m,n\}}/E^{\{m\}}$ accepts (m to n)/m repetitions of E for finite numbers m,n with $0 \le m \le n$.

[2] Where $\backslash s^*$ matches any whitespace characters 0 or more times, $\backslash xh_1h_2$ is the hexadecimal representation of the ASCII code "h_1h_2", [] represents a character class, which matches any character inside [], so $[\backslash x22\backslash x27]$ matches either a double quotation mark or a single quotation mark, similarly $[A{-}Za{-}z\backslash:\backslash\{{-}]$ matches an uppercase or lowercase English letters or ":" or "{" or "–", while $[\hat{}\backslash x22\backslash x27]$ matches any character other than a double quotation mark or a single quotation mark, $\backslash d$ matches any digital number.

- **Novelty.** We introduce a practical ReDoS detection and attack string generation method for non-backtracking engines which produces a novel form of attack strings that are effective and concise for vulnerable regexes.
- **Theoretical Analysis for ReDoS.** We provide a comprehensive computational and descriptional complexity analysis of the causes of ReDoS vulnerabilities on non-backtracking engines in §4.
- **Regex Constraint Solving.** We propose the k-SIMPLE STRING problem to model the attack string generation problem, which has not been considered by any of the regex solvers. We devise a novel incremental algorithm extended with language-theoretic heuristics to solve this problem and generate attack strings in §5.
- **Effectiveness and Practicality.** We give a comprehensive empirical study of our tool, comparing with the current state-of-the-art ReDoS detection tools in §6. The effectiveness of our tool is demonstrated by the results. We also apply our tool to 85 intensively-tested projects, and have identified 34 unrevealed ReDoS vulnerabilities.

2 Preliminaries

We will introduce the necessary formal definitions. Let Σ be a finite *alphabet* of symbols (or characters). *Words* (i.e. *strings*) are finite sequences over Σ, and *languages* are sets of words. The *empty word* and the *empty language* are denoted by ϵ and $\varnothing$, respectively. The *size* of a word w, denoted $|w|$, is the number of occurrences of symbols in w.

Regular Expression (Regex). *Regexes* are defined by the syntax $E ::= \epsilon \mid \varnothing \mid a \mid C \mid E|E \mid EE \mid (E) \mid E^{\{m,n\}} \mid E^{\{m,n\}?} \mid \backslash b \mid \backslash B \mid \hat{} \mid \$$, where $a \in \Sigma$, $m \in \{0,1,\ldots\}, n \in \{1,2,\ldots\} \cup \{+\infty\}$ and $m \leq n$. $C \subseteq \Sigma$ are *character classes*, such as $\backslash p\{Greek\}$, which denotes all symbols from the Greek alphabet. $E|E$ and EE (i.e. by juxtaposition) denote the *alternation* and *concatenation* of regexes, respectively. (E) denotes a *capturing group*, which stores the *submatch* matched by E for extraction, replacement, etc., e.g. $a(b)$ matches an input "ab", and (b) stores "b". $E^{\{m,n\}}$ and $E^{\{m,n\}?}$ denote the *greedy* and *lazy* quantifiers respectively, i.e. the *counting* operators. For an input "aa", $a^{\{1,2\}}$ repeat matching a as many times as possible to match "aa", while $a^{\{1,2\}?}$ prefer fewer times to match "a". *Anchors* include *word boundary* $\backslash b$, *non-word boundary* $\backslash B$, *start-of-line anchor* $\hat{}$, and *end-of-line anchor* $\$$. Anchors do not consume characters, but specify the non-character context. For the input "ab", $\backslash b$ specifies positions 0 and 2, whose one side is a word and the other side is not. $\backslash B$ specifies position 1, whose both sides are words (or non-words). And $\hat{}$ matches position 0, while $\$$ matches position 2. Notice $E^?$, E^*, E^+, $E^{\{m\}}$, $E^{\{m,\}}$ are abbreviations of $E|\epsilon$, $E^{\{0,+\infty\}}$, $E^{\{1,+\infty\}}$, $E^{\{m,m\}}$ and $E^{\{m,+\infty\}}$ respectively. The *language* of a regex E, denoted as $\mathcal{L}(E)$, is the set of all strings accepted by E.

In regex engines the matching behavior for regexes is specified through the *matching functions*. Intuitively, for a regex E and an input string w, the *partial matching* solves the problem of *sub-string matching by a regex* (i.e. whether $w \in \mathcal{L}(\Sigma^* E \Sigma^*)$), which can be implemented by prepending Σ^* to the left of E [61]; while *full matching* solves the *regex membership* problem (i.e. whether $w \in \mathcal{L}(E)$); more details can be found in §4.1. *Disambiguation rules* [70] are used in engines to guarantee a unique match, e.g. Perl-style policy [3] assigns the highest priority to the *left-most* matches and POSIX [70] prefers the longest matches. For example, $(a|aa)^*$ matches "a" from an input "aa" in Perl style and "aa" in POSIX style.

Finite automata. An NFA is a quintuple $\mathcal{M} = (Q, \Sigma, \delta, s, F)$, where Q is a finite set of states, Σ is an alphabet, $\delta \subseteq Q \times \Sigma \cup \{\epsilon\} \to \wp(Q)$ is a transition function where $\wp(Q)$ denotes the power-set of Q, $s \in Q$ is the starting (or initial) state, and $F \subseteq Q$ is a set of final states. The automaton is deterministic (DFA) if $\delta \subseteq Q \times \Sigma \to Q$. NFAs are denoted as ϵNFAs if the transitions can be labeled ϵ, and ϵ-free NFAs otherwise.

Next we discuss methods for transforming NFAs or regexes into DFAs, which is a basis of the DFA matchers. The standard method for NFA-DFA transformation is the *subset construction* [62]. For regex-DFA transformation, McNaughton and Yamada [57] proposed a construction ($\mathcal{M}_{MY}$), which is used in Hyperscan [77] whenever possible. Later, another construction (which we denoted as $\mathcal{M}_{grep}$) was implemented and described by Aho in [6], which is still being used by GNU grep [31]. $\mathcal{M}_{grep}$ is always smaller than or equal to $\mathcal{M}_{MY}$ [13].

Non-backtracking Regex Engines. Normally, modern non-backtracking regex engines are complex software systems, which primarily consist of DFA matchers, also possibly NFA matchers or even backtracking matchers, e.g. a backtracking matcher is used in grep to support backreferences. In this paper, we aim to find vulnerabilities for *industrial-strength* regex engines, which are rather *generalized*[3] as opposed to those *specialized* to process some subclasses of regexes, e.g. [40, 43, 50]. From now on, the term regex engine(s) refers to generalized regex engine(s).

The classification of non-backtracking engines is shown in Table 1. According to the type of DFA matchers, we categorize non-backtracking engines into (i) ϵNFA-based engines, such as RE2 [34], the regex engines in Go [32] , Rust [23], as well as TDFA [46] and RE2C [73]; (ii) position-based engines, which are based on $\mathcal{M}_{grep}$, e.g., grep [31], awk [30] and sed [29] or $\mathcal{M}_{MY}$ such as Hyperscan [77]; (iii) derivative-based engines, such as OCaml-re [75], SRM [64] and NonBacktracking[4] [60], by extending Brzozowski's derivatives [14], whose

[3] Generalized regex engines can handle the unrestricted class of regexes while specialized regex engines cannot. Though in fact, most such engines put restrictions on regexes for practical considerations, e.g. the upper bound of countings.

[4] To differentiate the two implementations written in C#, we write $\text{C\#}_\text{N}$ for NonBacktracking, and $\text{C\#}_\text{B}$ for the backtracking implementation.

Table 1: Non-backtracking regex engines, categorized.

	ϵNFA	Position	Derivative
Online	RE2, Go, Rust	grep, awk, sed, Hyperscan	SRM, C#$_N$
Offline	TDFA, RE2C	–	OCaml-re

states are called ACI-dissimilar derivatives.

Based on whether a matcher generates the DFA before processing the input string, DFA matchers can be further categorized into matchers using *ahead-of-time* (*offline*) determinisation or *just-in-time* (*online*) determinisation (i.e. offline/online DFA matchers). Offline DFA matchers process the input strings in linear time once the DFAs are constructed [6]. However due to the average performance issue resulted from the worst-case doubly exponentially large DFAs [27], they are rarely used in practice. In contrast, online DFA matchers construct the DFAs lazily: by each symbol in the input, at most one DFA state and transition are constructed and recorded.

ReDoS. We give the formal definition of a regex to be ReDoS vulnerable on a regex engine:

Definition 1. A regex E is *ReDoS vulnerable* on a regex engine M if and only if there exists an input word w, for which M can not decide whether $w \in \mathcal{L}(E)$ in time $O(|w|)$. The word w is called an *attack string* for E on M.

Definition 1 is based on the observation that ReDoS vulnerabilities are *engine dependent*, i.e. whether regexes are vulnerable is contingent on the engine that executes them.

Investigation on backtracking engines has shown that while the degree of the ReDoS vulnerabilities can be exponential, most of the ReDoS vulnerable regexes are in polynomial degree in the wild [21]. For non-backtracking engines, given a regex, the degree of the ReDoS vulnerabilities is polynomial. In this paper we use both machine-dependent and independent criteria to evaluate ReDoS vulnerabilities.

3 Overview

In this section, we start with a walkthrough of the procedure of ReDoS detection in EvilStrGen, and then analyse some ReDoS vulnerable regexes to show how different structures and matching functions result in vulnerability.

ReDoS Detection Framework. Figure 1 shows how to detect ReDoS vulnerabilities with our incremental determinisation algorithm to generate *candidate attack strings*, i.e. strings without being verified to be valid, and verify them in EvilStrGen. The input of EvilStrGen includes the regex, the expected attack string length, the matching function and the engine. The tool first preprocesses the input, e.g. for the functions using partial matching, a Σ^* is prepended to the input regex, etc., in step ① of Figure 1. Next, the tool calls the k-Simple String solver Inc_Det′ to generate ReDoS attack strings *bytewise* with incremental determinisation based on the DFA in the corresponding engine. The search for k-simple strings uses two complete and an incomplete

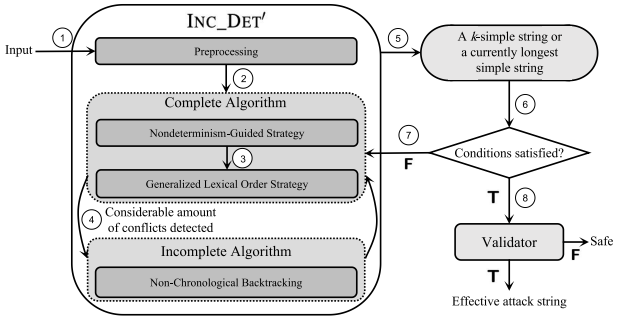

Figure 1: The system architecture of EvilStrGen.

strategies to optimize its efficacy. In step ②, the first strategy exploits the power of nondeterminism in automata theory to select the symbols that result in the largest DFA states in attack strings. The second strategy, i.e. step ③, mimics the Perl-style disambiguation rules to select the DFA state with the highest matching priority. When a considerable number of conflicts (see §5.2) is detected, step ④ uses an incomplete non-chronological backtracking to prune the state space. When the solver terminates, it outputs a k-simple string or a currently longest simple string in step ⑤. Next in step ⑥, considering matching function, anchors and the size of the simple string, EvilStrGen decides to go to the validation, or to step ⑦ to search repeatedly to obtain a candidate attack string of proper length by appending outputs to the former results. Finally in step ⑧, a validator is used to verify the string according to the criteria for ReDoS on corresponding engines, and either reports the vulnerability with the effective attack string or claims the regex to be safe.

Motivating Examples. To illustrate how EvilStrGen can find ReDoS vulnerabilities for non-backtracking engines, we list some ReDoS vulnerable regexes in Table 2. The time used to match the regexes with candidate attack strings of 100kB generated by EvilStrGen and GadgetCA [74] under different matching functions in RE2 is shown in milliseconds.

The 1^{st} and 2^{nd} regexes have exponential DFA states. Both of them having over a million DFA states in RE2. However, GadgetCA cannot expose an "enough" DFA states, thus failing to report the ReDoS vulnerabilities. In contrast, EvilStrGen successfully detects the vulnerabilities, showing the effectiveness of the strings generated by EvilStrGen.

The 3^{rd} and 4^{th} regexes have nested counting, which are not supported by GadgetCA. When the counting is forbidden to be nested, the doubly exponential state complexity of counting regexes [27] is never reached. Thus the ReDoS detectors that only able to handle subclasses of counting regexes may cause omission of ReDoS vulnerabilities or even errors.

The 5^{th} regex has at most 651,608 DFA states in RE2, which illustrates that regexes with only *unbounded countings* can also be ReDoS vulnerable. The 6^{th} regex is *bounded_counting-free*, it is ReDoS vulnerable mainly due to the nondeterminism and the discrete representation of the meta-character ".". These facts reveal that bounded countings

Table 2: Time [ms] used to match examples of ReDoS vulnerable regexes by RE2 under different function calls.

are not the only Achilles-heel of non-backtracking engines.

Under full matching, the 7^{th}, 8^{th} and 9^{th} regexes denote *finite languages*, i.e. only match strings of bounded length, and the engine terminates at the longest string in each language at most to match any input. Due to higher nondeterminism under partial matching, RE2 is slowed down by several orders of magnitude than full matching. Furthermore the 8^{th} regex also suffers from the discrete representation of multi-byte character classes in UTF-8 encoding, where $[\backslash p\{L\}\backslash p\{N\}\text{-}\_]$ requires 1,344 states in RE2. The implementation of GadgetCA does not differentiate matching functions or encoding, which results in the omission of detection.

The 9^{th} regex and its variants are used as the running example to explain the concepts and algorithms in this paper.

4 Analysis of Factors for ReDoS

This section gives an analysis of the major factors that could contribute to ReDoS vulnerabilities for non-backtracking engines, which is a prerequisite for effectively solving the ReDoS problem. From a theoretical point-of-view, we identify two classes of causes for ReDoS: Reaching the worst-case time complexity of matchers and matching functions (§4.1) and blow-up in DFA states due to nondeterminism and succinctness of counting or character classes (§4.2). Notice that the causes are *not* isolated or finitely enumerable into "patterns", but entangled and interactive. To better present the effect of different causes in ReDoS, the results using the running examples as inputs in RE2 are listed in Table 3.

4.1 Time Complexity Analysis of Matchers and Matching Functions

In this section, we denote the number of NFA states as m and the size of input as n.

Online DFA and NFA matchers. We first analyze the worst-case time complexity of online DFA and NFA matchers.

Online DFA matchers are unsafe. To process each symbol from the input, at most one state and transition is constructed and recorded in online DFA matchers, i.e. $O(n)$ states in total, where each transition has a time cost $O(m^2)$ [16], which can also be optimized into quasi-linear time w.r.t. m, e.g. using the disjoint-set data structure [72]. If a state is already found to be recorded by the matcher, it processes each symbol in $O(1)$. Using this lazy evaluation technique, online DFA matchers perform well on safe inputs [44]. However the worst-case time complexity of online DFA matchers is at least $O(mn)$, plus an exponential cost for DFA cache conflict testing [16].

Table 3: The numbers of DFA states of two regexes under different functions and encoding in RE2.

Function	$\backslash W\backslash D\$$		$(\backslash W\backslash D)^{\{5\}}\$$	
	ASCII	UTF-8	ASCII	UTF-8
`RE2::FullMatch`	4	399	12	1,987
`RE2::PartialMatch`	12	**659**	80	**678,980**

The worst-case time complexity of an NFA matcher is $O(m^2n)$ as described in [42]. In [6,20], it is considered $O(mn)$, when implemented properly, e.g. using the disjoint-set data structure. Evidently the worst-case performance of online DFA matchers is worse than NFA matchers, where the latter is considered the slowest matcher in Rust [23]. Thus reaching the worst-case time complexity of online DFA matchers is a direct factor for ReDoS vulnerabilities.

Falling back to NFAs. Non-backtracking engines usually set bounds for the DFA cache for online DFA matchers, e.g. C#$_{\text{N}}$ keeps at most 10,000 ACI-dissimilar derivatives in cache and Hyperscan's threshold is 16,384 distinct position subsets. When the bound is reached (some are reached twice [20]), or the online DFA is considered slow, engines dump the cache and fall back to NFA matchers (or even backtracking matchers, e.g. grep). Recall that the worst-case time complexity of an NFA matcher is $O(m^2n)$ or $O(mn)$, taking the exponential size of m w.r.t. the regexes in the worst case [48] into account, falling back to NFA makes non-backtracking engines unsafe, which contributes to ReDoS vulnerabilities.

Matching Functions. Matching functions also have an impact on ReDoS. There are two major algorithms to implement partial matching in DFA-based regex engines: to convert a regex E to Σ^*E [61], e.g. RE2, C#$_{\text{N}}$, or repeating DFA match starting from each symbol in the input, e.g. grep, awk.

The first approach assures the search in texts to be performed with the same time complexity as full matching. How-

ever this modification brings nondeterminism into the regex: For our running example under ASCII encoding, the number of DFA states for $\backslash W\backslash D\$$ triples under partial matching, while that of $(\backslash W\backslash D)^{\{5\}}\$$ is enlarged 5.67×. This also contributes to ReDoS vulnerabilities, as demonstrated in Table 2.

The second approach repeats the search with DFAs for $O(n)$ times, making the worst case time complexity $O(mn^2)$ at least, which becomes a non-negligible factor for ReDoS vulnerabilities. Indeed, ReDoS attacks on regexes with the Starting-with-Large-Quantifier pattern [52] for backtracking engines is directly connected to this algorithm.

Extracting or replacing submatch of the subregexes in capture groups as well as the find or replace all functions use partial matching to locate the matched sub-strings, where engines repeat partial matching for $O(n)$ times, leading to the worst case time complexity at $O(mn^2)$ at least. Those may also contribute to ReDoS vulnerabilities, e.g. the submatch extraction of RE2 can be 9.13× slower than Java's backtracking engine on ordinary inputs [36].

4.2 Descriptional Complexity Blow-up

The descriptional complexity of DFA for regexes has direct impact on the computational complexity of algorithms used in non-backtracking engines, which contributes to ReDoS.

Descriptional complexity analysis for ReDoS studies the size of automata to represent regexes, which is divided into the following topics: *Transformational state complexity* studies the complexity of transformations among regexes, NFAs and DFAs, while *operational state complexity* focuses on the state complexity of regex operators.

Determinisation Blow-up. Among transformational state complexity results, determinisation blow-up studies the NFA to DFA conversion due to nondeterminism: For an m state NFA, the subset construction producing a DFA with 2^m states is proven worst-case optimal [62]. In practice, authors of [81] observed that regexes having exponential DFA states cause high costs both in time and storage in deep packet inspection applications. So it is a factor for ReDoS vulnerabilities.

We list some forms of regexes that have linearly sized NFAs, yet exponentially sized minimal DFAs in Table 4, which we suggest the developers to avoid in practice. Part of those is collected (and translated from automata) from the literature (where the references are given), while others are newly discovered variants. In each form, α, β and γ represent disjoint subsets of Σ. Notice the minimal DFAs in this table are not completed with sink states.

Example 3. The 1^{st} vulnerable regex in Table 2 is selected from a real-world project in NuGet [2], which shows the impact on ReDoS due to descriptional complexity from determinisation blow-up in the wild. Consider the first example in Table 4, by substituting α by "a", β by "$[\hat{}a\backslash n]$", and assigning k as 300, $.^*a.^{\{300\}}$ (i.e., the 1^{st} regex in Table 2, considering that $a|[\hat{}a\backslash n] = .$) is obtained.

Table 4: Examples of regular languages E_k whose minimal DFAs have exponential numbers of states for $k \geq 1$.

Regex	Reference	States
$(\alpha\|\beta)^*\alpha(\alpha\|\beta)^k$	[6, 59]	2^{k+1}
$(\alpha\|\beta)^*\alpha(\beta\alpha^*)^k((\beta\alpha^*)^{k+1})^*$	[82]	2^{k+1}
$(\alpha\|\beta)^{\leq k}\alpha(\alpha\|\beta)^k$	[49, 65]	$2^{k+2}-2$
$(\alpha\|\beta)^*\alpha(\alpha\|\beta)^k\alpha(\alpha\|\beta)^*$	[24]	$2^{k+1}+1$
$(\alpha^*(\alpha\beta^*)^k\alpha)^*$	[24]	$2^{k+1}+2^{k-1}-1$
$(\alpha\|(\alpha\beta^*)^k\alpha)^*$	[51]	$2^{k+1}-1$
$(\alpha\|\beta)^*(\alpha\|\gamma)\alpha^*((\beta\|\gamma)\alpha^*)^k$	[12]	$2^{k+2}-1$
$(\alpha^*\|(\alpha\beta^*)^k\alpha)^*$	**New variant**	$2^{k+1}-1$
$(\alpha\|(\alpha\beta^?)^k\alpha)^*$	**New variant**	$2^{k+1}+2^{k-2}$
$(\alpha^*(\alpha\beta^?)^k\alpha)^*$	**New variant**	$2^{k+1}+2^k-2$
$\alpha^*((\alpha\beta^?)^k\alpha)^*$	**New variant**	$2^{k+1}+2^k+k-2$

Next we discuss the impact on DFA size due to the succinctness of regex operators.

Countings. In non-backtracking engines, counting regexes are unfolded into their semantically equivalent bounded_counting-free forms (some are unfolded lazily [60, 64]). However those unfolded regexes has exponential sizes in the worst case. Consider the running example, due to the unfolding, under partial matching and UTF-8 encoding, the DFA state number of $(\backslash W\backslash D)^{\{5\}}\$$ is 1030× bigger than that of $\backslash W\backslash D\$$, while the size of $(\backslash W\backslash D)^{\{5\}}\$$ is only 1× larger than $\backslash W\backslash D\$$.

Bounded counting has been considered in [74] for causing ReDoS vulnerabilities. Yet the automata that underlie the generation algorithm of GadgetCA [74] may change (i.e., over-approximate) the language of a regex, which can result in incorrect (e.g., false negative) output. Furthermore, *unbounded* counting in the form of $E^{\{m,\}}$ also contributes to ReDoS vulnerabilities: see the 5^{th} regex in Table 2.

Nested counting could make online DFA matchers to construct DFA states in exponential size w.r.t. the regex: Consider a DFA for $a^{\{0,k\}\{0,k\}\overset{n-3}{\cdots}\{0,k\}}$, $\delta(s,a) = (\{a_2, a_3, ..., a_{k^n}\})$, requiring at least $O(k^n)$ time to compute. Notice this is only triggered by a single symbol "a".

Nesting of counting and determinisation blow-up jointly lead to doubly-exponentially sized DFAs: For example, Gelade proved the minimal DFA of $E_n{=}(a|b)^*a(a|b)^{\{2^n\}}$ has 2^{2^n} states [27], where E_n is derived from the first example in Table 4. This can be achieved by an n-nested counting, i.e. E_n equals to $(a|b)^*a(\overset{n-3}{\cdots}(((a|b)^{\{2\}})^{\{2\}})\overset{n-3}{\cdots})^{\{2\}}$.

Next we analyse the impact of character classes on the descriptional complexity of regexes and ReDoS.

Discrete Representations of Character Classes. Resulted from the variable length encoding of UTF-8, the Unicode to UTF-8 conversion on non-backtracking regex engines can turn multi-byte Unicode character classes into representations with large numbers of states—which we call *discrete representations of character classes*, which affects the performance of engines [23], and becomes a common factor for ReDoS vulnerabilities. For example, in RE2, only 8 states are enough for

encoding the full Unicode range U+0000-U+10FFFF, i.e. the meta-character ".", while 1,441 states are needed to encode a discrete non-ASCII character class "$\backslash W$".

A discrete representation of character classes increases the cost of computation in engines to construct DFA states, which results in ReDoS vulnerabilities, e.g. the 8^{th} regex in Table 2. Besides, this also enlarges DFAs by a huge constant factor. For the running example under partial matching, when $\backslash W \backslash D\$$ is converted from ASCII to UTF-8, its DFA is enlarged by 55×, for $(\backslash W \backslash D)^{\{5\}}\$$ it is even by 8,487×.

Hooimeijer and Veanes [41] noted that the `System.Text` namespace in the .NET class library contains more than a dozen classes to deal with Unicode encoding. Because of the intricacy to process multi-byte character classes, in grep, some character classes can directly disallow DFA searches and grep degenerates into a backtracking matcher.

5 ReDoS Detection

In this section, we first introduce the notion of simple strings and the k-SIMPLE STRING problem in §5.1. Then we propose an incremental determinisation algorithm with multi-layered heuristic strategies to accelerate the search for k-simple strings in §5.2.

5.1 Simple Strings

From the complexity analysis in §4, a proper and most effective attack string for online DFA matchers should avoid being consumed by any recorded states, such that each byte of the string forces the engine to construct a new DFA state. In graph theory, finding the longest simple path between two given nodes is known to be an NP-hard problem which is even hard to approximate within a constant factor on bounded degree graphs [47]. Inspired by this problem, we propose the notion of *simple strings* for DFAs of regexes.

Definition 2. Given a DFA $\mathcal{M}$ of a regex E, a *simple string* is a finite word $w \in \mathcal{L}(E)$ where the states of the path of w on $\mathcal{M}$ contain only one final state and are pairwise distinct.

Definition 2 depends on the specific DFA construction method and the DFA is not necessarily minimal. Therefore, different DFAs of E may result in different sets of simple strings of E, which can be incomparable w.r.t set inclusion.

There has been work concerning descriptional complexity and properties for simple languages of automata, e.g. [28, 37]. It is known that (i) any non-null regexes have non-empty sets of simple strings; (ii) any of the simple strings of E is not a prefix of any others and the path of a simple string is acyclic [37]; (iii) the size of the minimal DFA to accept all the simple strings of $\mathcal{M}$ is proven to be exponential in the size of $\mathcal{M}$ [37].

For any DFA $\mathcal{M}$ of a regex E, the *longest* simple strings of E correspond to the longest acceptable simple paths (i.e., simple paths form the initial state to a final state) on $\mathcal{M}$. To illustrate the hardness of finding the longest simple strings, we define the decision problem k-SIMPLE STRING.

Problem 1. (k-SIMPLE STRING) The k-SIMPLE STRING problem w.r.t. a DFA $\mathcal{M}$ of a regex E is to decide whether a simple string of $\mathcal{M}$ whose length is at least k exists.

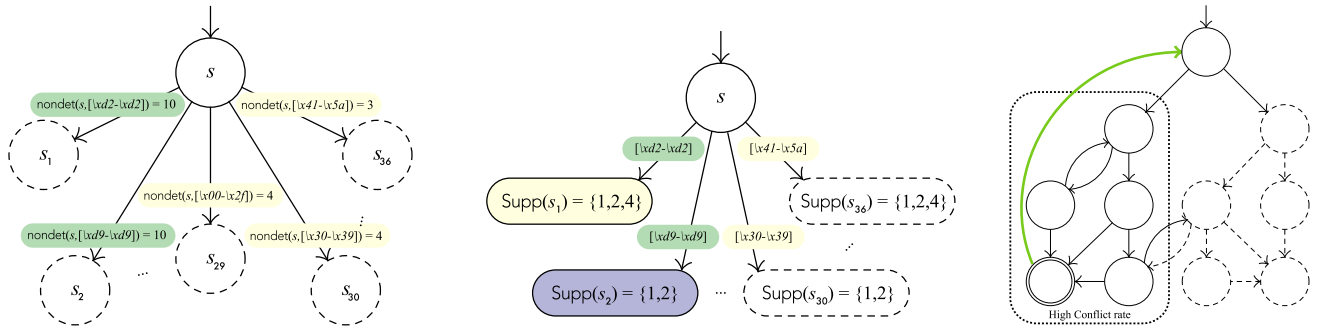
Theorem 1 shows the hardness of Problem 1.

Theorem 1. *k-SIMPLE STRING is EXPSPACE-hard.*

The proof is provided in Appendix A.2.

5.2 Incremental k-SIMPLE STRING Solving

Due to the hardness of Problem 1, a naïve algorithm based on explicit automata construction can be very inefficient and thus impractical. The key to accelerating k-SIMPLE STRING solving is the lazy evaluation strategy: Algorithms should construct DFAs on demand, during the search for k-simple strings. Once a k-simple string is found, the unvisited DFA states or transitions will never be constructed.



Additionally, two partial order relations are introduced as heuristics, where $\sqsupseteq_{\mathsf{Nondet}}$ (Equation 1 below) is used to choose the path by the highest degree of nondeterminism and $\sqsubseteq_{\mathsf{Lex}}$ (Equation 6 below) for selecting the DFA states with the lowest matching priority. The heuristics can be applied to the specific DFAs and encodings in any engines mentioned in §2, which may introduce subtle differences in implementation details. Below we select the DFA for grep, i.e., $\mathcal{M}_{grep}$, as an example to introduce our algorithm, i.e., Algorithm 1.

Algorithm 1 is composed of two procedures, INC_DET that searches for k-simple strings incrementally without explicit construction for automata and DECIDE that answers Problem 1. INC_DET starts the search with a non-null regex E and an integer k, and the output is a k-simple string if it exists and one of the longest simple strings otherwise. In the worst case, Algorithm 1 requires doubly exponential space to ensure completeness.

Supplementary Definitions. For any set X, its power-set $\wp(X)$ denotes the set of all the subsets of X. We write $\langle X; \leq \rangle$ for ordered sets. The composition of two functions $f : X \to Y$ and $g : Y \to Z$ is denoted as $g \circ f : X \to Z$.

Let $\mathbf{T}$ denote true and $\mathbf{F}$ denote false. We mark symbols in E with numerical subscripts and a linear regex $\overline{E}$ is obtained, where all the symbols in $\overline{E}$ occur no more than once. Let $\mathsf{Pos}(E)$ denote the alphabet of $\overline{E}$, i.e. the positions. We use the same notation for dropping off the subscripts from linear regexes: $\overline{\overline{E}} = E$.

For a regex E over Σ and a symbol $a \in \Sigma$, we define the following sets, which specify the first, the last and the characters following a from E: $\mathsf{First}(E) = \{b \mid bw \in \mathcal{L}(E), b \in \Sigma, w \in \Sigma^*\}$, $\mathsf{Last}(E) = \{b \mid wb \in \mathcal{L}(E), b \in \Sigma, w \in \Sigma^*\}$, $\mathsf{Follow}(E, a) = \{b \mid uabv \in \mathcal{L}(E), u, v \in \Sigma^*, b \in \Sigma\}$. Let $0 \notin \mathsf{Pos}(E)$, define $\mathsf{Follow}(\overline{E}, 0) = \mathsf{First}(\overline{E})$. For $S \in \wp(\mathsf{Pos}(E))$, let $\mathsf{Follow}(\overline{E}, S) =$

(a) (b) (c)

Figure 2: Examples of the three strategies in EVILSTRGEN, where the states or transitions not yet been constructed are shown as dashed lines. The runes preferred by $\sqsupseteq_{\mathsf{Nondet}}$ are highlighted in green, and the state preferred by $\sqsubseteq_{\mathsf{Lex}}$ is in purple, otherwise in beige.

$\bigcup_{s\in S}\mathsf{Follow}(\overline{E},s)$. There are various ways to compute $\mathcal{M}_{grep}$, e.g. [6, 7, 13]. We follow the definition in [13]:

Definition 3. The grep DFA of a regex E can be defined as $\mathcal{M}_{grep}(E)=(Q_{grep},\Sigma,\delta_{grep},s_{grep},F_{grep})$ where
$Q_{grep}\subseteq\wp(\mathsf{Pos}(E))\times\{\mathbf{T},\mathbf{F}\}$,
$\delta_{grep}(q,a)=(\mathsf{Follow}(\overline{E},p),p\cap\mathsf{Last}(\overline{E})\neq\varnothing)$, for $q\in Q_{grep}$, $p=\{s\in q\mid\overline{s}=a\}$ and $a\in\Sigma$,
$s_{grep}=(\mathsf{First}(\overline{E}),\mathsf{First}(\overline{E})\cap\mathsf{Last}(\overline{E})\neq\varnothing)$,
$F_{grep}=\{(\_,o)\in Q_{grep}\mid o=\mathbf{T}\}$.

Preprocessing. In line 3, the first preprocessing procedure of INC_DET is to unfold the regex into a bounded_counting-free regex by the rules defined in Appendix A.1. Then the linearization is applied to the character classes in Unicode following the disambiguation rules of Perl, before encoded in UTF-8, by assigning priority to the leftmost subregexes [70]: A larger number of the subscripts implies a higher matching priority. Furthermore, the lazy quantifiers are assigned with reversed priority w.r.t. greedy quantifiers according to [20].

Due to its popularity among regex engines and operating systems, we use UTF-8 standard as the default encoding. INC_DET then encodes the Unicode character classes of a regex E into UTF-8 standard to obtain $\overline{E}$. To implement this conversion, we refer to [20], where a hexadecimal-encoded range is called a *rune*. For example, $[a\text{-}z]$ is converted to a rune $[\backslash x61\text{-}\backslash x7a]$. All the runes transformed from a character class share the same labels, i.e. numerical subscripts.

Since $\overline{E}$ is a static object throughout this algorithm, we directly use the addresses of each rune as positions, instead of assigning an extra integer variable. This section uses the regex $\tau=.^*(\backslash W\backslash D)^{\{5\}}\$$ from running examples to illustrate INC_DET. Example 4 shows the above processing of τ.

Example 4. For $\tau=.^*(\backslash W\backslash D)^{\{5\}}\$$, $\mathsf{unfold}(\tau)=.^*\backslash W\backslash D\backslash W\backslash D\backslash W\backslash D\backslash W\backslash D\backslash W\backslash D\$$, $\mathsf{linearize}\circ\mathsf{unfold}(\tau)=.^*_1\backslash W_2\backslash D_3\backslash W_4\backslash D_5\backslash W_6\backslash D_7\backslash W_8\backslash D_9\backslash W_{10}\backslash D_{11}\$_{12}$. $\overline{\tau}=([\backslash x00\text{-}\backslash x7f]_1|[\backslash xc2\text{-}\backslash xdf]_1|...)^*[\backslash x00\text{-}\backslash x2f]_2...\$_{12}$.

Variables are initialized in line 4, including the current prefix string *wit*, the longest current prefix *ret*, the current $\mathcal{M}_{grep}$ state *cur* and the set Q storing the visited states.

Nondeterminism-Guided Strategy.

Algorithm 1: An incremental determinisation algorithm for k-SIMPLE STRING problem

```
1  INC_DET(Regex E, Int k) → String
2  begin
3      Ē ← encode ∘ linearize ∘ unfold(E);
4      (wit, ret, cur, Q) ← (ϵ, ϵ, {0}, {∅});
5      loop:
6      for Follow(Ē, cur) ≠ ∅ do
7          (C, P) ← (∅, Follow(Ē, cur));
8          for α ∈ ⟨Part(P); ⊒Nondet⟩ do
9              (q, o) ← ({p ∈ P | α ⊆ p}, q ∩ last(Ē) = ∅);
10             C ← C ∪ {(α, (Follow(Ē, q), o))};
11         for ([A]≡Nondet, S) ⊆ C do
12             for (α, s) ∈ ([A]≡Nondet, ⟨S; ⊑Lex⟩) do
13                 if s ∉ Q then
14                     (wit, cur, Q) ←
                         (wit + random(α), P, Q ∪ {P});
15                     if s ∈ F_grep then
16                         if |wit| ≥ k then
17                             return wit;
18                         break;
19                     else if |wit| > |ret| then
20                         ret ← wit;
21                     goto loop;
22                 else
23                     continue;
24     return ret;
25 DECIDE(Regex E, Int k) → Bool
26 begin
27     return |INC_DET(E, k)| ≥ k;
```

Motivation. Nondeterminism is a well-established concept in automata theory [49]. Mańdl [54] proved even a finite amount of nondeterminism in NFAs may lead to exponential size blow-up in DFAs. Here we introduce the degree of nondeterminism of a state.

Definition 4. For an ϵ-free NFA $\mathcal{M}=(Q,\Sigma,\delta,s,F)$, the *degree of nondeterminism*[5] of a state $q\in Q$ w.r.t a symbol $a\in\Sigma$,

[5] Also called *branching* in [33].

denoted as $\mathsf{nondet}(q,a)$, is the number of nondeterministic transitions labeled a from the state q, which is computed as $\mathsf{nondet}(q,a) = |\delta(q,a)|$.

If the degrees of nondeterminism of all of the states in an ϵ-free NFA $\mathcal{M}$ are 1, then $\mathcal{M}$ is a DFA and each DFA state is a singleton subset of Q.

Method. Nondeterminism-guided strategy chooses a rune that has the highest degree of nondeterminism from the DFA state, which also results in possibly bigger subsequent subsets. To exploit the power of nondeterminism on $\mathcal{M}_{grep}(E)$, let $\mathsf{nondet}(s,\sigma) = |\{\mathsf{Follow}(\overline{E},\overline{q}) \mid s = (Q,\_), \forall q \in \overline{Q}, \sigma \subseteq q\}|$, for $s \in Q_{grep}$ and $\sigma \in \wp(\Sigma)$. Next we define the following binary relation $\sqsubseteq_{\mathsf{Nondet}} \subseteq \wp(\Sigma) \times \wp(\Sigma)$: for $s \in Q_{grep}$ and $\sigma, \sigma' \in \wp(\Sigma)$, $\sigma \sqsubseteq_{\mathsf{Nondet}} \sigma'$ if and only if

$$\mathsf{nondet}(s,\sigma) \leq \mathsf{nondet}(s,\sigma'). \quad (1)$$

Denote $\sqsupseteq_{\mathsf{Nondet}}$ as the inverse of $\sqsubseteq_{\mathsf{Nondet}}$. By substituting $\leq$ by $=$ in Equation 1, an equivalence relation, denoted as $\equiv_{\mathsf{Nondet}}$, is obtained, which will be used in the second strategy below. In line 8, INC_DET first partitions $\bigcup \overline{\mathcal{P}}$ into disjoint subsets according to identical successors and obtain $\mathsf{Part}(\overline{\mathcal{P}})$. For each α from the partially ordered rune set $\langle \mathsf{Part}(\overline{\mathcal{P}}); \sqsupseteq_{\mathsf{Nondet}} \rangle$, INC_DET computes the set of positions q that include α and a Boolean variable o implying if q intersects $\mathsf{Last}(\overline{E})$, in line 9. Next INC_DET associates and records α with the $\mathcal{M}_{grep}$ state in $\mathcal{C}$ in line 10.

Example 5. Consider a state $s = (\mathcal{P}, \mathbf{F})$ from $\mathcal{M}_{grep}(\tau)$ in Figure 2 (a), where $\mathcal{P} = \{[\backslash x00\text{-}\backslash x7f]_1, [\backslash xc2\text{-}\backslash xdf]_1, ..., [\backslash xf4\text{-}\backslash xf4]_3\}$. Then $\mathsf{Part}(\overline{\mathcal{P}}) = \{[\backslash x00\text{-}\backslash x2f], ..., [\backslash xf5\text{-}\backslash xff]\}$. For $[\backslash x41\text{-}\backslash x5a]$, ..., $[\backslash xd2\text{-}\backslash xd2]$, $[\backslash xd9\text{-}\backslash xd9] \in \mathsf{Part}(\overline{\mathcal{P}})$, $\mathsf{nondet}(s, [\backslash xd2\text{-}\backslash xd2])) = 10$, $\mathsf{nondet}(s, [\backslash xd9\text{-}\backslash xd9])) = 10$, ..., and $\mathsf{nondet}(s, [\backslash x41\text{-}\backslash x5a])) = 2$. $\langle \mathsf{Part}(\overline{\mathcal{P}}); \sqsupseteq_{\mathsf{Nondet}} \rangle = \{[\backslash xd2\text{-}\backslash xd2], [\backslash xd9\text{-}\backslash xd9], ..., [\backslash x41\text{-}\backslash x5a]\}$.

Effect. Choosing the rune that has the maximal degree of nondeterminism results in higher costs in constructing the DFA states in online DFA matchers (recall §4.1). Also higher nondeterminism tends to lead to larger successor states, making the states less likely to be identical with the already visited $\mathcal{M}_{grep}$ states, consequently decreasing backtracks in the search and accelerating k-simple string generation.

Generalized Lexical Order Strategy.

Motivation. In UTF-8 encoding, each discrete character class in the partially ordered set $\langle \mathsf{Part}(\overline{\mathcal{P}}); \sqsupseteq_{\mathsf{Nondet}} \rangle$ usually consists of a large number of runes, where plenty of those have equal degrees of nondeterminism. To select a rune that reduces the chance of a search reaching a final state early, we introduce the generalized lexical order strategy.

Definition 5. (See [11].) Let $\langle \Sigma; \leqq \rangle$ be a partially ordered finite alphabet. The *generalized lexical order* on Σ^* is defined as follows: Let $u = a_0...a_h$ and $v = b_0...b_k$ be two words (where $a_0, ..., a_h, b_0, ..., b_k \in \Sigma$). u, v are ordered, i.e., $u \leq_{\mathsf{Lex}} v$, if and only if $|u| < |v|$, or $|u| = |v|$ and (1) u is a prefix of v or (2) $u = pa_ix$, $v = pb_iy$ and $a_i <_{\mathsf{Lex}} b_i$, where p is the longest common prefix of u and v.

For $a, b \in \langle \mathsf{Pos}(E); \leq_{\mathsf{Lex}} \rangle$, define $a \equiv_{\mathsf{Lex}} b$ to indicate that the labels of a and b are identical. When Algorithm 1 reaches a state $s' = (P', \_)$, for $a_0, ..., a_n \in \langle \mathsf{Part}(\overline{P'}); \sqsupseteq_{\mathsf{Nondet}} \rangle$, the simple strings going through s' can be represented as $u = pa_ix$, where $0 \leq i \leq n$. Since elements in $\langle \mathsf{Part}(\overline{P'}); \sqsupseteq_{\mathsf{Nondet}} \rangle$ are disjoint, p is the longest common prefix among $pa_0, ..., pa_n$. We then utilize the generalized lexical order to choose the DFA states (e.g. from $\delta_{grep}(s', a_0), ..., \delta_{grep}(s', a_n)$) that possibly lead to longer successor suffixes (e.g. the string x) by introducing a novel partial order between DFA states.

Method. Since the linearization applies to the character classes, each states in $\mathcal{M}_{grep}(E)$ has an ordered set from $\langle \mathsf{Pos}(E); \leq_{\mathsf{Lex}} \rangle$ and a multiset of labels, i.e. a partially ordered multiset of integers: The runes from the same labeled character class have identical labels, representing the same priority.

To establish the order between ordered multisets, we use the concept of the *support* [71] of multiset: Let $\mathsf{Supp}(q) = \{[Q]_{\equiv_{\mathsf{Lex}}} \mid q = (Q, \_)\}$, for a state $q \in Q_{grep}$. Next we define the following binary relation $\sqsubseteq_{\mathsf{Lex}} \subseteq Q_{grep}^2$:

Definition 6. For $q_1, q_2 \in Q_{grep}$, $p_0, ..., p_n \in \mathsf{Supp}(q_1)$ and $p'_0, ..., p'_m \in \mathsf{Supp}(q_2)$, $q_1 \sqsubseteq_{\mathsf{Lex}} q_2$ if and only if

1. $q_1 \in F_{grep} \Leftarrow q_2 \in F_{grep}$,
2. $n < m \vee n = m \wedge \exists 0 < j \leq n, \forall i < j, p'_i = p_i \wedge p'_j <_{\mathsf{Lex}} p_j$.

When the supports of two states are identical, INC_DET randomly chooses one to continue, since the matching priorities of those states are exactly the same. In line 11, Algorithm 1 divide the runes in $\mathcal{A}$ into *equivalence classes* based on $\equiv_{\mathsf{Nondet}}$. For each candidate state sorted by $\sqsubseteq_{\mathsf{Lex}}$ (line 12), we start to test whether it is already recorded in Q in line 13. If not, the current state *cur* is assigned as the candidate state s; moreover, $\mathcal{P}$ is recorded in Q, and a random symbol from α is appended to *wit* in line 14. If the state s is not a final state (line 15) and $|wit|$ has exceeded $|ret|$ (line 19), *ret* is replaced with *wit* (line 20). Then INC_DET continues the search in line 21. If s is already visited, INC_DET continues the search in line 23 and chooses another pair of (α, s) from $([\mathcal{A}]_{\equiv_{\mathsf{Nondet}}}, \langle \mathcal{S}; \sqsubseteq_{\mathsf{Lex}} \rangle)$.

Example 6. For the state s from Example 5, $\mathsf{Supp}(s) = \{\{[\backslash x00\text{-}\backslash x7f]_1, ..., [\backslash xe1\text{-}\backslash xef]_1\}, \{[\backslash x00\text{-}\backslash x2f]_2, ..., [\backslash xf4\text{-}\backslash xf4]_2\}, \{[\backslash x00\text{-}\backslash x2f]_3, ..., [\backslash xf4\text{-}\backslash xf4]_3\}\}$[6]. In Figure 2 (b), s_1 and s_2 are both resulted from runes with the highest degree of nondeterminism at 10 in Figure 2 (a). Since $\mathsf{Supp}(s_1) = \{1,2,4\}$ and $\mathsf{Supp}(s_2) = \{1,2\}$, $\langle \{s_1, s_2\}; \sqsubseteq_{\mathsf{Lex}} \rangle = \{s_2, s_1\}$, i.e. $s_2 \sqsubseteq_{\mathsf{Lex}} s_1$. INC_DET continues with s_2.

Effect. The effectiveness of generalized lexical order strategy is profoundly connected to Perl-style disambiguation rules, i.e. the Greedy rules, which are commonly used in non-backtracking engines. By exploiting $\sqsubseteq_{\mathsf{Lex}}$, we maintain the consistency with engines using Greedy rules and also select the DFA states that are less likely to lead to early termination.

[6] For ease of representation, we write $\mathsf{Supp}(s) = \{1,2,3\}$.

```
1 (b, Q') ← AnalyzeConfl(b, wit, Q);
2 if b ≥ CONFLICT_RATE then
3     backtrack(b, Q');
```

Figure 3: Code fragment for non-chronological backtracking.

Output. When a k-simple string is found (line 16), in line 17, the witness is returned. When the states of $\mathcal{M}_{grep}$ have been fully explored, yet there does not exist a k-simple string, INC_DET returns the longest simple string found in line 24. By deciding whether the length of output from INC_DET exceeds k in line 27, the algorithm DECIDE solves k-SIMPLE STRING for $\mathcal{M}_{grep}$ in a sound and complete manner.

Theorem 2. DECIDE(E,k) *is sound and complete.*

The proof is provided in Appendix A.3.

Non-Chronological Backtracking. To further improve the efficiency of our algorithm, we introduce an incomplete non-chronological backtracking algorithm [55] into INC_DET, resulting in INC_DET′. This algorithm allows INC_DET′ to jump back over several levels in the automata when a considerable number of conflicts[7] are detected.

The non-chronological backtracking is applied to INC_DET by substituting line 18 and 23 by the code fragment in Figure 3, where the integer b for the level of backtracking and state set Q' storing the currently visited states are global variables. When a conflict occurs, we analyze the conflict in line 1 by the rate between the increment in the length of *ret* and the increment in b: If INC_DET′ executes backtracking or the increment in length of *ret* exceeds a threshold[8], b is reset and Q' is updated as Q. When the rate of conflicts exceeds *CONFLICT_RATE*, the search backtracks to the state implied by b, where the search is continued with another choice and Q is rewritten as Q' to eliminate the pruned states. Figure 2 (c) illustrates the situation when the rate of conflict exceeds the threshold in the left part of the automaton; the algorithm prunes the state space and then jumps back several levels to find more promising branches. This mechanism accelerates the search at the cost of completeness, i.e. some of the solutions may be pruned, even though they are valid.

6 Evaluation

In this section, we describe the evaluation of EVILSTRGEN, our C++ implemention[9] of the methodology presented.

Research Questions. We conducted experiments to compare EVILSTRGEN with the current state-of-the-art ReDoS detectors to answer the following research questions (RQs):

RQ1: How is the capacity of EVILSTRGEN compared to the state-of-the-art ReDoS detectors on large-scale real-world regex benchmarks?

RQ2: Specifically, how is the performance of EVILSTRGEN compared to GadgetCA [74] on the datasets that GadgetCA supports?

RQ3: How do different heuristic strategies described in §5 affect the efficiency of EVILSTRGEN?

RQ4: How is the performance of our approach for detecting vulnerabilities in real-world applications?

6.1 Experiment Setup

Benchmark. Non-backtracking engines were considered as a "safe" substitute for backtracking engines [8] to mitigate ReDoS vulnerabilities. To demonstrate that EVILSTRGEN is able to detect ReDoS in non-backtracking engines which are *comparably severe* to those in backtracking engines, we use **SET736535**, a large-scale real-world benchmark of 736,535 regexes from a wide variety of sources for evaluation.

SET736535 is obtained from a collection of 850,279 regexes composed of nine datasets: (i) Corpus [17], (ii) RegExLib [52] and (iii) Regex101 [4] from ReDoS-related literature; (iv) Large-scale regex dataset extracted from over 190,000 software projects by Davis et al. [22]; (v) Maven [1], (vi) NuGet [2] and (vii) PyPI[10] obtained from real-world code repositories by Wang et al. [78]; (vii) Snort [25]; (viii) Zeek [26]; and (ix) Sagan [5] from network intrusion detection systems. We integrated and deduplicated the aforementioned datasets, resulting in a set of 839,670 unique regexes. By removing regexes having features not commonly supported by non-backtracking engines (e.g. lookarounds and backreferences), SET736535 is obtained.

Engines. We selected 8 non-backtracking engines using online DFA matchers and 8 backtracking engines for evaluating our approach. Among the engines discussed in §2, the selected non-backtracking engines include RE2, regex engine used in Rust and Go, SRM, C#$_{\mathsf{N}}$, awk, grep and Hyperscan. No comparison is made to sed, since GNU sed and awk share the same DFA implementation. The standard library backtracking engines for programming languages selected include Java, JavaScript, PCRE2, Perl, php, Python, Boost, and C#.

Baselines. To comprehensively evaluate the performance of EVILSTRGEN, we identified six state-of-the-art ReDoS detection tools for comparison, categorized into: (i) static analysis (GadgetCA [74], RegexStatic [79] and Rexploiter [80]); (ii) dynamic analysis (Regulator [56], ReScue [66]); (iii) hybrid approach (ReDoSHunter [52]). Among the baselines, the only tool designed for non-backtracking engines is GadgetCA.

Criteria for ReDoS. In previous literature addressing ReDoS, several different criteria have been proposed. For example[11]: Davis et al. [21] suggest that a regex is vulnerable if a string of 100K to 1M *characters* takes the (backtracking) engines 10s to match; Regulator [56] uses 1M characters for 10s as the

[7] A choice that coincides with a previously visited DFA state in Q or a final state before k is reached is considered a conflict.

[8] Empirically we set this value to $\frac{k}{20}$.

[9] https://doi.org/10.5281/zenodo.11502706

[10] https://pypi.org/

[11] Notice all the characters and strings mentioned here are in Unicode, and a Unicode character can be as long as 4 bytes.

criterion; To obtain attack strings, ReDoSHunter [52] repeats "pump" strings 30,000 times and tests if the string takes engine more than 1s to match; [78] repeats pump strings 15,000 times and tests if the string takes Java's regex engine more than 10^5 matching steps.

To better characterize the features of ReDoS on non-backtracking engines, we propose both machine-dependent and independent ReDoS criteria as follows:

<100kB/s: To detect ReDoS on non-backtracking engines which are comparable to those on backtracking engines, we unified machine-dependent criteria for ReDoS on different engines by proposing a throughput threshold of 100kB/s, i.e. the engine cannot process 100kB input per second. This criterion is prominently more stringent than the lowest criterion (0.5MB/s) in [74], and conforms with the criteria for ReDoS on backtracking engines [21, 52] to be closer to practice.

>10,000 states: From the analysis in §4.1, the number of DFA states constructed in a non-backtracking engine to match an attack string reveals the theoretical effectiveness of the string. Considering the state cache thresholds used in engines, we introduce a novel machine-independent DFA state number measure in non-backtracking engines, i.e. an attack string of 100kB should force the engine to construct more than $10,000$ distinct subsets or ACI-disimilar derivatives.

Configurations. All evaluations were performed on a PC with 3.40GHz Intel i7-6700 8 CPU and 8GB of memory, running Ubuntu 20. We deployed the baselines as their newest stable releases and configured in the settings reported in their original documents. A 10 minutes timeout was used. We cross-verified the strings generated by each detector for concrete vulnerabilities on engines to establish the ground truth.

We experiment with different configurations of our algorithm as follows. We denote the algorithm with all three strategies off as BRUTE-FORCE; When only the nondeterminism-guided strategy is enabled, the configuration is denoted as NONDETON; The tool with both nondeterminism-guided and generalized lexical order strategies enabled is denoted as LEXICALON; The default configuration in EVILSTRGEN, with all strategies enabled, is denoted as ALLSTRATON.

To maintain consistency with research on backtracking engines and avoid the highly impractical size at 50MB in [74], we keep the size of inputs at 100kB in all experiments. Analyses on related work [52, 78] and CVEs [21] show 100kB is practical to detect ReDoS for backtracking engines. It is common among network intrusion detection systems to impose length restrictions on the input. Also, inputs of 100kB can be used in web services such as those using Spread Toolkit[12], etc. In EVILSTRGEN, the length is user-adjustable according to practical demands. Since baselines targeting on backtracking engines generate strings in the form of $prefix{+}pump^n{+}suffix$ for some n [52], we set n to satisfy $|prefix|+|pump|\times n+|suffix|\approx 100$kB.

[12] http://www.spread.org/index.html

6.2 Performance on Large-Scale Real-World Regex Benchmark

The various results under the criterion of <100kB/s for each ReDoS detector on all 16 engines for SET736535 are shown in Table 5. The numbers show the sum of ReDoS vulnerabilities found by each tool on engines and the best numbers are in bold. The results reveal that the non-backtracking engines can also be ReDoS vulnerable, where some may even perform worse than backtracking engines.

As depicted in Table 5, for all of the selected non-backtracking engines, EVILSTRGEN achieved higher effectiveness than all the baselines. In comparison with GadgetCA, using all the strategies together, EVILSTRGEN identified 1.75×, 2.29×, 5.54×, 3.30×, 3.44×, 0.31×, 0.05× and 580.75× more ReDoS vulnerabilities on RE2, Rust, Go, SRM, C#$_{\mathsf{N}}$, awk, grep and Hyperscan, respectively. Noticeably, we found 2,327 ReDoS vulnerabilities in Hyperscan, which was considered *invincible* in [74]. This is due to the effective encoding of UTF-8 standard and bytewise generation in EVILSTRGEN, while GadgetCA, ReDoSHunter, etc. generate strings characterwise.

Furthermore, EVILSTRGEN is also the best ReDoS detector among baselines for backtracking engines in Java, JavaScript, PCRE2, Python, Boost and C#, with 13,465, 9,797, 1,633, 4,395, 3,811, and 10,947 more ReDoS vulnerabilities detected than the second best respectively.

The results also show the incapability of the detectors designed for backtracking engines to find ReDoS for non-backtracking engines. Our investigation further reveals many of the regexes in the benchmark causes awk and grep to fall back to use backtracking matchers due to reasons mentioned in §4.2, which explains the relatively better performance of some detectors for backtracking engines on those engines.

Next we give more detailed analyses of GadgetCA and EVILSTRGEN, the tools targeting non-backtracking engines. Figure 4 (a)-(h) show vulnerable regexes identified in SET736535 by each tool using an enhanced scatter plot. Each point displays a regex's throughput rates handling strings from EVILSTRGEN (x-axis) and GadgetCA (y-axis) but groups overlapping points into hexagonal bins and coloring them to represent density using Kernel Density Estimation (KDE), where the darker colors indicate the denser areas. A piecewise linear transformation is applied to safe regexes (both throughput $\geq$100kB/s) to enhance the visibility of the vulnerable ones. Points below the diagonal suggest EvilStrGen causes lower throughput, otherwise GadgetCA does. We also calculate the percentage of regexes for which EVILSTRGEN causes a more severe slowdown (e.g., "wins in 100.00% regexes"). EVILSTRGEN wins in 85.71% , 100%, 91.06%, 98.57%, 97.90%, 100%, 56.86%, 99.95% vulnerable regexes on RE2, Rust, Go, SRM, C#$_{\mathsf{N}}$, awk, grep and Hyperscan, respectively.

Figure 5 (a) displays a distribution of the number of DFA states constructed in RE2 to match the strings generated by

	RE2	Rust	Go	SRM	C#$_N$	awk	grep	Hyperscan
EVILSTRGEN BRUTE-FORCE	19	2	4	10	1	3	4	3
EVILSTRGEN NONDETON	43	4	2	51	20	15	23	15
EVILSTRGEN LEXICALON	87	11	12	96	44	26	68	22
EVILSTRGEN ALLSTRATON	**294**	**30**	**23**	**165**	**57**	**74**	**104**	**32**
GadgetCA	16	9	5	29	6	28	37	2

both tools using KDE. The higher the curve, the higher the density. The sum of the values represented by each curve equals 1, i.e. the entire set. The distribution shows that EVILSTRGEN can explore a larger state space on more regexes.

Furthermore, the dashed line marks the position corresponding to 10,000 states, with the area to the right of it considered to contain vulnerable regexes. EVILSTRGEN found 1.55% of regexes vulnerable w.r.t >10,000 states criterion, while only 0.4% of regexes are found vulnerable by GadgetCA. The results indicate that EVILSTRGEN is generally more effective than GadgetCA, achieving an average of 17,846 DFA states and a median of 14,813 states, whereas GadgetCA has only 7,535 and 4,459 states respectively.

We further analyze ReDoS in some subclasses of regexes. Table 6 shows the total numbers of regexes with (and without) some specific structures from SET736535 (the column "Total") and vulnerable regexes from those subclasses detected by our tool (the other columns). The statistics reveal that regexes from these subclasses are not rare to appear in practice. Owning to the effectiveness of the *k*-simple strings, EVILSTRGEN is capable of exposing vulnerabilities for different engines on seemingly safe subclasses such as bounded_counting-free regexes. However, the method is still not sufficient to ensure all the vulnerabilities are found, see discussions in §6.6.

Summary. Due to its capability to detect various kinds of ReDoS vulnerabilities on non-backtracking regex engines, EVILSTRGEN is far more effective than all baselines, detecting overall $2.16-3,042.41\times$ times more ReDoS vulnerabilities. Besides, EVILSTRGEN is also the best or close to the best detector for backtracking regex engines.

6.3 Comparison with GadgetCA on ABOVE20

As GadgetCA focused on ReDoS detection in a subclass of regexes, to evaluate RQ2, we fairly compare EVILSTRGEN with GadgetCA on the ABOVE20 benchmark. ABOVE20 is a restricted dataset of 8,099 regexes with counting whose sum of upper bounds are above 20 excluding those unsupported by GadgetCA from [74].

Under the criterion of <100kB/s, the ReDoS vulnerabilities detected by both tools are depicted in Table 7. From Table 7, it can be observed that using all of the strategies collectively, EVILSTRGEN identified 17.37×, 2.33×, 3.60×, 4.69×, 8.50×, 1.64×, 1.81× and 15.00× more ReDoS vulnerabilities compared to GadgetCA on RE2, Rust, Go, SRM, C#$_N$, awk, grep and Hyperscan, respectively.

Figure 4 (i)-(p) shows the ReDoS vulnerable regexes found by each tool in ABOVE20 under the criterion of <100kB/s. The result shows that EVILSTRGEN wins in 94.83%, 92.59%, 85.71%, 83.64%, 92.81%, 78.75%, 77.49%, 96.42% vulnerable regexes on RE2, Rust, Go, SRM, C#$_N$, awk, grep and Hyperscan, respectively. Figure 5 (b) displays a distribution of results on ABOVE20, which shows that EVILSTRGEN achieves an average of 54,730 DFA states and a median of 38,990 states, in contrast to GadgetCA's average and median of only 39,300 and 29,270 states, respectively. EVILSTRGEN found 7.2% of regexes vulnerable w.r.t >10,000 states criterion, while only 0.74% of regexes are found vulnerable by GadgetCA.

Summary. EVILSTRGEN outperforms GadgetCA in terms of both the number of vulnerabilities found among non-backtracking engines and the severity of vulnerabilities triggered on the benchmark which GadgetCA is specialized in.

6.4 Analysis of Different Configurations

The efficiency of different configurations of EVILSTRGEN is depicted in Figure 6 on SET736535, measuring the average length of candidate attack strings generated by each algorithm within 50s, where ALLSTRATON achieves an average length of 19,308 bytes in 50s, while LEXICALON, NON-

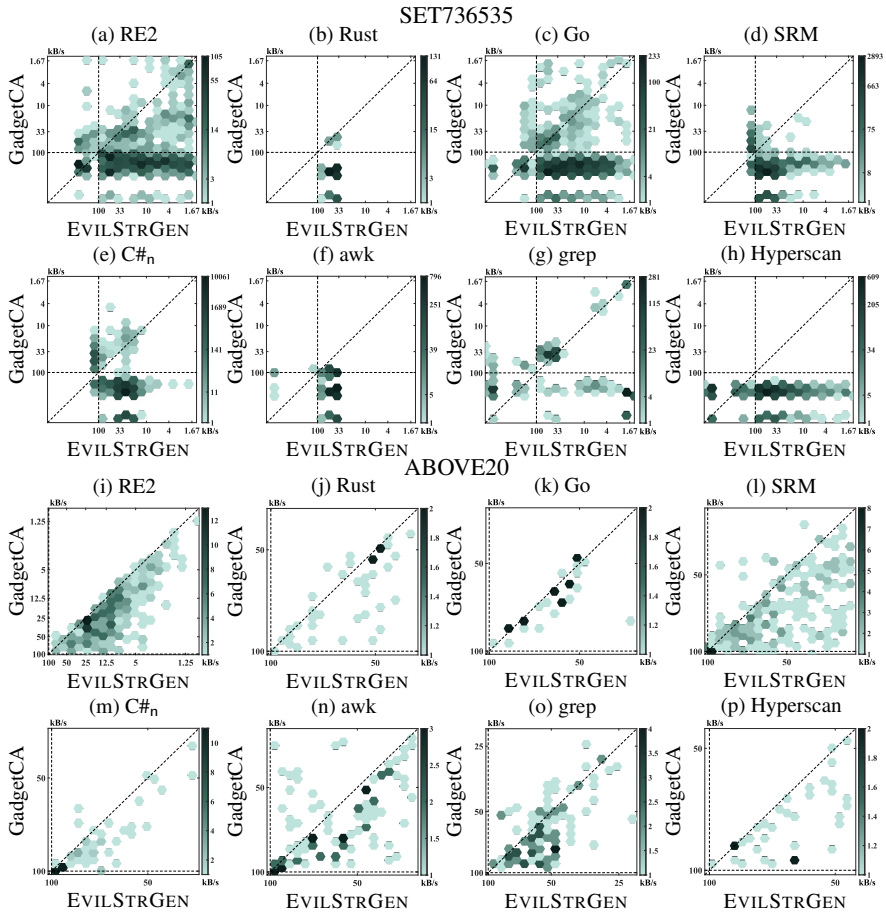

Figure 4: Throughput rate [kB/s] comparison of non-backtracking engines to match strings generated by EVILSTRGEN and GadgetCA.

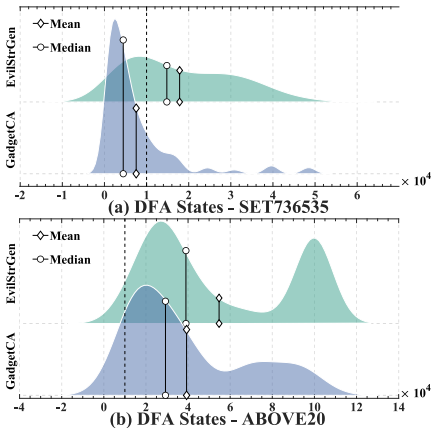

Figure 5: DFA states in RE2 to match strings generated by EVILSTRGEN and GadgetCA.

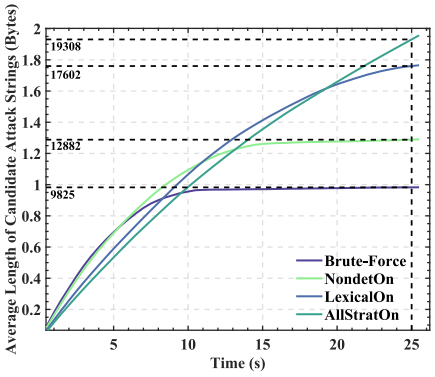

Figure 6: The average length of candidate attack strings generated by different configurations of EVILSTRGEN on SET736535.

DETON and BRUTE-FORCE achieve 17,602 bytes, 12,882 bytes and 9,825 bytes respectively.

In Figure 6, with more strategy enabled, the curves become flatter. Though more strategies enabled may decelerate the tool at the beginning, e.g. to generate 6,000 bytes, ALLSTRATON uses 11.37s on average, while LEXICALON, NONDETON and BRUTE-FORCE require 10.21s, 8.35s, 8.06s respectively, the curves for the other three configurations tend to stabilize in 50s, before reaching 100kB. From the overall results in Table 5 and Table 7, EVILSTRGEN is 13.4× more effective in ReDoS detection on non-backtracking engines using all our heuristics than using none.

The results also show a general improvement of each strategy on the BRUTE-FORCE algorithm. In addition, the complete algorithm LEXICALON also shows advantages over GadgetCA particularly on RE2, Go, SRM, C#$_N$ and Hyperscan on SET736535.

Summary. The results demonstrate empirically that each strategy that we have introduced provides a remarkable benefit in the efficiency of candidate attack string generation. For maximum efficiency, all of the strategies are used simultaneously in EVILSTRGEN.

6.5 Real-world Application

To illustrate the efficacy of EVILSTRGEN, it was deployed on real-world projects to identify exploitable ReDoS vulnerabilities. We have applied EVILSTRGEN on the well-starred and widely downloaded projects in Rust and Go from GitHub. The initial step involved crafting a script for extracting code segments using regexes from these projects. Next, EVILSTRGEN was employed to generate and verify attack strings according to different matching functions and engines. A manual examination was then conducted to ascertain the presence of code segment interfaces linked to the regexes that might be vulnerable to external injections.

Our investigation led to the identification and manual verification of 85 projects having potential ReDoS vulnerabilities, out of which 34 regexes were confirmed as ReDoS vulnerable within the real-world projects. Strikingly, GadgetCA was not able to recognize any of the newly revealed vulnerabilities. For details, see Appendix B.

Example 7. `unknwon/com` is an open-source project for commonly used functions for the Go programming language. As illustrated in Figure 7, a regex used for HTML tag re-

```
// ReDoS vulnerability
func StripTags(src string) string {
    re := regexp.MustCompile('(?s)<(?:style|script)[^<>]*>.*?</(?:style|script)
          >|</?[a-z][a-z0-9]*[^<>]*>|<!--.*?-->')
    src = re.ReplaceAllString(src, "")
  ...
}
// PoC: An 10MB input attack string was injected into CLI interface of the program
, taking 769s for the program to process.
StripTags(" <!- -\x04+\x05\x16\x0B<!- -<!- -X\x1A?<!- -LE*\x1A<!- -I\x09\x18
    \xF1<!- -\x04+\x05\x16\x0<!- -<!- -X\x1A?<!- -LE*\x1A<!- -I\x09\x18
    \x3C< <!- -\x04+\x05\x16\x0B... ")
```

Figure 7: A vulnerable regex in package `unknwon/com`.

moval is vulnerable to ReDoS. A PoC targeting this vulnerability significantly slows down the program, with the throughput rate of the engine dropping below 11kB/s and causing a 99% CPU load on average during the search on the attack string. This vulnerability affects 54 projects, posing significant risks, especially to cloud services, by potentially causing hardware failures or system shutdowns. Key affected projects include `seccome/Ehoney`, a honeypot management system, and `huaweicloud/external-sfs`, a cloud storage solution on Huawei Cloud, where disruptions could severely impact network security and data availability. Additionally, vulnerabilities in cloud management platforms like `nttcom/terraform-provider-ecl` could lead to extensive service outages and endangering data integrity.

Summary. The results show the high usability of EVILSTRGEN to reveal ReDoS vulnerabilities for programs using non-backtracking engines in practice.

6.6 Discussion

Limitations. Though EVILSTRGEN performs well in practice, there are following directions to improve. Firstly, the algorithm selection in engines, e.g. from DFA to NFA, is rather complex. As shown in the experiment, attack strings generated for backtracking engines might also perform well on grep. EVILSTRGEN should be combined with a non-trivial extension to **dynamic symbolic execution** to monitor the engines and know from which byte the different matchers are used and switch to generating targeted attack strings. Secondly, EVILSTRGEN selects the runes by the degree of nondeterminism *greedily*. However this does not guarantee to **maximize the degree of nondeterminism** in the whole attack string, or even performs worse than baselines. To avoid this, more comprehensive branching strategies should be introduced to avoid finding sub-optimal attack strings.

Discussion for Practioners. Cox has given several good suggestions on using non-backtracking engines in [20]. Apart from these, we strongly suggest using regexes from some rather safe subclasses of regexes for online DFA matchers, such as deterministic regular expressions [15, 19]. We also suggest to *not* using the structures and operators that may result in high descriptional complexity as mentioned in §4.2.

7 Related Work

ReDoS Detection for Backtracking engines. Previous works on ReDoS detection mainly focus on backtracking engines, which can be classified into the following methods.

Static Analysis. Static analysis methods for backtracking engines model ReDoS vulnerabilities but often fail due to modeling limitations, leading to high false positives and negatives. RXXR2 [63] detects ReDoS vulnerabilities by pumping analysis, struggling with polynomial ReDoS vulnerabilities. RegexStatic [79] estimates the worst case cost (linear, polynomial, or exponential) of regexes but faces challenges due to its less comprehensive modeling approach.

Dynamic Analysis. Dynamic analysis detects ReDoS vulnerabilities during actual runtime, having higher precision than static methods in the cost of efficiency. ReScue [66] targets time-intensive input strings using genetic algorithms, which leads to omission in lower polynomial instances due to the vast search space and the selection bias of genetic algorithms results in further limitations. Regulator [56] applies fuzz testing to regex byte-code with a mutation approach, which may cost too much time for generating attack strings.

Hybrid Approaches. Hybrid tools combine static and dynamic analysis. Revealer [53] uses an extended NFA based on regex engine in Java for static analysis. ReDoSHunter [52] identifies and verifies regexes with more fine-grained vulnerability patterns. Rengar [78] detects ReDoS vulnerabilities by combining "loop subregex"-based vulnerability modeling and disturbance-free attack string generation. However the existing work lacks theoretical foundations.

ReDoS Detection for Non-Backtracking engines. GadgetCA [74] is a detector targeting ReDoS vulnerabilities in non-backtracking engines, relying on the determinisation of counting automata to generate candidate attack strings for a restricted subclass of regexes, which may lead to false negatives in regexes that have non-uniform automata. Different from GadgetCA, EVILSTRGEN leverages a sound and complete algorithm and aims to find the "evilest" attack strings for online DFA matchers, i.e. simple strings, thus giving a better performance in detecting real-world ReDoS vulnerabilities.

8 Conclusion

In this paper, we presented a novel and effective approach to detect ReDoS vulnerabilities for non-backtracking regex engines. Our ReDoS detector EVILSTRGEN shows state-of-the-art performance on large-scale real-world benchmark for both non-backtracking and backtracking engines and exposes 34 new vulnerabilities in popular open-source projects. There are many promising optimizations remained to be explored, such as cooperating local search to accelerate the k-SIMPLE STRING solving and introducing symbolic execution to reveal more ReDoS vulnerabilities in programs using non-backtracking engines.

Acknowledgements. We would like to thank our shepherd and reviewers for their helpful comments and suggestions. We thank Ping Lu for his valuable advice on computational complexity and Zhiwu Xu for his careful reading and helpful comments on an earlier version of the paper. A Omitted Definitions and Proofs

A.1 Unfolding Rules

A regex E can be transformed into an equivalent bounded_ counting-free regex by recursively applying the rules:
$E^{\{0,\}} \to E^*$, $E^{\{0,\}?} \to E^{*?}$, $E^{\{0,0\}} \to \varnothing$, $E^{\{0,0\}?} \to \varnothing$,
$E^+ \to EE^*$, $E^{+?} \to EE^{*?}$,
$E^{\{m,n\}} \to EE^{\{m-1,n-1\}}$, $E^{\{m,n\}?} \to EE^{\{m-1,n-1\}?}$, for $n \geq m > 0$,
$E^{\{0,n\}} \to E^?E^{\{0,n-1\}}$, $E^{\{0,n\}?} \to E^{??}E^{\{0,n-1\}?}$, for $n > 1$,
$E^{\{m,\}} \to EE^{\{m-1,\}}$, $E^{\{m,\}?} \to EE^{\{m-1,\}?}$, for $m \geq 1$.

A.2 Proof for Theorem 1

Theorem 1. *k-Simple String is* EXPSPACE*-hard.*

Proof. We show that k-Simple String is EXPSPACE-hard by a reduction to Non-Empty Complement. Given a regex E defined on an alphabet Σ, the Non-Empty Complement problem of E is to decide whether $\mathcal{L}(\neg E) \neq \varnothing$. In [39], this problem is proven to be EXPSPACE-complete.

We note that a DFA $\mathcal{M}$ of E can be easily completed [42], thus we assume that all DFAs under consideration are complete and the sink state is denoted as d. Define the complemented $\mathcal{M}$ as $\mathcal{M}^c = (Q^c, \Sigma, \delta^c, s^c, F^c)$, where $F^c = (Q - F) \cup$

$\{d\}$. We modify the Definition 2 as a simple string w^c is a finite word $w \in \mathcal{L}(\mathcal{M}^c)$, where the states of the path of w on $\mathcal{M}^c$ of E contains only one final state and are pairwise distinct. This transformation is done in polynomial time. Therefore, any 0-simple string w^c of $\mathcal{M}^c$ of E satisfies $w^c \in \mathcal{L}(\neg E)$, i.e. an witness of NON-EMPTY COMPLEMENT. □

A.3 Proof for Theorem 2

Theorem 2. DECIDE(E,k) *is sound and complete.*

Proof. Let E be the regex and k the integer on which the algorithm is executed. First, we show the soundness of DECIDE. When DECIDE returns **T**, consequently INC_DET returns a string with at least length k. Any returned string of INC_DET has a path on $\mathcal{M}_{grep}$ thus is a string in $\mathcal{L}(E)$. As the search avoids recording identical states by condition $s \notin Q$ within the loop (line 13) and keep only one final state in a searching path by terminating this search once encountering a final state (line 15), thus the string is a k-simple string of E, w.r.t $\mathcal{M}_{grep}$. When DECIDE returns **F**, INC_DET returns a string shorter than k, indicating that the string is not a k-simple string. Above all, the algorithm DECIDE is sound.

For any given input regex E, INC_DET produces a simple string (as discussed above). If the length of this output string exceeds k by the termination condition $|wit| \geq k$, i.e., INC_DET finds a simple string longer than k and DECIDE returns **T**. If there is no simple string of length greater than k, when the finite set of states of $\mathcal{M}_{grep}$ is fully constructed, the algorithm terminates and returns a longest string found, which is lower than k, then DECIDE returns **F**. Accordingly, DECIDE is guaranteed to terminate correctly.

From the argument above, DECIDE(E,k) is sound and complete in solving k-SIMPLE STRING w.r.t. $\mathcal{M}_{grep}$. □

B Real-World Vulnerabilities

Table 8 shows ReDoS vulnerable regexes from Go and Rust projects, where their names and stars are listed. Only the source projects are shown for these regexes in supply chains.

Table 8: Real-world ReDoS vulnerable regexes and corresponding projects.

Abstract

The rise of mobile payment apps necessitates robust user authentication to ensure legitimate user access. Traditional methods, like passwords and biometrics, are vulnerable once a device is compromised. To overcome these limitations, modern solutions utilize sensor data to achieve user-agnostic and scalable behavioral authentication. However, existing solutions face two problems when deployed to real-world applications. First, it is not robust to noisy background activities. Second, it faces the risks of privacy leakage as it relies on centralized training with users' sensor data.

In this paper, we introduce FAMOS, a novel authentication framework based on federated multi-modal contrastive learning. The intuition of FAMOS is to fuse multi-modal sensor data and cluster the representation of one user's data by the action category so that we can eliminate the influence of background noise and guarantee the user's privacy. Furthermore, we incorporate FAMOS with federated learning to enhance performance while protecting users' privacy. We comprehensively evaluate FAMOS using real-world datasets and devices. Experimental results show that FAMOS is efficient and accurate for real-world deployment. FAMOS has an F1-Score of 0.91 and an AUC of 0.97, which are 42.19% and 27.63% higher than the baselines, respectively.

1 Introduction

Mobile payment apps [5], while enhancing transaction convenience, pose challenges in user authentication due to the prevalent device-sharing habit among friends and family. Traditional security measures like passwords and two-factor authentication occasionally fail, as evidenced by incidents of unauthorized transactions by minors using their parents' devices [66]. These issues underscore the need for innovative, non-intrusive authentication methods. While facial recognition via the front-facing camera is a potential solution [8], its intrusiveness makes it unpopular, particularly in public settings, prompting the exploration for more user-friendly authentication alternatives.

Recently, AuthentiSense [23] and KedyAuth [30] emerge as the state-of-the-art (SOTA) solution for transparent and user-friendly authentication. They utilize build-in sensors to capture distinctive user behavioral patterns in an imperceptible manner. These solution can prevent unauthorized payments and do not harm user experience.

Albeit the pioneering contribution of existing approaches, there are two limitations that impede their deployment in Alipay, a widely used payment application with one billion users, that we conduct experiments on in this paper. **The first limitation** is the negative influence of *background activities*[1] on sensor readings in real-world scenarios. They assume that users should keep stationary and similar actions while using mobile apps. Thus, they can detect subtle sensor patterns to differentiate individual users. However, in real-world usage, users are not always stationary. They may use their smartphones while walking or lying on a bed. These background activities introduce substantial noise to sensor readings, making it difficult to observe the subtle user-specific patterns and significantly degrading the accuracy of authentication. **The second limitation** is the violation of user privacy in the sensor data. The training strategy of existing approaches requires collecting users' sensor data and uploading all data to a remote server because the model must be trained in a centralized manner. However, collecting and uploading such data is not allowed by regulations (e.g., GDPR [62] and PIPL [16]). Thus many mobile apps opt not to collect users' sensor data to mitigate privacy concerns [75]. Therefore, it is not feasible to use them in real-world scenarios.

Addressing the two aforementioned limitations is inherently difficult. For the first limitation, how to deal with low signal-to-noise ratio data remains an open challenge in machine learning [31, 50]. In real-world scenarios, the noise introduced by background activities can overshadow the subtle user-specific features by several orders of magnitude [14, 57]. Isolating these subtle but distinct features from the massive dominant noise sources is difficult, if not impossible. For the

[1]We define background activities as the various conditions under which users are using their phones.

second limitation, although Federated Learning (FL) complies with privacy regulations, this technique is not compatible with the model design of existing approaches. This is because they require both positive (sensor data of the target user) and negative (sensor readings of other users) samples to train the model. This requirement inevitably shares sensor data across users, thus violating the basic privacy assumption of FL. Therefore, we need a novel solution to make user-transparent authentication more practical.

In this paper, we propose FAMOS, FederAted Multi-MOdal ContraStive Learning, to perform user-transparent authentication in noisy background activities while complying with privacy regulations. The key insight of FAMOS is that *by 1) fusing multi-modal sensor data and 2) clustering one user's data representation by action categories, we can effectively eliminate background activities and achieve user authentication without training data from other users.*

By fusing multi-modal sensors, we enhance user authentication by utilizing stable sensor data to counteract noise from unstable sensors. For example, while walking may affect accelerometer data, touch screen sensor readings remain consistent, allowing for accurate user authentication by combining these data sources. Conversely, when a user is lying down, the accelerometer provides more reliable data due to unstable hand movements affecting the touch screen sensor. This sensor data fusion aligns with FL paradigm, enabling training the user authentication only with their own data to ensure the privacy regulations.

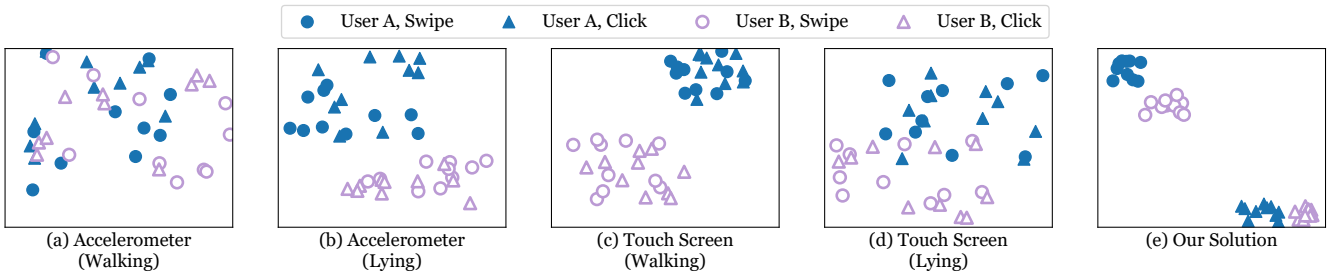
However, we encountered three technical challenges while implementing our insights. The first challenge is how to identify the stable sensors under different background activities. To address this challenge, we propose an attention mechanism that dynamically assigns different weights to different sensors based on each sensor's stability. This attention mechanism can automatically select stable sensors under different background activities. The second challenge is the intricacy of clustering the data representations by their respective action category. Specifically, clustering representations of identical actions closely while ensuring that representations of different actions are distanced poses a difficulty. To tackle this challenge, we introduce an action-aware contrastive learning strategy. By leveraging the combination of cross-entropy loss and contrastive loss, we can effectively project varied actions into distinct and uniformly distributed clusters within the representation space. The third challenge is that, due to the limited user-side computation resources, the authentication model should be small and efficient enough to be deployed to user devices. To address this challenge, we adopt a residual DNN model architecture [28] to project representatives from fused features. The proposed architecture is compact enough to be deployed in TrustZone [33,52] of mobile devices, further boosting user privacy and framework security [72].

We conducted a comprehensive evaluation of FAMOS using a real-world dataset collected from Alipay and an in-lab dataset. Our results demonstrate that, under realistic background noises, FAMOS achieves an F1-Score of 0.91 and an AUC of 0.97 for user authentication. On the contrary, the highest F1-Score and AUC of baselines are only 0.64 and 0.76. FAMOS outperforms baselines by 42.19% and 27.63% for F1-Score and AUC, respectively. Compared with using only one sensor, FAMOS improves the F1-Score by up to 31.88%, which demonstrates the effectiveness of the multi-modal sensor scheme. We also deploy FAMOS in the TrustZone to evaluate the on-device efficiency. On average, the memory consumption of FAMOS is only 8.58 MB for training and 3.95 MB for inference. CPU utilization increased by 23.77% during training and 16.36% during inference. Besides, the increase in battery consumption per hour is 1.32% for training and 0.48% for inference. The averaged training and inference times for FAMOS are 26.9 minutes and 135 milliseconds, respectively. It means that FAMOS is lightweight enough and can be deployed in real-world smartphones.

We summarize our contributions as follows:

- We identify two practical limitations, the influence of background noises and privacy violations, that impede the deployment of SOTA user authentication solutions to real-world applications.
- We propose a novel authentication framework, FAMOS, based on federated multi-modal contrastive learning. FAMOS can robustly authenticate users under noisy background activities without compromising user privacy.
- We comprehensively evaluate FAMOS using real-world datasets and devices. Experimental results demonstrate the robustness and efficiency of FAMOS in real-world scenarios.

2 Background and Motivation



In this section, we will discuss the background and the motivation of this paper with realistic data.

2.1 The Challenge of Background Noise

User-transparent authentication leverages the unique action patterns of users, discernible in sensor readings during mobile app interactions, for authentication [3, 10, 18, 23]. For example, variations in click strength produce distinct accelerometer vibrations [9, 25], enabling distinguishing users without hindering smartphone usage.

However, the use of sensor data in practice faces a significant challenge: *sensor readings are unstable due to noise from background activities* [17]. For instance, when users are walking, the accelerometer readings exhibit massive noise due to the larger body movements of walking. In contrast, when users lie down, the pressure differences on the touch screen become more significant, resulting in greater disparities between data.

Background activities can disrupt sensor readings, making distinguishing users challenging. We illustrate this with t-SNE

(a) Accelerometer (Walking) (b) Accelerometer (Lying) (c) Touch Screen (Walking) (d) Touch Screen (Lying) (e) Our Solution

Figure 1: The t-SNE representations of sensor readings.

visualizations [60] of Click and Swipe actions from two users in Figure 1, represented by blue solid (User A) and purple hollow (User B) markers, after converting sensor signals to embedding vectors via a CNN encoder [15]. Figure 1 (a) and (b) show the visualizations under walking and lying conditions show that users' accelerometer data overlap significantly during walking, indicating instability, but are distinct when lying, reflecting the relative stability of sensor readings in this state.

Existing research often overlooks the variances in sensor data due to background activities, which can restrict the practicality and user experience of interactive systems. Different sensors exhibit varying levels of stability across activities. As shown in Figure 1 (c) and (d), touch screen sensors perform better when users are walking but less stable when users are lying. This variability highlights the impracticality of manually selecting a universally stable sensor, underscoring the need for an automated system to determine the most reliable sensors for any given sensor.

Our key insight to address background noise is to *fuse different sensors*. We take advantage of the attention mechanism to automatically identify the stable sensors for different background activities. To further validate the effectiveness of sensor fusion, we use our proposed approach to generate feature vectors by combining sensor readings and visualize the fused feature vectors of the two users in Figure 1 (e). We can observe that the fused sensor readings are clearly clustered into different groups, and thus the two users can be accurately differentiated.

2.2 Privacy Challenge

Existing work has recognized sensor data as a privacy-sensitive resource and thus cannot be uploaded to centralized servers [23, 75]. Sensor data are private because they can be used to predict private user attributes such as age and gender [51]. Besides, regulations such as China's PIPL [16] and EU's GDPR [62] consider sensor data as personal data and do not allow applications to upload such data.

FL [47] is an effective privacy-preserving training approach for user authentication. Specifically, FL allows participants to share learned models without uploading raw sensitive data, thus enabling the collaborative training of multiple users. Thus, we can employ FL to train local models for each user and mitigate the risk of privacy breaches. However, the latest works [23, 30] cannot support FL framework because such work requires data from other users as negative samples to train the model. This requirement violates the constraint of FL because it inevitably shares data across different users.

3 Threat Model

We consider two stakeholders in our system model. One stakeholder is end *users* who utilize mobile apps to access online services such as payment and money transfer. The other stakeholder is a central *server* responsible for user authentication and the provision of online services. However, there are potential attackers who seek to compromise a user's mobile device or acquire their credentials. To achieve this goal, the attacker may exploit vulnerabilities inside the mobile device or induce the user to install malware [4, 11, 58]. The attacker can also be children who gain access to the parents' credentials [1]. Once the attacker successfully acquires the user's credentials, they can impersonate the user and deceive the server during the authentication process. As a result, the attacker has unauthorized access to downstream services, including those that are typically sensitive and rely on user authentication (e.g., bank service [34]).

In our threat model, we follow prior work to make assumptions on the attacks and defenses of user authentication [23]:

- The device is used by the owner in most cases but maybe occasionally accessed by the attacker [23, 30].
- The attack can get the credentials of the victim through technical or non-technical approaches.
- The sensor data is highly related to sensitive personal attributes, including a user's age, gender, and even potential health conditions. Thus, the collected data is protected by secure hardware such as TrustZone [33, 52], to prevent possible injection attacks or data leaks.
- The authentication model can be jointly trained by the user and the application server. We assume that the model is trustworthy since sensor data can be assigned exclusively to the model in the secure world. Even if the device is compromised, the malicious attacker cannot read the model from the secure world. Therefore, the authentication model is immune to typical model backdoor or poisoning attacks [26, 56].
- The server is trustworthy, adhering to the training protocol

to securely store models and execute computations [73]. The server can also invoke advanced authentication techniques (e.g., live-video face authentication) to verify that the collected data during a specific time period is from the victim him/herself.

• The communication channel is secure and trusted because it can be protected by a standard secure communication protocol (e.g., SSL/TLS [36]). Attackers cannot manipulate transmitted data or conduct attacks such as the MITM attack [23].

4 Design of FAMOS

We now introduce FAMOS, a new user-transparent authentication system designed for real-world applications, including mobile payment platforms like Alipay. We aim to achieve the following goals:

• **G1: Robustness.** FAMOS should be robust to noises introduced by background activities. For example, when a user is walking, accelerometer readings can be noisy. FAMOS should effectively filter out this noise and extract pertinent features for authentication purposes.

• **G2: Lightweight.** FAMOS should be deployable within the TrustZone of users' smartphones, safeguarding the model from potential theft by malicious apps. Additionally, FAMOS should ensure model security under attacks.

• **G3: Privacy-Preserving.** Since the sensor data constitutes sensitive user privacy, FAMOS should prioritize user privacy, minimizing the risk of data leakage. For instance, the raw sensor readings should not be uploaded to the server.

We propose multiple approaches to achieve the above three goals. For **G1**, we propose to fuse multi-modal sensors to extract more information and attenuate the side effects of noises. Specifically, we utilize the attention mechanism and contrastive learning to better fuse features and cluster representations.

For **G2**, we propose to design a residual DNN model architecture to achieve good performance while minimizing the model size. Thus, during deployment, both the model and sensor readings can be secured by TrustZone on devices. This solution can effectively prevent malicious attackers from potentially tampering with the model.

For **G3**, we propose to leverage the FL paradigm, which ensures local storage of private data and privacy-preserving model training while ensuring the model accuracy. We only upload the learned model to the server to aggregate the learned knowledge. Additionally, FAMOS does not require readings from other users as negative samples, further reducing the risk of privacy exposure.

4.1 Overview

FAMOS operates in three phases: data collection, training and authentication. The goal of data collection is to collect data in a user-transparent manner. The goal of the training phase is to train a model that can closely clusters the representation vectors of each action. The goal of the authentication phase is to distinguish whether a new action belongs to the device owner.

Data Collection Phase. FAMOS intermittently collects user data and trains the model in the background of users' daily usage, without impacting users' experience. Before data collection, FAMOS first provides a comprehensive notification to users, detailing the purpose of data collection, the specific types of collected data, and how the data will be stored locally. After obtaining user authorization, FAMOS notifies users when data collection starts and ends.

Specifically, each data collection step occurs only within one minute after the user passes real-time video face authentication, which ensures that the collected data originates from the target user. Each collection step will be terminated preventively if the user inputs an incorrect password, locks the screen, switches Alipay to the background, or remains inactive for 20 seconds. FAMOS repeats the collection step until the required amount of data is attained. Based on our empirical evaluation, active users typically spend over 2.4 minutes per Alipay session, execute approximately 26.3 valid actions per minute, and open the app 3.3 times daily. Therefore, collecting 350 action data samples is usually achieved within three days. Note that FAMOS is a user-transparent authentication method, which is supplementary to conventional authentification methods. The three-day data collection time is acceptable in practice since users can still use other authentication methods when FAMOS is not ready. Therefore, FAMOS does not require immediate user authentication upon the first login. Instead, it allows the system to take some time, with low power consumption, to complete data collection and model training. Besides, the data collection only needs to be conducted once before model training. After the model is trained, FAMOS does not need to collect new data in the next several months. Thus, the data collection phase does not impose a substantial burden on users' devices in the long term.

Training Phase. The training phase of FAMOS is also conducted in the background intermittently. The high-level pipeline of the training phase is illustrated in Figure 2. It consists of three modules: the sensor fusion module (Mod①), the contrastive learning module (Mod②), and the federated learning aggregation module (Mod③). The first two modules are combined as a deep neural network model and deployed in the secure area (e.g., TrustZone) of the users' devices. The Mod③ is deployed on a centralized server. All three modules do not require heavy computation and have low power consumption. Therefore, the training phase does not occupy many computational resources and will not introduce observable lag. As the training phase begins, FAMOS will send a notification to users to inform them that the training has started and another notification when the training is completed. This ensures that users are aware that their data is being processed to enhance security measures. In the notification of the training comple-

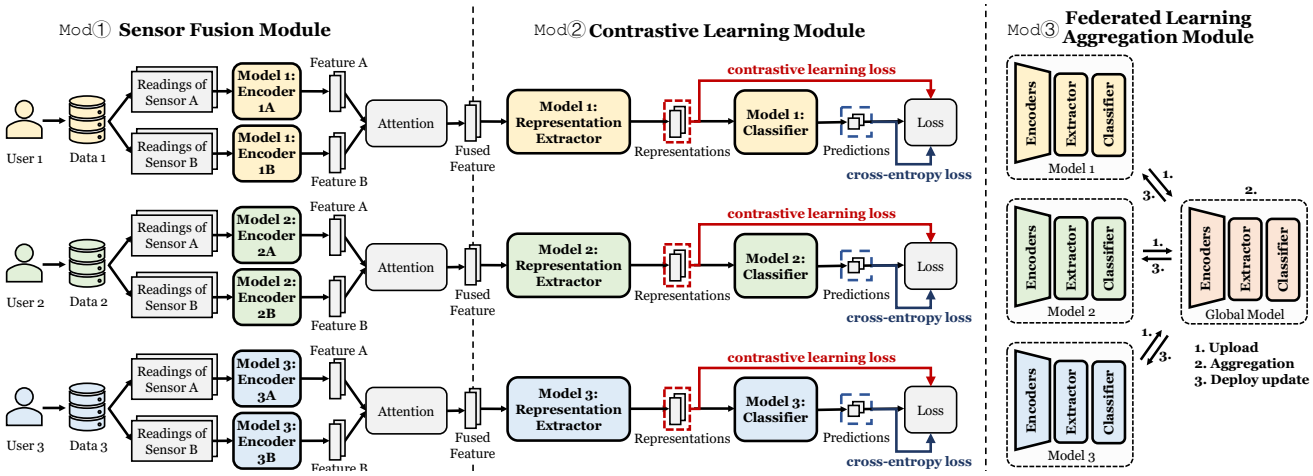


Figure 2: The high-level architecture of FAMOS's training phase.

tion, FAMOS will also inform users that the app could further provide authentication services.

During the training phase, FAMOS launches Mod① and Mod② following an FL paradigm (Mod③). First, it fuses readings from different sensors and clusters representation vectors based on actions. In FAMOS, we support five standard and common user actions within a mobile application, as presented in Table 1. These five actions cover all interactions in Alipay. Second, FAMOS uploads the trained model to the server, which employs Mod③ to aggregate the acquired knowledge from user models. Then, the server sends the aggregated model back to the user. The distributed models are used as the initial model for the next round of training. This process repeats multiple times until the desired performance is achieved.

For the new users that are continuously added to the framework, FAMOS adopts an incremental user selection strategy after the model has been trained [21]. For each new user, FAMOS automatically downloads the latest global model and uses the local data to compute the loss value. The loss values of all participants are uploaded to the server and the server selects the top k users with the highest loss values. This selection scheme steadily enhances the accuracy of local models when new users join the system. It is noteworthy that this process does not impose a substantial burden on computational resources, because new users tend to achieve convergence rapidly within a small amount of time.

Authentication Phase. During the authentication phase, FAMOS authenticates users periodically in the background in a user-transparent way. Specifically, FAMOS leverages the trained model to detect potential adversaries. This phase consists of two stages: an offline pre-processing stage and an online vector-comparison stage. Both stages are conducted on the user's device and do not upload any data to the server. The offline pre-processing stage computes the ground-truth vector for each action and defines a distance threshold.

After the pre-processing stage is complete, FAMOS authenticates the user at one-minute intervals. Specifically, given the sensor readings of a new action, the online vector-comparison stage predicts the action label a and produces the representation vector $\vec{r}_{new}$ based on sensor readings. Then FAMOS compares $\vec{r}_{new}$ with the ground-truth vector of the predicted action $\vec{r}_{gt}^{\,a}$ and computes the distance between them. If the distance exceeds the threshold, FAMOS considers the action pattern abnormal and the device may be compromised. Then, a more stringent authentication method will be invoked for the next payment.

Table 1: Five user actions that FAMOS supports.

Label	Action	Abbreviation
0	Click on the screen	Clk.
1	Swipe on the screen	Swp.
2	Click on the screen and hold	Hld.
3	Two fingers swipe on the screen	Two.
4	Shake the phone	Shk.

4.2 Sensor Fusion Module (Mod①)

The goal of Mod① is to fuse the readings from different sensors. This module takes the raw readings of sensors as input and generates fused feature vectors, in which the noises from background activities are eliminated.

The key challenge in fusing readings from different sensors is how to identify the stable sensor in the noisy environment and mitigate the negative effects of other unstable sensors. In practice, the data stability of different sensors varies under different background activities. For example, the accelerometer can capture more user-related activities when the user is lying compared to when the user is walking. Conversely, for walking, the touch-screen sensor can better capture the user-related activities. However, manually creating rules to identify stable sensors for different activities is impractical due to the diverse range and combinations of user activities and background activities.

To solve this problem, we leverage the attention mecha-

nism [61] to dynamically assign importance weights to different sensors and generate *fused features*. The attention mechanism enables us to automatically select stable sensor readings under different background activities. It is trained to learn the complementary knowledge through different sensor modalities, allowing FAMOS to capture the variance in both data quality and contributions from sensor data. This design takes advantage of multiple sensors to enhance the performance of fused features, thereby enabling FAMOS to achieve **G1**, i.e., robustness to noises from background activities.

Mod① comprises two steps. The first step is projecting the heterogeneous sensor readings to a unified feature space. This step is important because, in practice, the readings of different sensors can exhibit substantial variation. For example, the accelerometer sensor produces readings in three dimensions, while the data from the touch screen sensor only has six dimensions. The second step fuses the unified features from different sensors using the attention mechanism. We will elaborate on each of the steps in detail below.

Step 1: Sensor Feature Projection. Formally, for M sensors, let $\vec{x} = \{\vec{x}_1, \vec{x}_2, \ldots, \vec{x}_M\}$ represent the readings from the sensors, where j is the sensor index. $\vec{x}_j$ represents the reading from the j-th sensor. Hence, this step can be formalized as Equation 1, in which $\mathcal{G}_j$ is the encoder for the j-th sensor. Let Norm$(\cdot)$ represent the normalization operation and Flatten$(\cdot)$ represent the flatten operation. The goal of these two operations is to project the features to the unified dimensions, thus making it easier to fuse. The output $\vec{f}_j$ can be formulated as:

$$\vec{f}_j = \text{Norm}(\text{Flatten}(\mathcal{G}_j(\vec{x}_j))), j \in \{1, ..., M\} \quad (1)$$

In FAMOS, each encoder $\mathcal{G}_j$ consists of a single-layer convolutional neural network. The encoders take each sensor readings as input and output a feature vector of a uniform dimension. We chose the CNN architecture because it is better at extracting information from sparse sensor data and is commonly applied to sensor data [50].

Step 2: Attention-based Fusion. The second step of Mod① is to fuse the feature vectors of different sensors using an attention module. In this way, FAMOS can identify the stable sensors under different background activities. The attention mechanism can be formalized as Equation 2. Different sensors are assigned to different attention weights and each weight w_j represents the stability and importance of the j-th sensor. The output $\vec{f}'$ is the fused vector:

$$\vec{f}' = \sum_{j=1}^{M} w_j \vec{f}_j \quad (2)$$

To obtain w_j, we design the attention mechanism following prior work [50] that can fuse multi-modal heterogeneous data [45]. More specifically, we first compute the hidden representation $\vec{\mu}_j$ of $\vec{f}_j$ through a one-layer MLP (shown in Equation 3). Besides, we normalize the attention weights using a softmax function to control the magnitude of the importance weights (shown in Equation 4).

$$\vec{\mu}_j = \tanh(W \cdot \vec{f}_j + b), j \in \{1, ..., M\} \quad (3)$$

$$w_j = \frac{exp(\vec{\mu}_j \cdot \vec{f}_j)}{\sum_{j=1}^{M} exp(\vec{\mu}_j \cdot \vec{f}_j)}, j \in \{1, ..., M\} \quad (4)$$

4.3 Contrastive Learning Module (Mod②)

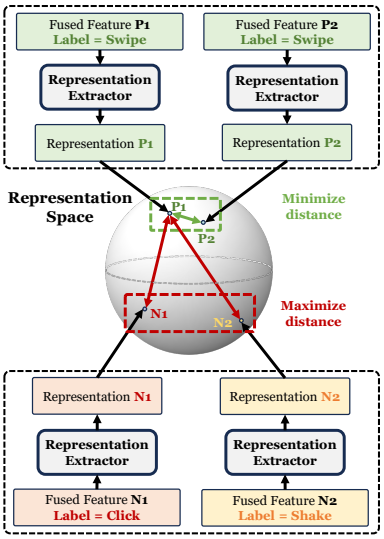

Figure 3: Design of the contrastive learning module.

The goal of Mod② is to cluster the representation vectors of the same action (positive samples) while pushing those of different actions (negative samples) far away. FAMOS can categorize representations into several compact clusters based on different actions. After training, the user's data samples are distributed to the corresponding cluster based on the action representation, while the data samples from other users are excluded by all clusters due to the feature dissimilarity. Therefore, during the authentication stage, we detect the identity of the user by measuring the distance between the representation vector of the current user and the representation vector of the registered user (i.e., ground truth).

Mod② is inspired by the recent advances of contrastive learning [50], which is an effective self-supervised learning approach to learn representations from unlabeled data. The advantage of this module is that we can train FAMOS only with the data from the current user and we do not need the data from other users. In practice, it is difficult to share such data across devices because, according to the regulations such as the GDPR, collecting and sharing such privacy-related data is illegal without the explicit consent of the users.

Module Design. At a high level, this module projects the fused sensor representation vectors to a representation space and minimizes the distances between the representations of the same user. Note that this is challenging due to the diversity

of user actions. A naive approach is to define the loss function as the cosine distance between the representation vectors of the same user. However, this approach converges to a sub-optimal solution in practice since different actions of the same user could be quite different. For example, the representation vectors of clicking are very different from those of swiping.

To address this challenge, we propose to make the training phase *action-aware*, which distinguishes different actions from the same user. The motivation is that the representation vectors of different actions should be far away from each other. The design of our action-aware contrastive learning module is shown in Figure 3. P1 and P2 represent two positive actions, and N1 and N2 are two negative actions. Mod② minimizes the representation distances from the same action (the green arrow in Figure 3) and maximizes the distances from different actions (the red arrows in Figure 3). Thus, we cluster the representation vectors of the same action close to each other and push other actions far away. In addition, the above action-aware design enables Mod② to use different actions from the same user as negative samples to train the model. Thus, Mod② does not need to use other users' data.

Loss Design. To realize the training procedure, we propose a new action-aware loss function $\mathcal{L}_{action}$ which is shown in Equation 5. The loss consists of two parts: $\mathcal{L}_{ce}$ is the classification loss of different actions, and $\mathcal{L}_{cont}$ is the contrastive loss between representation vectors of the same action. λ is a hyperparameter to balance the magnitude between two losses.

$$\mathcal{L}_{action} = \mathcal{L}_{ce} + \lambda \mathcal{L}_{cont} \tag{5}$$

The goal of $\mathcal{L}_{ce}$ is to identify different actions and push the representation vectors of different actions far away from each other. We use a cross-entropy loss to classify different actions. Let B denote a batch of training data, and $s \in B$ is a sample in the batch. $\vec{r}_s$ denotes the representation that is calculated as $\vec{r}_s = \mathcal{M}(\vec{f}'_s)$, where $\mathcal{M}$ denotes the representation extractor. Let $\mathcal{C}$, y_s, and cross_entropy$(\cdot)$ denote the classifier, the label of s, and the cross-entropy function, respectively. We formulate $\mathcal{L}_{ce}$ as:

$$\mathcal{L}_{ce} = \sum_{s \in B} \text{cross\_entropy}(y_s, \mathcal{C}(\vec{r}_s)). \tag{6}$$

By minimizing the cross-entropy loss, the model can automatically push the feature vectors of samples from different classes far away from each other [7].

The goal of $\mathcal{L}_{cont}$ is to minimize the distances of representation vectors of the same action from the same user by pushing these vectors close to each other in the space. The formulation of $\mathcal{L}_{cont}$ is shown in Equation 7. $PB(s)$ is the set of positive samples of s in the batch B, respectively. We define a sample as positive to s if it is from the same action as s. Otherwise, the sample is negative.

$\mathcal{L}_{cont}$ consists of two components. For the action s, $\cos(\vec{r}_s, \vec{r}_p)$ is the cosine distance between its representation vectors $\vec{r}_s$ and the representation vector of a positive sample p. $\cos(\vec{r}_s, \vec{r}_q)$ is the cosine distance between $\vec{r}_s$ and the representation of a negative sample q in the same batch. We then minimize the ratio between $\cos(\vec{r}_s, \vec{r}_p)$ and $\cos(\vec{r}_s, \vec{r}_q)$ to cluster the representation vectors of the same action:

$$\mathcal{L}_{cont} = -\sum_{s \in B} \sum_{p \in PB(s)} \log \frac{\cos(\vec{r}_s, \vec{r}_p)}{\sum_{q \in B - \{s\}} \cos(\vec{r}_s, \vec{r}_q)} \tag{7}$$

Note that we do not necessitate data samples from other users during training. This is based on findings from previous research [59], which suggests that in the representation space, the distance between samples from attackers and victims is sufficiently large. This distance arises because contrastive learning effectively clusters the representations of the victim's samples closely.

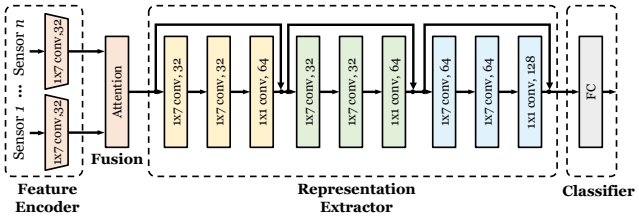

Figure 4: Residual DNN model architecture.

Model Architecture. Another challenge of Mod② is that the encoders should be small enough to fit in the TrustZone (**G2**). The size of TrustZone is typically limited on a mobile device, thus we must carefully design the model architecture so that Mod② can fit in the TrustZone and still has enough capacity to capture the features of sensor readings. A straightforward design will either introduce too many parameters (e.g., MobileNet [29]) or too little capacity which harms accuracy (e.g., LeNet-5 [35]). To balance the model size and performance, we choose a modified residual DNN architecture [28] because its skip connection design can achieve high accuracy with fewer parameters than other candidates [2].

The model architecture is shown in Figure 4, where we design encoders ($\mathcal{G}_j$) for different types of sensors. Specifically, we leverage a convolution layer as the architecture of the encoder that unifies the readings of sensors with different dimensions into features of the same size. Besides the sensor-specific encoders, we have two universal components: the representation extractor ($\mathcal{M}$) and the classifier ($\mathcal{C}$). The former component consists of three residual blocks (represented in yellow, green, and blue). Each block includes three convolution layers, in which the kernel size of the first two layers is 1×7 and the kernel size of the last layer is 1×1. The input and output of each block are connected by a skip connection to facilitate gradient propagation [28]. The classifier is composed of one FC layer. The representation extractor is used to compute $\mathcal{L}_{cont}$ and the classifier component computes $\mathcal{L}_{ce}$. The model size is only 1.81 MB with 1.17M parameters, which is small enough to fit in mobile secure world such as TrustZone.

4.4 FL Aggregation Module (Mod③)

FAMOS aims to achieve a high model performance while avoiding uploading the raw user data to the central server. With FL, users only need to upload locally-trained models. Without FL, FAMOS either suffers from degraded performance (when trained only with local data) or faces the risk of breaching user privacy (when user data is collected to a central server). For the former case, FAMOS experiences lower accuracy due to insufficient data. For the latter case, uploading raw user data to the server may violate regulations.

Using model aggregation in FL to improve the model performance in FL is a recognized practice in the AI community [39, 47, 73]. There are two reasons. First, aggregation enables the global model to learn patterns and features from different data distributions of diverse devices, thereby enhancing the robustness and generalization of the global model. Second, aggregation allows different devices to collaboratively contribute to the improvement of the global model.

In FAMOS, Mod③ aims to aggregate the general knowledge from the user-side model while leaving the user-specific knowledge on the device. This module takes the locally trained user model as input and outputs an aggregated model. The aggregated model is sent back to the user device to update the local model. The aggregation process is conducted on the server of the app owner. Because FAMOS only uploads the trained model, it does not leak any user data (**G3**).

Challenge. The key challenge of this module is that each user model contains not only general (i.e., user-agnostic) knowledge but also user-specific information. The general knowledge can improve FAMOS's ability to extract representation from sensor readings. Differently, FAMOS uses user-specific information to distinguish the user action from the potential adversary. Thus, an ideal aggregation strategy should only aggregate the general knowledge while not aggregating user-specific knowledge, to better accommodate diverse data distributions of different devices. However, if we directly use conventional FL techniques (e.g., FedAvg [47]), we would aggregate both general and user-specific information, which is undesirable.

Solution. To address this challenge, we aggregate all layers across the whole model except the `BatchNormalization` layer. Prior work has proved that the `BatchNormalization` layers contain most of the user-specific information, and thus leaving them on the device can prevent the aggregation of user-specific information [39]. Formally, let $\mathcal{M}_i$ be the representation extractor of user i and $\mathcal{M}_{global}$ be the aggregated extractor. Let ℓ be the layer index except the `BatchNormalization` layers. The aggregation rule is as follows:

$$\mathcal{M}_{global}^{(\ell)} = \frac{1}{\sum_{i=1}^{N} n_i} \sum_{i=1}^{N} n_i \mathcal{M}_i^{(\ell)}, \tag{8}$$

where n_i is the amount of training data of user i. Similarly, this aggregation strategy is applied to both feature encoders $\{\mathcal{G}_i\}$ and the classifier $\mathcal{C}_i$. The local training and server aggregation process repeat multiple times until the user models achieve desirable performance in the classification task. Therefore, Mod③ can enhance the representation extractor, accelerate convergence, and improve effectiveness.

4.5 Authentication

After the training, FAMOS uses the trained model to authenticate users on the devices. The authentication phase consists of two stages: the offline pre-processing stage and the online vector comparison stage. The first stage computes a *ground-truth vector* for each action and defines a distance threshold. The second stage continuously takes sensor readings as input, predicts the action label, and computes a *representation vector* for the input readings. Then FAMOS compares the representation vector with the ground-truth vector of the predicted action to determine whether the user action is abnormal.

Offline Pre-Processing. Due to the contrastive learning scheme, representations of the actions performed by the same user tend to be spatially proximate in the representation space [20]. Thus we construct ground-truth vectors $\vec{r}_{gt}^{\,a}$ for each action a by computing the center of correctly classified samples in the training data. Let $\mathcal{A}_i^a$ be the set of correctly classified samples of action a for the i-th user, the ground-truth vector is computed as:

$$\vec{r}_{gt}^{\,a} = \frac{1}{|\mathcal{A}_i^a|} \sum_{\vec{r}_i^{\,a} \in \mathcal{A}_i^a} \vec{r}_i^{\,a}. \tag{9}$$

The ground-truth vector acts as a reference point for the user's own data. After the vectors are computed, they are stored in the TrustZone of the user's device to prevent privacy leakage and tampering.

In the offline stage, FAMOS also computes the threshold t from the validation set to distinguish the abnormal user actions. Specifically, FAMOS chooses the threshold that achieves the best trade-off between the False Acceptance Rate and False Rejection Rate are equal in the validation set. A more detailed illustration of how to choose the threshold is included in Section 5.4.

Online Vector Comparison. This stage begins after the user logs into the payment application and periodically captures the interaction actions of the user at a certain interval. For each action, FAMOS uses the classifier $\mathcal{C}$ to predict the action label a. Then, FAMOS produces the representation vector $\vec{r}_{new}$ of the action and computes its cosine distance between the ground-truth vector $\vec{r}_{gt}^{\,a}$: $dis = 1 - \cos(\vec{r}_{new}, \vec{r}_{gt}^{\,a})$. At last, FAMOS uses the threshold t to determine whether the action passes ($dis < t$) the authentication or fails ($dis > t$). Note that this online stage is performed on the user's device and the data is never uploaded to the server. Thus the authentication phase does not leak the user's privacy.

5 Evaluation

In this section, we perform comprehensive experiments to evaluate the effectiveness of FAMOS. Our experiments aim to answer the following research questions:

- **RQ1**: How is FAMOS's performance compared with existing solutions?
- **RQ2**: How well can FAMOS mitigate background noises effectively?
- **RQ3**: Can contrastive learning cluster actions from different users?
- **RQ4**: Can federated learning improve the performance and facilitate training process?
- **RQ5**: How is the on-device efficiency of FAMOS?

5.1 Implementation

We use PyTorch 1.8 to implement FAMOS. We train the models (feature encoders, representation extractor, and classifier) in a decentralized manner. The encoders, representation extractor, and classifier are updated simultaneously. We trained the model using the contrastive and cross-entropy loss, which are provided by the library `pytorch.nn`.

We use the Grid Search [41] to find the optimal hyperparameter. Specifically, we set the optimizer to Adam, the learning rate to 1e-2, the batch size to 32, the feature length to 128, and the local training epoch to 5.

5.2 Ethical Disclaimer

We obtain the IRB approval from the ethics review committee in Alipay before we install Alipay-b and collect the data. Besides, all the volunteers are aware that the sensor readings are collected for research purposes. The data is not used for any other commercial purposes nor shared with any third party. We properly stored the data in an encrypted database.

5.3 Evaluation Protocol

To ensure the generalizability and soundness of our evaluation, we measure the performance of FAMOS with both real-world user data and carefully simulated in-lab data. We first use the real-world data to evaluate the overall performance of FAMOS in realistic settings. This experiment ensures the external validity of our evaluation. Then we take a well-controlled in-lab experiment to evaluate the performance of the internal components of FAMOS. This experiment ensures the internal validity of our experiments.

Our testbeds include a server and four smartphones from different brands. The server is used to evaluate the authentication accuracy, while the smartphone is used to measure the training and inference cost. The server is equipped with Ubuntu 20.04.6, 128 GB memory, an Intel Xeon CPU with 48 cores, and 4 NVIDIA GeForce GTX 2080Ti GPUs. We use four latest smartphones of different brands to measure the on-device performance and demonstrate the generalizability of FAMOS to different smartphone devices. The smartphones are Huawei Mate X3, Xiaomi 13 Pro, VIVO X100, and Honor Magic 6. The smartphones are equipped with TrustZone in which we can deploy our model, as discussed in the threat model (Section 3) and prior work [23] to prevent the model from being tampered with by attackers.

We use AuthentiSense [23] and KedyAuth [30] as the baselines because they are the latest state-of-the-art user-transparent authentication approach that was published on the top-tier conference. We rigorously implemented the baselines following the description in the paper as we did not find the source code of them. We use the same dataset as FAMOS to train and evaluate the baselines. Note that they do not fuse readings of different sensors. Instead, they directly sums the readings of the sensors as the input feature. Thus, existing baselines are not robust against background noises, as we will show in our evaluation.

We report both the averaged values and the specific values of each user model. To comprehensively evaluate FAMOS, we use six different metrics in the evaluation: False Acceptance Rate (FAR), False Rejection Rate (FRR), Equal Error Rate (EER), True Positive Rate (TPR), F1-Score, Area Under ROC Curve (AUC). These metrics are consistent with prior work [23].

5.3.1 Data Collection

To ensure that our experiments can faithfully simulate real-world user scenarios, we use a commercial mobile payment app, Alipay as the target app to evaluate FAMOS. We implemented Alipay-b by adding extra code for recording sensor readings in the callback functions for different user actions in the original version of Alipay. When the user takes an action (e.g., click or swiping), the corresponding callback will be invoked. Then, the added code will start a background thread that records the readings of sensors for *two* seconds and log the readings of the sensors along with the label of action. We call a tuple action-data tuple <*action, sensor_data*> as a data sample or sample for simplicity in this paper. Alipay-b records the five types of actions in Table 1.

sensor_data={Screen, IMU} contains the readings of touch screen sensors and IMU sensors. The touch screen sensor data *Screen* is a series of data points sampled as the rate of *twenty milliseconds*. Each point is a six-dimension vector that contains the following values:

- `start_x`: the X-coordinate of action's starting position.
- `start_y`: the Y-coordinate of action's starting position.
- `current_x`: the X-coordinate of current position.
- `current_y`: the Y-coordinate of current position.
- `duration`: the tap duration.
- `pressure`: the current tap pressure.

IMU={accelerometer, gyroscope, magnetometer} records the readings of three types of IMU sensors. Specifically, accelerometer measures the vibration or acceleration of the phone. Gyroscope measures the angular velocity of the phone

around the real-world coordinates. Magnetometer measures the Earth's magnetic field. These three IMU sensors all measure a vector in the three-dimensional real world. The data of accelerometer, gyroscope, and magnetometer are a series of data points with three-dimensional coordinates: `x`, `y`, and `z` for index at the X-, Y-, and Z- real-world coordination. The value of the coordinates is sampled every *ten milliseconds*.

5.3.2 Dataset Construction

We developed two datasets for our study: a real-world dataset for assessing FAMOS's overall performance in real-world environment and an in-lab dataset, which allows us to control background activities for a more precise evaluation of FAMOS's effectiveness in mitigating their impact.

Real-World Dataset. Our real-world dataset contains data from 70 realistic Alipay users. We delegated the developing team of Alipay to identify the candidates in our experiment and publish Alipay-b to users. We asked the experiment candidates to replace the original Alipay with Alipay-b and use the beta version in their daily lives. Note that we do not impose any restrictions on the background activities of the user actions. Hence, users are free to interact with phones in a natural manner under various background activities such as walking and lying. This makes the collected data more realistic and representative of the daily use cases.

We split the 70 users into two groups: 20 victims and 50 attackers. For each of the victims, we collect 500 data samples, 100 samples for each action. We then divided these samples by the ratio of 7:1:2 to form the training (350 samples), validation (50 samples), and test sets (100 samples), respectively. For the attackers, we collect 150 data samples (30 for each action) in total and divide the samples by 1:2 to form the validation (50 samples) and test sets (100 samples). For each victim user, the training set is used to train the authentication model. The validation and test sets are used to evaluate the model. For each victim user, the validation and test sets contain an equal number of victim samples (i.e., positive samples) and attack samples (i.e., negative samples). Note that the attacker's data is only used for evaluation the model in the validate and test sets. The attacker's data is not used for training FAMOS. This process simulates a typical attack scenario of user-transparent authentication as described in Section 3.

In-Lab Dataset. To build the in-lab dataset, we hired 24 volunteers from Ant Group, the mother company of Alipay, to collect data under specific background noises. The dataset construction process is approved by the IRB. Among the 24 volunteers, four act as victims and 20 as attackers. The 24 volunteers are divided into four groups, each group consists of one victim and five attackers. Each group uses one device to collect data from the victim and the attackers. The design of this volunteer setting is to simulate a realistic attack scenario that the victim and attackers use the same device. For background activities, we ask the volunteer to perform five activities: walking, lying, sitting, jogging, and climbing.

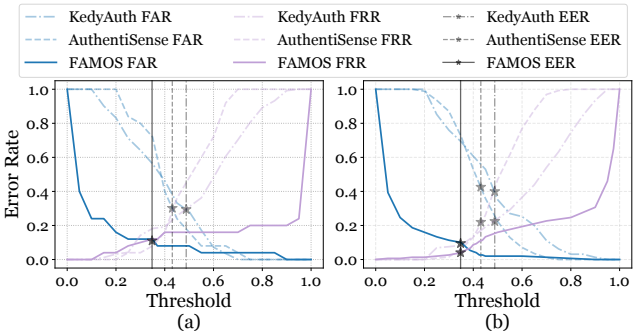

Figure 5: (a) FAR, FRR, and EER on the validation set. (b) FAR, FRR, and EER on the test set. EER is computed from the optimal threshold of the validation set.

For each victim users, we collected 1250 samples in total. Among 1250 samples, each action has 250 samples, 50 samples for each of the five background activities. All the samples of victims are divided into training, validation, and test sets by the ratio of 7:1:2. Thus each victim has 875 samples in the training set, 125 samples in the validation set, and 250 samples in the test set. For each of the attackers, we collected 75 samples. Each action has 15 samples, with three for each of the five background activity. These 75 samples are divided into validation and test sets by the ratio of 1:2. Thus each attacker has 25 samples in the validation set and 50 samples in the test set. For each victim user with five attackers, there are 125 attack samples in the validation set and 250 attack samples in the test set. This design ensures that the validation and test sets contain an equal number of victim samples (i.e., positive samples) and attack samples (i.e., negative samples).

5.4 RQ 1: Overall Effectiveness

In this section, we assess FAMOS's performance using a real-world dataset, comparing it with AuthentiSense across various metrics. Firstly, we determine the optimal threshold by computing the EER, FAR, and FRR on the validation set, which is then applied to the test set to ascertain the FAR and FRR. Second, we plot the ROC curve and compute the AUC score on the test set. Third, we evaluate F1-Score to report a fine-grained comparison between FAMOS and AuthentiSense.

FAR, FRR, and EER. The result of the first part is shown in Figure 5.The x-axis represents different thresholds and the y-axis represents the error rate. The blue line represents the FAR and the purple line represents the FRR. We mark the optimal threshold (chosen by the validation set) with a vertical dashed line. In each figure, FAMOS is represented by the solid lines and AuthentiSense is represented by the blurred lines. Figure 5 (a) shows the results on the validate set and Figure 5 (b) shows the results of the test set.

We use the validation set to find the optimal threshold that FAR equals to FRR (the intersection between the blue curve and the purple curve). The optimal threshold represents the setting that keeps both the FAR and FRR low. In Fig-

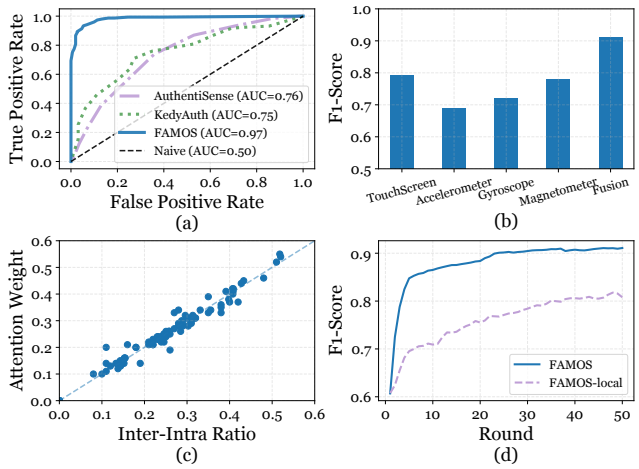

Figure 6: (a) Comparison of ROC curves. (b) F1-Score of different sensors and the sensor fusion. (c) The relationship of attention weight and the Inter-Intra Ratio. (d) Convergence curves of F1-Score of FAMOS and FAMOS-local.

ure 5 (a), we mark the optimal point with a black star (★). As the figure shows, the optimal threshold of FAMOS is 0.35, where the FAR=FRR=0.11. For AuthentiSense, the optimal threshold is 0.43, where FAR=FRR=0.30. For KedyAuth, the optimal threshold is 0.48, where FAR=FARR=0.29. As EER represents the optimal threshold to balance declined benign attempts (false positive) and accepted attack attempts (true negative), a lower EER of FAMOS represents a higher effectiveness for authentication.

For the results on the test set in Figure 5 (b), we report the EER based on the optimal threshold from the validation set. For FAMOS on the optimal threshold (0.35), FAR is 0.09 and FRR is 0.04. For AuthentiSense on the optimal threshold (0.43), FAR is 0.43 and FRR is 0.22. For KedyAuth on the optimal threshold (0.48), FAR is 0.40 and FRR is 0.23. In the authentication service, FAR is more important than FRR, because a false rejection only introduces an additional authentication step, while a false acceptance leads to malicious access and may cause severe security accidents. The FAR of FAMOS is over 4.44× lower than the other two baselines, which means FAMOS provides a more reliable authentication service in real-world scenarios. Meanwhile, the FRR of FAMOS is over 5.51× lower than baselines, which means it can effectively reduce the probability of identifying the user as an attacker, thus enhancing the user experience.

ROC and AUC. Figure 6 (a) shows the ROC score to detect malicious access on the test dataset. Except for FAMOS and two baselines, we also plot a *Naive* baseline to represent the result of random guess (AUC is 0.50). As shown in the figure, the AUC of FAMOS, AuthentiSense, and KedyAuth are 0.97, 0.76, and 0.75, respectively. The AUC of FAMOS approaches the optimal value of 1.00 and is 27.63% higher than baselines, which means FAMOS can detect malicious access more precisely.

F1-Score. For FAMOS, the average F1-Score of FAMOS is 0.91, which demonstrates that FAMOS could provide a more reliable authentication service that can effectively distinguish victim users from malicious attackers. On the contrary, the performance of baselines is much lower than FAMOS. The F1-Score of AuthentiSense and KedyAuth are only 0.62 and 0.64, which are 31.87% and 29.68% lower than FAMOS.

Overall Effectiveness. As a summary, FAMOS can achieve over 4.44× lower FAR, 5.51× lower FRR, 27.63% higher AUC, and 42.19% higher F1-Score than the two state-of-the-art baselines. FAMOS is more effective and reliable than existing approaches in the user authentication service.

5.5 RQ 2: Mitigating Background Activities

In this section, we evaluate whether combining different sensors can effectively mitigate background noises. To this end, we first evaluate the improvement of using fused sensor data of the real-world dataset. Then, we evaluate how our attention identifies stable sensors and eliminates background noises.

Improvement on Accuracy. To evaluate how much can fusing multiple sensors improve the overall accuracy, we removed the sensor fusion module of FAMOS and evaluated its accuracy on real-world data with different sensors. We report the results in Figure 6 (b). Each bar represents the F1-score of using only one sensor. For example, TouchScreen means we only use the touch screen data to achieve user authentication. The bar of Fusion represents the result of FAMOS.

As shown in Figure 6 (b), fusing different sensors indeed improves the overall accuracy. The F1-Score for using touch screen, accelerometer, gyroscope, and magnetometer only is 0.79, 0.69, 0.72, and 0.78, respectively. These are all at least 0.12 lower than the F1-Score of FAMOS, which is 0.91.

Insight Verification. Our insight to mitigate the background noises is that different sensors have different stability under different background activities. Thus, by fusing different sensors, they can mitigate the background noise for each other. To evaluate the validity of this insight, we evaluate how the attention can improve the quality of the feature vectors learned by `Mod`① (See Figure 4) with the In-lab dataset.

Specifically, we evaluate the quality of the features vectors learned by `Mod`① and the attention with the stability score, following previous studies [12, 53]. The stability is defined as the ratio between the action similarities between *different* users (Inter-User Similarity, represented as "Inter" in Table 2). and the action similarities from the *same* user(Intra-User Similarity, represented as "Intra" in Table 2). We denote the action similarities of a set of samples as the average of Euclidean distances of the feature vectors of the samples [48]. The feature vectors are computed through our feature encoder module. A higher stability means the samples from the different users are well clustered: samples from the same users are close while samples from different users are far from each other [70].

We report the results in Table 2, the first four columns represent the Intra-User Similarity, Inter-User Similarity, and

Table 2: Stability (Inter-Intra Ratio) of data samples of each sensor and fused sensor. The Touch Screen sensor is represented as "-" as it produces no readings during the "Shake" action. “BG.” denotes the background activity, “Act.” denotes the action.

Stability (Inter-Intra Ratio) for the four sensors we used in this paper (touch screen, accelerometer, gyroscopes, and magnetometer), respectively. The fusion column represents the results for FAMOS. From the results in Table 2, we can first observe that background noise can significantly affect the stability of sensor readings. For example, when walking, accelerometer and gyroscope have higher Intra-User Similarity and lower Inter-Intra Ratio than the touch screen and magnetometer. It means the accelerometers and gyroscopes are not stable under the background of walking. Similarly, we can observe that the touch screen and magnetometer are unstable under the background of lying. Therefore, we can conclude that background noise can significantly affect the stability of sensor readings and bring difficulties to user authentication. *This result confirms our insight that different sensors have different stability under different background activity.*

Second, according to the results in Table 2, we conclude that FAMOS improves the stability by fusing sensors. We can observe that the last column of Table 2 (column “Fusion”) has the highest Inter-Intra Ratio for all actions with both background activities. The Inter-Intra Ratio of fused sensors is 2.24× higher than a single sensor under two background activities (averagely 4.21 in walking, 4.93 in lying, 4.8 in sitting, 4.16 in jogging, and 4.18 in climbing).

Effectiveness of Attention. FAMOS uses the attention to identify stable sensors for authentication. To validate this insight, we report the average attention weight for each sensor under different background activities in Table 3. The sensor with higher stability (higher Inter-Intra Ratio) receives higher weights, while the sensor with lower stability receives lower weights. For example, when the background is walking, the touch screen sensor receives a relatively lower weight (averagely 0.19) as it exhibits weaker stability in this scenario.

Table 4: Compared of the averaged distance of fused features and representation vectors.

Action type	Features	Representations
Victim Samples (Different actions)	0.54	0.83
Victim Samples (Same action)	0.49	0.31
Victim & Attacker Samples (Same action)	0.52	0.50

Conversely, when the background is lying, the touch screen sensor receives a relatively higher weight (averagely 0.36).

Further, we display the correlation between the Inter-Intra Ratio and the attention weights in Figure 6 (c). To improve the clarity of the figure, we normalized the ratios of four sensors into the range [0,1] [2]. We can observe a positive linear correlation between the Inter-Intra Ratio and the attention weights, which are automatically learnt by FAMOS. This demonstrates that the attention module can effectively select stable sensors under different background noises.

5.6 RQ 3: Effective of Contrastive Learning

The goal of our contrastive learning (Mod②) is to cluster samples from the same user while pushing the samples from different users far from each other. To evaluate the effectiveness of contrastive learning, we compare the cosine distance of fused features (fused by the attention mechanism after the feature encoder) and representation vectors (learned by the representation extractor). In Table 4, we compared the distance of victim samples in different actions, the distance of victim samples in the same action, and the distance between victim and attackers samples in the same action.

Table 4 shows that before applying our representation extractor, distinguishing between different users or actions is challenging due to the minimal average distance differences in their features. Specifically, the distance between different actions is 0.54, very close to the distance between users and attackers, and only slightly higher than within-user sample distances. However, employing a contrastive learning-based representation extractor significantly improves differentiation: the distance between different actions' representation vectors jumps to 0.83, a 1.63 times increase that enhances user authentication accuracy by effectively clustering same-user actions closer and distancing those of different users or attackers.

5.7 RQ4: Effectiveness of Federated Learning

Different from previous approaches, our framework utilizes FL paradigm to aggregate the user-agnostic knowledge to facilitate the training process. In this part, we study how much the FL paradigm can improve the performance of FAMOS. As for the baseline, we create a local training version of FAMOS, denoted as FAMOS-local, by only training FAMOS with the private data of each user (i.e., without aggregation). We compare the F1-Score and the convergence speed of FAMOS and FAMOS-local to evaluate the effectiveness of FL, as shown in Figure 6 (d). On average, the F1-Score of FAMOS-local is only 0.80, about 15.1% lower than FAMOS (averaged F1-Score is 0.91). The results demonstrate that applying FL can effectively improve authentication accuracy. All user models are well-trained and get convergence within 26.21 aggregation rounds on average. This aligns with the average cost for modern FL tasks [42, 43]. On contrary, the FAMOS-local spends more than 42.73 rounds to convergence, about 62.98% slower than FAMOS.

[2] The range of the coordinate axis in Figure 6 (c) is set to [0,0.6] because we found that all the values of normalized ratios and attention weights are smaller than 0.06.

5.8 RQ5: On-device Performance

In this section, we study the on-device performance of FAMOS in the TrustZone of four different smartphones (Huawei Mate X3, Xiaomi 13 Pro, VIVO X100, and Honor Magic 6). We use MNN [32] library to convert the model to the `.mnn` format. This format is a highly optimized format for ARM architecture [44]. Then we deploy the converted model in the TrustZone and measure the on-device performance and usability.

Overhead. We measure the overhead of FAMOS in terms of four aspects: memory usage, CPU usage, battery consumption, and running time for both training and inference phases. For the first three types of overhead, we compare the performance of Alipay with FAMOS running in the background and Alipay without FAMOS. We report the increased value when FAMOS is running. For the running time, we measure the end-to-end training time until convergence and the end-to-end authentication inference time of one input sample. We use Android `dumpsys` tool, sample information from the `/proc/stat` file, and invoke the built-in APIs of TrustZone to comprehensively measure the memory usage, CPU usage, and battery utilization. Each experiment is conducted five times and report the average value. We manually checked the variance of the results and found that it is less than 5%.

The results of the overhead measurement results are shown in Table 5. On average, the additional memory consumption of FAMOS is only 8.58 MB for training and 3.95 MB for inference. CPU utilization increased by 23.77% during training and 16.36% during inference. Besides, the increase of battery consumption per hour is 1.32% for training and 0.48% for inference. These results demonstrate that FAMOS has a negligible impact on the Alipay system. Furthermore, FAMOS completes training in averagely 26.9 minutes (i.e., 1618K milliseconds) and requires 135 milliseconds for inference. Such overhead is acceptable for applications using TrustZone [49]. Note that the training stage only needs to perform once and is a one-time cost. According to the findings of prior works, when the inference time is less than one second, it will not harm the user experience [67], and can support online real-time services [69]. Thus, the overhead measurement demonstrate that FAMOS is practical in real-world deployment.

Usability. We hire the 24 volunteers of the in-lab dataset to conduct the study. Volunteers were asked to engage in three independent Alipay usage sessions in a randomized

Table 5: The overhead measurement of four devices.

Device	Memory (MB)		CPU (%)		Battery (%/h)		Time (ms)	
	Train	Infer	Train	Infer	Train	Infer	Train	Infer
Huawei Mate X3	8.42	3.94	23.83	16.21	1.34	0.52	1590K	132
Xiaomi 13 Pro	8.51	3.83	21.28	14.72	1.18	0.45	1542K	109
VIVO X100	8.74	4.11	25.11	17.61	1.22	0.51	1644K	143
Honor Magic 6	8.63	3.90	24.85	16.90	1.33	0.42	1698K	155
Average	8.58	3.95	23.77	16.36	1.32	0.48	1618K	135

order: one session using Alipay without FAMOS, one session with the training phase of FAMOS, and one session with the authentication phase of FAMOS. All the three sessions lasted for 10 minutes. Volunteers were not informed about which session they were currently participating in, and they were asked to carry out their usual activities as much as possible and to cover the five actions listed in Table 1. The goal of this user study is to investigate if there exist any obvious delays, including lags, freezes, or slowdowns during display, keystrokes, and button interactions. After each session, the volunteers complete a brief survey to provide feedback on the presence of delays. The first question in the survey is "Did you perceive any delays?" If the answer is "Yes," we ask further questions as "During which actions did you experience delays with the display/keystrokes/buttons?" "How significant was the impact of the delay?" and "How often did you experience delays?" We also record the response time of interactions in the three sessions to provide quantitative results.

21 out of 24 volunteers (87.5%) reported no noticeable delays. Two volunteers experienced about five instances of acceptable display delays during the training phase. One volunteer reported an experience about 10 instances of minor button press delays during training phase, stating that these were acceptable. For quantitative results, the average response time of interactions without FAMOS is 1242.43 milliseconds with a standard deviation (SD) of 979.22. The average response time of interactions during the training phase is 1502.63 milliseconds (SD is 1117.38), and the average response time of interactions during the authentication phase is 1263.85 milliseconds (SD is 994.84). To rigorously evaluate the user experience, we use Welch's t-test to conduct significance testing on the response times of the training phase and the authentication phase compared to the response times with FAMOS disabled. The null hypothesis is that there is no significant difference between the two sets of response times. The p-values for training and inference are 0.91 and 0.97, respectively. The p-values can not reject the null hypothesis ($p > 0.05$). Overall, these results indicate that users only experienced minor delays during the training phase, with no difference during the authentication phase.

6 Related Work

In mobile payment, user authentication is crucial for downstream services. While several approaches have been suggested, including passwords [55], SMS verification [54], and authenticators [46]. However, they often lack user-friendliness [23, 65] and are susceptible to sophisticated attacks [38, 64].

Researchers have studied various behavior patterns to authenticate users, such as touch gestures [13,24,68,74], motion sensor [3, 22, 27, 37, 40, 63], or correlated multi-modal feature [6, 9, 19]. AuthentiSense [23] and KedyAuth [30] are the latest works that leverage standard built-in sensors for continuous user authentication. They have two key limitations. First, they are not robust to actions under various background activities. Second, they rely on centralized training to learn user's behavioral biometrics, which violate users' privacy.

7 Discussion

Device-dependency implications. The four sensors used by FAMOS are commonly deployed in modern mobile devices and widely utilized in research related to user action patterns [30]. The data format generated by these sensors is generally consistent across different devices. Although there exist some differences in sensor data for different devices, such variation can be mitigated by the training process of FAMOS. Specifically, FAMOS employs local model training to enhance the accuracy and reliability of user authentication. The training process not only takes into account device-related variations but also aligns with the heterogeneity of sensor data in practice. Thus FAMOS is robust and effective across a variety of mobile devices.

Generalization. FAMOS is a general solution that can be integrated into other payment app due to two reasons. First, the four sensors used in FAMOS are commonly deployed in modern mobile devices and widely utilized in the research about user action patterns. Besides, the payment apps (e.g., AliPay and WeChat) have similar authentication requirements and interaction designs [71], allowing for the consistent deployment process of data collection, model training, and authentication.

8 Conclusion

In this paper, we introduce FAMOS to achieve robust privacy-preserving authentication. FAMOS integrates an attention mechanism to identify and utilize stable sensors, an action-aware model for clustering action-specific representations, and a residual DNN for effectively projecting representations. By incorporating the FL framework, FAMOS mitigates privacy concerns. Our comprehensive evaluation demonstrates FAMOS's effectiveness, significantly outperforming the SOTA with a 42.19% enhancement in F1-score and a 27.63% increase in AUC.

Abstract

We design a novel efficient membership inference attack to audit privacy risks in federated learning. Our approach involves computing the slope of specific model performance metrics (e.g., model's output and its loss) across FL rounds to differentiate members from non-members. Since these metrics are automatically computed during the FL process, our solution imposes negligible overhead and can be seamlessly integrated without disrupting training. We validate the effectiveness and superiority of our method over prior work across a wide range of FL settings and real-world datasets.

1 Introduction

Federated Learning (FL) [28, 35] enables multiple parties (namely, data holders) to train a global model collaboratively using their sensitive datasets, without sharing their data. While the training data remains unseen, the shared local updates can inadvertently leak substantial information about the local sensitive data [29, 31, 46], leading to *privacy concerns*. At the same time, recent data policies such as the European Union's General Data Protection Regulation (GDPR) [1] also legalize the safeguarding of data, including Data Protection Impact Assessment (DPIA). These situations underscore the pressing need for privacy auditing in federated learning, which has been widely used in sensitive domains [34, 41].

In this work, we study the problem of *auditing* privacy risk in federated learning, from the perspective of a participating party. Membership inference attack (MIA) [36] is a canonical framework for assessing such privacy risks in machine learning and has been adopted by popular machine learning platforms such as TensorFlow [1]. In particular, MIA ascertains whether a target data point was part of the training set, based on some metrics computed on it. Despite its comprehensive literature, existing MIA solutions often fall short of auditing privacy risks in federated learning. In FL, the adversary, who may be the server or a party, participates in the whole FL training process and observes multiple model snapshots during this process. How to extract membership information from the (sequence of) model snapshots effectively and efficiently is a challenging problem that is yet unsolved.

Most MIA solutions extract membership information from an isolated single model snapshot, leading to underestimation of privacy risks in FL (e.g., differentiate a member/non-member target point based on its loss computed on the final model [43]). On the other hand, an adversary in FL can observe multiple model snapshots through which the membership information gradually leaked in the FL process. Training a deep learning attack model to make use of all the observed information in FL such as the per-sample gradient/activation/loss history [31] demands substantial computation resources, potentially impeding FL. Such computation investment may also not be affordable for some parties in the first place. We provide a comprehensive review of the MIA literature in Section 3 about their limitations of privacy auditing in FL.

Free training attack. To address these limitations, we present the *free raining attack* (FTA) for auditing privacy risks in federated learning. Regarding efficiency, our solution does not need to train any additional complicated learning models or perform costly computations. It can be integrated by the parties seamlessly, without disrupting the FL process. In particular, FTA only takes the performance metrics of the FL model, such as the loss of the local training/validation datasets (which is already computed in the performance monitoring routine), as the inputs and performs elementary math operations on the inputs, incurring very little overhead. This flexibility, in turn, empowers the auditing party to choose her preferred means of privacy protection/intervention at any time to address the privacy risk she is facing. This is different from the traditional approach of applying a universal privacy-enhancing protocol to all parties throughout the entire process of FL, without understanding the empirical privacy risks that the parties face.

*Part of this work was done when the author was at Intel Corporation.

The effectiveness of our auditing algorithm relies on a simple but effective membership signal, called the *slope signal*. The slope signal exploits the fact that the model performances for members and non-members change at different speeds during the training process–the performance for members increases more rapidly, whereas the performance of non-members increases at slower rates. Our FTA predicts the membership of a target data point based on its slope signal computed across multiple FL model snapshots.

We validate the performance of our FTA on a wide spectrum of settings and real-world datasets. FTA outperforms the efficient baselines, which are also free of training additional models, by a clear margin. In addition, to our surprise, FTA also outperforms more costly baselines that train additional models. For instance, on the benchmark dataset CIFAR100, our FTA successfully identifies 54.4% of members while making only an error of 1%, outperforming all other baselines, which at most identify 15.2% of members under the same error. Supported by its effectiveness and efficiency, we use FTA to benchmark the privacy risks in different FL settings.

Enhanced auditing. Built upon the slope signal, we further enhance the performance of privacy auditing by integrating it with the strong centralized MIA algorithm which trains additional reference models [5, 42]. Such integration, however, is not trivial, as the parties in FL often have limited access to the underlying training data distributions, making it difficult to obtain reference models that emulate the target model well. To resolve this challenge, we incorporate knowledge transfer when training the reference models to force the closeness between the target model and the reference model. Validated on real-world datasets, our enhanced attack further improves the effectiveness of FTA, identifying 62.6% of members while making only an error of 1% on the CIFAR100 dataset.

2 Preliminaries and Problem Formulation

Federated learning and notations. We consider K parties in total. Each party $k \in [K]$ has access to her local dataset, denoted as S_k with $|S_k| = n_k$ where each data point of S_k is independently sampled from the underlying local data distribution π_k. In each round t ($t \in [T]$), the server sends the current global model $\bar{\theta}^t$ to all parties. Each party k updates the local model along the direction that minimizes the loss on her local dataset, written as follows, $\theta_k^{t+1} = \bar{\theta}^t - \eta \sum_{(x,y)\in S_k} \nabla \ell(\bar{\theta}_t; x, y)$, where ℓ is some pre-specified loss function and η is the local learning rate. Next, each party sends the local update to the server, which then computes a weighted average of the local updates, and obtains the new global model $\bar{\theta}^{t+1}$ as $\sum_{k\in[K]} \left(\frac{n_k}{N} \cdot \theta_k^{t+1}\right)$, where $N = \sum_{k\in[K]} n_k$.

Membership inference attack. The membership inference attack (MIA) aims to determine if a target point is used for training the target model. In particular, given a target point $z = (x, y)$ and the trained target model, the adversary outputs 0 or 1, predicting z as a non-member or a member, respectively. In the context of federated learning, an adversary's position can take one of two forms: it can either be the server or a participating party. An adversarial server can observe all local model updates from each party during the FL process as well as the global models, while an adversarial party is restricted to observing only the global model sent from the server. In either case, the adversary always has access to *multiple* model snapshots (local or global) across different FL rounds. We focus on semi-honest adversaries, who conduct passive inference attacks. Namely, the adversary infers membership without actively manipulating or interfering with the FL process.

Problem statement. Our goal is to design an algorithm for each party for auditing privacy risk during FL using MIA, explained as follows. Consider any round t, before sending the updated local model θ_k^{t+1} to the server, the party k may want to know how much privacy information has been leaked to decide if she/he still participates in the training process. To answer that question, the party runs an MIA algorithm and examines its effectiveness (i.e., accuracy) in distinguishing members and non-members with respect to her/his local dataset S_k. Higher accuracy indicates higher privacy risk, and vice versa. The MIA algorithm takes inputs from the global models sent from the server, namely, $\{\bar{\theta}^0, ..., \bar{\theta}^t\}$. In addition, when considering an adversarial server, the algorithm also takes inputs from the local updates shared by the party k, namely, $\{\theta_k^0, ..., \theta_k^t\}$. Our goal is to provide the party with an *effective and efficient* MIA algorithm so that the parties can obtain accurate privacy assessments on the fly without disrupting FL.

3 Prior Work

We review the existing representative MIA algorithms under different settings, followed by discussions on their limitations for auditing privacy in FL.

MIA in centralized setting. Adversaries under the traditional centralized setting attack the final model. When the adversary has *total access* to the parameters of the target model, we refer to this type of attack as *white-box attacks*. Nasr et al. [31] computes the gradient norm of the target data point (x, y) and decides it as a member if its norm is less than a certain threshold, and vice versa.

A more realistic threat model is when the adversary can only *query* the target model through APIs. We call such an attack a *black-box attack*. Given target (x, y), *Modified Entropy* [37] queries the confidence for the label predictions on x and computes $-(1-p_y)\log(p_y) - \sum_{y'\neq y} p_{y'} \log(1-p_{y'})$, where p_y is the confidence of the model on predicting y. The adversary decides (x, y) as a member if the score is less than a certain threshold, and vice versa. *Loss-based attack* [42, 43] queries the loss for the target data point (x, y), written as $\ell(\theta; (x, y))$. The adversary decides (x, y) as a mem-

ber if the score is less than a certain threshold, and vice versa. *Merlin* [18] compares the loss on the target point (x,y) with the losses on some other noisy examples with the same label y to get the membership scores. In particular, each noisy example is obtained as x perturbed with some random Gaussian noise. The score is computed as a simulation for $\mathbb{E}_{\xi\sim\mathcal{N}(0,\sigma^2 I)}\left[\mathbb{1}\{\ell\big(\theta;(x+\xi,y)\big)>\ell\big(\theta;(x,y)\big)\}\right]$. The adversary decides (x,y) as a member if the score is higher than a certain threshold, and vice versa.

Apart from black-box access, the adversary may also *train reference models*, hoping that the reference models can simulate the target model. The main idea is to train two sets of reference models, the IN models, which are trained with the target data point, and the OUT models, which are trained without the target data point. Then, the adversary compares the behaviors of the target model with the IN and OUT models and makes predictions. After obtaining the IN and OUT models, *LiRA* [5] computes the rescaled logit of the target data point (x,y) on the IN models and OUT models separately and fits two Gaussian distributions, denoted as $\mathcal{N}_{IN}$ and $\mathcal{N}_{OUT}$. Next, the adversary queries the rescaled logit r computed on target data point (x,y) using the target model and computes $\frac{\Pr[r \text{ is a sample from } \mathcal{N}_{IN}]}{\Pr[r \text{ is a sample from } \mathcal{N}_{OUT}]}$. The adversary decides (x,y) as a member if the score is higher than a certain threshold, and vice versa. *Distillation attack* and *reference attack* [42] only train the OUT models. After obtaining a set of reference models $\{\theta_{sh_1},\ldots,\theta_{sh_M}\}$. The adversary computes the fraction of reference models whose loss for the target data point (x,y) is larger than that computed on the target, written as $\frac{\sum_{m=1}^{M}\mathbb{1}\{\ell\left(\theta_{sh_m};(x,y)\right)>\ell\left(\theta;(x,y)\right)\}}{M}$. The adversary then decides (x,y) as a member if the fraction is higher than a certain threshold, and vice versa. Finally, [21, 25, 36] trains an additional attack model to differentiate the IN/OUT reference models, hoping that it will also perform well in differentiating whether the target data point is used or not for training the given target model.

Adaptation to FL and limitations. To adapt the aforementioned attacks to FL, the adversary runs attacks on the observed model snapshot in each round t independently. One major limitation of those attacks is their ineffectiveness. In particular, as the adversary only attacks one model snapshot at each round, she/he fails to exploit the membership information that is encoded in the incremental FL process, leading to an underestimation of the privacy risk. Moreover, the more advanced attacks in centralized settings often demand additional computation resources, e.g., for training reference models [5], and computing the per-sample gradient [31]. Such computation overhead burdens participating parties and also significantly slows down the FL process.

MIA in online learning setting. In the online learning setting, the target model is updated on the arrival of new data points in each round. Jagielski et al. [17] consider an adversary who has access to the *model snapshots* (before and after the updates) through APIs and is interested in the membership of the target data point in any datasets the model is trained on. This setting naturally applies to FL, where the adversary also observes multiple model snapshots. *Back-front attack* [17] computes the difference/ratio between the losses for the first model snapshot θ_0 and the final snapshot θ_T, namely, $\ell(\theta_0;(x,y))-\ell(\theta_T;(x,y))$ (or $\frac{\ell(\theta_0;(x,y))}{\ell(\theta_T;(x,y))}$). The adversary decides (x,y) as a member if the outcome is larger than a prefixed threshold, and vice versa. *Delta attack* computes the loss difference/ratio between model snapshots in *consecutive rounds*, namely, $\ell(\theta_{t-1};(x,y))-\ell(\theta_t;(x,y))$, or $\frac{\ell(\theta_{t-1};(x,y))}{\ell(\theta_t;(x,y))}$. The adversary decides (x,y) as a member if the loss difference/ratio at any two consecutive rounds is larger than the prefixed threshold.

Limitations. Although the above attacks utilize multiple model snapshots, the adversary's decision is ultimately determined using the information obtained from two rounds, rather than the entire FL process. As a result, they still fall short of effectiveness, as we will see in Section 5.

MIA in federated learning. Existing MIA solutions in FL settings leverage all snapshots of the models and we can directly apply them for privacy auditing. Nasr et al. [31] propose to train a *deep learning attack model*, which takes all the information one can compute on all model snapshots to make the prediction, including the concatenation of the per-sample gradient across all FL rounds. As the dimensions of such information change over time, in each round, a new attack model needs to be trained, demanding huge computation resources. Li et al. [22] find that, for overparameterized models, the *gradients* of different data points are nearly orthogonal. Based on this observation, they measure the cosine similarity between the gradient for the target data point and the local model update, written as $\frac{\langle\nabla\ell(\bar{\theta}_{t-1};(x,y)),\theta_t^k-\bar{\theta}_{t-1}\rangle}{\|\nabla\ell(\bar{\theta}_{t-1};(x,y))\|_2\|\theta_t^k-\bar{\theta}_{t-1}\|_2}$, where $\bar{\theta}_{t-1}$ represents the global model sent to the parties and θ_t^k represents the updated local model of party k. The adversary decides the target data point (x,y) as a member if the cosine similarity is larger than a threshold, and vice versa (according to their observation that the gradients of non-members should be orthogonal to those of members). Alternatively, the adversary can also compute $\|\theta_t^k-\bar{\theta}_{t-1}\|_2-\|\theta_t^k-\bar{\theta}_{t-1}-\nabla\ell(\bar{\theta}_{t-1};(x,y))\|_2$, and decide the target data point (x,y) as a member if the difference is larger than a certain threshold, and vice versa. The intuition is similar–when (x,y) is a non-member, the local update and the gradient on (x,y) are orthogonal, which gives the largest $\mathcal{L}_2$ norm $\|\theta_t^k-\bar{\theta}_{t-1}-\nabla\ell(\bar{\theta}_{t-1};(x,y))\|_2$.

Limitations. The main limitation of the above approaches is their computation overhead, as both approaches require computing per-sample gradients, which is far more expensive than local training itself. On top of that, the deep learning-based approach also trains different attack models at each round, further burdening the parties and slowing down FL.

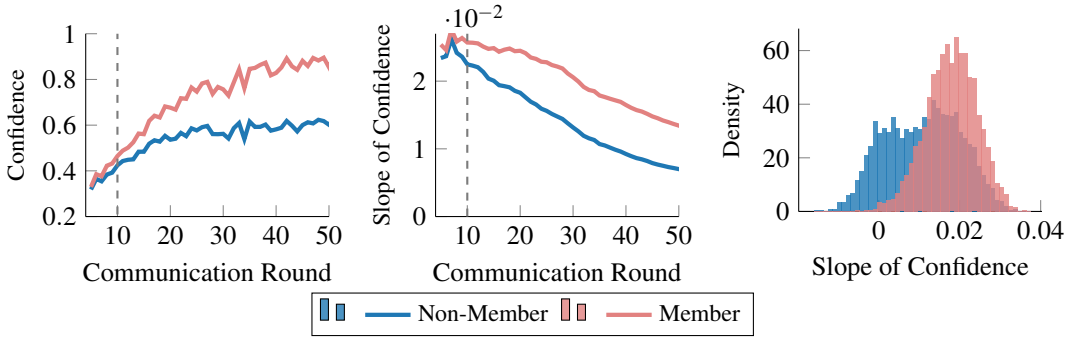

Figure 1: Prediction confidence trajectory of the local models on members and non-members, evaluated on the benchmark dataset CIFAR10. The left and middle figures show the prediction confidence and slope of the confidence for the members and non-members during FL rounds, respectively. The right figure shows the histogram of the slope of confidence for members and non-members at round 30.

4 Proposed Solution for Privacy Auditing

In this section, we present an effective and efficient MIA solution for auditing privacy, called free training attack (FTA).

4.1 Extracting Membership Efficiently

To avoid excessive overhead, an efficient MIA strategy is to compute some membership signal solely based on the target models and then compare it with some pre-fixed threshold, without computing high-dimensional statistics or training any additional models. The binary outcome of the comparison leads to the membership prediction.

Other than obtaining the model snapshots from different FL rounds, we note that in the standard FL routine, the parties also need to evaluate the model snapshots (namely, the target models from the adversary's perspective) on her/his local datasets, including the training and validation datasets, for monitoring the performance of FL. A (by)product of such evaluation is the calculation of the logit, confidence of labels, and losses of the data points. To be more specific, for each point (x,y) in the local training and validation sets, the party computes the outputs produced by the final network layer before the softmax function, which are referred to as the logit. Rescaled logit is referred to as the logit associated with the predicted label, normalized with respect to the values of other logit. A higher rescaled logit indicates that the model is more confident in the prediction confidence of the input data point. From the logit, the party proceeded to compute the prediction confidence and loss for the data point.

In what follows, we will present a membership signal that effectively extracts membership information from the above-mentioned performance statistics using straightforward arithmetic operations, thereby circumventing excessive computation overhead.

Trajectory of model performance. The foundation of our method hinges on a key observation–the differences between member and non-member data are revealed not only through the model's performance in isolated rounds but also through the performance trajectory leading up to each round. This is illustrated in Figure 1 (left), where we notice a marked difference in local model prediction confidence between members and non-members. This difference is manifested not just in the outcomes of each FL round but also in the *pace at which prediction confidence escalates*. In particular, members show a swift ascent in prediction confidence, whereas non-members (namely, the examples from the validation dataset) show a more stable rise.

Slope of trajectory. Building on this observation, we propose to use the rate of change in the model performance metric (namely, the slope) as the membership signal. In the middle of Figure 1, we plot the slope of average confidence for members and non-members. Just after the 10-th round, we observe a clear separation between them, and the separation remains noticeable in the final round. For a more detailed investigation, we draw the histogram of the slope signals for members and non-members at round 30 in the right of Figure 1. As the non-overlapping region of members and non-members is quite noticeable, the adversary could accurately infer membership based on this slope signal. Moreover, another advantage of such a membership signal lies in its simplicity of computation–computing the slope of a trajectory only involves elementary operations, as we will see later.

Next, we present how to extract the membership signal based on the trajectory of prediction confidence history. Consider any target data point (x,y) associated with the prediction confidence c_t at each round t, the slope up to the $t-$th round is computed as follows.

$$b_t = \sum_{u=1}^{t} w_u \cdot c_u, \tag{1}$$

where w_u is defined

$$w_u := 6 \cdot \frac{2tu - t^2 + 1}{t^4 - t^2}, \tag{2}$$

for u taking values from 1 to t. We refer interested readers to the well-established regression literature [8] for more detailed derivation.

Given our intuition, the value b_t for a member is expected to be larger than that for a non-member. Hence, the adversary decides the target data point as a member if b_t is larger than some threshold, and vice versa. Similar computations also apply to other performance metrics, such as rescaled logit and loss. Here we omit the formulations for brevity and their corresponding experimental results are shown in Section 5.

Summary. Our slope signal achieves effectiveness and efficiency at the same time. In Section 3, we have extensively discussed the limitations of adapting existing membership inference attacks for auditing privacy risks in federated learning from both effective and efficient perspectives. Compared to the centralized MIA solutions, where the membership signal is only computed on an isolated snapshot of the model, our slope signal captures the information that is encoded in the whole trajectory of the training. Compared to MIA solutions designed for online learning settings, our slope, instead of looking at the changes between two snapshots of the models, leverages the whole training trajectory for auditing. Compared to the solutions in FL, which require expensive computation, our slope signal can be computed very efficiently, as the parties only need to retrieve the performance metrics for each data point and compute a weighted average of these statistics across FL rounds.

4.2 Free Training Attack

Given the slope b_t computed on the target point, our free training attack strategy is straightforward, that is, comparing this value with a threshold. The output of our attack algorithm FTA, denoted as $\mathcal{A}_{\text{FTA}}$, is computed as follows:

$$\mathcal{A}_{\text{FTA}} := \mathbb{1}\Big[b_t \geq \tau\Big]. \tag{3}$$

Considering a set of target data points for privacy auditing, we note that for every selected threshold τ, there are two error types regarding the whole set of data. False Positive Rate (FPR) represents the fraction of non-members that are incorrectly identified as members, while False Negative Rate (FNR) represents the fraction of members that are incorrectly identified as non-members. Note that the auditor (namely, the participating party) has access to the ground truth for the membership of the target data points and hence, she/he can obtain the TPR and FPR. In practice, the auditor may be interested in a strict FPR tolerance γ such as 1%. To achieve that, we iterate through a spectrum of τ and pick the τ that results in the highest TPR with FPR below the tolerance γ. The highest TPR, constrained by the acceptable FPR, is reported as the privacy risk.

To avoid iterating infinitely many τ's from an unbounded range, in practice, the auditing party may select different quantiles (e.g., $1\%, 25\%, 50\%$) of some observed empirical distribution of the slope signal, e.g., on her/his local training/validation dataset, and use those quantiles as the candidates for τ. In the experiments, we use a non-overlapping dataset for computing such quantiles. As we will demonstrate, this dataset can be as small as $\frac{1}{50}$ of the training dataset, without affecting the performance of FTA. The above technique for determining the threshold τ for membership prediction is prevalent in the MIA literature [21, 22, 26, 42]. For a fair comparison, we adopt the above selection process of τ for all baselines and our solution in the empirical evaluation.

Adversary's observation. Regarding an adversarial party in FL, she/he could launch FTA based on the observed global model snapshots. On the other hand, regarding an adversarial server, she/he can launch two separate FTAs on the observed global and local model snapshots. To deal with the latter type of adversary, the auditing client may consider the higher attack performance (measured as TPR) as the privacy risk.

5 Empirical Evaluation

In this section, we evaluate the effectiveness and efficiency of FTA compared to existing baselines.

5.1 Baselines

Among many MIA solutions (see Section 3), we include the most representative ones as the competitors for our solution. For the attacks that were originally designed for other settings, we also adapt them to the FL setting. To ensure a fair comparison, we do not tune the hyperparameters in favor of any particular solution.

Efficient MIAs. Efficient attack algorithms that do not demand additional computation resources naturally fit as a good candidate for efficient privacy auditing in FL. We include the following ones as baselines in our evaluation: Modified Entropy [37], Population (01-Loss) [42, 43], Back-Front-Diff [16], and Back-Front-Ratio [16]. We also include the Fed-Loss that is also used in prior work [22]. Fed-Loss computes the average loss of the target data point across all FL rounds and predicts it as a member if the outcome is lower than a threshold.

Inefficient MIAs. We also include the algorithms which demand additional computation resources, including Merlin [18], Gradient Norm [31], Gradient-Cosine [22], and Gradient-Diff [22]. For Merlin, which evaluates the model

Table 1: Setup for experiments on the different datasets. For each setup, we uniformly split the datasets into four clients and use the Adam optimizer to train the local model.

performance on noisy perturbations of the input target data point, we follow the same hyperparameters as in the original implementation [18], which generates 100 noisy samples with $\sigma = 0.01$. For the Gradient Norm attack, we compute the norm in the last layer, as suggested in the original paper [31] since including more layers does not improve the performance of the attack. Gradient-Cosine and Gradient-Diff attacks [22] (recall Section 3) attack on a single layer only. To select the best layer to attack, they use a non-member dataset to find the layer that gives the smallest variance (across all data points) for the designated membership signal. In addition, for each target data point, they average the signals computed across different rounds and use that for predicting its membership. In our evaluation, we follow the same procedure.

Finally, as we have mentioned in Section 4.2, for all baselines, we also compute the membership signal on a non-member dataset to calibrate the threshold τ.

5.2 Setup

Dataset and model. Following prior works [5, 31, 42], we primarily focus on evaluating the two benchmark datasets CIFAR10 and CIFAR100 [20] and train a resnet56 model [10]. Besides, we also evaluate additional datasets in our extended experiments, including the Purchase dataset from Kaggle, the Texas hospital discharge dataset, the medical MNIST [3], the Pneumonia dataset, and the Retinal OCT image dataset [19], the CT Kidney dataset [13], and the skin disease dataset (http://www.dermnet.com/).

By default, we consider homogeneous data partitioning (in short, IID setting). For each dataset, we uniformly split it among 4 parties (we also provide ablation studies later). After data partitioning, each party takes 30% of their sampled data for training (referred to as members in privacy auditing) and another 30% for validation (referred to as non-members in privacy auditing). For the relatively small Pneumonia dataset, each party takes 40% of their sampled data for training and another 40% for validation. We train the models until convergence using FedAvg, the standard training algorithm used in FL [28], where each party trains the local model for one epoch and then sends the updated local model to the server. The detailed description of the model structures and hyperparameters is in Table 1.

Variants for FTA. For our FTA, we evaluate three of its variants on different model performance metrics, including the slope computed on loss, prediction confidence (in short, confidence), and rescaled logit (in short, logit). For loss, the members are expected to have a smaller slope than the non-members as the loss for members often decreases more rapidly compared with non-members. Accordingly, the direction of the inequality sign in Eq. (3) is flipped. We would also like to emphasize that due to the efficiency of our FTA, the auditing party can choose to assess the privacy risk using *all three variants* and use the *best performance* among all three variants as the estimation for the privacy risk.

Metrics. We are interested in two metrics, effectiveness and efficiency. The efficiency is measured by the time spent on the auditing in each round over the time spent on the local training in each round for one epoch. We measure the efficiency as the *GPU time* required for conducting the MIA/privacy auditing algorithm in each round. To ensure a fair comparison, the GPU time is computed with the same machine configuration with 1 NVIDIA Titan RTX GPU. On the other hand, the effectiveness is measured by the attack success rate. Following prior work [5, 42], we use the TPR at low a FPR as the measurement for effectiveness. A higher TPR at a low FPR indicates a better estimation of the privacy risks. All results are averaged across all parties over 5 independent runs. For clearer demonstration, in our experiments, we report the effectiveness results on the local and global models in separate figures and tables.

5.3 Main Results

We first compare our auditing algorithm with baselines based on privacy auditing for the local models (considering the adversarial server setting) with IID data partitioning on the benchmark datasets CIFAR10 and CIFAR100. We focus on the privacy risks with respect to the whole FL process (i.e., up to the final round). We compare the efficiency and effectiveness of different solutions in Table 2. We show the true posi-

Table 2: Effectiveness and efficiency of auditing the privacy risk for local models trained on CIFAR10 and CIFAR100 (abbreviated as C-10 and C-100, respectively). We focus on the local models with respect to the whole FL process and use benchmark datasets CIFAR10 and CIFAR100 (abbreviated as C-10 and C-100, respectively) with IID data partitioning. Efficiency is measured as the ratio between the GPU time used for auditing versus training. For each solution, we mark whether it uses multiple model snapshots by 'Final' or 'Multiple' in the 'Snapshots' column.

Algorithm	Snapshots	Efficiency	AUC		TPR @0.1% FPR		TPR @0.5% FPR		TPR @1% FPR	
		(C-10)	C-10	C-100	C-10	C-100	C-10	C-100	C-10	C-100

tive rate (TPR) at low false positive rates (FPR) (i.e., 0.1%, 0.5%, and 1%) and the area under the ROC curve (AUC). The best performance under each metric is bolded. We also measure the efficiency of auditing on CIFAR10.

As a reference, the GPU time for updating the local model for one round is around **2.3 seconds** (on average). For efficient MIA solutions, including our FTA and some baselines [16, 37, 42, 43], the additional cost is evaluating the model performance on the non-member dataset, which only takes around **1.2 seconds**. For Merlin [18], the additional cost is evaluating the model performance on 100 noisy versions of each point in both target and non-member datasets, which cost around **131.8 seconds**. For gradient-based approaches [22], the cost is computing the per-sample gradients for all samples in target datasets and non-member datasets, which cost around **860 seconds**. This is 373 times larger than the time spent on local training! Consider the case where FL takes 3 GPU hours with 4 parties. Using the auditing algorithm based on gradient information will slow down FL to more than 46 GPU days when simulating FL and auditing the privacy risk for each party, which may prevent researchers from understanding the risks in FL.

Regarding effectiveness, our FTA surpasses all the baselines by a significant margin. Notably, FTA achieves a TPR of 43.2% on CIFAR100 when FPR is 0.5%, which is more than 10 times higher than the best performance achieved by the gradient-based baseline [22]. On CIFAR10, our FTA achieves a TPR of 9.22% when FPR is 0.5%, which is 7 times larger than the best performance [22]. As claimed in the original paper [22], the key observation of the gradient orthogonality is highly dependent on the model structure. Furthermore, only after enough training epochs will the overparameterized model gradients of different data points be nearly orthogonal. Such limitations may contribute to the performance gap between our FTA and [22]. In addition, [22] requires more than 700 times more computation resources than our FTA.

Compared with efficient baselines, our improvement in effectiveness is even more significant. While FTA achieves a TPR of 43.2% on CIFAR100 when FPR is 0.5%, the most efficient baseline [17] only achieves a TPR of 0.8%. Although multiple model snapshots are utilized in [17], they are still processed in an isolated manner. In contrast, our FTA exploits the membership information from the entire FL trajectory, leading to much higher effectiveness. In conclusion, FTA not only stands out as the most effective approach in our experiments, but it also maintains this superior performance without imposing any significant computational burden, establishing itself as a practical auditing algorithm accessible to any party in FL.

Auditing global models. We next present the effectiveness results for auditing the privacy risk of the global models Table 3. For each solution, as the computation for auditing privacy is necessarily applied to the global model instead of the local model, the efficiency remains the same, and hence, is omitted from the table. We also omit the baselines, which give 0 for all settings. As we can see from Table 3, our FTA still outperforms the baselines, by a large margin. In addition, compared with the results for auditing local models in Table 2, our FTA can be more effective for auditing global models. We suspect

Table 3: Effectiveness of auditing global models on CIFAR10 and CIFAR100 with IID data partitioning.

	TPR@0.1%FPR		TPR@0.5%FPR	
Algorithm	CIFAR10	CIFAR100	CIFAR10	CIFAR100
Population	0.00%	0.00%	0.00%	1.76%

FTA (logit)	0.04%	0.22%	0.31%	4.31%

Table 4: Effectiveness of FTA (confidence) for auditing global models under different sizes of non-member set for selecting the threshold τ. We measure TPR when FPR is fixed at 0.5%.

Non-member Dataset	Size of Dataset						
	100	500	1000	2000	3000	4000	5000
CIFAR10	0.5%	5.5%	6.1%	6.3%	6.3%	6.5%	6.5%
SVHN	0.0%	0.0%	0.0%	1.8%	3.2%	3.8%	3.9%

that this is because, for global models, the performance trajectory is more stable, leading to a more stable slope signal for inferring membership. We support this hypothesis with Figure 2, where we plot the average prediction confidence of the global model and the local models on members and non-members. As we can see, the confidence for the global model is more stable, whereas there are more fluctuations for the local model. Finally, as we have discussed in Section 4.2, when auditing the risks with respect to a malicious server, the actual privacy risk should be computed as the *higher* one between the local and global model snapshots, as the adversary can observe both during FL process.

5.4 Ablation Studies and Extended Results

Effect of the validation data. Recall from Section 4.2 that, our FTA uses a non-member dataset for selecting the threshold τ. We first show how the size of this dataset influences the performance of our FTA (confidence) in Table 4. Remarkably, only 500 data points of CIFAR10 are enough for effective privacy auditing, achieving a TPR of 5.9% with an FPR of 0.5%, for the CIFAR10 dataset. As a reference, the best TPR of the baselines is only 1.4%. This suggests that parties need not reserve large validation datasets for auditing, further underscoring the practicality of the FTA approach. Instead of taking validation data from the target dataset CIFAR10, the auditor party may also use data from external sources, such as SVHN [33], to audit the privacy risk regarding CIFAR10. In particular, FTA produces a TPR of 3.9% with an FPR of

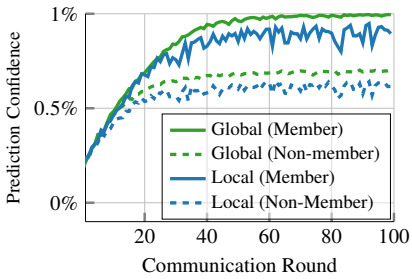

Figure 2: Prediction confidence of local and global models on CIFAR10 with IID data partitioning.

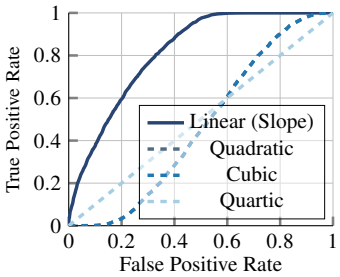

Figure 3: Comparison of fitting different polynomial functions for privacy auditing.

0.5%. This observation also suggests the high applicability of FTA even when access to validation data is limited.

Effect of linear fitting. In our approach, we have modeled the performance history as a linear function with respect to the FL round t. However, one might consider fitting other types of functions to the performance history, such as the quadratic function represented by $\ell_t = a + b \cdot t + c \cdot t^2$. To explore such kinds of alternatives, we apply more complex functions from the polynomial function family, including the quadratic (second-order function of the FL round t), cubic (third-order), and quartic functions (fourth-order), on the loss history. The results are shown in Figure 3. Interestingly, the application of more complex functions, as opposed to linear ones, appears to reduce the effectiveness of the attacks (the curves of quadratic and cubic functions overlap). This finding is remotely related to the Neural Tangent Kernel theory, highlighted by Jacot et al. [14], which posits that model outputs may evolve linearly during training.

Equipped with the powerful and efficient auditing tool of FTA, we further evaluate the privacy risks in FL under different settings. The following results are based on auditing the global models.

Results on different data partitioning settings. We vary the size of the local datasets in each party from $\frac{N}{10}$ to $\frac{N}{100}$ (N is the overall number of training data points) and the overall number of participating parties from 10 to 100 for the CIFAR10

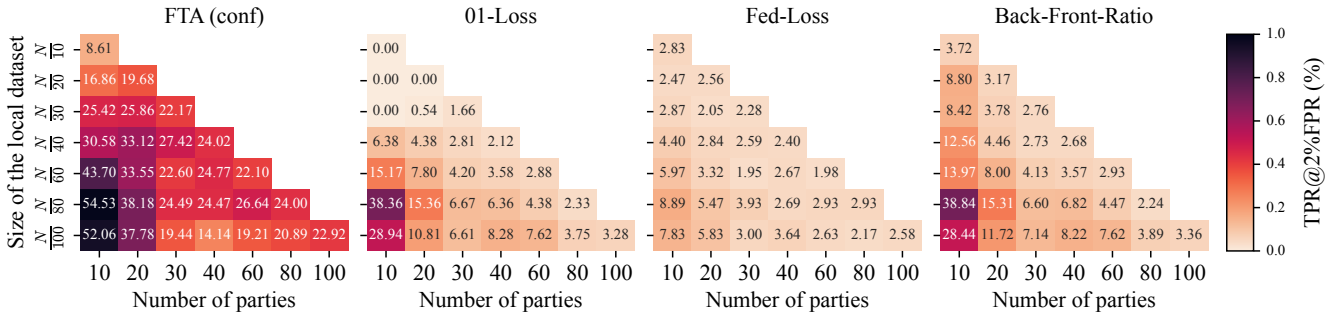

Figure 4: Effectiveness of auditing global models with varying numbers of parties and sizes of local datasets.

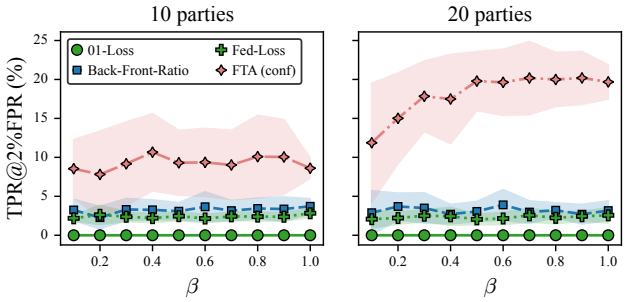

Figure 5: Effectiveness of auditing global models on CIFAR10 with varying data discrepancies. The error bar is computed on the standard deviation across all parties.

dataset with IID data partitioning. Overall, there are 28 different settings. We include results of the Back-Front-Ratio baseline, which achieves the best performance compared to the Back-Front-Diff, Delta-Diff, and Delta-ratio baselines. We have omitted the expensive baselines due to their timely costs. We present the resulting TPR at FPR 2% for different solutions for auditing the global models (as there are fewer data points, we increase the FPR tolerance) in Figure 4.

First, we note that our method outperforms the baselines *in all settings*, as indicated by the colors. Next, we fix the number of parties while reducing the size of local datasets (inspect each column separately), and observe an increase in privacy risks. This is because when the training dataset size is smaller, each data point has a larger impact on the model, leading to a higher privacy risk. In addition, we fix the size for each party while increasing the number of parties in FL (inspect each row separately), and observe a decrease in the privacy risks. For instance, when each party has $\frac{1}{100}$ of the whole training dataset, increasing the number of parties from 10 to 100 reduces the TPR of FTA (confidence) by almost a half (from 52.1% to 22.9%). Both results highlight the benefit of having more parties/data points in FL to reduce privacy risks.

Discrepancy in local datasets. We evaluate how the data discrepancies in the parties' local datasets may affect the privacy risk. Specifically, we consider the common heterogeneous setting (in short, non-IID setting). In particular, for each label $y \in \mathcal{Y}$, the distribution for the number of local samples of label y among parties is controlled by the Dirichlet distribution, as is done in prior works [24, 40, 44]. We use $\mathrm{Dir}_K(\beta)$ to represent a K-dimensional Dirichlet distribution of parameter β. Here, K represents the number of parties and β controls the degree of heterogeneity. For every class y, we first sample as $p_y \sim \mathrm{Dir}_K(\beta)$. Next, each dimension in the vector p_y is used to allocate a proportion $p_{y,k}$ of instances that belong to class y, to party k. This partitioning strategy was initially introduced by [44] and has been subsequently employed in several recent FL studies, e.g., [24, 40].

We fix the whole training dataset of CIFAR10 size and set the number of parties to 10 and 20. In both setups, we vary the discrepancy parameter β from 0.1 to 1.0. A smaller β indicates higher data discrepancy in class labels among the parties' partitions for CIFAR 10, and vice versa. When $\beta = 1.0$, it is the same as the setting of IID data partitioning.

In Figure 5, we report the performance (measured as TPR when FPR is fixed at 2%) using our FTA (confidence) as an illustration. The first observation is that the variance of privacy risks for parties is larger in the non-IID partitioning ($\beta < 1$) than in the IID setting ($\beta = 1$). This indicates that in FL with heterogeneous local data, parties are experiencing different levels of risk, especially in the Non-IID setting. The average privacy risk also reduces when increasing the discrepancies in the data between the parties. Such an effect cannot be observed using the existing baselines. These findings further highlight the importance of having an efficient and effective auditing algorithm that is available for all parties.

Varying model structures. We include the results for different models on CIFAR10 with IID data partitioning for 4 parties. Specifically, we consider three CNN models (with 16, 32, and 64 convolutional filters), and three Wide ResNets (WRN) with widths 1, 2, and 10. The results are shown in Figure 6. Under all setups, our FTA (confidence) consistently achieves the highest performance, highlighting the wide appli-

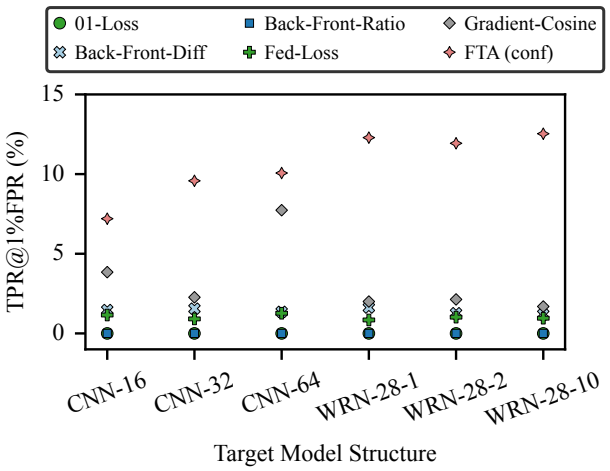

Figure 6: Effectiveness of auditing global models with different model structures.

cability of the *slope signal* regardless of the model structure. In addition, with more complicated models, the privacy risks increase. This is aligned with the observations in [5].

Auditing FedSGD. So far, our focus is on the FL algorithm of FedAvg. Next, we audit the privacy risk in FedSGD. We implement the FedSGD based on canonical settings, where each party computes the gradient on her/his local dataset and shares the gradient with the server in each communication round. We train the model on CIFAR10 that is uniformly partitioned among 4 parties for 2000 communication rounds. Regarding the evaluation of attack algorithms, we have omitted the gradient-based approaches in [22], which compute individual gradients and cost almost 20 GPU days in total (as a comparison, our FTA only costs 0.66 GPU hours in total). The results for auditing the global model are shown in Table 5. We have neglected the baselines that perform close to random guessing. Overall, our FTA (confidence) consistently achieves much better performance under all settings. In addition, we note that the privacy risk for FedSGD is low. We suspect this may be contributed by the fluctuations in training (as demonstrated in Figure 8 in Appendix). In particular, for members and non-members, the model performs similarly at each FL round. However, we note that FedSGD does not obtain a model with high accuracy. Even with 2000 rounds, the test accuracy for the model is 0.536. Due to the unsatisfactory model performance and large communication costs, we suspect that FedSGD is not an interesting subject to study for privacy-preserving FL.

Different datasets. We show the performance of our FTA (confidence) and different baselines for auditing the global models on the nine datasets introduced in Section 5.2 in Table 6. Overall, the results show that our FTA consistently

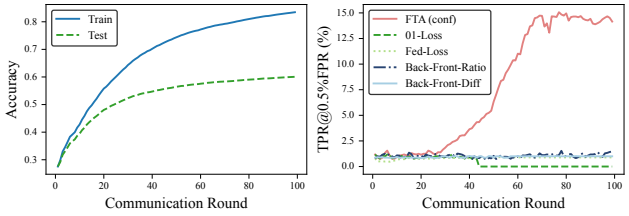

Figure 7: Classification accuracy of the global model and effectiveness of auditing global models during training on CIFAR10 with IID partitioning.

archives the best performance on *almost all datasets*, except for one trivial case where the inherent privacy risk is low. To be more specific, on the relatively easy dataset Medical-MNIST, the highest AUC is 0.51, which is only slightly better than random guessing (corresponding to an AUC of 0.5); and the highest TPR is 2.11% which is also only slightly better than the random baseline of 2%. Despite such a trivial case, the results demonstrate the universal effectiveness of our proposed FTA on different datasets and model structures. Such a difference in the privacy risks also highlights the importance of having an efficient auditing tool that is applicable to all kinds of datasets and model structures.

Privacy risks dynamics. Finally, we fix the FPR to 0.5% and see how the TPR varies as the training proceeds in FL. We focus on CIFAR10 with IID partitioning. From Figure 7, we see that FTA outperforms other baselines. Comparing the model performance (train and test accuracy) in Figure 7 (left) with the exhibited privacy risk in Figure 7 (right), we find that while the train and test accuracies of the global model stop rising at some point, the attack performance of our FTA (confidence) continues to increase. On the contrary, the TPR of other baselines barely changes over time. This further provides evidence that the proposed *slope signal* is a robust membership indicator throughout the FL process and also highlights its applicability, in particular, for discovering

Table 6: Effectiveness of auditing the global models on different datasets. We report the AUC and the TPR when FPR is fixed at 2%. When FPR is fixed at 2%, the random-guessing baseline for TPR is 2%.

the privacy risks in late training phases.

6 Enhanced Auditing

Certain parties in FL may invest more computation resources in exchange for a more accurate assessment of the privacy risk. To that end, we propose a more advanced solution that is built upon the *slope signal*, called Knowledge Transfer Attack (KTA), which combines the existing state-of-the-art centralized MIA algorithm [5] and our *slope signal*. We show that KTA further improves the effectiveness of FTA, validating the effectiveness and broad applicability of the *slope signal*.

6.1 Algorithm

Adapting slope signal to reference model attack. The original idea of [5] is to train reference models that simulate the behavior of the target model. In particular, they first obtain a set of reference models, referred to as the IN models, using datasets with the target data point; and then train another set of reference models, referred to as the OUT models, using datasets without the target data point. Next, the most straightforward way to decide if the target model was trained using the target data point is to look at the distributions of model parameters of the IN and OUT models, and then determine which distribution the target model's parameters are sampled from.

Indeed, estimating the distribution for the whole model parameters is intractable in practice. Thus, existing solution [5] estimates the distributions of the rescaled logit in the IN and OUT models, referred to as IN and OUT distributions (for rescaled logit). The adversary can query the rescaled logit on the target model and determine whether it is a sample of the IN or OUT distribution.

Now we adapt our proposed *slope signal* to this process for auditing privacy in FL. Without loss of generality, we focus on the performance metric of loss. In particular, the adversary fits two Gaussian distributions to the empirical slope of loss distributions for the IN and OUT reference models, and then determines which one is more likely–the slope computed for the target data point on the target model (referred to as the target slope) is sampled from the IN distribution or the OUT distribution. As we will explain next, such an adaptation is highly non-trivial in FL settings.

Improved training. In practical FL settings, the auditor can only train reference models using her/his own dataset, whereas an adversary may also have access to other datasets, leading to difficulties in obtaining IN and OUT reference models with fidelity. Consider an extreme case: party 1, tasked with auditing, possesses only truck images from CIFAR10, while other parties hold images of dogs. Accurately estimating the true slope distributions demands data access to both truck and dog images whereas the auditing party, could only obtain models relying on the truck image.

In what follows, we overcome this challenge by adding a regularization that *forces* the local reference models trained on truck images only obtained by the auditing party to be similar to the models trained on both images. In each round t, given the observed target model θ^t, the auditor trains the reference model θ_s to optimize the following objective.

$$\min_{\theta_s}(1-\alpha)L(\theta_s;S_{sh})+\alpha R(\theta_s,\theta^t), \tag{4}$$

where the S_{sh} represents the dataset used for training the local reference model (termed as reference data) and R is a regularizer that measures the closeness between the reference model θ_s and the target model θ^t. The overall objective is to minimize the reference model's loss on the reference data and the distance between the reference model and the target model at the same time. Parameter α controls the relative level of importance of the two minimization objectives. We study the effect of α is studied in our evaluation.

Choice of the regularizer. The regularizer R serves the objective of aligning the reference model closely with the target model based on the model outputs, which is a critical aspect

of knowledge transfer (KT). The idea of KT is to transfer knowledge from a larger model to a smaller one, even in the absence of shared training data. Among the literature, the Knowledge Distillation (KD) regularizer [11], which employs the Kullback-Leibler divergence [38], to measure the output distribution discrepancies between the two models, is particularly effective. We adopt this measurement as our choice of R in Eq. (4).

Optimizing training efficiency. To save the computation time for obtaining reference models, in each round t, the auditor fine-tunes the reference models from the previous round, instead of training from scratch. Accordingly, the reference models are updated as follows.

$$\theta_s^{t+1} = \theta_s^t - \eta\Big((1-\alpha)\nabla L(\theta_s^t; S_{sh}) + \alpha\nabla R(\theta_s^t, \theta^t)\Big), \quad (5)$$

where η is some pre-fixed learning rate, and θ_s^t and θ_s^{t+1} represent the old and newly-updated reference model at round t, respectively.

Knowledge transfer attack. We put everything together and present the complete attack procedure called Knowledge Transfer Reference Attack (KTA). Specifically, the party samples multiple reference datasets such that each point in the target dataset (union of local training and validation datasets) is included in exactly half of the reference datasets. Then the party trains one reference model for each reference dataset. This ensures that the target point is used by exactly half of the models (i.e., IN models) and not used by the rest (i.e., OUT models). The party computes the slope for the target point for all reference models. Based on the computed slope from the IN and OUT models, the adversary fits two Gaussian distributions, referred to as the IN Gaussian and OUT Gaussian distributions. As shown in Figure 1, the empirical distributions of the slope indeed look like Gaussian distributions. The idea of fitting the empirical distribution to a Gaussian was also used in [5]. Lastly, given the estimated slope distributions, we compute the likelihood that the target slope is a sample from the IN Gaussian and the OUT Gaussian and make the corresponding membership prediction. Our KTA relies on using the slope signal and apply knowledge distillation regularization for training the reference models, which are also compatible with recent more advanced reference model based attacks in centralized settings, including [45].

Comparison with [42] and [5]. Knowledge distillation is also employed by Ye et al. [42] and Liu et al. [25] for MIA in the centralized setting with a single target model (the final model). The main difference is that our KTA extracts membership information from multiple model snapshots. To further optimize efficiency, we repeatedly fine-tune reference models from previous rounds, instead of training models from scratch. Due to the high computational demands of Liu et al.'s method in auditing privacy risks in FL (recall Section 3), we exclude this baseline from our experiments. The original approach in [5] does not involve the regularizer. Namely, the only objective is to minimize the loss of the reference model on the reference dataset. As we will see next, such a design is unfavorable under the FL setting, compared with training reference models with regularization.

6.2 Empirical Results

Setup. The evaluation setup is the same as in Section 5. We empirically compare KTA with existing baselines with the existing state-of-the-art attacks [5, 42] in the centralized setting, both of which train reference models. For the baselines and our KTA, we train 16 reference models in total using the same optimizer and model structure as in Section 5. In practice, if parties possess greater computational resources, they can enhance their estimation of privacy risks by increasing the number of reference models, as demonstrated by the findings in [5]. By default, we set α as 0.8, which consistently performs better than other values across different settings.

Results. Table 7 summarizes the effectiveness results of our algorithms and the baselines on auditing local models trained on CIFAR10 and CIFAR100 under IID data partitioning, considering the whole FL process. We also include the best performance of FTA (among loss, confidence, and rescaled logit) for comparison.

Overall, our KTA outperforms the baselines [5, 42] under all settings. Among the three model performance metrics, confidence and rescaled logit lead to the highest performance for KTA. For example, on CIFAR100, KTA (rescaled logit) achieves a TPR of 32.4% with an FPR of only 0.1%, which is ten times larger than that of LiRA. The same conclusion applies to the same datasets with non-IID partitioning, as shown in Tables 9 in Appendix B.

Both LiRA and distillation attacks require training reference models, which cost about 76 GPU seconds to fine-tune reference models in each round. Note that we have applied the fine-tuning strategy for obtaining the reference models in each round (without it, the overall cost would be $76t$ GPU seconds at the t-th round). Our KTA costs about 94 GPU seconds to fine-tune reference models in each round. The additional 20 seconds is for calibrating our model to the regularizer. As a comparison, our FTA, which does not train any reference model, only costs around **1.2** GPU seconds. Despite such expenses, these baselines still perform worse than FTA. As we have mentioned, this is, again, attributed to the fact that our *slope signal* effectively exploits the membership information across FL rounds, whereas the compared baselines, which attack only one model snapshot, fail to extract such information.

Effect of parameter α. We study the effect of α, the param-

Table 7: Effectiveness of auditing local models with IID data partitioning. We show the TPR at low FPR rates, 0.1%, 0.5%, and 1%, as well as the AUC (area under the ROC curve). The highest performance under each setting is bolded.

Algorithm	AUC		TPR @0.1% FPR		TPR @0.5% FPR		TPR @1% FPR	
	CIFAR10	CIFAR100	CIFAR10	CIFAR100	CIFAR10	CIFAR100	CIFAR10	CIFAR100
FTA	**0.817**	0.975	5.0%	12.8%	9.2%	43.2%	12.9%	54.4%
Distillation [42]	0.608	0.583	1.0%	0.1%	2.1%	1.1%	3.7%	2.1%
Lira [5]	0.721	0.882	2.2%	3.1%	6.1%	6.9%	8.3%	15.2%
KTA (loss)	0.788	0.943	4.7%	7.0%	8.4%	19.1%	11.8%	29.4%
KTA (confidence)	0.796	0.975	**5.0%**	18.6%	**11.3%**	46.6%	**15.5%**	56.4%
KTA (logit)	0.682	**0.983**	3.0%	**32.4%**	9.6%	**53.5%**	12.5%	**62.6%**

Table 8: Effectiveness of KTA under different parameter α. We show the TPR when FPR is fixed to 0.5%.

Dataset	Partition	α					
		0	0.2	0.4	0.6	0.8	1.0
CIFAR10	IID	6.6%	6.8%	7.3%	9.4%	11.7%	3.1%
	Dir(0.5)	3.0%	5.3%	4.1%	4.7%	5.8%	1.1%
	Dir(0.1)	1.8%	2.1%	2.8%	2.7%	3.7%	0.9%
CIFAR100	IID	41.5%	46.8%	50.0%	49.6%	46.1%	25.4%
	Dir(0.5)	51.6%	51.7%	51.8%	51.1%	51.4%	26.3%
	Dir(0.1)	35.7%	43.0%	41.8%	37.8%	35.4%	19.6%

eter that controls the level of regularization in KTA. Recall Eq. (4), larger α means that we want the reference model to behave more similarly to the target model rather than to achieve minimal loss on the reference training dataset. The effectiveness results under different choices of α are shown in Table 8.

We first examine two extreme cases, $\alpha = 0$ and $\alpha = 1$. When $\alpha = 0$, a reference model is trained to minimize the loss on the reference dataset only (similar to LiRA [5]); and when $\alpha = 0$, the models are trained to minimize the distance between the reference model and the target model only (similar to [42]). We note that choosing $\alpha \in (0, 1)$ leads to better effectiveness. For instance, while the straightforward adaptations of LiRA and distillation attack using the *slope signal* achieve 41.5% and 25.4% TPR (with FPR fixed at 0.5%) on CIFAR100 with IID data partitioning, our KTA with $\alpha = 0.4$ further improves TPR to 50.0%. Recall from Table 7 that the original TPRs of Lira and distillation attack are lower than 7% for the same setting. Such performance improvement of KTA highlights the effectiveness of using **(i)** the *slope signal* and **(ii)** the *regularizer* for reference model training.

7 Other Related Works

We review the other directions in privacy-preserving federated learning.

Other privacy risks. Other than membership information, there are also other types of privacy risks in FL [7, 12, 23, 29, 46]. For instance, the adversary may also try to reconstruct the training data [4, 6, 9, 46] or infer the properties (e.g., label distribution [39]) of the training data. Auditing such privacy risks are left as future work directions.

Auditing DP algorithms. Auditing the differentially private (DP) algorithms aims to ensure that the algorithm preserves the privacy levels as claimed [2, 15, 27, 30, 32]. This line of work differs from ours in the sense that DP considers the *worst case* scenario, preventing the adversary from distinguishing any *any* pair of neighboring datasets with high confidence. In contrast, our auditing algorithm focuses on the empirical privacy risk that can be exploited by an adversary who is computationally bounded.

8 Conclusion and Future Work

We study privacy auditing for federated learning. We propose to use the *slope signal* to extract membership information from the training trajectory of FL. Built upon it, we propose FTA, which simultaneously achieves high effectiveness and efficiency for auditing privacy in FL, without disrupting the training process. We also propose an enhanced auditing algorithm called FTA, catering to parties who want to invest more computational power for a more accurate assessment of privacy risks. KTA further improves the performance of FTA, by incorporating the slope signal with the knowledge distillation technique.

For future work, we plan to utilize our solution to assess the privacy risks under different FL scenarios, including auditing the risks in personalized FL. Further improving the effectiveness of the slope signal is also a promising direction.

A Full Description of Algorithms

For completeness, we present the detailed algorithmic description for FTA and KTA as in Algorithms 1 and 2. For KTA, the adversary trains reference models such that the target point is included in exactly half of the models (i.e., "IN" models) and excluded in the rest (i.e., "OUT" models) and computes the slope for the target point for all reference models (Lines 3-11 in Algorithm 2). Based on the computed slope from the "IN" models and "OUT" models, the adversary estimates the slope distributions for the target point when it is in and not in the training dataset. As we show in Figure 1, the slope distribution looks like a Gaussian. Therefore, we fit the slope distribution into a Gaussian distribution, whose mean and variance are the empirical mean and empirical variance of the slope computed on the "IN" models and the "OUT" models) (Lines 13-16 in Algorithm 2). The idea of fitting the empirical distribution to a Gaussian was also used in [5]. Lastly, given the estimated slope distributions, we compute the likelihood ratio based on two distributions to determine if the point is used for training or not.

Algorithm 1 Free Training Attack (FTA)

Input: A sequence of models $\theta^1, ..., \theta^t$, the target point z, data population pool π (can be a subset of the validation dataset).

1: Let $\mathcal{B}_{pop} = \{\}$
2: $b_{obs} = B((\theta^1, ..., \theta^t), z)$ ▷*Initialize the membership signal set for non-members*
3: **for** M times **do**
4: $\quad z_{pop} \leftarrow \pi$ ▷*Sample a non-member from the distribution*
5: $\quad b_{pop} = B((\theta^1, ..., \theta^t), z_{pop}, \phi)$ ▷*Compute the slope of the signal for the non-member*
6: $\quad \mathcal{B}_{pop} = \mathcal{B}_{pop} \cup \{b_{pop}\}$ ▷*Update the membership signal set for non-members*
7: **end for** ▷*Compute the slope of the signal for the target data*
8: **return** $\frac{|\{b_{pop} \in \mathcal{B}_{pop} : b_{pop} \leq b_{obs}\}|}{|\mathcal{B}_{pop}|}$ ▷*Compute the likelihood that the target point is a non-member.*

B Additional Experiments

Datasets. For completeness, we describe the additional datasets we have used beyond the CIFAR datasets. For all datasets, we follow the same pre-processing as in [22].

Purchase: Derived from Kaggle's "acquire valued shopper" challenge, the dataset includes records for thousands of individuals and is processed as described in [36]. It features 600 binary attributes per instance, is divided into 100 classes, and contains 197,324 instances in total. This dataset is commonly utilized to assess membership inference attacks, employing the neural network model from [31].

Texas: The dataset comprises hospital discharge records published by the Texas Department of State Health Services and features information on inpatient stays across multiple facilities. This processed dataset, as described in [36], contains 67,330 records with 6,170 binary features representing the 100 most frequent medical procedures. It is divided into 100 classes, each corresponding to a different patient type, and is employed to evaluate membership inference attacks.

Medical MNIST [3]: The dataset contains $58,954$ MNIST-style medical images in 64×64 resolution across six classes. We sampled a balanced dataset with $53,724$ images, each class having $8,954$ images, and resized all images to 32×32.

Pneumonia [19]: The dataset consists of Chest X-ray images from pediatric patients aged one to five at Guangzhou Women and Children's Medical Center. We sub-sample a balanced dataset of $3,166$ X-rays, originally varying in size, and uniformly resize images to 64×64.

Retinal OCT Image [19]: The dataset includes $84,492$ high-resolution retinal OCT images for diagnosing conditions across four classes: CNV, DME, DRUSEN, and NORMAL. We sampled a balanced training set with $35,472$ images. We resize images to 64 uniformly because the original images

Algorithm 2 Knowledge Transfer Reference Attack (KTA).

Input: A sequence of models $\theta^1, ..., \theta^t$, the target point z, the data population pool π of target party k^* (the union of the local training and validation datasets).

$\mathcal{B}_{in} = \{\}, \mathcal{B}_{out} = \{\}$ ▷*Initialize the membership signal sets for the IN models and OUT models*
$b_{obs} = B(\{\theta^1, ..., \theta^t\}, z)$ ▷*Compute the slope of the signal on the target point from the target models*
for N times **do**
  $S_{sh} \leftarrow \pi^{n_{sh}}$ ▷*Sample a reference dataset of size n_{sh}*
  $\theta^1_{in}, \theta^2_{in}, ..., \theta^t_{in} \leftarrow \mathcal{T}_{sh}(\{\theta^1, \theta^2, ..., \theta^t\}, S_{sh} \cup \{z\})$ ▷*Train a reference model with the target point using Algorithm 3*
  $b_{z,in} = B(\{\theta^1_{in}, \theta^2_{in}, ..., \theta^t_{in}\}, z)$ ▷*Compute the slope of the signal based on the IN reference model*
  $\mathcal{B}_{in} = \mathcal{B}_{in} \cup \{b_{z,in}\}$ ▷*Update the membership signal set for IN models*
  $\theta^1_{out}, \theta^2_{out}, ..., \theta^t_{out} \leftarrow \mathcal{T}_{sh}(\{\theta^1, \theta^2, ..., \theta^t\}; S_{sh})$ ▷*Train a reference model without the target point*
  $b_{z,out} = B(\{\theta^1_{out}, \theta^2_{out}, ..., \theta^t_{out}\}, z)$ ▷*Compute the slope of the signal based on the OUT reference model*
  $\mathcal{B}_{out} = \mathcal{B}_{out} \cup \{b_{z,out}\}$ ▷*Update the membership signal set for OUT models*
end for
$\mu_{in} = \texttt{mean}(\mathcal{B}_{in})$ ▷*Model the slope distribution for IN models and OUT models using Gaussian distributions*
$\sigma^2_{in} = \texttt{var}(\mathcal{B}_{in})$
$\mu_{out} = \texttt{mean}(\mathcal{B}_{out})$
$\sigma^2_{out} = \texttt{var}(\mathcal{B}_{out})$
Return $\Lambda = \frac{p(b_{obs}|\mathcal{N}(\mu_{out}, \sigma^2_{out}))}{p(b_{obs}|\mathcal{N}(\mu_{in}, \sigma^2_{in}))}$ ▷*Compute the likelihood ratio of the target point based on estimated distributions*

Algorithm 3 Reference model training algorithm $\mathcal{T}_{sh}$.

Input: A sequence of target global models $\bar{\theta}^1, ..., \bar{\theta}^t$; the reference dataset S_{sh}.

Initialize reference model θ^0_s
for $u = 1...t$ **do**
Update the reference model parameter θ^u_s as in Eq. (5).
end for
return $\theta^1_s, \theta^2_s, ..., \theta^t_s$

are in different sizes.

CT Kidney [13]: The dataset is from PACS [13], collected from various Dhaka hospitals, includes diagnoses of "tumor," "cyst," "normal," or "stone" from coronal and axial CT scans. These images, from whole abdomen and urogram studies, were de-identified and converted to lossless jpg format after careful selection. A balanced dataset of 5,508 images, originally in various sizes, was uniformly resized to 64×64. Each image's accuracy was reconfirmed by a radiologist and a medical technologist.

Skin disease: The dataset is sourced from Dermnet (http://www.dermnet.com/), comprises approximately 19,559 images of 23 skin disease types, serving as an educational online dermatology resource. The dataset is accessible at https://www.kaggle.com/datasets/shubhamgoel27/dermnet. We formed a balanced dataset with 6,095 images.

Results in non-IID settings. In the Tabel 9, we show the performance of our algorithms and the baselines in the non-IID settings. Our algorithms, FTA and KTA, consistently outperform other baselines in all settings.

Table 9: Effectiveness of auditing local models with the Dir(0.5) data partitioning.

Method	TPR @0.1% FPR		TPR @0.5% FPR		TPR @1% FPR

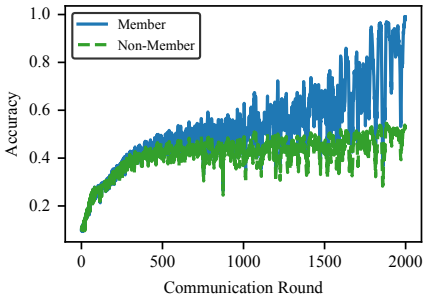

Figure 8: Classification accuracy of the global model in FedSGD during FL.

Training trajectory of FedSGD. We show the train and test performance of FedSGD in Figure 8. As we have mentioned in Section 5.4, the training and test accuracies of FedAvg are much more stable than FedAvg. This phenomenon explains why FedSGD exhibits lower privacy risks than FedAvg.

Defending Against Data Reconstruction Attacks in Federated Learning: An Information Theory Approach

Abstract

Federated Learning (FL) trains a black-box and high-dimensional model among different clients by exchanging parameters instead of direct data sharing, which mitigates the privacy leak incurred by machine learning. However, FL still suffers from membership inference attacks (MIA) or data reconstruction attacks (DRA). In particular, an attacker can extract the information from local datasets by constructing DRA, which cannot be effectively throttled by existing techniques, e.g., Differential Privacy (DP).

In this paper, we aim to ensure a strong privacy guarantee for FL under DRA. We prove that reconstruction errors under DRA are constrained by the information acquired by an attacker, which means that constraining the transmitted information can effectively throttle DRA. To quantify the information leakage incurred by FL, we establish a channel model, which depends on the upper bound of joint mutual information between the local dataset and multiple transmitted parameters. Moreover, the channel model indicates that the transmitted information can be constrained through data space operation, which can improve training efficiency and the model accuracy under constrained information. According to the channel model, we propose algorithms to constrain the information transmitted in a single round of local training. With a limited number of training rounds, the algorithms ensure that the total amount of transmitted information is limited. Furthermore, our channel model can be applied to various privacy-enhancing techniques (such as DP) to enhance privacy guarantees against DRA. Extensive experiments with real-world datasets validate the effectiveness of our methods.

1 Introduction

Federated learning (FL) [41, 58, 61, 62] is a new form of machine learning (ML), which protects privacy by transmitting gradients or parameters to avoid sharing raw data. Specifically, the parameters form a *communication channel* between the server and each client, so the server gets information from local datasets via such channels. Based on the Data Processing Inequality (DPI) [15], communication by parameters, which is a deterministic mapping of local data, instead of raw data, reduces the risk of data privacy. However, recent studies reveal that the parameter channel of FL still leaks privacy. For example, multiple literature indicates that adversaries can conduct membership inference attacks (MIA) with uploaded model parameters [10, 13, 40, 42, 44, 48], which breaks the anonymity of data privacy. Moreover, adversaries can completely steal training data by data reconstruction attacks (DRA) [11, 12, 24, 28, 63], resulting in serious privacy issues in FL.

In order to enhance privacy protection for FL, dimension reduction [36, 46, 52] or differential privacy (DP) [3, 34, 35] are widely adopted approaches. However, dimension reduction lacks theoretical guarantees of the defense ability against DRA, so it cannot flexibly configure defense capabilities according to different privacy requirements. DP's privacy protection can provide theoretical guarantees (e.g., the privacy budget ε) for MIA attacks [7, 22]. It aims to guarantee that changing any data point will not significantly affect the output distribution of a system. This goal is different from the one in defending against DRA, which focuses on preventing the attacker from reconstructing the whole distribution of the local dataset. Thus DP still cannot defend against DRA attacks [7, 14, 22, 26, 38]. For instance, in DP-SGD, algorithms with identical privacy budget but different training hyper-parameters (e.g., different batch size B) cannot guarantee the same success rate for DRA [26]. Moreover, quantifying information leakage is the basis for defending against DRA attacks. Previous technique like Quantitative Information Flow (QIF)[1] [5] quantifies information leak under a white-box and time-invariant setting[47]. It requires the knowledge of the correlation between the distributions of inputs and outputs, which cannot hold in FL systems.

[1]QIF focuses on a special security concern, namely the probability of guessing a secret in one try [5, 51]. This security concern is different from the one in DRA, where DRA focuses on reconstructing the whole distribution of local data.

It is difficult to defend against DRA attacks in FL due to the following challenges. (i) **the black-box model.** For DNN-based models, the correlation between the input distribution and output distribution is extremely complex, and we cannot obtain the exact mapping function between the two distributions, making theoretical analysis impossible. (ii) **the high-dimensional parameter space.** Traditional mathematical tools (e.g., eigen-decomposition) cannot process high-dimensional parameter spaces on the scale of thousands of millions due to the requirements for large-scale storage and high-performance computing. (iii) **the time-variant system.** During the training process, constant parameter updates change the model at each step, leading to a time-variant system in FL. The time-variant system, which changes the output distributions accordingly, leads to dynamic information leakage, requiring continuously changing quantifications.

To address the above challenges, we develop a theoretical framework based on mutual information (MI)[2] to evaluate privacy leakage caused by DRA in FL, and design methods to constrain information leakage to defend against DRA attacks. Specifically, we demonstrate that the lower bound of mean squared error (MSE), which serves as an indicator of DRA's precision in reconstruction (i.e., the smaller MSE means the higher precision for the attacker), is determined by the amount of acquired information, i.e., the MI between the local dataset and the shared parameters. Thus, MI can be utilized as the indicator for quantifying the information leakage in FL. Then we build a channel model to analyze information leaks under the black-box setting of FL. Through our proposed channel model, we find that the transmitted information (i.e., the information leakage) is decided by two factors: the channel capacity C, which represents the maximal ability to transmit information in a single training round; and the optimization rounds n, which is correlated to the information accumulation. For example, if the channel capacity is bounded by a threshold κ, and the number of optimization rounds is less than n, then the total amount of information leakage is less than $n \cdot \kappa$. Furthermore, our channel model can analyze various privacy-enhancing methods in defending against DRA, including DP, gradient compression, and utilizing large batch size.

Based on the channel model, we utilize DPI to transform the operations (e.g., eigen-decomposition and adding noise) of constraining channel capacity from the parameter space to the data space. This transformation significantly improves the training efficiency and the model accuracy of the high dimensional and time-variant model under constrained information leakage. Specifically, our *protecting goal* is to decide the covariance matrix for the added noise according to a given data distribution $\boldsymbol{D}$, which ensures privacy protection by constraining the reconstruction error above a certain threshold. Compared to conventional protection techniques, which directly deal with parameters after gradient mapping, constraining in the data space has two distinct advantages: firstly, it makes the computational complexity independent of the optimization rounds n and the model's dimensionality d_m, reducing it from $O(n \cdot d_m)$ to $O(d_D)$, where d_D denotes the dimensionality of the data and $d_D \ll d_m$. Secondly, data space preserves the correlations between data attributes, hence we can leverage the prior knowledge of relative importance to implement stronger safeguards for the critical attributes, which enhances the capability to balance the utility and the privacy.

Finally, according to the theoretical results, we propose three implementations for constraining the channel capacity. These implementations incorporate different prior knowledge in defending against DRA, which can be employed to flexibly balance the utility and the privacy.

In summary, the contributions of our paper are as follows:

- We demonstrate that the amount of transmitted information decides the lower bound of the reconstruction error for DRA attacks.
- We establish a channel model to quantify the information leakage of the black-box model in FL, which can be applied to analyze various privacy-enhancing methods for defending against DRA.
- We theoretically constrain the transmitted information through the operation in data space instead of parameter space for the first time and demonstrate that it significantly improves the training efficiency and the model accuracy under constrained information leakage.
- By incorporating different prior knowledge, we propose three implementations to constrain channel capacity, which can be utilized to flexibly balance the utility and the privacy.
- Extensive experiments demonstrate that the newly proposed methods effectively enhance the safety, efficiency, and flexibility of FL.

2 Background and Preliminary

This paper studies the FL problem based on information theory. Specifically, in the FL scenario, the server and clients communicate by sending model parameters. Even without direct data sharing, the MI between shared parameters and the local dataset grows accordingly, which enhances the ability for attackers to conduct DRA attacks. For clarity purposes, Tab. 1 lists major notations used in the paper, and we will describe the remaining variables when they are utilized.

2.1 Federated Learning

Regarding FL, a specific client, namely the victim, receives the initial parameter $\boldsymbol{W}_1$ from the server in a specific communication round and conducts the optimization process with

[2] Mutual information $I(X;Y)$ [16, 29, 49] represents the uncertainty decrement of X when we observe Y.

Table 1: Major Notation Explanation

Notations	Explanation
$F(\cdot)$, η	Loss function and learning rate for local optimization
$\boldsymbol{W}_i^{(t)}$, $\boldsymbol{W}_o^{(t)}$	The received (input) and shared (output) parameters of the victim at time t
$\boldsymbol{D}$	Random variable follows data distribution of the victim
B	Batch size for optimization
E, n	Local steps for one communication round and the total local steps for all communication rounds
$\mathcal{A}^{(t)}(\cdot)$	The aggregation method at time t
$\boldsymbol{V}^{(t)}$	Variables (e.g., gradients, parameters) collected by the server from clients other than the victim
$C^{(t)}$	The channel capacity (maximum transmitted information) of the victim at time t
κ	The threshold of $C^{(t)}$, i.e., the setted channel capacity
$\boldsymbol{\Sigma}_*$	The covariance matrix of random variable
λ and σ	Eigenvalues for the covariance matrix and noise variables
$I(\boldsymbol{X};\boldsymbol{Y})$	The mutual information between $\boldsymbol{X}$ and $\boldsymbol{Y}$
$\boldsymbol{\xi}$	The noise variable that is subject to Gaussian distribution

the victim's dataset as

$$\boldsymbol{W}_{t+1} \leftarrow \boldsymbol{W}_t - \eta \cdot \nabla_{\boldsymbol{W}} F(\boldsymbol{W}_t; \boldsymbol{D}),\ t = 1, \cdots, E, \quad (1)$$

where E is the number of local steps. Then the victim sends $\boldsymbol{W}_{E+1}$ back to the server. If we rewrite $\boldsymbol{W}_1$ and $\boldsymbol{W}_{E+1}$ as $\boldsymbol{W}_i$ and $\boldsymbol{W}_o$ respectively, the two parameters form a communication channel for information transmission (as illustrated in Fig. 2), and the local optimization process defined in Eq. (1) loads information from the dataset to the communication channel. Finally, the server collects the parameters from different clients (including the victim) for aggregation as

$$\boldsymbol{W}_i = \mathcal{A}(\boldsymbol{W}_o; \boldsymbol{V}). \quad (2)$$

2.2 Information Theory

Differential Entropy. The differential entropy of a random variable $\boldsymbol{X}$ is defined as follows

$$h(\boldsymbol{X}) = -\int_{\boldsymbol{X}} f(\boldsymbol{x}) \log f(\boldsymbol{x})\, d\boldsymbol{x}, \quad (3)$$

which is utilized to describe the degree of random uncertainty. For a dataset with high information entropy, i.e., a dataset with plentiful information, it is difficult for an attacker to conduct DRA attacks. While for the dataset with low information entropy, the opposite is true.

However, calculating the differential entropy by Eq. (3) is infeasible in practice since we cannot obtain the distribution function of the target variable. Therefore, we use the maximum entropy distribution to analyze the worst-case scenario. Specifically, with $\mathbb{E}[\boldsymbol{X}] = \boldsymbol{\mu}$ and $Cov(\boldsymbol{X}) = \boldsymbol{\Sigma}$, the maximum entropy distribution is the Gaussian distribution, i.e., $h(\boldsymbol{X}) \leq h(\mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma}))$.

Mutual Information. For two random variables $\boldsymbol{X}$ and $\boldsymbol{Y}$, the mutual information between them is

$$I(\boldsymbol{X};\boldsymbol{Y}) = h(\boldsymbol{X}) - h(\boldsymbol{X}|\boldsymbol{Y}) = h(\boldsymbol{Y}) - h(\boldsymbol{Y}|\boldsymbol{X}). \quad (4)$$

Specifically, the mutual information $I(\boldsymbol{X};\boldsymbol{Y})$ is a symmetric function, which describes the random uncertainty decrement of $\boldsymbol{X}$ when we observe $\boldsymbol{Y}$, and vice versa.

Specifically, in this paper, we utilize $I(\boldsymbol{D};\boldsymbol{W}_i,\boldsymbol{W}_o)$ to quantify the information leakage in FL. The intuition is that when an attacker observes the communication parameters of a victim, the random uncertainty of the victim's local dataset will decrease, which implies the attacker can extract information from the victim's local dataset to achieve more precise DRA.

Channel Capacity. The key factor in describing a communication channel is channel capacity. In information theory, traditional channel capacity is defined by the maximum MI between the sending variable $\boldsymbol{X}$ and the receiving variable $\boldsymbol{Y}$, i.e., $C = \max_{p(\boldsymbol{x})} I(\boldsymbol{X};\boldsymbol{Y})$, which is the maximum information that we can send by information coding.

In this work, the sending variable is $\boldsymbol{D}$, while the receiving variable is $\boldsymbol{W}_o$, which is decided by the variables $\boldsymbol{W}_i$ and $\boldsymbol{D}$ according to Eq. (1), hence the channel capacity can be formalized as $C = \max_{p(\boldsymbol{w}_o)} I(\boldsymbol{D};\boldsymbol{W}_o|\boldsymbol{W}_i)$, which is the upper bound of the transmitted information.

The reasons for choosing MI to measure the information leakage. Prior research like QIF and g-leakage utilizes min-entropy [5, 51] to measure the information leakage, which can only work in a white-box and time-invariant system [47]. However, FL is a black-box (e.g., deep neural networks) and time-variant (e.g., parameter updating in each round) system. Hence, these techniques are not applicable. Moreover, min-entropy is unsuitable for modeling the attack against FL, e.g., DRA. The min-entropy focuses on measuring the uncertainty of guessing the most likely output of random sources [23, 30], which is more related to cryptographic systems. However, in DRA, the attacker's target is to reconstruct the whole data distribution based on the victim's sharing parameters, instead of guessing a most likely data point. Therefore, the precision of DRA attacks depends on the difference between two distributions, which must take all data of the distributions into consideration. In this scenario, the Shannon entropy, i.e., MI, which is based on the expectation metric, can accurately measure the correlation between the whole distributions, thus is more suitable for analyzing the information leakage issue under DRA. Therefore, we choose MI to measure the information leakage in FL.

3 Key Observation and Method Overview

3.1 Key Observation

Regarding FL, different clients jointly optimize the model by passing parameters to the server instead of raw data. Since the parameters are the mapping of the original data, the attacker can still reconstruct the private data from the parameters, thereby stealing privacy. Correspondingly, the client can preserve privacy by perturbing the transmitted parameters. Therefore, we build a channel model to calculate the privacy

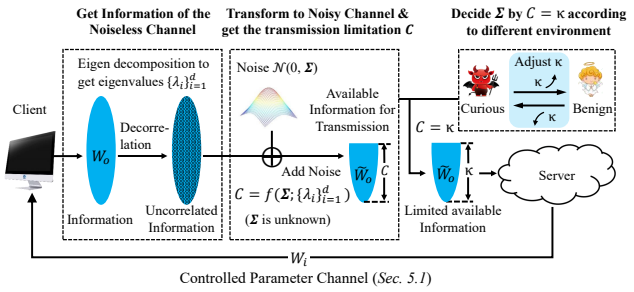

Figure 1: To enhance the capability for defending against DRA in FL, we develop techniques to constrain the amount of transmitted information below a certain threshold κ.

data contained in parameters. Moreover, based on the quantitative results, the privacy data in parameters can be flexibly adjusted to meet various privacy requirements.

In this section, we establish a formal correlation between the transmitted information, i.e., the MI, and the reconstruction error of DRA by the following theorem.

Theorem 1 (Lower bound for reconstruction error)**.** *For any random variable $\boldsymbol{D}$, $\boldsymbol{D} \in \mathbb{R}^d$ and $\boldsymbol{W}$, $\boldsymbol{W} \in \mathbb{R}^m$, we have*

$$\mathbb{E}[\|\boldsymbol{D} - \hat{\boldsymbol{D}}(\boldsymbol{W})\|^2/d] \geq \frac{e^{2h(\boldsymbol{D})/d}}{2\pi e} e^{-2I(\boldsymbol{D};\boldsymbol{W})/d}, \tag{5}$$

where $\hat{\boldsymbol{D}}(\boldsymbol{W})$ is an estimator of $\boldsymbol{D}$ constructed by $\boldsymbol{W}$.

Specifically, Eq. (5) denotes the lower bound of MSE in DRA, which represents the optimal error for data reconstruction. In the FL scenario, we denote $\boldsymbol{D}$ as the target data distribution and $\boldsymbol{W}$ as the shared parameter. Therefore $h(\boldsymbol{D})$ is the entropy of the target data distribution, which is a constant during machine learning. Moreover, the lower bound is negatively correlated to MI, i.e., $I(\boldsymbol{D};\boldsymbol{W})$, which indicates that if $\boldsymbol{W}$ contains more information of target data $\boldsymbol{D}$, i.e., a larger $I(\boldsymbol{D};\boldsymbol{W})$, the attacker can achieve a more precise reconstruction of $\boldsymbol{D}$. Consequently, large $I(\boldsymbol{D};\boldsymbol{W})$ exacerbates the privacy issue.

In FL, MI increases as the number of optimization rounds increases, thereby enhancing the precision of DRA. Therefore, constraining the overall MI in FL is the way to restrict the precision of DRA. To this end, we build a channel model to measure the increase of MI in Sec. 4, and propose three implementation methods to limit MI within a certain threshold.

3.2 Method Overview

In this study, we develop techniques to enhance FL's capability of privacy protection, in particular, defending against DRA. Normally, FL transmits information from the local dataset to the server by model parameters, i.e., the parameter channel. The transmitted information can be employed by an attacker to conduct various attacks. Hence, the objective of privacy protection is to constrain the amount of transmitted information. Specifically, for DRA, the reconstruction error is lower bounded by a function of MI (Thm. 1), which indicates that a smaller MI leads to a larger reconstruction error. Therefore, our technique is devoted to limiting the reconstruction ability by constraining the total MI in FL.

Threat Model. In this work, we focus on privacy leaks incurred by DRA in FL. Specifically, the attacker aims to reconstruct the data distribution $\boldsymbol{D}$ of a specific client (i.e., the victim) via parameters shared by the victim. We assume that the attacker can get the transmitted parameters by the victim (i.e., $\boldsymbol{W}_i$ and $\boldsymbol{W}_o$). Then the attacker can reconstruct a data distribution $\hat{\boldsymbol{D}}(\boldsymbol{W}_i, \boldsymbol{W}_o)$ to approximate the target data distribution $\boldsymbol{D}$ (Appendix A explains the details of DRA).

Our goal is to constrain the private data that the attacker can obtain according to the *transmitted parameters* in FL. Therefore, the attacker's ability to construct the DRA attack is limited.

Controlled parameter channel. As illustrated in Fig. 1, to restrict the transmitted information, we transform the noiseless parameter $\boldsymbol{W}_o$ to a noisy Gaussian channel by adding Gaussian noise $\mathcal{N}(\boldsymbol{0}, \boldsymbol{\Sigma})$ to it. Based on the theorem of Gaussian channel in information theory [15], the noisy Gaussian channel has limited capability for information transmission, which is the channel capacity. Thus, with the eigenvalues of $\boldsymbol{W}_o$, we derive a formula $f(\boldsymbol{\Sigma})$ to characterize the channel capacity of the Gaussian channel by the maximum entropy distribution. Finally, we solve the equation $f(\boldsymbol{\Sigma}) = \kappa$ to decide $\boldsymbol{\Sigma}$ for constraining the transmitted information within a threshold κ. We will explain how the controlled parameter channel constrains transmitted information in Sec. 4 and Sec. 5.1.

Constraining channel capacity in the data space. To overcome the efficiency issue caused by the high dimensional and time-variant model in FL, we theoretically transform operations of constraining channel capacity from the parameter space to the data space. Specifically, the information contained in the resulting parameter is decided by the input data, thus constraining channel capacity can be achieved by restricting the information contained in the input data. Moreover, this transformation significantly improves the training efficiency and the model accuracy under constrained information leakage. We will explain the transformation in Sec. 5.2.

Theoretically, when an attacker observes $\boldsymbol{W}_i$ and $\boldsymbol{W}_o$, the random uncertainty of the local data $\boldsymbol{D}$ decreases, which means the attacker gets more information to conduct DRA attacks, leading to more precise reconstruction. The amount of random uncertainty reduction ΔI (i.e., information leakage) in a round can be formalized as

$$\Delta I = I(\boldsymbol{D};\boldsymbol{W}_i, \boldsymbol{W}_o) - I(\boldsymbol{D};\boldsymbol{W}_i) = I(\boldsymbol{D};\boldsymbol{W}_o|\boldsymbol{W}_i),$$

which means the attacker gets ΔI information from $\boldsymbol{D}$ (as illustrated in Fig. 2). Moreover, this privacy leak occurs in each optimization round, which results in an increase in MI and consistently increases the risk of privacy.

As aforementioned, for defending against DRA, our technique constructs a controlled parameter channel by limiting

ΔI to less than a threshold κ for all optimization rounds. Then together with the bounded optimization rounds n, we provide $n \cdot \kappa$ guarantee for the total information leakage, thereby constraining the attack precision of DRA.

4 Channel Model of the Information Leakage

In this section, we formalize the problem of FL into a communication process based on information theory and then unfold the recurrent communication process into a time-dependent Markov Chain. Finally, we build a channel model to calculate the MI according to the unfolded communication process.

4.1 Accumulation of Mutual Information

As illustrated in Fig. 2, in the FL scenario, a specific client, i.e., the victim, communicates with the server through a logic channel: the parameters $\boldsymbol{W}_i$ and $\boldsymbol{W}_o$. Specifically, There are three different information flows: *the ingress flow*, i.e., the received parameter $\boldsymbol{W}_i$, which determines the background knowledge possessed by the server (i.e., the attacker); *the egress flow*, which is the information contained in the sharing parameter $\boldsymbol{W}_o$; and *the internal flow*, i.e., local optimization process, which loads the information contained in the local dataset to the egress flow. Particularly, due to privacy requests, the victim only communicates with the server by $\boldsymbol{W}_i$ and $\boldsymbol{W}_o$.

The information leakage of the communication channel depends on the MI increment when the server observes $\boldsymbol{W}_o$. Thus, it can be formalized as

$$I(\boldsymbol{D};\boldsymbol{W}_i,\boldsymbol{W}_o) = \underbrace{I(\boldsymbol{D};\boldsymbol{W}_i)}_{\text{Prior}} + \underbrace{I(\boldsymbol{D};\boldsymbol{W}_o|\boldsymbol{W}_i)}_{\text{Information Leakage } (\Delta I)}. \quad (6)$$

Eq. (6) is an immediate result according to the chain rule of MI. It indicates that the MI between $\boldsymbol{D}$ and the joint distribution $(\boldsymbol{W}_i,\boldsymbol{W}_o)$ can be divided into two parts: the prior knowledge and the information leakage ΔI. In the rest of this paper, we will utilize $I(\boldsymbol{D};\boldsymbol{W}_o|\boldsymbol{W}_i)$ instead of ΔI for more comprehensible analysis.

However, $\boldsymbol{W}_i$ and $\boldsymbol{W}_o$ are joint distributions of different rounds, which contain multiple local learning processes. Hence, connecting Eq. (6) to the internal flow is difficult. To resolve this issue, we unfold the recurrent process to a time-dependent Markov chain. As illustrated in Fig. 2, there is only one local optimization process within a round from $\boldsymbol{W}_i^{(t)}$ to $\boldsymbol{W}_i^{(t+1)}$, hence we can analyze MI increment at round t.

Specifically, according to Eq. (1) and Eq. (2), the relationship between $\boldsymbol{W}_i^{(t)}$ and $\boldsymbol{W}_o^{(t)}$ in Fig. 2 is

$$\boldsymbol{W}_o^{(t)} = \boldsymbol{W}_i^{(t)} - \eta \cdot \nabla_{\boldsymbol{W}} F(\boldsymbol{W}_i^{(t)};\boldsymbol{D}), \quad (7)$$

which represents the local learning process with SGD. While for $\boldsymbol{W}_o^{(t)}$ and $\boldsymbol{W}_i^{(t+1)}$, the relationship is

$$\boldsymbol{W}_i^{(t+1)} = \mathcal{A}^{(t)}(\boldsymbol{W}_o^{(t)};\boldsymbol{V}^{(t)}), \quad (8)$$

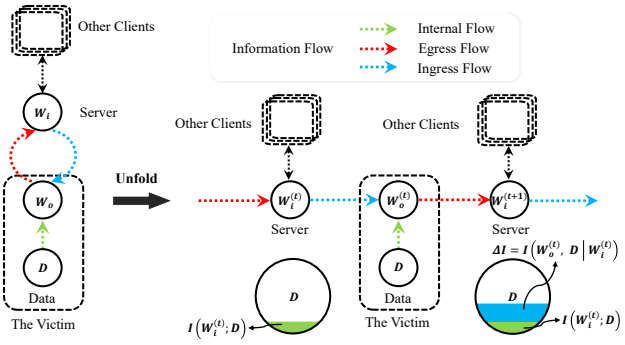

Figure 2: The process of FL can be unfolded to a time-dependent Markov chain. Hence we can analyze the mutual information in a round from $\boldsymbol{W}_i^{(t)}$ to $\boldsymbol{W}_i^{(t+1)}$.

where $\boldsymbol{V}^{(t)}$ are the variables uploaded by clients other than the victim.

Then based on the unfolded process, we transform the MI in Eq. (6) to the joint mutual information as

$$\begin{aligned} & I(\boldsymbol{D};\boldsymbol{W}_i^{(0)},\boldsymbol{W}_o^{(0)},\cdots,\boldsymbol{W}_i^{(n)}) \\ = \; & \textstyle\sum_{t=0}^{n} I(\boldsymbol{D};\boldsymbol{W}_i^{(t)}|\boldsymbol{W}_o^{(t-1)},\boldsymbol{W}_i^{(t-1)},\cdots,\boldsymbol{W}_o^{(0)},\boldsymbol{W}_i^{(0)}) \\ & + \textstyle\sum_{t=0}^{n-1} I(\boldsymbol{D};\boldsymbol{W}_o^{(t)}|\boldsymbol{W}_i^{(t)},\boldsymbol{W}_o^{(t-1)},\cdots,\boldsymbol{W}_o^{(0)},\boldsymbol{W}_i^{(0)}) \\ = \; & \underbrace{\textstyle\sum_{t=0}^{n-1} I(\boldsymbol{D};\boldsymbol{W}_o^{(t)}|\boldsymbol{W}_i^{(t)})}_{\Gamma_{client}} + \underbrace{\textstyle\sum_{t=0}^{n-1} I(\boldsymbol{D};\boldsymbol{W}_i^{(t+1)}|\boldsymbol{W}_o^{(t)})}_{\Gamma_{server}} \\ & + \underbrace{I(\boldsymbol{D};\boldsymbol{W}_i^{(0)})}_{\text{Prior}}, \end{aligned} \quad (9)$$

where the first equality depends on the chain rule of MI and the last equality is an immediate consequence of the Markov property of the learning process.

Specifically, Eq. (9) indicates that the overall MI is comprised of three parts: the prior, Γ_{server}, and Γ_{client}.

4.2 Analysis of Mutual Information

Regarding Eq. (9), the information can be divided into three parts: the prior, Γ_{server}, and Γ_{client}. The prior knowledge $I(\boldsymbol{D};\boldsymbol{W}_i^{(0)})$ is decided by the background knowledge of the attacker before the learning process.

For Γ_{server}, it represents the aggregation process on the server, hence it cannot be controlled by the local learning process. On the contrary, it can be exploited by an attacker. Without loss of generality, we focus on the general term $I(\boldsymbol{D};\boldsymbol{W}_i^{(t+1)}|\boldsymbol{W}_o^{(t)})$, $t \in \{0,\cdots,n-1\}$, which is the information increment on the server. Based on the relationship between the MI and the entropy, we rewrite it as

$$\begin{aligned} & I(\boldsymbol{D};\boldsymbol{W}_i^{(t+1)}|\boldsymbol{W}_o^{(t)}) \\ = \; & h(\boldsymbol{W}_i^{(t+1)}|\boldsymbol{W}_o^{(t)}) - h(\boldsymbol{W}_i^{(t+1)}|\boldsymbol{D},\boldsymbol{W}_o^{(t)}) \\ = \; & h(\mathcal{A}^{(t)}(\boldsymbol{W}_o^{(t)};\boldsymbol{V}^{(t)})|\boldsymbol{W}_o^{(t)}) - h(\mathcal{A}^{(t)}(\boldsymbol{W}_o^{(t)};\boldsymbol{V}^{(t)})|\boldsymbol{D},\boldsymbol{W}_o^{(t)}), \end{aligned}$$

the last equality is a substitution according to Eq. (8). The formula indicates that $I(\boldsymbol{D};\boldsymbol{W}_i^{(t+1)}|\boldsymbol{W}_o^{(t)})$ is decided by $\boldsymbol{V}^{(t)}$, which are variables independent of local learning process.

Specifically, if $\boldsymbol{V}^{(t)}$ is independent of $\boldsymbol{D}$, then $\boldsymbol{D} \to \boldsymbol{W}_o^{(t)} \to \boldsymbol{W}_i^{(t+1)}$ forms a Markov chain. Therefore, given the observation of $\boldsymbol{W}_o^{(t)}$, $\boldsymbol{D}$ is conditional independent of $\boldsymbol{W}_i^{(t+1)}$, i.e., $I(\boldsymbol{D};\boldsymbol{W}_i^{(t+1)}|\boldsymbol{W}_o^{(t)}) = 0$. In this situation, $\Gamma_{server} = 0$, which means the server (i.e., the attacker) cannot affect DRA attacks. On the contrary, if $\boldsymbol{V}^{(t)}$ has the information of $\boldsymbol{D}$ that is independent of $\boldsymbol{W}_o^{(t)}$, i.e., the attacker can get auxiliary information other than the local learning process, the mutual information $I(\boldsymbol{D};\boldsymbol{W}_i^{(t+1)}|\boldsymbol{W}_o^{(t)}) > 0$, which increases the risk of information leakage for the rest communication rounds when $T \geq t+1$. In this situation, the server (i.e., the attacker) can increase the risk of privacy by utilizing the information collected by means other than FL.

However, the analysis of Γ_{server} is beyond the protection of the local learning process in FL, since Γ_{server} is related to the auxiliary information for the attacker to conduct the DRA attack. Particularly, our target is to bound Γ_{client}, which is the information leakage of the local learning process in FL. Sec. 5 indicates that regardless of $\Gamma_{server} > 0$ or not, Γ_{client} is constrained by our methods.

Finally, we put emphasis on Γ_{client}, the most important part that is correlated to information leakage of the local learning process in FL. Similarly, we focus on the general term of Γ_{client}, i.e., $I(\boldsymbol{D};\boldsymbol{W}_o^{(t)}|\boldsymbol{W}_i^{(t)})$, which is the MI increment at round t, then we have

$$I(\boldsymbol{D};\boldsymbol{W}_o^{(t)}|\boldsymbol{W}_i^{(t)}) = h(\boldsymbol{W}_o^{(t)}|\boldsymbol{W}_i^{(t)}) - h(\boldsymbol{W}_o^{(t)}|\boldsymbol{D},\boldsymbol{W}_i^{(t)}). \quad (10)$$

Based on Eq (7), if $\boldsymbol{W}_i^{(t)}$ is observed, $\boldsymbol{W}_o^{(t)}$ is decided by a deterministic function of $\boldsymbol{D}$, which has a finite entropy. Moreover, if $\boldsymbol{W}_i^{(t)}$ and $\boldsymbol{D}$ are both observed, $\boldsymbol{W}_o^{(t)}$ is deterministic, thereby $h(\boldsymbol{W}_o^{(t)}|\boldsymbol{D},\boldsymbol{W}_i^{(t)}) \to -\infty$. The result is reasonable since the volume of a constant's support set[3] goes to 0, i.e., $2^{-\infty} = 0$. In this case, $I(\boldsymbol{D};\boldsymbol{W}_o^{(t)}|\boldsymbol{W}_i^{(t)}) \to +\infty$, which means a noiseless channel results in unlimited risk of privacy leaks.

To limit the information leakage, we add a Gaussian noise to $\boldsymbol{W}_o^{(t)}$, which transforms Eq. (10) to a noisy egress flow. Specifically, we turn to analyze

$$\widetilde{\boldsymbol{W}}_o^{(t)} = \boldsymbol{W}_o^{(t)} + \boldsymbol{\xi}, \quad (11)$$

where $\boldsymbol{\xi} \sim \mathcal{N}(\boldsymbol{0},\boldsymbol{\Sigma})$, and $\boldsymbol{W}_o^{(t)} = \lim_{\boldsymbol{\Sigma}\to\boldsymbol{0}} \widetilde{\boldsymbol{W}}_o^{(t)}$. Then the property of $\widetilde{\boldsymbol{W}}_o^{(t)}$ is implied by following lemma.

Lemma 1 (Maximum entropy distribution)**.** *Let $\boldsymbol{X}$ be a continuous random vector with $\mathbb{E}[\boldsymbol{X}] = \boldsymbol{\mu}_{\boldsymbol{X}}$, $Cov(\boldsymbol{X}) = \boldsymbol{\Sigma}_{\boldsymbol{X}}$. Let $\boldsymbol{Y} \sim \mathcal{N}(\boldsymbol{\mu}_{\boldsymbol{Y}},\boldsymbol{\Sigma}_{\boldsymbol{Y}})$ be a Gaussian random variable that is independent with $\boldsymbol{X}$, then $h(\boldsymbol{X}+\boldsymbol{Y})$ achieves its maximum when $\boldsymbol{X} \sim \mathcal{N}(\boldsymbol{\mu}_{\boldsymbol{X}},\boldsymbol{\Sigma}_{\boldsymbol{X}})$.*

[3]The volume of support set for a random variable $\boldsymbol{X}$ is $2^{h(\boldsymbol{X})}$ [15].

To analyze the noisy egress flow after transformation, we rewrite Eq. (10) as

$$I(\boldsymbol{D};\widetilde{\boldsymbol{W}}_o^{(t)}|\boldsymbol{W}_i^{(t)}) = h(\boldsymbol{W}_o^{(t)}+\boldsymbol{\xi}|\boldsymbol{W}_i^{(t)}) - h(\boldsymbol{W}_o^{(t)}+\boldsymbol{\xi}|\boldsymbol{D},\boldsymbol{W}_i^{(t)}). \quad (12)$$

As $\boldsymbol{\xi}$ is a Gaussian variable, Lemma 1 implies that the first term on the right-hand side of Eq. (12), i.e., $h(\boldsymbol{W}_o^{(t)}+\boldsymbol{\xi}|\boldsymbol{W}_i^{(t)})$, is upper bounded by the entropy of the Gaussian distribution. Moreover, when $\boldsymbol{D}$ and $\boldsymbol{W}_i^{(t)}$ are both observed, $\boldsymbol{W}_o^{(t)}$ is a constant, which means the only randomness of $\widetilde{\boldsymbol{W}}_o^{(t)} = \boldsymbol{W}_o^{(t)} + \boldsymbol{\xi}$ comes from $\boldsymbol{\xi}$, thus the second term on the right-hand side of Eq. (12) is $h(\mathcal{N}(\boldsymbol{0},\boldsymbol{\Sigma}))$. Let $\mathbb{E}[\boldsymbol{W}_o^{(t)}] = \boldsymbol{\mu}_{\boldsymbol{W}}$ and $Cov(\boldsymbol{W}_o^{(t)}) = \boldsymbol{\Sigma}_{\boldsymbol{W}}$, we have the upper bound of Eq. (12) as

$$I(\boldsymbol{D};\widetilde{\boldsymbol{W}}_o^{(t)}|\boldsymbol{W}_i^{(t)}) \leq h(\mathcal{N}(\boldsymbol{\mu}_{\boldsymbol{W}},\boldsymbol{\Sigma}_{\boldsymbol{W}}+\boldsymbol{\Sigma})) - h(\mathcal{N}(\boldsymbol{0},\boldsymbol{\Sigma})). \quad (13)$$

In practice, the distribution of $\boldsymbol{W}_o^{(t)}$ is extremely complex and time-variant, so we utilize upper bound (13) to limit the information leakage. The important parts of Eq. (13) are the covariance matrixes of $\boldsymbol{W}_o^{(t)}$ and $\boldsymbol{\xi}$. Moreover, Sec. 5 indicates that regardless of $\boldsymbol{\Sigma}_{\boldsymbol{W}}$, we can restrict $I(\boldsymbol{D};\widetilde{\boldsymbol{W}}_o^{(t)}|\boldsymbol{W}_i^{(t)}) \leq \kappa$, $\forall \kappa > 0$, by deciding $\boldsymbol{\Sigma}$.

Finally, for multiple local updates, the scenario is slightly different. We denote the number of local steps in one communication round as E, and the total number of local steps for all communication rounds as n, where n is divisible into E. These notations imply that the number of communications is $T = \frac{n}{E}$. Then the issue can be transformed to the one-step case by a time-dependent aggregation method as

$$\boldsymbol{W}_i^{(t)} = \begin{cases} \mathcal{A}^{(t)}(\boldsymbol{W}_o^{(t-1)};\boldsymbol{V}^{(t-1)}), & \text{if } E \,|\, t \\ \boldsymbol{W}_o^{(t-1)}, & \text{otherwise.} \end{cases} \quad (14)$$

Where $E \,|\, t$ represents we make aggregation on the server every E steps. If we set $E = n$, the FL problem reduces to classical ML without collaboration.

Based on the former analysis, the new aggregation rule only changes Γ_{server} in Eq. (9), while Γ_{client} remains the same. Hence, the privacy analysis for the local optimization process is identical to classical ML. Therefore, our analysis of Γ_{client} will focus on classical ML in the remainder of this paper.

5 Controlled Parameter Channel

Based on the former analysis, the important part of defending against DRA is $I(\boldsymbol{D};\widetilde{\boldsymbol{W}}_o^{(t)}|\boldsymbol{W}_i^{(t)})$, which represents the MI increment at round t. The key parameters to restrict the MI increment are $\boldsymbol{\Sigma}_{\boldsymbol{W}}$ and $\boldsymbol{\Sigma}$. In this section, we first propose a method for deciding $\boldsymbol{\Sigma}$ that ensures $I(\boldsymbol{D};\widetilde{\boldsymbol{W}}_o^{(t)}|\boldsymbol{W}_i^{(t)}) \leq \kappa$. Then, we transform the operations for constraining MI from the parameter space to the data space and propose three implementation methods for constraining the channel capacity.

Finally, we analyze existing techniques with our theoretical results in defending against DRA.

5.1 Controlled Channel Capacity

Channel capacity is the maximum ability to transmit information within a single round, i.e., max $I(\boldsymbol{D};\widetilde{\boldsymbol{W}}_o^{(t)}|\boldsymbol{W}_i^{(t)})$, which is the key parameter for constraining the information leakage.

To constrain the channel capacity, we have Thm 2.

Theorem 2 (Channel capacity)**.** *Let $\widetilde{\boldsymbol{W}}_o^{(t)} = \boldsymbol{W}_o^{(t)} + \sqrt{\sigma}\cdot\boldsymbol{\xi}$, where $\sigma \geq 0$ and $\boldsymbol{\xi} \sim \mathcal{N}(\mathbf{0},\mathbf{I})$, if $\boldsymbol{\mu}^{(t)}$ and $\boldsymbol{\Sigma}^{(t)}$ are the mean vector and covariance matrix of $\boldsymbol{W}_o^{(t)}$ when $\boldsymbol{W}_i^{(t)}$ is observed, we have $I(\boldsymbol{D};\widetilde{\boldsymbol{W}}_o^{(t)}|\boldsymbol{W}_i^{(t)}) \leq f^{(t)}(\sigma)$, where*

$$f^{(t)}(\sigma) := \frac{1}{2}\sum_{i=1}^{d} \ln\frac{\lambda_i^{(t)}+\sigma}{\sigma},\ \sigma\in(0,\ +\infty). \tag{15}$$

where $\lambda_i^{(t)}$ is the i-th eigenvalue of the covariance matrix $\boldsymbol{\Sigma}^{(t)}$ and d represents the dimension of $\boldsymbol{W}_o^{(t)}$.

Based on Lemma 1, $I(\boldsymbol{D},\widetilde{\boldsymbol{W}}_o^{(t)}|\boldsymbol{W}_i^{(t)})$ achieves its maximum $f^{(t)}(\sigma)$ when $\boldsymbol{W}_o^{(t)}$ conforms to the Gaussian distribution. According to the Central Limit Theorem, if we use mini-batch SGD, the distribution of $\boldsymbol{W}_o^{(t)}$ converges to the Gaussian distribution, which means upper bound (15) becomes tighter when we utilize larger batch size for local training.

Regarding Γ_{client}, if we denote $C^{(t)} = f^{(t)}(\sigma^{(t)})$, where $\sigma^{(t)}$ represents σ at time t, we have $I(\boldsymbol{D};\widetilde{\boldsymbol{W}}_o^{(t)}|\boldsymbol{W}_i^{(t)}) \leq C^{(t)}$, which indicates $\boldsymbol{W}_i^{(t)}$ and $\widetilde{\boldsymbol{W}}_o^{(t)}$ form a communication channel with channel capacity $C^{(t)}$.

Specifically, according to Eq. (15), $C^{(t)}$ is decided by two components: $\{\lambda_i^{(t)}\}_{i=1}^d$ and $\sigma^{(t)}$. First, $\{\lambda_i^{(t)}\}_{i=1}^d$ represent the eigenvalues of $\boldsymbol{\Sigma}^{(t)}$. Based on Eq. (7), $\boldsymbol{W}_o^{(t)}$ is related to $\boldsymbol{W}_i^{(t)}$, which is the parameter received from the server. Therefore, the server (i.e., the attacker) can craft $\boldsymbol{W}_i^{(t)}$ to get more information from the local dataset (as displayed in Fig. 3).

Second, $\sigma^{(t)}$ is related to the added noise. Based on the monotonicity of $C^{(t)} = f^{(t)}(\sigma^{(t)})$, we conclude that for any $\boldsymbol{W}_i^{(t)}$, there exists an unique $\sigma^{(t)}$ that satisfies $f^{(t)}(\sigma^{(t)}) = \kappa$, where $\kappa \geq 0$ is a certain threshold.

If we denote $\lambda_i^{(t)} = \lambda^{(t)}$, $i \in \{1,\cdots,d\}$, we have $C^{(t)} = \frac{d}{2}\ln(\frac{\lambda^{(t)}+\sigma^{(t)}}{\sigma^{(t)}})$. In this scenario, the channel capacity can be displayed as Fig. 3. Specifically, the channel capacity is an increasing function of $\lambda^{(t)}$ and a decreasing function of $\sigma^{(t)}$. Moreover, it is worth noting that even the server can change the channel capacity by crafting $\boldsymbol{W}_i^{(t)}$, the victim can constrain the transmitted information within κ by solving $f^{(t)}(\sigma^{(t)}) = \kappa$ after receiving $\boldsymbol{W}_i^{(t)}$, which decides the added noise $\sigma^{(t)}$.

5.2 Limiting Channel Capacity in Data Space

For a controlled parameter channel, our target is to constrain the transmitted information at round t, i.e., $I(\boldsymbol{D};\widetilde{\boldsymbol{W}}_o^{(t)}|\boldsymbol{W}_i^{(t)})$. Based on Thm. 2, there are two steps for solving the equation $C^{(t)} = \kappa$ in the parameter space: the eigen-decomposition of $\boldsymbol{\Sigma}^{(t)}$ and solving the high order equation with corresponding eigenvalues. Whereas, $\boldsymbol{W}_o^{(t)}$ is a high-dimensional and time-variant parameter, which leads to an extremely large number of calculations. Hence, the implementation of the aforementioned method in the parameter space is computationally expensive.

Regarding $\boldsymbol{W}_o^{(t)}$ in Fig. 2, when $\boldsymbol{W}_i^{(t)}$ is observed, it is conditional independent with the previous parameters $\boldsymbol{W}_*^{(s)}$, $\forall s < t$, and all of the previous local learning processes. Therefore, if $\boldsymbol{W}_i^{(t)}$ is observed, $\boldsymbol{W}_o^{(t)}$ is purely decided by the local learning process at round t, i.e., $\boldsymbol{D} \to \boldsymbol{W}_o^{(t)}|\boldsymbol{W}_i^{(t)}$. Then based on these properties, we design a random function $M(\cdot)$ to map the raw data $\boldsymbol{D}$ to the noisy data $\widetilde{\boldsymbol{D}}$, and then utilize the noisy data for the local training, i.e., $\widetilde{\boldsymbol{W}}_o^{(t)} = \boldsymbol{W}_i^{(t)} - \eta\cdot\nabla_{\boldsymbol{W}}F(\boldsymbol{W}_i^{(t)};\widetilde{\boldsymbol{D}})$.

If we use the random function $M(\cdot)$ before the local learning process, the variables form a Markov Chain, i.e., $\boldsymbol{D} \to \widetilde{\boldsymbol{D}} \to \boldsymbol{W}_o^{(t)}|\boldsymbol{W}_i^{(t)}$. According to the DPI [15], we have

$$I(\boldsymbol{D};\boldsymbol{W}_o^{(t)}|\boldsymbol{W}_i^{(t)}) \leq I(\boldsymbol{D};\widetilde{\boldsymbol{D}}|\boldsymbol{W}_i^{(t)}) = I(\boldsymbol{D};\widetilde{\boldsymbol{D}}), \tag{16}$$

where the last equality results from the independence between $M(\cdot)$ and $\boldsymbol{W}_i^{(t)}$. Therefore, we can bound $I(\boldsymbol{D};\widetilde{\boldsymbol{D}})$ so as to restrict $I(\boldsymbol{D};\boldsymbol{W}_o^{(t)}|\boldsymbol{W}_i^{(t)})$. Moreover, bounding $I(\boldsymbol{D};\widetilde{\boldsymbol{D}})$ enables us to limit the channel capacity in the data space. Specifically, we use $\widetilde{\boldsymbol{D}} = M(\boldsymbol{D}) = \boldsymbol{D}+\boldsymbol{\xi}$ as the random function, where $\boldsymbol{\xi} \sim \mathcal{N}(\mathbf{0},\boldsymbol{\Sigma}_{\boldsymbol{\xi}})$, and the key parameter is $\boldsymbol{\Sigma}_{\boldsymbol{\xi}}$.

The rationale of constraining transmitted information in data space. In addition to the upper bound derived by DPI, we can explain the rationale of constraining in data space by Taylor's expansion for a more comprehensible analysis. Specifically, if we use a Gaussian noise in the data space to constrain the information leakage, we can expand the gradient mapping as follows

$$\begin{aligned}\nabla_{\boldsymbol{W}}F(\boldsymbol{W};\boldsymbol{D}+\boldsymbol{\xi}) \quad &= \nabla_{\boldsymbol{W}}F(\boldsymbol{W};\boldsymbol{D}) + \nabla_{\boldsymbol{D}}\nabla_{\boldsymbol{W}}F(\boldsymbol{W};\boldsymbol{D})^{\mathrm{T}}\cdot\boldsymbol{\xi} \\ &\quad + O(\|\boldsymbol{\xi}\|^2).\end{aligned} \tag{17}$$

Eq. (17) indicates that constraining the transmitted information in the data space is equivalent to adding an adaptive noise $\nabla_{\boldsymbol{D}}\nabla_{\boldsymbol{W}}F(\boldsymbol{W};\boldsymbol{D})^{\mathrm{T}}\cdot\boldsymbol{\xi}$ to the parameter.

Moreover, the coefficient $\nabla_{\boldsymbol{D}}\nabla_{\boldsymbol{W}}F(\boldsymbol{W};\boldsymbol{D})$is the variation of $\nabla_{\boldsymbol{W}}F(\boldsymbol{W};\boldsymbol{D})$. If $\nabla_{\boldsymbol{W}}F(\boldsymbol{W};\boldsymbol{D})$ changes significantly according to the data $\boldsymbol{D}$, which means the gradient has a high distinction degree with regard to the data, i.e., the gradient leaks more information, the large coefficient will provide strong privacy protection. Otherwise, the small coefficient leads to better utility without violating the privacy requirements.

Additionally, Fig. 4 provides a toy example for understand-

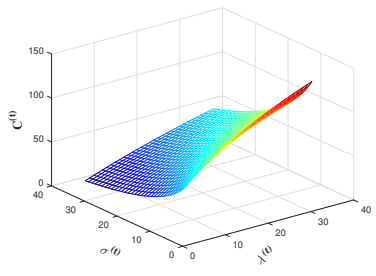

Figure 3: The channel capacity $C^{(t)}$ is the maximum MI increment at round t. It is an increasing function of $\lambda^{(t)}$ and a decreasing function of $\sigma^{(t)}$.

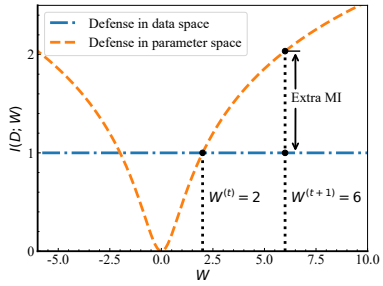

Figure 4: A toy example to explain the rationale for constraining in data space, which is equivalent to adding an adaptive noise to the parameter.

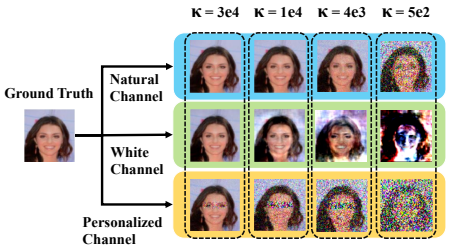

Figure 5: Visualizations for CelebA when we apply different channel implementations (Natural, White, and Personalized) and utilize different channel capacities.

ing the rationale of constraining in the data space. Specifically, we set $D \sim \mathcal{N}(-1,1)$ and our target is to decide the model W that minimizes $F(W;D) = W^2 D$ through gradient descent. Particularly, we require the information leakage to be less than 1, i.e., $C^{(t)} = 1$. As illustrated in Fig. 4, when we use the method in the parameter space to limit $C^{(t)} = 1$ at $W^{(t)} = 2$, i.e., adding the noise $\xi \sim \mathcal{N}(0, \frac{16}{e^2-1})$ to the gradient $\nabla_W F(W;D) = 2WD$, the resulting noise cannot guarantee $C^{(t+1)} = 1$ at next round $W^{(t+1)} = 6$ (we set the learning rate to 1), which implies that we need to recalculate the covariance matrix for the noise at each round. On the contrary, constraining in the data space (adding the noise $\xi \sim \mathcal{N}(0, \frac{1}{e^2-1})$ to the data D) results in an adaptive noise to guarantee $C^{(t)} = 1$ for all t regardless of $W^{(t)}$, leading to the $O(1)$ time-complexity for achieving the privacy requirement.

By incorporating different prior knowledge, we propose three implementation methods for deciding $\boldsymbol{\Sigma_\xi}$.

Natural Channel. For Natural Channel, the relative importance of different data attributes is naturally decided by the data itself. Specifically, based on Thm. 2, with substituting $\widetilde{\boldsymbol{D}}$ for $\widetilde{\boldsymbol{W}}_o^{(t)}$, we have

$$I(\boldsymbol{D};\widetilde{\boldsymbol{D}}) \le f(\sigma) = \frac{1}{2}\sum_{i=1}^{d} \ln \frac{\lambda_i + \sigma}{\sigma},\ \sigma \in (0, +\infty), \tag{18}$$

where λ_i and d represents the i-th eigenvalue and the dimension of data $\boldsymbol{D}$, respectively. In this case, we chose $\boldsymbol{\Sigma_\xi} = \sigma\mathbf{I}$. Moreover, $f(\sigma)$ is a monotone function of σ, hence there is a unique σ satisfying $f(\sigma) = \kappa$. Meanwhile, this σ guarantees $I(\boldsymbol{D};\widetilde{\boldsymbol{D}}) \le f(\sigma) = \kappa$. Combining it with Eq. (16), we conclude that the information leakage at time t is less than κ. However, $f(\sigma) = \kappa$ is a polynomial equation of order d, hence we need to solve it with numerical methods (e.g., binary search). In summary, the process of Natural Channel is

1. Make the eigen-decomposition of $\boldsymbol{\Sigma_D}$, which is the covariance matrix of data $\boldsymbol{D}$, to get $\Lambda = diag(\lambda_1, \cdots, \lambda_d)$
2. Solve the equation $f(\sigma) = \kappa$ to get σ with binary search
3. Get $\widetilde{\boldsymbol{D}} = \boldsymbol{D} + \boldsymbol{\xi}$, where $\boldsymbol{\xi} \sim \mathcal{N}(\mathbf{0}, \sigma\mathbf{I})$

White Channel. In the method of the White Channel, we treat the relative importance of all attributes to be equal, which provides much stronger protection for the local dataset. For such a purpose, we add a constraint to Eq. (18) as

$$f(\boldsymbol{\Psi}) = \frac{1}{2}\sum_{i=1}^{d} \ln \frac{\lambda_i + \sigma_i}{\sigma_i} = \kappa \tag{19}$$
$$s.t. \quad \ln \frac{\lambda_i + \sigma_i}{\sigma_i} = \ln \frac{\lambda_j + \sigma_j}{\sigma_j},\ \text{for } 1 \le i < j \le d,$$

where $\boldsymbol{\Psi} = \text{diag}(\sigma_1, \cdots, \sigma_d)$ represents the eigenvalues of $\boldsymbol{\Sigma_\xi}$. Then we can get $\sigma_i = \frac{\lambda_i}{\exp(2\kappa/d)-1}$ by solving Eq (19). Finally, we need to transform $\boldsymbol{\Psi}$ back to $\boldsymbol{\Sigma_\xi}$. According to Eq. (25) in the proof of Thm. 2, we have $\boldsymbol{\Sigma_D} = \boldsymbol{Q\Lambda Q}^T$, where $\boldsymbol{Q}$ is an orthogonal matrix composed with the eigenvectors of $\boldsymbol{\Sigma_D}$. Then with a similar process, we have $\boldsymbol{\Sigma_\xi} = \boldsymbol{Q\Psi Q}^T$. Therefore, the typical process of the White Channel is

1. Make the eigen-decomposition of $\boldsymbol{\Sigma_D}$ to get $\Lambda = diag(\lambda_1, \cdots, \lambda_d)$ and the eigenspace $\boldsymbol{Q}$
2. Get $\boldsymbol{\Psi} = \text{diag}(\sigma_1, \cdots, \sigma_d)$ by $\sigma_i = \frac{\lambda_i}{\exp(2\kappa/d)-1}$
3. Get $\boldsymbol{\Sigma_\xi} = \boldsymbol{Q\Psi Q}^T$
4. Get $\widetilde{\boldsymbol{D}} = \boldsymbol{D} + \boldsymbol{\xi}$, where $\boldsymbol{\xi} \sim \mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma_\xi})$

Personalized Channel. In practice, the relative importance of different attributes in data is different. For example, [59] claims that for online diagnosis, our target is to extract disease-relevant features but remove identity features from the facial images of patients, which means we add more noise to the identity features compared to the disease-relevant features. For analyzing the problem, we assume the relative importance of different dimensions is $\boldsymbol{\beta} = (\beta_0, \cdots, \beta_{d-1})^T$, e.g., (height, weight)=(1, 2) represents the relative importance of the height to the weight is 1 : 2.

The relative importance decides the level of noise addition. In other words, if the attribute is more important, we add more noise to it for stronger protection. To utilize the prior knowledge $\boldsymbol{\beta}$, we chose $\boldsymbol{\Sigma_\xi} = \sigma \cdot \text{diag}(\boldsymbol{\beta})$. According to the proof of Thm. 2, σ is decided by

$$f(\sigma) = \frac{\ln\det[\mathbf{\Sigma_D} + \sigma \cdot \mathrm{diag}(\boldsymbol{\beta})]}{2\sum_{i=1}^{d} \ln(\sigma \cdot \beta_i)} = \kappa. \tag{20}$$

However, the intrinsic correlations of local data bring difficulties in solving Eq. (20), so we derive the following theorem for simplifying the calculation.

Theorem 3 (Upper bound of Personalized Channel.)**.** *Let* $\mathbf{\Sigma} = \mathbf{\Sigma}_{d-1}$*, we can rewrite* $\mathbf{\Sigma}$ *as*

$$\mathbf{\Sigma}_i = \begin{pmatrix} \mathbf{\Sigma}_{i-1} & \boldsymbol{\rho}_i \\ \boldsymbol{\rho}_i^{\mathrm{T}} & c_{i,i} \end{pmatrix}, \ i \in \{0, \cdots, d-1\} \tag{21}$$

where d *represent the dimension of* $\mathbf{\Sigma}$*, then we have*

$$\ln\det(\mathbf{\Sigma} + \mathrm{diag}(\boldsymbol{\beta})) \leq \min[\sum_{i=0}^{d-1} \ln(c_{i,i} + \beta_i), \sum_{i=0}^{d-1} \ln(u_i + k_i)],$$

$$u_i = c_{i,i} - \boldsymbol{\rho}_i^{\mathrm{T}} \mathbf{\Sigma}_{i-1}^{-1} \boldsymbol{\rho}_i, \ k_i = \beta_i + (\mathbf{\Sigma}_{i-1}^{-1} \boldsymbol{\rho}_i)^{\mathrm{T}} \mathrm{diag}(\boldsymbol{\beta}) (\mathbf{\Sigma}_{i-1}^{-1} \boldsymbol{\rho}_i).$$

Combining Thm. 3 with Eq. (20), we can get an upper bound of the channel capacity for the Personalized Channel

$$U(\sigma) = \frac{\min[\sum_{i=0}^{d-1} \ln(c_{i,i} + \sigma\beta_i), \sum_{i=0}^{d-1} \ln(u_i + \sigma k_i)]}{2\sum_{i=1}^{d} \ln(\sigma \cdot \beta_i)}.$$

Moreover, $U(\sigma)$ decouples $\mathbf{\Sigma}$ and $\mathrm{diag}(\boldsymbol{\beta})$,hence we can use a pre-processing to reduce the calculation of solving $U(\sigma) = \kappa$. The process of the Personalized Channel is

1. Get u_i and k_i according to Thm. (3)
2. Solve the equation $U(\sigma) = \kappa$ to get σ with binary search
3. Get $\mathbf{\Sigma_\xi} = \sigma \cdot \mathrm{diag}(\boldsymbol{\beta})$
4. Get $\widetilde{\boldsymbol{D}} = \boldsymbol{D} + \boldsymbol{\xi}$, where $\boldsymbol{\xi} \sim \mathcal{N}(\mathbf{0}, \mathbf{\Sigma_\xi})$

Finally, we visualize $\widetilde{\boldsymbol{D}}$ of different implementations according to different channel capacities in Fig. 5.

Furthermore, constraining in the data space brings two advantages: first, compared to the parameter space, data space is white-box, low-dimensional, and time-invariant. Second, in the data space, the relative importance of attributes is preserved, which makes it easier to leverage prior knowledge.

Guidelines for noise injection. In summary, for defending against DRA, the important target is to restrict the transmitted information by noise addition. Here we provide guidelines for the noise injection:

- For privacy-enhancing techniques (e.g., DP and gradient compression) in FL, the reconstruction error for DRA is theoretically above a threshold (Thm. 1) when we restrict the transmitted information within κ. It can be achieved by solving $f(\sigma) = \kappa$, where $f(\sigma)$ is defined in Eq. (18). This equation decides the injection noise with corresponding statistics.
- For defending against DRA in FL, we can inject noise to the training data instead of transmitted parameters. This transformation can produce an adaptive noise, which reduces the computational complexity brought by the high dimensional and time-variant system in FL.
- For any pre-processing process such as embedding, we can get the same theoretical guarantee by substituting $\mathbf{\Sigma}_{embedding}$ for $\mathbf{\Sigma_D}$ in Eq. (18), where $\mathbf{\Sigma}_{embedding}$ and $\mathbf{\Sigma_D}$ are covariance matrixes calculated by embeddings and data, respectively.
- In our method, a larger batch size leads to a tighter upper bound and a stronger ability to defend against DRA.

5.3 Channel Capacity for Existing Methods

With Thm. 1 and Thm. 2, we can analyze existing methods for defending against DRA by the channel capacity $C^{(t)}$.

Existing privacy-enhancing methods in FL can be divided into three categories: perturbation, compression, and utilizing large batch size. The method of perturbation is represented by DP. Moreover, we demonstrate that for defending against DRA, the methods of gradient compression and utilizing large batch size are equivalent to adding more noise for perturbation, and the intrinsic mechanism of them are restricting the transmitted information.

Perturbation. As a method with theoretical guarantee, DP focuses on the problem of protecting individual information. In this work, we consider the event-level DP [35, 37] because we focus on the privacy issue for a specific client (i.e., the victim). That is, whether the attacker can reconstruct the local dataset with the victim's shared parameters. Specifically, the widely used DP technique in FL is the Gaussian mechanism, thus we analyze the Gaussian mechanism in this section. A typical process of the Gaussian mechanism for (ε, δ)-DP consists of two stages: gradient clipping, which guarantees the sensitivity of the gradient is bounded; noise addition, which provides the (ε, δ)-DP guarantee based on the bounded sensitivity. To analyze DP based on information theory, we have the following theorem.

Theorem 4 (Channel capacity for DP)**.** *In FL, if the sensitivity of the gradient mapping is upper bounded by S, i.e.,* $\|\boldsymbol{g}\|_2 \leq S$*, the channel capacity of* (ε, δ)*-DP, i.e.,* C_{DP}*, is upper bounded by following formulas:*

(1) $C_{DP} \leq \frac{B \cdot S^2}{\sigma}$,

(2) $C_{DP} \leq \frac{B \cdot \varepsilon^2}{2\log(1.25/\delta)}$,

where B *represents the batch size and* σ *is the noise scale.*

Compared to the conventional DP theorem, Thm. 4 indicates that batch size B is a key factor of the defense ability to defend against DRA, which has been overlooked by prior literature. Specifically, increasing B reduces DP's ability to defend against DRA, which has been validated by experiments in Fig. 6 (the details are explained in Appendix D).

Compression. Another defense technique is compression, it intuitively focuses on reducing transmitted information by reducing the dimension of shared parameters. However, most of these methods lack theoretical guarantees.

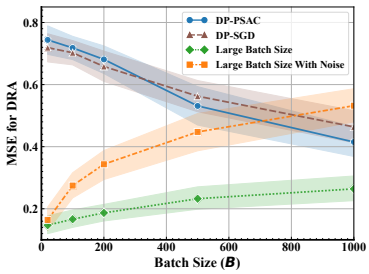

Figure 6: Defensive capabilities of DP and utilizing large batch size according to different batch sizes.

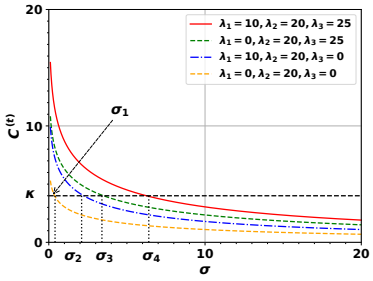

Figure 7: Reducing the dimensionality of a gradient is equivalent to adding more noise into the original gradient.

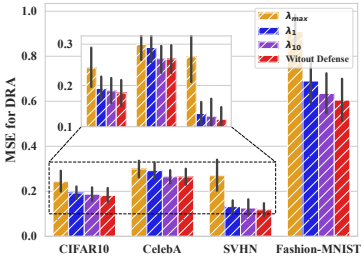

Figure 8: DRA becomes more difficult when we compress the dimension with a large eigenvalue.

Specifically, information is contained in each dimension of the gradient (i.e., the parameter), and the channel capacity decreases accordingly when we reduce the dimension of it. If we analyze the compression in the eigenspace, dimension reduction can be theoretically described by Thm. 2. Specifically, the total channel capacity is $C^{(t)} = \frac{1}{2}\sum_{i=1}^{d} \ln \frac{\lambda_i^{(t)}+\sigma}{\sigma}$, and the general term $\frac{1}{2}\ln\frac{\lambda_i^{(t)}+\sigma}{\sigma}$ represents the channel capacity of the i-th dimension. Compressing the i-th dimension in the eigenspace, i.e., setting $\lambda_i^{(t)} = 0$, leads the channel capacity of i-th dimension to be 0, thereby reducing the total channel capacity. As illustrated in Fig. 7, when we compress the gradient, i.e., setting eigenvalues to be 0, the results are equivalent to adding more noise for perturbation. As displayed in Fig. 8, we also conduct experiments to validate our theoretical result, the experiments indicate that the improvement of the defense ability becomes more significant when we compress the dimension with a larger eigenvalue (the details are explained in Appendix D).

Large Batch Size. Another defense strategy for privacy protection in FL is utilizing large batch size [63]. Our model can theoretically formalize this strategy. If we denote the batch size as B, then the gradient in mini-batch SGD is $\frac{1}{B}\sum_{i=1}^{B}\nabla_{\boldsymbol{W}} F(\boldsymbol{W}_i^{(t)}; \boldsymbol{D}_i)$, where $\{\boldsymbol{D}_i\}_{i=1}^{B}$ represents the set of iid data points sampled from the dataset. The covariance matrix with large batch size is scaled by B, i.e., $\boldsymbol{\Sigma}_B^{(t)} = \frac{1}{B}\boldsymbol{\Sigma}^{(t)}$. Hence, with substituting $\boldsymbol{\Sigma}_B^{(t)}$ for $\boldsymbol{\Sigma}^{(t)}$ in Thm. 2, we have

$$C_B^{(t)} = f_B^{(t)}(\sigma) := \frac{1}{2}\sum_{i=1}^{d} \ln \frac{(\lambda_i^{(t)}/B+\sigma)}{\sigma}. \tag{22}$$

With the constant noise addition, $C^{(t)}$ is a decreasing function of B, which means we can enhance the ability to defend against DRA by increasing B. Fig. 6 experimentally validates this theory and we put the details of Fig. 6 in Appendix D due to the space limitation.

Guidelines for hyper-parameters. Finally, to improve existing defensive algorithms, we provide several guidelines for choosing the hyper-parameters in FL:

- A smaller batch size in DP algorithm is more effective to defend against DRA.
- Compressing the dimension with larger eigenvalue results in the stronger ability to defend against DRA.
- A larger batch size leads to a stronger defense ability to defend against DRA when we add a constant noise to the parameter during training.

6 Experiment

In this section, we conduct experiments with various models and datasets to validate our theories and compare our methods with other privacy-enhancing techniques. All experiments are performed upon a Supermicro SYS-420GP-TNR server with two Intel(R) Xeon(R) Gold 6348 CPUs (2×28 cores), Ubuntu 18.04.1, 10GB memory, and four NVIDIA A100 PCIe 80GB GPUs. Meanwhile, to eliminate the impact of randomness, each experiment is repeated 10 times.

6.1 Experimental Settings

Datasets. Dataset is a task-dependent factor, which means we cannot change the dataset when the training task is decided. In our experiments, we resize the data to 32*32 for comparison, and utilize four classical datasets, including CIFAR10 [31], CelebA [39], SVHN [45], and Fashion-MNIST [57].

Basic Models. In this work, we experiment with four classical model architectures, including LeNet [33], AlexNet [32], VGG16 [50], and ResNet10 [27]. Moreover, model architectures are task-independent, we can select architectures according to different goals, e.g., utility or privacy.

Attacks. We test our methods on two typical attacks in FL: *MIA* and *DRA*, the details of different attacks are as follows.

Membership Inference Attack. For MIA, we use the white-box attack [38, 44]. Meanwhile, we employ a partial knowledge attacker, which means the attacker can access to part of the training dataset. In this case, the attacker has much stronger background knowledge. Moreover, we use four inputs for attacking [38]: the samples' ranked posteriors, classification loss, gradients of the last layer, and one-hot encoding of the true label. These inputs are fed into different neural networks to get different embeddings, then we concatenate all embeddings as the input of a 4-layer MLP to get the inference.

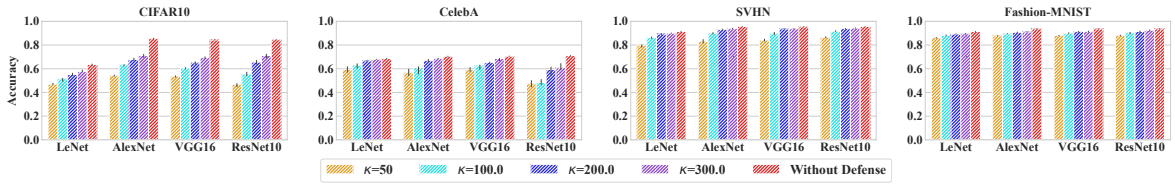

Figure 9: The effect of channel capacities (κ) for model accuracy (Natural Channel).

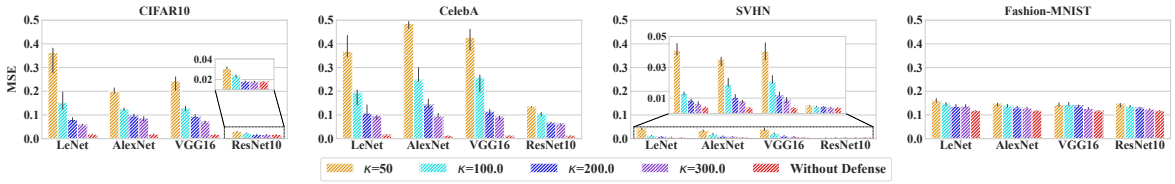

Figure 10: The effect of channel capacities (κ) for DRA (Natural Channel).

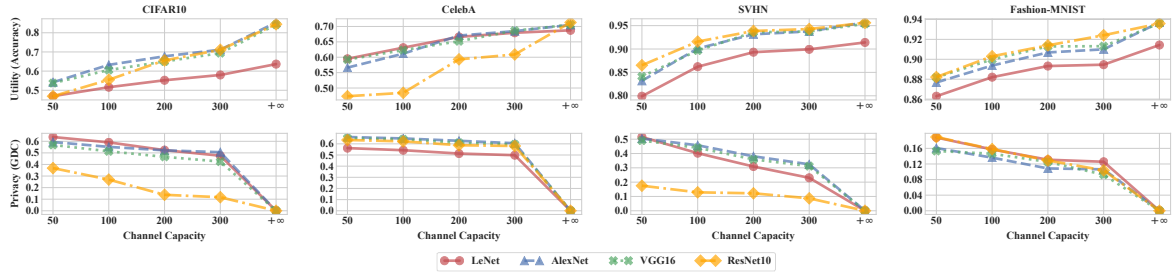

Figure 11: Utility privacy tradeoff according to different channel capacities.

Data Reconstruction Attack. For DRA, we employ two representative attacks: model inversion attack and gradient inversion attack. For model inversion attack [20, 38], we first construct a dummy input with auxiliary information (i.e., the mean value of images that are not in the training dataset) as the input for the target model, then utilize different target labels to optimize the dummy input. We use Adam optimizer with a learning rate of 1e-2 for 600 iterations. Additionally, we employ the settings proposed by Geiping et al. [21] to investigate the defense ability for gradient inversion attacks.

Metric. We evaluate our design with various criteria, including the model utility, the defense capability against different attacks, the utility-privacy trade-offs, and the efficiency. To this end, we employ the following metrics for evaluation.

Test Accuracy. FL searches for an accurate model for classification, hence we use test accuracy as the metric for utility.

AUC. We use the attack AUC to measure the attack performance for MIA. It's worth noting that a smaller AUC means a stronger defense capability.

MSE. We use MSE as the main metric for DRA since MSE is a general metric that indicates the convergence of random variables. That is, if the MSE of two random variables is 0, we conclude that they have identical distributions [55], which means a perfect reconstruction. Additionally, a large MSE means a stronger ability to defend against DRA. Specifically, for model inversion attacks, we calculate the metric between the reversed data and the center of the corresponding class for different classes. We use the median of all classes as the final metric. For gradient inversion attacks, we employ the mean value of the metric between the reconstructed data and the target data.

General Defense Capability (GDC). For evaluating the comprehensive defense capability, we use the improvements of the aforementioned attacks. Specifically, for MIA, we define the improvement as

$$IMP_{MIA} = (AUC_{without\_def} - AUC)/AUC_{without\_def}.$$

While the improvement for DRA is

$$IMP_{DRA} = (\frac{1}{MSE_{without\_def}} - \frac{1}{MSE})/\frac{1}{MSE_{without\_def}}.$$

Finally, we define general defense capability as

$$GDC = (IMP_{MIA} + IMP_{DRA})/2,$$

and a larger *GDC* means a stronger defense capability.

Default parameter configuration. In our experiments, we mainly utilize natural channel to investigate the channel parameters. Specifically, we fix the optimization rounds as $n = 1 \times 10^4$ and utilize κ in {50, 100, 200, 300} to investigate the effect of different channel capacities. Additionally, we fix $\kappa = 300$ and utilize $TotalInfo$ in $\{5 \times 10^5, 1 \times 10^6, 2 \times 10^6, 3 \times 10^6\}$ to investigate the effect of different n, where $n = \lfloor \frac{TotalInfo}{\kappa} \rfloor$ and $\lfloor \cdot \rfloor$ is the floor function. We will explicitly explain it when we utilize different configurations.

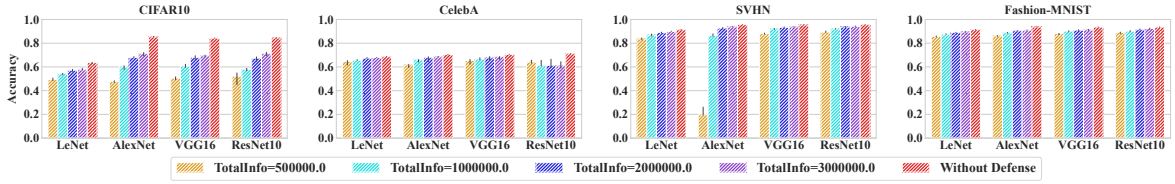

Figure 12: The effect of optimization number (n) for model accuracy when $\kappa = 300$ (Natural Channel).

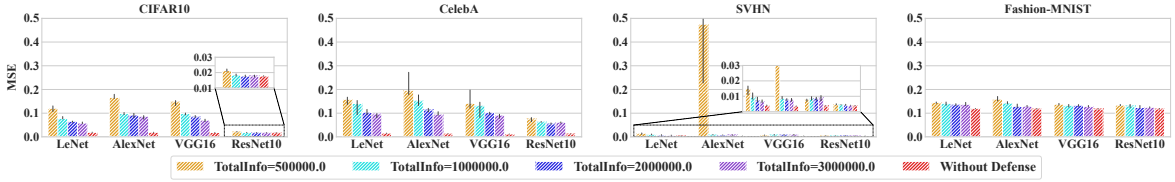

Figure 13: The effect of optimization number (n) for DRA when $\kappa = 300$ (Natural Channel).

6.2 The Effect of Controlled Channel

Impact of channel capacity (κ). κ represents the upper bound of information leakage in a single training round. As illustrated in Fig. 9, when we enhance the channel, i.e., increase κ, the accuracy increases accordingly regardless of the datasets and the model architectures, which means a wider channel leads to a better utility. However, the increasing utility is at the cost of reducing data privacy. Fig. 10 displays the corresponding defense capability against DRA. Specifically, for DRA attacks, the MSE decreases according to the increasing κ, which means the reconstructed data is closer to the target data. These results indicate that in the practical scenario, we can adjust channel capacity by κ to balance the utility and the privacy according to various requirements.

Moreover, we explicitly display the utility-privacy tradeoff in Fig. 11. Specifically, the utility increases with the increase of channel capacity κ, while the ability of privacy protection decreases with the increase of κ. These results are reasonable since channel capacity constrains the transmitted information, and the reconstruction error, i.e., the MSE, can be theoretically restricted when the transmitted information is limited based on Thm. 1. Meanwhile, more available information results in a more accurate model, indicating that the adjustable channel capacity can be utilized to balance the utility-privacy tradeoff.

Impact of optimization rounds (n). Different from the channel capacity C, the number of optimization rounds n affects the parameter channel through another dimension: information accumulation. Similarly, the results in Fig. 12 and 13 imply that n is another parameter to influence the utility and the defense ability of the controlled channel. Increasing n results in obtaining more information from the local dataset, thereby enhancing the utility while reducing the defense ability.

Defense ability against gradient inversion attack. We randomly select 30 images from each dataset as the target data and evaluate the defense abilities to defend against gradient inversion attacks. As shown in Fig. 14, the MSE of data reconstruction consistently increases as we decrease the threshold κ, which means a smaller κ leads to a stronger ability to defend against DRA. The MSE of the White Channel and the Personalized Channel are larger than the Natural Channel, indicating that the other two methods provide stronger defense capability compared to the Natural Channel.

6.3 Comparing with Other Methods

In this section, we compare our methods with two classic perturbation mechanisms: DP-SGD [1] and DP-PSAC [56]. Specifically, DP-SGD first utilizes DP for ML and DP-PSAC is the state-of-art method to improve DP-SGD by adaptively clipping the gradients.

Utility-Privacy trade-off. We first compare our methods with DP-SGD and DP-PSAC in the utility-privacy plane. The plane is formed by two axes: the x-axis represents GDC, which is the general ability for privacy protection. While the y-axis represents the accuracy, which represents the utility. For all methods, we use the model of LeNet and fix the rounds as $n = 1 \times 10^4$. The results are displayed in Fig. 15. Specifically, in our methods, we use channel capacity in {50, 100, 200,

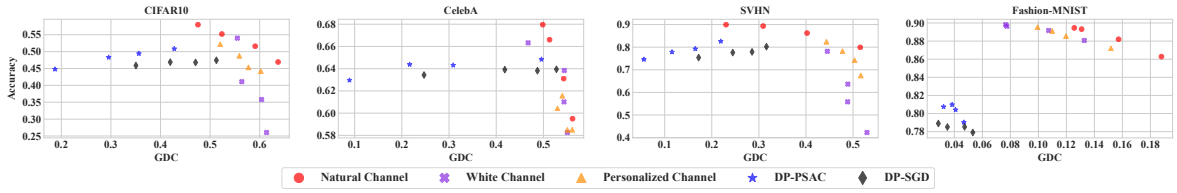

Figure 15: Evaluating different methods in the Utility-Privacy plane.

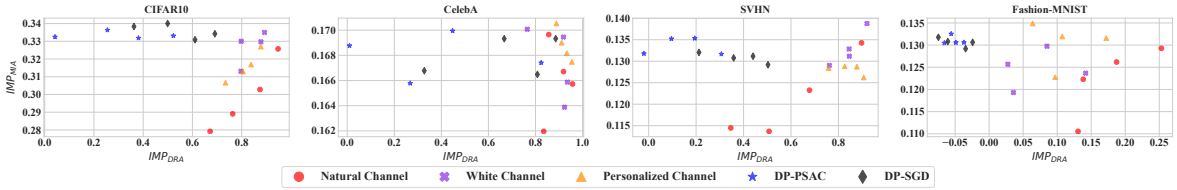

Figure 16: Evaluating different methods in the Defense-Defense plane.

300} for the Natural Channel, and {500, 800, 1000, 1500} for the White Channel and the Personalized Channel. Additionally, we use 1:50 in β for the Personalized Channel to protect the attributes around the eyes (Appendix C indicates the details of β). For DP-SGD and DP-PSAC, we use the clipping bound $S = 1.0$, $\delta = 1 \times 10^{-5}$ ($\delta = 3 \times 10^{-6}$ for CelebA), and the multiplier $\sqrt{\sigma}$ in {0.8, 0.57, 0.46, 0.2066} (the corresponding privacy budget ε for these DP training are {1.705, 5.120, 12.026, 331.668}, respectively) . According to Thm. 4, these σ result in channel capacities in {100, 200, 300, 1500} when we utilize $B = 64$, which are identical to the channel capacities of our methods. As in Fig. 15, the Natural Channel achieves the best utility-privacy trade-off. The reason is that it utilizes the original importance to maintain the information in data attributes, and the constrained channel capacity ensures the ability to defend against DRA.

Comparison of the details in defense ability. To investigate the detailed defense ability of different methods, we decouple the defense capabilities to display them in the defense-defense plane. Specifically, x-axis represents IMP_{DRA} and y-axis represents IMP_{MIA}. As displayed in Fig. 16, DP specializes in defending against MIA but is weaker in defending against DRA, this is reasonable since DP focuses on protecting individual information. Compared to DP, our methods specialize in defending against DRA. Moreover, our methods achieve the best comprehensive defense capability for both attacks.

Table 2: Training time (s) for 25 epochs of different models

Model	Parameters	SGD	DP-SGD	Ours
LeNet	6.20×10^4	283.43±0.95	445.45±20.41 (+57.16%)	312.99±1.40 (+10.43%)
ResNet10	4.90×10^6	624.23±8.66	1397.34±17.38 (+123.85%)	651.29±10.39 (+4.33%)
AlexNet	3.59×10^7	374.13±2.68	1023.83±2.85 (+173.66%)	406.02±1.04 (+8.52%)
VGG16	1.34×10^8	581.69±5.35	3402.91±4.72 (+485.00%)	612.99±4.62 (+5.38%)

Efficiency of constraining in the data space. As displayed in Tab. 2, we compare the efficiency of our method with DP-SGD, which is a method that works in the parameter space. We use OPACUS 1.1.2 [60] for the implementation of DP-SGD. The results indicate that when we transform the operations to the data space, it significantly reduces the amount of calculation, i.e., the training time, especially when the dimension of the parameter increases.

7 Related Work

Differential Privacy. Differential Privacy [18] is an important technique for privacy protection. For the definition of differential privacy, Mironov [43] proposes to utilize Rényi divergence, which leads to compact and accurate privacy loss. Moreover, Abadi et al. [1] propose an empirical algorithm DP-SGD for applying DP to ML training, then multiple literature tries to improve the performance of DP-SGD [3, 6, 9, 56]. Most of them focus on the utility, trying to adaptively clip the gradients or add suitable perturbations. For the application of DP, Levy et al. [35] propose to protect user-level DP instead of ensuring the privacy of individual samples, which makes DP more reliable to FL. Truex et al. [53] present a protocol LDP-Fed to formally ensure data privacy in collecting local parameters with high precision. However, DP is still vulnerable to DRA, several researchers indicate that they can reconstruct the data without violating the requirements of DP [14, 17], implying that the algorithms are still vulnerable to DRA. Compared to DP, our work aims to defend against DRA based on information theory.

Limiting Mutual Information. Another related concept of privacy protection depends on MI. Several studies connect MI with DP by deriving the upper bound of MI for a distinct DP mechanism [4, 8, 16]. For privacy protection, Li et al. [36] propose to train a feature extractor that minimizes MI between the output features and the assigned label while maximizing the MI between output features and the original

data. Similarly, Osia et al. [46] propose to train an extractor with the variational lower bound for MI estimation. Moreover, Hannun et al. [25] utilize Fisher Information to measure the information leakage, and the conclusions are consistent with our theories. Finally, we can also model FL based on information theory [2, 54], which measures the MI between different variables in FL. Compared to the former methods, our technique models the communication channel of FL directly based on information theory and utilizes its upper bound to derive practical methods for constraining the transmitted information, which leads to the strong ability to defend against DRA.

8 Discussion and Conclusion

Our method constrains the information leakage of the black-box model according to an upper bound derived by maximum entropy distribution (Lemma 1). We can tighten the upper bound by utilizing a large batch size or incorporating domain knowledge. Among them, utilizing large batch size for training causes the output distribution to be closer to a Gaussian distribution, while incorporating domain knowledge enables us to get more properties of the output distribution. If we get a tighter upper bound, the tradeoff between utility and privacy can be further improved.

In summary, as the reconstruction error of DRA is decided by the transmitted information, we build a channel model to measure the information leakage of the black-box model in FL. The model indicates that the amount of transmitted information is decided by the channel capacity C and the number of optimization rounds n. Guided by the model, we develop methods to constrain the channel capacity within a threshold κ. Combining it with the limited optimization rounds n, the upper bound of the total transmitted information remains below $n \cdot \kappa$, which ensures the ability to defend against DRA. Furthermore, we transform the operations of constraining channel capacity from the parameter space to the data space. The transformation significantly improves the training efficiency and the model accuracy under constrained information leakage. Finally, extensive experiments with real-world datasets validate the benefit of our methods.

A The detail explanation of DRA

For DRA in FL, the attacker aims to build a reconstruction $\hat{\boldsymbol{D}}(\boldsymbol{W}_i, \boldsymbol{W}_o)$ to approximate the data $\boldsymbol{D}$, where $\boldsymbol{W}_i$ and $\boldsymbol{W}_o$ are the transmitted parameters in FL. Moreover, if the MSE between $\hat{\boldsymbol{D}}(\boldsymbol{W}_i, \boldsymbol{W}_o)$ and $\boldsymbol{D}$ achieves 0, i.e., $\mathbb{E}\|\hat{\boldsymbol{D}}(\boldsymbol{W}_i, \boldsymbol{W}_o) - \boldsymbol{D}\|^2 = 0$, we conclude that $\hat{\boldsymbol{D}}(\boldsymbol{W}_i, \boldsymbol{W}_o)$ and $\boldsymbol{D}$ have identical distributions [55].

Additionally, with the definition of $\boldsymbol{D}$, i.e., the random variable that follows the distribution of the local dataset, the MIA [10] can be viewed as inferring whether a particular data point belongs to the support set of $\boldsymbol{D}$.

B Proofs of Lemmas and Theorems

B.1 Proof of Theorem 1

Before the proof of Thm. 1, we have the following lemma.

Lemma 2. *For any d-dimensional semi-positive definite matrix $\boldsymbol{A}$, i.e., $\boldsymbol{A} \in \mathbb{R}^{d\times d}$, we have* $\det(\boldsymbol{A}) \leq \left(\frac{\mathrm{tr}(\boldsymbol{A})}{d}\right)^d$.

Proof. Since $\boldsymbol{A}$ is a semi-positive definite matrix, we have its eigen values, i.e., $\{\lambda_i\}_{i=1}^d$, are non-negative. we can get

$$\det(\boldsymbol{A}) = \prod_{i=1}^{d} \lambda_i \leq \left(\frac{\sum_{i=1}^{d}\lambda_i}{d}\right)^d = \left(\frac{\mathrm{tr}(\boldsymbol{A})}{d}\right)^d,$$

where the inequality depends on the AM-GM inequality. □

Then based on Lemma 2, we can prove Thm. 1.

Proof. As $Cov(\boldsymbol{D})$ is the covariance matrix of $\boldsymbol{D}$, we have

$$\begin{aligned}
h(\boldsymbol{D}|\boldsymbol{W}) &\overset{(1)}{\leq} \mathbb{E}_{\boldsymbol{W}}[\frac{d}{2}\log(2\pi e) + \frac{1}{2}\log\det(Cov(\boldsymbol{D}|\boldsymbol{W}))] \\
&\overset{(2)}{\leq} \frac{d}{2}\log(2\pi e) + \mathbb{E}[\frac{d}{2}\log(\frac{\mathrm{tr}(Cov(\boldsymbol{D}|\boldsymbol{W}))}{d})] \\
&\overset{(3)}{\leq} \frac{d}{2}\log(2\pi e) + \mathbb{E}[\frac{d}{2}\log(\frac{\mathbb{E}[\|\boldsymbol{D}-\hat{\boldsymbol{D}}(\boldsymbol{W})\|^2|\boldsymbol{W}]}{d})] \\
&\overset{(4)}{\leq} \frac{d}{2}\log(2\pi e) + \frac{d}{2}\log(\frac{\mathbb{E}[\mathbb{E}[\|\boldsymbol{D}-\hat{\boldsymbol{D}}(\boldsymbol{W})\|^2|\boldsymbol{W}]]}{d}) \\
&= \frac{d}{2}\log(2\pi e) + \frac{d}{2}\log(\frac{\mathbb{E}[\|\boldsymbol{D}-\hat{\boldsymbol{D}}(\boldsymbol{W})\|^2]}{d}),
\end{aligned}$$

where (1) is a consequence that with identical mean vector and covariance matrix, Gaussian distribution is the maximum entropy distribution. (2) depends on Lemma 2. The reason for (3) is that mean vector is the optimal estimator in terms of mean squared error, and (4) is a consequence of Jensen's inequality. Hence,

$$\begin{aligned}
\mathbb{E}[\|\boldsymbol{D}-\hat{\boldsymbol{D}}(\boldsymbol{W})\|^2/d]) &\geq \frac{1}{2\pi e}e^{2h(\boldsymbol{D}|\boldsymbol{W})/d} \\
&= \frac{e^{2h(\boldsymbol{D})/d}}{2\pi e}e^{-2I(\boldsymbol{D};\boldsymbol{W})/d},
\end{aligned}$$

where the last equality is a consequence of Eq. (4). □

B.2 Proof of Lemma 1

Proof. Firstly, as $\boldsymbol{X}$ and $\boldsymbol{Y}$ are independent, then $\mathbb{E}[\boldsymbol{X}+\boldsymbol{Y}] = \boldsymbol{\mu}_{\boldsymbol{X}} + \boldsymbol{\mu}_{\boldsymbol{Y}}$ and $Cov(\boldsymbol{X}+\boldsymbol{Y}) = \boldsymbol{\Sigma}_{\boldsymbol{X}} + \boldsymbol{\Sigma}_{\boldsymbol{Y}}$.

Secondly, with a specific mean vector and covariance matrix, the maximum entropy distribution is Gaussian, which implies that $h(\boldsymbol{X}+\boldsymbol{Y}) \leq h(\mathcal{N}(\boldsymbol{\mu}_{\boldsymbol{X}}+\boldsymbol{\mu}_{\boldsymbol{Y}}, \boldsymbol{\Sigma}_{\boldsymbol{X}}+\boldsymbol{\Sigma}_{\boldsymbol{Y}}))$.

Finally, if $\boldsymbol{X} \sim \mathcal{N}(\boldsymbol{\mu_X}, \boldsymbol{\Sigma_X})$, then $\boldsymbol{X}+\boldsymbol{Y} \sim \mathcal{N}(\boldsymbol{\mu_X}+\boldsymbol{\mu_Y}, \boldsymbol{\Sigma_X}+\boldsymbol{\Sigma_Y})$, which concludes the proof. □

B.3 Proof of Theorem 2

Proof. According to the relationship between mutual information and differential entropy, we have

$$\begin{aligned} & I(\boldsymbol{D}, \widetilde{\boldsymbol{W}}_o^{(t)} \mid \boldsymbol{W}_i^{(t)}) \\ &= h(\widetilde{\boldsymbol{W}}_o^{(t)} \mid \boldsymbol{W}_i^{(t)}) - h(\widetilde{\boldsymbol{W}}_o^{(t)} \mid \boldsymbol{D}, \boldsymbol{W}_i^{(t)}) \\ &= h(\widetilde{\boldsymbol{W}}_o^{(t)} \mid \boldsymbol{W}_i^{(t)}) - h(\mathcal{N}(\boldsymbol{0}, \sigma \cdot \mathbf{I})) \\ &\leq h(\mathcal{N}(\boldsymbol{\mu}^{(t)}, \boldsymbol{\Sigma}^{(t)} + \sigma \cdot \mathbf{I})) - h(\mathcal{N}(\boldsymbol{0}, \sigma \cdot \mathbf{I})), \end{aligned} \tag{23}$$

where the second equality depends on the fact that $\boldsymbol{W}_o^{(t)}$ is a constant when $\boldsymbol{W}_i^{(t)}$ and $\boldsymbol{D}$ are both observed. The last inequality is an immediate consequence of Lemma 1 with $\widetilde{\boldsymbol{W}}_o^{(t)} = \boldsymbol{W}_o^{(t)} + \sqrt{\sigma} \cdot \boldsymbol{\xi}$.

Then with the differential entropy of Gaussian distribution, we can further transform Eq. (23) to

$$\begin{aligned} & h(\mathcal{N}(\boldsymbol{\mu}^{(t)}, \boldsymbol{\Sigma}^{(t)} + \sigma \cdot \mathbf{I})) - h(\mathcal{N}(\boldsymbol{0}, \sigma \cdot \mathbf{I})) \\ =& \frac{1}{2} \ln (2\pi e)^d \det(\boldsymbol{\Sigma}^{(t)} + \sigma \cdot \mathbf{I}) - \frac{1}{2} \ln (2\pi e)^d \sigma^d, \end{aligned} \tag{24}$$

where $\det(\cdot)$ denotes the determinant of a matrix and the second term of Eq. (24) is decided by $\det(\sigma \cdot \mathbf{I}) = \sigma^d$.

Next, we focus on the first term of Eq. (24). Note that $\boldsymbol{\Sigma}^{(t)}$ is the covariance matrix of $\boldsymbol{W}_o^{(t)}$, hence it's a real symmetric matrix, then according to eigen decomposition, we have

$$\boldsymbol{\Sigma}^{(t)} = \boldsymbol{Q}^{(t)} \boldsymbol{\Lambda}^{(t)} \boldsymbol{Q}^{(t)\mathrm{T}} = \boldsymbol{Q}^{(t)} \mathrm{diag}(\lambda_1^{(t)}, \cdots, \lambda_d^{(t)}) \boldsymbol{Q}^{(t)\mathrm{T}}, \tag{25}$$

where $\boldsymbol{Q}^{(t)}$ is an orthogonal matrix, i.e., $\boldsymbol{Q}^{(t)} \boldsymbol{Q}^{(t)\mathrm{T}} = \mathbf{I}$. Hence, $\sigma \cdot \mathbf{I} = \boldsymbol{Q}^{(t)} (\sigma \mathbf{I}) \boldsymbol{Q}^{(t)\mathrm{T}}$. Then we have

$$\begin{aligned} & \det(\boldsymbol{\Sigma}^{(t)} + \sigma \cdot \mathbf{I}) \\ =& \det(\boldsymbol{Q}^{(t)} \mathrm{diag}(\lambda_1^{(t)}, \cdots, \lambda_d^{(t)}) \boldsymbol{Q}^{(t)\mathrm{T}} + \boldsymbol{Q}^{(t)} (\sigma \mathbf{I}) \boldsymbol{Q}^{(t)\mathrm{T}}) \\ =& \det(\mathrm{diag}(\lambda_1^{(t)}, \cdots, \lambda_d^{(t)}) + \sigma \mathbf{I}) = \prod_{i=1}^{d} (\lambda_i^{(t)} + \sigma). \end{aligned}$$

Then we have $I(\boldsymbol{D}, \widetilde{\boldsymbol{W}}_o^{(t)} \mid \boldsymbol{W}_i^{(t)}) \leq \frac{1}{2} \ln \frac{\prod_{i=1}^{d} (\lambda_i^{(t)} + \sigma)}{\sigma^d}$, which immediately completes the proof. □

B.4 Proof of Theorem 3

Before the proof of Thm. 3, we have the following lemma.

Lemma 3. *For any d-dimensional semi-positive definite matrix $\boldsymbol{A}$ and $\boldsymbol{B}$, we have*

(1) $\boldsymbol{\alpha}^{\mathrm{T}} (\boldsymbol{A}+\boldsymbol{B})^{-1} \boldsymbol{\alpha} \leq \boldsymbol{\alpha}^{\mathrm{T}} \boldsymbol{A}^{-1} \boldsymbol{\alpha}$,
(2) $\boldsymbol{\alpha}^{\mathrm{T}} (\boldsymbol{A}+\boldsymbol{B})^{-1} \boldsymbol{\alpha} \leq \boldsymbol{\alpha}^{\mathrm{T}} \boldsymbol{B}^{-1} \boldsymbol{\alpha}$,

where $\boldsymbol{\alpha}$ is a d-dimensional vector.

Proof. Here we only prove inequality (1), and the proof for inequality (2) is the same as inequality (1). First, we have

$$(\boldsymbol{A}+\boldsymbol{B})^{-1} = \boldsymbol{A}^{-1} - \boldsymbol{A}^{-1} (\boldsymbol{A}^{-1} + \boldsymbol{B}^{-1})^{-1} \boldsymbol{A}^{-1}, \tag{26}$$

hence, we can get following result.

$$\boldsymbol{\alpha}^{\mathrm{T}} (\boldsymbol{A}+\boldsymbol{B})^{-1} \boldsymbol{\alpha} = \boldsymbol{\alpha}^{\mathrm{T}} (\boldsymbol{A}^{-1} - \boldsymbol{A}^{-1} (\boldsymbol{A}^{-1} + \boldsymbol{B}^{-1})^{-1} \boldsymbol{A}^{-1}) \boldsymbol{\alpha}.$$

Then we need to prove

$$\boldsymbol{\alpha}^{\mathrm{T}} \boldsymbol{A}^{-1} (\boldsymbol{A}^{-1} + \boldsymbol{B}^{-1})^{-1} \boldsymbol{A}^{-1} \boldsymbol{\alpha} \geq 0. \tag{27}$$

As $\boldsymbol{A}^{-1}$ is a symmetric matrix, we can rewrite Eq. (27) as

$$\tilde{\boldsymbol{\alpha}}^{\mathrm{T}} (\boldsymbol{A}^{-1} + \boldsymbol{B}^{-1})^{-1} \tilde{\boldsymbol{\alpha}} \geq 0, \tag{28}$$

where $\tilde{\boldsymbol{\alpha}} = \boldsymbol{A}^{-1} \boldsymbol{\alpha}$. As $\boldsymbol{A}$ and $\boldsymbol{B}$ are semi-positive definite, we have $(\boldsymbol{A}^{-1} + \boldsymbol{B}^{-1})^{-1}$ is a semi-positive definite matrix either, hence inequality (28) holds, which concludes the proof. □

Then with Lemma 3, we can prove Thm. 3.

Proof. As we can rewrite $\boldsymbol{\Sigma}_i$, $i \in \{0, \cdots, d-1\}$, as

$$\begin{aligned} \boldsymbol{\Sigma}_i &= \begin{pmatrix} \boldsymbol{\Sigma}_{i-1} & \boldsymbol{\rho}_i \\ \boldsymbol{\rho}_i^{\mathrm{T}} & c_{i,i} \end{pmatrix} \\ &= \begin{pmatrix} \boldsymbol{I}_{i-1} & \boldsymbol{0} \\ \boldsymbol{\rho}_i^{\mathrm{T}} \boldsymbol{\Sigma}_{i-1}^{-1} & 1 \end{pmatrix} \begin{pmatrix} \boldsymbol{\Sigma}_{i-1} & \boldsymbol{\rho}_i \\ \boldsymbol{0} & c_{i,i} - \boldsymbol{\rho}_i^{\mathrm{T}} \boldsymbol{\Sigma}_{i-1}^{-1} \boldsymbol{\rho}_i \end{pmatrix}, \end{aligned} \tag{29}$$

Hence, the determinant is

$$\det \boldsymbol{\Sigma}_i = (c_{i,i} - \boldsymbol{\rho}_i^{\mathrm{T}} \boldsymbol{\Sigma}_{i-1}^{-1} \boldsymbol{\rho}_i) \det \boldsymbol{\Sigma}_{i-1}. \tag{30}$$

Based on this result, with substitution $\boldsymbol{\Sigma}_i + \boldsymbol{\beta}_i$ for $\boldsymbol{\Sigma}_i$, we have

$$\det(\boldsymbol{\Sigma}_i + \boldsymbol{\beta}_i) = v_i \cdot \det(\boldsymbol{\Sigma}_{i-1} + \mathrm{diag}(\boldsymbol{\beta}_{i-1})), \tag{31}$$

$$v_i = c_{i,i} + \beta_i - \boldsymbol{\rho}_i^{\mathrm{T}} (\boldsymbol{\Sigma}_{i-1} + \mathrm{diag}(\boldsymbol{\beta}_{i-1}))^{-1} \boldsymbol{\rho}_i, \tag{32}$$

where $\boldsymbol{\beta}_i = (\beta_0, \cdots, \beta_{i-1})$. Then as $(\boldsymbol{\Sigma}_{i-1} + \mathrm{diag}(\boldsymbol{\beta}_{i-1}))^{-1}$ is a semi-positive definite matrix, we have $v_i \leq c_{i,i} + \beta_i$.

Furthermore, we can rewrite v_i as

$$\begin{aligned} v_i = \; & c_{i,i} + \beta_i - \boldsymbol{\rho}_i^{\mathrm{T}} \boldsymbol{\Sigma}_{i-1}^{-1} \boldsymbol{\rho}_i \\ & + \boldsymbol{\rho}_i^{\mathrm{T}} \boldsymbol{\Sigma}_{i-1}^{-1} (\boldsymbol{\Sigma}_{i-1}^{-1} + \mathrm{diag}(\boldsymbol{\beta}_{i-1})^{-1})^{-1} \boldsymbol{\Sigma}_{i-1}^{-1} \boldsymbol{\rho}_i \\ \leq \; & c_{i,i} + \beta_i - \boldsymbol{\rho}_i^{\mathrm{T}} \boldsymbol{\Sigma}_{i-1}^{-1} \boldsymbol{\rho}_i + \boldsymbol{\rho}_i^{\mathrm{T}} \boldsymbol{\Sigma}_{i-1}^{-1} \mathrm{diag}(\boldsymbol{\beta}_{i-1}) \boldsymbol{\Sigma}_{i-1}^{-1} \boldsymbol{\rho}_i, \end{aligned}$$

where the first equality is based on Eq. (26), and the last inequality depends on Lemma 3. Finally, according to Eq. (30), we have $\ln \det \boldsymbol{\Sigma}_{d-1} = \sum_{i=0}^{d-1} \ln v_i$ by induction. Combining above results, we can immediately conclude the proof. □

B.5 Proof of Theorem 4

Proof. For the first stage, if we denote the threshold of gradient clipping as S and denote the added noise as $\sigma \cdot \mathbf{I}$, we get $\|\boldsymbol{g}^{(t)}\|_2 \leq S$, where $\boldsymbol{g}^{(t)} = \nabla_{\boldsymbol{W}} F(\boldsymbol{W}_i^{(t)}; \boldsymbol{D})$ is a random vector as a function of $\boldsymbol{D}$. Hence, we have

$$\mathrm{tr}(\boldsymbol{\Sigma}^{(t)}) \leq \mathrm{tr}(\mathbb{E}(\boldsymbol{g}^{(t)} (\boldsymbol{g}^{(t)})^T)) = \mathbb{E}(\|\boldsymbol{g}^{(t)}\|_2^2) \leq S^2, \tag{33}$$

where the first inequality depends on the relationship between covariance matrix and the auto-correlation matrix, i.e., $\mathrm{tr}[\mathbb{E}(\boldsymbol{g}^{(t)} (\boldsymbol{g}^{(t)})^T) - \boldsymbol{\Sigma}^{(t)}] = \mathrm{tr}[\mathbb{E}(\boldsymbol{g}^{(t)}) \mathbb{E}(\boldsymbol{g}^{(t)})^T)] \geq 0$.

Then we have $\sum_{i=1}^{d}\lambda_i^{(t)} = \mathrm{tr}(\mathbf{\Sigma}^{(t)}) \le S^2$. Based on AM-GM inequality and the fact $\lambda_i^{(t)} \ge 0$, the channel capacity derived by Eq. (15) has an upper bound as

$$f^{(t)}(\sigma) \le \hat{f}^{(t)}(\sigma) = d \cdot \ln \frac{\sigma + \frac{\sum_{i=1}^{d}\lambda_i^{(t)}}{d}}{\sigma} \le d \cdot \ln \frac{\sigma + S^2/d}{\sigma}.$$

Therefore, if we treat σ as a constant, and denote $u_\sigma(d) := d \cdot \ln \frac{\sigma+S^2/d}{\sigma}, d \ge 0$, we have $f^{(t)}(\sigma) \le u_\sigma(d)$. We observe that $u_\sigma^{'}(d) = \ln \frac{\sigma+S^2/d}{\sigma} + \frac{\sigma}{\sigma+S^2/d} - 1$. Hence

$$u''_\sigma(d) = -\frac{S^2(2\sigma d + S^2)}{d(\sigma d + S^2)^2} \le 0 \Rightarrow u_\sigma^{'}(d) \ge u_\sigma^{'}(+\infty) = 0,$$

which implies $u_\sigma(d)$ is an increasing function of the dimension d. Based on L'Hospital's rule, we can conclude that

$$C^{(t)} = f^{(t)}(\sigma) \le u_\sigma(d) \le u_\sigma(+\infty) = \frac{S^2}{\sigma}. \tag{34}$$

For the second stage, which provides a (ε, δ)-DP, the authors in [19] demonstrate that we need to choose $\sigma \ge S^2 \cdot \frac{2\log(1.25/\delta)}{\varepsilon^2}$, then with a substitution in Eq. (34), we have $C^{(t)} \le \frac{\varepsilon^2}{2\log(1.25/\delta)}$. Hence, the channel capacity of (ε, δ)-DP in the FL scenario is upper bounded by $\frac{\varepsilon^2}{2\log(1.25/\delta)}$.

Finally, as illustrated in [19], for mini-batch SGD in DP, i.e., the batch size $B > 1$, the mechanism becomes $\boldsymbol{g} = \frac{1}{B}(\sum_{i=1}^{B}\bar{\boldsymbol{g}}_i + \boldsymbol{\xi})$, let $\tilde{\boldsymbol{g}} = \frac{1}{B}\sum_{i=1}^{B}\bar{\boldsymbol{g}}_i$ and $\tilde{\boldsymbol{\xi}} = \frac{1}{B}\boldsymbol{\xi}$, we have $\mathbf{\Sigma}_{\tilde{\boldsymbol{g}}} = \frac{1}{B}\mathbf{\Sigma}_{\boldsymbol{g}_i}$ and $\mathbf{\Sigma}_{\tilde{\boldsymbol{\xi}}} = \frac{1}{B^2}\mathbf{\Sigma}_{\boldsymbol{\xi}}$. By substitution them into Eq. (33), we can immediately conclude the proof. □

C Details of the Prior Knowledge

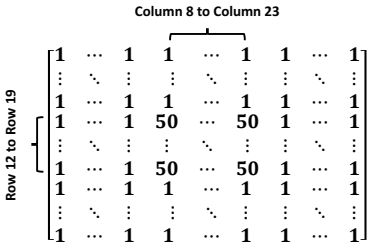

Figure 17: The prior knowledge $\boldsymbol{\beta}$ used for the Personalized Channel in Sec. 6. Specifically, the number in the matrix represents the coefficient for the added noise.

For the Personalized Channel, the prior knowledge $\boldsymbol{\beta}$ used in Sec. 6 is a $32*32*c$ tensor, where c represents the number of image channel (e.g., $c = 1$ for Fashion-MNIST dataset and $c = 3$ for CIFAR-10 dataset, respectively). The number in $\boldsymbol{\beta}$ represents the coefficient for the added noise, which means we add more noise to the dimension if the coefficient of this dimension is larger. In these experiments, we employ position-based prior knowledge, which means the prior knowledge for all image channels are identical. Therefore, the important parameters are the numbers of one channel, which is a $32*32$ matrix (as displayed in Fig. 17).

Specifically, as we aim to protect the private information around eyes for the data in CelebA (as displayed in Fig. 5), we set the number of these positions (i.e., the sub-matrix with row 12 to 19 and column 8 to 23.) to be 50, and set the rest number of the matrix to be 1. Therefore, this prior knowledge adds 50 times noise to the chosen positions (i.e., the positions around the eyes) to provide stronger privacy protection for this area. Additionally, we also use this prior knowledge for other datasets, including Fashion-MNIST, CIFAR10, and SVHN.

D Validating the theories of existing methods

The impact of batch size for DP and utilizing large batch size in defending against DRA. To improve the existing defense algorithm for defending against DRA, we design experiments to validate the roles of B by gradient inversion attack on CIFAR-10. Specifically, to keep identical reconstruction difficulties for different B, we only reconstruct one image from the gradient as the mean restoration $\mathbb{E}[\hat{\boldsymbol{D}}]$. Then we calculate the MSE between $\mathbb{E}[\hat{\boldsymbol{D}}]$ and the mean value of local dataset $\mathbb{E}[\boldsymbol{D}]$, i.e., $\|\mathbb{E}[\hat{\boldsymbol{D}}] - \mathbb{E}[\boldsymbol{D}]\|^2$. Due to the convexity of MSE, the difference between $\hat{\boldsymbol{D}}$ and $\boldsymbol{D}$ is lower bounded, i.e., $\mathbb{E}\|\hat{\boldsymbol{D}} - \boldsymbol{D}\|^2 \ge \|\mathbb{E}[\hat{\boldsymbol{D}}] - \mathbb{E}[\boldsymbol{D}]\|^2$. Moreover, we utilize clipping bound $S = 1.0$ and the noise multiplier $\sigma = 1.3$ for the DP training. The results are displayed in Fig. 6. If we utilize DP for privacy protection, the performance for defending against DRA consistently decreases with an increasing B. This phenomenon is consistent with Thm. 4, indicating that the small B is beneficial for DP in defending against DRA.

Additionally, when we do not apply any defense technique for privacy, the defense ability increases according to the increasing B. This phenomenon is consistent with Eq. (22) due to the intrinsic noise in the collected data. Moreover, the performance improvement becomes more significant when we add a constant noise to the parameters. The conclusion is that when we add a constant noise to the parameter, a larger B leads to a stronger ability to defend against DRA.

The impact of eigenvalues in compression. We also validate our theories for compression on CIFAR-10 datasets. In these experiments, we utilize the gradient inversion attack to reconstruct data from the gradients. For the compression, we set the eigenvector to be $\mathbf{0}$ to reduce the information in the corresponding dimension. Then we map the training data to the compressed eigenspace. For comparison, we only compress one dimension according to the eigenvalue. The results are displayed in Fig. 8. Specifically, the eigenvalues $\{\lambda_{max}, \lambda_1, \lambda_{10}\}$ are as follows: $\{222.21, 85.08, 9.91\}$ for CIFAR10, $\{346.21, 71.01, 12.82\}$ for CelebA, $\{313.0, 28.04, 4.67\}$ for SVHN, and $\{101.88, 61.80, 3.21\}$ for Fashion-MNIST. The experiment results demonstrate that the compression on the dimension with a larger eigenvalue leads to a stronger defensive ability to defend against DRA, which is consistent with our theories.

Lotto: Secure Participant Selection against Adversarial Servers in Federated Learning

Zhifeng Jiang[1] Peng Ye[1] Shiqi He[2,*] Wei Wang[1] Ruichuan Chen[3] Bo Li[1]
[1]*HKUST* [2]*University of Michigan* [3]*Nokia Bell Labs*

Abstract

In Federated Learning (FL), many privacy-enhancing techniques, such as secure aggregation and distributed differential privacy, provide security guarantees under the assumption of having an *honest majority* among participants. However, an adversarial server can strategically select compromised clients to create a dishonest majority, thereby undermining the system's security guarantees. In this paper, we present Lotto, an FL system that addresses this fundamental, yet underexplored issue by providing secure participant selection in the presence of an adversarial server. Lotto supports two selection algorithms: *random* and *informed*. To ensure random selection without a trusted server, Lotto enables each client to autonomously determine their participation using *verifiable randomness*. For informed selection, which is more vulnerable to manipulation, Lotto approximates the algorithm by employing random selection within a *refined client pool*. Theoretical analysis shows that Lotto effectively aligns the proportion of server-selected compromised participants with the base rate of dishonest clients in the population. Large-scale experiments further reveal that Lotto achieves time-to-accuracy performance comparable to that of insecure selection methods.

1 Introduction

Edge devices, such as smartphones and laptops, are becoming increasingly powerful and can collaborate to build high-quality machine learning (ML) models using data collected on the devices [36]. To protect data privacy, major companies like Google and Apple have adopted *federated learning* (FL) [44] for tasks in computer vision (CV) and natural language processing (NLP) across client devices [31, 56, 66]. In FL, a server dynamically samples a small subset of clients from a large population in each training round. The sampled clients, aka *participants*, compute individual local updates using their own data and upload only the updates to the server for global aggregation, without revealing the training data [11].

However, simply keeping client data undisclosed is insufficient to preserve data privacy. Recent studies have shown that sensitive data can be leaked through individual updates during FL training [28, 64, 68, 69, 71], and it is also possible to infer a client's data from trained models [16, 46, 53, 57] by exploiting their ability to memorize information [16, 57]. To minimize data leakage, current FL systems use *secure aggregation* techniques [8, 11, 12] to ensure that adversaries only learn the aggregated updates, not individual ones. Additionally, these systems may employ *distributed differential privacy* (DP) [6,35,58] to limit the extent of data leakage from the aggregated update (§2.2). Since the server may not always be trusted, these privacy-enhancing techniques commonly assume that the *majority* of the participants act honestly and can jointly detect and prevent server misbehavior.

Nonetheless, this assumption may not hold in practice – an adversarial server can strategically select compromised clients with whom it colludes, resulting in a practical attack. While the overall client population is large, the number of participants selected in each round is often limited to a few hundred for efficiency reasons [11]. Consequently, even if the majority of the population is honest (e.g., 99% out of 100,000 clients), the server can still select enough adversaries to create a dishonest majority among participants.

The presence of a dishonest majority undermines the downstream privacy-enhancing techniques, leading to significant security vulnerabilities. As shown in §2.3, the privacy guarantees provided by distributed DP degrade rapidly as the dishonest cohort expands [6, 35, 58]. Additionally, secure aggregation can only tolerate a certain proportion of clients colluding with the server; exceeding this limit would enable the adversary to reconstruct a client's update [12]. It is hence crucial to prevent the server from maliciously manipulating the client selection process.

Despite its importance, this problem remains largely unaddressed in the literature. The main challenge arises from the use of a *central server* in the cross-device FL scenarios [36].

*Work done while the author was doing research internship at HKUST.

In the absence of efficient peer-to-peer communication across a vast array of heterogeneous devices [38, 67], the server acts as a central hub for facilitating message exchanges between clients. Since the server is untrusted, an honest client lack a reliable view of other clients, such as their availability, utility, and integrity. Consequently, it is difficult for a client to verify whether the server has correctly executed the prescribed participant selection algorithm, as this requires the true knowledge of and/or inputs from other clients.

In this paper, we present Lotto, a novel framework that enables secure participant selection in FL for the first time. Lotto aims to provide the following desired property: **among the selected participants, the proportion of the compromised ones approximately aligns with the base rate of dishonest clients in the overall population**. Lotto uses *verifiable randomness* in the selection process.

Specifically, to achieve secure random selection [44], Lotto allows each client in the population to determine its participation in a training round by computing *verifiable random functions* (VRFs) [23, 45] using its secret key and public inputs. When a client chooses to participate, Lotto collects the generated randomness and the associated VRF proof, which can be verified by other participants to ensure the integrity and validity of the randomness. This approach ensures that each client's participation is provably independent, fair, and unpredictable for other clients. However, it is still possible for an adversarial server to exploit this process and increase the number of dishonest clients by, for example, sending incorrect and/or a selectively chosen messages. To mitigate such misconduct, Lotto lets honest clients verify critical messages, adding an additional layer of security. Lotto *provably ensures* that the compromised fraction of selected participants remains close to the base rate in the population (§3.4).

Lotto also provides security guarantee for more advanced algorithms, referred to as *informed selection*, which are commonly used in FL to select the best-performing participants for optimal training efficiency [17, 37, 39, 47, 61, 70]. These algorithms rely on client-specific measurements, such as processing speed and data quality, which are difficult to verify. Instead of precisely following the selection logic of these algorithms, Lotto *approximates* them by transforming an informed selection problem into a random one. To achieve this, it lets the server *refine* the client pool by excluding a small fraction of low-quality clients based on the specified measurements. Lotto then performs secure random selection within the refined pool. Although an adversarial server may attempt to manipulate this process by excluding honest clients, the security of Lotto's random selection ensures that any advantage it gains is provably small (§3.5).

We have implemented Lotto as a library[2] (§4) and evaluated its performance with various FL tasks in a large EC2 cluster configured to emulate a cross-device scenario (§5). Compared to insecure selection algorithms, Lotto slightly increases the duration of each training round by less than 10% while achieving comparable or even better time-to-accuracy performance and inducing negligible network cost.

[2]Lotto is available at https://github.com/SamuelGong/Lotto.

2 Background and Motivation

In this section, we begin by providing an overview of the standard FL workflow (§2.1). We then discuss the privacy concerns and prevalent privacy-preserving approaches that critically rely on an honest majority among participants (§2.2). Following this, we highlight the privacy vulnerabilities that arise when encountering a dishonest majority (§2.3) and ultimately present the motivation for our work.

2.1 Federated Learning

Federated learning (FL) [36, 44] emerges as a new private computing paradigm that enables a large number of *clients* to collaboratively train a global model under the orchestration of a *server*. The standard FL workflow is an iterative process that comprises three steps in each training round [11]. ① Participant Selection: the server samples a subset of eligible clients from the entire *population* as participants, where the eligibility criteria may include factors such as charging status and whether being connected to an unmetered network. ② Local Training: the server distributes the global model to each participant, who then trains the model using its private data to compute a *local update*. ③ Model Aggregation: the server collects local updates from participants and computes an *aggregated update*. This step is often coupled with additional privacy-enhancing techniques (§2.2). The server then uses the aggregated update to refine the global model. As participants only expose their local updates instead of raw data to other parties, FL adheres to the data minimization principle [21, 36] mandated by many privacy regulations [60]. Consequently, FL has been deployed to facilitate a broad range of edge intelligence applications [31, 56, 66].

2.2 Enhancing Data Privacy in FL

Despite the fact that client data is not directly revealed during the FL training process, extensive research has demonstrated that it is still possible to disclose sensitive data using individual updates or trained models. Specifically, an adversary can reconstruct a client's training data from its local updates through *data extraction* [28, 64, 68, 69, 71]. For image classification tasks, even with a huge number of local gradient steps (e.g., 15k) and large models like ResNet-18 [32], state-of-the-art attackers [69] can successfully recover high-quality training images at both the pixel-level and semantic-level using a single local update. Given only an aggregated update or a trained model, the adversary can also infer whether a

client's private text has been used in the training set through *membership inference* [16, 46, 53, 57].

To effectively control the exposure of clients' data against these attacks, FL systems commonly employ two privacy-enhancing techniques: secure aggregation and distributed differential privacy.

Secure Aggregation (SecAgg) [12]. SecAgg is a secure multi-party computation (SMPC) protocol that enables the server to learn only the sum of participants' updates and nothing beyond that. In SecAgg, each participant i first generates two key pairs (sk_i^1, pk_i^1), (sk_i^2, pk_i^2), where the public keys (pk_i^1, pk_i^2) are shared with others. Each pair of participants (i, j) then engage in a key agreement to derive a shared key $s_{i,j} = \mathsf{KA.Agree}(sk_i^1, pk_j^1)$. Each participant i then uses a pseudorandom number generator to derive a pairwise mask, $\boldsymbol{p}_{i,j} = \mathsf{PRNG}(s_{i,j})$, for each other participant j, and adds it to its update following $\boldsymbol{y}_i = \boldsymbol{x}_i - \sum_{j<i} \boldsymbol{p}_{i,j} + \sum_{j>i} \boldsymbol{p}_{i,j}$. As a result, after all participants' masked updates are aggregated, the pairwise masks cancel out, i.e., $\sum \boldsymbol{y}_i = \sum \boldsymbol{x}_i$.

In case of client dropout, SecAgg removes the pairwise masks of the dropped participants to ensure that the remaining pairwise masks can still cancel out when aggregated. To achieve this, each participant i secret-shares its key sk_i^1 to each other participant j using a t-out-of-n secret sharing scheme, where t is the minimum number of participants required to recover the shared key. Therefore, if participant i later drops out, a sufficient number of remaining clients ($\geq t$) can help the server reconstruct its key sk_i^1, thereby enabling the recovery of the missing pairwise masks.

A security concern remains in that the server can falsely claim the dropout of participant i to recover its pairwise masks: removing these masks, the server can uncover participant i's local update x_i. To address this concern, SecAgg introduces an additional mask $\boldsymbol{q}_i = \mathsf{PRNG}(b_i)$ where b_i is independently generated by participant i and also secret-shared with each other. The modified masking process for participant i becomes:

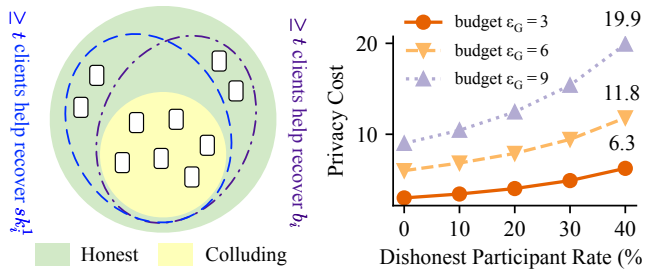
$$\boldsymbol{y}_i = \boldsymbol{x}_i \underbrace{- \sum_{j<i} \boldsymbol{p}_{i,j} + \sum_{j>i} \boldsymbol{p}_{i,j}}_{A} + \underbrace{\boldsymbol{q}_i}_{B}. \tag{1}$$

By requiring that the server only requests secret shares of either sk_i^1 (to recover part A if participant i drops out) or b_i (to recover part B otherwise) from other remaining participants, SecAgg ensures that part A and B cannot be removed simultaneously, and the secrecy of $\boldsymbol{x}_i$ is preserved. Subsequent work, such as SecAgg+ [8], has been proposed to reduce the runtime overhead of SecAgg and increase its scalability.

Distributed Differential Privacy (DP) [6, 35]. Simply concealing individual local updates using SecAgg is insufficient as client data can still leak through the aggregated updates. Differential privacy [22, 25] can prevent this by ensuring that no specific client's participation significantly increases the likelihood of any observed aggregated update by potential adversaries. This guarantee is captured by two parameters, ε and δ. Given any neighboring training datasets D and D' that differ only in the inclusion of a single participant's data, an aggregation procedure M is (ε, δ)-differentially private if, for any given set of output R, $\Pr[M(D) \in R] \leq e^{\varepsilon} \cdot \Pr[M(D') \in R] + \delta$. Therefore, a change in a participant's contribution yields at most a multiplicative change of e^{ε} in the probability of any output R, except with probability δ.

To achieve a privacy goal $(\varepsilon_G, \delta_G)$ in an R-round training, each aggregated update needs to be perturbed by a random noise r calibrated based on ε_G, δ_G, R, and the sensitivity of the aggregated update Δ (defined as its maximum change caused by the inclusion of a single client's data). Given the use of SecAgg, the required level of noise can be achieved without relying on the (untrusted) server by having each participant i add an even share of the noise r_i to its local update, i.e.,

$$\sum_i r_i \overbrace{\sim}^{(\varepsilon_G, \delta_G)\text{-DP}}_{R, \Delta} r. \tag{2}$$



This DP model is referred to as distributed DP in the literature [36], given its distributed fashion of noise addition.

2.3 Privacy Loopholes in Common Defenses

Strong Assumption on Honest Majority in Participants. The above privacy-enhancing techniques commonly assume that the *majority* of participants are honest, relying on them to detect and/or prevent the server's misbehavior. However, this assumption often proves inaccurate due to the necessity of participant selection in FL systems. While the overall population may be extensive, FL usually involves a limited number of sampled clients at each training round, typically in the range of a few hundred [11, 36]. This limitation arises because including additional clients beyond a certain threshold only yields marginal improvements in terms of convergence acceleration [44, 63]. Unfortunately, if the server acts maliciously, it can manipulate the selection process by intentionally selecting compromised clients that it colludes with, resulting in a majority of dishonest participants among those involved. Without an honest majority among participants, these techniques encounter significant security vulnerabilities.

Case #1: SecAgg. SecAgg safeguards a participant i's plaintext update $\boldsymbol{x}_i$ from server probing by distributing secret shares of sk_i^1 and b_i among other participants and requiring them to disclose only the shares of *either* secret to the server (§2.2). However, this can not be achieved if a malicious server colludes with a sufficiently large fraction of participants.

Consider a scenario with s participants, x of which collude with the server. Let t denote the threshold used by the t-out-of-n secret sharing scheme in SecAgg. As depicted in Figure 1a, when $x \geq 2t - s$, the server can identify two separate sets of honest participants, each containing at least $t - x$ members. In this case, by announcing participant i's contradictory dropout outcome to either set, the server can collect at least $t - x$ secret

(a) SecAgg. (b) Distributed DP.

Figure 1: Example impacts of dishonest majority.

shares for both sk_i^1 and b_i. Combining them with the shares provided by the x colluding clients, the server can reconstruct sk_i^1 and b_i, simultaneously. Ultimately, SecAgg fails to protect the local update of participant i, as implied by Equation (1).

Case #2: Distributed DP. Distributed DP, being built upon SecAgg, inherits the aforementioned security vulnerability. When the number of dishonest participants surpasses a specific threshold ($2t - n$ as mentioned earlier), a malicious server can deduce the precise local update of participant i, which is perturbed solely by its noise share r_i (but not r).

Even if this threshold is not exceeded, the security of distributed DP can still be impacted by dishonest participants. If they choose not to add any noise to their local updates, the cumulative noise added to the aggregated update will *fall below* the required level. This results in increased data exposure, causing the system to exhaust its privacy budget more rapidly than planned. To demonstrate this issue in a practical FL scenario, we conduct an analysis on a testbed where 700 clients collaborate to train a CNN model over the FEMNIST dataset for 50 rounds. Each round involves 70 randomly selected clients, with the task of noise addition distributed equally among all participants. However, dishonest participants will abstain from adding any noise. Figure 1b illustrates that as the fraction of dishonest participants increases (while remaining below the SecAgg's threshold mentioned earlier), the privacy deficit grows explosively, regardless of the prescribed privacy budget. For example, when 40% participants are dishonest, training with a global privacy budget $\varepsilon_G = 6$ ends up consuming an ε of 11.8 at the 50th round.

3 Lotto: Secure Participant Selection

Taking the first stab at the mentioned issues, we present Lotto, a framework that secures participant selection in FL. We first formalize the participant selection problem (§3.1), establish the threat model (§3.2), and briefly introduce the cryptographic primitives used (§3.3). Next, we describe how Lotto accomplishes our goal in two scenarios: random selection (§3.4) and informed selection (§3.5). We finally provide security (§3.6) analysis for these methods.

3.1 The Participant Selection Problem

In the FL literature, participant selection is commonly approached in two forms, both of which we aim to safeguard.

Random Selection. The Federated Averaging (FedAvg) algorithm [44], considered the canonical form of FL, adapts local SGD [30, 59] on a randomly selected subset of clients during each round. To achieve random selection, the server can perform *subsampling without replacement*, where a subset of the population is chosen uniformly at random. Alternatively, it can conduct *Bernoulli sampling*, where each client is independently included with the same probability. We focus on the former as it guarantees a fixed sample size.

Informed Selection. Given the large heterogeneity in device speed and/or data characteristics, several FL advancements go beyond random sampling by employing informed selection algorithms [17, 37, 39, 47, 61, 70]. These algorithms leverage *client-specific measurements* to identify and prioritize clients who have the greatest potential to rapidly improve the global model. Among these measurements, some can be directly monitored by the server, e.g., response latencies, while the others rely on clients' self-reporting, e.g., training losses.

For example, Oort, the state-of-the-art informed algorithm, ranks each client i with a utility score U_i^{Oort} that jointly considers the client's data quality and system speed:

$$U_i^{Oort} = \underbrace{|B_i|\sqrt{\frac{1}{|B_i|}\sum_{k\in B_i} Loss(k)^2}}_{\text{Data quality}} \times \underbrace{\left(\frac{T}{t_i}\right)^{\mathbb{1}(T<t_i)\times\alpha}}_{\text{System speed}}. \quad (3)$$

The first component is the aggregate training loss that reflects the volume and distribution of the client's dataset B_i. The second component compares the client's completion time t_i with the developer-specified duration T and penalizes any delay (which makes the indicator $\mathbb{1}(T < t_i)$ outputs 1) with an exponent $\alpha > 0$. Oort prioritizes the use of clients with high utility scores for enhanced training efficiency.

Design Goal. Let n represent the population size, with c being the number of dishonest clients, and s the target number of participants in a training round. Ideally, regardless of the selection approach and the base rate of dishonest clients in the population c/n, the proportion of compromised participants x/s should match c/n, where x represents the number of compromised participants. For practical purposes, we allow for a slight relaxation of this ideal goal. Specifically, our objective is to align x/s with $\eta c/n$, where η is a small value slightly greater than 1.

3.2 Threat Model

Cross-Device Scenarios with Server-Mediated Network. Each client has a *private authenticated channel* established with the server, ensuring that their transmitted messages cannot be eavesdropped on by external parties. We do not assume a peer-to-peer network among clients due to concerns regarding efficiency and scalability. Instead, clients rely on the server to mediate communication between them.

Public Key Infrastructure (PKI). We assume a PKI that facilitates the registration of client identities and the generation of cryptographic keys on their behalf. During the setup phase, each client *i registers* its public key, denoted as (i, pk_i^{reg}), to a public bulletin board maintained by the PKI. The bulletin board only accepts registrations from clients themselves, preventing malicious parties from impersonating honest clients. Also, the PKI is responsible for *generating* the required public/secret key pair for client i to use in Lotto, $(pk_i^{Lotto}, sk_i^{Lotto})$. The PKI encrypts the secret key sk_i^{Lotto} using pk_i^{reg} to securely transmit them to client i. Meanwhile, the public key pk_i^{Lotto} is registered on the public bulletin board. The communication with the PKI is *not* mediated by the server.

Malicious Server with Colluding Clients in Population. We assume a malicious server colluding with a subset of clients in the population and they can *arbitrarily deviate* from the protocol. They may send incorrect or chosen messages to honest clients, abort or omit messages, or engage in Sybil attacks [24] to increase the portion of clients under their control. We do *not* assume a specific fraction of dishonest clients within the population to provide fundamental security. Even in the presence of a dishonest majority in the population, our objective remains to ensure that, among the selected clients, the proportion of the compromised ones aligns with the base rate of dishonest clients in the population (§3.1). In other words, client selection cannot be manipulated.

3.3 Cryptographic Primitives

Lotto uses the following cryptographic primitives.

Verifiable Random Function (VRF) [23, 45]. A VRF is a public-key PRF that provides proof that its outputs were computed correctly. It consists of the following algorithms:

- $(pk, sk) \xleftarrow{\$} \mathtt{VRF.keygen}(1^\kappa)$. The key generation algorithm randomly samples a public/secret key pair (pk, sk) from the security parameter κ.
- $(\beta, \pi) \leftarrow \mathtt{VRF.eval}_{sk}(x)$. The evaluation function receives a binary string x and a secret key sk and generates a random string β and the corresponding proof π.
- $\{0,1\} \leftarrow \mathtt{VRF.ver}(pk, x, \beta, \pi)$. The verification function receives a public key pk and three binary strings x, β, and π, and outputs either 0 or 1.

A secure VRF should have unique provability and pseudorandomness. The former requires that for every public key pk and input x, there is a unique output β for which a proof π exists such that the verification function outputs 1. The latter requires that no adversary can distinguish a VRF output without the accompanying proof from a random string.

Signature Scheme. A signature scheme allows a message recipient to verify that the message came from a sender it knows. It consists of the following algorithms:

- $(pk, sk) \xleftarrow{\$} \mathtt{SIG.gen}(1^\kappa)$. The key generation algorithm randomly samples a public/secret key pair (pk, sk) from the security parameter κ.
- $\sigma \leftarrow \mathtt{SIG.sign}_{sk}(m)$. The sign function receives a binary string m and a secret key sk and generates a signature σ.
- $\{0,1\} \leftarrow \mathtt{SIG.ver}(pk, m, \sigma)$. The verification function receives a public key pk and two strings m and σ, and outputs either 0 or 1.

For correctness, a signature scheme must ensure that the verification algorithm outputs 1 when presented with a correctly generated signature for any given message. For security, we require that no PPT adversary, when given a fresh honestly generated public key and access to a signature oracle, can produce a valid signature on a message on which the oracle was queried with non-negligible probability.

Pseudorandom Function (PRF) [29]. A secure $\mathtt{PRF}_k(x)$ is a family of deterministic functions indexed by a key k that map an input x into an output y in such a way that y is computationally indistinguishable from the output of a truly random function with input x.

3.4 Secure Random Selection

A faithful execution of random selection naturally achieves our goal (§3.1). However, enforcing this in the presence of a malicious server poses two key challenges:

- *Correctness* (**C1**): A malicious server can deviate from random selection while falsely claiming adherence to the protocol. How can clients prevent such misbehavior?
- *Consistency* (**C2**): Even if the protocol is faithfully executed, how can we ensure that the participants in the subsequent workflow are indeed those who were selected?

Self-Sampling with Verifiable Randomness. To address **C1**, we propose a *self-sampling* approach where each individual client in the population is responsible for determining whether it should participate in a training round based on publicly available inputs. The intuition is that honest clients have a *strong incentive* to follow a reasonable selection plan due to concerns about preserving their own privacy. For security, we need to tackle the following issues simultaneously:

- *T1.1*: Ensuring that dishonest clients cannot participate without following the prescribed self-sampling protocol.
- *T1.2*: Ensuring that honest clients who choose to participate do not get arbitrarily omitted by the malicious server.

To accomplish T1.1, Lotto introduce *verifiable randomness* to the self-sampling process to allow each participant to verify the integrity of other peers' execution. Specifically, we utilize a VRF with range $[0,m)$, and assume that the FL training needs to randomly sample s out of n clients for a specific training round r. At the beginning of the round, the server first announces s, n, r to all clients in the population. Each client i then generates a random number β_i and the associated proof π_i using its private key sk_i^{Lotto} via $\beta_i,\pi_i = \mathtt{VRF}_{sk_i^{Lotto}}(r)$. To achieve an expectation of s sampled clients, only those clients with $\beta_i < sm/n$ will claim to participate by uploading their β_i's and π_i's to the server, while the remaining clients abort. Next, the server takes all the surviving clients P as participants and dispatches the collected $\{\beta_i,\pi_i\}_{i\in P}$ to each of them. Finally, each participant i verifies the validity and eligibility of its peers' randomness, i.e., checking if $\mathtt{VRF.val}(pk_j^{Lotto},r,\beta_j,\pi_j) = 1$ and $\beta_j < sm/n$ for each $j \in P$. It aborts upon any failure, or refers to this set of participants throughout the remaining stages of the training round.

By pseudorandomness of VRFs (§3.3), if each sk_i^{Lotto} is uniformly random (guaranteed by the PKI as implied in §3.2), this process is pseudorandom where each client is selected equally likely with probability s/n. Also, the adversary cannot forge a random value that falls inside the range of $[0,sm/n)$ to help a dishonest client get selected. By VRF's unique provability (§3.3), if client i's original randomness generated with sk_i^{Lotto} and r falls outside the range, no eligible proof can be produced for supporting any forged β_i' to pass an honest client's verification test that takes pk_i^{Lotto} and r as inputs.

Regarding the round index r, it should be (i) unique for each round to avoid replay attacks, and (ii) consistently used by honest clients to preserve the sampling randomness. Lotto achieves (i) by allowing each client to abort if the announced r has been used previously, and also guarantees (ii) with a consistency check (as later detailed). The above design, together with the key-pair integrity guaranteed by PKIs, ensures that each participant's randomness must be honestly generated.

Over-Selection with Controlled Residual Removal. While VRFs securely achieve Bernoulli sampling, our primarily desired form of random selection is subsampling without replacement (§3.1). To achieve a fixed sample size, Lotto further employs over-selection with residual removal based on the above process. Specifically, instead of directly targeting s sampled clients, Lotto slightly increases the expected sample size by a factor $\alpha > 1$. In this case, clients identify themselves as candidate participants C when their associated β_i's satisfy $\beta_i < \alpha sm/n$. Next, the server samples s candidates out of C uniformly at random to finalize the set of participants P, if the total number of candidates is no less than the required sample size s (the probability of this event is given by Theorem 1) and aborts otherwise. As we observed in practice (Figure 2), $\alpha \geq 1.3$ suffices to sample enough clients with a high success rate (i.e., making Theorem 1's probability close to 1). On receiving P, clients verify whether $|P| = s$ and abort if not.

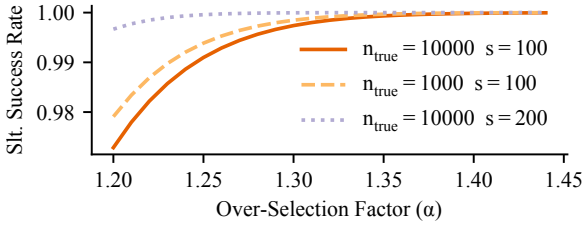


Figure 2: A small over-selection factor (α) suffices in practice.

Theorem 1 (Effectiveness of Over-Selection)**.** *Using an over-selection factor $\alpha > 0$, the described process in Lotto results in at least s candidates with probability of $1-\sum_{i=0}^{s-1}\binom{n_{true}}{i}p^i(1-p)^{n_{true}-i}$ where $p = \alpha s/n$ and n_{true} and n is the actual size of the population and that used by clients, respectively.*

In the above process, a malicious server can intentionally remove honest candidates, not just the ones with randomly chosen indices, to gain an advantage in growing a dishonest cohort. Consider a scenario where there are c dishonest clients among a population of size n_{true}, while the server announces a population size n that may not necessarily align with n_{true}. Suppose that the candidate set C ($|C| \geq s$) contains x dishonest clients after over-selection, then the expected proportion of them in C, p_{cand}, is equal to the base rate of those in the population, i.e., $p_{cand} = \mathbb{E}\left[\frac{x}{|C|}\middle||C| \geq s\right] = c/n_{true}$. Next, in the worst-case scenario where all the clients removed by the server are honest, the expected proportion of dishonest clients in the final s participants, p_{final}, is upper bounded as

$$\begin{aligned} p_{final} &= \mathbb{E}\left[\frac{x}{s}\middle||C| \geq s\right] = \frac{1}{s}\mathbb{E}\left[x\middle||C| \geq s\right] \\ &= \frac{1}{s}\cdot\frac{\mathbb{E}[x] - \mathbb{E}\left[x\middle||C| < s\right]\cdot\Pr[|C| < s]}{\Pr[|C| \geq s]} \\ &< \frac{1}{s}\cdot\frac{\mathbb{E}[x]}{\Pr[|C| \geq s]} \approx \frac{1}{s}\mathbb{E}[x] = \frac{1}{s}\cdot\frac{\alpha cs}{n} = \frac{\alpha c}{n}. \end{aligned}$$

Thus, in expectation, the server can grow the proportion of dishonest clients by a factor approximately up to $\lambda = \frac{\alpha n_{true}}{n}$.

To ensure that λ is reasonably small (T1.2), Lotto fixes the use of α to be a small value around 1.3 since it suffices to sample enough clients as above mentioned. Lotto also ensures that n is large enough through a propose-acknowledge process. Specifically, the server proposes only once the value of n to a client during its check-in. The client then compares n with its intended number n_{min}, i.e., the population size necessary to prevent substantial inflation of the dishonest cohort from its standpoint, and proceeds with the federation only if $n \geq n_{min}$.

The Lotto Protocol for Secure Participant Selection

- **Offline Setup**:
  - All parties are given the security parameter κ, the target number of sampled clients in a round s, the over-selection factor α, a range $[0,m)$ to be used for PRF or VRF, the population threshold n_{min}, and a timeout l. All clients also have a private authenticated channel with the server and the PKI, respectively. The server knows the exact population size n.

Client i {
- Generate a key pair $(pk_i^{reg}, sk_i^{reg}) \leftarrow \mathtt{KA.gen}(pp)$ for signature and send the public key pk_i^{reg} to the PKI for registration.
- Receive the secret key for Lotto's use, sk_i^{Lotto}, from the PKI. Send the public key pk_i^{reg} to the server for registration.

Server {
- Receive all clients' registration keys $\{pk_i^{reg}\}$. Use them to query the PKI on the application public keys $\{pk_i^{Lotto}\}$.

- ***[Online Stage 0 (Population Refinement):]***

Server {
- Based on specific criteria, select n clients with the best utility from the population and take this set of clients as the new population.

- **Online Stage 1 (Client-Centric Selection)**:

Server {
- Announce to all clients in the population the beginning of round r and the population size n.

Client i {
- Upon receiving the population size n, verify that $n \geq n_{min}$. Abort if it fails.
- Generate a random number $\beta_i, \pi_i = \mathtt{VRF.eval}_{sk_i^{Lotto}}(r)$. Send to the server (β_i, π_i) and claim to join only if $\beta_i < \alpha sm/n$.

Server {
- Insert responding clients into the candidate set C and store their reported self-selection outcomes $\{(\beta_i, \pi_i)\}$ until timeout after l.

- **Online Stage 1 (Server-Centric Selection)**:

Server {
- For each client i in the population, compute $\beta_i = \mathtt{PRF}_{pk_i^{Lotto}}(r)$ and insert the client into the candidate set C only if $\beta_i < \alpha sm/n$.

- **Online Stage 2 (Client Verification)**:

Server {
- If $|C| < s$, abort the current round r. Otherwise, select s clients from C uniformly at random to form the participant set $P \triangleq \{(i, pk_i^{reg}, \beta_i, \pi_i)\}$. Broadcast to all participants $i \in P$ this participant set P and the used population size n.

Client i {
- Receive from the server a participant set P_i and query the PKI on the public key pk_j^{Lotto} for each participant $j \in P_i$ using pk_j^{reg}.
- Verify whether r has been used before, $(i, pk_i^{reg}, \beta_i, \pi_i) \in P_i$, $|P_i| = s$, $n \geq n_{min}$, $\beta_i < \alpha sm/n$, and $\mathtt{VRF.val}(pk_j, r, \beta_j, \pi_j) = 1$ (or, $\mathtt{PRF}_{pk_j^{Lotto}}(r) < \alpha sm/n$) for $\forall j \in P_i$.
- Abort if any of the test fails. Sign the observed participant list P_i via $\sigma_i = \mathtt{SIG.sign}_{sk_i^{reg}}(r||P_i)$ and send the signature σ_i to the server.

- **Online Stage 3 (Consistency Check)**:

Server {
- Collect signatures from participants in $P' \subseteq P$ and abort in case of timeout after l. Broadcast $\{j, \sigma_j\}_{j \in P'}$ to each participant $i \in P'$.

Client i {
- Receive from the server the set $\{j, \sigma_j\}_{j \in P_i'}$.
- Verify $P_i' = P_i$ and $\mathtt{SIG.ver}(pk_j^{reg}, r||P_i, \sigma_j) = 1$ for $\forall j \in P_i'$. Abort on any failure, or refer to P_i as participants at round r hereafter.

Figure 3: A detailed description of the Client-Centric and Server-Centric protocol for secure participant selection in Lotto (§3). *[Italicized parts inside square brackets are additionally required for informed selection.]*

Inter-Client Consistency via Signature Scheme. While we have ensured that each participant i receives a selection outcome where each member appears with upper-bounded probability, the issue of guaranteeing identical outcomes among all participants remains. To address this concern, Lotto employs a secure signature scheme, which operates as follows:

- Each client signs its received selection outcome P_i with its registration secret key sk_i^{reg}, generating a signature $\sigma_i = \mathtt{SIG.sign}_{sk_i^{reg}}(r||P_i)$ where $||$ denotes concatenation.
- After collecting all signatures from the set of all responding clients P', the server broadcasts to them the set $\{(j, \sigma_j)\}_{j \in P'}$ containing the received signatures.
- Upon receiving $\{(j, \sigma_j)\}_{j \in P_i'}$, each client i verifies the correctness of all signatures and ensures that the corresponding participant lists are consistent with its observed one, i.e., $P_i' = P_i$ and $\mathtt{SIG.ver}(pk_j^{reg}, r||P_i, \sigma_j) = 1$ for $\forall j \in P_i'$. If any failure occurs during verification, the client aborts.

In summary, by addressing **C1** with the above design, honest participants are ensured to proceed only with a consistent participant list P_i' of size s with each member randomly presenting with probability less than $\alpha s/n_{min}$. This upper bound remains *invariant* during the training, as it is fully determined by public values α, s, and n_{min}. Hence, this bound can be used to derive practical security guarantees (§3.6), regardless of misbehaviors exhibited by the server.

Inherent Inter-Stage Consistency with SecAgg. Ensuring consistency in participant sets used by the server throughout the entire FL workflow (**C2**) poses inherent challenges. Indeed, if the privacy-preserving protocol used in the later stage mandates that all participants observe a genuine selection outcome to ensure valid computation, **C2** is immediately addressed. *However*, if the server can secretly involve a participant set different from the announced one without being noticed by honest clients, the attainability of **C2** becomes an open problem (§6), as honest participants cannot detect such deception with limited trusted source of information (§3.2).

Fortunately, the protocol commonly employed in the remaining workflow is SecAgg (or the distributed differential privacy built upon it) (§2.2), where the server has an incen-

Table 1: Lotto's **com**putation and **com**munication complexity.

Variant	Client-Centric				Server-Centric			
	Server		Participant		Server		Participant	
	cp	cm	cp	cm	cp	cm	cp	cm
Random	$O(1)$	$O(n+s^2)$	$O(s)$		$O(n)$	$O(s^2)$	$O(s)$	
Informed	$O(n)$							

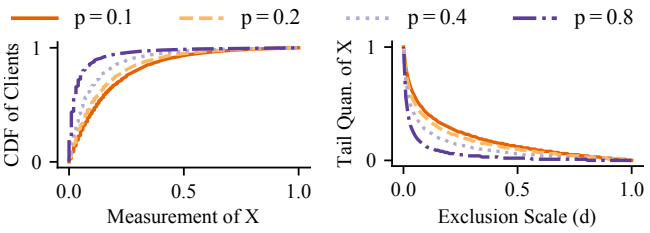
tive to uphold the actual selection outcome during the entire training. *First*, it gains no advantage by secretly involving additional dishonest clients. In SecAgg integrated with Lotto, an honest participant i establishes secure channels with peer j solely by using the public key pk_j^{reg} contained in the selection outcome P_i finalized by Lotto. Therefore, it will not share any additional secrets with clients outside of P_i, even if they participate in the halfway. *Second*, the server will not pretend arbitrarily many dropout events of selected honest participants, e.g., by omitting their messages. This is because SecAgg enforces a minimum number of participants (i.e., t) remaining in the final stage, beyond which the aggregation will abort without providing any meaningful information.

Full Protocol: Client-Centric v.s. Server-Centric. Figure 3 summarizes Lotto's overall design. We refer to this algorithm as `Client-Centric` since the selection primarily occurs at the client end. `Client-Centric` effectively achieves the security goal outlined in §3.1. We provide a detailed analysis of its security at §3.6 and its complexity in Table 1.

It is worth noting that there exists an alternative design that may initially appear to be a natural choice. This design retains the core elements of `Client-Centric` but relies on the server to perform the random selection. Specifically, for each client i in the population, the server uses a PRF with range $[0,m)$ to generate a random value $\beta_i = \mathsf{PRF}_{pk_i^{Lotto}}(r)$, and selects it as a participant if $\beta_i < \alpha sm/n$. The selection outcome, along with the associated randomness, is communicated to each participant for verification purposes. We refer to this design as `Server-Centric`. Intuitively, it offers the same security as `Client-Centric` does in a *single training round*, as it also provides honest clients with a consistent participant list with members presenting with upper-bounded probability.

However, `Server-Centric` faces a unique security challenge during *multiple-round training*. As the selection outcome relies solely on public inputs, a malicious server can accurately predict, before online training, whether an honest participant i will be selected in any round r. This opens up opportunities for the adversary to exploit the system. For instance, during residual removal after over-selection, the server can deliberately preserve the predicted most frequently appearing candidate. In the context of DP training, this coordination behavior implies a weaker level of privacy. We defer a rigorous assessment to Appendix B. Considering the similar runtime cost of the two designs (§5.2), we adopt `Client-Centric` as the first choice for its stronger security.

3.5 Secure Informed Selection



We first note that the server, despite the potential of being malicious, is unlikely to tamper with the model utility. This is because the server invests computing power in training and gains no advantage by doing otherwise. If, however, it is indeed irrational, the need for informed selection becomes unnecessary, and we can safely fall back to using Lotto's secure random selection. In both cases, Lotto aims to prevent a malicious server from manipulating the selection process for privacy attacks (§3.1).

Challenges. Unlike random selection, informed selection does not inherently incorporate randomness, but heavily relies on client measurements (§3.1). This presents two challenges in our pursuit of controlling the number of dishonest participants. Consider Oort [39] as an example, where a client's response latency and training loss are employed as proxies for data quality and system speed, respectively (§3.1). *First*, the adversary can manipulate these metrics for selecting more colluding clients. Lacking a ground truth view on these metrics, detecting such deception is hard for honest clients. *Second*, even if adversaries refrain from actively corrupting any measurements, they can still involve more dishonest clients by genuinely improving their data quality or system speed. Such exploitation is more covert to detect.
